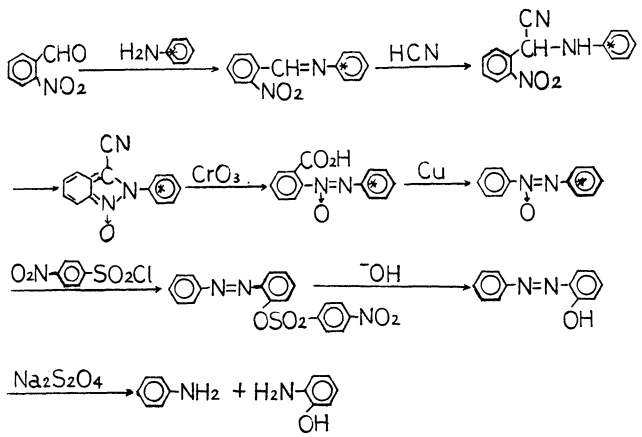
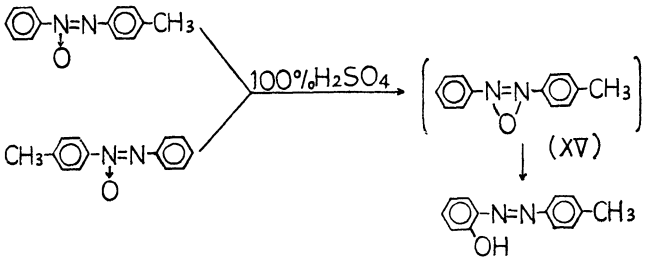
		6.62×10^4 "
		3.62×10^4 "



Earlier, Hahn and Jaffé[15] reported that the Wallach rearrangement of both α- and β-isomers of 4-methyl-azoxybenzene yields 2-hydroxy-4′-methylazobenzene as the sole rearrangement product. They suggested that



the initial step of this rearrangement is the formation of a common intermediate, probably 3-membered NNO ring XV. In this new rearrangement with arenesulfonyl chloride, the formation of a symmetrical 3-membered ring is quite unlikely since the migratory aptitude did not change with the variation of the reaction conditions, as is shown in Table 4. These data reveal that two-thirds of the migration of the sulfonyloxy group proceeds *via* Path B, while one third proceed A through Path A. The mode of the migration of the sulfonyloxy group in this reaction is similar to that in the photolysis of azoxybenzene.[16] A plausible model for the migration of the sulfonylation to azoxybenzene is illustrated by XII. The azoxybenzene molecule is plannar, and the sulfonyl group approaches the plane of azoxybenzene in a nearly perpendicular direction. Thus, one of the two *p* orbitals of the azoxy oxygen can lie parallel in the plane of azoxybenzene. To rearrange to the *ortho* position intramolecularly, it is necessary for the lone pair of azoxy oxygen to overlap with the *p*-orbitals of the *ortho* carbon atom in the phenyl ring. Therefore, the freedom of rotation around the C–N bond is necessary for the rearrangement to the *ortho* position. Meanwhile, the distance between the oxygen atom and the *ortho* carbon atom (A) in XII is longer than that between the oxygen atom and the other *ortho* carbon (B). Perhaps these factors are at least in part responsible for the facile rearrangement at the *ortho* position through Path B.

Although, a somewhat greater scrambling of ^{14}C was observed in the case of the *para* rearrangement of the sulfonyloxy group, there is a tendency similar to that of the *ortho* rearrangement, as is shown in Table 5. The data in Tables 4 and 5 reveal an unequal distribution of ^{14}C. These data imply that the presence of a symmetrical intermediate like dication II or a 3-membered NNO ring XV, as was seen in Wallach rearrangement, is unlikely in the course of sulfonyloxy migration for either the *ortho* or *para* position. On the basis of the ^{18}O and ^{14}C tracer experimental data, perhaps such intermediates XII and VIII are conceivable for the *ortho* and the *para* rearrangements respectively.

Experimental

Materials. *p*-Bromobenzenesulfonyl chloride (mp 75—76°C from ligroin) was obtained by the chlorosulfonylation of

		9.03×10^4 "

bromobenzene with chlorosulfonic acid. *p*-Nitrobenzenesulfonyl chloride (mp 76—77°C from ligroin) was prepared by the oxidative chlorination of *p,p'*-dinitrodiphenyldisulfide in nitric and hydrochloric acids through bubbling with Cl_2 at 65°C. Benzo[*c*]cinnoline-1-oxide (mp 137—138°C from aq. ethanol) was synthesized from 2-nitro-2-aminobiphenyl and 1N methanolic sodium hydroxide. 4,4'-Dimethylazoxybenzene (mp 69—71°C from ethanol) was synthesized by the reduction of *p*-nitrotoluene with methanolic sodium hydroxide. ^{18}O-Labeled *p*-bromobenzenesulfonyl chloride was synthesized from *p*-bromothiophenol and ^{18}O-labeled water in dry chloroform by bubbling Cl_2 through at 0°C. ^{18}O-Labeled *p*-nitrobenzenesulfonyl chloride was synthesized similarly.

Azoxybenzene-1-^{14}C was prepared by the condensation of *o*-nitrobenzaldehyde with aniline-1-^{14}C in four steps according to the process reported by Behr.[12] Aniline-1-^{14}C was synthesized, starting from barium carbonate-^{14}C, through seven steps. The synthetic method was described previously.[17]

The Reaction of Azoxybenzene with Arenesulfonyl Chloride. A typical run was carried out as follows. Azoxybenzene and an excess of *p*-nitrobenzenesulfonyl chloride were mixed in nitrobenzene as solvents. The mixture was then heated at 110°C for 25 hr. After the reaction was completed, the nitrobenzene was steam-distilled. The residue was dissolved in methylene chloride, washed with water, dried with sodium sulfate, and chromatographed through an active alumina column, using methylene chloride as the eluent. The *o*- and *p*-(*p*-nitrobenzenesulfonyloxy)azobenzene were separated by recrystallization. These compounds were identified by a comparison of their properties with those of the authentic samples which were synthesized by reacting *o*- or *p*-hydroxyazobenzene with *p*-nitrobenzenesulfonyl chloride in pyridine. The yield was determined by the isotopic dilution technique. The other reactions were carried out similarly.

Isotopic Dilution Method. A typical run was carried out as follows. A mixture of azoxybenzene-1-^{14}C (0.10720 g) and *p*-toluenesulfonyl chloride (0.5 g) in nitrobenzene (2.0 m*l*) was heated at 110°C for 50 hr. After the reaction was completed, authentic samples of *o*-(*p*-toluenesulfonyloxy)azobenzene (0.09190 g) and *p*-(*p*-toluenesulfonyloxy)azobenzene (0.05486 g) were added to the reaction mixture. After the nitrobenzene had been removed by steam distillation, the residue was chromatographed and recrystallized from ethanol. Thus, *o*-(*p*-toluenesulfonyloxy)azobenzene (1.50×10^5 dpm/mmol) and *p*-(*p*-toluenesulfonyloxy)azobenzene (1.76×10^4 dpm/mmol) were separated. The recrystallization was continued until the specific radioactivity was settled. The ratio of the products was determined by calculation with the following equation:

$$W_x = \frac{W_1}{\left(\frac{S_0}{S_2}-1\right)}$$

where W_x: the weight of the desired substance
W_1: the weight of the added authentic substance
S_0: specific activity of the desired substance
S_2: specific activity of the separated substance

The results are given in Table 1.

Measurement of ^{14}C Activity. All the compounds were counted with a liquid scintillation counter (TEN) in a toluene solution, using POPOP as the scintillator.

The Reaction of 4,4'-Dimethyl Azoxybenzene with p-*Bromobenzenesulfonyl Chloride.* A mixture of 4,4'-dimethylazoxybenzene (0.80 g) and *p*-bromobenzenesulfonyl chloride (1.0 g) was heated in nitrobenzene at 110°C for seven hours. 2-(*p*-Bromobenzenesulfonyloxy)-4,4'-dimethylazobenzene (mp 139—140°C from ethanol: 0.54 g) was obtained by the procedure described above. This compound was identified by comparison with the authentic sample synthesized by reacting 2-hydroxy 4,4'-dimethylazobenzene with *p*-bromobenzenesulfonyl chloride in pyridine.

^{18}O-Tracer Study. The reactions of azoxybenzene with ^{18}O-labeled *p*-bromobenzenesulfonyl and *p*-nitrobenzenesulfonyl chlorides were carried out and the ^{18}O analysis was carried out in the usual way.[18] A typical run was as follows. A mixture of azoxybenzene (3.0 g) and ^{18}O-labeled *p*-bromobenzenesulfonyl chloride (4.0 g) in nitrobenzene (30 m*l*) was heated at 110°C for 30 hr. 2-(*p*-Brosyloxy)azobenzene (mp 100—101°C, 1.0 g) and 4-(*p*-brosyloxy)azobenzene (mp 175—176°C, 1.5 g) were then obtained by usual work-up, and a 0.4 g portion of the azoxybenzene recovered was subjected to ^{18}O analysis. The hydrolysis of 4-(*p*-brosyloxy)azobenzene (1.2 g) was carried out under refluxing in 20 m*l* of 20% sodium hydroxide for 5 hr. Then the solution was acidified with 10% HCl and extracted with ether. After the removal of the solvent, recrystallization from benzene gave 4-hydroxyazobenzene (mp 152—154°C, 0.3 g). The aqueous layer was carefully neutralized with Na_2CO_3, using phenolphthalein as the indicator. Then, a 10% EtOH solution of *s*-benzylisothiuronium salt (0.4 g) was added to the neutral solution. The precipitate thus formed was collected and recrystallized from ethanol. This crystal (mp 174—176°C 0.3 g) were identified as the thiuronium salt of *p*-bromobenzenesulfonic acid by comparing it with the authentic sample. 2-(*p*-Brosyloxy)-azobenzene was hydrolyzed similarly. The ^{18}O-analytical results of these esters and the hydrolyzed compounds are listed in Table 2.

Degradation of o-(p-*Nitrobenzenesulfonyloxy)azobenzene*-x-^{14}C. A mixture of the title compound (1.0 g) in 10 m*l* of ethanol and 2 m*l* of water was subjected to alkaline hydrolysis with

17) S. Oae, N. Furukawa, M. Kise, and M. Kawanishi, This Bulletin, **39**, 1212 (1966).

18) S. Oae, T. Kitao, and Y. Kitaoka, *Tetrahedron*, **19**, 827 (1964).

5.0 g of sodium hydroxide under reflux for five hours. After the reaction has subsided, the reaction mixture was poured into ice cold water and filtered. The filtrate was acidified with 10% hydrochloric acid and extracted with ether. After the evaporation of the ether, crude *o*-hydroxyazobenzene was obtained and recrystallized from ethanol (mp 81—82°C): 0.3 g of the pure compound was thus obtained. Into a mixture of 0.205 g of *o*-hydroxyazobenzene (0.001 mol) and 0.53 g of sodium hydrosulfite (0.003 mol) in 2 m*l* of water, 0.24 g of sodium hydroxide (0.006 mol) was added. The solution was then heated at 80°C for eight hours until the red color of *o*-hydroxyazobenzene disappeared. After the reaction, two times as much water was added to the reaction mixture and the solution was extracted with ether. Then, 0.05 g of benzoyl chloride was added to the ether solution. After heating on a hot plate, the ether was evaporated and the residue was recrystallized from ethanol to obtain benzanilide (mp 161—163°C, 0.034 g) After acidification with 10% hydrochloric acid, the water layer was made weakly alkaline with sodium carbonate and extracted with ether. After the subsequent evaporation of the ether, crude *o*-aminophenol was recrystallized with ethanol (mp 172—174°C) to obtain 0.043 g of the pure sample. The degradation of *p*-(*p*-toluenesulfonyloxy)-azobenzene was carried out similarly.

Photochemical Rearrangement of Azoxybenzene-1-^{14}C. A mixture of 0.544 g of azoxybenzene-1-^{14}C in 200 m*l* of ethanol was irradiated for 48 hr using a high-pressure mercury arc lamp at 20—25°C. After the condensation of the reaction mixture, it was poured into an alkaline solution, *i.e.*, 3 g of sodium hydroxide in 200 m*l* of water, and filtered under reduced pressure. The filtrate was acidified with 10% hydrochloric acid and extracted with ether. After the evaporation of the ether, crude *o*-hydroxyazobenzene was recrystallized from ethanol. The degradation of the ^{14}C-labeled *o*-hydroxyazobenzene to aniline and *o*-aminophenol was done by the procedure used previously.

Phenylazo *p*-Tolyl Sulfone as a Source of Phenyl Radical[1)]

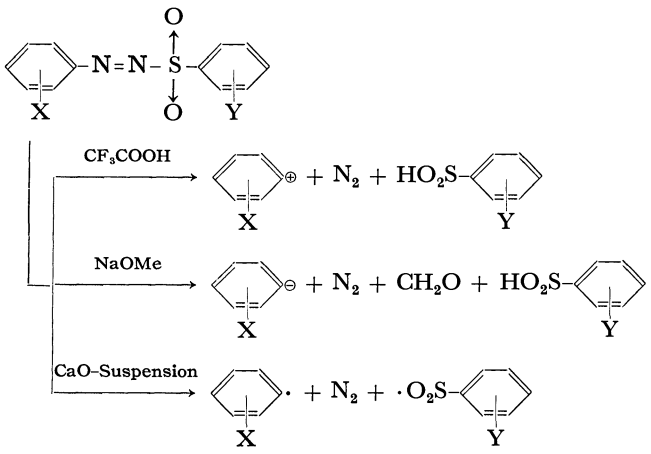
Michio KOBAYASHI, Hiroshi MINATO, Minoru KOJIMA, and Nobumasa KAMIGATA

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received March 16, 1971)

Mechanism of the decomposition of phenylazo *p*-tolyl sulfone(I) was investigated. Orientations and partial rate factors of substituted biphenyls produced by the decomposition of I in benzene-substituted benzene mixtures were used as the criteria for judging the nature of the decomposition. When CaO- or MgO-suspension was present, autocatalytic heterolysis of I was suppressed to some extent, but for complete suppression 20—40 w/v % CaO or MgO was necessary. Pyridine and quinoline were found to be effective for suppression of the autocatalysis. When sufficient amount of pyridine, quinoline, MgO or CaO were present, orientations and partial rate factors for phenylation of substituted benzene were similar to those obtained by phenyl radical produced by benzoyl peroxide on *N*-nitrosoacetanilide. The rate of decomposition of I was determined in PhC_2H_5, $PhOCH_3$, PhCl, $PhNO_2$, pyridine and DMF in the presence of pyridine. An isokinetic relationship was found to hold for activation parameters for the decomposition in these solvents, and the isokinetic temperature was 88.6°C. Values of activation enthalpy and entropy were rather large; $\Delta H^{\ddagger}=39.6$ kcal/mol and $\Delta S^{\ddagger}=34.4$ e.u./mol in DMF.

When trifluoroacetic acid is present in the medium, phenylazo *p*-tolyl sulfone decomposed heterolytically, yielding phenyl cation, nitrogen and *p*-toluenesulfinic acid.[2)] Bunnett and Happer reported that when sodium methoxide is present *o*-halophenylazo phenyl sulfone yielded *o*-halophenyl anion, nitrogen, formaldehyde and benzenesulfinic acid.[3)] Rosenthal and Overberger reported that in the presence of suspended calcium oxide phenylazo phenyl sulfone decomposed homolytically, yielding phenyl and benzenesulfonyl radicals.[4)] Kice and Gabrielsen reported that phenylazo methyl sulfone also decomposed homolytically when suspended calcium oxide was present.[5)]



Azosulfones are interesting compounds as the source for aryl radicals and arenesulfonyl radicals, but it seems that the conditions which guarantee completely homolytic decomposition of azosulfones have not been established yet. It is not certain that to what extent the

heterolytic decomposition of azosulfones is suppressed when suspended calcium oxide is present. Further detailed investigation of the mechanism of decomposition of azosulfones seemed desirable. Such investigation was carried out in our laboratories, and the effectiveness of added bases such as calcium oxide, magnesium oxide, pyridine, and quinoline was determined. In order to determine whether or not phenyl cation is being produced, orientations and partial rate factors for phenylation in aromatic solvents were measured. These results will be described in this paper.

Experimental

Materials. Aromatic solvents were purified according to conventional methods.[2]

Phenylazo *p*-tolyl sulfone was synthesized by the reaction between benzenediazonium chloride and sodium *p*-toluenesulfinate, and recrystallized from methanol; mp 90—91°C (decomp.).

Pyridine and quinoline were refluxed over potassium hydroxide and then distilled; pyridine, 114—115°C/760 mmHg, quinoline, 137°C/45 mmHg.

Calcium oxide was ground to fine powder and then used. Magnesium oxide which is available as fine powder was used as received.

Kinetic Measurements. A flask containing a mixture of 60 m*l* of a solvent and 8—13 mmol of pyridine was placed in a constant temperature bath. After the temperature of the mixture reached that of the bath, 3 mmol of I was dissolved (the concentration is about 0.05 mol/*l*). Amounts of nitrogen gas generated were measured by a gas buret.

Analysis of Phenylated Products. Three mmol of I was dissolved in aromatic solvents (a mixture of 0.12 mol of benzene and 0.12 mol of a substituted benzene) containing 3—20 mmol of pyridine or quinoline, and a flask containing the solution was placed in a constant temperature bath.

Since azobenzene is one of the products and it interferes the gas-chromatographic determination of biphenyls, it had to be removed by reduction. To the reaction mixtures containing anisole, chlorobenzene or ethylbenzene, zinc powder and methanolic hydrochloric acid were added and azobenzene was reduced; then the mixture was washed with water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure. The reaction mixtures containing benzonitrile or nitrobenzene were washed with a 5% sodium carbonate solution and water, dried over anhydrous magnesium sulfate, and then concentrated.

When calcium oxide or magnesium oxide was used in place of pyridine or quinoline, the reaction mixtures were filtered and then treated in a similar manner.

Biphenyls in the concentrated mixtures were determined by a Hitachi K-53 Gas Chromatograph.

Results and Discussion

Rosenthal and Overberger reported that when 0.13—0.33 w/v% calcium oxide was present the autocatalysis by acidic products (arenesulfinic acids and arenesulfonic acids) were prevented and the decomposition followed a first-order rate law.[4] We determined the orientations and partial rate factors for the phenylation of substituted benzenes (0.12 mol benzene +0.12 mol a substituted benzene) with I in the absence of CaO and in the presence of 0.5 g CaO (0.5 g CaO corresponds to 2.19 w/v% in the case of benzene-chlorobenzene). The results are shown in Table 1.

Partial rate factors in the presence of 0.5 g CaO are quite different from those in the absence of CaO, but they are still different from the partial rate factors for phenylation with phenyl radical produced from benzoyl peroxide[6] or *N*-nitrosoacetanilide.[7] This finding indicates that the autocatalytic heterolysis is not completely suppressed. Therefore, the amounts of calcium oxide suspension were increased. Since magnesium oxide is commercially available as powder much finer than calcium oxide, some experiments were carried out in the presence of magnesium oxide. The results of experiments with benzene-chlorobenzene are shown in Table 2.

When 5.0 g of MgO was present (21.9 w/v%), the orientations and partial rate factors are similar to those by phenyl radical, and no further change was observed when amounts of magnesium oxide were increased. Therefore, the orientations and partial rate factors for

the phenylation of various substituted benzenes were determined in the presence of 5.0 g magnesium oxide. The results are shown in Table 3. These values are comparable to those reported for phenylation with phenyl radical.[6,7]

Since the systems containing calcium oxide and magnesium oxide are heterogeneous, variation of the size of particles and the rate of stirring influence on the results of experiments. Some organic compounds usable in place of calcium oxide are desirable for reproducibility and convenience in the experiments generating phenyl radicals from azosulfones. Experiments were carried out with pyridine and quinoline as organic weak bases, and the results are shown in Tables 4 and 5. Both orientations and partial rate factors are similar to those obtained with 5.0 g magnesium oxide, and these data show that both pyridine and quinoline are effective in preventing autocatalytic heterolysis of I.

Abramovitch and Saha[8] reported that in the presence of pyridine benzenediazonium salts decompose homolytically according to a scheme shown below.

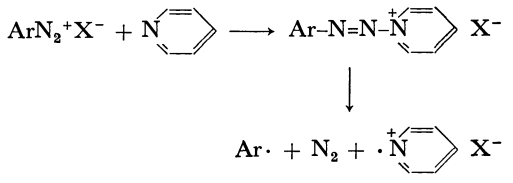
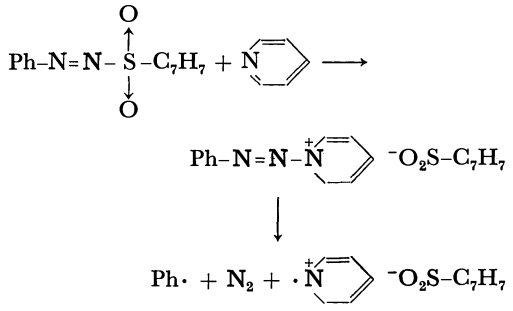
8) R. A. Abramovitch and J. G. Saha, *Tetrahedron*, **21**, 3297 (1965).



In the presence of pyridine, I could undergo a similar reaction.



However, such possibility can be rejected on the basis of the following considerations; a) magnesium oxide and calcium oxide can be used in place of pyridine and similar results are obtained, b) the infrared spectrum of I in pyridine showed no absorptions at 2260—2280 cm^{-1} ascribable to a diazonium salt, c) rates of decomposition of I in the presence of pyridine are quite different from those of diazonium salts in the presence of pyridine, and d) orientations and partial rate factors obtained with I in the presence of pyridine are considerably different from those obtained with diazonium salts in the presence of pyridine.

Figure 1 shows the Hammett plots of *para* partial rate factors against Hammett σ values. The ρ values obtained from the right half line was 1.21 (at 60°C), which is comparable to the ρ value for phenylation with *N*-nitrosoacetanilide (1.27, at 20°C) or that with benzoyl peroxide (1.14, at 80°C), but somewhat different from that with phenylazotriphenylmethane (0.93, at 60°C).[9] These data show that the phenylation with phenyl radical is very little dependent on the temperature but considerable dependent on the source of phenyl radical.

The effect of temperature on the phenylation with phenyl radical has not been investigated in detail. Therefore it has not been established whether or not it is meaningful to compare the orientations and partial rate factors obtained at different temperatures with

different phenyl radical sources. In order to clarify this question, orientations of phenylation with I at various temperatures were measured, and the results are shown in Table 6. When the temperature was raised, phenylation at *ortho* position gradually decreased and phenylation at *meta* or *para* position gradually increased. Such tendency was greatest for the phenylation of chlorobenzene. However, the changes are not so significant even in the case of chlorobenzene. These findings indicate that activation energies for phenylation at *ortho*, *meta*, and *para* positions do not differ greatly. This finding supports the commonly accepted interpretation that the similarity in the data on the phenylations with benzoyl peroxide or *N*-nitrosoacetanilide at different temperatures must arise from the same intermediate, phenyl radical.

The rates of decomposition of I in various solvents were determined by measuring the nitrogen gas evolved. As shown in Fig. 2, autocatalysis is observed in the absence of calcium oxide or pyridine (curve b) where-

a) $[p\text{-}TsN_2Ph]_0=0.05$ mol/*l*, $[\text{pyridine}]_0/[p\text{-}TsN_2Ph]_0=2$—4 (mol ratio), except the decomposition in pyridine as the solvent.

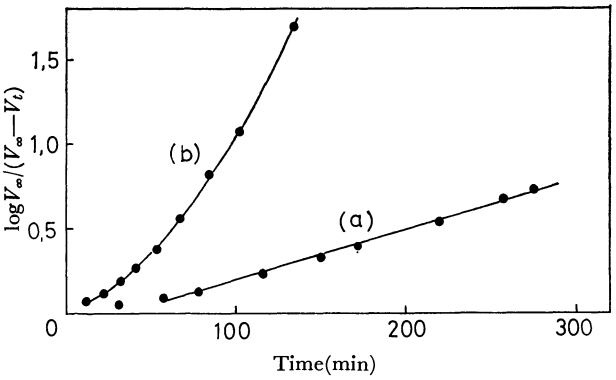

Fig. 2. Rate of decomposition of *p*-TsN_2Ph in PhCl at 85.4°C. *V*: volume of nitrogen evolved, $[p\text{-}TsN_2Ph]_0=0.05$ mol/*l* a) [pyridine]=0.135 mol/*l* b) [pyridine]=0

as the rates of decomposition followed a first-order rate equation when pyridine is present (line a). The molar ratio, [pyridine]/[I], was kept in the range of 2—4, and the rate constants, *k*, were not influenced by the concentration of pyridine. First-order rate constants for the decomposition of I in solvents of various dielectric constants were determined in the presence of pyridine, and the results are shown in Table 7.

Rate constants in Table 7 are not dependent on the dielectric constants of media, and this fact also supports the homolytic nature of the decomposition of I in the presence of pyridine. Activation parameters for the decompositions in these solvents were obtained, and shown in Table 8. An isokinetic relationship holds for these activation parameters, as shown in Fig. 3, and the isokinetic temperature, β, was 88.6°C.

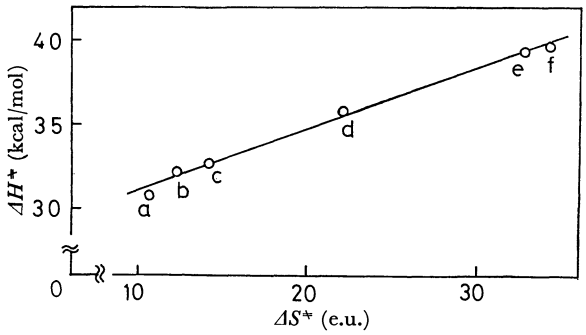

Fig. 3. Isokinetic relationship for the decomposition of *p*-TsN_2Ph in the presence of pyridine in various solvents. β=88.6°C; a, PhC_2H_5 b, C_5H_5N c, $PhNO_2$ d, $PhOCH_3$ e, PhCl f, DMF

Table 8. Activation parameters for the decomposition of *p*-TsN_2Ph in the presence of pyridine

Solvent	ΔH^*(kcal/mol)	ΔS^*(e.u.)
PhC_2H_5	30.8	10.7
pyridine	32.2	12.3
$PhNO_2$	32.6	14.1
$PhOCH_3$	35.9	22.2
PhCl	39.4	32.8
DMF	39.6	34.4

Variation in activation parameters in these solvents is fairly large, but cannot be rationalized easily. However, it is of interest to note that activation entropies for decomposition of this azosulfone are rather large compared with those of common radical initiators with similar activation enthalpies; this azosulfone, in chlorobenzene, $\Delta H^*=39.4$ kcal/mol, $\Delta S^*=32.8$ e.u., *t*-butyl peracetate,[10] in chlorobenzene, $\Delta H^*=38$ kcal/mol, $\Delta S^*=17$ e.u., di-*t*-butyl peroxide,[11] in *t*-butylbenzene, $\Delta H^*=37.8$ kcal/mol, $\Delta S^*=13.8$ e.u. Because of these rather large activation entropies, this azosulfone decomposes at temperatures lower than those used for di-*t*-butyl peroxide or *t*-butyl peracetate. Compounds decomposing with activation entropies comparable to those of this azosulfone are phenylazo phenyl sulfides; van Zwet and Kooyman reported that E_a and ΔS^* for the decomposition of *p*-tolylazo *p*-*t*-butylphenyl sulfide in benzene were 36 kcal/mol and 33 e.u., respectively.[12]

Studies of Azo Colors. VIII.[1] The Azo-coupling Reactions of Active Methylene Compounds

Yōji HASHIDA, Morio KOBAYASHI, and Kohji MATSUI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma

(Received March 17, 1971)

The kinetics of the azo-coupling reactions of various active methylene compounds with diazobenzene-4-sulfonic acid have been studied spectrophotometrically. In the reactions of all the active methylene compounds used, it was found that the reaction rate was proportional to both the concentration of the diazonium salt and the carbanion (or enolate ion) of the azo component. In the reactions of a series of β-dicarbonyl compounds, a plot of the logarithms of the rate constants against the pK_a values of active methylene compounds gave a straight line. However, the correlation between the reactivity and pK_a was found unsatisfactory in the case of active methylene compounds with such electron-withdrawing substituents as NO_2, CN, COR, SO_2R, and Cl. These results are discussed in terms of the nucleophilicity of these carbanions.

The reaction of aromatic diazo compounds with aromatic amines or phenols is well known to be a diazo-coupling reaction, and the kinetics of the reaction has been extensively studied in connection with the reaction mechanism and the effects of the substituents on the reactivity.[2]

On the other hand, aliphatic compounds containing an activated methylene or methyl group are known to react also with aromatic diazonium salts to form azo compounds or their tautomers. Although many active methylene compounds are known,[3,4] no systematic quantitative studies of their coupling reactions have yet been made. Therefore, little is known concerning the reaction mechanism and the relationship between the reactivity and the structure.

This paper will report the kinetics of the coupling reaction of various active methylene compounds with diazobenzene-4-sulfonic acid, and the structural effect of the active methylene compound on the reactivity.

Experimental

Materials. Bis(methylsulfonyl)methane and bis(ethylsulfonyl)methane were prepared by the method of Fromm.[5] Ethyl nitroacetate was prepared by the method of Arndt[6] from ethyl acetoacetate and nitric acid. *p*-Nitroacetoacetanilide was prepared according to the method of Fierz-David.[7] The other active methylene compounds and sulfanilic acid were of commercial origin and were used after purification by recrystallization or distillation. Their purities were confirmed by their physical constants and by thin-layer chromatography or gas chromatography.

pK_a *Measurement.* The pK_a value of the azo component was measured spectrophotometrically at a appropriate wavelength in water (ionic strength, μ; 0.25) at 20±0.1°C. In the case of ethyl cyanoacetate, due to the decomposition in an alkaline solution, the extinction of carbanion was taken as a function of the time and was extrapolated back to zero time. The decomposition of ethyl cyanoacetate, however, was negligibly small in the pH range where kinetic measurements were performed. The results are given in Table 2 and Table 3.

Kinetic Measurements. The general experimental techniques are quite similar to those used in an earlier experiment.[8] The kinetic measurements were carried out when the azo component was present in at least a twenty-five-fold excess as compared to the diazonium salt. The apparent rate constant (k') was calculated using Eq. (1) by measuring the concentration of the product spectrophotometrically in a buffered aqueous solution at 20±0.1°C:

$$k't = 2.303 \log \frac{a}{a-x} = 2.303 \log \frac{E_\infty}{E_\infty - E_t} \quad (1)$$

a: concentration of the dyestuff at an infinite time (a is proportional to the E_∞ extinction)

x: concentration of the dyestuff at time t (x is proportional to the E_∞ extinction)

The bimolecular rate constant (k_2) was obtained from Eq. (2):

$$k_2 = k'/[A^-] = k'[H^+]/K_a^{AH}[AH] \quad (2)$$

where $[A^-]$, $[AH]$, and K_a^{AH} represent the concentration of the carbanion, the undissociated form of the azo component, and the dissociation constant of AH respectively. The results are tabulated in Table 2 and Table 3. The initial concentration of the diazonium salt was 4×10^{-5} mol/l in all of the kinetic runs. The components of the buffer solutions used were as follows:

pH	Component			
2.0	0.066 mol	CH_3COONa	+0.084 mol	HCl/l
2.8	0.063 mol	CH_3COONa	+0.063 mol	HCl/l
3.7	0.066 mol	CH_3COONa	+0.059 mol	HCl/l
4.3	0.040 mol	CH_3COONa	+0.080 mol	CH_3COOH/l
4.7	0.063 mol	CH_3COONa	+0.047 mol	CH_3COOH/l
5.2	0.063 mol	CH_3COONa	+0.031 mol	CH_3COOH/l
5.8	0.040 mol	CH_3COONa	+0.003 mol	CH_3COOH/l
6.2	0.013 mol	Na_2HPO_4	+0.038 mol	KH_2PO_4/l
6.8	0.011 mol	Na_2HPO_4	+0.009 mol	KH_2PO_4/l
7.2	0.015 mol	Na_2HPO_4	+0.005 mol	KH_2PO_4/l

The ionic strength of the buffer solution was adjusted to 0.25, by the addition of potassium chloride.

Results and Discussion

Kinetic Equation. The mechanism expressed by the following equations is suggested as the most probable for the coupling of an active methylene compound:[9]

$$\mathrm{X}\diagdown \mathrm{CH_2} + \mathrm{B} \underset{k_{BH}}{\overset{k_B}{\rightleftharpoons}} \mathrm{X}\diagdown \overset{-}{\mathrm{C}}\mathrm{H} + \mathrm{BH^+} \quad (3)$$
$$\mathrm{Y}\diagup \qquad\qquad\qquad\quad \mathrm{Y}\diagup$$

$$\mathrm{X}\diagdown \overset{-}{\mathrm{C}}\mathrm{H} + \mathrm{Ar}\overset{+}{\mathrm{N}}_2 \xrightarrow{k_2}$$
$$\mathrm{Y}\diagup$$

$$\mathrm{X}\diagdown \mathrm{CH{-}N{=}N{-}Ar} \qquad \mathrm{X}\diagdown \mathrm{C{=}N{-}NH{-}Ar} \quad (4)$$
$$\mathrm{Y}\diagup \qquad\qquad\quad \mathrm{Y}\diagup$$

For instance, in the reactions of acetoacetanilide[10] and pyrazolones,[11,12] the ionization of the methylene group occurs first, followed by the rate-controlling step of the reaction; the rate of the coupling has been expressed by Eq. (5):

$$v = k_2[\mathrm{Ar}\overset{+}{\mathrm{N}}_2][\mathrm{X{-}}\overset{-}{\mathrm{C}}\mathrm{H{-}Y}] \quad (5)$$

The kinetic equation is similar to that for the coupling to phenols.[1]

On the other hand, in the case of nitroethane, the ionization of the C–H bond occurs slower than the second step, and a kinetic expression (6) has been presented:[13]

$$v = k_B[\mathrm{B}][\mathrm{X{-}CH_2{-}Y}] \quad (6)$$

Equation (6) is similar to the one that applies to the base catalyzed halogenation of aliphatic compounds containing an activated methylene group. Thus, at present, two types of kinetic equations are known for the coupling reactions of active methylene compounds. Therefore, the reactions of other aliphatic compounds with diazonium salts are of interest with respect to the kinetic equation. In this paper, the active methylene compounds shown in Table 2 and Table 3 have been examined from the above point of view.

As is shown in Table 1, the first-order dependence with the diazonium salt was confirmed in the reaction of malononitrile according to Eq. (1) by using an excess of the azo component; the reaction also shows a first-order dependence on the concentration of malononitrile, judging from the results using different concentrations at a constant pH.

The dependence of log k' on pH was linear, as is shown in Fig. 1, with a unit slope over the pH range where

Table 1. Coupling rate constant of diazobenzene-4-sulfonic acid with malononitrile (20°C, μ: 0.25)

pH	Concentration of malononitrile (mol/l) $\times 10^3$	k' (min^{-1})	k_2 (l/mol·min) $\times 10^{-8}$
4.37	1.00	0.0965	4.21
4.38	4.00	0.356	3.80
4.38	2.00	0.205	4.37
2.88	2.00	0.00623	4.19
3.74	2.00	0.0417	3.90
4.74	2.00	0.498	4.65

the concentration of the dissociated form of malononitrile is much lower than that of the undissociated form. This result is consistent with a presumption that the rate determining step is the reaction of a carbanion with a diazonium salt.[10–12,14] Therefore, a second-order rate constant (k_2) was determined from Eq. (2). The k_2 values thus obtained are independent of the acidity of the medium, as is shown in Table 1.

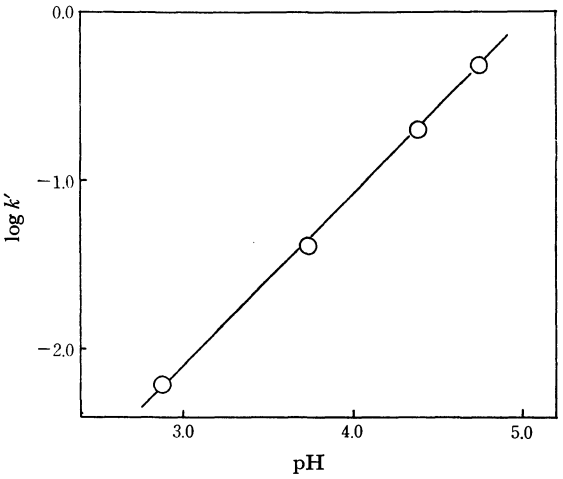

Fig. 1. Dependence of the rate constant (k') for the coupling reaction of diazobenzene-4-sulfonic acid with malononitrile on pH. (Concentration of malononitrile: 2×10^{-3} mol/l)

In all the active methylene compounds studied, it was found that the rate of coupling was expressed by Eq. (5) under the given set of conditions (Table 2 and Table 3) in a manner similar to that described above. Thus, in the present work we have found that the kinetic expression differs from that used for the reaction of nitroethane. It is assumed that a difference in the relative rates of the stages (3) and (4) is responsible for the difference in their kinetic expressions (5 and 6). In the active methylene compounds used, not only the reaction circumstances, such as the component of the buffer solution, which affect the velocity of stage (3) as a base, but also the magnitude of k_2, are not same as in the case of nitroethane. However, it is assumed that the slow ionization of nitroethane is at least partly responsible for the kinetic equation, Eq. (6), which differs from those of the other active methylene compounds. It is well known that the ionization of nitro-

ethane occurs substantially more slowly than those of the other active methylene compounds of the same acid strength.[15]

Effect of the Structure of the Azo Component on the Reactivity. Although many investigations concerning carbanion have been reported in the literature, there have been only fragmentary reports about the structural effect of the carbanion on the reactivity. Therefore, it seemed that is would be of interest to compare the reactivities of various carbanions towards the diazonium salt.

It may be seen in Table 2 that the effects of substituents in the benzene ring, including *ortho*-substituents, on the reactivity are small in acetoacetanilide (No. 1—7), and that the reaction is accelerated by an electron-donating substituent (No. 4 and 5). This result may be

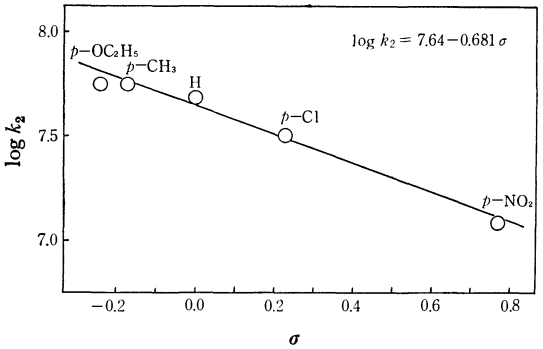

Fig. 2. Hammett plot for the reaction of diazobenzene-4-sulfonic acid with substituted acetoacetanilides.

interpreted on the basis of the increase in the nucleophilic character of the enolate ion, as will be described later. Figure 2 represents the linear dependence of log k_2 on the substituent constnat (σ). The small ρ value (0.681) can be explained in terms of the insulating effect of the NH–CO group for the transmission of the electronic effect of the substituent.

In β-dicarbonyl compounds (No. 1—17), the k_2 value varies considerably with the nature of the neighboring group. In Table 2, it may be seen that in general, the higher the pK_a value of a β-dicarbonyl compound, the more readily does the reaction occucr. The correlation between the reactivity and the pK_a value of an azo component is represented graphically in Fig. 3 by plotting the logarithms of the rate constants against the pK_a values.

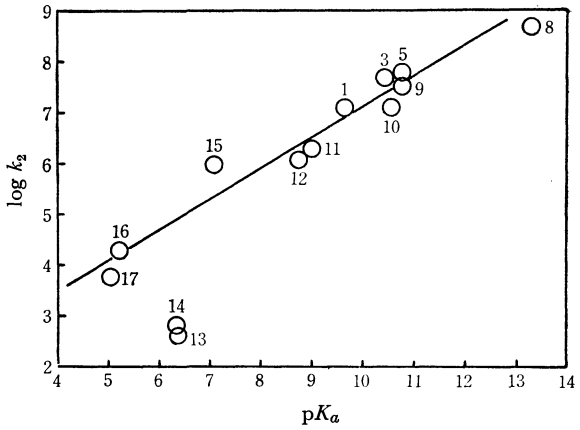

Fig. 3. Relation between pK_a values and rate constants (k_2) for the reaction of diazobenzene-4-sulfonic acid with β-dicar bonyl compounds. (The numbers refer to the β-dicarbonyl compounds as listed in Table 2.)

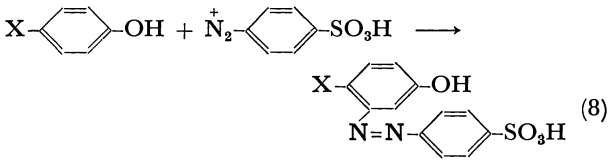
It is apparent from Fig. 3 that the plots of all the β-dicarbonyl compounds including alicyclic derivatives (No. 15—17), except for trifluoro-derivatives (No.13 and 14), are on a straight line. These results indicate that the reactivity of an enolate ion (7), that is, the nucleophilicity of an enolate ion towards the diazonium cation, is closely related to its pK_a value.

(7)

A similar relationship between the reactivity and the pK_a of phenols has been found in the coupling reaction (8) of *p*-substituted phenols with diazobenzene-4-sulfonic acid.[16]



(8)

A similar parallelism between reactivity and pK_a has been observed for various active methylene compounds which include such activating substituents as CN, NO_2, COR, and Cl, as is shown in Table 3.

However, it is clear from Fig. 4 that, in contrast to the case of the β-dicarbonyl compound, a simple correlation was not observed. These results shown that the pK_a value is not a decisive measure of the nucleophilic reactivity of a carbanion in the coupling reaction.

Table 3. Rate constants of the coupling reaction of diazobenzene-4-sulfonic acid with various active methylene compounds (20°C, μ: 0.25)

Exp. No.	Active methylene compound	pK_a	k_2 (l/mol·min)	pH

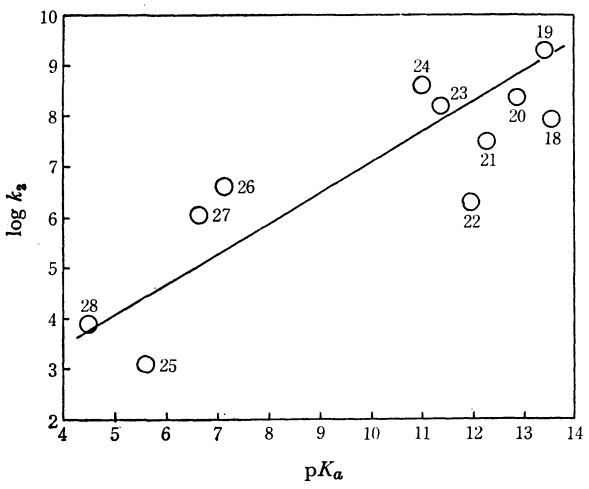

Fig. 4. Relation between pK_a values and rate constants (k_2) for the reaction of diazobenzene-4-sulfonic acid with various active methylene compounds. (The numbers refer to the compounds as listed in Table 3. The line here is drawn to same as that in Fig. 3.)

In general, there is no theoretical reason to expect a close parallelism between the nucleophilicity and the basicity,[17-9] since the nucleophilicity reflects a kinetic phenomenon, while the basicity is concerned with an equilibrium phenomenon. Nevertheless, it may be pointed out that the nucleophilicity is fairly well correlated with the basicity, and good correlations have been obtained by restricting nucleophilic reagents with a similar limited structure, such as substituted anilines or phenols.[2] However, with nucleophilic reagents with different structures, a close parallelism between basicity and nucleophilicity has not been found to hold;[21] the deviations from the line are usually explained by such factors as the polalizability, the steric effect, and the α-effect[22]

The above generalization fits our results. Within β-dicarbonyl compounds or *p*-substituted phenols, the reactivity was found to correlate well to the pK_a scale, whereas only an unsatisfactory linear relation has been observed over the wide range of active methylene compounds examined, as is shown in Table 3. These results can be explained by assuming that, in the former, the influencing factors on reactivity other than the pK_a value are the same, while in the latter cofactors exert different effects on the reaction rate. It is not easy to account for the deviation from the pK_a-log k_2 relationship. Unfortunately, there are not sufficient data available on the reactivities of a series of carbanions. Therefore, it is not apparent that the order of reactivity of carbanions illustrated in Figs. 3 and 4 is applicable to other reactions. This problem is now under investigation.

Photocycloaddition of Thiocarbonyl Compounds to Multiple Bonds. VII. The Reaction of Thiobenzophenone with Acetylenic Compounds

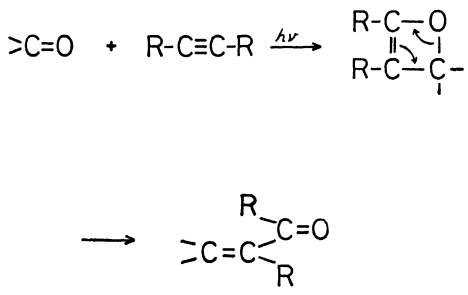
Atsuyoshi OHNO, Tamotsu KOIZUMI, and Yutaka OHNISHI
Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa

(Received March 22, 1971)

Photocycloaddition of thiobenzophenone to acetylenic compounds, R-C≡C-R′ (R=COOH, Ph, CH_2OH, and CN; R′=H: R=COOMe; R′=COOMe), affords 1-phenyl-2-thia-1,2-dihydronaphthalene derivatives. The key step to the product is an intra-molecular aromatic substitution of the composite vinylic biradical **13**. The difference in reactivity of acetylenic and olefinic compounds as well as that between thiobenzophenone and benzophenone are discussed. Ethoxyacetylene does not undergo the reaction. This is interpreted in terms of electronegativity of a radical center in **13**. It is found that cyanoacetylene reacts with butanethiyl radical in contrast to its olefin analog, acrylonitrile.

It has been reported that the photocycloaddition of thiobenzophenone to olefins leads to the formation of 1,4-dithiane derivatives or to thietane derivatives depending on the wavelength of light utilized and the structure of the olefin.[1,2] Similar reactions with ketones are well known and always result in the formation of oxetane derivative.[3,4]

The Paterno-Büchi reaction is also applicable to acetylenic compounds. However, the oxetene derivatives formed are too unstable to be isolated and the final products are α,β-unsaturated ketones.[5,6] It is



(1)

interesting to see whether the difference between ketones and thioketones observed in the reactions with olefins is also observed in the reactions with acetylenic compounds. Thus, we have studied the photocycloaddition of thiobenzophenone to several acetylene derivatives[7] and found that the reaction has completely different features from those involving olefins.

Results

The reactions of propiolic acid (**1**), phenylacetylene (**2**), propargyl alcohol (**3**), cyanoacetylene (**4**), and dimethyl acetylenedicarboxylate (**5**) yielded 1-pnenyl-2-thia-1,2-dihydro-4-naphthoic acid (**7**), 1,4-diphenyl-2-thia-1,2-dihydronaphthalene (**8**), 1-phenyl-2-thia-1,2-dihydro-4-hydroxymethylnaphthalene (**9**), 1-phenyl-2-thia-1,2-dihydro-4-cyanonaphthalene (**10**), and dimethyl 1-phenyl-2-thia-1,2-dihydronaphthalene-3,4-dicarboxylate (**11**), respectively, after irradiation with 5890 Å light from sodium lamps (480 W). The

reaction with ethoxyacetylene (**6**) did not proceed under these conditions. Reaction conditions and yields of products are summarized in Table 1.

The structures of the products were identified by NMR, IR, Mass spectra, elemental analyses, and chemical reactions. When **8** was treated with Raney Ni (W-2), it afforded 1,3-diphenylindane in 73% yield by reductive desulfuration.[8,9] The compound **9** was synthesized independently in 89% yield by reduction of **7** with lithium aluminum hydride. The carboxylic acid was also converted into **10** in several steps (27%).

When **8** was titrated with bromine in carbon tetrachloride, one equivalent of bromine was consumed and, after recrystallizations from ethanol, 1,4-diphenyl-2-thia-1,2-dihydro-3-ethoxynaphthalene (**12**) was isolated.

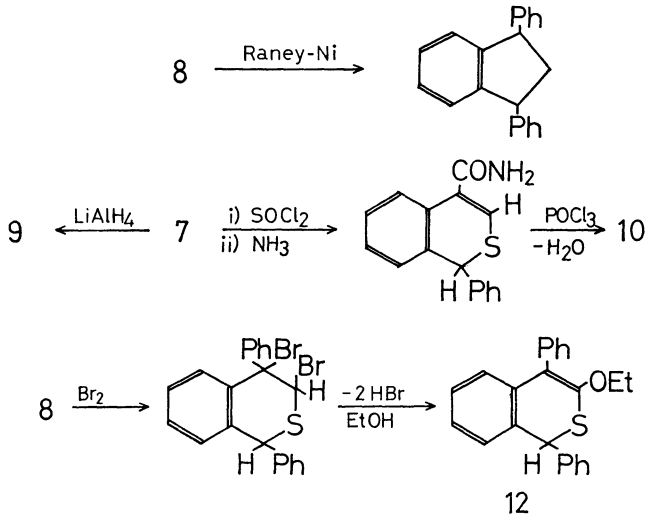
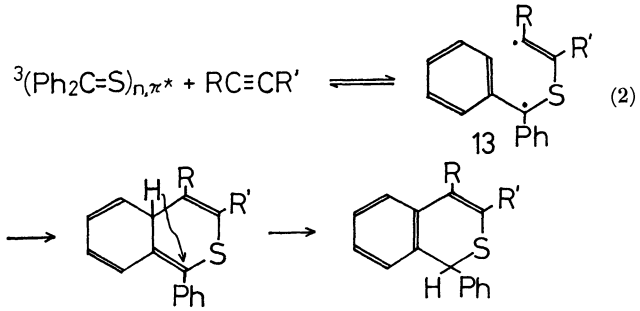
a) Reactions were carried out at the temperature of running water.
b) Based on thiobenzophenone.



Discussion

As previously reported,[1a] it is evident that irradiation with 5890 Å light excites thiobenzophenone to its n,π^* singlet state, which is rapidly deactivated to n,π^* triplet state by intersystem crossing. Since the n,π^* triplet state of thiobenzophenone behaves similarly to a thiyl radical,[1a] the reaction is undoubtedly initiated by the attack of the n,π^* triplet state of thiobenzophenone to an unsaturated carbon atom[10] and the following is the most reasonable mechanism:

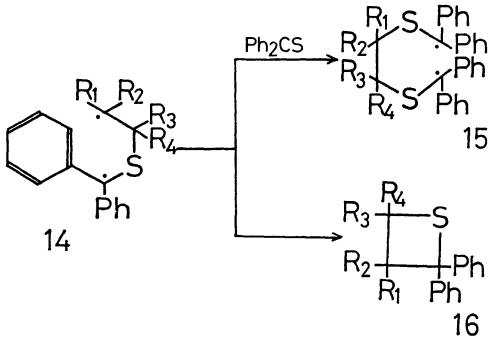
$$Ph_2C{=}S \xrightarrow{5890\text{Å}} {}^3(Ph_2C{=}S)_{n,\pi^*}$$



10) A. A. Oswald and K. Griesbaum, in "The Chemistry of Organic Sulfur Compounds," Vol. 2, ed. by N. Kharasch and C. Y. Meyers, Pergamon Press, New York, N. Y. (1966), pp. 246—254.

The last step of the reaction, intra-molecular hydrogen migration, has been proved by the aid of deuterium-labelling technique. Thus, no deuterium was incorporated in the product even when the reaction was carried out in perdeuterated isopropyl alcohol or in deuterated chloroform as a solvent. However, since this is thermally forbidden 1,3-sigmatropic migration,[11] the actural course might be more complicated.

The above results exemplify the difference in reactivity of σ- and π-radicals. When an olefin is employed as a substrate, the radical center at the end carbon in the intermediate biradical **14**, where an odd electron exists in a p-orbital (π-radical), either attacks another molecule of thiobenzophenone forming another composite biradical **15**, or combines with the radical center at the benzhydryl position forming a stable molecule **16**. The reaction course depends on the nature of the R groups. It is known that the thiocarbonyl-sulfur is preferentially attacked by such carbon radicals.[12]



On the other hand, the corresponding radical center in **13** contains an odd electron in a sp^2 orbital (σ-radical) and can only attack the thiocarbonyl-sulfur with difficulty, which is in contrast to the facile attack on the aromatic ring.[13-15] Thus, the reactivity toward a phenyl ring and that toward a thiocarbonyl-sulfur are reversed in **13** and **14**. The fact that the reaction with **6** does not proceed, contrary to the expectation that the

11) J. B. Hendrickson, D. J. Cram, and G. S. Hammond, "Organic Chemistry," 3rd Ed., McGraw-Hill Book Co., New York, N. Y. N. Y. (1970), pp. 860—862.

12) G. Tsuchihashi, M. Yamauchi, and A. Ohno, This Bulletin, **43**, 968 (1970). The lower the ionization potential of a radical, the larger the tendency to attack thiobenzophenone.

addition of n,σ^* triplet state of thiobenzophenone to an electron-rich carbon-carbon triple bond might be fast,[1a, 16] supports the interpretation. That is, an α-oxygen increases the inoization potential of an odd electron by its inductive effect. This reduces the facility of a radical to attack the aromatic ring. Since the electronegativity of an orbital of σ-radical that has an α-oxygen is not as small as that of a π-radical, it cannot attack the thiocarbonyl-sulfur either. Consequently, the thiobenzophenone is regenerated from **13** by the reverse reaction. It should be noted that all these reactions are competitive.

Although no concrete evidence has yet been obtained for a discussion of factors that result in combination of two radical centers in carbonyl compounds (Eq. (1)) and aromatic substitution in thiocarbonyl compounds (Eq. (2)), one possible explanation is that a longer bond length and smaller bond angle in the C–S–C moiety than in the C–O–C leads **13** to favorable cyclization over its oxygen analog.[17] It should be noted that the attack to an aromatic ring must take place from the side of out-of-plane with the ring and the biradical should be helical.[18] An alternative possibility is the n,π^* singlet state being the active species in the reaction of carbonyl compounds, where a four-membered ring is formed in one-step.[19] We cannot expect a larger reactivity of the *ortho*-position in the thiobenzophenone moiety in **13** than that of its oxygen analog, because spin densities at *ortho*–positions in thiobenzophenone ketyl and in benzophenone ketyl are almost equivalent.[20]

Herein arises another important difference between olefinic and acetylenic compounds. The potocycloaddition of thiobenzophenone to acrylonitrile and methyl acrylate proceeds *via* an ionic mechanism. Thus, only irradiation with 3660 Å light is effective, because this wavelength excites thiobenzophenone to its π,π^* singlet state, which has the character of a thiolate anion.[1a,c] Irradiation with 5890 Å light, however, is ineffective in producing photocycloadducts with these olefins, because a thiyl radical-like species is produced in this process. In contrast, the corresponding acetylene analogs, **4** and **1**, undergo the reaction on irradiation with 5890 Å light. It is highly unlikely to expect the n,π^* singlet state of thiobenzophenone as reactive species in the reaction with acetylenes under the above conditions.[21] Thus, we should expect that these acetylenic compounds react with the n,π^* triplet state of thiobenzophenone or a thiyl radical.

This difference can be interpreted in terms of molecular orbital considerations. Since an acetylenic bond is composed of two orthogonal π-orbitals, even if electrons in one orbital are withdrawn by an electron-attracting group, others in the second orbital will be rearranged to compensate the charge-separation in the molecule. Consequently the electron-deficiency at the end carbon is not as great as that in the corresponding position in olefinic compounds and this is still susceptible to the electrophilic attack of a thiyl radical. The situation is visualized in Figure 1 with **4**, where two molecular orbitals of π-symmetry ($\chi\pi_1$ and $\chi\pi_2$) are calculated by McLean and Yoshimine with SCF-LCAO-MO method with Slater–type functions.[22]

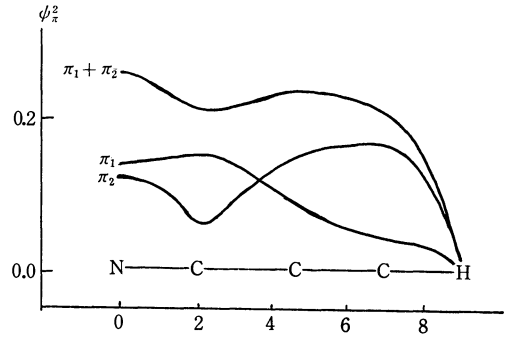


Fig. 1. A diagram for the π-electron densities in cyanoacetylene.

In order to test whether the above theoretical consideration is applicable to true thiyl radicals, we have studied radical additions of butanethiol to cyanoacetylene and found that cyanoacetylene *does* add the thiol, affording 2-(*n*-butylthio)acrylonitrile, under conditions where the reaction with acrylonitrile does not proceed,[23] indicating larger susceptibility of cyanoacetylene than acrylonitrile to the attack of thiyl radicals. We do not, of course, consider this to be the only reason for the difference between acetylenic and olefinic compounds.

Experimental

Material. Thiobenzophenone was prepared and puri-

fied as previously described.[24,25] Commercial acetylenes were used except for cyanoacetylene.[26] They were purified by distillation prior to use.

Photocycloaddition. The reaction was carried out in tetrahydrofuran, ether, or cyclohexane as an inert solvent. Isopropyl alcohol-d_8 and chloroform-d_1 were also inert to the reaction. The apparatus and detailed procedure have been described.[18,25]

Characterization of 1-Phenyl-2-thia-1,2-dihydro-4-naphthoic Acid (7). After the reaction, the solvent was evaporated under reduced pressure. A mixture of ether and *n*-hexane was added to the residue, which was allowed to stand in a refrigerator until precipitation occurred. The crystals were filtered and the filtrate was subjected to silica gel column chromatography with *n*-hexane - chloroform (8:3) mixture as an eluent. Crystals thus obtained were combined to the former ones and recrystallized from aq-acetone giving 0.88 g (26% yield) of **7**: mp 164—166°C: NMR δ ($CDCl_3$, TMS); 5.13 (d, H, J=1.5 Hz), 7.90 (d, R′=H, J=1.5 Hz), 6.90—7.44 and 8.00—8.12 (m, H_{ar}), and 10.21 (s, CO_2H): IR; 3050, 3010, 1660, 1420, and 1260 cm^{-1}: MS *m/e* (species, %); 268 (M^+, 100), 250 (M^+-18, 10), 235 (M^+-SH, 14), 221 (M^+-HCO_2H, 24), 191 (M^+-Ph, 134), and 145 (PhC_2HCO_2, 13): MW; Calcd for $C_{16}H_{12}O_2S$: 268. Found: 265.

Found: C, 71.61; H, 4.56; S, 11.94%. Calcd for $C_{16}H_{12}O_2S$: C, 71.64; H, 4.48; S, 11.94%.

Characterization of 1,4-Diphenyl-2-thia-1,2-dihydronaphthalene (8). The solvent was evaporated from a reaction mixture under reduced pressure. The residue was chromatographed on silica gel with *n*-hexane — chloroform (8:3) mixture as an eluent yielding 2.55 g (56% yield) of a pale green glassy solid, **8**. All attempts, for further purification including separation on tlc, were unsuccessful.[27] However, the structure was confirmed by chemical reactions as well as the following spectral data: NMR δ (CCl_4, TMS); 4.96 (d, H, J=1.0 Hz), 6.19 (d, R′=H, J=1.0 Hz), and 6.85—7.20 (m, H_{ar}): IR; 3050, 3010, 1600, and 1450 cm^{-1}: MS *m/e* (species, %): 300 (M^+, 100), 267 (M^+-SH, 27), 223 (M^+-Ph, 103), and 178 (PhC_2HPh, 10): MW; Calcd for $C_{21}H_{16}S$: 300. Found; 275.

Characterization of 1-Phenyl-2-thia-1,2-dihydro-4-hydroxymethylnaphthalene (9). The residue obtained from the usual treatment was chromatographed on silica gel. The chromatogram was developed by 300 m*l* of *n*-hexane — chloroform (4:6) mixture and was then eluted by chloroform yielding 1.08 g (28% yield) of pale yellow oil, **9**. This compound is highly hygroscopic.[27] The structure was confirmed by chemical and spectral evidence: NMR δ ($CDCl_3$, TMS); 2.90 (broad s, OH), 4.51 (Broad s, CH_2), 5.05 (d, H, $J<0.5$ Hz), 6.36 (d, R′=H, $J<0.5$ Hz), and 6.90—7.54 (m, H_{ar}): IR 3500—3100, 3040—3000, 765, and 695 cm^{-1}: MS *m/e* (species, %); 254 (M^+, 100), 221 (M^+-SH, 20), 177 (M^+-Ph, 156), and 115 (PhC_3H_3, 34).

Characterization of 1-Phenyl-2-thia-1,2-dihydro-4-cyanonaphthalene (10). The residue obtained was chromatographed on silica gel with *n*-hexane — chloroform (9:1) mixture as an eluent. The solid thus obtained was recrystallized from aq-ethanol yielding 0.615 g (20% yield) of **10**: mp 70—72°C: NMR δ ($CDCl_3$, TMS); 5.21 (d, H, $J<0.5$ Hz), 7.10 (d, $J<0.5$ Hz),[28] and 6.80—7.85 (m, H_{ar}): IR; 3080—3000, 2217, 1580, 1540, and 1440 cm^{-1}: MS *m/e* (species, %); 249 (M^+, 100), 222 (M^+-HCN, 8), 216 (M^+-SH, 12), and 172 (M^+-Ph, 172).

Found: C, 76.85; H, 4.74; N, 5.53; S, 12.88%. Calcd for $C_{16}H_{11}NS$: C, 77.07; H, 4.45; N, 5.62; S, 12.86%.

Characterization of Dimethyl 1-Phenyl-2-thio-1,2-dihydronaphthalene-3,4-dicarboxylate (11). The residue obtained was chromatographed on silica gel with *n*-hexane - chloroform (8:3) as an eluent. Crystals thus obtained were recrystallized from *n*-hexane - benzene mixture, yiedling 1.45 g (28.3% yield) of **11**; mp 90—91°C: NMR δ (CCl_4, TMS); 3.66 (s, CH_3), 3.80 (s, CH_3), 5.05 (s, H), 6.78—6.94 and 7.02—7.50 (m, H_{ar}): IR; 1710—1745 cm^{-1} ($\nu_{C=O}$): MS *m/e* (species, %); 340 (M^+, 100), 309 (M^+-OCH_3, 22), 307 (M^+-SH, 9), 263 (M^+-Ph, 170), and 221 ($PhC_6H_4\cdot C_2S$, 98).

Found: C, 67.08; H, 4.96; S, 9.42%. Calcd for $C_{19}H_{16}O_4S$: C, 67.04; H, 4.74; S, 9.42%.

Reductive Desulfuration of 8. A mixture of 0.73 g of **8** and excess Raney Ni (W-2) in benzene was refluxed for 27hr. After the reaction, the mixture was filtered and the solvent was evaporated from the filtrate under reduced pressure. The remaining crystals were recrystallized from benzene-methanol (1:1) mixture giving 0.48 g (73% yield) of 1,3-diphenylindane: mp 157—159°C (lit,[29] 156—157°C). The spectral data also supported the structure.

Bromination of 8. An ice-cooled carbon tetrachloride (3 m*l*) solution of **8** (4.33×10^{-4} mol) was titrated with 6.25×10^{-2}N solution of bromine in carbon tetrachloride. The bromine was consumed when 7 m*l* of the solution (4.375×10^{-4} mol of Br_2) had been added. The mixture was stirred for additional 1 hr. A small amount of precipitate thus obtained was filtered and recrystallized from ethanol. The structure of the crystal was identified by NMR and mass spectra to **12**: NMR δ (DMSO-d_6, TMS); 1.12 (t, 3H), 3.43 (q, 2H), 6.78 (s, 1H), and 7.40 (m, 14H): MS *m/e* (species, %); 344 (M^+, 100), 300 (M^+-CH_3CHO, 422), 267 (M^+–Ph and/or 300–SH, 56), 223 (300–Ph, 81), and 165 ($PhC\cdot C_6H_4$, 69).

Reduction of 7 to 9.[30] Into a three-necked flask containing 47 mg of $LiAlH_4$ and 5 m*l* of dry ether, 263 mg of **7** in 20 m*l* of dry ether was added slowly with stirring. The mixture was stirred for 10 hr under refluxing. Ethanol, water, and 10% H_2SO_4 were then added successively to decompose excess $LiAlH_4$. The organic materials were extracted with ether and the ether layer was dried over Drierite. After the solvent was evaporated under reduced pressure, 0.221 g (89% yield) of pale yellow oil remained, whose NMR, IR, and mass spectra were identical with those of **9** obtained by photocycloaddition.

Conversion of 7 to 10.[31,32] A mixture of **7** (0.968 g) and $SOCl_2$ (1.0 g) was kept at 30—35°C for 3 hr. The mixture was cooled in an ice-bath and 30 m*l* of conc. NH_4OH was added dropwise. The organic materials were extracted with chloroform and the chloroform layer was dried over Drierite. Crude crystals of the amide (0.35 g) were obtained after evaporation of the solvent under reduced pressure: mp 145—149°C: NMR δ ($CDCl_3$, TMS); 5.15 (d, 1H, $J<0.5$ Hz), 5.94 (broad

s, 2H), and 7.10—7.50 (m, 10H): IR; 3990, 3190, 1640, 1613, 1485, and 1414 cm^{-1}.

To a mixture of the amide (0.35 g), NaCl (1.5 g), and CCl_4 (10 m*l*) ,0.3 g of $POCl_3$ was added with stirring, and the mixture was refluxed for 3 hr. The mixture was cooled to room temperature. The precipitate was filtered and the filtrate was dried over Drierite. After evaporation of the solvent under reduced pressure, 0.23 g (27% yield based on **7**) of **10** was obtained: mp 70—72°C. Spectral data were identical with those of **10** obtained by photocycloaddition.

Photoaddition of n-*Butanethiol to* ***4***. A mixture of *n*-butanethiol (1.76 g) and **4** (1.0 g) was prepared in a dry box under an atmosphere of CO_2. To a half portion of this mixture was added 50 mg of benzoylperoxide (BPO). The two half portions were placed in Vycor ampules. The ampules were vacuum-sealed and subjected to irradiation with light of 2537 Å from a 160 W low-pressure mercury lamp (Riko-Kagaku Sangyo) for 3 hr at room temperature. The oily products obtained after evaporating volatile materials were chromatographed on silica gel with *n*-hexane containing 10% benzene as an eluent. The products were identified to be *cis*-2-(*n*-butylthio)acrylonitrile, contaminated by a small amount of the *trans*-isomer, by the following evidence: NMR δ (CCl_4, TMS); 0.95 (m, 3H), 1.57 (m, 4H), 2.90 (t, 2H, J= 6.8 Hz), 5.22 (d, 1H, J=10.5 Hz), and 7.11 (d, 1H, J=10.5 Hz).

Yields were determined by vpc (Hitachi K-53 (FID) with a column of 20% SE-30 at 150°C) to be 13.7% (without BPO) and 27.0% (with BPO).

We thank Dr. G. Tsuchihashi of SCRC and Professor R. L. Schowen of the University of Kansas for their helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2515—2520 (1971)

Selective Cleavage of Cysteine Peptides

Toshishige INUI

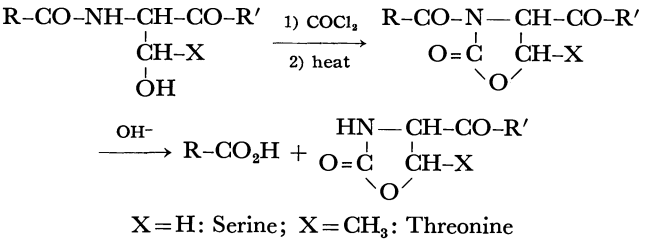
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received March 25, 1971)

The cysteine peptides such as IV were cyclized to thiazolidone peptides through the corresponding *S*-chlorocarbonyl derivatives. In some peptides such as XXII, however, no cyclized products were isolated because of decomposition of the *S*-chlorocarbonyl intermediates. By the mild alkaline hydrolysis of the thiazolidone peptide the carboxylic acid from the *N*-terminal amino acid or peptide and 2-oxothiazolidine-4-carbonyl derivatives were isolated as a result of the selective cleavage of the peptide bond in which an amino group of cysteine residue participated. This cleavage reaction was applied to several cysteine peptides. The same results were observed whenever the corresponding thiazolidone peptides were formed.

In studying the sequence of amino acid residues in proteins, the selective cleavage of peptide bonds on the special amino acid residue by enzyme or by chemical modification is very valuable in the elucidation of their structure.[1] The use of cyanide ion on cystinyl peptides gives rise to cleavage at the peptide linkage involving the amino group of the cysteine residue.[2] Treatment with base on *S*-acylcysteinyl peptides also afforded a similar cleavage on peptide bond.[3] Modification of cysteinyl residues to *S*-2-aminoethylcysteinyl residues[4] and dehydroalanyl residues[5] can be used to cleave on its residue in proteins.

Protected serine and threonine peptides were cleft selectively by treatment with alkali on their corresponding oxazolidone peptides, which were obtained by the action of phosgene, to give *N*-protected amino acids or



X=H: Serine; X=CH_3: Threonine

peptides and the corresponding oxazolidone derivatives.[6] Cysteine peptides may be expected to cause a similar cleavage because of the reactivity of thiol group. Actually ethyl *N*-benzoyl-L-cysteinate (I) was cyclized to the corresponding thiazolidone derivative (II) by

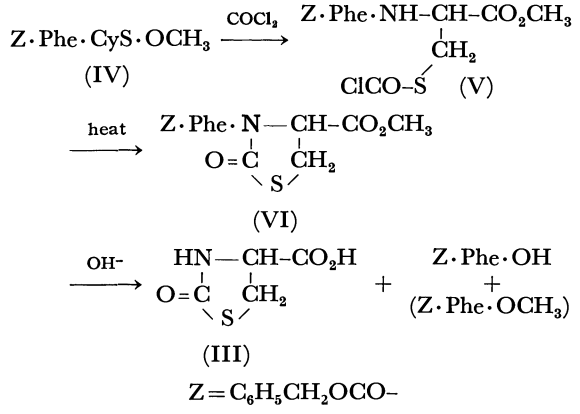
treatment with phosgene followed by refluxing in xylene. Hydrolysis of II with alkali in 70% ethanol provided L-2-oxothiazolidine-4-carboxylic acid (III) without any racemization.[7] If cysteine peptides are cyclized with phosgene to the corresponding thiazolidone peptides at their cysteine residue, the peptides thus obtained will selectively be cleft in two parts at the amino group of cysteine residue by alkaline hydrolysis.

First, *N*-benzyloxycarbonyl-L-phenylalanyl-L-cysteine methyl ester (IV) in which cysteine residue was located in the *C*-terminal position was studied as a model peptide for the cleavage reaction. Reduction of *N*, *N'*-bis(*N*-benzyloxycarbonyl-L-phenylalanyl)-L-cystine dimethyl ester with zinc and hydrochloric acid in methanol gave IV which was converted with phosgene into *S*-chlorocarbonyl compound (V) by using a method



similar to that in previous papers.[6,7] The *S*-chlorocarbonyl compound V was heated in xylene under reflux to cyclize the thiazolidone peptide VI in good yield. The thiazolidone peptide VI was treated with a mixture of 1 N potassium hydroxide and methanol (1:2.5, v/v) at room temperature to give *N*-benzyloxycarbonyl-L-phenylalanine and L-2-oxothiazolidine-4-carboxylic acid (III, $[\alpha]_D$ −58°)[7] without any racemization in yields of 64 and 82%, respectively. The structures of the products isolated were confirmed by comparison of their properties such as melting point and optical rotation with those of the corresponding authentic specimens. On the other hand, the alkaline hydrolysis of VI with about 0.3N methanolic potassium hydroxide solution afforded *N*-benzyloxycarbonyl-L-phenylalanine and methyl *N*-benzyloxycarbonyl-L-phenylalaninate, which was characterized as *N*-benzyloxycarbonyl-L-phenylalanine hydrazide. Another component, however, 2-oxothiazolidine-4-carboxylic acid was obtained as a racemic form ($[\alpha]_D$ −3.9°). The same cleavage reactions also occurred on *N*-benzyloxycarbonyl-L-alanyl-L-cysteine methyl ester (VII) and *N*-benzyloxycarbonyl-L-phenylalanylglycyl-L-cysteine methyl ester (X), both giving the corresponding cleavage products as shown in Table 1. From the results, we see that the peptides are cleft selectively at the peptide linkage involving the amino group of the cysteine residue though the optical properties of the products vary with experimental conditions.

Next, *N*-benzoyl-L-cysteinyl-L-phenylalanine methyl ester (XV) was chosen as a model compound containing cysteine which was located in the middle of the peptide chain. In a similar way to that reported for the S→N acyl group migration of *S*-acylcysteine derivatives,[8,9] peptide XV was prepared from *S*-benzoyl-L-cysteinyl-L-phenylalanine methyl ester hydrochloride (XIV). The cyclized product, L-3-benzoyl-2-oxothiazolidine-4-carbonyl-L-phenylalanine methyl ester (XVII)

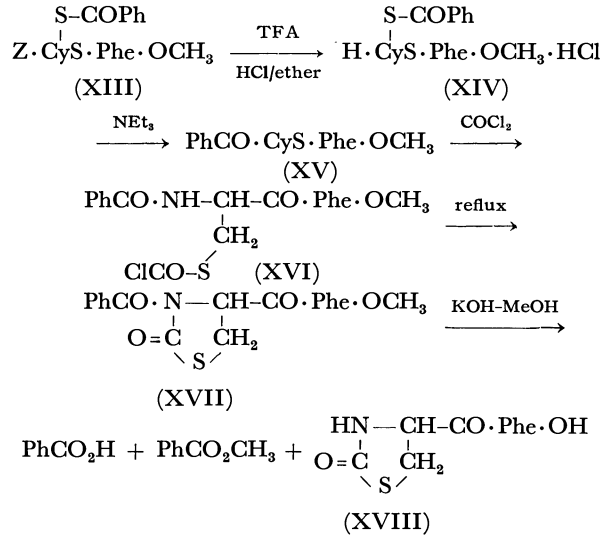


Table 1. Results of cleavage reaction of cysteine peptides

Peptide	Thiazolidone derivative	Condition[a]	Products isolated by cleavage reaction (yields)[b]	
IV	VI	KOH–MeOH	Z·Phe·OH (64%)	III (82%)
IV	VI	KOH/MeOH	Z·Phe·OH (27%) Z·Phe·OCH_3 (34%)	III (74%) (Racemized)
VII	IX	KOH–MeOH	Z·Ala·OH (54%)	III (39%)
X	XII	KOH–MeOH	Z·Phe·Gly·OH (70%)	III (80%)
X	XII	KOH/MeOH	Z·Phe·Gly·OH (32%) (Partially racemized)	III (67%) (Racemized)
XV	XVII	KOH–MeOH	$PhCO_2H$ (10%) $PhCO_2CH_3$ (28%)	XVIII (68%)

a) KOH-MeOH: mixture of 1N potassium hydroxide and methanol (1:2.5, v/v)and KOH/MeOH: 0.3N methanolic potassium hydroxide solution.
b) Unless otherwise stated, the amino acid residue has an L-configuration.

was obtained from XV *via* the corresponding *S*-chlorocarbonyl intermediate XVI in a relatively poor yield. Similarly, hydrolysis of XVII with alkali afforded methyl benzoate, benzoic acid and L-2-oxothiazolidine-4-carbonyl-L-phenylalanine (XVIII) which was purified as its cyclohexylammonium salt (Table 1). Similar cyclizations on *N*-benzoyl-L-cysteinylglycine methyl ester (XIX) and *N*-benzyloxycarbonyl-L-phenylalanyl-L-cysteinylglycine methyl ester (XXII) to their thiazolidone derivatives through the corresponding *S*-chlorocarbonyl compounds (XX and XXIII) were studied. XX was cyclized to the thiazolidone derivative (XXI) in only a small yield, the alkaline hydrolysis of which could not be carried out, and was accompanied with formation of a cystine peptide. In the case of XXIII, no cyclized product was obtained since the corresponding *S*-chlorocarbonyl intermediate XXIII, was decomposed by heating in toluene with the evolution of bad smelling gas.

In conclusion, selective cleavage of cysteine peptide takes place at the amino group of cysteine residue in original peptide whenever its *S*-chlorocarbonyl derivative is cyclized to the corresponding thiazolidone derivative.

Experimental[10]

N,N'-Bis(N-benzyloxycarbonyl-L-phenylalanyl)-L-cystine Dimethyl Ester. To a suspension of dimethyl cystinate hydrochloride (8.5 g, 0.025 mol) in chloroform (150 m*l*) were added triethylamine (7.0 m*l*, 0.050 mol) and a solution of *N*-benzyloxycarbonyl-L-phenylalanine (15.0 g, 0.050 mol) in chloroform (70 m*l*). A solution of *N,N'*-dicyclohexylcarbodiimide (11.2 g, 0.054 mol) in chloroform (20 m*l*) was added and the reaction mixture was allowed to stand overnight at room temperature. *N,N'*-dicyclohexylurea thus precipitated was removed by filtration and the filtrate was successively washed with water, dilute hydrochloric acid and dilute aqueous sodium hydrogen carbonate solution. The dried solution was evaporated *in vacuo* to give white crystals which were recrystallized from ethanol. Yield, 15.1 g (72.6%), mp 137—139°C, $[\alpha]_D^{22}$ −88.9° (*c* 3.12, *N,N*-dimethylformamide).

Found: C, 60.98; H, 5.59; N, 6.88%. Calcd for $C_{42}H_{46}N_4O_{10}S_2$: C, 60.71; H, 5.58; N, 6.74%.

N-Benzyloxycarbonyl-L-phenylalanyl-L-cysteine Methyl Ester (IV). According to the method employed in the reduction of cystine derivatives to cysteine derivatives by Zervas,[11] a suspension of the above cystine peptide (15.1 g, 0.018 mol) in methanol (150 m*l*) containing concentrated hydrochloric acid (12.0 m*l*) was treated with zinc dust (6.0 g) in small portions at a time for 30 min at about 50°C. Undissolved zinc was then filtered off and the filtrate was diluted with water to separate IV as white crystals. Yield, 11.6 g (76.8%), mp 126—127°C after recrystallization from ethyl acetate-petroleum ether (50—90°C), $[\alpha]_D^{20}$ −14.4° (*c* 2.19, methanol), lit,[8] mp 125—127°C.

Found: C, 60.32; H, 5.80; N, 6.60; S, 7.48%. Calcd for $C_{21}H_{24}N_2O_5S$: C, 60.56; H, 5.81; N, 6.73; S, 7.70%.

N-Benzyloxycarbonyl-L-phenylalanyl-S-chlorocarbonyl-L-cysteine Methyl Ester (V). Phosgene was passed through a solution of IV (14.6 g, 0.035 mol) and *N,N*-dimethylaniline (4.3 g, 0.035 mol) in dioxane (140 m*l*) for 30 min at 10—12°C. The reaction mixture was stirred for 4 hr below 20°C and bubbled with a stream of carbon dioxide (or nitrogen) to remove excess phosgene. The separated *N,N*-dimethylaniline hydrochloride was filtered off and the crystals obtained by evaporation of the filtrate were washed with benzene and water. Yield, 10.7 g (64%), mp 154—155°C after recrystallization from benzene, $[\alpha]_D^{22}$ −5.6° (*c* 2.15, dioxane).

Found: C, 55.45; H, 5.20; N, 5.92%. Calcd for $C_{22}H_{23}N_2O_6SCl$: C, 55.17; H, 4.84; N, 5.85%.

Treatment of a solution of V in benzene with an etheral solution of aniline gave *N*-benzyloxycarbonyl-L-phenylalanyl-*S*-(*N*-phenylcarbamoyl)-L-cysteine methyl ester; mp 165.3—165.5°C, $[\alpha]_D^{22}$ −51.5° (*c* 2.10, *N,N*-dimethylformamide).

Found: C, 63.06; H, 5.46; N, 7.76; S, 5.52%. Calcd for $C_{28}H_{29}N_3O_6S$: C, 62.79; H, 5.46; N, 7.85; S, 5.99%.

Methyl L-3-(N-Benzyloxycarbonyl-L-phenylalanyl)-2-oxothiazolidine-4-carboxylate (VI). A solution of V (7.2 g, 0.015 mol) in xylene (140 m*l*) was heated under reflux for 5 hr. Evaporation of the solvent afforded an oil which was crystallized by seeding or by scratching on the wall of the vessel. Yield, 5.8 g (88%), mp 103—105°C. Recrystallization from ethyl acetate raised the melting point to 112.0—112.5°C, $[\alpha]_D^{20}$ −75.8° (*c* 1.47, methanol).

Found: C, 59.88; H, 5.07; N, 6.34; S, 7.12%. Calcd for $C_{22}H_{22}N_2O_6S$: C, 59.72; H, 5.01; N, 6.33; S, 7.25%.

Alkaline Hydrolysis of VI. a) With Potassium Hydroxide in Aqueous Methanol: To a suspension of VI (3.10 g, 7 mmol) in methanol (35.0 m*l*) was added 1N potassium hydroxide (14.0 m*l*, 14 mmol) and the reaction mixture was stirred for 1.5 hr at room temperature. After evaporation of the solvent *in vacuo*, the residue was diluted with water and the aqueous solution was acidified with 1N hydrochloric acid (8.0 m*l*) to pH 3. The separated oil was extracted twice with ethyl acetate. Evaporation of the dried solution *in vacuo* provided an oily *N*-benzyloxycarbonyl-L-phenylalanine which was crystallized by seeding. Yield, 1.35 g (64.3%), mp 82—89°C and 88—89°C after recrystallization from ethyl acetate-petroleum ether (50—90°C), lit,[12] mp 88—89°C. A mixed melting point with the authentic sample showed no depression.

It was also identified as its cyclohexylammonium salt,[13] mp 168—169°C, $[\alpha]_D^{19}$ +37.4° (*c* 1.69, ethanol).

An additional 1N hydrochloric acid (8.0 m*l*) was added to the remaining aqueous solution. The residue obtained by evaporation of the acidic solution was extracted three times with hot ethyl acetate. The extract was evaporated *in vacuo* to dryness leaving III as a crystalline residue. Yield, 0.85 g (82.5%), mp 157—164°C and 172—173°C after recrystallization from acetone-petroleum ether (50—90°C), $[\alpha]_D^{22}$ −57.9° (*c* 1.89, water), lit,[7] mp 171—172.5°C, $[\alpha]_D^{16}$ −57.3° (*c* 2.7, water).

Hydrolysis of this sample with 6N hydrochloric acid and subsequent oxidation with air by the usual procedure afforded L-cystine in a yield of 57%, $[\alpha]_D^{19}$ −211° (*c* 1.18, 1N hydrochloric acid), lit,[14] $[\alpha]_D^{25}$ −212° (*c* 1, 1N hydrochloric acid).

b) With Methanolic Potassium Hydroxide Solution: In a manner similar to that described above, a suspension of VI (3.10 g, 7 mmol) in methanol (35.0 m*l*) was treated with 1N methanolic potassium hydroxide solution (14.5 m*l*, 14.5 mmol). After evaporation of the solvent, the residue was diluted with water to give an oil which was extracted twice

10) All melting points are uncorrected.

13) An authentic sample was prepared from *N*-benzyloxycarbonyl-L-phenylalanine by treatment with cyclohexylamine; mp 169.0—169.5°C, $[\alpha]_D^{22}$ +37.1° (*c* 2.06, ethanol). Found: C, 69.37; H, 7.81; N, 7.10%. Calcd for $C_{23}H_{30}N_2O_4$: C, 69.32; H, 7.59; N, 7.03%.

14) J. P. Greenstein and M. Vinitz, "Chemistry of the Amino Acids" Vol. 3, John Wiley & Sons, New York (1961) p. 1879.

with ethyl acetate. Evaporation of the dried extract provided methyl *N*-benzyloxycarbonyl-L-phenylalaninate as an oil (wt, 1.24 g). Infrared spectra of this sample were identical with those of an authentic sample which was prepared from methyl L-phenylalaninate and benzyloxycarbonyl chloride. Treatment of a solution of the oil in methanol with a solution of an excess of hydrazine hydrate (about 95%) in methanol gave *N*-benzyloxycarbonyl-L-phenylalanine hydrazide. Yield, 0.75 g (34.2%), mp 161—163°C and 170.5—171°C after recrystallization from ethanol, $[\alpha]_D^{24}$ −6.9° (*c* 1.24, *N*, *N*-dimethylformamide), lit, mp 167—168°C[15], mp 168°C.[16] A mixed melting point with the authentic sample [mp 171.0—171.5°C, $[\alpha]_D^{24}$ −7.0° (*c* 1.28, *N*,*N*-dimethylformamide)] showed no depression.

Found: C, 65.34; H, 6.02; N, 13.45%. Calcd for $C_{17}H_{19}N_3O_3$: C, 65.16; H, 6.11; N, 13.41%.

The aqueous solution was acidified to pH 3. From ethyl acetate extract, *N*-benzyloxycarbonyl-L-phenylalanine was isolated as its cyclohexylammonium salt. Yield, 0.74 g (26.6%), mp 160—162°C and 169.5—170.0°C after recrystallization from ethanol-ether, $[\alpha]_D^{21}$ +37.9° (*c* 2.28, ethanol). No melting point depression upon the authentic sample[13] was observed.

As the third product, III was obtained from the acidic solution. Yield, 0.76 g (74.5%), mp 151—153°C and 153.5—154.5°C after recrystallization from acetone-petroleum ether (50—90°C), $[\alpha]_D^{20}$ −3.9° (*c* 2.92, water).

Hydrolysis of this sample with 6N hydrochloric acid and subsequent oxidation gave cystine having $[\alpha]_D^{20}$ −24.8° (*c* 1.39, 1N hydrochloric acid).

N-Benzyloxycarbonyl-L-alanyl-L-cysteine Methyl Ester (VII). In a similar way to that described for the preparation of IV, *N,N'*-bis(*N*-benzyloxycarbonyl-L-alanyl)-L-cystine dimethyl ester[17] (10.2 g, 15 mmol) was reduced to thiol peptide VII with zinc (9.0 g) and concentrated hydrochloric acid (19.5 ml) in methanol (120 ml). Yield, 8.1 g(79.5%), mp 114—116°C and 116.5—118.0°C after recrystalization from ethyl acetate, $[\alpha]_D^{20}$ −26.5° (*c* 1.27, methanol), lit,[8] mp 114—116°C.

Found: C, 53.03; H, 5.99; N, 8.20%. Calcd for $C_{15}H_{20}N_2O_5S$: C, 52.93; H, 5.92; N, 8.23%.

N-Benzyloxycarbonyl-L-alanyl-S-chlorocarbonyl-L-cysteine Methyl Ester (VIII). In the same manner as has been described for the preparation of V, a solution of VII (10.2 g, 0.030 mol) in dioxane (120 ml) was treated with a gentle stream of phosgene in the presence of *N,N*-dimethylaniline (3.6 g,0.030 mol) at 9—11°C for 25 min. After removal of excess phosgene by passage of carbon dioxide, VIII was obtained as a syrup which was crystallized by seeding. Yield, 10.5 g(86.8%), mp 94.5—95.5°C after recrystallization from chloroform-petroleum ether (50—90°C).

Found: C, 48.12; H, 4.66; N, 7.09%. Calcd for $C_{16}H_{19}N_2O_6SCl$: C, 47.70; H, 4.75; N, 6.95%.

It was also identified as *N*-benzyloxycarbonyl-L-alanyl-*S*-(*N*-phenylcarbamoyl)-L-cysteine methyl ester by treating with aniline; mp 158.5—159.5°C after recrystallization from benzene, $[\alpha]_D^{22}$ −30.4° (*c* 1.90, *N*,*N*-dimethylformamide).

Found: C, 57.42; H, 5.22; N, 9.07%. Calcd for $C_{22}H_{25}N_3O_6S$: C, 57.50; H, 5.48; N, 9.14%.

Methyl-L-3-(N-Benzyloxycarbonyl-L-alanyl)-2-oxothiazolidine-4-carboxylaye(IX). Heating of VIII (6.1 g, 15 mmol) in xylene (120 ml) under reflux for 5 hr followed by evaporating *in vacuo* gave IX as a syrup, wt, 5.6 g (101%). It gave a negative Beilstein's test and exhibited a main spot, accompanied by three minor spots, upon thin-layer chromatography with silica gel G(tlc).

This was used for the following cleavage reaction without further purification.

Alkaline Hydrolysis of IX. Hydrolysis of IX (3.68 g,10 mmol) was carried out in methanol (49.0 ml) by adding 1N potassium hydroxide (21.0 ml, 21 mmol) and by keeping the solution at room temperature for 1.5 hr. After methanol had been evaporated *in vacuo*, the residue was diluted with water and acidified with 1N hydrochloric acid (11.0 ml) to pH 3. Extraction with ethyl acetate and subsequent evaporation of the solvent gave *N*-benzyloxycarbonyl-L-alanine as a syrup which was purified as its cyclohexylammonium salt.[18] Yield, 1.85 g (54.4 %), mp 86—87°C after recrystallization from acetone-ether, $[\alpha]_D^{24}$ −10.2° (*c* 3.14, water). A mixed melting point with the authentic sample showed on depression.

Found: C, 59.83; H, 8.41; N, 8.05%. Calcd for $C_{17}H_{26}N_2O_4\cdot H_2O$: C, 59.98; H, 8.29; N, 8.23%.

On the other hand, the aqueous layer separated from the ethyl acetate extract was further acidified with an additional 1 N hydrochloric acid (11.0 ml) and evaporated *in vacuo* to give a residue. From the residue, III was isolated by extracting with hot ethyl acetate. Yield, 0.57 g (39.3%), mp 169—170°C and 172—173°C after recrystallization from acetone-petroleum ether(50—90°C), $[\alpha]_D^{23}$ −58.0° (*c* 2.31, water).

Properties of this sample such as infrared spectra were identical with those of the authentic sample.[8]

N-Benzyloxycarbonyl-L-phenylalanylglycyl-L-cysteine Methyl Ester (X). A mixed solution of *N*-benzyloxycarbonyl-L-phenylalanylglycine[19] (8.9 g, 0.025 mol) and methyl L-cysteinate, prepared from its hydrochloride[11] (4.3 g, 0.025 mol) and triethylamine (3.5 ml, 0.025 mol), in chloroform (90 ml) was treated with a solution of *N,N'*-dicyclohexylcarbodiimide (5.3 g, 0.026 mol) in chloroform (15 ml) at room temperature for 4 hr. After *N,N'*-dicyclohexylurea had been removed by filtration, the filtrate was washed successively with water, dilute hydrochloric acid, dilute aqueous sodium hydrogen carbonate solution and water. Evaporation of the dried solution gave a solid which was dissolved into ethyl acetate. The ethyl acetate solution separated from another *N,N'*-dicyclohexylurea was concentrated *in vacuo* to give X as white crystals. Yield, 9.7 g (82.8%), mp 129—132°C and 135—136°C after recrystallization from ethyl acetate, $[\alpha]_D^{22}$ −25.2° (*c* 1.96, *N*,*N*-dimethylformamide).

Found: C, 58.23; H, 5.78; N, 8.88%. Calcd for $C_{23}H_{27}N_3O_6S$: C, 58.34; H, 5.75; N, 8.87%.

It was oxidized with 1/10 N iodine-potassium iodide solution to the disulfide, *N,N'*-bis(*N*-benzyloxycarbonyl-L-phenylalanylglycyl)-L-cystine dimethyl ester, mp 187—188°C, $[\alpha]_D^{22}$ −49.7° (*c* 1.83, *N*,*N*-dimethylformamide).

Found: C, 58.26; H, 5.39; N, 8.70%. Calcd for $C_{46}H_{52}N_6O_{12}S_2$: C, 58.46; H, 5.55; N, 8.89%.

16) J. I. Harris and J. S. Work, *Biochem. J.*, **46**, 196 (1950).

17) This peptide was synthesized by the carbodiimide method in a similar manner to that for *N,N'*-bis(*N-benzyloxycarbonyl*-L-phenylalanyl)-L-cystine dimethyl ester as shown above. Yield, 75—80%, mp 160—161°C after recrystallization from ethanol, $[\alpha]_D^{22}$ −67.0° (*c* 1.98, *N*,*N*-dimethylformamide). Found: C, 53.20; H, 5.58; N, 8.09%, Calcd for $C_{30}H_{38}N_4O_{10}S_2$: C, 53.08; H, 5.64; N, 8.25%.

18) The authentic sample was prepared as a hydrate from *N*-benzyloxycarbonyl-L-alanine by treatment with cyclohexylamine; mp 85.5—86.0°C, $[\alpha]_D^{23.5}$ −10.2° (*c* 2.78, water). Found: C, 59.79; H, 8.34; N, 8.18%. Calcd for $C_{17}H_{26}N_2O_4\cdot H_2O$: C, 59.98; H, 8.29; N, 8.23%.

19) D. W. Clyaton, J. A. Farrington, G. W. Kenner, and J.M. Turner, *J. Chem. Soc.*, **1957**, 1398.

It was also identified as an *S*-benzoyl derivative, *N*-benzyloxycarbonyl-L-phenylalanylglycyl-*S*-benzoyl-L-cysteine methyl ester, by treating with benzoyl chloride in pyridine; mp 152—153°C, $[\alpha]_D^{22}$ −36.2° (*c* 2.67, *N,N*-dimethylformamide).

Found: C, 62.40; H, 5.41; N, 7.27%. Calcd for $C_{30}H_{31}N_3O_7S$: C, 62.38; H, 5.41; N, 7.27%.

N-Benzyloxycarbonyl-L-phenylalanylglycyl-S-chlorocarbonyl-L-cysteine Methyl Ester (XI). In a way similar to that for the preparation of V phosgene was passed through a solution of X (4.73 g, 10 mmol) in dioxane (50 m*l*) in the presence of *N,N*-dimethylaniline (1.21 g, 10 mmol) at 15°C for 20 min. From the reaction mixture, XI was obtained as crystals. Yield, 3.61 g(67.4%), mp 144—145°C (decomp.).

Found: C, 54.33; H, 4.89; N, 7.71%. Calcd for $C_{24}H_{26}N_3O_7SCl$: C, 53.78; H, 4.89; N, 7.84%.

Methyl L-3-(N-Benzyloxycarbonyl-L-phenylalanylglycyl)-2-oxothiazolidine-4-carboxylate (XII). A solution of XI (5.85 g, 10.9 mmol) in xylene (120 m*l*) was heated for 3 hr under reflux. The reaction mixture was cooled to room temperature to deposit XII as crystals. Yield, 4.85 g(89.0%), mp 175.5—177.0°C and 177.5—178.5°C after recrystallization from ethanol, $[\alpha]_D^{22}$ −81.5° (*c* 1.43, *N,N*-dimethylformamide).

Found: C, 57.60; H, 5.00; N, 8.63%. Calcd for $C_{24}H_{25}N_3O_7S$: C, 57.71; H, 5.04; N, 8.41%.

Alkaline Hydrolysis of XII. a) With Potassium Hydroxide in Aqueous Methanol: XII (3.30 g, 6.6 mmol) was hydrolyzed with a mixture of 1 N potassium hydroxide (14.0 m*l*, 14.0 mmol) and methanol (35.0 m*l*). After evaporation of the solvent, the residue was diluted with water and acidified with 1 N hydrochloric acid to pH 3. From ethyl acetate extract, *N*-benzyloxycarbonyl-L-phenylalanylglycine was isolated; Yield, 1.65 g (70.2%), mp 151.5—153.0°C. Recrystallization from ethyl acetate raised the melting point to 153—154°C, $[\alpha]_D^{20}$ −9.1° (*c* 3.12, acetic acid), lit,[19] mp 154°C, $[\alpha]_D^{18}$ −10.2°C (*c* 4.3, acetic acid)

From the acidic solution separated from ethyl acetate extract, III was isolated as crystals. Yield, 0.78 g (80.4%), mp 164—166°C and 171.5—172.5°C after recrystallization from acetone-petroleum ether (50—90°C), $[\alpha]_D^{22}$ −58.0° (*c* 2.65, water).

b) With Methanolic Potassium Hydroxide Solution: XII (3.20 g, 6.4 mmol) was hydrolyzed with 0.3 N methanolic potassium hydroxide solution (45.0 m*l*, 13.5 mmol). After evaporation of the solvent, the residue was dilute with water and acidified with 1N hydrochloric acid to pH 3. From ethyl acetate extract, *N*-benzyloxycarbonylphenylalanylglycine was isolated; yield, 0.72 g (31.6%), mp 152—153°C, $[\alpha]_D^{24}$ −6.0° (*c* 1.93, acetic acid).

From the aqueous solution, III was isolated; yield, 0.63 g (67.0%), mp 153—154°C, $[\alpha]_D^{24}$ −2.4° (*c* 2.94, water).

N-Benzyloxycarbonyl-S-benzoyl-L-cysteinyl-L-phenylalanine Methyl Ester (XIII). To a mixed solution of *N*-benzyloxycarbonyl-*S*-benzoyl-L-cysteine[20] (36.0 g, 0.10 mol) and methyl L-phenylalaninate prepared from its hydrochloride (22.0 g, 0.10 mol) and triethylamine (14.0 m*l*, 0.10 mol) in chloroform (450 m*l*) a solution of *N,N'*-dicyclohexylcarbodiimide (22.0 g, 0.11 mol) in chloform (50 m*l*) was added, and the reaction mixture was allowed to stand overnight at room temperature. After filtration of *N,N'*-dicyclohexylurea, the filtrate was worked up in the usual way. Yield, 41.4 g (79.6 %), mp 136—137°C after recrystallization from ethanol, $[\alpha]_D^{20}$ −30.7° (*c* 1.01, ethanol).

Found: C, 64.38; H, 5.44; N, 5.39%. Calcd for $C_{28}H_{28}N_2O_6S$: C, 64.60; H, 5.42; N, 5.38%.

20) L. Zervas, I. Photaki, and N. Ghelis, *J. Amer. Chem. Soc.*, **85**, 1337 (1963).

S-Benzoyl-L-cysteinyl-L-phenylalanine Methyl Ester Hydrochloride (XIV). A solution of XIII (5.20 g, 10 mmol) and phenol (2.0 g) in trifluoroacetic acid (15 m*l*) was heated for 30 min under reflux. Evaporation of the solvent followed by addition of ether gave *S*-benzoyl-L-cysteinyl-L-phenylalanine methyl ester trifluoroacetate as crystals. Yield, 3.24 g (64.8%), mp 137°C.

To a solution of the trifluoroacetate (23.5 g, 0.047 mol) in methanol (40 m*l*) was added absolute ether (120 m*l*) saturated with hydrogen chloride. The reaction mixture was diluted with ether (400 m*l*) to separate XIV as crystals. Yield, 16.4 g (82.4%), mp 151—152°C (decomp.) and 153.5—154.0°C (decomp.) after recrystallization from methanol-ether, $[\alpha]_D^{24}$ +1.5° (*c* 2.61, ethanol); +3.1° (*c* 4.55, ethanol).

Found: C, 56.67; H, 5.39; N, 6.61%. Calcd for $C_{20}H_{22}N_2O_4S \cdot HCl$: C, 56.80; H, 5.48; N, 6.62%.

N-Benzoyl-L-cysteinyl-L-phenylalanine Methyl Ester (XV). A suspension of XIV (1.51 g, 3.57 mmol) in chloroform (20 m*l*) was treated with triethylamine (0.50 m*l*, 3.57 mmol) and the reaction mixture was stirred for 4 hr at 25—35°C. After evaporation of the solvent, the residue was dissolved into ethyl acetate and the ethyl acetate solution was washed successively with water, dilute hydrochloric acid, dilute aqueous sodium hydrogen carbonate solution and water. Evaporation of the dried solution provided XV as white crystals. Yield, 1.16 g (84.0%), mp 154—155°C after recrystallization from ethyl acetate, $[\alpha]_D^{20}$ −32.1° (*c* 1.32, ethanol).

Found: C, 62.31; H, 5.64; N, 7.48%. Calcd for $C_{20}H_{22}N_2O_4S$: C, 62.16; H, 5.74; N, 7.25%.

When the reaction was carried out below 25°C, pure XV was not isolated.

N-Benzoyl-S-chlorocarbonyl-L-cysteinyl-L-phenylalanine Methyl Ester (XVI). In a similar way to that for the preparation of V, phosgene was passed through a slution of XV (5.80 g, 15 mmol) in dioxane (60 m*l*) in the presence of *N,N*-diemthylaniline (1.82 g, 15 mmol) at 10—15°C for 20 min. From the reaction mixture, XV was isolated as crystals melted at 133—134°C (decomp.). Yield, 5.58 g (82.8%). Recrystallization from benzene raised the melting point to 137.0—137.5° C (decomp.), $[\alpha]_D^{25}$ −40.0° (*c* 2.06, dioxane).

Found: C, 56.36; H, 4.66; N, 5.72%. Calcd for $C_{21}H_{21}N_2O_5SCl$: C, 56.18; H, 4.72; N, 6.24%.

Methyl L-3-Benzoyl-2-oxothiazolidine-4-carbonyl-L-phenylalaninate (XVII). A solution of XVI (3.00 g, 6.68 mmol) in xylene (60 m*l*) was heated for 3.5 hr under reflux. The crude product XVII precipitated when the reaction mixture was cooled to room temperature. Yield, 1.06 g (38.5%), mp 213.5—214.5°C. It gave a negative Beilstein's test. Recrystallization from ethyl acetate raised the melting point to 216—217°C, $[\alpha]_D^{23.5}$ +34.2° (*c* 1.29, *N,N*-dimethylformamide).

Found: C, 61.45; H, 4.88; N, 6.59%. Calcd for $C_{21}H_{20}N_2O_5S$: C, 61.15; H, 4.89; N, 6.79%.

Alkaline Hydrolysis of XVII. A suspension of XVII (2.06 g, 5.0 mmol) in methanol (30 m*l*) was treated with 1 N potassium hydroxide (11.0 m*l*, 11.0 mmol) for 1.5 hr at room temperature with stirring. After evaporation of the solvent, the residue was diluted with water to separate an oil which was extracted with ethyl acetate. Methyl benzoate was isolated as a sweet-smelling oil from the extract; yield, 0.19 g (27.9%). Properties of this sample such as infrared spectra were identical with those of the authentic sample.

The aqueous solution separated from the ethyl acetate extract was acidified with 1 N hydrochloric acid to pH 1 to give an oily product which was extracted twice with ethyl acetate. Evaporation of the dried extract left a syrup (wt, 1.54 g) which was extracted three times with hot petroleum ether (50—90°C). The extract was evaporated *in vacuo* to

give crystals which were identified as benzoic acid by its infrared spectra; yield, 0.06 g (10.0%).

From the remaining syrup (wt, 1.50 g), XVIII was isolated as its cyclohexylammonium salt by treating with cyclohexylamine. Yield, 1.34 g (68.0%), mp 204.5—205.5°C (decomp.) and 207.5—208.0°C (decomp.) after recrystallization from ethanol-ether, $[\alpha]_D^{22}$ −6.0° (*c* 1.66, ethanol).

Found: C, 57.98; H, 7.02; N, 10.48%. Calcd for $C_{19}H_{27}N_3O_4S$: C, 57.99; H, 6.92; N, 10.68%.

N-Benzoyl-L-cysteinylglycine Methyl Ester (XIX). In a way similar to that described for the preparation of XV, a solution of *S*-benzoyl-L-cysteinylglycine methyl ester hydrochloride[20] (6.65 g, 20 mmol) and triethylamine (2.80 m*l*, 20 mmol) in chloroform (80 m*l*) was stirred for 4 hr at room temperature. From the reaction mixture, pure XIX was isolated. Yield, 4.49 g (75.7%), mp 114—115°C, $[\alpha]_D^{20}$ −32.3° (*c* 2.69, methanol).

Found: C, 52.64; H, 5.40; N, 9.35%. Calcd for $C_{13}H_{16}N_2O_4S$: C, 52.69; H, 5.44; N, 9.45%.

Oxidation of XIX by 1/10 N iodine-potassium iodide solution gave a disulfide, *N,N'*-bisbenzoyl-L-cystinyldiglycine dimethyl ester; mp 226—227°C, $[\alpha]_D^{20}$ −211° (*c* 1.65, *N,N*-dimethylformamide).

Found: C, 52.80; H, 4.68; N, 9.56%. Calcd for $C_{26}H_{30}N_4O_8S_2$: C, 52.87; H, 5.12; N, 9.49%.

N-Benzoyl-S-chlorocarbonyl-L-cysteinylglycine Methyl Ester (XX). In a manner similar to that for the preparation of V, XX was obtained from a solution of XIX (5.50 g, 18.6 mmol) in dioxane (75 m*l*) by treatment with an excess of phosgene in the presence of *N,N*-dimethylaniline (2.25 g, 18.6 mmol). Yield, 3.35 g(50.3%), mp 109—110°C (decomp.).

Methyl L-3-Benzoyl-2-oxothiazolidine-4-carbonylglycinate (XXI) and N,N'-Bisbenzoyl-L-cystinylglycine Dimethyl Ester. A solution of XX (2.51 g, 7.0 mmol) in xylene (50 m*l*) was heated for 2 hr under reflux and cooled to room temperature to separate out crystals (wt, 0.49 g, mp 189—192°C). It gave a negative Beilstein's test and exhibited two spots upon tlc.

The crude product was dissolved into ethanol (50 m*l*) and kept for a short time at room temperature to separate crystals. Yield, 0.14 g (6.8%), mp 205—208°C and 224°C after recrystallization from ethanol, $[\alpha]_D^{20}$ −206° (*c* 1.06, *N,N*-dimethylformamide). Its structure was confirmed to be *N,N'*-bisbenzoyl-L-cystinyldiglycine dimethyl ester by comparison of the properties with those of the oxidized product of XIX.

The mother liquor separated from crystals was allowed to stand overnight at room temperature. XXI was separated as the second product. Yield, 0.14 g (6.2%), mp 203—204°C. Recrystallization from ethanol changed the melting point to 202.5—203.0°C, $[\alpha]_D^{20}$ −36.7° (*c* 0.98, *N,N*-dimethylformamide).

Found: C, 52.08; H, 4.21; N, 8.45%. Calcd for $C_{14}H_{14}N_2O_5S$: C, 52.16; H, 4.38; N, 8.69%.

N-Benzyloxycarbonyl-L-phenylalanyl-S-trityl-L-cysteinylglycine Methyl Ester. A solution containing *N*-benzyloxycarbonyl-L-phenylalanine (7.93 g, 26.5 mmol), *S*-trityl-L-cysteinylglycine methyl ester hydrochloride[21] (12.50 g, 26.5 mmol), and triethylamine (3.70 m*l*, 26.5 mmol) in methylene chloride (100 m*l*) was treated with a solution of *N,N'*-dicyclohexylcarbodiimide (5.47 g, 26.5 mmol) in methylene chloride (10 m*l*). The crystalline peptide was obtained by the usual procedure; yield, 15.10 g (79.6%), mp 165—167°C. Recrystallization from ethanol raised the melting point to 176.0—176.5°C, $[\alpha]_D^{20}$ −12.6° (*c* 2.23, *N,N*-dimethylformamide).

Found: C, 70.40; H, 5.83; N, 6.11; S, 4.39%. Calcd for $C_{42}H_{41}N_3O_6S$: C, 70.47; H, 5.77; N, 5.87; S, 4.48%.

N-Benzyloxycarbonyl-L-phenylalanyl-L-cysteinylglycine Methyl Ester (XXII). A solution of the above *S*-trityl peptide (7.16 g, 10 mmol) in acetic acid (200 m*l*) was treated with a solution of mercuric chloride (5.43 g, 20 mmol) in methanol (20 m*l*) followed by a solution of crystalline sodium acetate (1.37 g, 10 mmol) in methanol (25 m*l*). After standing for 4 hr at room temperature, the precipitates were collected and washed with aqueous acetic acid, water, and ether. Yield, 5.85 g (82.6%).

A stream of hydrogen sulfide was passed through a solution of the above *S*-chloromercury compound in a mixture of *N,N*-dimethylformamide (40 m*l*) and methanol (20 m*l*) for 15 min, and the precipitated mercuric sulfide was filtered off. The filtrate was diluted with water (250 m*l*) to give a thiol peptide XXII as crystals. Yield, 2.43 g (75.7%), mp 164—165°C. After recrystallization from ethyl acetate, the melting point was raised to 171—172°C, $[\alpha]_D^{20}$ −15.9° (*c* 2.26, *N,N*-dimethylformamide).

Found: C, 58.36; H, 5.84; N, 8.61; S, 6.72%. Calcd for $C_{23}H_{27}N_3O_6S$: C, 58.34; H, 5.75; N, 8.87; S, 6.77%.

It was oxidized to *N,N'*-bis(*N*-benzyloxycarbonyl-L-phenylalanyl)-L-cystinyldiglycine dimethyl ester by the treatment with 1/10 N iodine-potassium iodide solution; mp 220—223°C, $[\alpha]_D^{20}$ −86.4° (*c* 2.20, *N,N*-dimethylformamide), lit,[20] mp 223—224°C, $[\alpha]_D^{25}$ −87° (*c* 1, *N,N*-dimethylformamide).

Found: C, 58.54; H, 5.52; N, 8.88%. Calcd for $C_{46}H_{52}N_6O_{12}S_2$: C, 58.46; H, 5.55; N, 8.89%.

N-Benzyloxycarbonyl-L-phenylalanyl-S-chlorocarbonyl-L-cysteinylglycine Methyl Ester (XXIII). In a way similar to that for the preparation of V, XXIII was obtained from a suspension of XXII (4.73 g, 10 mmol) in dioxane (50 m*l*) by treatment with excess phosgene in the presence of *N,N*-dimethylaniline (1.21 g, 10 mmol). Yield, 3.65 g (68.1%), mp 142—144°C (decomp.) and 153—154°C (decomp.) after recrystallization from benzene, $[\alpha]_D^{20}$ −33.4°C (*c* 2.87, dioxane).

Found: C, 53.95; H, 4.87; N, 7.86%. Calcd for $C_{24}H_{26}N_3O_7SCl$: C, 53.78; H, 4.89; N, 7.84%.

In order to obtain a cyclized product, a solution of XXIII (2.5 g, 4.7 mmol) in toluene (50 m*l*) was heated for 3 hr under reflux and then concentrated to dryness to give a brownish syrup, from which no detectable substance was isolated.

Studies on Aminosugars. XXVII. Synthesis of Several Glycosides Containing (6-Amino-6-deoxy-D-glucopyranosyl)-2-deoxystreptamine[1]

Yoshio NISHIMURA, Tsutomu TSUCHIYA, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received April 7, 1971)

Racemic *O*-isopropylidene derivative of *N,N'*-diethoxycarbonyl-2-deoxystreptamine was glycosidized with 6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl chloride to afford two kinds of positional isomers of α-glucoside, which led to 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)- and 6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine. In a similar manner, 4-*O*-(6-amino-6-deoxy-α and β-D-glucopyranosyl)-6-*O*-(α-D-glucopyranosyl)-2-deoxystreptamines and 4-*O*-(6-amino-6-deoxy-α and β-D-glucopyranosyl)-6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamines were synthesized.

A number of chemotherapeutically useful compounds of 2-deoxystreptamine aminoglycosides have been obtained from the metabolites of microorganisms. The compounds include neomycins, kanamycins, paromomycins and gentamicins. In order to investigate the relationship between structure and antibiotic activity, the structural modification of either the aminocyclitol[2] or the sugar moiety[3,4] has been made. It appears so far that alterations have a profound effect on antibiotic activity and that the 2-deoxystreptamine moiety plays an important role in exhibiting activity. We have recently reported the total syntheses of kanamycin A,[5] B,[6] and C[7] as well as the syntheses of paromamine[8] and neamine.[4c] In relation to these syntheses, we were interested in altering the sugar moieties of kanamycin, and reported[9] the syntheses of the positional isomers of α-D-glucosyl-2-deoxystreptamines as a basic experiment of the syntheses of α-glycosides of 2-deoxystreptamine.

2-Deoxystreptamine has three hydroxyl groups at C-4,5, and 6, and there exist three kinds of 2-deoxystreptamine glycosides. As for the glycosyl components of 4-*O*-glycosyl-2-deoxystreptamines, 2-amino-2-deoxy-D-glucose (in kanamycin C, paromomycins, and gentamicin A), 6-amino-6-deoxy-D-glucose (in kanamycin A), 2,6-diamino-2,6-dideoxy-D-glucose (in kanamycin B, neomycins, and neamine), and partially substituted 2,6-diamino-2,3,4,6-tetradeoxy-D-glucose (in gentamicin C_1, C_2, and C_{1a}) are found. They are attached to the 2-deoxystreptamine with an α-glucosidic linkage. As for the glycosyl component of 6-*O*-glycosyl-2-deoxystreptamines, 3-amino-3-deoxysugars such as 3-amino-3-deoxy-D-glucose (in kanamycins), gentosamine[10] (in gentamicin A) and garosamine[11] (in gentamicin C) are found. They are also linked to the 2-deoxystreptamine with an α-linkage. As for the glycosyl component of 5-*O*-glycosyl-2-deoxystreptamines, only D-ribose is found, linked with β-linkage, in paromomycins, neomycins, and vistamycin.[12] On the other hand, 5-*O*-(2-amino-2-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine[3,13] was synthesized and found to have antibacterial activity against mycobacteria.

This paper reports the synthesis of 4-*O*- and 6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**7a** and **7b**), 4,6-di-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**20**) and 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-6-*O*-(α-D-glucopyranosyl)-2-deoxystreptamine (**14**). In addition some derivatives containing β-glycosidic linkages are described. Since 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine moiety[14] is considered to be the origin of the antibacterial activity of kanamycin A and 3-amino-3-deoxy-D-glucose moiety attached to C-6 of 2-deoxystreptamine is considered the enhacing factor of the activity, the latter moiety has been changed.

Synthesis of Glucosides. 6-Azido-2,3,4-tri-*O*-benzyl-

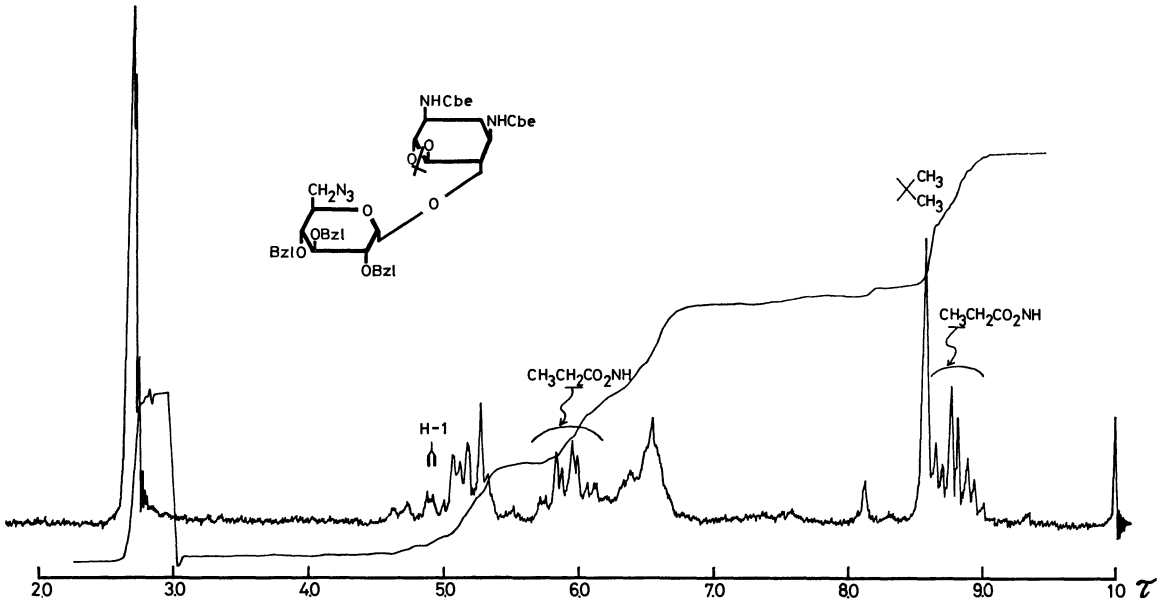

Fig 1. The NMR spectrum of **3b** in $CDCl_3$.

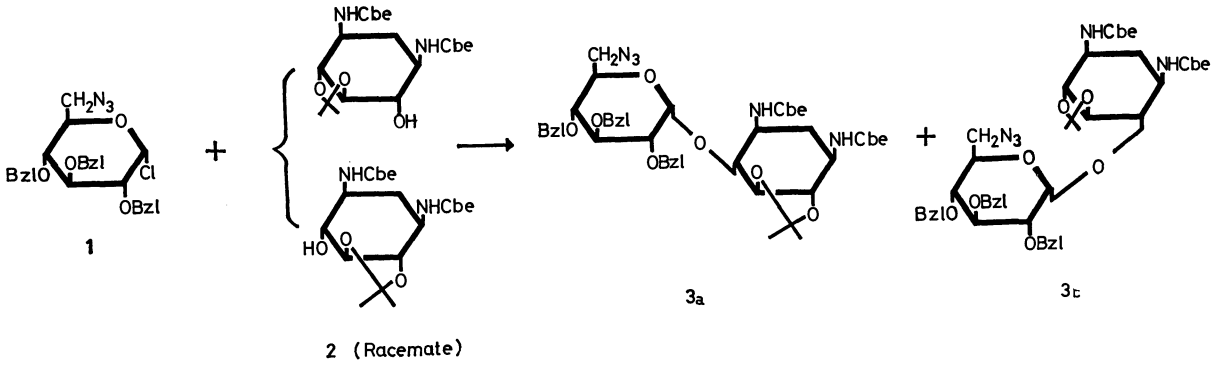

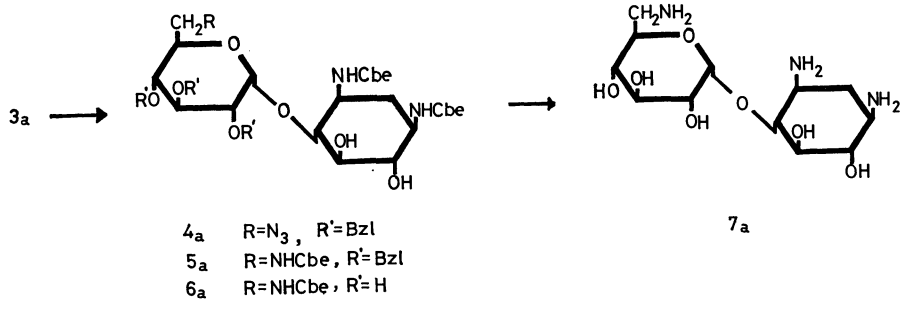

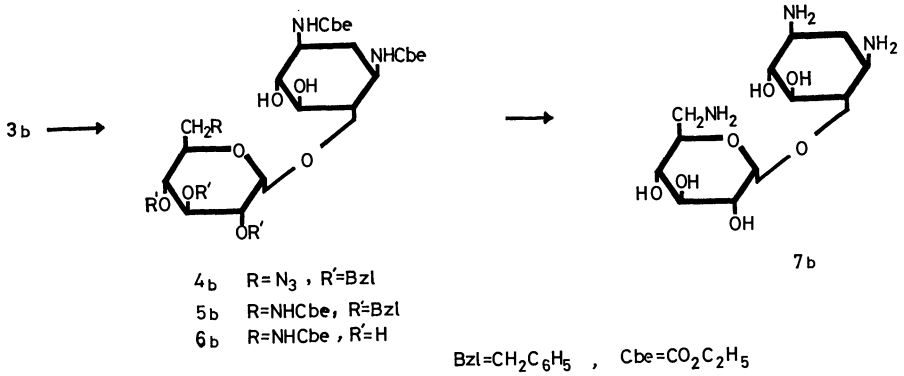

Bzl=$CH_2C_6H_5$, Cbe=$CO_2C_2H_5$

Chart 1.

6-deoxy-α-D-glucopyranosyl chloride (**1**)[15] was condensed with a racemic mixture (**2**) of *N,N'*-diethoxycarbonyl-4,5- and 5,6-*O*-isopropylidene-2-deoxystreptamine[9] in dry benzene-dioxane in the presence of mercuric cyanide and freshly prepared Drierite (Chart 1). The azide derivative of glycosyl chloride has been found to be more suitable for glycosidation than the acylamino or aryloxycarbonylamino derivatives of glycosyl halides, since the azide derivatives is more stable and easily hydrogenated into an amino derivative. Solvents, completely dried, were indispensable for the condensation. Benzene was dried over lithium aluminum hydride and dioxane was dried with sodium metal under reflux. The condensation products were purified by column chromatography. The main product (R_f 0.51) was still proved to be a mixture of two products. The major product in the mixture was isolated by recrystallization from ethanol-aqueous ammonia in a yield of 40%. The compound was proved to be 6-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-4,5-*O*-isopropylidene-2-deoxystreptamine (**3b**) by its IR, NMR (Fig. 1) and elemental analysis and by the fact that it was led to 6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine.

The mother liquor of the recrystallization described above contained the 4-*O*-isomer, namely 4-*O*-(6-azide-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-5,6-*O*-isopropylidene-2-deoxystreptamine (**3a**) accompanied by **3b**. Since the difficulty in separation of **3a** from **3b** remained, the isopropylidene groups were removed by acid and the deacetonated mixture (**4a** and **4b**) was chromatographed on silica gel to give **4a** and **4b** in yields of 12 and 48% (including that from **3b** obtained by recrystallization) based on **2**, respectively. It is noteworthy that we came across a low yield of 4-*O*-glucosides in the preparation of 4-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-5,6-*O*-isopropylidene-2-deoxystreptamine.[9] Since 4,6-di-*O*-glucosides (**9** and **16**) were prepared in good yields (60—70%) from mono-6-*O*-glucosides (**8** and **4b**) and **1**, the low yields of 4-*O*-glucosides may be not due to the intrinsic nature of C_4-OH, but to the presence of a 5,6-*O*-isopropylidene group.

Azide groups of **4a** and **4b** were reduced with Raney nickel and hydrogen to the amino groups, which were ethoxycarbonylated to give 4-*O*- and 6-*O*-(2,3,4-tri-*O*-benzyl-6-deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-2-deoxystreptamine (**5a** and **5b**), respectively. The subsequent debenzylation with palladium black and hydrogen gave 4-*O*- and 6-*O*-(6-deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-2-deoxystreptamine (**6a** and **6b**) respectively. When simultaneous reduction and debenzylation of **4a** or **4b** were performed by use of palladium black and hydrogen, several undeterminable products were obtained. The reaction was not pursued any further. However, Ainsworth's work suggests[16] that the amino groups liberated are damaged during the reaction. Treatment of **6a** and **6b** with hot 1N barium hydroxide gave 4-*O*- and 6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**7a** and **7b**), respectively, in good yields.

6-*O*-(2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-2-deoxystreptamine[9] (**8**) and **1** were condensed to give 4-*O*-(6-azide-2,3,4-tri-*O*-benzyl-6-deoxy-α- and β-D-glucopyranosyl)-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-2-deoxystreptamine (**9** and **10**) in yields of 71 and 10%, respectively (Chart 2). In order to determine whether the newly formed glycosides **9** and **10** are a 4-*O*-glycoside or 5-*O*-glycoside, the end products (**14** and **15**) derived from them were oxidized with periodate and followed by acidic hydrolysis. Paper chromatography of

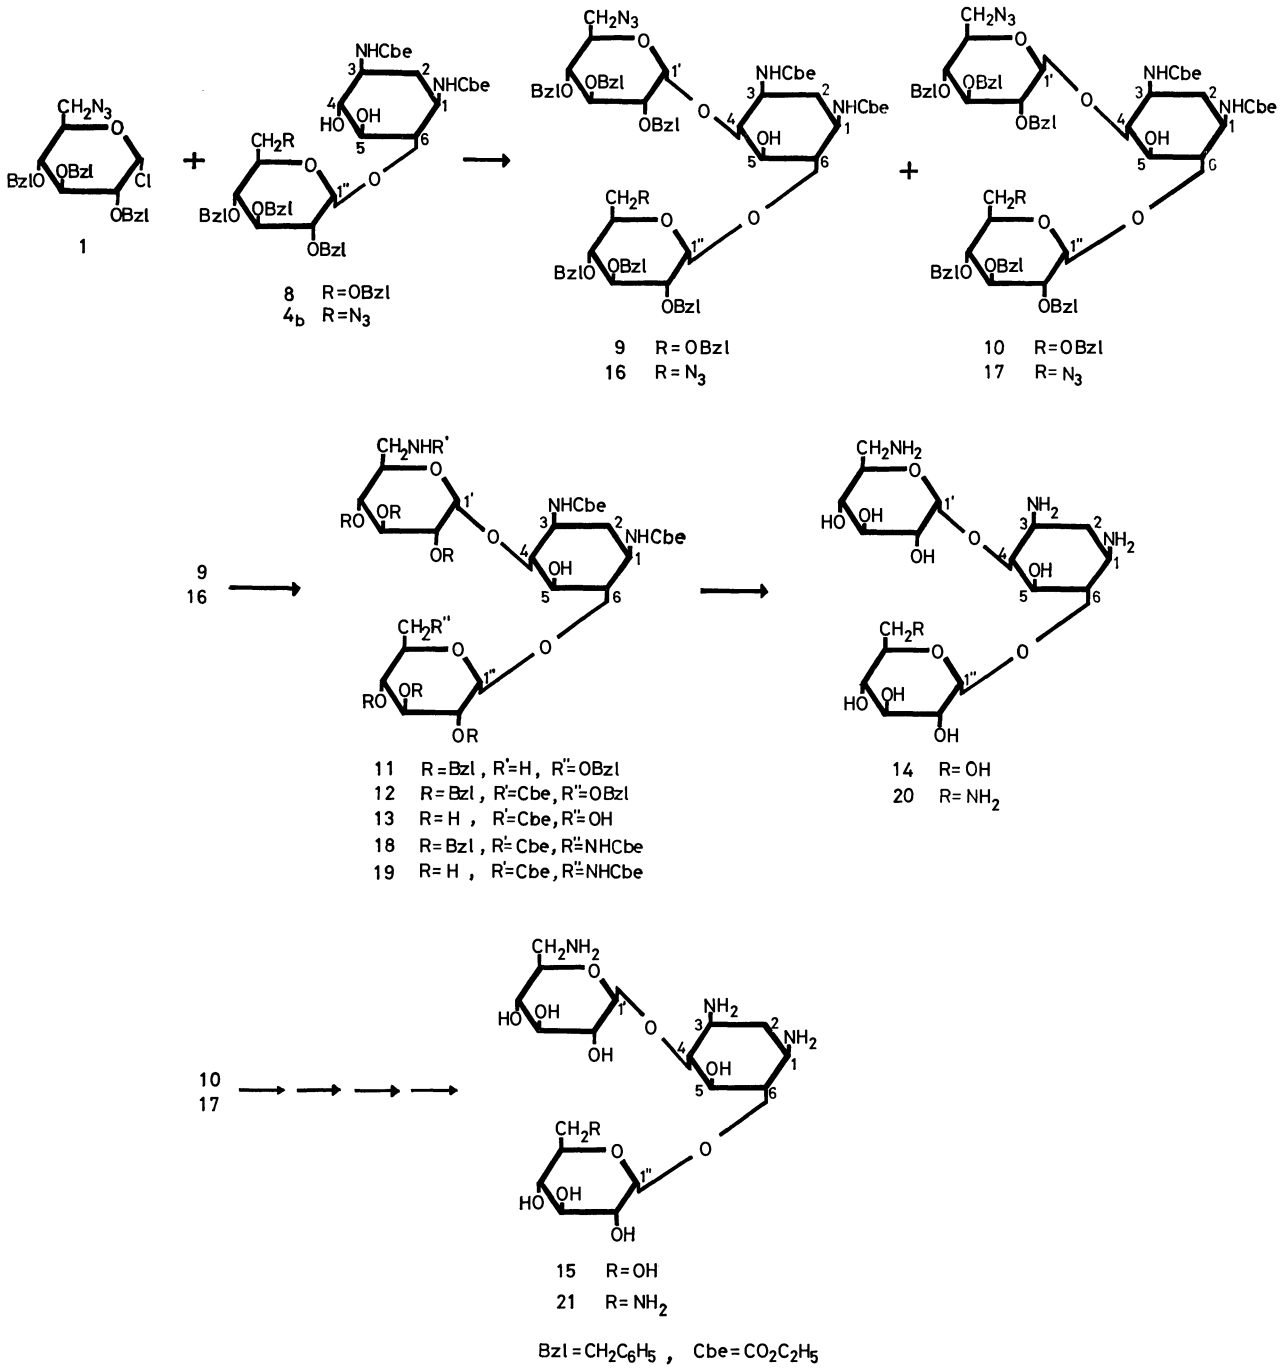

Chart 2.

the hydrolyzates showed the presence of 2-deoxystreptamine, indicating both **9** and **10** are 4,6-di-*O*-glycosides. The main product **9** was reduced with Raney nickel and hydrogen to give 4-*O*-(6-amino-2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N'*-diethoxycarbonyl-2-deoxystreptamine (**11**), which was then *N*-ethoxycarbonylated to give a tri-*N*-ethoxycarbonyl derivative (**12**). Subsequent debenzylation gave **13** and deethoxycarbonylation the final product, 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-6-*O*-(α-D-glucopyranosyl)-2-deoxystreptamine (**14**). The corresponding β-isomer, 4-*O*-(6-amino-6-deoxy-β-D-glucopyranosyl)-6-*O*-(α-D-glucopyranosyl)-deoxystreptamine (**15**) was similarly prepared, starting from **10**.

A similar scheme was also carried out for the preparation of 4-*O*-(6-amino-6-deoxy-α and β-D-glucopyranosyl)-6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**20** and **21**) starting from **4b** and **1** (Chart 2). The NMR spectrum of a condensation product, 4,6-di-*O*-(6-azido-2,3,4-tri-*O*-benzyl-6-deoxy-D-glucopyranosyl)-*N*,*N'*-diethoxycarbonyl-2-deoxystreptamine (**16**) is shown in Fig 2.

The characteristic features of the above mentioned synthesis and that reported previously[9] are: 1) α-glucoside is the main product and the yield of β-isomer is very low, even though it is formed, 2) 4-O and 6-O positional isomers are successfully separated by recrys-

tallization or by column chromatography of either the condensed products or the deacetonation products.

Structural assignment. α-glucosidic structures of 4-*O*- and 6-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**7a** and **7b**, respectively) were proved by their specific rotations ($[\alpha]_D^{20}+89°$ as **7a**·dihydrochloride and +82° as **7b**·dihydrochloride) and coupling constants (each ~3 Hz) of anomeric protons in their NMR spectra.

Assignment of 4-*O*- and 6-*O*-glycoside to **7a** and **7b**, respectively, were performed by the determination of the values of Δ[M] in tetramminecopper(II) sulfate solutions (**TACu**).[17] The Δ[M] values of **7a** and **7b** were +645° and −230° respectively. The former was in accord with that (+640°) of natural 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine,[13] and the sign and the absolute value of the Δ[M] indicated that **TACu** formed a complex between C-1 NH_2 and C-6 OH in deoxystreptamine moiety. Since methyl 6-amino-6-deoxy-α-D-glucopyranoside shows Δ[M]+80°[17] indicating that the C-6 amino group gives almost no effect on the Δ[M] value, the above assignment for **7a** is substantiated. On the other hand, Δ[M]−230° of **7b** is anomalously low in absolute value. However, the deviation from the normal value (900—700°) will be interpreted by considering the steric state of **7b**. If 6-amino-6-deoxy-D-glucose and 2-deoxystreptamine moieties of **7a** and **7b** are situated as far as possible from each other as seen in kanamycin, which is indicated by X-ray crystallographic analysis,[18] the C-6 amino groups of **7a** and **7b**, can come near the C-3 NH_2 and C-5 OH groups, respectively, of 2-deoxystreptamine moiety. Thus the anomalous Δ[M] value of **7b**, can be explained by assuming the complexing between C-5 OH in 2-deoxystreptamine moiety and C-6 NH_2 group in sugar moiety occurs and the value of Δ[M] attributable to the complexing is fairly large and the sign is positive.

Antibiotic Activity. The antibacterial activities of synthetic compounds **7a**, **7b**, **14**, **15**, **20**, and **21** were tested. It is particularly noteworthy that the 4-*O*-isomer (**7a**), which was proved to be the same as the natural origin,[14] has antibacterial activity (Table 1), while the 6-*O*-isomer (**7b**) has no antibacterial activity. **7a**, **14**, and **20** which contain 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine have antibacterial activity, even though it is low. This shows that 3-amino-3-deoxy-D-glucose moiety attached to C-6 OH of 2-deoxystreptamine especially enhances the activity of 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine moiety. Since 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine have no antibacterial activity, this conclusion may be substantiated.

It has been confirmed that **15** and **21** which contain 4-*O*-(6-amino-6-deoxy-β-D-glucopyranosyl)-2-deoxystreptamine show no antibacterial activities, indicating that the α-glucosidic linkage at C-4 of 2-deoxystreptamine is indispensable for exhibiting antibacterial activity.

Experimental

The NMR spectra were measured with a Varian A-60D spectrometer. Tetramethylsilane (τ 10.00; for the solutions other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (τ 10.00; for the solutions of deuterium oxide) were used as internal standards. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel, and the spots were visualized with sulfuric acid. Paper chromatography (ppc) was carried out on Toyo Roshi No. 50 paper.

*6-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-4,5-O-isopropylidene-2-deoxystreptamine (**3b**,) and a Mixture of **3b** and 4-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-5,6-O-isopropylidene-2-deoxystreptamine (**3a**).* A mixture of **1** syrup, ($[\alpha]_D^{24}+119°$ (*c* 1, $CHCl_3$), 8.3 g, 17 mmol) and freshly prepared Drierite (7 g) in dry benzene-dioxane (4:1, 75 ml)[19] was heated at 60°C under stirring for 30 min, and **2** (racemic mixture, 3.76 g, 11 mmol) and well dried powder mercuric cyanide (9 g) were added to the mixture, which was refluxed for 26 hr under vigorous stirring. The reaction mixture was filtered and the residue was washed with chloroform. The filtrate and the washings combined were evaporated to

17) S. Umezawa, T. Tsuchiya, and K. Tatsuta, This Bulletin, **39**, 1235 (1966).

18) G. Koyama, Y. Iitaka, K. Maeda, and H. Umezawa, *Tetrahedron Lett.*, **1968**, 1875.

19) Benzene and dioxane were dried strictly as follows: benzene was distilled with a fractionating column and the main portion was dried over lithium aluminum hydride. After storage for several days, the upper layer was taken for use. Dioxane was distilled and the main portion was refluxed with sodium metal for several hours and used immediately.

give a syrup, which was dissolved in chloroform and the solution was washed with 2% sodium bicarbonate solution and water. The solution was dried over sodium sulfate and evaporated. The syrup (~14 g) was chromatographed on a column (45×410 mm) of alumina (E. Merck AG, 650 g) with benzene - acetone (5:1). The condensation product was eluted, after the chloride (**I**) remained eluted, giving a paleyellow syrup (~12 g). On tlc with chloroform - ethyl acetate (3:1), the syrup showed two spots of R_f 0.50 (major) and 0.37 (minor). One fourth of the syrup was chromatographed on a column (35×315 mm) of silica gel (Wako Gel, 130 g) with chloroform-ethyl acetate (3:1) and the portion (360—460 m*l*) containing the major product (R_f 0.50) was evaporated to give a syrup (1.58 g). The syrup, however, on tlc with benzene - acetone (5:1), showed still two spots of R_f 0.51 (major) and 0.60 (minor). Further chromatography on a column (28×530 mm) of silica gel (Wako Gel, 150 g) with benzene - acetone (5:1) gave a syrup (R_f 0.51, **3a**+**3b**, 1.4 g). Recrystallization from ethanol containing a small quantity of aqueous ammonia gave crystals of **3b**, 0.88 g (47%), mp 184.5—185.5°C, $[\alpha]_D^{16}$+48° (*c* 1, chloroform); IR (KBr): 2100 (N_3), 1695 (amide I), 1540 cm^{-1} (amide II); NMR ($CDCl_3$): τ 8.83 and 8.78 (3H, t. each, *J* 7 Hz, $CH_2C\underline{H}_3$), 8.58 (6H, s., isopropylidene), 2.67, 2.68, and 2.71 (5H s. each, $OCH_2C_6\underline{H}_5$).

Found: C, 63.07; H, 6.87; N, 8.50%. Calcd for $C_{42}H_{53}N_5O_{11}$: C, 62.75; H, 6.65; N, 8.71%.

Evaporation of the mother liquor gave a syrup (0.5 g) which was still a mixture of **3a** and **3b**.

*4-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**4a**) and 6-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**4b**).* *a) From the mixture of **3a** and **3b**:* A solution of the mixture (1.94 g) in 80% acetic acid (10 m*l*) was heated at 90°C for 20 min and poured into water. The resulting precipitate (1.78 g) was chromatographed on a column of silica gel (Mallinckrodt, 200 g) with benzene-methyl ethyl ketone (3:1). **4a** (R_f 0.17 on tlc with the same solvent system) was obtained from the early fractions, yield 1.08 g (12.3%, based on one-half of **2**). From the late fractions, **4b** (R_f 0.12) was obtained, yield 0.55 g. **4a** was recrystallized from acetone to give needles, but not **4b**.

*b) **4b** from **3b**:* The crystalline **3b** (3.2 g) was treated as above to give **4b** quantitatively, yield, 3.12 g. Total yield of **4b** by a) and b) was 48% based on one-half of **2**.

Compound **4a**: mp 218—219°C, $[\alpha]_D^{26}$+74.3° (*c* 1, chloroform); IR (KBr): 2100 (N_3), 1690, 1540 cm^{-1}; NMR (in $CDCl_3$ containing D_2O): τ 8.80 and 8.78 (3H t. each, *J* 7 Hz, $CH_2C\underline{H}_3$), 6.1—6.7 (11H, skeleton protons), 5.89 and 5.86 (2H q. each, *J* 7 Hz, $C\underline{H}_2CH_3$), 5.35 (1H, d., *J* 11 Hz) and 5.08 (1H d., *J* 11 Hz) forming an AB quartet ($OC\underline{H}_2C_6H_5$ at C-2(?)), 5.17 and 5.08 (2H s. each, $OC\underline{H}_2C_6H_5$ at C-3 and C-4), 5.00 (1H, d., *J* 3 Hz, H-1′[20]), 2.69 (5H s., $OC\underline{H}_2C_6H_5$), 2.65 (10H s., $OC\underline{H}_2C_6H_5$).

Found: C, 61.56; H, 6.43; N, 8.86%. Calcd for $C_{39}H_{49}N_5O_{11}$: C, 61.32; H, 6.47; N, 9.17%.

Compound **4b**: mp 178—179°C $[\alpha]_D^{22}$+38° (*c* 0.5, chloroform); IR: a similar pattern with that of **4a**; NMR (in $CDCl_3$ containing D_2O): τ 8.85 and 8.76 (3H t. each, *J* 7 Hz, $CH_2C\underline{H}_3$), 6.1—6.7 (11H, skeleton protons), 5.92 and 5.85 (2H q. each, *J* 7 Hz, $C\underline{H}_2CH_3$), 4.9—5.5 (~7 H m.), 2.67, 2.63 and 2.61 (each 5H s., $OCH_2C_6\underline{H}_5$).

Found: C, 61.18; H, 6.21; N, 8.87%. Calcd for $C_{39}H_{49}N_5O_{11}$: C, 61.32; H, 6.47; N, 9.17%.

*4-O-(2,3,4-Tri-O-benzyl-6-deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**5a**).* Compound **4a** (0.40 g) was dissolved in aqueous ethanol (1:16, 8.5 m*l*) by heating and the solution was hydrogenated with Raney nickel (T-4) and hydrogen under 50 lb/sq. inch pressure at 40—45°C for 12 hr. On tlc with benzene-methyl ethyl ketone (2:1), **4a** (R_f 0.3) disappeared and a product (R_f 0) appeared. Filtration and evaporation of the solution gave a solid (0.38 g), which was dissolved in acetone (5 m*l*), and water (5 m*l*) was added under vigorous stirring to the solution. To the resulting suspension, anhydrous sodium carbonate (0.42 g) was added and after agitation for a while, carboethoxy chloride (0.28 g) was added slowly. After agitation was continued for 30 min, a product (R_f 0.15) appeared on tlc. The solution was evaporated to give a residue, which was dissolved in chloroform and the solution was washed with water. Drying over sodium sulfate and evaporation gave a residue (0.41 g). Recrystallization from equeous ethanol gave a colorless solid, 0.36 g (86%), mp 198—199°C, $[\alpha]_D^{23}$+24° (*c* 0.7, chloroform); IR: no peak near ~2100 cm^{-1} (N_3) was observed; NMR (in pyridine-d_5 containing small amount of D_2O): τ 8.80 (9H t., *J* 7 Hz, $CH_2C\underline{H}_3$), 2.65 (15H s., $OCH_2C_6\underline{H}_5$).

Found: C, 62.32; H, 6.91; N, 5.06%. Calcd for $C_{42}H_{55}N_3O_{13}$: C, 62.28; H, 6.85; N, 5.19%.

*6-O-(2,3,4-Tri-O-benzyl-6-deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**5b**).* A solution of **4b** (0.23 g) in aqueous ethanol (1:20, 10.5 m*l*) was hydrogenated for 20 hr as in the procedure for **4a** and the reduction product (0.21 g, R_f 0 with benzene-acetone 2:1) was allowed to react with carboethoxy chloride to give **5b** (0.21 g). Recrystallized from aqueous ethanol; a colorless solid 0.18 g (74%), mp 243—244°C, $[\alpha]_D^{26}$ +24° (*c* 0.6, acetone); NMR (in pyridine-d_5 containing small amount of D_2O): τ 8.87 and 8.82 (6H and 3H t. respectively, $CH_2C\underline{H}_3$), 4.05 (1H d., *J* 3 Hz, H-1″), 2.4—2.6 (15H m., $OCH_2C_6\underline{H}_5$).

*4-O-(6-Deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**6a**).* Compound **5a** (0.31 g) was dissolved in a mixture of ethanol (11 m*l*) and water (4 m*l*) by heating. After addition of several drops of acetic acid, the solution was hydrogenated with freshly prepared palladium black and hydrogen under 50 lb/sq. inch pressure at 40—45°C for 12 hr. On tlc with benzene-methanol (4:1), **5a** (R_f 0.6) disappeared and a product (R_f 0.2) appeared. Filtration and evaporation of the solution gave a solid, which was treated with aqueous acetone (2:1) to give an amorphous solid, 0.20 g (97%), mp 266—267°C, $[\alpha]_D^{20}$+44° (*c* 0.7, aqueous ethanol 1:1); IR (KBr): 3200—3500, 1695, and 1545 cm^{-1}; NMR (in a mixture of D_2O and pyridine-d_5 of approximately 1:1): τ 8.90 (9H t., *J* 7 Hz, $CH_2C\underline{H}_3$), 6.8—6.3 (11H, skeleton protons), 6.01 (6H q., *J* 7 Hz, $C\underline{H}_2CH_3$), 4.82 (1H, d., *J* 3 Hz, H-1′). No benzyl protons were observed. Found: C, 46.44; H, 7.24; N, 7.55%. Calcd for $C_{21}H_{37}N_3O_{11}$: C, 46.75; H, 6.91; N, 7.79%.

*6-O-(6-Deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (**6b**).* **6b** was prepared from **5b** likewise as described above and the product was reprecipitated from aqueous acetone (3:1), yield 97%. Mp 242.5—244°C, $[\alpha]_D^{20}$+67° (*c* 0.6, aqueous ethanol 1:1); NMR (in a mixture of D_2O and pyridine-d_5 of approximately 1:1): τ 8.90, 8.87, and 8.82 (3H t. each, *J* 7 Hz, $CH_2C\underline{H}_3$), 6.4—5.6 (~17 H), 4.43 (1H d., *J* 3 Hz, H-1″).

Found: C, 46.83; H, 6.91; N, 7.42%. Calcd for $C_{21}H_{37}N_3O_{13}$: C, 46.75; H, 6.91; N, 7.79%.

*4-O-(6-Amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (**7a**).* A solution of **6a** (0.14 g) in 1N barium hydroxide

20) The anomeric hydrogen of a glycoside moiety attached to C-4 and C-6 of 2-deoxystreptamine is designated as H-1′ and H-1″ respectively; See Ref. 4e.

(6 ml) was heated at 90°C for 5 hr and the resulting solution was neutralized with carbon dioxide. The suspension was boiled for a while, centrifuged, and the upper layer was filtered. The residue was washed with boiling water several times. The filtrate and washings combined were evaporated. The resulting residue was dissolved in water and the solution was filtered and the filtrate was evaporated. The procedure was repeated twice more. The residue was charged on a column (10×140 mm) of Amberlite IRC 50 (NH_4^+ form) and after washing with water developed with 0.1N ammonia. The portion (70—160 ml) containing **7a** was evaporated to give a colorless solid, 0.06 g (69%). An aqueous solution of the product was neutralized with hydrochloric acid to pH 3 and the solution was concentrated. Addition of acetone gave **7a**·dihydrochloride, $[\alpha]_D^{22}+89°$ (*c* 0.3, water), $[\alpha]_{436}^{22}+153°$ (*c* 0.3, water), $[\alpha]_{436TACu}^{22}+316°$ (*c* 0.3, TACu), $\Delta[M]_{TACu}^{22}$[16] $+645°$; $R_{f\,2\text{-deoxystreptamine}}$ 0.38 (ppc with *n*-butanol-pyridine-water-acetic acid 6:4:3:1) IR spectrum was quite the same as that obtained from the natural antibiotic.[14] NMR (in D_2O): τ 8.75 (1H q., $J\sim12$ Hz, H_{ax}-2), 7.97 (1H double triplets, $J\sim3$ and ~12 Hz, H_{eq}-2), 4.73 (1H d., $J\sim3$ Hz, H-1′)

Found: C, 36.34; H, 7.21; Cl, 17.51%. Calcd for $C_{12}H_{25}N_3O_7\cdot2HCl$: C, 36.37; H, 6.87; Cl, 17.89%.

The value of $\Delta[M]_{TACu}^{22}$ corresponded to that (+640°) of the natural product.

6-O-(6-Amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (7b). **6b** was treated similarly as in the procedure for **7a** yielding **7b**, yield 65%. Dihydrochloride, $[\alpha]_D^{22}+82°$ (*c* 0.3, water), $[\alpha]_{436}^{22}+150°$ (*c* 0.3, water), $[\alpha]_{436(TACu)}^{22}+92°$ (*c* 0.3, TACu), $\Delta[M]_{TACu}$ −230°; $R_{f\,2\text{-deoxysteptamine}}$ 0.45 (ppc with *n*-butanol-pyridine-water-acetic acid); The IR spectra of **7b** was the same as that of **7a**. NMR (in D_2O): τ 8.53 (1H q., $J\sim12$ Hz, H_{ax}-2), 7.83 (1H double triplet, $J\sim3$ and ~12 Hz, H_{eq}-2), 4.87 (1H, d., $J\sim3$ Hz, H-1″).

Found: C, 36.54; H, 7.03; Cl, 17.42%. Calcd for $C_{12}H_{25}N_3O_7\cdot2HCl$: C, 36.37; H, 6.87; Cl, 17.89%.

4-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-α- and β-D-glucopyranosyl)-6-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (9 and 10, respectively). A mixture of **1** (1.21 g, 2.4 mmol) and freshly prepared Drierite (1.5 g) in anhydrous benzene-dioxane (3:1, 20 ml) was heated at 60°C under stirring for 30 min and **8**[9] (1.35 g, 1.6 mmol) and well dried mercuric cyanide (1.24 g) were added to the mixture, which was refluxed for 10 hr under vigorous striring. Mercuric cyanide (1.24 g) was again added and the reaction was further continued for 10 hr. The mixture was filtered and the residue was washed with chloroform. The filtrate and washings combined were evaporated to give a syrup which was dissolved in chloroform. The solution was washed with water, dried over sodium sulfate and evaporated to give a thick syrup (2.3 g). On tlc with benzene-acetone (10:1), the syrup showed four spots of R_f 0.43 (major), 0.33 (minor), 0.28 (minor), and 0.20 (minor). The syrup was chromatographed on a column (27×330 mm) of silica gel (Mallinckrodt, 120 g) with benzene-acetone (10:1), and the fractions of 200—300 ml and 360—450 ml containing the major (R_f 0.43) and minor (R_f 0.20) products were evaporated to give solids, respectively (**9**, 1.50 g, 71% based on **8**; **10**, 0.33 g, 16% based on **8**). **10** was recrystallized from ethanol, but not **9**. Compound **9**: mp 53—57°C, $[\alpha]_D^{20}+80°$ (*c* 0.8, acetone); IR (KBr): 2100 cm^{-1} (N_3); NMR (in $CDCl_3$): τ 8.86 and 8.83 (3H t. each $J\sim7$ Hz, $CH_2C\underline{H}_3$, overlapped with peaks of H_{ax}-2), 5.7—6.8 ($\sim$21H, skeleton protons and $C\underline{H}_2CH_3$), 4.8—5.7 ($\sim$17H; seven $OC\underline{H}_2C_6H_5$, two anomeric protons and one amide proton (?)), 4.0 (1H, amide proton), 2.55—2.75 (35H, five singlets, seven $OCH_2C_6\underline{H}_5$).

Found: C, 68.44; H, 6.43; N, 5.51%. Calcd for $C_{73}H_{83}N_5O_{16}$: C, 68.15; H, 6.50; N, 5.44%.

Compound **10**: mp 176—176.5°C, $[\alpha]_D^{20}+82°$ (*c* 0.7 acetone); IR (KBr): 2120 cm^{-1} (N_3); NMR (in $CDCl_3$): τ 8.86 and 8.84 (3H t. each), 5.7—6.8 ($\sim$21H), 4.95—5.7 ($\sim$16H), 4.80 (1H d., $J\sim3$ Hz), 3.7 (1H, amide proton), 2.6—2.75 (35H).

Found: C, 68.01; H, 6.64: N, 5.35%. Calcd for $C_{73}H_{83}N_5O_{16}$: C, 68.15; H, 6.50; N, 5.44%.

4-O-(6-Amino-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-6-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (11). Compound **9** (0.65 g) was dissolved in hot aqueous ethanol (16:1, 8.5 ml) and the solution was hydrogenated with Raney nickel (T-4) and hydrogen under a pressure of 50 lb/sq. inch at 40—45°C for 5 hr. On tlc with benzene-acetone (1:1), **9** (R_f 0.94) disappeared and a product (R_f 0.61) appeared. Filtration and evaporation of the solution gave a colorless solid (0.56 g), which was recrystallized from ethanol to give crystals of **11** (0.51 g, 80%), mp 130—131°C, $[\alpha]_D^{22}+59°$ (*c* 0.8, $CHCl_3$); IR (KBr): no peak near 2100 cm^{-1} (N_3). NMR (in $CDCl_3$): τ 8.83 and 8.80 (3H t. each, *J* 7 Hz, $CH_2C\underline{H}_3$ overlapped with H_{ax}-2 peaks), $\sim$7.9 (1H unresolved m. H_{eq}-2), 6.9—7.5 (3H m., NH_2 and OH), 5.7—6.9 (21H, skeleton protons and $C\underline{H}_2CH_3$), 5.0—5.65 (14H, seven $OC\underline{H}_2C_6H_5$), 4.95 (1H d., $J\sim3$ Hz, anomeric proton at 1″ (?)), 4.78 (1H d., $J\sim3$ Hz, anomeric proton at 1′ (?)), 4.28 and 3.96 (1H each, amide protons), 2.6—2.75 (35H four singlets, seven $OCH_2C_6\underline{H}_5$).

Found: C, 69.26; H, 6.71; N, 3.61%. Calcd for $C_{73}H_{85}N_3O_{16}$: C, 69.56; H, 6.80; N, 3.33%.

4-O-(2,3,4-Tri-O-benzyl-6-deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-6-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (12). Water (5 ml) and sodium carbonate (0.22 g) were added to a solution of **11** (0.34 g) in acetone (5 ml), under vigorous stirring, and carboethoxy chloride (0.15 g) was added to the resulting suspension. The reaction was continued under stirring for 30 min at room temperature. On tlc with benzene-acetone (3:1), the starting material **11** (R_f 0.13) disappeared and a product (R_f 0.75) appeared. The solution was evaporated and the residue was dissolved in chloroform. The solution was washed with water, dried over sodium sulfate and evaporated to give a thick syrup of **12**; 0.37 g (97%), $[\alpha]_D^{20}+54°$C (*c* 1.2, acetone); NMR (in $CDCl_3$): τ 8.85, 8.82, and 8.77 (3H t. each $CH_2C\underline{H}_3$, overlapped with H_{ax}-2 peaks), $\sim$8.0 (1H m., H_{eq}-2), 5.65 $\sim$6.7 (23H), 4.7—5.6 (17H), 3.95 (1H), 2.55—2.7 (35H, seven $OC\underline{H}_2C_6\underline{H}_5$).

Found: C, 68.67; H, 6.76; N, 3.44%. Calcd for $C_{76}H_{89}N_3O_{18}$: C, 68.50; H, 6.73; N, 3.15%.

4-O-(6-Deoxy-6-ethoxycarbonylamido-α-D-glucopyranosyl)-6-O-(α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (13). A solution of **12** (0.33 g) in aqueous ethanol (1:7, 16 ml) containing several drops of acetic acid was hydrogenated with palladium black and hydrogen under 50 lb/sq. inch pressure at 40—45°C for 15 hr. Filtration and evaporation of the solution gave a residue. Recrystallization was accomplished by dissolving the residue in aqueous ethanol (1:1, 8 ml) with subsequent addition of acetone; 0.15 g (84%), mp 164.5—165.5°C, $[\alpha]_D^{20}+88°$ (*c* 0.5, aqueous ethanol 1:1); IR (KBr): 1690 (sharp), 1545 cm^{-1}; NMR (in pyridine-d_5 containing small amount of D_2O): τ 8.75, 8.72 and 8.69 (3H t. each, $CH_2C\underline{H}_3$), $\sim$7.7 (1H, H_{ex}-2), 5.35—6.3 ($\sim$23H), 4.2—4.7 (overlapped with DOH).

Found: C, 45.03; H, 6.82; N, 6.15%. Calcd for $C_{27}H_{47}N_3O_{18}\cdot H_2O$: C, 45.05; H, 6.86; N, 5.84%.

4-O-(6-Amino-6-deoxy-α-D-glucopyranosyl)-6-O-(α-D-gluco-

pyranosyl)-2-deoxystreptamine (14). A solution of **13** (0.14 g) in 1N barium hydroxide (6 m*l*) was heated at 90°C for 5 hr and then neutralized with carbon dioxide. A product ($R_{f\,2\text{-deoxystreptamine}}$ 0.32) appeared on paper chromatography with *n*-butanol – pyridine – water – acetic acid (6:4:3:1). By a similar procedure to that for **7a**, a crude product was obtained. The product was passed through a short column (11×40 mm) of Sephadex G 10 and the fraction containing the product was concentrated to a small volume which was again passed through a short column of Dowex 1×2 (OH form, 0.5 m*l*). The solution obtained was evaporated to give a colorless solid (88 mg), which was purified by dissolving in a mixture of water, methanol and ethanol with subsequent addition of acetone; a hygroscopic solid, 79 mg (82%), $[\alpha]_D^{22}$ +135° (*c* 0.5, water), NMR (in D_2O): τ 8.3—9.0 (1H unresolved m., H_{ax}-2), 7.85—8.2 (1H unresolved m., H_{eq}-2), 5.8—7.3 (~17H, skeleton protons), 4.87 (1H d., J~3 Hz, H-1″), 4.55 (1H d., J~3 Hz, H-1′).

Found: C, 44.35; H, 7.21; N, 8.36%. Calcd for $C_{18}H_{35}N_3O_{12}$: C, 44.53; H, 7.27; N, 8.66%.

4-O-(6-Amino-6-deoxy-β-D-glucopyranosyl)-6-O-(α-D-glucopyranosyl)-2-deoxystreptamine (15). Compound **10** (0.17 g) was reduced with Raney nickel and hydrogen and the amino derivative formed (0.15 g, R_f 0 on tlc with benzene - acetone (10:1) was acylated with carboethoxy chloride to give the corresponding hepta-*O*-benzyl-tri-*N*-ethoxycarbonyl derivative (R_f 0.24) accompanied by a by-product (R_f 0.1). The main product was isolated by column chromatography on silica gel with benzene-acetone (10:1). After being debenzylated with palladium black and hydrogen, the product was hydrolyzed with 1N barium hydroxide and the product was purified by a similar procedure as in the preparation of **14** to give the final product **15** (30 mg, 47%), $[\alpha]_D^{22}$ +63° (*c* 0.6, water): NMR spectrum (in D_2O) of **15** showed a similar pattern to that of **14** except for the peaks of one of anomeric protons: τ 5.37 (1H d., J~7 Hz, H_{ax}-1′), 4.87 (1H d., J~3 Hz, H_{eq}-1″)

Found: C, 44.64; H, 7.33%. Calcd for $C_{18}H_{35}N_3O_{12}$: C, 44.53; H, 7.27%.

4,6-Di-O-(6-azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (16) and 4-O-(6-Azido-2,3,4-tri-O-benzyl-6-deoxy-β-D-glucopyranosyl)-6-O-(6-azido-2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (17). A mixture of **1** (1.7 g, 3.5 mmole) and freshly prepared Drierite (1.5 g) in dry benzene-dioxane (3:1, 20 m*l*) was heated at 60°C for 30 min under stirring, and **4b** (1.88 g, 2.5 mmol) and well dried powder mercuric cyanide (1.9 g) were added. The mixture was refluxed under stirring. The reaction was monitored by tlc with benzene - acetone (20:1). After 6 hr mercuric cyanide (1.9 g) was again added. After 10 hr mercuric cyanide (1.9 g) was further added and the reaction was continued for 10 hr (26 hr in total). The mixture was filtered and treatment was carried out as in the preparation of **3a** to give a syrup. On tlc with benzene - acetone (20:1) the syrup showed three spots of R_f 0.16 (**16**), 0.1 and 0.04 (**17**). The syrup was chromatographed on a column (35×330 mm) of silica gel (Mallinckrodt, 150 g) with benzene-acetone (20:1) and the fractions of 240—360 m*l* and 510—960 m*l* were evaporated to give a solid, 1.8 g (**16**, 60%) and 0.58 g (**17**, 19%), respectively. Both **16** and **17** were recrystallized from ethanol.

Compound **16**: mp 158—159°C $[\alpha]_D^{22}$ +91° (*c* 0.9, chloroform); IR (KBr): 2100 cm^{-1} (N_3); NMR (in $CDCl_3$): τ 8.85 and 8.81 (3H t. each, $CH_2C\underline{H}_3$), 5.6—6.8 (~21H), 4.8—5.5 (~15H), 4.15 (1H), 2.55—2.7 (30H, five singlets, six OCH_2-$C_6\underline{H}_5$).

Compound **17**: mp 185.5—186.5°C, $[\alpha]_D^{22}$ +62° (*c* 0.7, chloroform); IR (KBr): 2100 cm^{-1} (N_3).

Found: C, 65.13; H, 6.12; N, 8.94%. Calcd for $C_{66}H_{76}N_8O_{15}$: C, 64.90; H, 6.27; N, 9.18%.

4,6-Di-O-(6-ethoxycarbonylamido-2,3,4-tri-O-benzyl-6-deoxy-α-D-gluco-pyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (18). Compound **16** (0.7 g) was dissolved in hot aqueous ethanol 1:11, 9 m*l*) and hydrogenated with Raney nickel and hydrogen under the pressure of 50 lb/sq. inch at 40—45°C for 14 hr. On tlc with benzene - acetone (20:1), the starting material (R_f 0.28) disappeared and a product (R_f 0) appeared. Filtration and evaporation of the solution gave a solid (0.64 g) which was treated with carboethoxy chloride (0.32 g) in a similar manner as described in the preparation of **5a** to give a crude solid (0.70 g). The product was passed through a column (25×65 mm) of silica gel (Mallinckrodt, 12 g) with the aid of benzene-acetone (5:1). From the fraction of 30—130 m*l*, the final product was obtained as a syrup (0.65 g, 86%) which crystallized on standing, mp 79—81°C, $[\alpha]_D^{23}$ + 36° (*c* 0.9, chloroform); NMR (in $CDCl_3$): τ 8.86, 8.82, 8.80, and 8.77 (3H t. each, $CH_2C\underline{H}_3$), 2.6—2.73 (30H, OCH_2-$C_6\underline{H}_5$).

Found: C, 66.05; H, 6.58; N, 4.25%. Calcd for $C_{72}H_{88}N_4O_{19}$: C, 65.84; H, 6.75; N, 4.27%.

4,6-Di-O-(6-ethoxycarbonylamido-6-deoxy-α-D-glucopyranosyl)-N,N′-diethoxycarbonyl-2-deoxystreptamine (19). Compound **18** (0.5 g) was dissolved in hot aqueous ethanol (3.5:10, 13.5 m*l*) and hydrogenated with palladium black and hydrogen. On tlc with benzene - methanol (4:1), **18** (R_f 0.78) disappeared and a product (R_f 0.2) appeared. Filtration and evaporation of the solution gave **19** which was recrystallized from aqueous ethanol (1:1), 0.25 g (97%); mp 282—283°C, $[\alpha]_D^{20}$+73° (*c* 0.8, aqueous ethanol 1:1); NMR (in pyridine-d_6 containing a little D_2O): τ 8.79, 8.77, 8.72, and 8.70 (3H t. each, J 7 Hz, $CH_3C\underline{H}_2$)

Found: C, 46.37; H, 6.90; N, 6.98%. Calcd for $C_{30}H_{52}N_4O_{19}$: C, 46.63; H, 6.78; N, 7.25%.

4,6-Di-O-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (20). Compound **19** was hydrolyzed in a smilar manner as in the preparation of **7a** and **20** was obtained in 75% yield; $[\alpha]_D^{23}$ +138° (*c* 0.5, water); NMR (in D_2O): τ 4.88 (1H d., J~3 Hz, H-1″), 4.58 (1H d., J~3 Hz, H-3′).

Found: C, 44.78; H, 7.33%. Calcd for $C_{18}H_{36}N_4O_{11}$: C, 44.62; H, 7.49%.

4-O-(6-Amino-6-deoxy-β-D-glucopyranosyl)-6-O-(6-amino-6-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (21). Compound **17** was hydrogenated with Raney nickel and the corresponding amino compound was *N*-ethoxycarbonylated. The product had R_f 0.44 on tlc with benzene - acetone (5:1). Debenzylation and deethoxycarbonylation were accomplished by similar procedures as in the preparation of **15** to give the final product **21** in 59% yield (based on **17**); $R_{f\,2\text{-deoxystreptamine}}$ 0.23 (ppc with *n*-butanol - pyridine - water - acetic acid 6:4:3:1), $[\alpha]_D^{22}$ +65° (*c* 0.7, water); NMR (in D_2O): τ 5.37 (1H d., J 7 Hz, H_{ax}-1′), 4.87 (1H d., J~3 Hz, H_{eq}-1″).

Found: C, 44.91; H, 7.39%. Calcd for $C_{18}H_{36}N_4O_{11}$: C, 44.62; H, 7.49%.

The authors wish to thank Dr. Masa Hamada and members of the Institute of Microbial Chemistry for bioassay and Mr. Saburo Nakada for the elemental analysis. The authors also wish to thank Messrs. Kazuo Goto, Toshio Sumida, and Ryujiro Namba for their technical assistance.

Studies on Aminosugars. XXVIII. Synthesis of β-L-Idopyranosides through the Corresponding 5-Enopyranosides[1]

Daishiro IKEDA, Tsutomu TSUCHIYA, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received April 7, 1971)

Methyl 6-deoxy-β-L-idopyranoside (**7**), methyl 2-amino-2,6-dideoxy-β-L-idopyranoside (**13**) and methyl 3-amino-3,6-dideoxy-β-L-idopyranoside (**28**) have been prepared through the corresponding suitably protected 5-enopyranoside precursors in good yields.

As part of the investigation of the syntheses and reactions of aminosugars, the preparation and reaction of several 5-enoses were carried out. This paper reports the syntheses of 5-enoses starting from methyl α-D-glucopyranoside, methyl 2-amino-2-deoxy-α-D-glucopyranoside and methyl 3-amino-3-deoxy-α-D-glucopyranoside, and the behavior of these unsaturated sugars toward catalytic hydrogenation.

Helferich and Himmen described[2,3] the transformation of methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-iodo-α-D-glucopyranoside and methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-bromo-β-D-glucopyranoside to methyl 2,3,4-tri-*O*-acetyl-6-deoxy-α-D-*xylo*-hex-5-enopyranoside (**5**) and its β-D isomer, by reaction with silver fluoride in pyridine. We used the general method for the present purpose. Regarding C-6 halogeno compounds, the starting materials, Evans, Long, and Parrish[4] recently described a convenient synthesis of methyl 6-chloro-6-deoxy-α-D-glucopyranoside (**2**) by selective chlorination of the primary hydroxyl group of methyl α-D-glucopyranoside (**1**) by use of methanesulfonyl chloride in dimethylformamide (DMF). We accordingly tried the reaction of **2** with silver fluoride, but the chloro derivative hardly reacted at all with it. The corresponding bromo derivative, namely methyl 6-bromo-6-deoxy-α-D-glucopyranoside (**3**), was prepared analogously by the method of Evans *et al.* and the product was found to react with silver fluoride but not as expected. As shown by Hough and Otter[5] in the case of 5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-xylofuranose, it seems that the presence of free hydroxyl groups in **3** prevents the formation of an enose. **3** was therefore acetylated to the tri-*O*-acetyl derivative (**4**) and treated with silver fluoride.

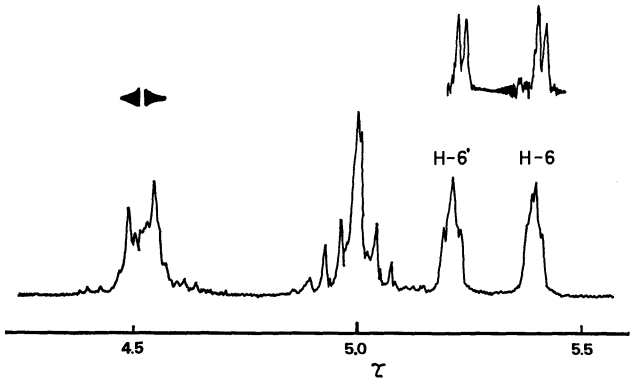

Fig. 1. The NMR Spectrum of **5** in $CDCl_3$.

By this reaction **5** was successfully prepared. The NMR spectrum (Fig. 1) of **5** showed narrow multiplets at τ 5.36 and 5.18. Irradiation at τ 4.53 resulted in the collapse of multiplets to a pair of resolved doublets (J 1.7 Hz). Small coupling is typical for terminal methylene protons supporting the structure **5**.

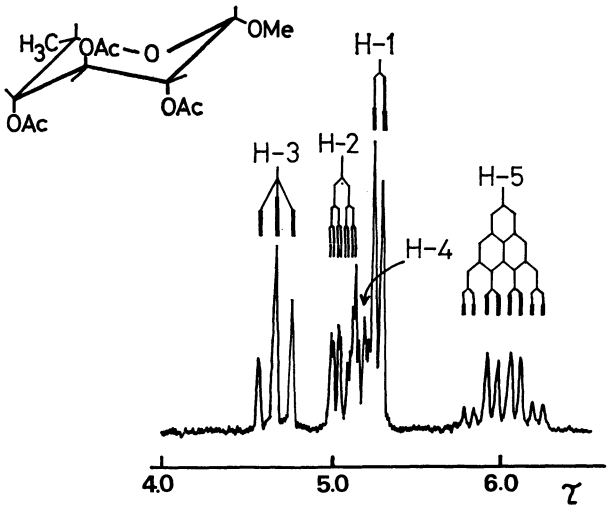

Fig 2. The NMR Spectrum of **6** in $CDCl_3$.

5-Enopyranoside (**5**) was then hydrogenated with palladium black and hydrogen to give methyl 2,3,4-tri-*O*-acetyl-β-L-idopyranoside (**6**) quantitatively. The NMR spectrum of **6** is shown in Fig. 2. The exclusive formation of β-L-idopyranoside is noteworthy in contrast with the hydrogenation of 1,2,3,4-tetra-*O*-acetyl-6-deoxy-β-D-*xylo*-hex-5-enopyranose. It has recently been reported that the latter was converted[6] into a mixture of 96% of the 6-deoxy-D-gluco and 4% of the 6-deoxy-L-ido isomer by hydrogenation with the same catalyst. Hydroboration[7] of methyl 6-deoxy-α-D-*xylo*-hex-5-enopyranoside has also been reported to afford a mixture of methyl α-D-gluco and β-L-ido isomer in the ratio 1:2.5. The anomeric α-*O*-methyl group in **5**, therefore, may be the dominating cause for exclusive formation of the β-L-ido derivative in the hydrogenation with palladium black and hydrogen.

The protecting groups of **6** were finally removed in a basic condition to give methyl 6-deoxy-β-L-idopyrano-

side (**7**). As for 6 deoxy-L-idose, it was prepared by Meyer and Reichstein[8] and Wolfrom and Hanessian[9] from 1,2,*O*-isopropylidene-D-glucofuranose through multi-step procedures.

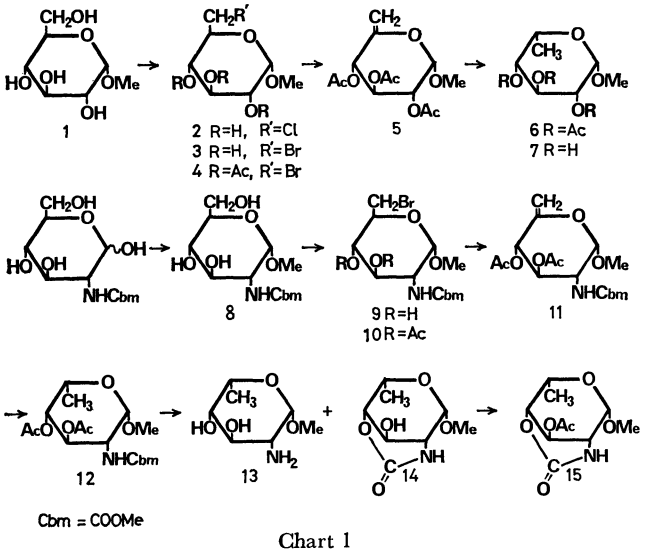

Chart 1

The above synthesis has been extended to amino-sugars, and methyl 2-amino-2,6-dideoxy-β-L-idopyranoside (**13**) has been prepared from methyl 2-deoxy-2-methoxycarbonylamino-α-D-glucopyranoside (**8**). 2-Amino-2-deoxy-D-glucose was *N*-methoxycarbonylated and then treated with hydrogen chloride in methanol to give **8** in 78% yield with no detectable formation of β-isomer. Glucoside (**8**) was brominated in a similar manner as in the preparation of **3**. The resulting 6-bromo derivative (**9**) was acetylated and then treated with silver fluoride in DMF. In this case the reaction to make 5,6-unsaturation was appreciably slower than that in the case of **5**, and methyl 3,4-di-*O*-acetyl-2,6-dideoxy-2-methoxycarbonylamido-α-D-*xylo*-hex-5-enopyranoside (**11**) was obtained in 30% yield, leaving much starting material (**10**) unchanged. In regard to the synthesis of an aminoglucoside having 5-eno structure, Kiss and Burkhardt[10] reported the preparation of methyl 4-*O*-acetyl-3-*O*-benzyl-2-benzyloxycarbonylamido-2,6-dideoxy-α-D-*xylo*-hex-5-enopyranoside from the corresponding 6-iodo precursor in a good yield.

Hydrogenation of the 5-eno derivative (**11**) gave β-L-idopyranoside (**12**) in 90% yield, and subsequent hydrolysis with 1N barium hydroxide gave methyl 2-amino-2,6-dideoxy-β-L-idopyranoside (**13**) in 56% yield. The NMR spectrum of **12** is shown in Fig. 3. In this hydrolysis, another product (**14**) was formed in 33% yield, which resisted further hydrolysis. Even after 3 hr heating at 100°C in 1N barium hydroxide solution, only half of the product was transformed to **13**. The structure of **14** was determined through the NMR spectrum (Fig. 4) of its acetyl derivative (**15**) as methyl

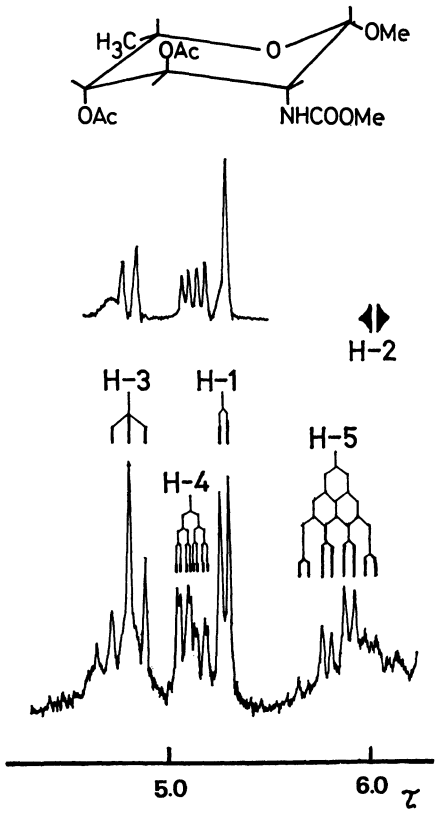

Fig. 3. The NMR spectrum of **12** in $CDCl_3$.

2-amino-2,6-dideoxy-β-L-idopyranoside 2,4-carbamate, but not 2,3-carbamate. In the NMR spectrum of **15**, H-2 resonated at τ 6.27 and appeared as double triplets (J 4.4 and 2 Hz). Double irradiation technique showed that the coupling constants relating to H-2 were $J_{2,3}$ 4 Hz, $J_{2,NH}$ 4 Hz, $J_{2,4}$ 2 Hz and $J_{2,1}$ 0 Hz. These coupling constants and others ($J_{3,4}$ 4 Hz, $J_{4,5}$ ~0 Hz) suggest that the preferred conformation of **15** is IC chair. Moreover, observation of a long-range coupling ($J_{2,4}$ 2 Hz) in **15** as well as the position of acetoxyl methyl resonance at τ 7.85, situated in the region of an axial acetoxyl methyl,[11] also support the IC conformation in which H-2 and H-4 are in di-equatorial orientation.

3-Amino-3-deoxy-D-glucose was led to the corresponding L-idopyranoside by a series of similar reactions. 3-Amino-3-deoxy-D-glucose prepared by the fermentation[12] of *Bacillus aminoglucosidicus* was *N*-methoxycarbonylated and glycosidated with hydrogen chloride - methanol to afford a mixture of α- (**16**) and β-anomer (**17**). Separation of the anomers was performed by resin column chromatography. The α-anomer was brominated in an analogous manner to those described above to give 6-bromo derivative (**18**) in 85% yield. After subsequent acetylation, the acetyl derivative (**19**) was treated with silver fluoride in pyridine. It was found that unsaturation does not

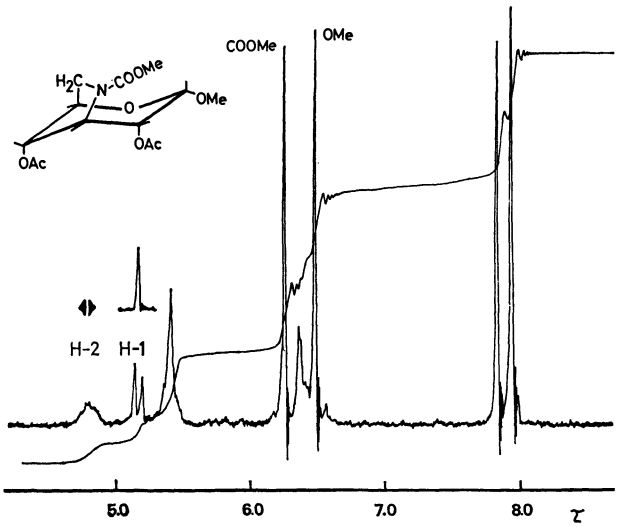

Fig. 5. The NMR spectrum of **20** in $CDCl_3$.

occur and a 3,6-imino derivative (**20**) was formed instead. No absorption ascribable to amide II was observed in its IR spectrum. The NMR spectrum indicated the presence of two axial acetyls, O–CH_3, $NCOOCH_3$, one anomeric proton and six other protons (Fig. 5). Irradiation at τ 4.80 caused the doublet of H-1 at τ 5.15 to collapse to a singlet. The broadened signal (τ 4.68—4.88) centered at τ 4.80 was therefore assigned to H-2; at the same time, the unresolved pattern and the narrow half-height width (~8 Hz) of H-2 suggested the presence of a long-range coupling between H-2 and H-4 as well as a small coupling between H-2 and H-3. These results and the presence of a narrow multiplet (τ 5.3—5.5) of H-3, 4, and 5 complex suggest the preferred conformation of **20** to be IC and, consequently, **20** has a 3,6-imino structure. Formation of structurally related 3,6-imino derivatives from suitably protected 6-*O*-mesyl or 6-*O*-tosyl precursors by the action of sodium acetate were recently

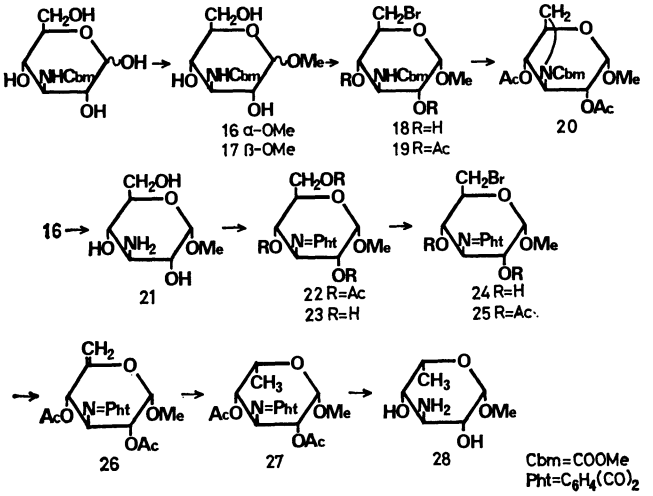

Chart 2

reported by Reckendorf *et al.*[13]

Failure of the formation of a 5,6-unsaturated compound from **19** was presumed to be due to the presence of an amino hydrogen in **19**. Accordingly, an attempt was made to use a 3-phthalimido derivative in place of **19**. Methyl 3-amino-3-deoxy-α-D-glucopyranoside (**21**) was prepared by alkaline hydrolysis of **16**, and then treated with phthalic anhydride and acetic anhydride to give an *O*-acetylated 3-phthalimido derivative (**22**). Subsequent deacetylation gave a 3-phthalimido derivative (**23**). Bromination of **23** in an analogous manner as described above gave a 6-bromo derivative (**24**), which was then acetylated. The reaction of the acetylated product (**25**) with silver fluoride proceeded smoothly, and afforded a 5,6-unsaturated compound (**26**) in 79% yield. The NMR spectrum of **26** is shown in Fig. 6. The catalytic hydrogenation of 5-enopyranoside gave β-L-ido derivative (**27**) in 87% yield. The NMR spectrum of **27** is shown in Fig. 7. The protecting groups of **27** were finally removed with *n*-butylamine to give methyl 3-amino-3,6-dideoxy-β-L-idopyranoside (**28**) in 77% yield.

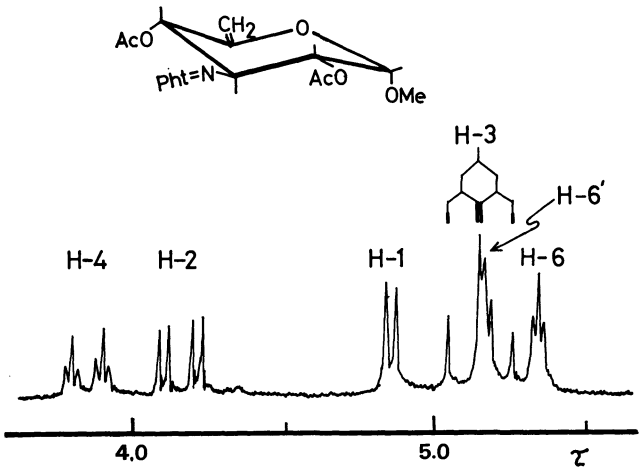

Fig. 6. The NMR Spectrum of **26** in $CDCl_3$.

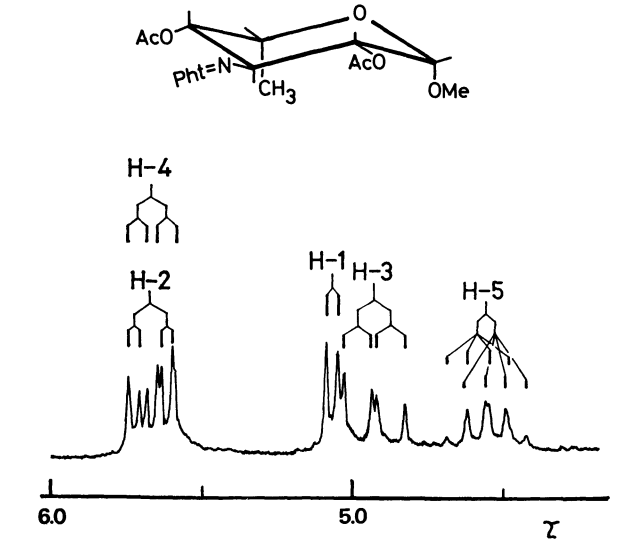

Fig 7. The NMR spectrum of **27** in $CDCl_3$.

Conformations of β-L-Ido Compounds. The NMR spectra of these final products **7**, **13**, and **28** were compared. Each proton having the same structural number of these compounds had almost the same splitting pattern and couplings. The shift-values of the corresponding protons also were in accord except for the shift-value of the proton bearing an amino group: the H-2 and H-3 protons in **13** and **28** resonated at 0.75 and 0.76 ppm higher field than that of the resonance of H-2 and H-3 of **7**, respectively. These findings show that **7**, **13**, and **28** have the same conformation. The values of the vicinal coupling constants of these compounds, $J_{1,2}$ 2, $J_{2,3}$ ~5, $J_{3,4}$ ~5 and $J_{4,5}$ 3 Hz suggested that the preferred conformation of **7**, **13**, and **28** is IC chair, but not CI. A twist-boat structure as shown by Coxon[14] was also considered, but the observation of a long-range coupling between H-2 and H-4 ($J_{2,4}$ ~1Hz) in **7** and **28** suggested that H-2 and H-4 are in diequatorial orientation and a twist-boat structure is improbable. The small $\Delta[M]_{TACu}$[15] value (+159°) of **13** also supports the view that 2-amino and 3-hydroxyl groups of **13** are not diequatorial. The results show that the structural change from α-D-gluco to β-L-ido form caused conformational change from CI to IC, and this may be responsible for the easy formation of 2,4-carbamate (**14**) from **12**. Compounds **6** and **12**, both having β-L-ido structure, also were presumed to have IC conformation. Comparison of their NMR spectra with the spectrum of methyl 2,3,4-tri-*O*-acetyl-6-deoxy-α-D-glucopyranoside (**6'**) support the above conclusion. On the other hand, compound **27** was presumed to have CI conformation. This is supported by a comparison of the τ-value of the C-methyl protons (τ 8.58) of **27** with the τ-values of the C-methyl protons of **6**, **7**, **12**, **13**, and **28** (τ ~8.70), suggesting that the C-methyl group of **27** is axial. The fact that only **27** of the β-L-ido derivatives has CI conformation may be interpreted by the presence of a bulky phthalimide group.

Experimental

The NMR spectra were measured with a Varian A-60D or a Varian HA-100 (at 100 MHz) spectrometer. Tetramethylsilane (τ10.00; for the solution other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (τ 10.00; for the solution of deuterium oxide) were used as the internal standards. Thin-layer chromatography (TLC) was carried out on microscope slides coated with silica gel, and the spots were visualized with sulfonic acid. Paper chromatography (ppc) was carried out on Toyo Roshi No. 50 paper.

Methyl 6-Bromo-6-deoxy-α-D-glucopyranoside (3). To a stirred solution of methyl α-D-glucopyranoside (**1**) (1.0 g) in dry DMF (10 m*l*, dried over calcium hydride), mesyl bromide[16] (1.6 g) was added dropwise and the solution was

maintained at 65°C for 18 hr. On TLC with ethyl acetate-ethanol-water (45:5:3), the solution showed two spots of R_f 0.64 and 0.85 in approximately equal strength. The solution was evaporated and coevaporated with toluene to give a brown syrup which was dissolved in methanol and the solution was then neutralized with 2.4M sodium methoxide in methanol. On TLC, the spot of R_f 0.85, which was supposed to originate from an *O*-formyl by-product[4] disappeared, and a spot (R_f 0.17) corresponding to the starting material (**1**) appeared. The solution was evaporated and the residue was charged on a column of silica gel (100 g) and developed with the solvent mixture described above. The portion (180—300 ml) containing the substance of R_f 0.64 was evaporated to give a colorless solid which was recrystallized from ethyl acetate yielding 770 mg (58%), mp 136—137°C (lit,[17] 126—127°C), $[\alpha]_D^{20}$+126° (*c* 1, methanol) (lit,[17] +137°); IR spectrum (KBr): no peaks between 1500—2500 cm^{-1}, 940, 897, 887, 815(vw), 757, 750 (sh), and 694 cm^{-1}; NMR (in D_2O): τ 6.56 (3H s., OCH_3), 6.0—6.65 (6H), 5.18 (1H d., J 3 Hz, H-1).

Found: C, 33.00; H, 5.23; Br, 30.57%. Calcd for $C_7H_{13}O_5Br$: C, 32.70; H, 5.10; Br, 31.09%.

Methyl 2,3,4-Tri-O-acetyl-6-bromo-6-deoxy-α-D-glucopyranoside (4). To a solution of **3** (688 mg) in pyridine (12 ml), acetic anhydride (1.7 g) was added and the solution was allowed to stand overnight. A spot (R_f 0.44) appeared on TLC with benzene-ethyl acetate (6:1). After addition of a small amount of water (0.2 ml) followed by standing for 1 hr, the solution was evaporated and the residue was dissolved in chloroform. The solution was washed in turn, with saturated potassium hydrogensulfate solution, water, saturated sodium hydrogencarbonate solution and water, dried over sodium sulfate and evaporated to give a colorless solid. Recrystallization from ethanol yielding 956 mg (98%), mp 125—125.5° $[\alpha]_D^{20}$+121° (*c* 1, chloroform).

Found: C, 40.92; H, 5.33; Br, 20.41%. Calcd for $C_{13}H_{19}O_8Br$: C, 40.74; H, 5.00; Br, 20.86%.

IR spectrum (KBr): 1750; 931, 910(w) 880(w), 810, 752, and 682(w) cm^{-1}; NMR (in $CDCl_3$): τ 7.96, 7.92, and 7.89 (each 3H s., OAc), 6.48 (3H s., OCH_3), 5.94 (1H octet, J 3.6 and 9.7 Hz, H_{ax}-5), 4.48 (1H triplet with small splittings (~0.5 Hz), J 8.5 Hz, probably H_{ax}-3); $J_{4,5}$ 9.7 Hz, $J_{5,6}$ 3 Hz, $J_{5,6'}$ 6 Hz

Methyl 2,3,4-Tri-O-acetyl-6-deoxy-α-D-xylo-hex-5-enopyranoside (5). To a solution of **4** (1.01 g) in dry pyridine (12 ml, dried over calcium hydride), anhydrous silver fluoride (1.5 g) was added and the mixture was stirred at 50°C for 20 hr in the dark. A spot (R_f 0.72) and three weak spots (R_f 0.55, 0.50 and 0.35) appeared on TLC with benzne - ethyl acetate (3:1). The main spot showed fluorescence[18] by the sodium fluorescein-bromine test according to Stahl for double bond although it has an identical R_f-value with that of **4**. Addition of ether (50 ml) to the reaction mixture gave precipitates which were filtered and washed with ether. The ether layer and washings combined were evaporated and the residue was again dissolved in ether. The solution was washed successively with potassium hydrogensulfate solution, sodium hydrogencarbonate solution and water, dried over sodium sulfate and evaporated to give a solid (680 mg) which was negative to the Beilstein test for halogens. The solid was chromatogrqphed on a column of silica gel (60 g) with benzene - ethyl acetate (3:1) and the portion containing **5** was evaporated to give a residue, which was recrystallized from ethanol yielding 430 mg (54%), mp 93—94°C, $[\alpha]_D^{20}$+117° (*c* 1, chloroform) (lit,[2] +117°).

Found: C, 51.44; H, 6.15%. Calcd for $C_{13}H_{18}O_8$: C, 51.65; H, 6.00%.

IR spectrum (KBr): 1755 (s., ester), 1660 (alkene); 955 (m), 935, 907 (m), 897 (m), 872, 783, and 737 cm^{-1}; NMR (in $CDCl_3$): τ 7.95, 7.90 and 7.86 (each 3H s., OAc), 6.51 (3H s., OCH_3), 5.36 (1H m., half-height width was ~3 Hz, H-6), 5.18 (1H m., half-height width was ~4 Hz, H-6'), 4.65—5.1 (2H unresolved m.), 4.2—4.6 (2H unresolved m.). Irradiation at τ 4.53 caused the multiplets at τ 5.36 and 5.18 to collaspse to two clear-cut doublets (each has J 1.7 Hz) showing that the small coupling originated from geminal olefinic protons of H-6,6'.

Methyl 2,3,4-Tri-O-acetyl-6-deoxy-β-L-idopyranoside (6). A solution of **5** (100 mg) in dioxane (1.5 ml) was hydrogenated with palladium black and hydrogen under 50 lb/sq. inch pressure at 40°C overnight. A spot (R_f 0.45) appeared on TLC with benzene - ethyl acetate (3:1). After filtration the solution was evaporated to give a solid, which was recrystallized from ethanol yielding 98 mg (99%), mp 93.5—94°C, $[\alpha]_D^{20}$+46° (*c* 1, chloroform).

Found: C, 51.30; H, 6.31%. Calcd for $C_{13}H_{20}O_8$: C, 51.31; H, 6.63%.

IR spectrum (KBr): 1760, 1740; 972 (m), 952, 926 (m), 915, 876, 782, and 700 (m) cm^{-1}; NMR (in $CDCl_3$): τ 8.68 (3H d., J 6.7 Hz, C_5-CH_3), 7.87 (6H s., OAc), 7.86 (3H s., OAc), 6.43 (3H s., OCH_3), 5.82 (1H octet, J 6.7, 6.7, 6.7, and 3 Hz (=$J_{4,5}$), H_{eq}-5), 5.20 (1H d., $J_{1,2}$ 2.2 Hz, H-1), 5.08—5.23 (1H m., H-4), 5.02 (1H octet, J 2.2, 4.8, and ~0.8 Hz (=$J_{2,4}$), H-2), 4.69 (1H t., $J_{2,3}$=$J_{3,4}$ 4.8 Hz, H-3).

Small coupling constants of $J_{2,3}$, $J_{3,4}$ and $J_{4,5}$ and the occurrence of long-range coupling of $J_{2,4}$ suggested the preferred conformation of **6** to be IC chair. The conformtion was also substantiated by comparison of the NMR spectrum of **6** with that of methyl 2,3,4-tri-*O*-acetyl-6-deoxy-α-D-glucopyranoside (**6'**) prepared by hydrogenation of 6-bromo derivative (**4**).

Compound **6'**: mp 60—61°C (lit,[19] 77—78°), $[\alpha]_D^{20}$+152° (*c* 1, chloroform) (lit,[19]+153.6°, chloroform); IR spectrum (KBr): 1755; 930, 900, 893, 840 (w), and 753 cm^{-1}; NMR (in $CDCl_3$): τ 8.79 (3H d., J 6.5 Hz, C_5-CH_3), 8.00, 7.97, and 7.93 (each 3H s., OAc), 6.58 (3H, s. OCH_3), 6.05 (1H octet, J 6.5, 6.5, 6.5, and 10.0 Hz, H-5). The three equatorial acetoxy methyl protons of **6'** resonated at τ 7.93, 7.97, and 8.00, whereas those of **6** resonated at τ 7.86, 7.87, and 7.87 suggesting the presence of three axial acetoxyl groups in **6** in its preferred conformation.[12]

Methyl 6-Deoxy-β-L-idopyranoside (7). A solution of **6** (110 mg) in dry methanol (2 ml) was treated with sodium methoxide. After addition of a small amount of Amberlite IR-120 (H^+ form) pretreated with methanol, the solution was filtered, evaporated, and the residue was recrystallized from ethyl acetate to give a solid, 60 mg (98%), mp 81—81.5°C, $[\alpha]_D^{25}$+74° (*c* 1, water).

Found: C, 47.48; H, 7.92%. Calcd for $C_7H_{14}O_5$: C, 47.18; H, 7.92%.

IR spectrum (KBr): 1055, 1020, 1003, 970, 916, 808, and 761 cm^{-1}; NMR (in D_2O): τ 8.69 (3H d., J 6.7 Hz, C_5-CH_3), 6.45 (3H s., OCH_3), 6.35—6.52 (1H m., H-4), 6.28 (1H octet, J 5, 2, and 1 Hz, H-2), 5.97 (1H t., J 5 Hz, H-3), 5.84 (1H octet, J 6,7, 6.7, 6.7, and 3Hz, H-5), 5.20 (1H d., J 2 Hz, H-1); $J_{1,2}$ 2 Hz, $J_{2,3}$=$J_{3,4}$ 5 Hz, $J_{4,5}$ 3Hz, and $J_{2,4}$ ~1 Hz.

Methyl 2-Deoxy-2-methoxycarbonylamido-α-D-glucopyranoside (8). To a mixture of glucosamine hydrochloride (12 g) and anhyd-

rous sodium carbonate (7.75 g) in 50% aqueous acetone (200 ml), methoxycarbonyl chloride (9 ml) was added under stirring and the clear solution was allowed to stand at room temperature for 15 min. A spot (R_f 0.39) of *N*-methoxycarbonylglucosamine appeared on TLC with ethyl acetate-methanol (5:1). The solution was evaporated and the residue was dried *in vacuo*. The residue was suspended in 4% hydrogen chloride in methanol (200 ml) and the mixture was refluxed for 18 hr, whereupon a brown clear solution resulted. A new spot (R_f 0.48) appeared on TLC with the same solvent mixture as described above. The brown solution was neutralized with basic lead carbonate, centrifuged, and the supernatant layer was evaporated. The residue was then chromatographed on a column of silica gel (300 g) with ethyl acetate - methanol (5:1), and the portion containing the substance of R_f 0.48 was evaporated to give a colorless solid which was recrystallized from methanol-ether; 10.5 g (78%), mp 126—128°C $[\alpha]_D^{22}$ +135° (*c* 2, methanol).

Found: C, 42.94; H, 6.93; N, 5.75%. Calcd for $C_9H_{17}NO_7$: C, 43.01; H, 6.82; N, 5.57%.

IR spectrum (KBr): 1700, 1550; 950 (w), 940 (w), 925 (w), 900, 850, 785, 760, 720 (w), and 700 (w) cm^{-1}; NMR (in D_2O): τ 6.60 (3H s., OCH_3), 6.32 (3H s., $NHCOOC\underline{H}_3$), 6.1—6.6 (6H m., H-2,3,4,5,6,6'), 5.18 (1H d., J 2 Hz). No signal corresponding to H_{ax}-1 was observed indicating that the product was a pure α-isomer.

Methyl 6-Bromo-2,6-dideoxy-2-methoxycarbonylamido-α-D-glucopyranoside (9). Compound **8** (6.65 g) in DMF (60 ml) was treated with mesyl bromide (6.8 g) at 65°C for 15 hr. After evaporation, the residue was treated with sodium methoxide in methanol as usual, and the crude product obtained was chromatographed on a column of silica gel with benzene - methyl ethyl ketone (1:2) to separate the product (R_f 0.42) and **8** (R_f 0.22). The product was recrystallized from benzene - ethyl acetate (1:2) yielding 5.34 g (64%); mp 138—140°C, $[\alpha]_D^{25}$ +114° (*c* 0.5, methanol).

Found: C, 34.49; H, 5.03; N, 4.31; Br, 25.38%. Calcd for $C_9H_{16}NO_6Br$: C, 34.39; H, 5.14; N, 4.46; Br, 25.47%.

IR spectrum (KBr): 1730, 1530; 972, 945, 895, 772, and 717 (w) cm^{-1}; NMR (in D_2O): τ 6.56 (3H s., OCH_3), 6.30 (3H s., $NHCOOC\underline{H}_3$), 5.17 (1H d., J 2 Hz, H-1).

Methyl 3,4-Di-O-acetyl-6-bromo-2,6-dideoxy-2-methoxycarbonylamido-α-D-glucopyranoside (10). Prepared from **9** by the general procedure. Mp 104—105°C, $[\alpha]_D^{22}$ +111° (*c* 0.5, chloroform).

Found: C, 39.11; H, 4.99; N, 3.54; Br, 20.44%. Calcd for $C_{13}H_{20}NO_8Br$: C, 39.21; H, 5.06; N, 3.52; Br, 20.07%.

IR spectrum (KBr): 1760, 1730, 1535; 940, 925, 880, 780, 760, and 725 (w) cm^{-1}; NMR (in $CDCl_3$): τ 7.99 and 7.94 (each 3H s., OAc), 6.52 (3H s., OCH_3), 6.4—6.65 (2H m., H-6,6'), 6.32 (3H s., $NHCOOC\underline{H}_3$), 6.07 (1H q., J 3.5 and 10 Hz, H-2), 5.75—6.15 (1H m., H-5), 5.20 (1H d., J 3.5 Hz, H-1), τ 4.55—5.2: eight peaks which were analyzed as XABY(=$H_2H_3H_4H_5$) system: τ 5.00 (1H q., $J_{4,5}$ ~8 Hz, $J_{3,4}$ ~9.5 Hz, H-4), τ 4.77 (1H q., $J_{2,3}$ ~10 Hz, $J_{3,4}$ ~9.5 Hz, H-3).

Methyl 3,4-Di-O-acetyl-2,6-dideoxy-2-methoxycarbonylamido-α-D-xylo-hex-5-enopyranoside (11). To a solution of **10** (2.83 g) in dry pyridine (28 ml), anhydrous silver fluoride (3.3 g) was added and the mixture was stirred at 65°C for 18 hr in the dark. Two spots (R_f 0.68 and 0.62) appeard on TLC with benzene - ethyl acetate (5:2). The former spot was proved to originate from both **10** and **11** (they had the same R_f value) and the latter from a by-product, which increased with the prolongation of reaction. Ether was added to the reaction mixture and the resulting mixture was treated as in the preparation of **5**. The crude product obtained was then chromatographed on a column of silica gel (80 g) with benzene - ethyl acetate (5:2) and the portion containing **10** and **11** was evaporated to give a syrup (1.29 g) which was crystallized by addition of ethanol to give **11** (411 mg). Another crop (121 mg) was obtained from the mother liquor. Total yield was 30%. The mother liquor was proved to be constituted mainly from **10**. Attempted change in the reaction conditions could not raise the yield of **11**. Mp 85—88°C, $[\alpha]_D^{25}$ +89° (*c* 0.5, chloroform)

Found: C, 48.94; H, 6.10; N, 4.30%. Calcd for $C_{13}H_{19}NO_8$: C, 49.21; H, 6.04; N, 4.41%.

IR spectrum (KBr): 1760, 1740, 1670 (C=C), 1540; 945, 930 (w), 900 (w), 875, 852 (w), 790 (sh), 780, 748 (w), and 725 (w) cm^{-1}; NMR (in $CDCl_3$): τ 7.96 and 7.88 (each 3H s., OAc), 6.53 (3H s., OCH_3), 6.30 (3H s., $NHCOOC\underline{H}_3$), 5.85 (1H double triplets, J ~10, ~10, and 3.5 Hz, H-2), 5.38 (1H t., J ~1.8 Hz, H-6), 5.20 (1H t., J ~1.8 Hz, H-6'), 5.15 (1H d., J 3.5 Hz, H-1), ~5 (1H broad doublet, J ~10 Hz, $N\underline{H}COO$-), 4.77 (1H t., J 9.7 Hz, H-3), 4.48 (1H double triplets, J ~1.8, ~1.8, and ~10 Hz); $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 9.7 Hz, $J_{3,4}$ 9.7 Hz, $J_{4,6}=J_{4,6'}=J_{6,6'}$ ~1.8 Hz.

Methyl 3,4-Di-O-acetyl-2,6-dideoxy-2-methoxycarbonylamido-β-L-idopyranoside (12). Compound **11** was hydrogenated in dioxane with palladium black and hydrogen on 90% yield in a similar manner as in the preparation of **6**. Syrup, $[\alpha]_D^{22}$ +45° (*c* 1, chloroform)

Found: C, 48.73; H, 6.75; N, 4.65%. Calcd for $C_{13}H_{21}NO_8$: C, 48.90; H, 6.63; N, 4.39%.

IR spectrum (KBr): 1760, 1730, 1525; 930, 890, 860, 805, 778, 760, and 723 (w) cm^{-1}; NMR (in $CDCl_3$ at 60 and 100 MHz): τ 8.74 (3H d., J 6.7 Hz, C_5-CH_3), 7.88 and 7.90 (each 3H s., OAc), 6.48 (3H s., OCH_3), 6.30 (3H s., $NHCOOC\underline{H}_3$), 6.03 (1H unresolved m., H-2), 5.85 (1H octet, J 6.7, 6.7, 6.7, and 3 Hz, H-5), 5.27 (1H d., J ~2.5 Hz, H-1), 5.10 (1H quartet with small splittings (~0.8 Hz) and the pair in the lower field being most intense; J 3, 4.8, and ~0.8 Hz, H-4), 4.82 (1H t., J 4.8 Hz, H-3), 4.6—4.9 (1H, $N\underline{H}COO$-?); $J_{1,2}$ ~2.5 Hz, $J_{2,3}$ 4.8 Hz, $J_{3,4}$ 4.8 Hz, $J_{4,5}$ 3 Hz, $J_{2,4}$ ~0.8 Hz.

Irradiation of H-2 caused the H-1 doublet to collapse to a singlet, the H-4 octet to a quartet (J 3 and 4.8 Hz), and the H-3 triplet to a doublet. Irradiation at τ 5.85 (H-5) caused the doublet at τ 8.74 (CH_3) to collapse to a singlet, the doublet at τ 5.27 (H-1) to an incomplete doublet, and the octet at τ 5.10 (H-4) to a doublet (J 4.8 Hz). Irradiation of H-4 caused the H-5 octet to collapse to a quartet (J 6.7 Hz) and the H-3 triplet to a doublet.

Methyl 2-Amino-2,6-dideoxy-β-L-idopyranosie (13) and Methyl 2-Amino-2,6-dideoxy-β-L-idopyranoside 2,4-Carbamate (14). Compound **12** (643 mg) in 1N barium hydroxide (25 ml) was heated in a boiling water bath for 1 hr. After carbon dioxide was introduced, the mixture was heated for a while, centrifuged, and the supernatant layer was evaporated. The residual precipitates were treated with hot water several times and the solution was evaporated. The combined residues were extracted with methanol and the solution was evaporated to give a solid (~840 mg). On TLC with ethyl acetate-methanol (5:1), the solid gave two spots of R_f 0.13 (**13**, major, ninhydrin positive) and R_f 0.79 (**14**, minor, ninhydrin negative), the latter differering from the spot of the starting material (**13**, R_f 0.94). An aqueous solution of the solid was chromatographed on a column of Amberlite IRC-50 (H^+ form, 30 ml) with water. The portion containing **14** was evaporated to give a solid, 136 mg (33%), mp 177—180°C $[\alpha]_D^{25}$ +64.5° (*c* 0.8, methanol). IR spectrum (KBr): 1695; 950, 905, 893, 845, 765, 750, and 705 cm^{-1}.

Found: C, 47.24; H, 6.68; N, 6.59%. Calcd for C_8H_{13}-

NO_5: C, 47.29; H, 6.45; N, 6.89%.

The resin column was then treated with 0.3N ammonia and the solution containing **13** was evaporated to give a syrup, 198 mg (56%), R_f 0.66 (ppc with *n*-butanol-pyridine-water-acetic acid 6:4:3:1), $[\alpha]_D^{20}$ +97.4° (*c* 1.4, methanol), $\Delta[M]_{TACu}$+159°. IR spectrum (KBr): 945, 895 (w), 865, 840 (w), 775, and 700 (w) cm^{-1}.

Found: C, 47.60; H, 8.72; N, 8.12%. Calcd for $C_7H_{15}NO_4$: C, 47.45; H, 8.53; N, 7.90%.

NMR spectrum of **13** (in D_2O):τ 8.70 (3H d., *J* 6.7 Hz, C_5-CH_3), 7.03 (1H octet, *J* 4.5, 2, and 1Hz, H-2), 6.45 (3H s., OCH_3), 6.35—6.55 (1H m., H-4), 6.02 (1H t., *J* 4.5 Hz, H-3), 5.88 (1H octet, *J* 6.7, 6.7, 6.7, and 3 Hz, H-5), 5.22 (1H d., *J* 2 Hz, H-1); $J_{1,2}$ ~2 Hz, $J_{2,3}=J_{3,4}$ 4.5 Hz, $J_{4,5}$ 3 Hz, $J_{2,4}$ ~1 Hz. These coupling constants showed the preferred conformation of **13** to be IC.

Methyl 3-O-Acetyl-2-amino-2,6-dideoxy-β-L-idopyranoside 2,4-Carbamate (15). To a solution of **14** (90 mg) in pyridine (1.8 ml), acetic anhydride (0.08 ml) was added and the solution was allowed to stand overnight. On TLC with ethyl acetate, a spot (R_f 0.54) appeared accompanied by two weak spots of R_f 0.21 (**14**) and R_f 0.36. The solution was evaporated and the residue was dissolved in chloroform. The solution was washed successively with saturated potassium hydrogensulfate solution, saturated hydrogencarbonate solution and saturated sodium chloride solution, dried over sodium sulfate and evaporated to give a residue. The residue was dissolved in chloroform and the solution was passed through a short column of silica gel (3 g) with the aid of ethyl acetate and the eluate containing **15** was evaporated to give a colorless solid, 84 mg (80%). Recrystallization from ethanol, mp 165—166°C $[\alpha]_D^{24}$+26° (*c* 1.7, chloroform).

Found: C, 48.62; H, 6.15; N, 5.53%. Calcd for $C_{10}H_{15}NO_6$: C, 48.98; H, 6.17; N, 5.71%.

IR spectrum (KBr): 1755, 1725, 1700; 950, 912, 900 (sh), 885, 838 (w), 795 (w), 765 (sh), 760, 750, and 697 cm^{-1}. No peak was observed between 1475—1650 cm^{-1}; NMR (in pyridine-d_5 at 100 MHz): τ 8.63 (3H, d., *J* 6.7 Hz, C_5-CH_3), 7.85 (3H s., OAc), 6.53 (3H s., OCH_3), 6.27 (1H double triplets, *J* 4, 4, and 2 Hz, H-2), 5.85 (1H q., *J* 6.7 Hz, H-5), 5.75 (1H quartet with small splittings (*J* ~0.5 Hz), *J* 4 and 2 Hz, H-4), 5.13 (1H s., H-1), 4.47 (1H t., *J* 4 Hz, H-3), 1.08 (1H d., *J* 4 Hz, NHCOO–); $J_{1,2}$ ~0 Hz, $J_{2,3}$ 4 Hz, $J_{3,4}$ 4 Hz, $J_{4,5}$ 0—0.5 Hz, $J_{5,6}$ 6.7 Hz, $J_{NH,2}$ 4 Hz, $J_{2,4}$ 2 Hz.

Irradiation at τ 1.08 (NH) caused H-2 double triplets to collapse to a quartet (*J* 4 and 2 Hz). Irradiation of H-3 caused the H-4 multiplet to collapse to a singlet (not a quite sharp singlet), H-2 double triplets to an incomplete doublet. Irradiation of H-4 caused H-2 double triplets to collapse to a triplet (*J* 4 Hz) and H-3 triplet to a doublet (*J* 4 Hz), Irradiation of H-5 caused methyl doublet (τ 8.63) to collapse to a singlet. Irradiation of H-2 caused the H-4 multiplet to collapse to a doublet (*J* 4 Hz) and doublet of NH to a singlet.

Methyl 3-Deoxy-3-methoxycarbonylamido-α and β-D-glucopyranoside (16 and 17). Crude 3-amino-3-deoxy-α-D-glucose (2 g) obtained by fermentation[13] was dissolved in 50% aqueous acetone (40 ml). Anhydrous sodium carbonate (1.5 g) and methoxycarbonyl chloride (1.9 ml) were added successively to the solution under stirring and the mixture was stirred for 1 hr at room temperature. A ninhydrin negative spot (R_f 0.46) appeared on TLC with methyl ethyl ketone-methanol (5:1). The solution was evaporated and the residue was extracted with methanol. Evaporation of the extract gave a brown powder, which was dissolved in 4% hydrogen chloride in methanol (40 ml) and the solution was refluxed for 20 hr. A new spot (R_f 0.54) appeared on TLC. The resulting solution was neutralized with basic lead carbonate, filtered, and evaporated. An aqueous solution of the residue was chromatographed on a column of Dowex 1×2 (OH form, 500 ml) with water. From the earlier eluate (600—750 ml), **16** was obtained as a colorless solid which was recrystallized from ethanol-ethyl acetate yielding 803 mg, mp 178—181°C $[\alpha]_D^{20}$+152° (*c* 1, methanol); NMR (in D_2O): τ 6.55 (3H s., OCH_3), 6.32 (3H s., $NHCOOCH_3$), 5.17 (1H d., $J_{1,2}$ 3 Hz, H-1).

Found: C, 43.25; H, 7.04; N, 5.63%. Calcd for $C_9H_{17}NO_7$: C, 43.01; H, 6.82; N, 5.57%.

From the late eluate (780~930 ml) **17** was obtained as a colorless solid which was recrystallized from ethanol-ethyl acetate yielding 209 mg, mp 146—148°C, $[\alpha]_D^{22}$+6° (*c* 1, methanol); NMR (in D_2O): τ 6.42 (3H s., OCH_3), 6.31 (3H s., $NHCOOCH_3$), 5.54 (1H d., $J_{1,2}$ 7.5 Hz, H-1).

Found: C, 43.12; H, 6.95; N, 5.60%.

Methyl 6-Bromo-3,6-dideoxy-3-methoxycarbonylamido-α-D-glucopyranoside (18). Compound **16** (443 mg) in DMF (4.8 ml) was treated with mesyl bromide (570 mg) at 65°C for 15 hr. A new spot (R_f 0.62) and a very weak spot (R_f 0.25) appeared on TLC with methyl ethyl ketone. Successive de-*O*-formylation[4] gave a slight amount of starting material (**16**, R_f 0.25) in contrast to the case of **3**. Crude product obtained was purified by column chromatography with silica gel (20 g) with methyl ethyl ketone - ethyl acetate yielding a solid of 478 mg (85%), mp 197—198°C, $[\alpha]_D^{20}$+128° (*c* 0.8, methanol).

Found: C, 34.80; H, 5.16; N, 4.67, Br. 24.90%. Calcd for $C_9H_{16}NO_6Br$: C, 34.39; H, 5.14; N, 4.46; Br. 25.45%.

Methyl 2,4-Di-O-acetyl-6-bromo-3,6-dideoxy-3-methoxycarbonylamido-α-D-glucopyranoside (19). Compound **18** was acetylated in a similar manner as in the case of **3** to give **19**, mp 205—210°C, $[\alpha]_D^{20}$+95° (*c* 1, chloroform).

Found: C, 39.48; H, 5.09; N, 3.36; Br, 19.76%. Calcd for $C_{13}H_{20}NO_8Br$: C, 39.21; H, 5.06; N, 3.52; Br, 20.07%.

IR spectrum (KBr): 1750, 1710, 1550; 981, 925, 800 (w), 773(m), 760, and 710 (w) cm^{-1}; NMR (in $CDCl_3$): τ 7.91 (6H s., OAc), 6.51 (3H s., OCH_3), 6.34 (3H s., $NHCOOCH_3$), 5.96 (1H octet, *J* 3, 6, and 9.7 Hz, H_{ax} -5); No peak in the field lower than τ 4.95 was observed (compare with the spectrum of **4**).

Methyl 2,6-Di-O-acetyl-3,6-dideoxy-3,6-imino-N-methoxycarbonyl-α-D-glucopyranoside (20). A mixture of **19** (256 mg) and silver fluoride (240 mg) in dry pyridine (1.8 ml) was stirred at 60°C overnight in the dark. On TLC with benzene-ethyl acetate (2:1), two spots (R_f 0.18 and 0.44 (minor)) appeared but the latter was proved to be that of the starting material (**19**). The reaction mixture was extracted with ether and the organic layer was treated in a similar manner as in the preparation of **5**. The crude mixture obtained was chromatographed on a column of silica gel with benzene - ethyl acetate (2:1) and the portion containing the substance showing R_f 0.18 was evaporated to give a colorless syrup, 165 mg (80%), $[\alpha]_D^{20}$+70° (*c* 1, chloroform).

Found: C, 49.41; H, 6.20; N, 4.61%. Calcd for $C_{13}H_{19}NO_8$: C, 49.21; H, 6.04; N, 4.41%.

IR spectrum (KBr): 1750, 1715, 1540 (w); 930, 910, 880 (m), 830, 770, 725 (w), and 685 cm^{-1}; NMR (in $CDCl_3$):τ 7.91 and 7.81 (each 3H s., OAc), 6.46 (3H s., OCH_3), 6.22 (3H s., $NHCOOCH_3$), 6.3—6.6 (2H m., H-6,6′), 5.3—5.5 (3H m., H-3,4,5), 5.15 (1H d., J 3.3 Hz, H-1), 4.68—4.88 (1H unresolved broad peak having half-height width of ~8Hz, H-2).

Methyl 3-Amino-3-deoxy-α-D-glucopyranoside (21). To an aqueous solution (40 ml) of **16** (800 mg), barium hydroxide octahydrate (1.8 g) was added and the mixture was heated at 95°C for 1.5 hr. After introducting carbon dioxide, the

mixture was heated for a while, centrifuged, and the supernatant layer was evaporated. The residue was extracted with methanol and the solution was evaporated to give a solid which was dissolved in a small amount of methanol. Ethyl acetate was added to the solution to give ninhydrin-positive crystals (546 mg, 92%), mp 175—176°C (lit,[20] 167—168°C), $[\alpha]_D^{23}$+165° (*c* 0.6, methanol) (lit,[20] +144.4° (water)).

Methyl 2,4,6-Tri-O-acetyl-3-deoxy-3-phthalimido-α-D-glucopyranoside (22). To a solution of **21** (459 mg) in dry pyridine (9 ml), phthalic anhydride (510 mg) was added and the solution was heated at 90°C for 30 min. A phthalimido derivative (R_f 0.54 with tailing on TLC with methyl ethyl ketone - methanol 4:1) was produced. To the resulting pale yellow solution, acetic anhydride (9 ml) was added and the solution was heated at 90°C for 1 hr. A spot (R_f 0.68) appeared on TLC with benzene - ethyl acetate (5:3). The solution was evaporated and the residue was dissolved in chloroform. The solution was washed successively with potassium hydrogensulfate solution, soldium hydrogencarbonate solution, and water, dried over sodium sulfate and evaporated to give a solid. The product was dissolved in a mixture of benzene - ethyl acetate (2:1) and passed through a short column of silica gel with the aid of the same solvent mixture. The eluate was evaporated and the residue was recrystallized from ethanol yielding pale yellow crystals, 914 mg (87%), mp 175—177°C, $[\alpha]_D^{22}$+75° (*c* 1, chloroform).

Found: C, 56.13; H, 5.06; N, 3.28%. Calcd for $C_{21}H_{23}NO_{10}$: C, 56.12; H, 5.16; N, 3.12%.

IR spectrum (KBr): 1755, 1725; 732, 724 cm^{-1}; NMR (in $CDCl_3$): τ 8.11, 8.06 and 7.89 (each 3H s., OAc). It is noteworthy that two acetyl methyl protons resonated at higher field than usual. The signal at τ 7.89 seems to originate from protons of 6-*O*-acetyl (compare with the spectrum of **25**). τ 6.51 (3H s., OCH_3), 5.4—6.1 (3H m., H-5,6,6'), 5.18 (1H q., *J* 10, 11 Hz, H-3), 4.88 (1H d., *J* 3.5 Hz, H-1), 4.31 (1H, t., *J* 9.8 Hz, H-4), 4.22 (1H q., *J* 3.5, 11 Hz, H-2), 1.9—2.35 (4H m.); $J_{1,2}$ 3.5 Hz $J_{2,3}$ 11 Hz, $J_{3,4}$ 10 Hz, $J_{4,5}$ ~9.8 Hz.

Methyl 3-Deoxy-3-phthalimido-α-D-glucopyranoside (23). A solution of **22** (802 mg) in methanol was treated with sodium methoxide. A spot (R_f 0.58) appeared on TLC with ethyl acetate. The product was recrystallized from acetone yielding 570 mg (98%), mp 194—197°C, $[\alpha]_D^{22}$+103° (*c* 1, methanol); IR spectrum (KBr): 1775 (w), 1710; 970 (w), 910, 873 (w), 847 (vw), 802 (w), 777 (w), and 730 cm^{-1}.

Found: C, 55.85; H, 5.49; N, 4.02%. Calcd for $C_{15}H_{17}NO_7$: C, 55.72; H, 5.30; N, 4.33%.

Methyl 6-Bromo-3,6-dideoxy-3-phthalimido-α-D-glucopyranoside (24). To a solution of **23** (499 mg) in dry DMF (5.5 ml), mesyl bromide (770 mg) was added and the solution was heated at 65°C overnight. On TLC with benzene - ethyl acetate (1:2), two spots of R_f 0.79 (**24**) and 0.70 (an *O*-formyl compound) appeared in approximately equal color strength. The solution was evaporated and the residue was neutralized with sodium methoxide in methanol. On TLC, the spot of R_f 0.70 disappeared and a spot (R_f 0.25, **23**) appeared. In contrast to the case of the preparation of **18**, the bromination of **23** turned out to compete with *O*-formylation. The bromination procedure was repeated to raise the yield of **24**. The above methanolic solution was evaporated and the residue was coevaporated with toluene. The residue was dissolved in DMF (4.5 ml) and treated with mesyl bromide (730 mg). After the de-*O*-formylation of the resulting product with sodium methoxide in methanol, the mixture was subjected to chromatography on a column of silica gel (13 g) with benzene - ethyl acetate (1:2). From the earlier eluate (37—70 ml), **24** was obtained as a solid, which was recrystallized from benzene - ethyl acetate (3:1) yielding 360 mg (61%); mp 178—178.5°C, $[\alpha]_D^{22}$+88° (*c* 0.5, methanol); IR spectrum (KBr): 1725, 1715; 928 (w), 905, 870 (w), 802 (w), 780 (w), 726, and 717 cm^{-1}.

Found: C, 46.43; H, 4.38; N, 3.88; Br, 20.33%. Calcd for $C_{15}H_{16}NO_6Br$: C, 46.65; H, 4.18; N, 3.63; Br, 20.69%.

From the late eluate, the starting material (**23**, 120 mg) was recovered.

Methyl 2,4-Di-O-acetyl-6-bromo-3,6-dideoxy-3-phthalimido-α-D-glucopyranoside (25). Prepared from **24** by the general procedure. The final product was a syrup, which was solidified by trituration with water, mp 76.5—79.5°C, $[\alpha]_D^{23}$+49.2° (*c* 0.8, chloroform).

Found: C, 48.87; H, 4.47; N, 3.08; Br, 16.52%. Calcd for $C_{19}H_{20}NO_8Br$: C, 48.53; H, 4.29; N, 2.98; Br, 16.99%.

IR spectrum (KBr): 1755, 1725, 927, 887, 868, 798, 772 (w) and 725 (s) cm^{-1}; NMR (in $CDCl_3$): τ 8.09 and 8.07 (each 3H s., OAc), 6.47 (3H s., OCH_3), 6.4—6.6 (2H m., H-6,6'), 5.85 (1H octet, *J* 4, 6, and 10 Hz, H-5), 5.17 (1H q., *J* 10 and 11 Hz, H-3), 4.85 (1H d., *J* 3.5 Hz, H-1), 4.33 (1H t., *J* 10 Hz, H-4), 4.26 (1H q., *J* 3.5, 11 Hz, H-2), 1.9—2.35 (4H m.); $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 11 Hz, $J_{3,4}$ 10 Hz, $J_{4,5}$ 10 Hz, $J_{5,6}$ 6 Hz, $J_{5,6'}$ 4 Hz.

Methyl 2,4-Di-O-acetyl-3,6-dideoxy-3-phthalimido-α-D-xylo-hex-5-enopyranoside (26). Compound **26** was prepared from **25** in a similar manner as for the preparation of **5** from **4**. Recrystallization from ethanol gave pale yellow crystals (79%), mp 191—192°C, $[\alpha]_D^{20}$+50° (*c* 0.5, chloroform); R_f 0.52 (TLC with benzene - ethyl acetate 5:1).

Found: C, 58.68; H, 4.91; N, 3.69%. Calcd for $C_{19}H_{19}NO_8$: C, 58.61; H, 4.92; N, 3.60%.

IR spectrum (KBr): 1760, 1725, 1670 (C=C); 960, 932, 908 (w), 898, 878 (w), 845 (w), 800, and 725 (s) cm^{-1}; NMR (in $CDCl_3$ at 100 MHz): τ 8.07 and 8.03 (each 3H s., OAc), 6.50 (3H s., OCH_3), 5.35 (1H triplet with very small splittings (<0.3 Hz), *J* ~2 Hz, H-6), 5.18 (1H t., *J* ~2 Hz, H-6'), 5.16 (1H q., *J* 10 and 11 Hz, H-3), 4.85 (1H d., *J* 3 Hz, H-1), 4.16 (1H q., *J* 3 and 11 Hz, H-2), 3.85 (1H double triplets, *J* 2, 2 and 10 Hz, H-4), 1.95—2.35 (4H m.); $J_{1,2}$ 3 Hz, $J_{2,3}$ 11 Hz, $J_{3,4}$ 10 Hz, $J_{4,6}$=$J_{4,6'}$ ~2 Hz, $J_{6,6'}$ ~2 Hz.

Irradiation of H-4 resulted in collapse of the H-6 and H-6' triplets to two doublets (each *J* ~2 Hz), and of H-3 triplet to a doublet (*J* 11 Hz).

Methyl 2,4-Di-O-acetyl-3,6-dideoxy-3-phthalimido-β-L-idopyranoside (27). A solution of **26** (294 mg) in dioxane (3 ml) was hydrogenated with palladium black and hydrogen in a similar manner as for the preparation of **6**. A spot (R_f 0.58) appeared (the R_f of **26** was 0.62) on TLC with benzene-ethyl acetate (5:1). After filtration the solution was evaporated to give a solid which was passed through a short column of silica gel with the above solvent mixture. The eluate was evaporated to give a solid, 253 mg (87%), mp 66—69°C, $[\alpha]_D^{22}$+59° (*c* 0.9, chloroform).

Found: C, 58.17; H, 5.32; N, 3.69%. Calcd for $C_{19}H_{21}NO_8$: C, 58.31; H, 5.41; N, 3.58%.

IR spectrum (KBr): 1780, 1755, 1725; 935, 925 (sh), 907 (sh), 872 (m), 810, 800, and 725 (s) cm^{-1}: NMR (in $CDCl_3$ at 100 MHz): τ 8.58 (3H d., *J* 6.7 Hz, C_5-CH_3), 8.08 (6H s., OAc), 6.52 (3H s., OCH_3), 5.45 (1H double quartet, *J* 6.7, 6.7, 6.7 and 6 Hz, H-5), 5.06 (1H q., *J* 11 and 9 Hz, H-3), 4.93 (1H d., *J* 3.5 Hz, H-1), 4.35 (1H q., *J* 9 and 6 Hz, H-4), 4.33 (1H q., *J* 3.5 and 11 Hz, H-2); $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 11 Hz $J_{3,4}$ 9 Hz, $J_{4,5}$ 6 Hz.

Irradiation at τ 4.38 caused the H-5 multiplet to collapse to a quartet, the H-3 quartet to a broad singlet and the H-1

Intramolecular Fluorescence Quenching Effect by *p*-Nitrophenyl and *p*-Nitrophenoxy Groups

Kiyoshi MUTAI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo

(Received April 15, 1971)

The intramolecular fluorescence quenching efficiency of *p*-nitrophenyl and *p*-nitrophenoxy groups in homologous series of *p*-$O_2NC_6H_4(CH_2)_nNH$-1-Naphthyl (I, $n=1$—7) and *p*-$O_2NC_6H_4O(CH_2)_nNH$-1-Naphthyl (II, $n=2$—6), respectively, has been determined. The quenching effect is observed even in the highest homologs of both series. From the fact that the fluorescence intensity of $n=2$ homolog of I is higher than that of $n=1$, together with spectroscopic data it is concluded that the higher intensity of $n=2$ than $n=1$ of the across-space intramolecular charge-transfer band is due to the larger absorbance per interacting molecule of n=2, the origin of which might be attributed to the different interacting conformations of these homologs. The effect of the number of methylene groups (n) on the fluorescence spectral shape has also been found.

Although *intermolecular* charge-transfer (CT) interaction has been studied extensively, it is only recently that across-space *intramolecular* CT interaction has begun to draw the attention of chemists.[1] One of the characteristics of the latter type interaction is that the interaction under more or less restricted conditions can be observed, and accompanying CT spectral features may provide valuable data for a further understanding of the CT phenomenon. In this paper some conformational effects on the CT spectrum are shown by the aid of fluorescence spectroscopy.

The *p*-nitrophenyl, *p*-$O_2NC_6H_4$–, group can play the role of electron-acceptor in the across-space intramolecular CT interaction in a series of *p*-$O_2NC_6H_4$-$(CH_2)_n$-NHAr.[2] It has been found that the intensity of the CT band of $n=2$ homolog is higher than that of $n=1$ homolog regardless of the Ar group. For instance, the ratios of the apparent absorption coefficients, $\varepsilon(n=2)/\varepsilon(n=1)$, observed in carbon tetrachloride solution for the derivatives of Ar=phenyl, =*p*-methoxyphenyl, and =1-naphthyl are 3.0, 1.7, and 1.4, respectively. A similar phenomenon has been reported in other homologous series of compounds.[1a,1f] On the other hand, the position of the CT band of the $n=1$ homolog is a little longer in wavelength, that is, the transition energy is smaller in this homolog. These spectral characteristics could be attributed to the presence of intramolecular N—H$\cdots\pi$ interaction, but the same order of intensities observed in the *N*-alkylated derivatives of I[3] suggests that this explanation is incorrect. In connection with the CT interacting state there are

two possibilities for the interpretation of the spectral features. (1) The CT interaction is favorable in $n=1$ as is noted in the transition energy, and the number of interacting molecules per mole is larger than that in $n=2$. This situation is probable from the viewpoint of entropy for the two interacting groups to meet, but the interacting conformation subject to the restrictions caused by the shorter methylene chain diminishes the CT intensity per interacting molecule. (2) The interaction in the higher homolog ($n=2$) is favored with regard to the interacting energy, since a scale model indicates that the π-electron clouds of the two group can overlap more sufficiently in this homolog, and its higher intensity reflects larger population of the interacting molecule than in $n=1$.

It would be easy to find a correct explanation if the absorption intensities per interacting molecule or the ratios of the interacting to non-interacting molecule for both homologs could be determined. Unfortunately, only a part of the molecules interact and there is no reliable way to determine their values. However, for the present purpose, it is not necessary to know the precise values. It is adequate only to determine in which of the two homologs the population is larger or, in other words, the interacting groups have a greater chance of access to each other.

The approach employed in the present study is fluorescence quenching effect,[4] since the phenomenon is known to be greatly dependent on the distance between a fluorescer and a quencher by whichever mechanism it takes place.[5,6] This characteristic is convenient for comparing the degree of proximity of the two groups in a homologous series of compounds, if one group is fluorescer and the other can quench it. In the present case the 1-naphthyl group is introduced to the amino nitrogen, thus producing a 1-naphthylamino group known as a strong fluorescent moiety. This group, of course, can work as an electron-donor in across-space intramolecular CT interaction with the *p*-nitrophenyl group.

Results

Fluorescence spectra due to the 1-naphthylamino moiety in *p*-$O_2NC_6H_4(CH_2)_nNH$-1-Naphthyl (I) are reproduced in Fig. 1 and data given in Table 1. Benzene-cyclohexane mixture (1:4) was used as a solvent because benzene increases the dissolving power of the solvent. A slight decrease in the fluorescence intensity was observed in this solvent as compared with cyclohexane which is a typical inert solvent with poor dissolving power, but no appreciable change in spectral shape was found. The order of fluorescence intensity is $n=1<2<3<5<4<6<7$. Obviously the quenching effect increases as n or chain length decreases with the exception of $n=4$. Even in the highest homolog studied ($n=7$) in which neither the CT interaction nor N–H$\cdots\pi$ interaction, hence no intramolecular force advantageous for the two groups to be close together, has been detected, the quenching effect by *p*-nitrophenyl group

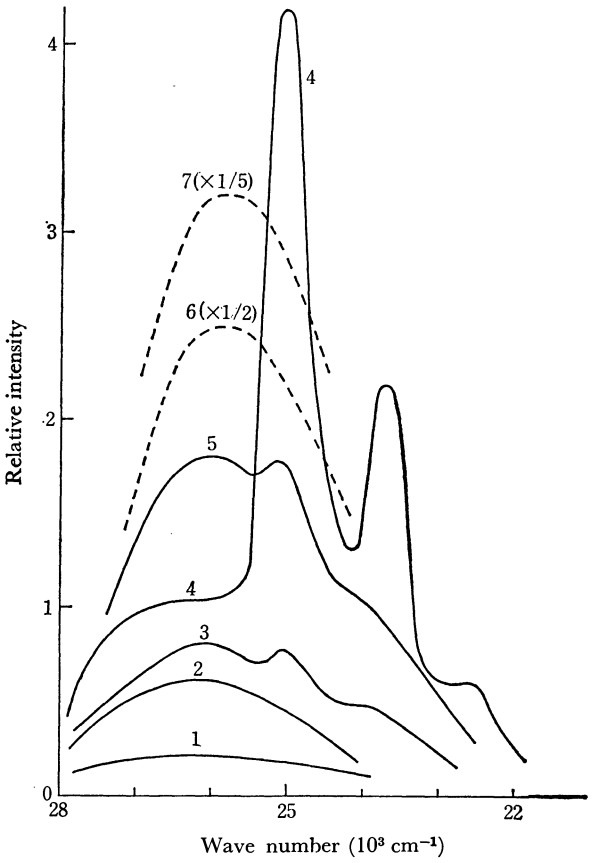

Fig. 1. Fluorescence spectra of *p*-$O_2NC_6H_4(CH_2)_nNH$-1-Naphthyl in benzene-cyclohexane (1:4) mixture. Figures attached to the curves denote n, the number of methylene groups. The scale of the curves of $n=6$ and $n=7$ is reduced to 1/2 and 1/5, respectively. The excitation wavelength was 313 nm.

Table 1. Relative integrated fluorescence intensity of $Ar(CH_2)_nNH$-1-Naphthyl

Ar=*p*-$O_2NC_6H_4$ (I)		Ar=*p*-$O_2NC_6H_4O$ (II)

is obvious in comparison with *N*-ethyl-, *N*-benzyl-, or *N*-(*p*-chlorobenzyl)-1-naphthylamine (Table 1). The latter compounds can be regarded as model ones which exhibit fluorescence free of any quenching effect. For this purpose, the latter two which are solid at room temperature have an advantage with respect to easy handling and stability over liquid *N*-ethyl derivative which becomes wine-red on standing overnight in the dark after distillation.

In the spectra of $n=3$, 4, and 5, vibrational progressions were observed, especially well-developed in that of $n=4$. The separation between the peaks is approximately 1330—1350 cm^{-1}.

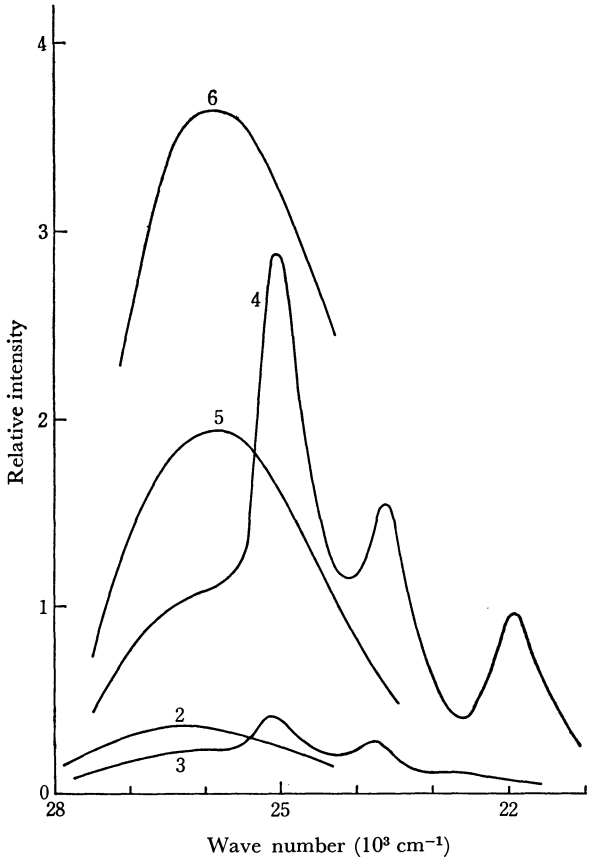

Fig. 2. Fluorescence spectra of *p*-$O_2NC_6H_4O(CH_2)_nNH$-1-Naphthyl in benzene-cyclohexane (1:4) mixture. The figures attached to the curves denote *n*. The excitation wavelength was 313 nm.

The *p*-Nitrophenoxy group in a homologous series of *p*-$O_2NC_6H_4O(CH_2)_nNH$-1-Naphthyl (II) also showed fluorescence quenching effect, the fluorescence spectra of which are reproduced in Fig. 2. The lowest homolog of this series used in the present study is $n=2$, since the $n=1$ homolog is too unstable. In this series the chain length (the number of atoms combining two groups) with *n* methylenes corresponds to that with $n+1$ methylenes in I, since an ether oxygen is inserted between *p*-$O_2NC_6H_4$- and CH_2 groups in II. Probably the different bond distance of C–O and C–C makes no significant effect on quenching efficiency. Thus it is noteworthy that vibrational structure also appeared in II only when $n=3$ and 4.

The relative intensities of I and II measured in a common medium are summarized in Table 1. Since the fluorescent moiety is common to both series, the values could be a measure of efficiency of the quenchers.

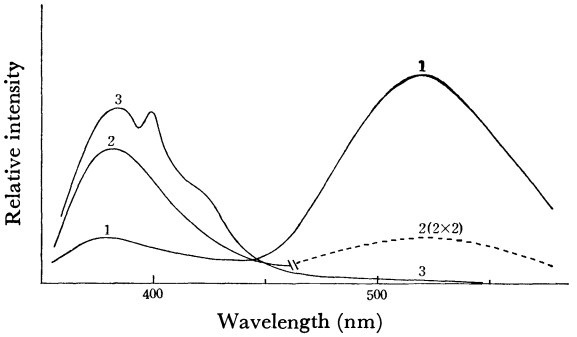

Fig. 3. Fluorescence spectra of *p*-$O_2NC_6H_4(CH_2)_nNH$-1-Naphthyl in benzene-cyclohexane (1:4) mixture. The scale of the curve of $n=2$ in longer wavelength region is doubled The excitation wavelength was 313 nm.

In the longer wavelength region than that of the fluorescence due to 1-naphthylamine moiety, a broad peak appears in the lower homologs of I (Fig. 3) and II. The origin of this peak has been assigned to the excited CT state on the basis of its intramolecular characteristics and excitation spectrum.[7,8]

Discussion

From the fluorescence intensities of I, we might conclude that naphthylamino and *p*-nitrophenyl groups have a greater chance of access in $n=1$ homolog than in $n=2$. However, the conclusion should be scrutinized from the viewpoint of quenching or energy transfer mechanism.

In the higher homologs ($n\geqq4$) in which the CT interaction of N–H$\cdots\pi$ interaction is scarcely observed, the quenching effect takes place undoubtedly beyond collisional diameters of the two aromatic groups. This long-range effect suggests that a resonance-energy transfer mechanism is predominating.

In the lower ones, exchange transfer mechanism as well as resonance mechanism is possible as suggested by the occurrence of the intramoledular CT interaction, because both exchange mechanism and the CT interaction require the overlap of the π-electron clouds of the aromatic rings. Examination of a scale molel shows that only partial overlap of the electron clouds is allowed for $n=1$ owing to the limitation of bond angles but sufficient overlap is possible for $n\geqq2$ in which two aromatic rings can assume a parallel face-to-face arrangement. In the study of the excimer, this latter conformation is regarded as an important, if not essential, condition for excimer formation on theoretical[9] and experimental[10] grounds. As an example, in a series of diphenyl end-substituted alkanes $Ph(CH_2)_nPh$, only

$n=3$ shows excimer emission[10a] which is not observed in $n=2$. Therefore, as far as exchange mechanism is concerned, the greater quenching efficiency and lower fluorescence intensity are expected for $n=2$ if the population of the CT interacting molecule is the same as or greater than $n=1$.

As for resonance mechanism, which does not require the overlap of the electron clouds, and is largely dependent on the distance between two groups, the intensity of $n=2$ should be lower if the population of $n=2$ is the same as or greater than $n=1$, since the flexibility of the longer chain of $n=2$ permits closer approach of the aromatic rings with each other. The above supposition may be cited as an evidence that in a series of alkanes substituted by 1-naphthyl on one end, $Ar(CH_2)_n$-1-Naphthyl, the intramolecular energy transfer efficiency is nearly the same in $n=2$ and $n=3$ when Ar is 9-anthryl (energy acceptor),[11] and $n=2<n=3$ when Ar is 4-benzoylphenyl[12] (here, $n=2$ and $n=3$ correspond to $n=1$ and $n=2$ homologs of I, respectively, in the number of chain atoms). The same order of interaction effects has also been reported in a series of 9,9′-polymethylene-bisadenines from a study of their hypochromism of absorption spectra and emission spectra.[13] This suggests that in I higher fluoroescence intensity or lower quenching effect should be observed in $n=1$.

In order to explain the results the presence of the intramolecular CT interaction should be taken into account. The overlap of the π-electron clouds is insufficient in $n=1$, but if the population of the CT, interacting molecule of $n=1$ exceeds that of $n=2$, then more quenching effect on lower fluorescence intensity is expected for $n=1$. As is seen in Fig. 3, the transition from the excited intramolecular CT state to the ground state in another radioactive process. In this sence, as far as the fluorescence of the amine moiety is concerned, the CT interaction is a quenching process, since the interacting molecules absorb a part of incident light to decrease the apparent quantum yield of the fluorescence process of the amine moiety. The order of intensities of the CT fluorescence bands ($n=1>n=2$) may be an evidence of the difference of population of the CT interacting molecules. Another evidence has been obtained from the infrared study of I. It has been shown that in the lower homologs there exists intramolecular N-H$\cdots\pi$ interaction which fixes molecular conformation to prohibit the overlap of the π-electron clouds of the aromatic rings, and the population of the free molecule from this interaction is abnormally large in $n=1$.[14] It has also been established that this "free" state is competitive with or more stable than the N-H$\cdots\pi$ interacting state,[15] indicating that the "free" state contains another interacting state, *viz.*, the CT interaction. This shows the population of the CT interacting molecule is larger in $n=1$ than in $n=2$. This conclusion, in turn, suggests the larger intensity of the CT absorption for an interacting molecule of $n=2$. The difference is probably due to the different interacting conformations of the compounds in which more sufficient orbital overlap is possible for $n=2$, resulting in larger value of the transition moment of the CT absorption of $n=2$.[16,17] If the explanation is correct, this may be an example of the conformational effects on the spectral features of the CT interaction.

The quenching effect of both *p*-nitrophenyl and *p*-nitrophenoxy groups is due to the overlap of their absorption spectra with the fluorescence spectrum of the naphthylamine moiety. The region of the overlap is larger in *p*-nitrophenoxy group. This is probably the reason why larger quenching efficiency is observed in II when the fluorescence intensities of the homologs of I and II with the same number of chain atoms are compared. Lack of the quenching effect in benzyl and *p*-chlorobenzyl groups can be attributed to the small overlap of their absorption spectra with the fluorescence.

It is interesting that the appearance of vibrational structure depends strongly on the number of methylene groups. The peak separation suggests its relation with C–N stretching vibtation. Perhaps certain numbers of methylenes make a contribution through a certain type of their vibrational mode to allow the transition to the upper vibrational levels of the ground state.[18] The structure is most remarkable in $n=4$ of I and II in which the fluorescence intensities are more than those expected from the values of their next lower and higher homologs. This suggests that the originally radiationless or forbidden transition becomes radiative due to the same cause as the appearance of the structure.

Experimental

Materials. The compounds used were purified through the known methods.

N-[ω-(*p*-Nitrophenyl)alkyl]-1-naphthylamines (I, $n=4$, 5, and 6). Syntheses of this series of compounds were performed as described previously.[2,14]

N-[ω-(*p*-Nitrophenoxy)alkyl]-1-naphthylamines (II, $n=2$—6). These compounds were prepared by the same procedure as has been reported.[20]

The mp's and results of elemental analyses of the products are given in Table 2.

Spectral Measurement. Fluorescence spectra were recorded on an Aminco-Bowman spectrophotofluorometer. In every series of measurements, the CT fluorescence band was used as a reference of intensity in order to determine a factor for adjusting photomultiplier sensitivity and fluctuation of the intensity of incident light. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2541—2545 (1971)

Thermal Decomposition of Benzoyl *p*-Toluenesulfonyl Peroxide[1]

Ryuki HISADA, Hiroshi MINATO, and Michio KOBAYASHI
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received April 24, 1971)

Benzoyl *p*-toluenesulfonyl peroxide (BTP) was synthesized by addition of barium hydroxide and water to a mixture of *p*-toluenesulfonyl chloride and peroxybenzoic acid in dichloromethane at −15°C. Rates of decomposition of BTP in inert solvents increased rapidly as the decomposition proceeded. This autocatalysis was prevented and the reaction followed a first-order rate equation when magnesium oxide suspension was present in the medium for removal of *p*-toluenesulfonic acid produced by the decomposition. The products of decomposition were analyzed. When magnesium oxide suspension was present, main products were those ascribable to homolysis (biphenyl, 44 mol%, in benzene; chlorobenzene, 44 mol%, hexachloroethane, 27 mol%, in carbon tetrachloride), but products ascribable to ionic reactions were also present (phenyl *p*-toluenesulfonyl carbonate, 22—26 mol%).

Investigations in our laboratories revealed that *m*-nitrobenzenesulfonyl peroxide decomposed homolytically in chloroform, whereas its O–O bond was cleaved heterolytically in aromatic solvents.[2] Razuvaev, Likhterov, and Etlis studied the decomposition of acetyl cyclohexanesulfonyl peroxide in several solvents, and their products indicated that both homolytic and heterolytic reactions were taking place.[3] They also studied the decomposition of benzoyl alkanesulfonyl peroxide in benzene and carbon tetrachloride, and they found no products ascribable to homolytic cleavage of the O–O bond.[4]

Aroyl arenesulfonyl peroxides have not been reported in the literature. As an example of these unknown peroxides, synthesis of benzoyl *p*-toluenesulfonyl peroxide has been attempted in order to determine its properties and the nature of its decomposition under various conditions.

Results and Discussion

A literature survey revealed a paper describing an unsuccessful attempt for synthesis of benzoyl benzenesulfonyl peroxide. Kirmse and Horner mixed benzenesulfonyl chloride and sodium perbenzoate in 1:1 water-dioxane at 0°C, and the products were benzoyl peroxide, benzoic acid and carbon dioxide.[5]

After numerous attempts, it was found that addition of barium hydroxide and water to a mixture of *p*-

toluenesulfonyl chloride and peroxybenzoic acid in dichloromethane at −15°C resulted in the formation of benzoyl *p*-toluenesulfonyl peroxide (BTP).

When BTP was decomposed in benzene or carbon tetrachloride, the rate of decomposition increased rapidly with the progress of decomposition, as Figs. 1 and 2 show. When trifluoroacetic acid was added, the rate was very fast from the beginning, and the decomposition was complete in 3 hr at room temperature. These findings indicate that the decomposition of BTP is much accelerated by the *p*-toluenesulfonic acid produced by the decomposition. In order to investigate the possibility of the homolysis of BTP, such ionic autocatalysis must be prevented, and it was found that when powdery magnesium oxide was suspended in the medium the acceleration of rates was prevented and the decomposition followed a first-order rate equation till about two half-lives in benzene and one half-life in carbon tetrachloride. Rate constants and activation parameters

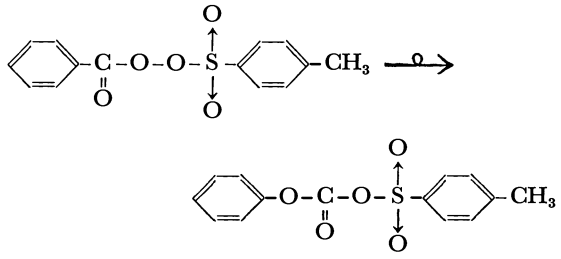
a) Temperature, 45°C; Reaction time, 15 hr.

In the absence of suspended magnesium oxide, one of the major products was phenyl *p*-toluenesulfonyl carbonate formed by carboxy inversion process.



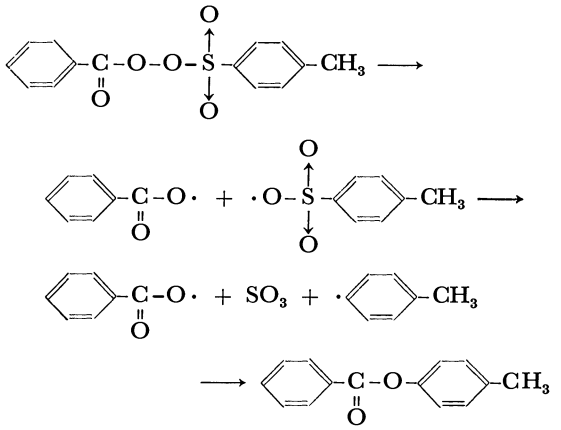
When trifluoroacetic acid was present, 71 mol% of BTP was converted to the mixed anhydride, and this finding shows that this rearrangement is accelerated by acid.

Even when suspended magnesium oxide was present in benzene or carbon tetrachloride to adsorb *p*-toluenesulfonic acid produced, about 22—26 mol% of BTP rearranged to the mixed anhydride. Therefore, the tendency for such rearrangement must be interpreted to be inherent in this peroxide rather than given by acid catalyst. The electron-withdrawing power of a *p*-toluenesulfonyloxy group is far greater than that of a benzoyloxy group, and even under the conditions which ensure the absence of acid in the medium the rearrangement proceeded at moderate rates at these temperatures.

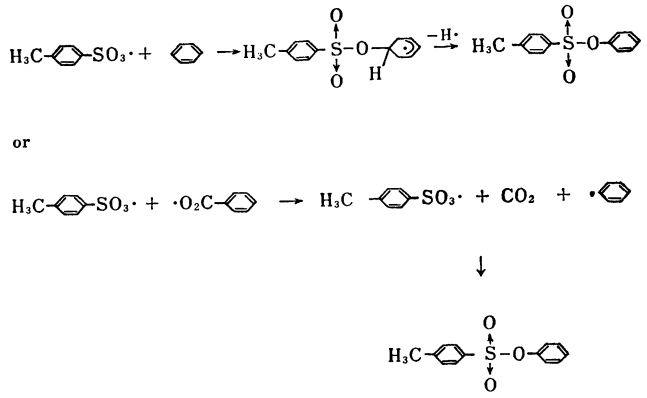
However, when magnesium oxide was added, the yield of biphenyl increased from 1 to 44 mol% in benzene, and the yields of chlorobenzene and hexachloroethane in the carbon tetrachloride increased from 26 to 44 mol% and from 12 to 27 mol%, respectively. These data show that magnesium oxide is effective in reducing heterolysis and promoting homolysis.

When BTP was decomposed in carbon tetrachloride in the presence of magnesium oxide, the yield of chlorobenzene was 44 mol% whereas that of hexachloroethane was 27 mol%; the latter corresponds to 54 mol % of trichloromethyl radical. Thus about 10 mol% trichloromethyl radical must be produced by abstraction of chlorine atom from carbon tetrachloride by radicals other than phenyl radicals. Therefore, benzoyloxy radical and/or *p*-toluenesulfonyloxy radical must abstract chlorine atom from carbon tetrachloride.

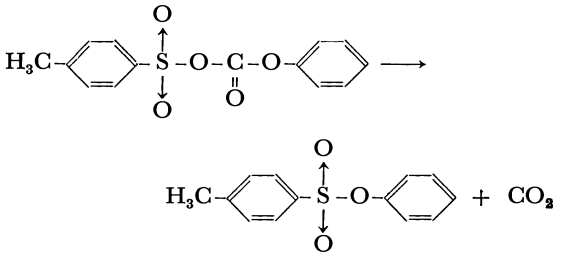
Formation of *p*-tolyl benzoate can be accounted for by the following recombination of radicals in cage.



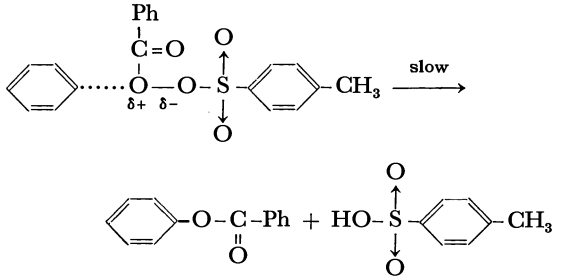
Formation of phenyl *p*-toluenesulfonate can be explained by addition of *p*-toluenesulfonyloxy radical to benzene and subsequent hydrogen abstraction from the cyclohexadienyl radical or by geminate cage recombination of *p*-toluenesulfonyloxy radical with phenyl radical produced by fragmentation of benzoyloxy radical.



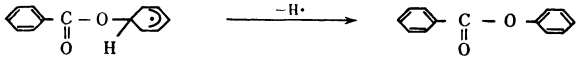
However, the fact that some sulfonate was formed even in the decomposition of BTP in the presence of trifluoroacetic acid indicates that at least part of the sulfonate arose from the mixed carbonate by an ionic path.



When *m*-nitrobenzenesulfonyl peroxide was decomposed in benzene, the main reaction products were *m*-nitrobenzenesulfonic acid and phenyl *m*-nitrobenzenesulfonate produced by electrophilic attack of a peroxidic oxygen atom on benzene.[6] If a similar reaction takes place with BTP, phenyl benzoate is the product expected in benzene. However, the yield of this ester in the absence of magnesium oxide was only 4 mol%, and this finding shows that positive character of the benzoyloxy oxygen of BTP is not large enough to accept nucleophilic attack of benzene readily.



When magnesium oxide was added, the yield of phenyl benzoate was doubled (8%), but the majority of this amount probably arose from attack of benzoyloxy radical on benzene.



6) R. L. Dannley and G. E. Corbet, *J. Org. Chem.*, **31**, 153 (1966).

Razuvaev, Likhterov, and Etlis[4] studied the decomposition of benzoyl ethanesulfonyl peroxide. They found that in benzene phenyl ethanesulfonyl carbonate was produced in 83 mol% yield and no biphenyl was found, whereas in carbon tetrachloride neither chlorobenzene nor hexachloroethane was formed. Therefore, BTP has greater tendency to undergo homolytic cleavage of the O–O bond than benzoyl ethanesulfonyl peroxide.

Experimental

Materials. Benzene was washed with concentrated sulfuric acid and water successively, dried over anhydrous calcium chloride and distilled at 80.0°C. Carbon tetrachloride was washed with a 10% sodium carbonate aqueous solution and water, dried over anhydrous calcium chloride, and distilled over phosphorus pentoxide. Boiling point was 76.7°C. *p*-Toluenesulfonyl chloride was recrystallized from *n*-hexane; mp 69—70°C. Peroxybenzoic acid was prepared according to Braun's method.[7] Magnesium oxide was used after heating in a crucible for 2 hr.

Preparation of Benzoyl p-*Toluenesulfonyl Peroxide (BTP).* A solution of 19.1 g of *p*-toluenesulfonyl chloride (0.1 mol) in 160 m*l* of dichloromethane was cooled to −15°C in a 500 m*l* three-necked flask equipped with a mechanical stirrer, an addition funnel, and a thermometer. A solution of 17.9 g of peroxybenzoic acid (0.13 mol) in 150 m*l* of dichloromethane was slowly added into the cooled and stirred solution. After the temperature of the mixture became below −15°C, 5 m*l* of water was slowly added and then 41.0 g of barium hydroxide (0.13 mol) was added in portions in 15 min. The temperature of the mixture should be kept below −12°C during the addition. After the addition was completed, the mixture was stirred at −12°C for 1.5 hr, and then washed with 10 *l* of ice water. The dichloromethane solution was dried over anhydrous magnesium sulfate, and the solvent was removed under reduced pressure. A brownish residue obtained was recrystallized from ether at −20°C, and 16.1 g of light yellowish crystals was obtained; yield, 52.8%. Recrystallization was repeated for two more times, and the crystals melting at 59.5°C were used for experiments. Iodometric analyses indicated the purity of 99.80%. The main infrared absorptions appeared at 1790, 1400, 1225, 1195 and 1180 cm^{-1} (in CCl_4). BTP was stable at −20°C, and no appreciable decomposition was observed when it was stored at −20°C for one month.

Found: C, 57.77; H, 3.85; S, 11.05%. Calcd for $C_{14}H_{12}O_5S$: C, 57.53; H, 4.14; S, 10.97%.

Kinetic Measurements. All the measurements were carried out under nitrogen atmosphere. A solution of 1.91 g of BTP (6.5 mmol) in 190 m*l* of benzene or carbon tetrachloride was deaerated by bubbling nitrogen for 30 min at 10°C. The solution was placed in a constant temperature bath, and after suitable intervals 15.0 m*l* aliquots of the solution were withdrawn and subjected to the iodometric analysis using a 0.05N sodium thiosulfate solution.[8]

When the runs were carried out in the presence of 2.62 g (65 mmol) of magnesium oxide suspension, 20.0 m*l* aliquots were withdrawn, the magnesium oxide was removed by a centrifuge, and 15.0 m*l* of the solution was subjected to the iodometric analysis.

Products of Decomposition of BTP. *(1) In Benzene*: A 0.1M solution of BTP in benzene was decomposed at 45.0±0.1°C for 15 hr. The reddish brown solution obtained was washed with water and then with a 10% sodium bicarbonate solution. The *p*-toluenesulfonic acid which dissolved into the water washings was titrated with bromothymolblue as the indicator. The sodium bicarbonate extracts were acidified by addition of hydrochloric acid, and the benzoic acid obtained was extracted with ether. The amount of benzoic acid was determined gravimetrically after evaporation of ethereal extracts. The benzene layer was dried over anhydrous magnesium sulfate, and then divided to three portions. One portion was used for determination of biphenyl and phenyl benzoate by vapor phase chromatography (Column: Apiezon L, 2 m; internal standard, dibenzyl). Another portion was used for determination of *p*-tolyl benzoate and phenyl *p*-toluenesulfonate by vapor phase chromatography after refluxing the solution with added aniline for 30 min, washing with water and then drying (Colum: Apiezon L, 2 m; internal standard, phenyl *p*-chlorobenzoate). The other portion was used for determination of phenyl *p*-toluenesulfonyl carbonate by elution chromatography after removal of benzene under reduced pressure (Wako Gel Q22 200 mesh; eluant, 1:2 *n*-hexane - benzene). The identities of biphenyl, phenyl benzoate, *p*-tolyl benzoate, and phenyl *p*-toluenesulfonate were established by comparison of the infrared spectra of these products, obtained by elution chromatography, with those of the authentic samples.

(2) In Carbon Tetrachloride: A 0.029M solution of BTP in carbon tetrachloride was decomposed at 45.0±0.1°C for 15 hr under nitrogen atmosphere. The carbon dioxide generated was absorbed in a 0.1N sodium hydroxide solution, which was titrated with a 0.2N sulfuric acid solution.[9] Then this solution was titrated for chloride ion by a 0.1N silver nitrate solution with potassium chromate as an indicator. The carbon tetrachloride solution was washed with water and a 10% sodium hydrogen carbonate solution, and then dried over anhydrous magnesium sulfate. The aqueous extracts were titrated by a 0.1N sodium hydroxide solution for *p*-toluenesulfonic acid and hydrogen chloride, and then titrated for chloride ion by a 0.1N silver nitrate solution with potassium chromate as the indicator. The $NaHCO_3$-extracts were acidified, and the benzoic acid separated was extracted with ether and determined gravimetrically. The carbon tetrachloride solution was divided into three portions. One portion was used for determination of chlorobenzene and hexachloroethane by vapor phase chromatography (Column, Silicone oil SE30, 2 m; internal standard, *p*-dichlorobenzene). Another portion was used for determination of ester by vapor phase chromatography after the treatment of the solution with aniline and then with water. The other portion was used for determination of phenyl *p*-toluenesulfonyl carbonate by elution chromatography.

(3) In Benzene and Carbon Tetrachloride with Suspended Magnesium Oxide: A 0.05M solution of BTP in benzene or a 0.029M solution of BTP in carbon tetrachloride containing suspended magnesium oxide was stirred with a mechanical stirrer under nitrogen for 15 hr at 45.0°C. Then magnesium oxide was dissolved by addition of dilute sulfuric acid, and the mixture was refluxed for 5 min. Carbon dioxide and hydrogen chloride expelled were titrated by the methods described above. (Expulsion of hydrogen chloride from the water-containing mixtures must be incomplete, and hence the actual amounts of hydrogen chloride produced were probably

9) K. Uneyama, W. Tagaki, I. Minamida, and S. Oae, *Tetrahedron*, **24**, 5271 (1968).

greater than the values obtained by titration.)

The mixture was separated into aqueous and organic layers, and both layers were analyzed by the methods described above. Since the amount of *p*-toluenesulfonic acid cannot be determined by acid-base titration, it was determined gravimetrically by converting it into its *S*-benzylisothiuronium salt as follows. The aqueous layer was made alkaline, and evaporated under reduced pressure. The sodium *p*-toluenesulfonate in the residue was dissolved by hot methanol, and the methanolic solution was evaporated under reduced pressure. Some water and hydrochloric acid was added, and *p*-toluenesulfonic acid was converted to its *S*-benzylisothiuronium salt.

(4) In Benzene Containing Trifluoroacetic Acid: After a 0.1M solution of BTP in benzene and a benzene solution of trifluoroacetic acid were deaerated separately by nitrogen, they were mixed and stirred at room temperature. After 1 hr, the color of the solution was reddish brown. After 15 hr, the benzene solution was washed with water and then with a sodium hydrogen carbonate solution. The products of the reaction were analyzed according to the methods described above. The amount of *p*-toluenesulfonic acid was determined after it was converted into its *S*-benzylisothiuronium salt.

Synthesis of Phenyl p-*Toluenesulfonyl Carbonate.* To a solution of 11.8 g (0.04 mol) of anhydrous silver *p*-toluenesulfonate in 100 m*l* of acetonitrile, 6.4 g (0.04 mol) of phenyl chloroformate (94—95°C/41 mmHg) was added, and the mixture was refluxed for 18 hr. After the silver chloride was filtered, the acetonitrile was evaporated under reduced pressure. Recrystallization of the residue in 1:1 *n*-hexane-ether yielded 8.6 g of phenyl *p*-toluenesulfonyl carbonate (67%), mp 64—65°C.

Found: C, 57.83; H, 4.17; S, 10.97%. Calcd for $C_{14}H_{12}O_5S$; C, 57.53; H, 4.14; S, 10.97%. IR: 1795, 1395, 1230, 1180 cm^{-1} (KBr).

Synthesis of Three New Azaparacyclophanes Containing Four Benzene Rings

Yoshikuni URUSHIGAWA,[1] Takahiko INAZU, and Tamotsu YOSHINO
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka
(Received August 1, 1970)

As a part of studies of paracyclophane chemistry in our laboratory,[2] three new azaparacyclophanes containing four benzene rings connected with four bridges in the para-position, such as *N,N'*-dimethyl-2,18-dimethyl-2,18-diaza[3.1.3.1]paracyclophane (V), *N,N'*-dimethyl-2,19-diaza[3.2.3.2]paracyclophane (IX), and *N,N',N'',N'''*-tetramethyl-2,11,20,29-tetraaza[3.3.3.3]-paracyclophane (XIII), were synthesized.

The objects of this experiment were to synthesize the azaparacyclophanes with different lengths of bridges, to compare their spectral properties, and to determine whether or not they form an inclusion compound. The synthetic method and results will be described below.

For the synthesis of the above-mentioned compounds, we adopted an amide-formation method in the critical ring-closing step. The azaparacyclophanes, V, IX, and XIII, were prepared by the condensation of each diacid chloride and diamine and by subsequent reduction, while compound V was obtained by the further *N*-methylation of the corresponding cyclic secondary amine, IV.

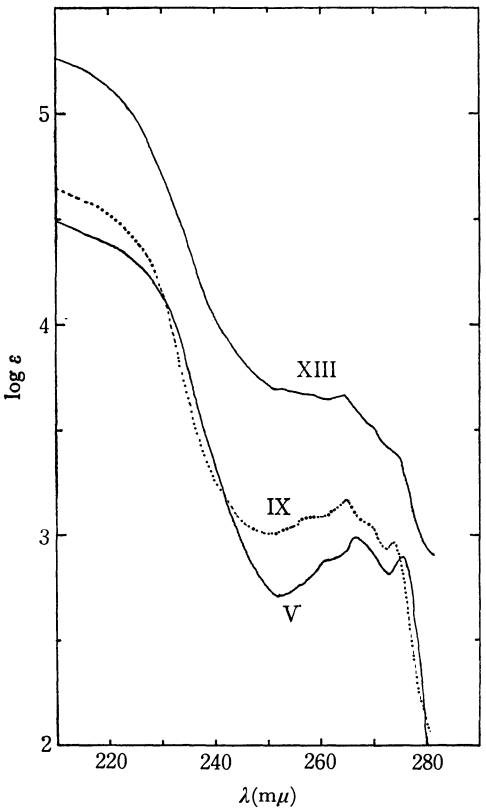

Fig. 1. UV spectra of azaparacyclophane V, IX, and XIII in ethanol.
V: λmax 266.5 mμ, log ε=2.99
IX: λmax 264.5 mμ, log ε=3.16
XIII: λmax 264.5 mμ, log ε=3.15
Curve XIII is displaced upward by 0.5 unit from the two curves below.

Figure 1 records the UV spectra of the azaparacyclophanes, which may be separated into two groups with respect to the length of the bridges. Compounds IX and XIII both contain bridges of more than one methylene unit and have almost equal intensities and wavelengths in λ max. On the other hand, compound V which contains one methylene unit, shows a shift to a slightly longer wavelength and a lower intensity compared to the others. The same effect has been pointed out by Cram[3] in a series of diphenylalkanes and related to the proximity of the benzene rings in the diphenylmethane moiety. The above facts may indicate the presence of a transannular electronic effect between benzene rings in V.

The crystallization of the compound XIII from benzene or dioxane gave crystals whose composition corresponded to that of a molecular compound consisting of one molecule of XIII and one molecule of benzene or dioxane. The presence of benzene or dioxane in the isolated substance mentioned above was concluded from the NMR spectra and the composition. In the case of the other paracyclophanes with methylene or ethylene as bridges, no such molecular compound has yet been isolated. It is now under investigation whether or not the benzene or dioxane molecules are included in the empty space of the paracyclophane ring.

Experimental

All melting points are uncorrected; they were measured in a sealed tube filled with nitrogen. The UV spectra were measured on a Hitachi EPI-3T spectrometer in ethanol. The NMR were measured with a Varian A-60 spectrometer in carbon tetrachloride. The molecular weights were measured by means of a Hitachi Perkin-Elmer 115 molecular-weight-determination apparatus, using benzene as the solvent.

2,18-Diaza[3.1.3.1]paracyclophane-3,17-dione (III). The diacid chloride I (3.22 g, 0.011 mol) in 500 m*l* of distilled benzene was subjected to cyclization with the diamine II (5 g, 0.022 mol) in 500 m*l* of distilled benzene over a 10 hr period, in a 5 *l* flask containing 2 *l* of benzene, under refluxing and stirring, according to the procedure of Stetter.[4] The still-hot reaction mixture was filtered, and then the solvent was

evaporated to give 1.2 g of a white precipitate. After crystallization from dioxane, 1 g (20%) of white crystals melting at 312—313°C was obtained. Found: C, 80.56; H, 5.82; N, 6.30%. Calcd for $C_{30}H_{26}N_2O_2$: C, 80.69; H, 5.87; N, 6.27%.

N,N′-Dimethyl-2,19-diaza[3.2.3.2]paracyclophane-3,18-dione (VIII). The diacid chloride VI (2.8 g, 0.009 mol), in 500 m*l* of distilled benzene was subjected to cyclization with the diamine VII (4.8 g, 0.018 mol) in 500 m*l* of distilled benzene over a 9 hr period, using the same procedure as was used for compound III. By treating the reaction mixture as above, 3.1 g (65%) of a crystalline product were obtained. A small portion of the product was crystallized from benzene to give white prisms melting at 239—240°C. Found: C, 81.06; H, 6.97; N, 5.26%. Calcd for $C_{34}H_{34}N_2O_2$: C, 81.24; H, 6.82; N, 5.57%.

N,N′,N″,N‴-Tetramethyl-2,11,20,29-tetraaza[3.3.3.3]paracyclophane-3,10,21,28-tetraone (XII.) The diacid chloride (1.5 g, 0.007 mol), in 500 m*l* of distilled benzene, was subjected to cyclization with the diamine XI (2.5 g, 0.015 mol) in 500 m*l* of distilled benzene over a 8 hr period, using the procedure described above. By treating the reaction mixture as above, we obtained 1.45 g (67%) of a white powder which gave white needles decomposing over 380°C by extraction with methanol using a Soxhlet-extractor. Found: C, 73.65; H, 6.29; N, 9.48%. Calcd for $C_{36}H_{36}N_4O_4$: C, 73.45; H, 6.16; N, 9.52%.

2,18-Diaza[3.1.3.1]paracyclophane (IV). A mixture of 1 g of compound III, 1 g of lithium aluminum hydride, and 150 m*l* of dioxane was refluxed for 64 hr under stirring. After the reaction mixture had then cooled, dilute hydrochloric acid was added to the mixture so that the inorganic substances were dissolved in solution, leaving the amine hydrochloride. After treatment with sodium hydroxide and crystallization from benzene, the hydrochloride gave 660 mg of white needles melting at 210.5—211.5°C (70%). Found: C, 86.49; H, 7.21; N, 6.43%. Calcd for $C_{30}H_{30}N_2$: C, 86.08; H, 7.22; N, 6.69%.

N,N′-Dimethyl-2,18-diaza[3.1.3.1]paracyclophane (V). A mixture of 40 m*l* of formic acid, 660 mg of compound IV, and 3 m*l* of 37% formalin was refluxed for 24 hr. After cooling, 10 m*l* of conc. hydrochloric acid were added, and the excess formalin and formic acid were removed by evaporation. The colorless residue was treated with a sodium hydroxide solution and extracted with benzene. After evaporation, 619 mg of white powder were obtained. White crystals melting at 254—256°C were obtained by crystallization from benzene (550 mg, 78.6%). Found: C, 86.09; H, 7.67; N, 6.00%; mol wt, 439. Calcd for $C_{34}H_{34}N_2$: C, 86.05; H, 7.67; N, 6.27%; mol wt, 446.6.

N,N′-Dimethyl-2,19-diaza[3.2.3.2]paracyclophane (IX). A mixture of 1.35 g of compound VIII, 1 g of lithium aluminum hydride, and 150 m*l* of dioxane was refluxed for 48 hr under stirring. The complex thus formed and the excess lithium aluminum hydride were decomposed by adding methanol and then a sodium sulfate solution. The reaction mixture was warmed and filtered, and the filtrate was concentrated to give white prisms melting at 236—238°C (763 mg, 61.4%). Found: C, 85.95; H, 8.10; N, 5.92%; mol wt 463. Calcd for $C_{34}H_{38}N_2$: C, 86.03; H, 8.07; N, 5.90%; mol wt, 474.6.

N,N′,N″,N‴-Tetramethyl-2,11,20,29-tetraaza[3.3.3.3]paracyclophane (XIII). A mixture of 377 mg of compound XII, 1 g of lithium aluminum hydride, and 100 m*l* of dioxane was refluxed for 72 hr under stirring. To the reaction mixture were added 1 m*l* of a 15% sodium hydroxide solution, and 3 m*l* of water. The mixture was warmed and filtered, and the filtrate was concentrated to give 148 mg (37%) of white needles, XIII-D, which contained dioxane. After heating at 90°C under reduced pressure, XIII-D gave pure XIII: mp 196—198.5°C; NMR (CCl_4) τ 7.68 (12H, singlet, N–CH_3), 6.71 (16H, singlet, PH–CH_2–N), 2.81 (16H, singlet, aromatic); mol wt, 534 (calcd. 532.7); Found: C, 81.28; H, 8.36; N, 10.44%. Calcd for $C_{36}H_{44}N_4$: C, 81.16; H, 8.33; N, 10.52%.

On the other hand, the data of XIII-D were as follows: mp 188—196°C; NMR (CCl_4) τ 6.41 (8H, singlet, dioxane) in addition to the bands of XIII; Found: C, 76.96; H, 8.40; N, 8.89%. Calcd for $C_{36}H_{44}N_4+C_4H_8O_2$: C, 77.38; H, 8.44; N, 9.02%. These results clearly show the presence of dioxane in a ratio of one to one. The crystallization of XIII from benzene also gave the same type of compound containing the benzene: mp 191—197°C; NMR (CCl_4) τ 2.73 (6H, singlet, benzene) in addition to the band of XIII; Found: C, 82.12; H, 8.47; N, 9.07%. Calcd for $C_{36}H_{44}N_4+C_6H_6$: C, 82.58; H, 8.25; N, 9.17%.

Reaction Rates in Binary Mixed Solvents. VI.[1] An Sn Ar Reaction in a Methanol-Acetonitrile Mixture

Yasuhiko KONDO, Kohei UOSAKI, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received August 3, 1970)

The present authors have previously developed a method of estimating the solvation patterns of the solute species involved in a reaction by analyzing the relation between the observed rate constants and the composition of the solvent.[1-3]

Since many data on rate constants and solvent activity coefficients were accumulated for **Sn Ar** reactions by Parker *et al.*,[4,5] the reaction is very appropriate for a discussion of the validity of our methods and the consistency between our method and Parker's parameters.

When an inorganic salt is involved as a reactant, one of the most important problems is how to evaluate the salt effects on reaction rates.[6] In some cases, these effects were ascribed to the incomplete dissociation of the inorganic salt in non-aqueous solvents;[7-10] in other cases, there are different reasons.[11-13]

In this report, first we will describe the quantitative treatment of the dependence of the observed rate constant on the initial concentration of potassium thiocyanate, a nucleophile; next, we will consider the solvation patterns of the species involved in the reaction based on the present authors' method and Parker's parameters.

Experimental

Materials. 2,4-Dinitroiodobenzene was prepared by refluxing 2,4-dinitrochlorobenzene and sodium iodide in dimethylformamide.[14] The crude product was recrystallized three or four times from a benzene-petroleum benzin mixture.

Potassium thiocyanate and sodium thiocyanate of a guaranteed-grade reagent were dried over silica gel.

The solvents used were purified by a method described elsewhere.[15,16]

Kinetic Procedure. The reaction rates were measured by two methods. In the first, a solution of 2,4-dinitroiodobenzene was added to a solution of potassium thiocyanate in a long-necked reaction vessel maintained at the reactions temperature. Aliquots of 5 m*l* were withdrawn at given intervals from the vessel. In the other method, the reaction were carried out in a high-pressure glass vessel with a volume of *ca.* 20 m*l* with a stainless steel screw stopper.

In either case the reactions were stopped by pouring the reaction mixture into a vessel containing water and light petroleum. After the extraction of inorganic salts from the organic layer, the concentration of the iodide ion produced was determined potentiometrically using a silver nitrate solution.

Results and Discussion

Salt Effects. The reaction followed the second-order kinetics for each run. The rate expression can then be written as follows:

$$\frac{dX}{dt} = k_{obs}\,(\text{2,4-dinitroiodobenzene})(\text{KSCN}) \qquad (1)$$

where X denotes the concentration of iodide ions formed in the reaction. The observed rate constant, k_{obs}, decreased as the initial concentration of potassium

thiocyanate increased. Typical examples are shown in Fig. 1. The experimental error of each rate constant was estimated to be less than ±2% from duplicate runs.

The method of analyzing the salt effects is based on the Acree hypothesis.[6-10,17] According to this hypothesis, the observed rate constants are expressed as sums of two components, *i.e.*, a rate constant for free ions, k_i, and a rate constant for ion pairs, k_{ip}, as follows:

$$k_{obs} = k_i\alpha + (1-\alpha)k_{ip} \quad (2)$$

where α stands for the degree of dissociation of potassium thiocyanate.

Since, for an ion pair, a thermodynamic dissociation constant, K_d, and a dissociation constant defined in terms of the concentration, K_c, are expressed by Eq. (3),[10] Eq. (2) can be rearranged to Eq. (4):

$$K_d = C\alpha^2 f_\pm^2/(1-\alpha) = K_c f_\pm^2 \quad (3)$$

$$k_{obs} = [\{-K_c+(K_c^2+4K_cC)^{1/2}\}/2C](k_i-k_{ip}) + k_{ip} \quad (4)$$

where $f_\pm$ and C stand for an activity coefficient and the stoichiometric concentration of potassium thiocyanate.

The experimental results were analyzed on the basis of Eq. (4) using a NEAC 2200—500 computer by the steepest descent method; the calculated values of k_i, k_{ip}, and K_c are listed in Table 1. The lines in Fig. 1 show the values calculated on the basis of these parameters.

Table 1. Calculated values of k_i, k_{ip}, and K_c at 40°C

Solvent	Nucleophile	$10^5\times k_i$	$10^5\times k_{ip}$	K_c
Acetonitrile	NaSCN	72.0	—	0.0165
Acetonitrile	KSCN	69.1	—	0.0635 (0.0380[19])
Acetonitrile Methanol (90:10 mol%)	KSCN	17.7	8.28	0.0827
Acetonitrile Methanol (70:30 mol%)	KSCN	5.04	4.34	0.0804
Acetonitrile Methanol (50:50 mol%)	KSCN	2.89	2.43	0.0819
Acetonitrile Methanol (25:75 mol%)	KSCN	2.03	1.79	0.0850
Methanol	KSCN	1.95	1.56	0.0909[a]
Acetone	KSCN	1125	96.6	0.0045 (0.0034[18])

Unit: k_i and k_{ip} : ($l\cdot mol^{-1}\cdot sec^{-1}$), K_c; ($mol\cdot l^{-1}$)

Values in parentheses show the dissociation constant determined by conductivity measurements.

a) The value from the reference[20] was used for the calculation.

Rate Constant in Binary Mixed Solvents. As a first approximation, assuming that the difference in k_i between methanol and acetonitrile results from the specific solvation of the thiocyanate ion by methanol and that all the other systems, *i.e.*, thiocyanate ion-acetonitrile, 2,4-dinitroiodobenzene-solvent mixtures and an activated complex-solvent mixture, form ideal solutions, by simplifying Eqs. (13) and (14) in Part IV[3] of this series the following equations are obtained:

$$(k_1/k_4) = (K_r+1) = 35.4 \quad (5)$$

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 + x_4 \ln (K_r+1) - \ln (x_4K_r+1) \quad (6)$$

where methanol is indicated by the subscript 4 and where K_r refers to the equilibrium constant of the hypothetical reaction of methanol with the thiocyanate ion. The solid curve in Fig. 2 is the theoretical value calculated from these equations.

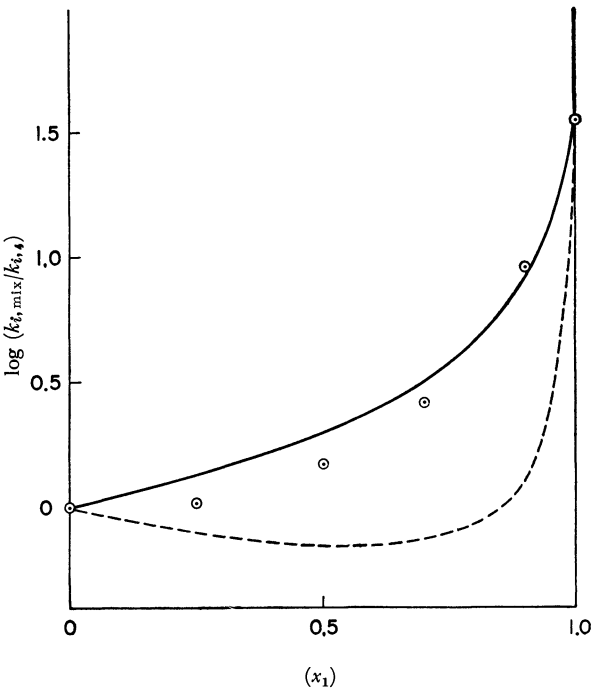

Fig. 2. Comparisons of calculated values with observed values. ———, calculated values by first model; ------, calculated values by the second model; ⊙, free ion rate constants

In the second approach, the concept of solvent activity coefficients[4] has been taken into account.

The relation between the solvent activity coefficient reported by Parker *et al.*,[4] γ, and the activity coefficient used by the present authors,[2] β_i, is given by Eq. (7), and the coefficient, ${}^4\gamma^1$, can be correlated to the equilibrium constant of the hypothetical reaction, K, on the basis of the definition of Ref. 2, when a solute is more stabilized in the solvent 1 than in the solvent 4.

$${}^4\gamma^1 = (\beta_1/\beta_4) = ({}^1\gamma^4)^{-1} = 1/(K+1) \quad (7)$$

Making use of the following solvent activity coefficients,[4] the relation,[2] Eq. (11), and several rules,[2] the final equation for rate constants in mixed solvents is obtained as follows:

$$\log {}^0\gamma^s_{SCN^-} = 2.6\ ^{4)} \quad (8)$$

$$\log {}^0\gamma^s_{RX} = -0.4\ ^{4)} \quad (9)$$

19) H. L. Yeager and B. Kratochvil, *ibid.*, **74**, 963 (1970).

20) P. G. Sears, R. R. Holmes, and L. R. Dawson, *Trans. Electrochem. Soc.*, **102**, 145 (1955).

$$\log {}^{0}\gamma_{M}^{s}* = 0.65 \quad (10)$$ [21]

$$k_{mix} = k_0 \frac{(\beta_{SCN^-,mix}\beta_{RI,mix})}{\beta_{M^*,mix}} \quad (11)$$

$$\begin{aligned}\ln k_{mix} = {} & x_1 \ln k_1 + x_4 \ln k_4 \\ & + x_4 \ln (K_{SCN^-}+1) - \ln (x_4 K_{SCN^-}+1) \\ & + x_1 \ln (K_{RX}+1) - \ln (x_1 K_{RX}+1) \\ & - \{x_4 \ln (K_{M^*}+1) - \ln (x_4 K_{M^*}+1)\} \end{aligned} \quad (12)$$

where the subscript 1 refers to acetonitrile, and the subscript 4, to methanol, and where $K_{SCN^-}=3.97\times 10^2$, $K_{RX}=1.51$, and $K_{M^*}=3.47$.

The values calculated by means of Eq. (12) are shown by a dotted curve in Fig. 2.

21) $\log {}^{0}\gamma_{M}^{s}*$ was estimated by means of the relation[4]:
$\log {}^{0}\gamma_{M}^{s}* = \log {}^{0}\gamma_{SCN^-}^{s} + \log {}^{0}\gamma_{RX}^{s} - \log (k^s/k^0)$

Of the three solvent activity coefficients, that of the thiocyanate ion is the largest; this is equivalent to the idea that the rate of the reaction is controlled by the strong solvation of the thiocyanate ion by methanol. In the former treatments, this factor has been taken into account as the hypothetical reaction of thiocyanate ion with methanol. In the latter treatments, the solvent activity coefficients have been transformed into equilibrium constants in order to reproduce Parker's concept in our model.

Both models can explain the general behavior of the rate constant in a mixed solvent, and there is consistency between our model and the solvent activity coefficient reported by Parker *et al.* in that a strong solvation of the thiocyanate ion by methanol is the main factor making the rate in methanol slower than in acetonitrile.

Studies of Ethylenediamine-*N,N'*-diacetatocobalt(III) Complexes. II. The Preparation and Identification of Ethylenediamine-*N,N'*-diacetatocobalt(III) Complexes, with Some Anions as the Additional Ligand

Kashiro KURODA and Kiyokatsu WATANABE

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime

(Received December 9, 1970)

Several authors[1-8] have reported cobalt(III) complexes which contain the tetradentate ethylenediamine-*N,N'*-diacetate (EDDA). However, the number of such complexes is still small in comparison with those of such other series as the triethylenetetraminecobalt(III) series, and only a few anionic species have been isolated. The reason for this situation has been discussed in the preceding report.[1] It has also been discussed there how chloro(ethylenediamine-*N,N'*-diacetato)aquocobalt(III) or ethylenediamine-*N,N'*-diacetato(diaquo)cobalt(III) perchlorate has a character suitable as a starting material for the preparation of the series, and the preparations of some cationic species from these complexes have been illustrated. In this report, two new anionic species as well as the known oxalato complex, which have been derived from the chloroaquo or the diaquo complex, will be dealt with. The geometrical configuration of the complexes obtained was identified by means of their electronic absorption spectra and NMR spectra.

Experimental

Materials, Analysis, Apparatus, and Measurements. Ethylenediamine-*N,N'*-diacetic acid (Dotite Reagents), cesium chloride and acetate (Wako Pure Chemicals), and all the other reagent-grade chemicals were used without further purification. The apparatus used and the procedures for the analysis and the measurements have been described in the preceding report.[1]

Preparations. *(1) Cesium Dinitro(ethylenediamine-*N,N'*-diacetato)cobaltate(III) Monohydrate, $Cs[Co(EDDA)(NO_2)_2]\cdot H_2O$*: In 30 m*l* of water, 0.4 g of the chloroaquo complex $[Co(EDDA)(Cl)(H_2O)]\cdot H_2O$,[1] was suspended and heated until the complex dissolved completely. After the subsequent addition of 0.2 g of sodium nitrite, the mixture was evaporated to dryness at ~70°C; during the evaporation the color changed to a deep orange-red. The residue was extracted with ~2 m*l* of water, and after the addition of 0.4 g of cesium chloride to the extract, it was kept at 0°C for one day. The orange-red precipitate thus formed was recrystallized from a small amount of water by the addition of cesium chloride, and washed with ethanol and ether. Yield, 0.3 g.

Found: C, 14.87; H, 2.56; N, 11.61%. Calcd for $Cs[Co(EDDA)(NO_2)_2]\cdot H_2O = CoC_6H_{12}O_9N_4Cs$ (476.02): C, 15.14. H, 2.54; N, 11.77%.

*(2) Cesium Diazido(ethylenediamine-*N,N'*-diacetato)cobaltate(III), $Cs[Co(EDDA)(N_3)_2]$*: In 30 m*l* of water, 0.4 g of the chloroaquo complex was dissolved as in the case of (1). After the addition of 0.18 g of sodium azide, the solution was evaporated to dryness at ~70°C. The residue was dissolved in 2 m*l* of water, and then 0.2 g of cesium chloride was added;

A dark green precipitate appeared upon cooling. It was recrystallized from a small amount of water by the addition of cesium chloride, and then washed with methanol and ether. Yield, 0.3 g.

Found: Co, 12.92; C, 15.76; H, 2.36; N, 24.75%. Calcd for $Cs[Co(EDDA)(N_3)_2]=CoC_6H_{10}O_4N_8Cs$ (450.04): Co, 13.10; C, 16.01; H, 2.24; N, 24.90%.

(3) Cesium α-cis-*Oxalato(ethylenediamine*-N,N′-*diacetato)cobaltate(III) Dihydrate, α-cis-Cs[Co(EDDA)(ox)]·2H_2O*:

(4) Sodium β-cis-*Oxalato(ethylenediamine*-N,N′-*diacetato)cobaltate(III) Monohydrate, β-cis-Na[Co(EDDA)(ox)]·H_2O*: These two isomers were separated from a reaction product. The *β-cis* isomer was also prepared independently from the diaquo complex.

Into a mixture of cobalt(II) chloride hexahydrate (2.3 g), ethylenediamine-*N,N′*-diacetic acid (1.8 g), and sodium oxalate (2.7 g) in 50 m*l* of water, we bubbled air at ~55°C for 2 hr, during which time 10 m*l* of hydrogen peroxide (30%) was added drop by drop. The resulting mixture was kept at 0°C overnight, and then the undissolved excess sodium oxalate was filtered off. The red-violet filtrate was concentrated on a steam bath to ~15 m*l*, and 30 m*l* of methanol was added. The precipitate thus formed was collected on a glass filter; then it was fractionally extracted with 5 m*l* of cold water and with 10 m*l* portions of warm (~35°C) water twice. The first extract was discarded. Two-gram portions of cesium acetate were added to the second and the third extracts. In the second extract a large amount of a precipitate formed immediately, while in the third a small amount of a precipitate appeared after a while. The precipitate was recrystallized from warm water upon the addition of cesium acetate. The filtrate from the third fraction was placed in a refrigerator overnight; a large amount of a precipitate which was apparently different from the above one thus appeared. This precipitate was recrystallized from warm water with the addition of sodium perchlorate; the appearance of crystals was also slow. The color of the former was violet, while that of the latter was deep red-violet.

Found: C, 19.50; N, 5.69% for the violet isomer. Calcd for $Cs[Co(EDDA)(ox)]\cdot 2H_2O=CoC_8H_{14}O_{10}N_2Cs$ (490.05): C, 19.61; N, 5.72%. Found: C, 26.04; N, 7.68% for the red-violet isomer. Calcd for $Na[Co(EDDA)(ox)]\cdot H_2O=CoC_8H_{12}O_9N_2Na$ (362.12): C, 26.54; N, 7.74%.

By the evaporation of the second extract *in vacuo* without cesium acetate (the temperature depressed during the process), sodium salt of the violet isomer appeared as deep violet needles. This crystal dissolved in its own water of crystallization as the temperature was raised. This indicates that the sodium salt of the violet isomer is more soluble than that of the red-violet isomer.

The same product as the red-violet isomer was also obtained from $[Co(EDDA)(H_2O)_2]ClO_4$.[1] A mixture of the diaquo complex (0.37 g) and sodium oxalate (0.13 g) in 5 m*l* of water was heated on a water bath; deep red-violet crystals appeared as the evaporation proceeded. The yield was nearly quantitative (0.33 g).

Results and Discussion

Preparative Procedures. Most of the Co(III)-EDDA complexes in the literature were synthesized directly from a cobalt(II) salt, EDDA, and the necessary ligand. The method of preparation used in this study, in contrast, utilized the substitution reaction of the starting chloroaquo or diaquo complex with the various anions. One advantage of this method is that we can mix equivalent amounts of the reactants; therefore, we can reduce the number of components in the reaction mixture as much as possible. Hence, the crystallization of the product becomes easier. It was found that the cesium ion made a good precipitate in aqueous media with most of the anionic species studied.

The potassium salt of the α-*cis* isomer of the oxalato complex was first obtained by Van Saun and Douglas,[6] and the sodium salt of the β-*cis* isomer (dihydrate), by Coleman *et al*[8]. The violet and the red-violet isomer in this study showed absorption spectra identical with those of their respective complexes, although the analyses indicated that our β-*cis* isomer was the monohydrate. Coleman *et al.* separated the β-*cis* isomer by means of ion-exchange chromatography; hence, their method took a long time. The preparation has been simplified in two ways. First, the α-*cis* and the β-*cis* isomers were separated from a reaction mixture by the use of fractional extraction and fractional precipitation with the cesium ion; hence, no special or time-consuming technique was needed. Second, the sodium salt of the β-*cis* isomer was easily obtained by evaporating a solution of $[Co(EDDA)(H_2O)_2]ClO_4$ and sodium oxalate. Despite the α-*cis* configuration of the diaquo complex,[1] the deposit was exclusively the β-*cis* isomer; this means that the β-*cis* isomer is supplied by the shift of the equilibrium between the two isomers:

α-*cis* isomer ⇌ β-*cis* isomer

↓

deposit

—·—·—: β-*cis*-Na[Co(EDDA)(ox)]

pattern originating from the two equivalent glycinate and symmetrical A_2B_2 absorptions from the ethylene protons are observable. The nitro and the violet oxalato complexes also showed analogous spectra. It is, therefore, certain that the nitro and the azido complexes are α-*cis* isomers. The numerical values are summarized in Table 1.

Electronic Absorption Spectra. The electronic absorption spectra are shown in Fig. 2, while the numerical values of the maxima are summarized in Table 2. In the spectrum of the nitro complex, it is clearly indicated that a band exists at $\sim 23 \times 10^3$ cm^{-1}. There is a slight but distinct shoulder around 24×10^3 cm^{-1} in that of the azido complex, too. The shoulder of the azido complex may be assigned to the second band covered by the strong ligand-specific band. On the other hand, the band of the nitro complex can not be the second band, since the position is in too low a wave-number region for the second band of this complex. As the nitro complex has the α-*cis* configuration (*trans* with respect to O), and hence belongs approximately to the *trans*-[CoA_4B_2]-type, a large split of the first band can be expected; such a split has been observed in the spectra of a large number of *trans*-[CoA_4B_2]-type complexes. Therefore, it is reasonable to assign the band to the Ib band; in other word, the presence of this band is further evidence that the complex is an α-*cis* isomer. Mori *et al*[2] previously reported the preparation and absorption spectrum of the nitro complex, but their spectrum differs considerably from that of our complex; especially, the band mentioned above can not be clearly observed. We considered that their complex was a different kind of nitro complex or that it included impurities because it was precipitated by ethanol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2552—2553 (1971)

Über die Umsetzungen von Ammonium Tetracarbonyl Kobaltat mit Aromatischen Aldehyden

Ilsong RHEE, Membo RYANG, und Shigeru TSUTSUMI

Abteilung für Petroleum-Chemie, Fakultät der Ingenierwissenschaft, Osaka Universität, Suita, Osaka

(Eingegangen am 26. Dezember, 1970)

Vor kurzem haben wir berichtet, dass die *N*-unsubstituierten Imin Komplexe durch die Umsetzung von Aldehyden mit Kobalt-hexaammin-Komplexen erhalten wurden und eine neuartige Synthese von Nitrilen durch Oxidation von denselben Imin-Komplexen mit Brom gefunden wurde.[1] Weil das zu Kobalt koordinierende Ammoniak in Vergleich zum freien Ammoniak sehr unterschiedlich auf Aldehyde wirkt, haben wir die Reaktion von Aldehyden mit Ammonium Tetracarbonyl Kobaltat [$NH_4 \cdot Co(CO)_4$] eingehend untersucht.

Bei der Umsetzung von Hydrido Tetracarbonyl Kobaltat [$HCo(CO)_4$] mit Lewis-Basen (B) entstehen die Salze mit der Formel [$BHCo(CO)_4$].[2] Wir unter-

1) I. Rhee, M. Ryang, und S. Tsutsumi, *Tetrahedron Lett.*, **1970**, 3419.

2) R. F. Heck, *J. Amer. Chem. Soc.*, **86**, 2819 (1964).

suchten spektroskopisch die Bildung von $NH_4 \cdot Co(CO)_4$ bei der Umsetzung von $HCo(CO)_4$ mit Ammoniak und beobachteten weiter, dass $NH_4 \cdot Co(CO)_4$ mit aromatischen Aldehyden zu primären Amin Derivaten leicht reagierte.

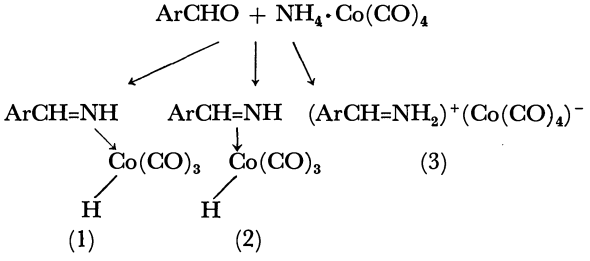
Die aus $HCo(CO)_4$ und Ammoniak erhaltene ölige Substanz löst sich in polaren Lösungsmitteln und war stabil unter Stickstoff oder Kohlenmonoxid, war jedoch sehr luftempfindlich. Das IR Spektrum in Acetonitril wies auf Anwesenheit von ν_{NH} (3350 cm^{-1}) und ν_{CoCO} (1880—1960 cm^{-1}) hin. Die kurzwellige Verschiebung der ν_{CoCO} Bande in dem Kobalt Komplex deutet auf eine höhere Elektronendichte auf Kobalt als im Falle des $HCo(CO)_4$ (ν_{CoCO} 2049 und 2066 cm^{-1}). Das NMR Spectrum in Acetonitril wies auf ein Signal bei τ 6.78 hin, doch erschien das Proton-Signal von $HCo(CO)_4$ bei τ 20.0 und zeigte das Signal des freien Ammoniak in Acetonitril bei τ 9.36. Aus dem obigen Resultat wurde die Bildung des $NH_4 \cdot Co(CO)_4$ angenommen, obgleich das Molekulargewicht noch nicht bestimmt werden konnte.

$$HCo(CO)_4 + NH_3 \rightleftharpoons NH_4 \cdot Co(CO)_4$$

Liess man die Reaktion von dem obigen Öl, NH_4-$Co(CO)_4$, mit Benzaldehyd in Acetonitril unter dem Normaldruck des Kohlenmonoxids bei 45—55°C für 5 Stdn. laufen, so konnte man in 80.5%[3] Ausbeute Benzylbenzalamin isolieren. Die jeweilige Ausbeute in den verschiedenen Lösungsmitteln betrug 78.0 (in *n*-Pentan), 70.5 (in Ethanol) und 80.0% (in Pyridin). Analog verläuft die Reaktion mit *p*-Methoxybenzaldehyd zu dem entsprechenden primären Amin-Derivat (86.0%).

Aus der Reaktion von Benzaldehyd mit Ammoniak in Acetonitril bei 45—55°C entstand 1,3,5-Triphenyl-2,4-diazapentadien-(1,4) (83.3%), jedoch liess sich Benzylbenzalamin nicht erkennen.

Daher ershien es wahrscheinlich im Falle des NH_4-$Co(CO)_4$, dass das intermediär auftretende Imin durch Komplex-Formation mit Kobalt stabilisiert wurde.



Obgleich die Information für das intermediäre Produkt infolge dessen Unhaltbarkeit noch nicht erhalten werden konnte, wurde angenommen, dass die *N*-substituierte Imin- oder Immonium-Gruppe intermediär mittels $HCo(CO)_4$ zu primärem Amin reduziert wurde und das Amin bei Reaktion mit Aldehyd Aldimin ergab.

$$\text{Intermediär} \xrightarrow{HCo(CO)_4} ArCH_2NH_2 \xrightarrow{ArCHO} ArCH_2N{=}CHAr$$

Experimenteller Teil

Umsetzung von $HCo(CO)_4$ mit Ammoniak. Nachdem eine trockene Gas-Mischung von Ammoniak (10 ccm) und Kohlenmonoxid (10 ccm/min) in die *n*-Pentanlösung (10 ccm) des $HCo(CO)_4$[4] (2 ccm) bei −50°C (2 Stdn.) eingeführt wurde, wurde das überschüssige Ammoniak durch Einführung des Kohlenmonoxids bei Raumtemperatur völlig abgejagt. Von der zurückbleibenden *n*-Pentanlösung trennt sich das gelbliche Öl, $NH_4 \cdot Co(CO)_4$, ab.

Reaktion von $NH_4 \cdot Co(CO)_4$ mit Aromatischen Aldehyden. In Lösung von $NH_4 \cdot Co(CO)_4$ (2.0 ccm, 15 mMol) in Acetonitril (20 ccm), dargestellt in einem 30 ccm Reaktionsrohr mit Tropftrichter und Rückflusskühler, wird Aldehyd (30 mMol) zugetropft. Die Badtemperatur hält man während der ganzen Reaktionszeit (4 Stdn.) bei 45—55°C. Das Reaktionsgemisch wurde mit Jod-Methanol (3 g/20 ccm) zersetzt und mit Äther extrahiert. Die vereinigten Ätherextrakte wurden je 3 mal mit 10 ccm 10 proz. $Na_2S_2O_3$-Lösung und 10 ccm Wasser gewaschen, über $MgSO_4$ getrocknet und i. Vak. eingedampft. Man destilliert den Rückstand.

Benzylbenzalamin: Sdp. 135—140°C/3 mmHg, 0.8 g. IR-Spektrum; $\nu_{C=N}$ 1650 cm^{-1}. NMR-Spektrum (CCl_4); τ 1.78 (1H, t, J=2.0 Hz), 2.55 (10H, m) und 5.30 (2H, d, J=2.0 Hz). Massenspektrum; Molmasse 195.

Gef.: C, 86.11; H, 6.71; N, 7.17%. Ber. für $C_{14}H_{13}N$ (195): C, 86.04; H, 6.62; N, 7.05%.

1,3,4,6-Tetraphenyl-2,5-diazahexadien-(1,4); Schmp. 171°C (aus Ethanol). IR-Spektrum; $\nu_{C=N}$ 1650 cm^{-1}. NMR-Spektrum ($CDCl_3$); τ 2.12 (2H, s), 2.62 (20H, m) und 5.28 (2H,s) Massenspektrum; M^+/e=388, m^+/e=194 ($Ph\overset{+}{C}H{=}CHPh$).

Synthesis of Carboxylic Acid Derivatives of Adenine and Theophylline

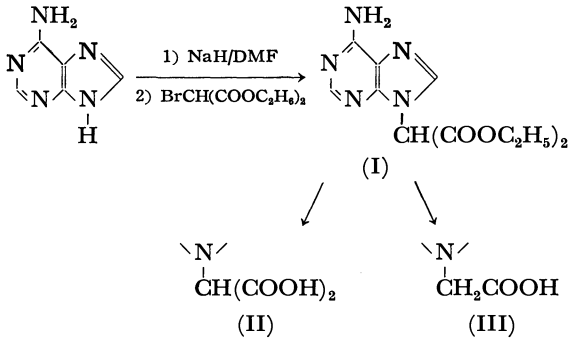
Koichi KONDO, Mikiji MIYATA, and Kiichi TAKEMOTO
Faculty of Engineering, Osaka University, Suita

(Received March 1, 1971)

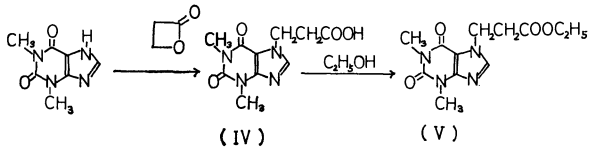
Michael-type addition reaction of purine with ethyl acrylate gives the corresponding *N*-β-carboxyethyl derivatives,[1] which are also obtained by the reaction of purine with β-halopropionate under base-catalyzed conditions.[2]

In this communication, we report new syntheses of carboxylic acid derivatives of adenine and theophylline.

When sodium salt of adenine[3] was treated with diethyl bromomalonate in dimethylformamide (DMF), diethyl adenyl-9-malonate (I) was easily obtained. It was hydrolyzed in alkaline solution to give its carboxylic acid derivatives (II and III).

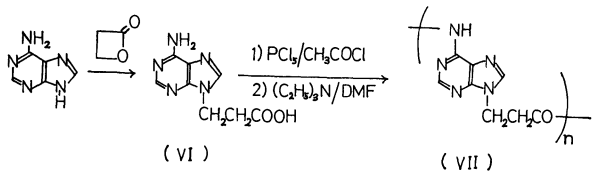


7-(β-carboxyethyl)theophylline (IV) was prepared when theophylline was allowed to react with β-propiolactone in DMF under base-catalyzed conditions. Its ethyl ester (V) was prepared from IV in ethanol in the presence of acetyl chloride.



Adenine was also converted into 9-(β-carboxyethyl)-adenine (VI) under the same reaction conditions. A similar result concerning the reaction of adenine with γ-butyrolactone has also been reported.[4]

The reaction of VI with phosphorus pentachloride gave the hydrochloride salt of acid chloride derivative, which was treated with triethylamine in DMF to afford a substance assumed to be a polymer containing adenine nuclei in the main chain (VII). The infrared spectrum of VII showed a new C=O stretching band corresponding to amide structure at 1630 cm^{-1}. The molecular weight of VII was not determined because of its insolubility in common solvents.



Ultraviolet spectra of I and VI showed λ_{max} near 260 nm, which suggests that the derivatives in question correspond to adenine substituted in 9-position. In the case of IV and V, λ_{max} appeared at 274 nm, which shows that the substituent was introduced into 7-position.

Carboxylic acid derivatives II and III as well as polymer VII thus obtained showed no melting points below 300°C, and were insoluble in common organic solvents.

Experimental

Diethyl-9-Adenylmalonate (I). A suspension of 1.35 g (10 mmol) of adenine and 0.52 g of 54% oily sodium hydride in 50 m*l* of DMF was stirred at ambient temperature for 1.5 hr. To the solution was added 3.5 g (14.7 mmol) of diethyl bromomalonate. After stirring for 6.5 hr, the reaction mixture was evaporated to dryness *in vacuo*. The residue was recrystallized from aqueous ethanol; yield 1.43 g (38%). Colorless needles, mp 172—173°C. IR (KBr): 3270, 3100 (ν_{N-H}), 1770, 1745 ($\nu_{C=O}$), 1670 ($\nu_{C=N}$), 1600 (δ_{N-H}), 1215 (ν_{C-O}), 2950 (ν_{C-H}), cm^{-1}. UV (C_2H_5OH): λ_{max} 259 (ε=11300), 209 (ε=14000).

Found: C, 49.18; H, 5.31; N, 24.10%. Calcd for $C_{12}H_{15}N_5O_4$: C, 49.15; H, 5.12; N, 23.89%.

9-Adenylmalonic Acid (II). In 200 m*l* of aqueous solution of sodium hydroxide (1.6 g) was dissolved 3.0 g (10 mmol) of I. The mixture was stirred at ambient temperature for 16 hr and then was adjusted to pH 3 with concd. hydrochloric acid. The resulting precipitate was then filtered off and washed thoroughly with water; yield 1.85 g (76%). Colorless crystals. IR (KBr): 3380, 3100 (ν_{N-H}), 2800—2500 (ν_{OH}), 1705, ($\nu_{C=O}$), 1680 ($\nu_{C=N}$), 1605 (δ_{N-H}) cm^{-1}.

Found: C, 40.54; H, 2.95; N, 29.95%. Calcd for $C_8H_7N_5O_4$: C, 40.50; H, 2.95; N, 29.50%.

9-Carboxymethyladenine (III). To a solution of water-ethanol mixture (3:1) containing 0.4 g of sodium hydroxide was added 1.4 g of I, and stirred for 3 days at ambient temperature. The clear solution was then evaporated to dryness. The residue was dissolved in 10 m*l* of water and the solution was adjusted to pH 5 with concd. hydrochloric acid. The resulting precipitate was then filtered off and washed with water and ethanol; yield 0.15 g (16%). Colorless crystals. IR (KBr): 3400, 3150 (ν_{N-H}), 2800—2500 (ν_{OH}), 1705 ($\nu_{C=O}$),

1605 (δ_{N-H}), 1680 ($\nu_{C=N}$) cm^{-1}.

Found: C, 43.37; H, 3.46; N, 36.35%. Calcd for $C_7H_7N_5O_2$: C, 43.52; H, 3.62; N, 36.27%.

7-(β-Carboxyethyl)theophylline (IV). 150 m*l* of DMF solution containing 16.2 g (90 mmol) of theophylline hydrate, 9.7 g (135 mmol) of β-propiolactone, and a trace of sodium hydroxide was refluxed for 4.5 hr. The solution was then concentrated under reduced pressure. The oily residue was crystallized with water. Recrystallization from water and ethanol gave a colorless crystal; yield 12.0 g (53%), mp 200—210°C (lit,[2] 204—205°C). (Found: C, 47.74; H, 4.86; N, 22.24%).

7-(β-Ethoxycarbonylethyl)theophylline (V). To an ethanol solution (15 m*l*) containing acetyl chloride (3.5 m*l*) was added 1.0 g of IV. The mixture was shaken vigorously for a few minutes until most of the solid dissolved and kept for 24 hr at ambient temperature. Pyridine (2 m*l*) was then added and after 48 hr at ambient temperature, the mixture was concentrated under reduced pressure. The oily residue was crystallized by trituration with water. Recrystallization from ethanol gave colorless crystals; yield 0.4 g (36%), mp 110°C (lit,[2] 105—106°C). (Found: C, 51.15; H, 5.93; N, 19.40%).

9-β-Carboxyethyladenine (VI). DMF solution (20 m*l*) containing 0.81 g (6.0 mmol) of adenine, 0.69 g (9.6 mmol) of β-propiolactone, and a trace of sodium hydroxide was refluxed for 2 hr. The solution was then evaporated to dryness *in vacuo*, the residue was recrystallized from water; yield 0.51 g (43%). Colorless needles, mp 272—278°C (dec.) (lit,[1] 284—228°C). IR (KBr): 3100, 3200 (ν_{N-H}), 3000—2600 (ν_{OH}) cm^{-1}. UV (H_2O): λ_{max} 260 (ε=10100), 206 (ε=14600). (Found: C, 46.25; H, 4.43; N, 33.69%).

Polymer derived from VI (VII). 0.5 g of 9-(β-carboxyethyl)adenine and 0.4 g of phosphorus pentachloride, protected carefully from moisture, was stirred in 3 m*l* of acetyl chloride at ambient temperature for 24 hr. The crude product was separated by filtration from the mixture and washed with petroleum ether. To this was rapidly added a solution of triethylamine (10 m*l*) in 100m*l* of DMF. After being stirred at ambient temperature for one week, the resulting precipitate was collected and recrystallized from hot water; yield 0.047 g (10%). IR (KBr): 1630 (amide $\nu_{C=O}$), 1680 ($\nu_{C=N}$) cm^{-1}.

Found: C, 50.60; H, 3.55; N, 36.72%. Calcd for $C_8H_7N_5O$: C, 50.52; H, 3.68; N, 36.84%.

Raman, IR, NMR, and NQR of Chlorofluorosilanes

Keinosuke HAMADA*, G. A. OZIN, and E. A. ROBINSON
Department of Chemistry, University of Toronto, Toronto, Canada

(Received March 1, 1971)

Excellent-quality Raman spectra of chlorofluorosilanes have been observed using a laser Raman spectrometer. These Raman spectra will be reported here and compared with the IR spectra of those compounds. In additon, the fluorine NMR and the chlorine NQR of chlorofluorosilanes have been measured. The fluorine chemical shifts of chlorofluorosilanes increase with an increase in the number of fluorine atoms in each compound. The chlorine quadrupole resonance has been observed only for trichloromonofluorosilane, and the resonance frequency is 19.753 MHz at −196°C.

Experimental

Materials. The chlorofluorosilanes were prepared using the method of Booth and Swinehart,[1] in which a Swarts-type reaction was used. Silicon tetrachloride was partially fluorinated using antimony trifluoride and incorporating antimony pentachloride as a catalyst, and the chlorofluorosilanes were separated using trap-to-trap distillation techniques. The separated fractions were found to be sufficiently pure for Raman and IR spectroscopic measurements.

Measurements. Raman spectra were recorded on a Spex 1401 using an argon or a krypton-ion laser. The infrared measurements were done with a Perkin-Elmer 521 spectrometer whose optic material was silver chloride. The NMR spectra of fluorine for the compounds were obtained with a Varian Associate HR-60 high-resolution spectrometer operating at 56.4 MHz. The NQR measurements of chlorine for the compounds were done with a super-regenerative-type spectrometer.

Results and Discussion

Raman and IR. Table 1 shows the Raman and IR spectra for chlorofluorosilanes in the gas phase. The vibrational data for tetrafluorosilane and tetrachlorosilane have previously been reported,[2-4] and the figures for tetrachlorosilanes are cited from Ref. 4. The vibrational data for chlorofluorosilanes are tabulated in Table 1 with reference to the correlation diagram, the polarization data, the band contours of some infrared spectra, and the vibrational spectra of other SiX_mY_{4-m}-type molecules.

NMR. The fluorine chemical shifts of chlorofluorosilanes relative to an inner standard, trichloromonofluoromethane, are shown in Table 2. The fluorine chemical shifts, δ ppm, increase with an increase in the number of fluorine atoms. This trend in the chemical shifts for $SiCl_mF_{4-m}$ is same as that in the BCl_mF_{3-m}, $POCl_mF_{3-m}$, PCl_mF_{5-m}, and CCl_mF_{4-m} series

Raman spectra are obtained at 600 mmHg and 25°C, and IR at 30 mmHg and 25°C.
ia means IR inactive and *a*, IR active, but the IR spectrum did not appear because of AgCl optic material.

Table 2. Chemical shifts of $SiCl_mF_{4-m}$ to CCl_3F

Compound	Chemical shift	
	Hz	δ ppm
SiF_4	−9188	163
$SiClF_3$	−7640	135
$SiCl_2F_2$	−6320	112
$SiCl_3F$	−5316	94

and is opposite to that in the PCl_mF_{3-m} and $P(NMe_2)_mF_{3-m}$ series[5,6] in direction. The chemical shifts in the $Si(Et)_mF_{4-m}$ and $Si(Me)_mF_{4-m}$ series have the minimum value of a chemical shift at 2 or 3 fluorine atoms in each series.

NQR. The only chlorine quadrupole resonance frequency observed for trichloromonofluorosilane at −196°C is a resonance of 19.753 MHz between the running frequencies of 18.8 and 22.0 MHz. Silicon tetrachloride has four resonance lines whose average value is 20.391 MH.[7] It is not sure whether trichloromonofluorosilane has only one resonance line like trichlorosilane,[8] or whether the lines other than the one line have just not yet appeared. The chlorine quadrupole resonance for dichlorodifluorosilane has not yet been found. This might be because the present authors have not been able to get a NQR spectroscopically-pure substance. They have also not been able to obtain NQR spectroscopically-pure trifluoromonochlorosilane.

The authors are grateful to Professor R. L. Armstrong and his collaborators of the University of Toronto for the NQR measurements.

Proton and Nitrogen-14 Nuclear Magnetic Resonance Study of Pyridine - Water System

Yuri KASUGAI, Yoji ARATA, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 8, 1971)

This note reports the results of ^{1}H and ^{14}N Nuclear Magnetic Resonance (NMR) study of the pyridine-water system. Using ^{1}H and ^{14}N line width data for pyridine, the anomalous concentration dependence of macroscopic quantities such as viscosity and density is discussed in terms of the formation of hydrogen-bonding.

Proton and ^{14}N NMR spectra were collected at room temperature using JEOLCO JNM 4H-100 and Varian VF-16 spectrometers operating at 100 MHz and 4.15 MHz, respectively. Proton NMR samples were vacuum degassed by repeated freeze-pump cycles.

A remarkable dependence on concentration was observed for the line widths of the α protons and ^{14}N of pyridine. The line width of the α protons for the neat pyridine sample is about 1.5 Hz. On adding water, the line width of the α protons decreases until it becomes minimum at $M=0.3$, where M denotes the mole fraction for pyridine, increasing again with further addition of water. In parallel with the behavior of the ^{1}H line widths, the line width for ^{14}N has its maximum at $M=0.3$. Figure 1 shows the change of the ^{14}N relaxation time calculated from the line width by assuming that the line shape is Lorentzian. The variation of viscosity with concentration[1] is also given in Fig. 1, which shows that the viscosity has a maximum at $M=0.3$.

It has been suggested from infrared [2,3] and Raman[4] data that hydrogen-bonded complexes are formed between pyridine and water molecules. When the amount of pyridine is much smaller than that of water, the dominant species is supposed to be [pyridine·H_2O] for which the formation constant has been estimated at 2.8 l/mol.[4]

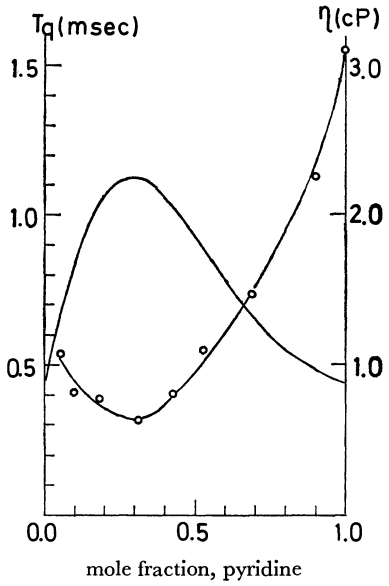

Fig. 1. Concentration dependence of the viscosity and the relaxationtime of ^{14}N.
—○—: Relaxation time of ^{14}N.
———: Viscosity (Ref. 1).

Over the whole range examined, a single line is observed in the ^{14}N spectra, which suggests that there is a rapid exchange of pyridine molecules between free and hydrogen-bonded (to water) sites. In this case, the line width ΔH may be given by

$$\Delta H = p\Delta H_{\text{coord}} + (1-p)\Delta H_{\text{free}}, \qquad \text{(A)}$$

where p is the fractional population of the hydrogen-bonded pyridine molecules, and ΔH_{coord} and ΔH_{free} are the line widths for the hydrogen-bonded and free pyridine molecules, respectively. The fractional population p was calculated with the use of the equilibrium constant $K=2.8$ l/mol;[4] ΔH_{free} was taken as the line width of neat pyridine, and ΔH_{coord} from the region $M \leqq 0.1$ of the mixture. The line widths ΔH_{coord} and ΔH_{free} were divided by the viscosity to eliminate any effect due to viscosity. In Fig. 2, ΔH thus obtained

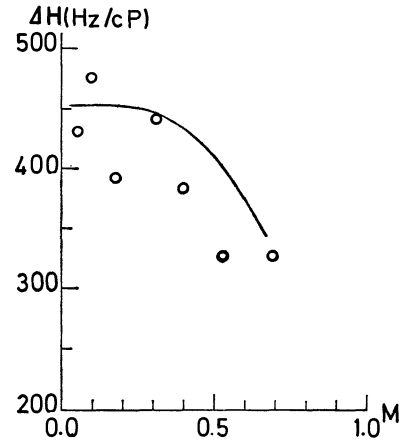

Fig. 2. Calculated and observed line width.
——: Line width calculated from the expression (A).
○: Observed line width corrected for viscosity.

is compared with the observed line width (corrected with respect to the viscosity). Thus in the region $M <$ 0.5, the gross features of the line width are well reproduced by the assumption of the formation of [pyridine·H_2O] complex. These results suggest that the formation of the hydrogen-bonded complex is responsible for the anomalous concentration dependence of the vis-

cosity and density. For the region where M is sufficiently large, complexes other than [pyridne·H_2O] will be formed and the above assumption does not hold.

The authors are grateful to Mr. Keikichi Nakamura, National Research Institute for Metals, for the measurements of the ^{14}N spectra.

A Convenient Method for Detection of NH Containing Compounds on Thin Layer Chromatograms

Yasuo ARIYOSHI, Naotake SATO, Hideo ZENDA,* and Kikuo ADACHI*

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki, Kanagawa

**Katsura Chemical Co., Inc., Kurihara, Zama, Kanagawa*

(Received March 16, 1971)

The technique of thin layer chromatography is frequently used to detect various compounds in the course of studies of amino acids or peptides. The compounds with amino or imino group can be easily detected with ninhydrin at μg level on chromatogram. However, the compounds without amino or imino group, such as N-protected amino acids and cyclic peptides, cannot be detected with this reagent. It is known that the compounds with NH group can be detected by chlorination of NH to NCl and subsequent spraying with starch-potassium iodide. As chlorinating reagent, chlorine gas[1-4] and aqueous sodium hypochlorite[5-6] were used. In some cases, they cause background coloration and give indistinct chromatograms. This can be improved by use of tertiary butyl hypochlorite,[7] but this reagent is unstable and expensive.

We will report here a convenient method of chlorinating NH group on a thin layer chromatogram of silica gel. When the silica gel chromatogram was exposed to gas generated from bleaching powder (calcium hypochlorite) and hydrochloric acid, NH group was found to be easily chlorinated in a short period of time at room temperature. Subsequent sprayings of ethanol and aqueous starch-potassium iodide gave a clear violet spot on chromatogram without any background coloration.

This method is recommended for detection of peptides, cyclic peptides, amino acid esters, amino acid amides, N-protected amino acids. It is also applicable to other NH containing compounds such as nucleosides and related compounds and acid amides. The detectable threshold of amino acids or peptides is 0.1—0.25 μg after chromatography. Table 1 shows the results when glass plate coated with silica gel G of 0.25 mm thickness was charged with 0.5 μg of various compounds, developed in butanol-acetic acid-water (4:1:2) system, and stained by this method.

Acetanilide	0.85	S

Abbreviations used are: S, strong; M, medium; and W, weak coloration

Experimental

Five μl of sample solution was spotted on a silica gel G plate (5×20 cm) of 0.25 mm thickness. The plate was developed with *n*-butanol-acetic acid-water (4:1:2 v/v). After being dried, the plate was put in a cylinder (22 cm in height and 7 cm in diameter), at the bottom of which a small beaker (1.5 cm in height and 3 cm in diameter) containing 3 g of calcium hypochlorite (available chlorine content is 60%) was placed. The back of the plate was preferably placed to face the beaker to keep the chromatogram from spots caused by

dispersed bleaching powder on addition of hydrochloric acid. One m*l* of concentrated hydrochloric acid was added to the bleaching powder in the beaker, and the cylinder was covered loosely with a glass plate. Chlorination proceeded at room temperature in 7—10 min. The plate was removed from the cylinder, exposed to a stream of air for 1 min, and then sprayed with a small amount of ethanol. After being dried in a rapid current of air for 1—2 min, the plate was sprayed with a starch-iodide reagent prepared by dissolving 0.5 g of soluble starch and 0.5 g of potassium iodide in 100 m*l* of water. Violet spots of the compounds in the sample appeared immediately on the clear background.

Nuclear Magnetic Resonance Spectra of Carbanions. VII.[1] 1,1,4,4-Tetraphenylbutadiene Dianion[2]

Masahiro USHIO, Mikio TAKAKI, Kensuke TAKAHASHI, and Ryuzo ASAMI

Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya

(Received March 29, 1971)

The carbanions produced from α-methylstyrene and 1,1-diphenylethylene were studied in our previous reports.[3,4] The studies have now been extended to the carbanion produced from 1,1,4,4-tetraphenylbutadiene (TPB). Furthermore, we have tried, but failed, to observe the spectra of the carbanion produced from 1,4-diphenylbutadiene (DPB).

Experimental

The procedures used in this study are similar to those described in the previous reports.[3,4] Commercially-available TPB and DPB were used as sources of carbanions after two or three recrystallizations from acetone and methanol respectively. The pmr spectra were observed at about 60 MHz with a frequency-swept Hitachi R-20B spectrometer. The chemical shifts of the carbanions were evaluated from the higher-shielding methylene peak of the solvent, THF, used as an internal reference. This peak of THF was taken to be 1.79 ppm from TMS. All the chemical shifts were calibrated by means of a frequency counter (Takeda Riken TR-3824X).

Results and Discussion

The signals appearing in the aromatic-proton region of the carbanion produced from TPB with sodium as counterion are divided into three groups. They show the structures of a doublet, a triplet, and a triplet from lower to higher shielding, with an intensity ratio of about 2:2:1. They can, therefore, easily be identified as the signals of the ortho-, meta-, and para-protons respectively. The chemical shifts of the carbanions are given in Table 1, along with other previously-reported values for the sake of comparison. On treatment with H_2O, the carbanion forms a mixture of 1,1, 4,4-tetraphenylbutene-1 and -2, whose pmr peak positions are 2.82 (2H, triplet, $J=7._5$ Hz), 4.00 (1H, triplet, $J=7._5$ Hz), 5.90 (1H, triplet, $J=7._5$ Hz), 7.00 (weak), and 7.06 (strong) for the former, and 4.72_5 (2H, double doublet, apparently, $J=4$ and $1._5$ Hz), 5.85_5 (2H, double doublet, apparently $J=4$ and $1._5$ Hz), and 7.10_5 ppm for the latter in a CCl_4 solution. The charge localized in the phenyl rings of the carbanion is then estimated to be given in Table 2, taking the reference for the neutral phenyl proton as 7.20 ppm. This charge estimation is not self-consistent because the charge on a carbon with no proton can not be estimated on the proton spectra. However, a series of the data may be compared with each other and may give some information as to the charge distribution of the carbanions. Furthermore, the magnetic anisotropy of the adjacent phenyl ring may contribute to the aromatic proton shifts, especially to the ortho-proton shifts in the carbanion. If we assume the twist angle of the phenyl ring to be 30°, the anisotropy effects will compensate for each other for two far and near ortho-protons, as has been described before.[4] Table 2 shows that the charge localization on the phenyl rings is about 40% for the TPB dianion. The lower charge localization in the phenyl rings of the TPB dianion as compared with that of the 1,1-diphenylethylene dimer dianion is ascribable to the structural difference between I and II, that is, to the presence of a pi-system in the middle part of II:

We have tried, but failed, to observe the spectra of

the carbanion produced from 1,4-diphenylbutadiene, using potassium, sodium, and lithium as counterions. Our failure is ascribable to the contamination of the radical anion formed, because the samples used for the NMR measurements gave strong ESR signals. The pmr spectra of the TPB dianion was observed only with sodium counterions. Even in this case, the NMR sample gave weak ESR signals and the PMR spectra are broader than usual spectra. The TPB dianion with potassium as counterions did not give any resolved spectrum in spite of several trials. No information on the *cis-trans* isomerization of the TPB dianion and 1,1,4,4-tetraphenylbutene-2 can be obtained at present. Further studies along this line are in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2560—2562 (1971)

A Naturally-occurring Bromo-compound, Aplysin-20 from *Aplysia kurodai*

Shosuke YAMAMURA* and Yoshimasa HIRATA
Chemical Institute, Nagoya University, Chikusa, Nagoya

(Received April 6, 1971)

Two bromo-compounds, aplysin and aplysinol, were isolated from *Aplysia kurodai*, whose structures have already been established.[1] We could further isolate a small amount of a third bromo-compound, aplysin-20, from the same materials, which were gathered at Hokkaido (in September.)[1] However, no bromo-compound has been found in the *Aplysia kurodai* which were gathered at Sugashima, Mie-ken (in June).[2] The above different results seem to result from the different kinds of marine plants which were eaten by *Aplysia kurodai*.[3] Especially, the biogenesis of aplysin-20 strongly suggests that its origin must be attributable to the marine plants, as will be discussed later.

Aplysin-20, mp 146—147°C, is regarded as a diterpenoid bromo-compound on the basis of its molecular formula ($C_{20}H_{35}O_2Br$) and spectral data, as will be shown below. In addition to an end absorption in the UV spectrum of aplysin-20, the IR absorption band at 1675 cm^{-1} and a triplet at δ 5.41 ppm (1H, J=7.0 Hz) in the NMR spectrum (see Table 1) indicate the presence of an isolated double bond.

Aplysin-20 was treated with acetic anhydride-pyridine to give a monoacetate (mp 59—62°C; *m/e* 430 and 428 (M^+): ν_{max} 3520, 1730 sh., 1713, 1675 and 1260 cm^{-1}), which could be converted into the starting material with methanolic potassium hydroxide. The acetylation study suggests that aplysin-20 has a primary or secondary hydroxyl group as well as a tertiary one (ν_{max} 3520 cm^{-1}). Furthermore, when the NMR spectra of aplysin-20 and its monoacetate were compared, the doublet at δ 4.16 ppm (2H, J=7.0 Hz) and the triplet at δ 5.41 ppm (1H, J=7.0 Hz) were shifted to the doublet at δ 4.60 ppm (2H, J=7.0 Hz) and the triplet at δ 5.60 ppm (1H, J=7.0 Hz) respectively. The remaining signals are nearly identical in both compounds except for the appearance of the singlet at δ 2.02 ppm (3H, CH_3COO–) in the latter. The above fact, coupled with the observation of the methyl broad

2) We can catch them in Sugashima only during the rainy season, and the attempted isolation of bromo-compounds has failed.

singlet at δ 1.70 ppm, indicates the presence of the partial structure (I). Furthermore, when considered in the light of the partial structure (I) and the presence

$$-CMe=CH-CH_2OR$$
(I) R=H; (II) R=Ac

of two hydroxyl groups in aplysin-20 (or the partial structure (II) in a monoacetate with a tertiary hydroxyl group), the appearance of a pair of strong peaks (*m/e* 272 and 270), coupled with the strongest peak in their mass spectra at *m/e* 191, suggests the presence of the partial structure (III) in aplysin-20, as was discussed

$$-CH_2CH_2-CMe=CH-CH_2OH \quad (III)$$

in connection with Scheme I. Accordingly, aplysin-20, which has four tertiary methyl groups (see Table 1) and the partial structure (III),[4] may be regarded as a bicyclic diterpene with a side chain (III); thus, it is analogous to many bicyclic diterpenes with the same number of methyl or potential methyl groups and the same type of side chain as aplysin-20.[5] Manool (IV) and sclareol (V) are typical bicyclic diterpenes; both have the carbon skeleton (VI) with the side chain (VII).[6] Therefore, the structure (VIII) has been proposed for aplysin-20 except for the position of the bromine atom.[7] The tentative structure (VIII) can be satisfactorily explained by means of the mass spectra of both aplysin-20 and its monoacetate (in Scheme I) except for the following point: there are no typical peaks corresponding to the fragmentation, A, which can be found in the spectra of manool, sclareol, and other diterpenes with the exocyclic double bond or equatorial hydroxyl group at the C_8-position (in VI).[8] Accordingly, it seems that aplysin-20 has a configuration different from that of sclareol at the C_8-position or a carbon skeleton different from those of usual bicyclic diterpenes. The final structure was deduced by X-ray analysis,[9] indicating that aplysin-20 has the absolute configuration (IX), which is different from those of manool, sclareol, and streoids. The biogenesis of aplysin-20 is shown in Scheme II. The most interesting point in this study is that aplysin-20 has an axial hydroxyl group at the C_8-position and an equatorial bromine atom located at the C_3-position, a position usually substituted in diterpenes and steroids. From a biogenetic point of view particularly, aplysin-20 is the first bicyclic diterpene with an axial hydroxyl group at the C_8-position

with a Rudolph and San polarimeter. The NMR spectra were measured in $CDCl_3$ with Nihondenshi JNM-3 and Varian A-60 analytical NMR spectrometers (60 MHz). The values are given in ppm relative to tetramethyl silane as an internal reference (s: singlet; d: doublet; q: quartet; t: triplet: m: multiplet). The mass spectra were measured by the Atlas Werke Co., Ltd., Germany (70 eV).

Isolation of Aplysin-20. Dried *Aplysia kurodai* (2 kg) was treated according to the method described in Ref. 1, and the insoluble materials were removed. The *n*-hexane solution was concentrated to about 100 m*l* and then chromatographed on silica gel (Wakojunyaku Co., Ltd.) (350 g). After elution with *n*-hexane to give debromoaplysin, aplysin, and aplysinol,[1] the second fraction, eluted with *n*-hexane-ether (10:1), was rechromatographed on alumina (Wakojunyaku Co., Ltd.) (15 g). After subsequent elution with *n*-hexane-ether (10:1) to give a yellow liquid, the second fraction, when eluted with *n*-hexane-ether (4:5), afforded a white solid which was then recrystallized from methanol to give colorless needles of aplysin-20 (320 mg),[10] mp 146—147°C; *m/e* 370 and 368 (4) (M^+-18), 352 (19), 350 (19), 289 (2) (M^+-Br), 272 (30), 271 (17), 270 (30), 257 (10), 255 (10), 191 (100, base peak), 175 (13), 149 (16), 147 (10), 135 (29), 134 (32), 133 (11), 123 (19), 121 (18), 119 (12), 109 (22), 107 (21), 105 (10), 98 (39), 97 (12), 96 (11), 95 (41), 94 (11), 93 (22), 91 (10), 84 (15), 83 (20), 82 (18), 81 (62), 79 (14), 71 (46), 69 (64), 68 (17), 65 (20), 57 (14), 55 (43), 43 (39), and 41 (56); ν_{max} 3500—3300 and 1675 cm^{-1} (Found: C, 61.98; H, 9.01%. Calcd for $C_{20}H_{35}O_2Br$: C, 62.00; H, 9.11%).

Acetylation of Aplysin-20. Alpysin-20 (100 mg) was dissolved in a solution of acetic anhydride and pyridine (1:1; 1 m*l*). The reaction solution was allowed to stand at room temperature overnight, and then the unreacted reagent was removed under reduced pressure to give a white solid. Recrystallizaton from methanol afforded colorless crystals of monoacetate (75 mg); mp 59—62°C; *m/e* 430 and 428 (0.4) (M^+), 370 (13), 368 (13), 352 (7), 350 (7), 312 (5), 310 (5), 289 (16) (M^+–Br), 272 (10), 271 (10), 270 (10), 257 (4), 255 (4), 191 (37), 175 (10), 152 (15), 149 (18), 147 (10), 137 (11), 135(23), 134 (16), 133 (10), 123 (19), 121 (20), 119 (15), 118 (17), 109 (26), 107 (23), 105 (11), 99 (13), 98 (15), 97 (10), 95 (41), 94 (10), 93 (23), 84 (15), 83 (12), 82 (12), 81 (50), 79 (14), 71 (37), 69 (68), 68 (12), 67 (20), 57 (17), 55 (39), 43 (100, base peak) and 41 (53); ν_{max} 3520, 1730 sh, 1713, 1675 and 1260 cm^{-1}; δ0.97 (3H, s), 1.00 (3H, s), 1.10 (3H, s), 1.13 (3H, s), 1.30—2.30 (15 H, br.m), 1.66 (3H, br. s), 2.02 (3H, s), 3.75 (1H, br.), 4.60 (2H, d, J=7.0 Hz) and 5.60 ppm (1H, t, J=7.0Hz) (Found: C, 61.20; H, 8.50%. Calcd for $C_{22}H_{37}O_3Br$: C, 61.53; H, 8.68%).

Hydrolysis of the Monoacetate. A solution of the monoacetate (30 mg) in 2N methanolic potassium hydroxide (2 m*l*) was stirred at room temperature for 2hr, poured into a large amount of water, and then extracted with ether. The ethereal solution was washed well with a saturated NaCl solution and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure to give a crystalline solid (20 mg), which was then recrystallized from methanol to afford colorless needles of aplycin-20 (mp and IR spectrum).

The authors wish to express their thanks to Professor Minoru Yamada, Hokkaido University, for providing us with the *Aplysia kurodai*, and also to Professor Yoshiyuki Toyama, formerly of Nagoya University, for his suggestions.

10) Aplysin-20 was used directly for the X-ray analysis.

The Mercury-Photosensitized Reaction of Cyclooctene Vapor

Setsuo TAKAMUKU, Kazuyoshi MORITSUGU, and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received April 12, 1971)

In connection with the studies of the photoelimination of ethylene from cyclooctadienes,[1] we have examined the mercury-photosensitized reaction of cyclooctene and found a unique isomerization into bicyclic compounds, along with the elimination of ethylene. Cyclooctene vapor (99.5%, glc) was irradiated with a low-pressure mercury lamp in the presence of mercury vapor at room temperature. The photolysis products observed were hydrogen, ethylene, 1,5-hexadiene, 1,7-octadiene (I), bicyclo[4.2.0]octane (II), bicyclo[3.3.0]-octane (III), and cyclooctane. Of these products, I, II, and III were isolated by glc (PEG 6000, 80°C) and were identified by a comparison of the NMR, mass spectra, and glc with those of authentic samples which has been independently synthesized (II and III)[2,3] or obtained commercially I[(I)NMR(CCl_4 solution): τ 4.2 (2H, m), 5.0 (2H, m), 5.2 (2H, m), 8.0 (4H, m), and 8.6 (4H, m); mass spectrum; parent peak at *m/e* 110; (II) NMR: τ 7.7 (2H, m), *ca.* 8.2 (4H, m) and 8.5(8H, m), no peaks at τ less than 7.5; mass spectrum: important peaks at *m/e* 110, 82, 81, 67, 54, and 41; (III)NMR: τ 7.6 (2H, m) and *ca.* 8.5 (12H, m), and no peaks at τ less than 7.4; mass spectrum: important peaks at *m/e* 110, 82, 67, 54, and 41]. The product yields are shown in Table 1, together with the effects of added radical scavengers.

Because of the diversity of the photolysis products, several different mechanistic pathways should be considered. Scheme 1 for the formation of ethylene, 1,5-hexadiene, and I may be suggested from the observa-

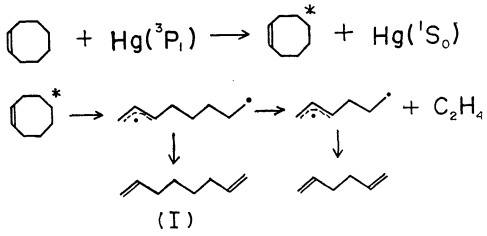
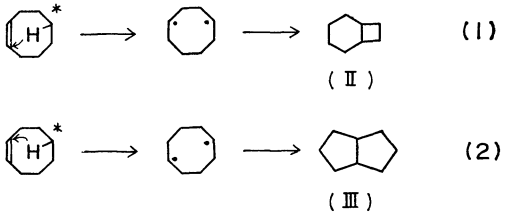
tions that (i) the products other than cyclooctane were not appreciably affected by the addition of several kinds of radical scavengers (though oxygen affects the formation of almost all products, this effect may be caused by the quenching of triplet cyclooctene), and (ii) the yields of ethylene and 1,5-hexadiene were equal within the limits of experimental error:



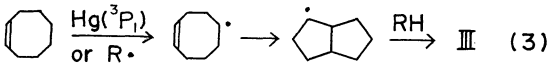
Scheme 1

In Scheme 1, a diradical intermediate, which is produced by the familiar allylic C–C bond cleavage, may undergo unimolecular isomerization to I or further C–C bond cleavage, yielding ethylene and a new diradical resulting in a similar isomerization to 1,5-hexadiene. Such an allylic diradical intermediate has been widely proposed in the mercury-photosensitized reaction of cyclopentene,[4] cyclohexene,[5] cycloheptene,[5] where the ring closure to the respective vinylcycloalkanes has been observed as one of the typical reactions of the intermediate. The yield of vinylcyclohexane expected from the intermediate was very low in the present photolysis of cyclooctene. Thus, the allylic diradical intermediate seems to show different reactivities depending on the vibrational excess energy or the molecular structure.

On the other hand, the most reasonable pathway for the formation of bicyclic compounds (II and III) is presumed to be the hydrogen transfer from an appropriate methylene group to the olefinic double bond with subsequent or simultaneous C–C bond formation. The transannular hydrogen abstraction from C-5 methylene *via* six- (1,5-shift) or five-center (1,4-shift) processes, leading to the formation of II or III through the respective diradical intermediates, is given below:



Though the mechanistic details, whether concerted or step-by-step, are not clear, the larger yield of II compared with that of III shows a preference for 1,5-hydrogen transfer *via* a six-center process over other hydrogen transfers.



An alternate diradical process (3), which is presumed by an analogy with a free radical transannular cycloaddition to 1,5-cyclooctadiene, thus forming bicyclo[3.3.0]octane derivatives,[6] may be ruled out on the basis of the experiments with radical scavengers.

The Charge-transfer Complexes of Metal Chelates of 8-Quinolinol with Various Halogen-substituted *p*-Benzoquinones

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 23, 1971)

Much attention has been paid to a large number of charge-transfer complexes made from electron donors and acceptors.[1] However, there are few donor molecules that are known to be composed of organic metal chelates. In 1965 the charge-transfer complexes of 8-quinolinol and its copper, palladium, and nickel chelates with *p*-chloranil were first prepared by Bailey *et al.*[2] Recently, we have reported that bis(8-quinolinolato)palladium(II), ($Pd(Ox)_2$), and bis(8-quinolinolato)copper(II), ($Cu(Ox)_2$), form stable crystalline (1:1) charge-transfer complexes with 2,5-diazido-3,6-dichloro-1,4-benzoquinone and 2,5-diazido-3,6-dibromo-1,4-benzoquinone.[3]

In the present work, we found that $Pd(Ox)_2$ and $Cu(Ox)_2$ can also form stable crystalline (1:1) charge-transfer complexes with various halogen-substituted *p*-benzoquinones. Measurements of the diffuse reflection spectra of these solid complexes were attempted in order to study the charge-transfer interaction between the metal chelates of 8-quinolinol and the halogen-substituted *p*-benzoquinones.

The following crystalline complexes were prepared according to a method similar to that described by Bailey *et al.*[2]: $Pd(Ox)_2$-*p*-Bromanil, $Pd(Ox)_2$-*p*-Iodanil, $Pd(Ox)_2$-*p*-QBr_2Cl_2,[4] $Pd(Ox)_2$-*p*-QBr_3Cl,[4] $Cu(Ox)_2$-*p*-Bromanil, $Cu(Ox)_2$-*p*-Iodanil, $Cu(Ox)_2$-*p*-QBr_2Cl_2, and $Cu(Ox)_2$-*p*-QBr_3Cl. The complexes were pulverized and diluted with potassium bromide. The diffuse reflection spectra of these complexes were recorded as the difference in the reflectance between the mixture and pure potassium bromide, as determined by means of a Beckman DK-2A spectroreflectometer. The solid-state spectra were then obtained by plotting the diffuse reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance.

The $Pd(Ox)_2$ Complexes

The solid-state spectrum of the $Pd(Ox)_2$-*p*-Bromanil complex (Fig. 1, Curve a) shows the band peaks at 14.6 kK and 23.5 kK and a shoulder around 29 kK. The band at 23.5 kK and the shoulder arise from the absorptions due to the component molecules, while the band at 14.6 kK appears in the low-energy region, where neither of the component molecules are absorbed. The value for this low-energy band was found to be close to that for the band of the $Pd(Ox)_2$-*p*-Chloranil complex at 14.8 kK, which Bailey *et al.* assigned to the charge-transfer transition from $Pd(Ox)_2$ to *p*-chloranil. Therefore, the band at 14.6 kK for the $Pd(Ox)_2$-*p*-Bromanil complex is also attributable to the charge-transfer transition from $Pd(Ox)_2$ to *p*-bromanil. These results seem to indicate that the electron affinity for *p*-bromanil is almost the same as that for *p*-chloranil. Since the molecular sizes and the shapes of these acceptors are almost identical, the crystal structure of the $Pd(Ox)_2$-*p*-Bromanil complex may be similar to that of the $Pd(Ox)_2$-*p*-Chloranil complex determined by Kamenar *et al.*[5]

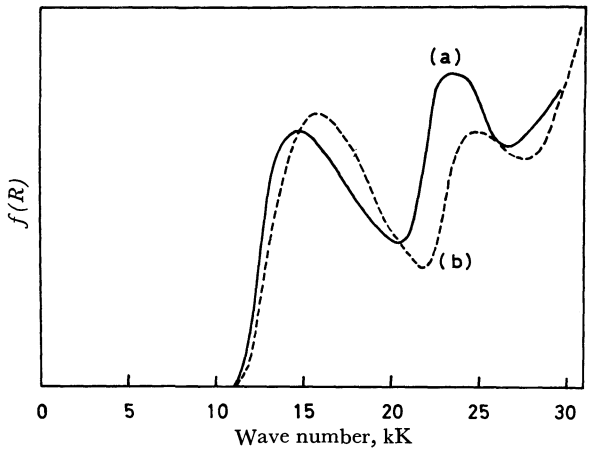

Fig. 1. The solid-state spectra of (a) $Pd(Ox)_2$-*p*-Bromanil and (b) $Cu(Ox)_2$-*p*-Bromanil.

The spectroscopic features for the complexes of $Pd(Ox)_2$ with the other halogen-substituted *p*-benzoquinones are quite analogous to that for the $Pd(Ox)_2$-*p*-

TABLE 1. THE SPECTROSCOPIC DATA ON THE MAXIMUM POSITIONS OF THE CHARGE-TRANSFER BANDS
(in unit of 10^3 cm^{-1})

Acceptor	$Pd(Ox)_2$	$Cu(Ox)_2$
p-Chloranil	14.8[a]	15.9[a]
p-Bromanil	14.6	15.9
p-Iodanil	14.3	15.7
p-QBr_2Cl_2	14.8	16.0
p-QBr_3Cl	14.8	16.0

3) S. Koizumi and Y. Iida, This Bulletin, **44**, 1436 (1971).

4) 2,5-Dibromo-3,6-dichloro-1,4-benzoquinone and tribromomonochloro-*p*-benzoquinone are abbreviated as *p*-QBr_2Cl_2 and *p*-QBr_3Cl respectively.

5) The crystal structure of the $Pd(Ox)_2$-*p*-Chloranil complex has a triclinic symmetry. The planar $Pd(Ox)_2$ and *p*-chloranil molecules, which are alternately stacked, are arranged in planes approximately parallel to the crystallographic (111) plane. See B. Kamenar, C. K. Prout, and J. D. Wright, *J. Chem. Soc.*, **1965**, 4851.

Bromanil complex or for the $Pd(Ox)_2$-*p*-Chloranil complex. The energy values for the charge-transfer bands of the complexes are collected in Table 1. Table 1 shows that the charge-transfer-band positions for the $Pd(Ox)_2$ complexes, practically, do not depend on the acceptors now under investigation. This means that the electron affinities of these halogen-substituted *p*-benzoquinones are very similar to one another.

The $Cu(Ox)_2$ Complexes

The solid-state spectrum of the $Cu(Ox)_2$-*p*-Bromanil complex (Fig. 1, Curve b) shows the band peaks at 15.9 kK and 25.0 kK, and a shoulder around 30 kK. The low-energy band at 15.9 kK can also be assigned to the charge-transfer transition from $Cu(Ox)_2$ to *p*-bromanil; this energy value was found to be in good coincidence with the value for the $Cu(Ox)_2$-*p*-Chloranil complex (15.9 kK).[2] However, we can see that the charge-transfer energy for the $Cu(Ox)_2$-*p*-Bromanil complex is larger than that for the $Pd(Ox)_2$-*p*-Bromanil complex by 1.3 kK. For a common acceptor, the variation in the charge-transfer energy arises mostly from the difference in the ionization potentials of the donor molecules. Therefore, it seems that the ionization potential of $Cu(Ox)_2$ is higher than that of $Pd(Ox)_2$ by about 1.3 kK.

The spectroscopic features of the complexes of $Cu(Ox)_2$ with the other halogen-substituted *p*-benzoquinones are found to be quite similar to those of the $Cu(Ox)_2$-*p*-Bromanil complex. The charge-transfer bands of the complexes are given in Table 1.

Discussion

The solid-state spectra clearly indicate that the ionization potential of a metal chelate of 8-quinolinol is much affected by the species of the central metal ion. The ionization potential of $Cu(Ox)_2$ is appreciably larger than that of $Pd(Ox)_2$. For the above four acceptors, the magnitude of this difference is estimated to be 1.3 ± 0.2 kK (0.16 ± 0.025 eV).

Bailey *et al.* examined the charge-transfer complexes of $Cu(Ox)_2$, $Pd(Ox)_2$ and various aromatic hydrocarbons with common acceptors and compared their charge-transfer energies.[2] By the use of the relationship between the charge-transfer-band energies and the ionization potentials of the donors, they proposed that the values for the ionization potentials of $Cu(Ox)_2$ and $Pd(Ox)_2$ were 7.3 eV and 7.1 eV respectively.[2] The difference in the ionization potentials between $Cu(Ox)_2$ and $Pd(Ox)_2$ is 0.2 eV, which is in good agreement with the value determined by the present investigation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2565—2566 (1971)

A Remark on the Applicability of the CNDO Calculation to the Chemical Reactivity Theory

Hiroshi FUJIMOTO, Shoichi SUGIHARA, Shinichi YAMABE, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received April 23, 1971)

The usefulness of the CNDO calculation for the interpretation of the chemical and physical properties of organic molecules has been verified in numerous cases.[1] The extended Hückel MO method gave good results with respect to the calculation of the chemical reactivity index, the frontier electron density, of hydrogens in the E2 reaction of some halogenated hydrocarbons, in the base-catalyzed allylic rearrangement of some olefins, and in the halogenation of norbornane.[2-4] It has been reported, however, that the extended Hückel MO method sometimes fails to give satisfactory results when it is applied to a molecule containing polar bonds.[5] The discrepancy may partly be attributed to the unreasonable parametrizations due to the ambiguity of the physical meaning of the one-electron Hamiltonian operator in this method.[6] Hence, it may be expected that the CNDO method can be a convenient means for discussing the chemical reactivity of sizable molecules, since the electron populations are smoothed out by the self-consistent-field iteration procedure. The purpose of this note is to present the results of our CNDO calculation of the chemical reactivity of the hydrogens of some substituted and unsubstituted hydrocarbons. The method of calculation is CNDO/2, using the integrals given in the literature.[1]

Chemical Reactivity of Hydrogens toward Nucleophilic Abstraction. The frontier electron density of a hydrogen for nucleophilic reactions is defined by;[7]

$$f_r^{(N)} = 2(C_r^{(LU)})^2$$

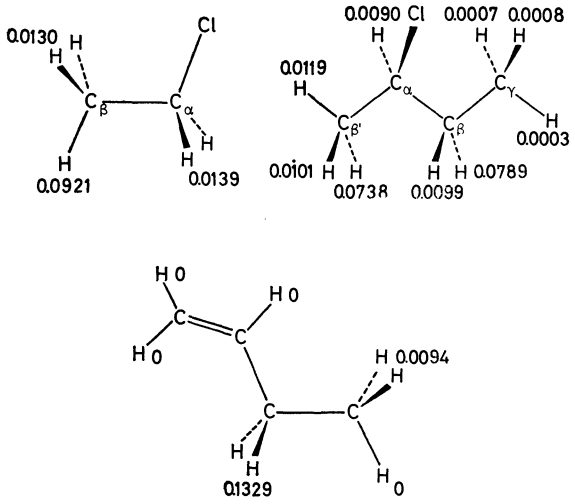

Fig. 1. Frontier electron densities of hydrogens toward nucleophilic abstraction.

where $C_r^{(LU)}$ is the coefficient of the hydrogen, 1s AO r, in the lowest unoccupied (LU) MO. Figure 1 shows that β-hydrogens of ethyl chloride and 2-chlorobutane which are located *trans* to chlorine are most reactive toward the attacking nucleophile, while, in the case of butene-2, the allylic hydrogens have the largest frontier electron density, which is in accordance with the experimental results.[8,9]

Chemical Reactivity of Hydrogens toward Homolytic Abstraction. The frontier electron density of a hydrogen for homolytic reactions is defined by;

$$f_r^{(R)} = (C_r^{(HO)})^2 + (C_r^{(LU)})^2$$

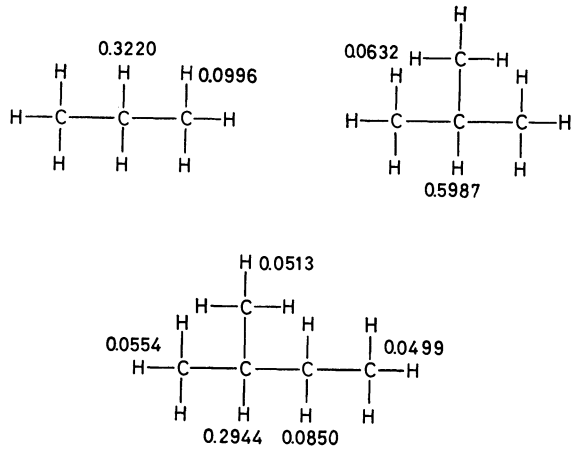

Fig. 2. Frontier electron densities of hydrogens toward homolytic abstraction.

where HO implies the highest occupied MO. Figure 2 shows the $f_r^{(R)}$ values of hydrogens in propane, isobutane, and isopentane. The values indicate the averages with respect to three hydrogens of primary carbons and two hydrogens of secondary carbons. The frontier electron densities decrease in this order:

$$\text{tertiary} > \text{secondary} > \text{primary}$$

showing a good agreement with the well-established experimental results.[10]

In some unfortunate cases, the MO levels calculated by the CNDO method may happen to be in an unrealistic order. The present results suggest, however, that the chemical reactivity index, the frontier electron density, obtained from the CNDO MO wave function can be a suitable measure for an intramolecular comparison of the chemical reactivities in a variety of organic compounds.

SHORT COMMUNICATIONS

Friedelin and Related Compounds. Part XI.[1] Identification of a Saturated Nor-Aldehyde from Ultraviolet Irradiation of Friedelin

Robert STEVENSON, Takahiko TSUYUKI, Reiko AOYAGI,* and Takeyoshi TAKAHASHI*

Department of Chemistry, Brandeis University, Waltham, Massachusetts, U.S.A.

** Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*

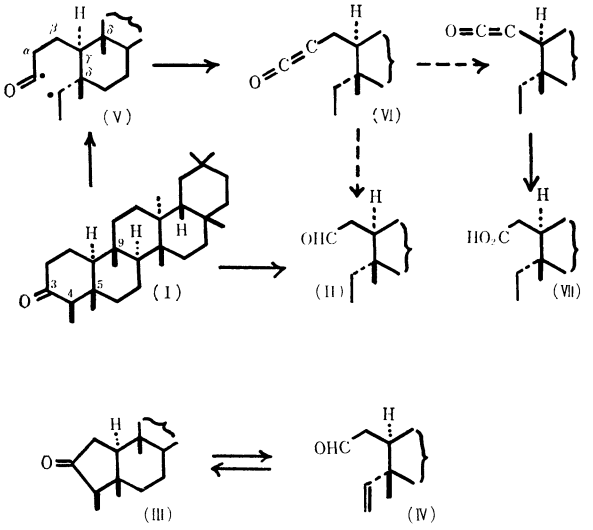
(Received May 7, 1971)

In previous works,[2,3] it was reported that the ultraviolet irradiation of friedelin (I) in diethyl ether solution yields a mixture of hydrocarbons, an unidentified aldehyde, ketones,[4,5] and hydroxycarbonyl compounds.

In this communication, we present evidence that the aldehyde has the structure 5α-ethyl-10β-formylmethyl-des-A-friedelane (II). Isolation of a *saturated nor*-secoaldehyde by photochemical degradation of a cyclic ketone is apparently unprecedented.

A solution of friedelin (1.0 g) in diethyl ether (1 *l*) was irradiated at room temperature under a nitrogen atmosphere for 2.25 hr with a high pressure quartz mercury vapour lamp (Hanovia 8A-36). This procedure was repeated and the combined residue, after solvent removal, was chromatographed on silica gel (300 g, Merck). The crude aldehyde fraction (84 mg) was then purified by further chromatography on alumina (Woelm, neutral, 15 g, then repeated on 20 g), and then crystallized from ether to give 5α-*ethyl*-10β-*formylmethyl-des*-A-*friedelane* (II) as needles (18 mg), mp 182°C. The empirical formula, $C_{29}H_{50}O$, was confirmed by mass spectrum determination (*m/e*, relative intensity %): 414 (65%, M^+), 399 (29, M−15), 386 (21, M–28; aldehyde), 385 (8, M–29), 371 (10, M–43; loss of $-CH_2CHO$), 358 (8, M–56; 3,4-seco-friedelane), 273 (69), 261 (18), and 205 (100). Other analytical and spectroscopic data were as previously reported.[3]

The proposed structure(II) was confirmed by comparison (IR, NMR, mass spectrum, analytical TLC) with a specimen, mp 181—181.5°C, prepared by catalytic hydrogenation (palladium-carbon, ethanol) of 5α-vinyl-10β-formylmethyl-des-A-friedelane (IV) produced



by photo-irradiation of *nor*-friedelin (III) in hexane.[6]

The pathway for the well-documented photo-cleavage of cyclohexanones to yield δ-*unsaturated* aldehydes by α-cleavage followed by transfer of a hydrogen atom from a δ-carbon atom (six-membered transition state) is unavailable for friedelin (quaternary C-5 and C-9). It seems probable, consequently, that the initial di-radical species (V) is stabilized by hydrogen transfer from C-2 to the alkyl radical (six-membered transition state) to yield the ketene (VI) which undergoes the unusual degradation to the *nor*-seco aldehyde (II). It is of interest, in this connexion, that a *nor*-seco carboxylic acid (VII) was identified as a product of irradiation of friedelin in hexane.[7] Experiments aimed at elucidation of the mechanism of formation of II and VII are in progress.[8]

8) In this connexion, it is significant that the saturated nor-aldehyde (II) is *not* detected on similar irradiation of nor-friedelin (III).

Molecular-weight Determination by the Vapor-pressure-Depression Method using Gas Chromatography[1)]

Yozaburo Yoshikawa, Kimiko Arita, Akira Inaba, and Kiyoko Sasaki
Institute of Chemistry, College of General Education, Osaka University, Machikaneyama Toyonaka
(Received May 10, 1971)

The molecular-weight-determination method based on the principle of vapor-pressure depression has not been widely utilized because of the difficulty of measuring precisely small differences in the vapor pressure.

Now, however, we have been able to measure conveniently the degree of vapor-pressure depression of the solution by means of gas chromatography and determine the molecular weight of the solute within an error of 3%.

The method and the obtained results will be reported here.

According to Raoult's law, the degree of the depression of the solvent vapor in a dilute solution is equal to the mole fraction of the solute. The next equation is thus obtained:

$$(p^\circ - p)/p^\circ = n/(N+n) \qquad (1)$$

p°= vapor pressure of a pure solvent
p= vapor pressure of the solvent in the solution
n= mole number of the solute dissolved in N mol of the solvent

When w grams of a solute is dissolved in W grams of a solvent with a molecular weight of M, the term of $(p^\circ-p)/p^\circ$ can be calculated from the peak height of the chromatograms of the pure solvent (h°) and the solvent in the solution (h).

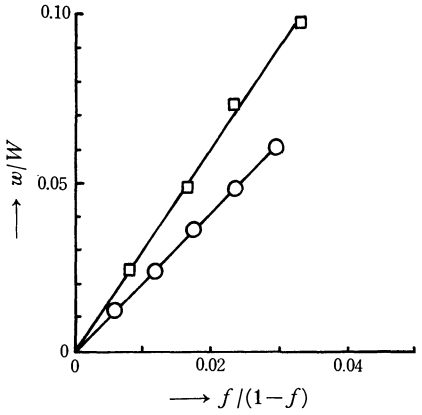

Fig. 1. Relation of molality and depression degree of vapor pressure of benzoic acid in acetone and benzene solution.
○ Benzoic acid in acetone solution
□ Benzoic acid in benzene solution

1) A part of this work was presented at the 23 rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970.

Table 1. Molecular weight data determined by vapor pressure depression method

Solute	Solvent	Experimental value	Theoretical value	Error (%)
Naphthalene	Acetone	128.52	128.17	0.27
	Benzene	127.58		0.46
	Carbon tetrachloride	128.66		0.38
	Ethyl alcohol	130.94		2.16
Benzoic acid	Acetone	123.42	122.12	1.06
	Benzene	236.85*	*dimer 244.24	3.03
	Carbon tetrachloride	234.78*		3.87
	Ethyl alcohol	125.65		2.89
Dipyridin-coppernitrate	Acetone	344.18	345.76	0.46
Benzene	Toluene	79.65	78.11	1.97
n-Hexane	*n*-Heptane	86.39	86.18	0.24
Carbon tetrachloride	Toluene	155.62	153.82	1.17

Hence, the molecular weight of the solute, m, is obtained using this equation:

$$m = w \cdot M/W[1-(h^\circ-h)/h^\circ \,/\, (h^\circ-h)/h^\circ] \qquad (2)$$

Equation (2) can then be transformed to the next equation when $(h^\circ-h)/h^\circ$ is represented as f:

$$m/M = w/W\,/f/(1-f) \qquad (2)'$$

In Fig. 1, the concentration of each solution (w/W) *vs.* $f/(1-f)$ is plotted. From this slope ($=m/M$) of the plot, the molecular weight of the solute can be calculated.

The obtained results are shown in Table 1.

In this experiment, the vapor of a pure solvent or solution was saturated in a glass flask at a constant temperature slightly lower than room temperature. A Teflon stopper was used for this flask. A glass syringe and a stainless-steel pipe were attached to this stopper; the fromer was used for pushing out the sample gas in the flask, while the latter was used for introducing the sample vapor to the gas sampler of the gas chromatograph.

The concentration of the solution used was higher than 0.05 molality. Now, an experiment on the solution of less than 0.05 molality is in progress.

The Facile Reduction of Acyl Halides into Aldehydes *via* Acylcarbonylferrates

Yoshihisa WATANABE, Take-aki MITSUDO, Masato TANAKA, Kazuo YAMAMOTO, Toshiharu OKAJIMA, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 11, 1971)

Previously, we reported that alkyl halides such as *n*-propyl iodide[1] and ethyl α- or β-bromopropionate[2] react with an ethanolic solution of tetracarbonylferrate, $Fe(CO)_4^{2-}$, with the absorption of carbon monoxide, to give a mixture of the corresponding carbonylated products, ethyl *n*-butyrate and *n*-butyraldehyde, and diethyl succinate and diethyl methylmalonate, respectively.

Recently, Cooke carried out an analogous reaction in tetrahydrofuran (THF) in the presence of triphenylphosphine; quenching it with acetic acid, he found that alkyl bromides are carbonylated to the corresponding aldehydes in high yields.[3] In these reactions, it can reasonably be considered that acylcarbonylferrate complexes are formed as the reaction intermediates.[1-3]

In this communication, we wish to report a facile reduction of acyl halides into aldehydes, which is considered to proceed *via* acyltetracarbonylferrates.

Acyl halides react with an equivalent mole of $Na_2Fe(CO)_4$ in THF at 0—60°C to give, after quenching with acetic acid, the corresponding aldehydes in high yields. This fact strongly suggests that sodium acyltetracarbonylferrates (I)[4] are directly formed in high yields by the nucleophilic attack of $Fe(CO)_4^{2-}$ on the acyl carbon atom. Some results of typical reactions are shown in Table 1.

$$R-\underset{\underset{O}{\|}}{C}-Cl + Na_2Fe(CO)_4 \rightarrow \underset{(I)}{Na^+[Fe(CO)_4COR]^-} + Na^+Cl^-$$

$$(I) + AcOH \rightarrow R-\underset{\underset{O}{\|}}{C}-H$$

The reduction of benzoyl chloride to benzaldehyde illustrates a typical procedure. A THF solution of $Na_2Fe(CO)_4$[3,5] (7.3 mmol) was prepared by adding, drop by drop, 1.0 m*l* of $Fe(CO)_5$ in 25 m*l* of THF to 4 m*l* of a 1% sodium amalgam in 25 m*l* of THF under argon at room temperature. After the amalgam had been removed through a side arm, to this solution was added 0.85 m*l* (7.3 mmol) of benzoyl chloride at 30°C; the mixture was stirred vigorously for 1 hr and then treated with 1.2 m*l* of glacial acetic acid. The mixture was stirred for an additional 5 min, then poured into 50 m*l* of water, and extracted with 20 m*l* of pentane and then 20 m*l* of ethyl ether, after which the organic extracts were submitted to glpc analysis.[6]

Aromatic and aliphatic acyl halides are readily reduced to the corresponding aldehydes in high yields, indicating that the corresponding acyltetracarbonylferrates (I) are formed in high yields and that these complexes are thermally stable in the solution, even in the absence of a stabilizing ligand such as triphenylphosphine.[3] The branched acyl complex, isobutyryltetracarbonylferrate, is also stable in the solution even at 60°C and does not isomerize to the normal acyl complex, in contrast with the branched acylcarbonylcobalt, which isomerizes to *n*-acylcarbonylcobalt.[7]

The high yield of the aldehydes and the facility of the reaction procedures enable us to utilize this reaction instead of the Rosenmund reduction[8] and reduction with $LiAlH(OR)_3$.[9]

The acyltetracarbonylferrate (I) can possibly be utilized as a starting material for further organic syntheses. These reactions will be discussed in the near future.

TABLE 1. THE REDUCTION OF ACYL CHLORIDES TO ALDEHYDES WITH $Na_2Fe(CO)_4$ IN THF

Mössbauer Spectroscopic Studies of the Oxidation State of ^{57}Fe produced in ^{57}Co-doped and γ-irradiated Trisacetylacetonatoiron(III)

Hirotoshi SANO, Keiko SATO, and Hiroko IWAGAMI

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Tokyo

(Received July 2, 1971)

A number of cobalt compounds labelled with ^{57}Co used as Mössbauer sources have shown the presence of one or more "anomalous" charge states. The formation of iron-atom charge states less positive than the charge state of the cobalt atom in the parent compound has been interpreted in terms of the "internal pressure hypothesis" by Hazony and Herber,[1] based on the similarity between the Mössbauer spectra of $Fe(acac)_3$ under a high external pressure[2] and that of a $^{57}Co(acac)_3$ source experiment.[3] This hypothesis has also been supported by the fact that such anomalous charge states were not observed in the IT(IC) decay of ^{119m}Sn in the various tin compounds.[1] We have, however, recently reported experimental evidence for the presence of an "anomalous" charge state in the IT(IC) decay of ^{119m}Sn in $K_6Sn_2(C_2O_4)_7 \cdot 4H_2O$.[4] It is debatable, therefore, whether or not the lattice can generate a high local internal pressure. Here we will describe the Mössbauer spectra of the first excited state of ^{57}Fe produced in a $Fe(acac)_3$ host crystal doped with $^{57}Co(acac)_3$. The Mössbauer spectra of γ-irradiated $Fe(acac)_3$ are also shown for comparison.

An (Fe, ^{57}Co)$(acac)_3$ source was prepared from a solution containing 50 mg of ferric iron and 2 mCi of ^{57}Co by following the method described in Ref. 5. Another source was prepared by the extraction method. Carrier-free 2 mCi $^{57}Co(acac)_3$ was extracted from the aqueous solution into the benzene phase by following the method described in Ref. 6. To the benzene phase were added 50 mg of $Fe(acac)_3$ or $^{56}Fe(acac)_3$ prepared from natural iron or ^{56}Fe-enriched iron, and the benzene solution was filtered. After freezing the filtrate in liquid nitrogen, the frozen solution kept at -15°C was pumped out through a liquid nitrogen trap in order to remove the benzene and the excess acetylacetone. The source was then kept in a cryostat, and the Mössbauer spectra were measured against an ^{57}Fe-enriched stainless-steel absorber moving in a constant acceleration mode at room temperature. All the sources showed the same Mössbauer spectrum. The (Fe, ^{57}Co)$(acac)_3$ source prepared from natural iron was also used as an "absorber" against a 10 mCi ^{57}Co(Pt) source in order to confirm the absence of species other than $Fe(acac)_3$. X-ray diffraction data indicate that the doped sample has the same crystal structure as the host $Fe(acac)_3$ if the content of $Co(acac)_3$ incorporated in $Fe(acac)_3$ is less than 10%.

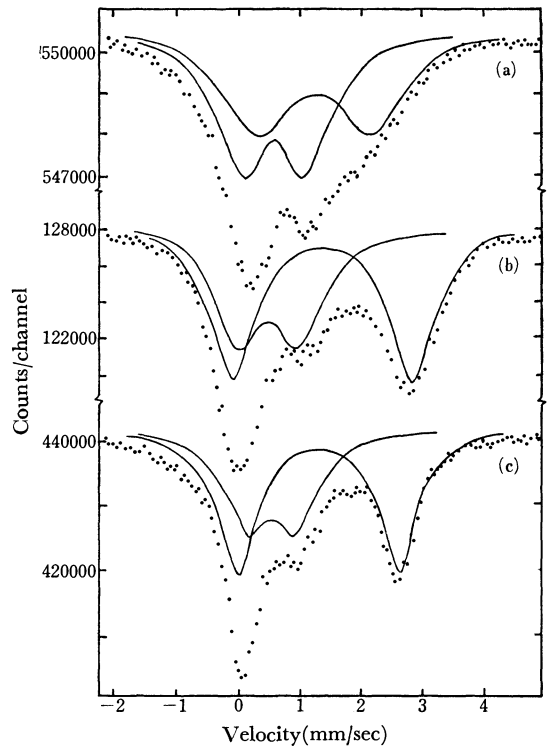

Fig. 1. Mössbauer spectra of (a) (Co, ^{57}Co)$(acac)_3$ source (kept at 78°K) *vs* ^{57}Fe-stainless steel absorber, (b) (^{56}Fe, ^{57}Co)$(acac)_3$ source (kept at 78°K) *vs* ^{57}Fe-stainless steel absorber, and (c) γ-irradiated (10^{10} r) $Fe(acac)_3$ absorber (kept at 78°K) *vs* ^{57}Co(Pt) source. All the velocity scales were normalized with respect to iron.

Typical Mössbauer spectra are shown in Fig. 1. The experiment involving the ^{57}Co(Pt) source and the (Fe, ^{57}Co)$(acac)_3$ "absorber" shows the absence of species other than $Fe(acac)_3$. The experiment using the (Fe, ^{57}Co)$(acac)_3$ source kept at 78°K and a stainless-steel absorber clearly shows the presence of divalent ^{57}Fe species. The experiment using the ^{57}Co (Pt) source and the γ-irradiated $Fe(acac)_3$ absorber kept at 78°K shows the same spectral pattern as that found in the (Fe, ^{57}Co)$(acac)_3$ source experiment.

The results indicate that the divalent ^{57}Fe species are still produced. As ^{57}Co was incorporated into a similar trisacetylacetonatoiron(III) matrix, the "internal-pressure effect" is supposed to be no longer working in the (Fe, ^{57}Co)$(acac)_3$ source. One possible mechanism is auto-radiolysis including an electronic excitation process initiated by the Auger effect. The latter would be followed by the decomposition of the acetylacetonate ligands to various fragments, such as carbon monoxide, carbon dioxide, methane, ethane, and hydrogen, which were detected in the gas chromatography of the γ-irradiated $Fe(acac)_3$.

Explosion during the Preparation of Ethylphenyl Thallic Acetate Perchlorate

Sakae UEMURA, Yoshihiro IKEDA,* Osamu ITOH,* and Katsuhiko ICHIKAWA*

Institute for Chemical Research, Kyoto University, Uji, Kyoto

**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto*

(Received June 3, 1971)

We have reported a method of preparing arylthallic acetate perchlorate monohydrates[1] ($RC_6H_4TlOAc\text{-}ClO_4\cdot H_2O$), with the syntheses of phenyl, tolyl, three isomeric xylyl, and anisyl derivatives. On applying this method to the preparation of ethylphenyl derivative, a violent explosion occurred in the last stage of concentration of the reaction mixture carried out with a rotary vacuum evaporator. The procedure was as follows. Into acetic acid (180 m*l*) containing $Tl(OAc)_3$ (45 g), 70% $HClO_4$ (18 g), and then ethylbenzene (25 g) were added at 65°C under stirring. After 5 hr the precipitated thallium(I) salts (*ca.* 5 g) were filtered off and the solvent in the filtrate was evaporated slowly at *ca.* 60°C in a vacuum with a rotary vacuum evaporator to give *ca.* 30 m*l* of white pasty residue. Soon after evaporation was stopped, a violent explosion occurred.

Before this experiment, two runs of the same reaction were carried out safely to give the expected product in 14.7% yield and a trace amount. About 150 runs of preparative experiments were carried out without any trouble. However, care should be taken during the process of evaporating the solvent and too much evaporation should be avoided.

We would like to add the following remark with respect to the handling of perchloric acid. When one drop of 70% perchloric acid was added to 10 m*l* of dimethylsulfoxide (DMSO) at room temperature, a violent explosion occurred. Reactions in DMSO with perchloric acid should be avoided.

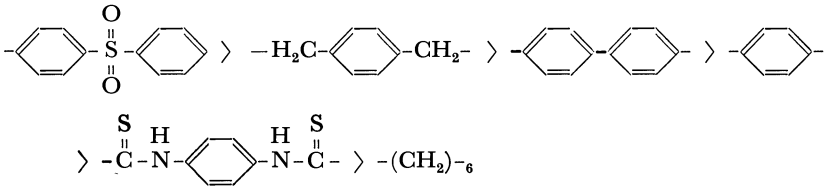
Photoconduction of Polystyrylpyrimidines

Ryo HIROHASHI, Yasushi HISHIKI, and Masahiro HARUTA
Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received August 14, 1970)

Eight polystyrylpyrimidines were synthesized from *p*-xylylpyrimidine with *p*-phenylene diisothiocyanate (DIT), terephthaloylchloride (TPC), *p*-xylylenedibromide (XDB), *p*-phenylenediamine (PDA), 4,4'-diaminodiphenyl (BD), 4,4'-diamino diphenylsulfone (DPS), hexamethylene diamine (HMD), and 4,4'-diaminodiphenylmethane (DPM). These polymer films have a fairly large photoconductive character; using a surface-type photoconductive cell, the logarithmic relation of the photo-current (I_p) to the applied potential was found to be linear. Further, it was found that the slopes (n) obtained from the logarithmic relation ($I_p=kL^n$) of the photocurrent to the light intensity (L) have values from 1.0 to 2.4. The peaks of the spectral response of the photocurrent of the eight samples exit around 500—600 mμ and/or near the ultraviolet wavelength region. The photoconduction of these polymers was enhanced by the bridging groups attached to xylylpyrimidine; the enhancement is in the following order;



These have in recent years been a large number of reports on the photoconduction of polycyclic aromatics and also of polymers.[1] However, scarcely systematic research on the relation between the photoconduction and the chemical structure has been carried out.[2]

It was been widely noted that polyvinylcarbazole shows quite a large photoresponse, one which is influenced by sensitizers.[3] The cause of this photoresponse is assumed to be that polyvinylcarbazole has a large side group which shows an energy transfer by means of dipole-dipole resonance between carbazole molecules.[4] As other organic photoconductive materials, polystyrene,[5] polyvinylacridine,[6] and polyhalogenated vinyl,[7] and so on have been investigated. However, the photoconduction of the polymer containing a hetero-ring in the main chain has not yet been investigated.

Recently, many sorts of electrophotographic techniques have been developed. The main requirements for good electrophotographic materials are as follows; the ratio between the photoconductivity and the dark conductivity should be large, and the spectral response of the photoconduction should cover a wide visible and ultraviolet wavelength region. If the relation between the molecular structure and the photoconductive character could be find, materials suitable for electrophotographic printing could be prepared.

In this report, we will describe the variation in the photoconductive characters of eight sorts of polystyrylpyrimidines as a function of the molecular structure.

Experimental

1. Synthesis of the Polymers. The polycondensations of *p*-xylylpyrimidine (1.00×10^{-2} mol) with various diamines (1.00×10^{-2} mol) were carried out for 5—10 hr 100 m*l* three-necked flask equipped with a stirrer, a nitrogen gas inlet, and a calcium chloride drying tube at 150°C. Inorganic catalysts were not used, since inorganic impurities obviously affect their electrical properties. Triethylamine (5 wt% for monomer) was used as a catalyst for polycondensation. During the synthesizine procedure, highly polar solvents dimethylformamide and dimethylacetamide were used to accelerate the reaction. The reaction mixture was poured into ethanol, and the precipitated polymer was filtered and washed successively with hot water and alcohol. The powders separated from the reaction mixture were purified by a Soxlet extraction, dried at 100°C under a vacuum, and stored over a desicant.[8] The polymer was found to have no ash content. Table 1 shows the structures and the nitrogen analyses for the polymers obtained from *p*-xylylpyrimidine reacted with and various monomers.

2. Measurement of the Semiconductive Properties and Photoconductivity. The electrical resistivity of the powdered samples compressed between stainless-steel electrodes by a pressure of 50 kg/cm^2 was measured *in vacuo*. The details of this procedure already have been presented.[9] The resistivity decreased with an increase in the temperature, and a good linear relationship was obtained between the logarithm of the resistivity (ρ) and the reciprocal of the temperature, this indicates the applicability of the following formula.[10]

$$\rho=\rho_0\exp(\Delta E_G/2kT)$$

cm^2 surface area and *ca.* 0.5—1.0 mm thick) was made by the compression of about 0.1 g of a finely-powdered at about 200 kg/cm^2. Silver paste (du Pont conducting silver paint No. 4817) was painted in two stripes on the surface of a tablet with a 1 mm gap. A 750 watt tungsten lamp was used, associated with metallic interference filteres in order to isolate narrow particular wavelength regions. The maximum transmissive wavelengths of the regions, which were 10—61 mμ in the half-band width, ranged from 398 mμ to 1340 mμ, with intervals of 50—100 mμ.[11] The photoconduction of the polymer was measured in a conductivity cell by illumination with a tungsten lamp or a hydrogen-discharge lamp. The electric current was measured by means of the DC amplifier. As the voltage source applied to an organic photocell, we used a DC voltage supply of up to 1000 V.

The absolute measurements of the intensity of the incident light on an organic photocell were made by means of a Nihonbunko vacuum thermopile which was placed at the position of the photocell. The maximum intensity, 3.70—4.73 $\times$ 10^{15} photons/sec·cm^2, was obtained for the light which was isolated by a 848 mμ filter.[12]

Results and Discussion

The voltage dependence of the surface photo-current and the dark-current of the polymers was measured. Most of the observations were made *in vacuo* with a

surface-type photocell in order to avoid the effects of the space charge which are occasionally observed with sandwich-type photocells. The potential dependence for the photocurrent is reproducible, as in the case of the dark-current. Figures 1 and 2 show the electric-field(V) dependence of the dark-current (I_d) and of the photo-current (I_p).

Ohmic behavior derived from the I_d-V relation was observed for all samples except the P7- and P8-samples for the dark-current. On the other hand, ohmic relations for the photo-current against the applied potential were obtained for all samples except P3. Figure 3 shows the I_d-V relation under illumination by a hydrogen-discharge lamp.

Table 2 shows the values of the slopes(α and β) of the I-V relation for polystyrylpyrimidines. The values of α and β were calculated from the $I_d=kV^\alpha$ and $I_p=kV^\beta$ relation respectively. The specific resistivities, the values of the energy gap, and the temperature-possessed kink of the energy gap are shown in Table 2.

A summary of the results for surface-type cells is presented in Table 3. The ratios of the photo-current (I_p) to the dark-current (I_d) reveal the effects of the molecular structures sufficiently well.

The photo-current decreases in air ($I_p=4.5\times10^{-13}$ Å) more than in a vacuum ($I_p=4.3\times10^{-11}$ Å). As a general rule, upon illumination by incandescent lamp the photo-current does not immediately rise to its equilibrium value. Usually the current-time curve shows a peak shortly after the light has been switched

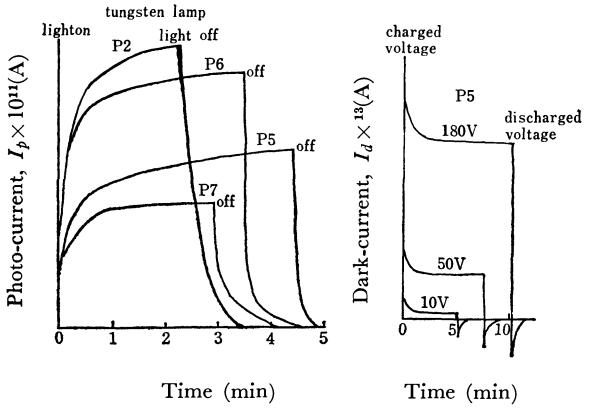

Fig. 4. Dependence of the absorption current on chemical structure and charged voltage.

on as in Fig. 4.

This indicates the formation of a space-charge effect[13] and shows the influence of the contact between electrodes and the specimen. On the other hand, the photo-current upon illumination by the photo-current to its equibrium value. After switching on the field, the currents rises to a peak value, which then slowly decreases to equilibrium. When the supply of the field is stopped, a back current is obtained. The photo-current markedly depends on the voltages and light intensities used.

The Spectral Dependence of the Photo-currents of Polystyrylpyrimidines. A number of investigations of photoconduction in organic solids have been reported. Most of them have been concerned with simple compounds, especially with the anthracene crystal. The spectral response curve of photoconduction was in a closed relation to the absorption spectrum of the anthracene crystal[14] and to those for polycyclic aromatic compounds.[15]

The absorption spectra in the ultraviolet and visible regions of polystyrylpyrimidines, dissolved in concentrated sulfuric acid, were recorded at room temperature. Figure 5 shows the absorption spectra.

Figure 6 shows the spectral dependence of the photo-current of polystyrylpyrimidines. In order to normalize the photo-current, it was divided by the incident-light intensity for each wavelength. The photo-

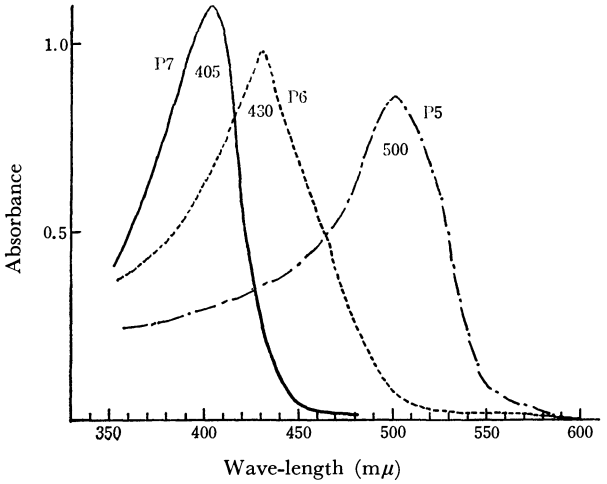

Fig. 5. Absorption spectra of polystyrylpyrimidines. (in concentrated sulfuric acid)

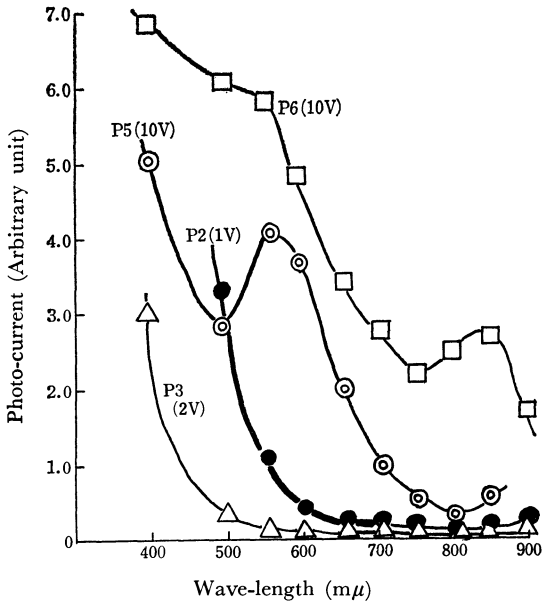

Fig. 6. The spectral dependence of the photo-current of polystyrylpyrimidines. (with metalic interfacial filters.)

current is produced by the light energy which is absorbed into the bulk of the polymeric solid. Generally, the main feature of the spectral response curves is that their peaks correspond to the minima of the absorption spectrum; that is, a higher extinction coefficient will lead to a lower photo-current in the region of the absorption spectrum.

The number of carriers is proportional to the number of photons absorbed into the bulk, with a definite coefficient of the quantum yield. The photo-current curve of polystyrylpyrimidines possesses quite a long tail, one extending to the near-infrared wavelength region. The sensitivity of photoconduction decreases more or less with an increase in the wavelength and continues to extend over the infrared region. In this experiment, the threshold value for photo-conduction could not be found, but the value should be located near the ultraviolet region judging from our results.

The Incident-light-intensity Dependence of the Photo-

current. The measurements of the photo-current with a variation in the intensity of the incident light indicated that the current observed was almost proportional to the light intensity. The dependence of the photo-current (I_p) on the illumination intensity (L) is expressed by the equation; $I_p=kL^n$. Going to the longer-wavelength region, it approaches more and more linearity until, at 748 mμ, the photo-current is proportional to the light intensity. Table 4 shows the values of n for the tungsten lamp and for each wavelength.

The values of n changed as a function of the applied voltage, the wavelength, and the atmosphere. In the presence of oxygen, the value of n is less than unity; the cause of this decrease is assumed to be the fact that the oxygen absorbs on the polymer films.[16]

(Received September 29, 1970)

Raman spectrum of α-aminobutyric acid has been observed in its 15% aqueous solution (neutral). By comparing it with the Raman and infrared spectra of crystal A (in which 40% of the total molecules are the T-form molecules, 36% G_a-, and 24% G_b-form molecules), crystal B (which consists only of T-form molecules), and a complex crystal of this amino acid with calcium chloride (in which 85% are the G_a-form molecules), it has been shown that the G_a-form molecules are predominant in the aqueous solution. Here, T-, G_a-, and G_b-forms have respectively the amino group, the hydrogen atom, and the carboxy group in the position trans to the methyl group in the internal rotation around the C_α-C_β bond. Proton magnetic resonance spectrum was observed of a C_γ-deuterated product ($CD_3CH_2CH\ NH_3{}^+COO^-$) in its aqueous solution at several temperatures in the −1.5 to 91°C range. It has been indicated that the C_α-form is more stable by about 300 cal/mole than the other two forms.

For DL-α-aminobutyric acid, two crystalline modifications, A and B, were previously found.[1] An analysis of X-ray diffraction[2,3] indicated that in crystal A the methyl group on the β-carbon does not take a fixed position. It was found to be distributed among the three sites in the internal rotation around the C_α–C_β axis. One site is nearly trans to the amino group (designated as T-form), another is nearly trans to the hydrogen atom (G_a-form), and the other nearly trans to the carboxy group (G_b-form) (see Fig. 1). The occupancy factors of these three positions were found to be 40, 36, and 24%, respectively, at room temperature. In crystal B, only T-form was found.[2,3] Recently, Akimoto and Iitaka[4] found that, in a complex crystal of DL-α-amino-*n*-butyric acid with calcium chloride, 85% of the amino acid molecules are in G_a-form. Thus, it is probable that T-, G_a-, and G_b-forms are three stable rotational isomers. The purpose of the present work is to examine which of

these three forms are involved in neutral aqueous solution of this amino acid.

Experimental

DL-*α-Aminobutyric Acid and Its Crystals.* The sample of DL-α-aminobutyric acid used in this investigation was obtained from a commercial source and was purified by recrystallization with water and ethanol.

Crystal A was obtained by dissolving the amino acid in water and by adding ethanol. When a small amount of precipitate came out, this was dissolved again by adding a small amount of water. The solution was then placed in a refrigerator at 5—10°C, and, a few days after, crystals were obtained which were found to be all in A-form.

From aqueous solutions with 1 M NaCl, always crystal B was obtained. Crystal B could be also obtained, however, by adding a greater amount of ethanol into an aqueous solution of this amino acid. When a good amount of precipitate came out, this mixture was placed in a refrigerator. The crystals thus obtained were found to be in B form.

The crystal of the complex with $CaCl_2$ was obtained by adding $CaCl_2$ into an aqueous solution of the amino acid so that the mole ratio of amino acid/$CaCl_2$ became about 2/1.5, and then by gradual evaporation of the solvent. What was obtained was a hygroscopic, monoclinic crystal elongated along the c axis. Elementary analysis was made of a sample completely dried by means of an Abderhalden's dryer.

Found: C, 27.4; H, 6.35; N, 8.00%. Calcd for $C_8H_{20}N_2O_6CaCl_2$: C, 27.35; H, 5.70; N. 8.00%.

A crystallographic analysis[4] of this crystal indicated that its chemical unit is $CaCl_2$ - 2(DL-α-amino-*n*-butyric acid) - $2H_2O$.

Raman Spectrum Raman spectrum of DL-α-aminobutyric acid was observed in its neutral aqueous solution by the use of a Perkin-Elmer LR-1 Raman Spectrometer with a 10 milliwatt He–Ne laser. The concentration was about 15% and the solution was placed in a 2.5-m*l* multi-reflection cell.

The Raman spectrum of this aqueous solution was observed also by the use of 5145 Å radiation of an argon ion laser. The results of the measurements with two different light sources agreed well, so that the Raman lines of this amino acid in its neutral aqueous solution could be fixed with a high degree of certainty.

The Raman spectra of the crystals were observed in the form of powder by the use of a JRS-01B spectrophotometer of Japan Electron Optics Laboratory Co., Ltd. with the 4880 Å and/or 5145 Å line of an argon ion laser.

Infrared Spectra. Infrared spectrum of an aqueous solution with the concentration 15% was observed with a CaF_2 cell by the use of a Perkin-Elmer 621 spectrometer.

Infrared spectra of crystals were observed in the forms of the Nujol and hexachlorobutadiene mulls. The spectral region of 4000—300 cm^{-1} was covered by the use of a Perkin-Elmer 621 Spectrometer. Each spectrum was observed not only at a room temperature but also at lower temperatures by the use of dry ice+acetone and of liquid nitrogen as cryogens. At lower temperatures, most absorption bands were observed at slightly higher frequencies, were narrower in their widths, and were observed with a higher resolution than those observed at the room temperature.

Preparation of DL-*α-aminobutyric-4-*d_3 *Acid.* The C-deuterated product $CD_3CH_2CH(NH_3^+)COO^-$ was prepared from acetic acid-d_4 containing over 99% deuterium (purchased from E. Merck and Co.) *via* the following steps:

$$CD_3CO_2D \rightarrow CD_3CH_2OH \rightarrow CD_3CH_2Br \rightarrow$$

$$CD_3CH_2\underset{\displaystyle NHCOCH_3}{\underset{|}{C}}(CO_2C_2H_5)_2 \rightarrow CD_3CH_2\underset{\displaystyle NH_3^+}{\underset{|}{C}}HCOO^-$$

Ethanol-2-d_3: A solution of 11.0 g (0.17 M) of acetic acid-d_4 in 50 m*l* of diethyl carbitol was added to a slurry of 10 g of lithium aluminum hydride in 100 m*l* of diethyl carbitol at room temperature. The reaction mixture was kept stirring for 8 hours at 60—70°C. After the reaction was completed, the mixture was cooled, and 260 m*l* of monobutyl carbitol was added below 20°C with stirring. Stirring was continued for additional 4 hr. The resulting ethanol-2-d_3 was distilled under 10^{-3}—10^{-4} mmHg at the bath temperature of 60—70°C, and collected in a trap chilled with liquid nitrogen. The yield was 7.3 g (87%).

Ethyl-2-d_3 *Bromide*: To 7.3 g of ethanol-2-d_3, prepared as described above, was added 27 g of phosphorus tribromide at −10°C. The reaction mixture was subjected to a fractional distillation, and the product was dried over potassium carbonate. Yield 10.3 g (62%).

Ethyl Acetamido (Ethyl-2-d_3*) Malonate*: In a solution of 16.3 g of ethyl acetamidomalonate plus 30 m*l* of absolute ethanol was dissolved 1.73 g of sodium. To the solution was added the deuterated ethyl bromide dissolved in 20 m*l* of ethanol. The mixture was refluxed for 13 hr, and then poured into ice-cold water. The resulting crystals were collected by filtration, washed with cold water, and recrystallized from ethanol-water. Yield 15 g (86%).

α-Aminobutyric-4-d_3 *Acid*: The deuterated ethyl acetamido (ethyl)malonate was hydrolyzed and decarboxylated by refluxing with 100 m*l* of concentrated hydrochloric acid for 7 hr. The mixture was concentrated to dryness. The residue was dissolved in a small amount of aqueous ethanol and 15 m*l* of pyridine was added dropwise to the solution. By filtration of the precipitate, 3.8 g (57%) of the crude crystals was obtained. It was recrystallized from hot 96% ethanol.

Proton Magnetic Resonance. Proton magnetic resonance of DL-α-aminobutyric-4-d_3 acid, $CD_3CH_2CH(NH_3^+)COO^-$, was observed in D_2O solution by the use of a Varian HA-100 spectrometer. The concentration of the sample was again about 15%. The temperature of the sample solution was controlled with a Varian V6040 Controller.

Results and Interpretations

Raman spectrum of DL-α-aminobutyric acid in its aqueous solution (15%) is shown at the top of Fig. 2 and also of Fig. 3. Raman spectra of the same amino acid in its crystalline states (crystal B, complex with $CaCl_2$, and crystal A) are given in the lower part of Fig. 2. Infrared absorption spectra of the aqueous solution and crystals are given (with absorption upward) in Fig. 3. The infrared spectra of the three crystals given here are all what were observed at about −180°C (with liquid nitrogen). By comparing the Raman spectra of the three crystals with one another, many of the Raman lines can be assigned to the T, G_a, or G_b form molecule. By a similar comparison of the infrared spectra, the assignments of the absorption bands are also made. In addition, by comparing the Raman and infrared spectra, it is shown that each of the broad Raman peaks of crystal A at 650, 770, 875, 1050, 1120, 1170, and 1270 cm^{-1} must consist

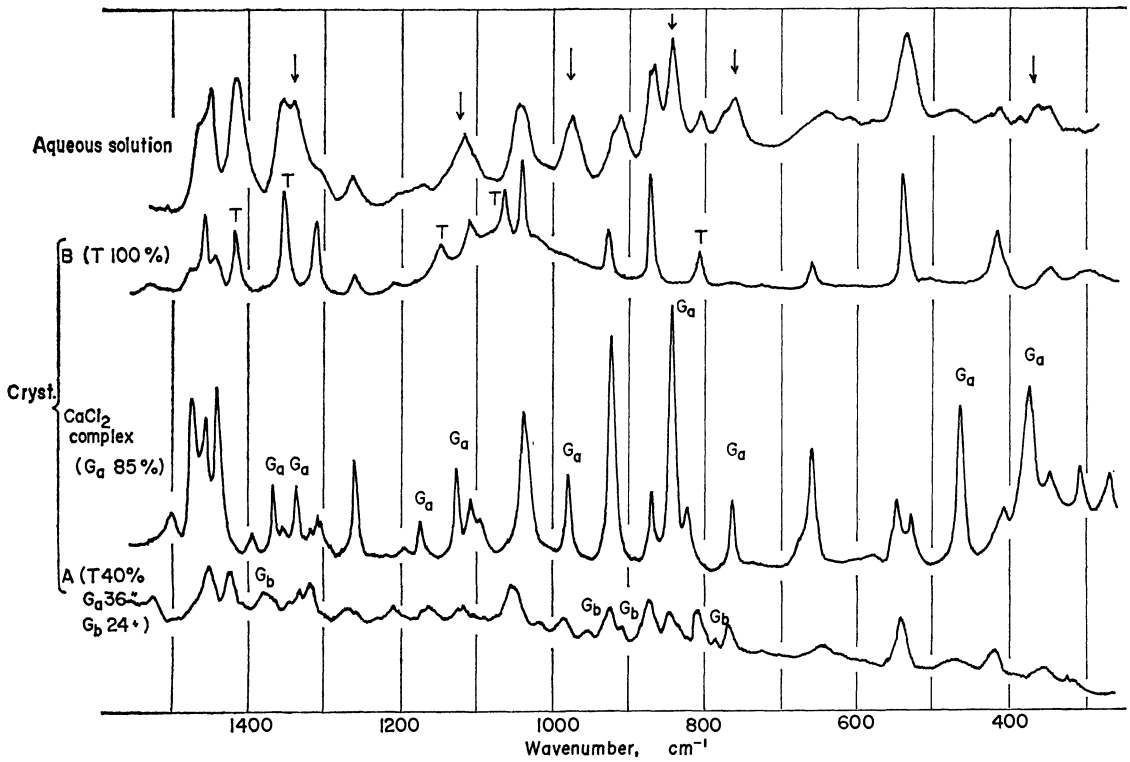

Fig. 2. Raman spectra of DL-α-aminobutyric acid in aqueous solution (top) and of three crystals: B-form, $CaCl_2$-complex, and A-form.

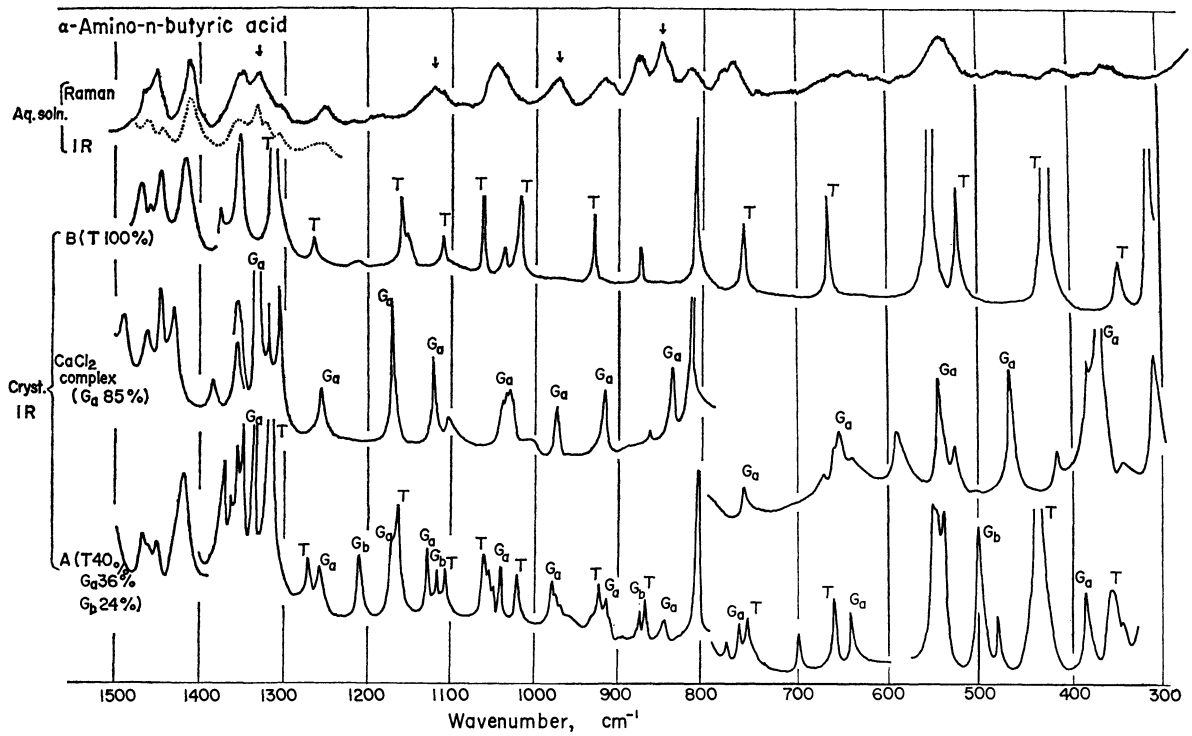

Fig. 3. Raman and infrared spectra of DL-α-aminobutyric acid in aqueous solutions (top) and infrared spectra of three crystals: B-form, $CaCl_2$-complex, and A-form.

of T, G_a, and/or G_b lines. The assignments of the Raman lines and infrared bands to the T, G_a, and G_b forms are given in Figs. 2 and 3. The appearance of strong Raman lines at 765, 843, 970, 1120, and 1340 cm^{-1} (indicated by arrows in Fig. 2) suggests that the G_a form is predominant in the aqueous solution at room temperature. A strong infrared band at 1340 cm^{-1} and a weak Raman line at 375 cm^{-1} give a support to this idea.

Proton magnetic resonance spectrum (Fig. 4) of deuterated α-aminobutyric acid ($CD_3CH_2CH(ND_3^+)COO^-$) in D_2O solution, gives its methylene (AB)

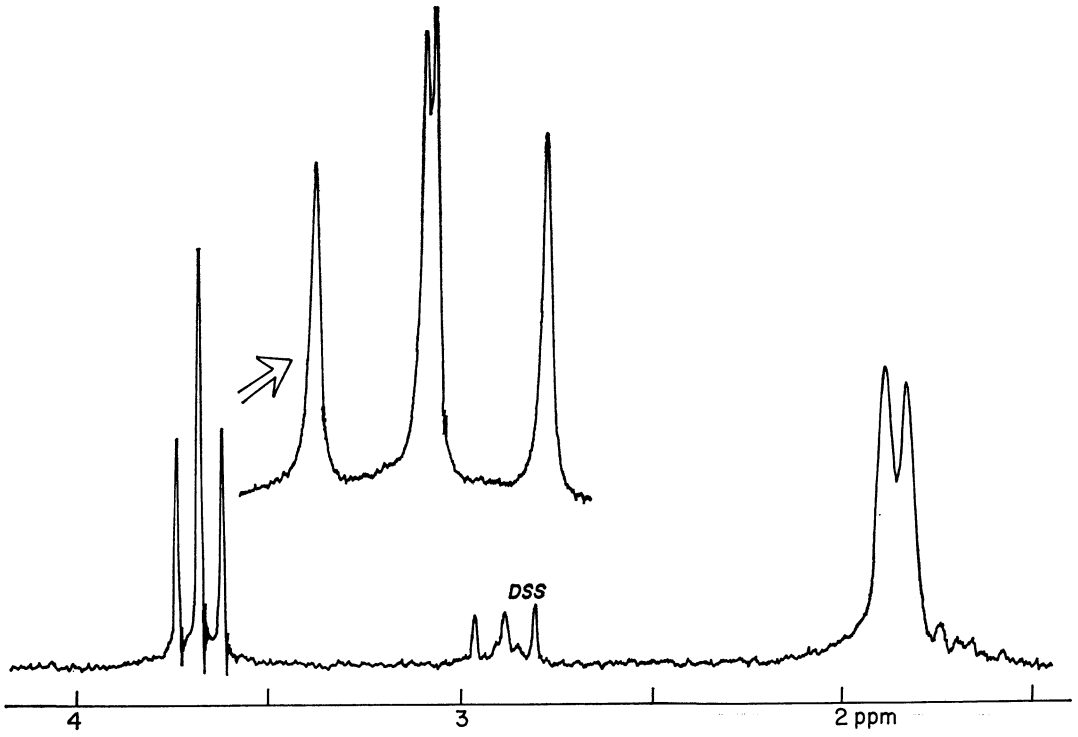

Fig. 4. Magnetic resonance signal of the proton on the α-carbon in α-aminobutyric acid-4-d_3 in D_2O solution.

signal (doublet) at 1.85 ppm (from internal DSS[5]) and the signal of the proton on C_α at 3.68 ppm (X). The latter signal consists of four components (see Fig. 4) which are caused by coupling with the methylene protons. Each value of the coupling constants J_{AX} and J_{BX} cannot easily be determined from the spectrum, but the value of $|J_{AX}+J_{BX}|$ can be determined by measuring the separation between the outermost peaks. As is shown in Table 1 and in Fig. 5, this value was found to change slightly but appreciably with the temperature of the solution.

Table 1. Vicinal coupling constants in α-aminobutyric acid-4-d_3 and the population of G_a form

Temperature °C	$J_{AX}+J_{BX}$ Hz	$\alpha(G_a)$	K	ΔF kcal/mol
−1.5	11.70	0.407	1.37_2	−0.165
8.5	11.82	0.396	1.31_1	−0.152
34	11.92	0.387	1.26_3	−0.142
46.5	11.99	0.381	1.23_1	−0.132
69	12.00	0.380	1.22_5	−0.136
91	12.04	0.376	1.20_5	−0.135

The temperature effect of the $|J_{AX}+J_{BX}|$ value is attributable to a conformational change of the amino acid in the aqueous solution. The fact that the $|J_{AX}+J_{BX}|$ value *increases* with the temperature indicates that G_a form is the most stable form among the three postulated rotational isomers. Thus, in form G_a both of the methylene C-H bonds are at gauche positions with respect to the C_α–H bond around the C_α–C_β axis, whereas in forms T and G_b one at trans and the other at gauche positions (see Fig. 1). As is now well known, the vicinal coupling constant (J_g) is much smaller when the H–C–C–H system is in a gauche form than that (J_t) when it is in a trans form. Therefore, the $|J_{AX}+J_{BX}|$ value should be smaller for G_a form than that for T or G_b form, and the fact that this value increases with the temperature should mean that the population of form G_a decreases and those of form T and/or form G_b increase with the temperature.

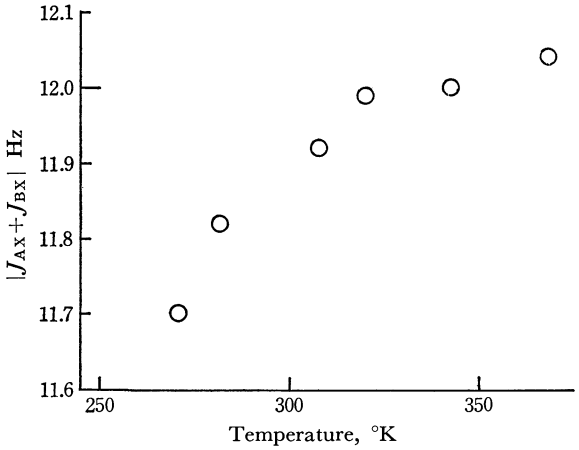

Fig. 5. Temperature dependence of the *vicinal* coupling constants in α-aminobutyric acid-d_3.

If, according to Pachler,[6] the J_g and J_t values are assumed to be 2.60 and 13.56 Hz, respectively, then the mole fraction $\alpha(G_a)$ of G_a form molecules can be calculated by an equation,

$$\alpha(G_a) = [(J_t+J_g) - |J_{AX}+J_{BX}|]/(J_t-J_g) \cdot$$
$$= (16.16 - |J_{AX}+J_{BX}|)/10.96 \quad (1)$$

5) DSS=Sodium-2,2-dimethyl-2-silapentane-5-sulfonate.

The equilibrium constant K between G_a form and the other two forms is given as

$$K = \alpha(G_a) \Big/ \frac{[1-\alpha(G_a)]}{2}. \quad (2)$$

Here, it is tentatively assumed that T and G_b forms have always equal populations to each other. The $\alpha(G_a)$, K and ΔF (free energy difference) values calculated from the $|J_{AX}+J_{BX}|$ value at each temperature are given in the last three columns of Table 1. The energy difference ΔE between the G_a form and the other two forms is to be estimated as usual from the slope of the $\ln K$ *versus* $1/T$ curve. As may be seen in Fig. 6, the $\ln K$-$1/T$ plot does not result in a straight line. This fact may be interpreted as indicating that the ΔE value depends on the temperature. It is also possible, however, that this dependence is merely an apparent one which is caused by neglecting the free energy difference of the T and G_b forms. The apparent ΔE value is obtained as $\Delta E = -0.4$ kcal/mol at 20°C and $\Delta E = -0.2$ kcal/mol at 50°C.

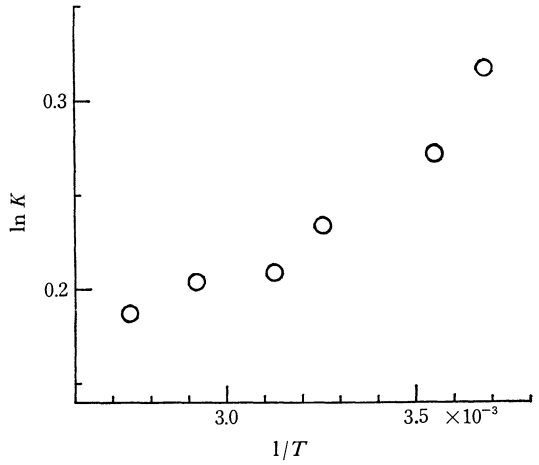

Fig. 6. Natural logarithm of the equilibrium constant K (see Eq. 2) plotted against $1/T$.

Discussion

Rotational isomerism of α-aminobutyric acid in aqueous solution was previously studied by Pachler.[6,7] He drew a conclusion that all of the three isomers have almost equal residence times to one another at about 30°C. This conclusion, however, was based upon the results of his NMR examination of an alkaline and an acidic solutions, while our present study was made of a neutral solution. In addition, he obtained only an approximate (±0.5 Hz) vicinal coupling constant of the CH_2–CH system. A more precise NMR study of undeuterated α-aminobutyric acid should involve a rather elaborate A_3MNX treatment for the CH_3CH_2CH system. Even if a decoupling experiment were done, this would not provide coupling constant values with an accuracy of ±0.02 Hz.

To overcome the difficulties, we have deuterated the methyl group of this amino acid in our present study. The NMR of the CH_2CH group can now be treated as an ABX problem. A precise value of $|J_{AX}+J_{BX}|$ can now be obtained, and a detailed discussion of the temperature effect on this value is now significant. We have also obtained in our present study a quite independent set of data—*i.e.* the vibrational spectrum.

As has been described above, our present NMR study clearly indicated that G_a form is the most stable among the three rotational isomers. Both of our NMR and Raman data showed that, in a neutral aqueous solution at room temperature, G_a form molecules are most abundant. From the NMR data, the mole fraction of G_a form has been estimated to be 0.387 which is only slightly greater than 1/3. It should be pointed out here, however, that this figure is based upon an assumption that every proton in the CH_2–CH system in every rotational isomer is located at an exact trans or an exact gauche position with respect to another proton, so that the proton-proton coupling constant should be 13.56 or 2.60 Hz. It is not improbable that the actual rotational isomers take conformations somewhat deviated from such "standard" conformations. For such deviated conformations, the effective J_t value would be slightly smaller than 13.56 Hz and the effective J_g value would be slightly greater than 2.60 Hz. If so, $\alpha(G_a)$ should be estimated (Eq. (1)) to be somewhat greater than 0.387.

One might be puzzled by our present conclusion that G_a form is the most stable among the three possible rotational isomers, because this form should undergo the strongest intramolecular steric repulsion. The steric repulsion between the methyl group and the carboxyl and/or amino group looks certainly a factor of making G_a form less stable. Thus, when the methyl group is substituted by the OH group (which is smaller than CH_3) the population of G_a form becomes greater (0.61 at room temperature[8]). When the methyl group is substituted by the carboxyl or SH group (which is greater than CH_3), on the other hand, the population of G_a form becomes smaller (0.22 for L-aspartic acid and 0.38 for L-cystein[6,7]). For all of these amino acids, however, it is necessary to postulate a factor which makes G_a form more stable. It is not likely that this factor is related with the electric dipole moment of the molecule or with an electrostatic interaction within the molecule, because the position of the methyl group should not cause great change in the dipole moment or in the electrostatic interaction. It is probable that the factor is related with the extent to which the water structure is disturbed by bringing the amino acid molecule into water. Perhaps it is worthwhile to point out here that G_a form is the most globular among the three rotational isomers. A preliminary examination of a space-filling model has indicated that the largest and smallest radii of the molecule are respectively 6.8 and 5.2 Å in G_a form whereas they are 7.2 and 4.4 Å in both T and G_b forms.

In the present study we could estimate only the

population $\alpha(G_a)$ of G_a form but could not estimate those of T and G_b forms. The latter would be possible if we can deuterate selectively one of the two hydrogens on the β-carbon. An NMR spectrum of such a deuterated product $CD_3CHDCH(NH_3^+)COO^-$ should give J_{AX} or J_{BX} value.

The Measurement of Reaction Rates under Pressure by using a Manganin Pressure Gauge

Takashi MORIYOSHI

Department of Chemical Engineering, Faculty of Engineering, Tokushima University, Minamijōsanjima-cho, Tokushima

(Received December 28, 1970)

An apparatus capable of following reaction rates under pressure without sampling has been designed and constructed. The pressure change due to the progress of a reaction in a closed system could be accurately measured to about 0.08 atm by means of a "fixed bridge" combined with a manganin pressure gauge, in which the unbalanced e.m.f. generated at a constant bridge current was potentiometrically determined to 0.1 μV. The rates of the acid-catalyzed inversion of sucrose and the base-catalyzed decomposition of diacetone alcohol, with the expansion in volume and the contraction respectively, were measured in order to verify the applicability of this apparatus. The agreement between the results obtained by this method and those obtained by the analytical method was satisfactory. From these results, it has been confirmed that the method is sufficiently applicable to the measurement of reaction rates under pressure.

The techniques for measuring reaction rates under pressure may be generally classified into two kinds. One is the method usually employed, which requires the sampling of the reaction mixture for analysis with or without the release of pressure, while the other is that which immediately determines the reaction rates without any sampling by following the change in the physical properties of the reaction mixture due to the conversion. The latter method is essentially restricted in the range of its application by the character of the measured reaction, but if a suitable means of following the change is found, then it becomes very useful. A conductance method is typical of this kind of means and has been employed conveniently for the measurement of the rates of several solvolyses under pressure.[1] The technique of following the rate by using a manganin pressure gauge, which is called the piezometric method (or occasionally the dilatometric method), is of the same kind and has recently been used by several workers in studying some liquid-phase reactions.[2-4] Since this method involves measuring the pressure change caused when the reaction takes places in a closed pressure vessel, the desired accuracy should be insured in the measurement of the pressure.

As was pointed out by Withey and Whalley,[3] the pressure change caused by the reaction results in a change in the rate constant, a change dependent on the magnitude of the volume of activation, therefore, the extent of pressure change during the kinetic measurement, which may be allowed for measuring the rate constant with the same accuracy, is entirely limited by the absolute value of this parameter, being small for the reaction with a large value, but large for that with a small one. For instance, in order to obtain the rate constant with an accuracy of 1 per cent for the reaction whose volume of activation is ± 5 cm^3/mol, the total pressure change measured must be less than 50 atm; hence, it is desired that the sensitivity of the pressure in the measurement is greater than 0.5 atm.

The "fixed-bridge" method has been employed in the present work because it is most suitable for measuring by means of a manganin gauge coil, the resistance change dependent on such a small pressure change. This method, first employed by Adams *et al.*,[5,6] is essentially based on the measurement of the unbalanced electromotive force (e.m.f.) generated in a Wheatstone bridge with four fixed arms and containing the gauge coil when at a constant bridge current; it is more accurate than directly measuring the resistance change itself. Withey and Whalley[3] also adopted the same method in principle and made an apparatus capable of measuring the pressure change automatically. The measurements of the e.m.f. in this work were carried out with a potentiometer in order to determine exact absolute values comparable

with those estimated theoretically.

The present paper will describe a technique for following the reaction rate piezometrically and will present some results obtained for the acid- and base-catalyzed reactions under pressure.

Apparatus

A schematic diagram of the high-pressure apparatus used is shown in Fig. 1. It consists principally of four components: a pressure vessel, a manganin pressure gauge, a Bourdon gauge, and a high-pressure hand-operated pump. The pressure vessel, with a capacity of about 180 cm^3, was a cylinder made of SUS-27 stainless steel, 11 cm in diameter and 24 cm in length; it was sealed by means of an O-ring, with a back-up ring made of Teflon. The reaction vessel was a hypodermic syringe with a Teflon plug, with a capacity of about 90 cm^3; it was put in a pressure vessel filled with silicone oil as the pressure-transmitting fluid. The manganin pressure gauge used was that made by the Harwood Engineering Co., Inc.; it consisted of two non-inductively would manganin coils which both had 120±0.1 ohm resistance at atmospheric pressure. The one was a pressure-active coil which had a pressure coefficient of 2.446×10^{-6} atm^{-1}; it was exposed to the pressure system, but was enclosed by a bronze bellows filled with methyl butane in order to isolate it from the pressure fluid. The other, a compensating coil, was located in the cap of the gauge cell. These coils were connected in series to form a Wheatstone bridge with two other precise resistance coils.

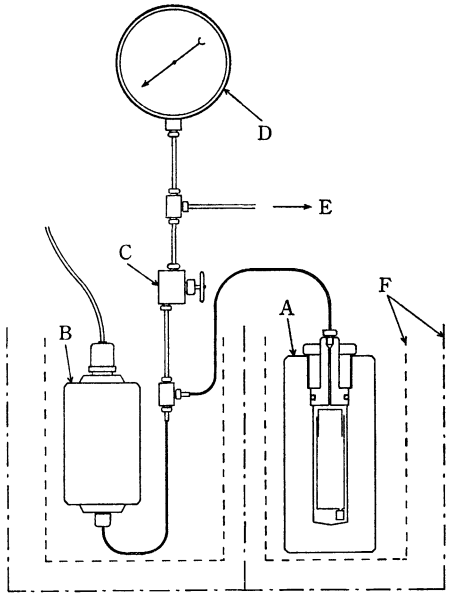

Fig. 1. Schematic diagram of the high pressure apparatus.
A: Pressure vessel, B: Manganin pressure gauge, C: Valve, D: Bourdon gauge, E: Pressure pump, F: Thermostat.

The pressure vessel and the manganin gauge were separately immersed in each thermostat, which was doubly thermostatted and was capable of controlling the temperature to 0.001°C; its temperature was measured to 0.001°C by means of a precise Beckmann thermometer. It has been found that the pressure coefficient of the resistance of manganin may actually be regarded as a function of the temperature and that it increases by about 2×10^{-2} of itself for each degree the temperature rises at 0—70°C.[6] Hence, the manganin gauge in the present work was maintained near 30°C for over a year for ease in controlling; the resistance of manganin was thus relatively less sensitive to the temperature change, because the temperature coefficient of manganin becomes zero in the vicinity of room temperature.[6,7] The connection between the pressure vessel and the manganin gauge was made through a junction of stainless steel tubing 1/8 inch in outer diameter and 0.024 inch in inner diameter in order to make the volume of the unthermostatted part as small as possible. During the measurement of the reaction rate, their components were isolated from the Bourdon gauge and the pressure pump by shutting a valve, as is shown in Fig. 1. Pressure was directly applied by means of the pressure pump and was measured with an accuracy of 7 atm by means of a Heise Bourdon gauge, which was calibrated up to 1400 atm from time to time against a pressure balance made by the American Instrument Co., Inc. The resistance change of the gauge coil caused by the pressure change in the closed system was measured by means of the "fixed-bridge" method.[5,6] The arrangement is shown schematically in Fig. 2, in which R_1 and R_2 represent the active and the compensating coils respectively; these coils are mounted in the gauge cell. R_3 and R_4 are both precise resistance coils of 100±~1 ohm. A constant current through the bridge was supplied by a Takasago model GPO 50-2 DC power supply and was finely adjusted. The unbalanced e.m.f. was measured to 0.1 μV by means of a Yokogawa model P-7 potentiometer.

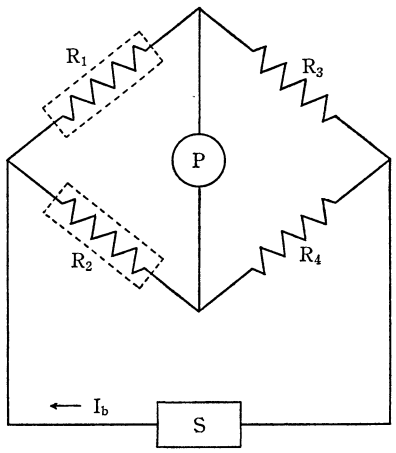

Fig. 2. The "fixed bridge" arrangement.
P: Potentiometer, S: DC power supply.

Fundamentals of Measurement

In the bridge arranged as in Fig. 2, the resistance change, ΔR, with the pressure, P, of the gauge coil,

7) H. E. Darling and D. H. Newhall, *Trans. Amer. Soc. Mech. Engrs.*, **75**, 311 (1953).

R_1, generates across the bridge at a constant current, I_b, an unbalanced e.m.f., E_p, expressed by:

$$E_p = \frac{(R_1 \cdot R_4 - R_2 \cdot R_3 + R_4 \cdot \Delta R) I_b}{R_1 + R_2 + R_3 + R_4 + \Delta R} . \quad (1)$$

Assuming that the pressure coefficient, α, of the gauge coil has no appreciable change over the whole range of applied pressures, ΔR at a constant temperature is given by:

$$\Delta R = \alpha \cdot R_1 \cdot P . \quad (2)$$

Since the ΔR for the coil used of 120 ohm, as estimated from Eq. (2), is only a few ohm even at 10000 atm, and since it is negligible as compared with the other terms in the denominator on the right hand side of Eq. (1), one can convert Eq. (1) to a relation linear with respect to the pressure by using Eq. (2); that is,

$$E_p = E_1 + \frac{\alpha \cdot R_1 \cdot R_4 \cdot I_b \cdot P}{R_1 + R_2 + R_3 + R_4} , \quad (3)$$

where E_1 denotes an unbalanced e.m.f. that will develop when $R_1 \cdot R_4 \neq R_2 \cdot R_3$ at atmospheric pressure, E_1 being given by:

$$E_1 = \frac{(R_1 \cdot R_4 - R_2 \cdot R_3) I_b}{R_1 + R_2 + R_3 + R_4} . \quad (4)$$

Thus, it follows that E_p is proportional to only the pressure acting on the gauge coil at a constant bridge current. This suggests that one can follow the reaction with any pressure change under given conditions by measuring the unbalanced e.m.f. instead of the pressure itself. Substituting the numerical value for each term and the one used, 20.00 mA, for I_b into Eq. (3), and assuming that $R_1 \cdot R_4 = R_2 \cdot R_3$, the following equation is obtained as an approximately calculated one:

$$E_p = 1.334 \times 10^{-3} \cdot P, \quad (5)$$

where E_p is given in mV, and P, in atm. To verify Eq. (5), blank experiments when the pressure vessel entirely filled with the pressure fluid and the gauge cell were controlled at 35.00°C and 29.10°C respectively were carried out at pressures up to 2000 atm. Pressures up to 1250 atm were directly measured with an accuracy of about 0.07 atm by means of a pressure balance, and the higher pressures by means of a calibrated Bourdon gauge; the e.m.f. values were determined by averaging those obtained at increasing and decreasing pressures. The results are shown, together with the calculated line given by Eq. (5), in Fig. 3, in which the increment, $E_p - E_1$, dependent on the pressure is conveniently plotted for purposes of comparison. They are almost exactly proportional to the measured pressure of the system, as is expected from Eq. (3). The most reasonable relationship between the unbalanced e.m.f. and the pressure was obtained from the observed data using the method of least squares; it was expressed by:

$$E_p = 0.0139 + 1.320 \times 10^{-3} \cdot P \text{ mV}, \quad (6)$$

The standard deviation from this relationship was found to be 0.0125. The difference in the pressure dependence from Eq. (5) is about 1 per cent; it is not surprising and is, in fact, quite satisfactory considering that E_1 has a small definite value, as is shown in Eq. (6),

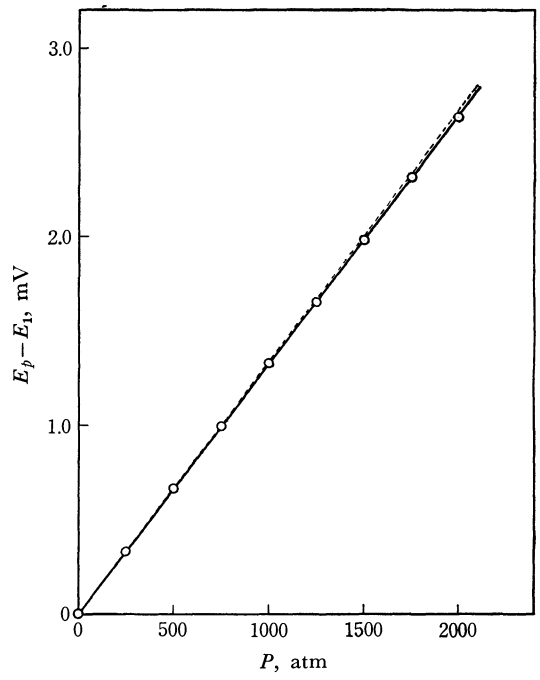

Fig. 3. Relationship between unbalanced e.m.f. and pressure.
Full line: Experimental one.
Dashed line: Calculated one.

because there is a small unbalance ($R_1 \cdot R_4 \neq R_2 \cdot R_3$) between the inherent values of the four resistances at atmospheric pressure. If one assumes that all the resistances have approximately the same extent of error, from which the above difference arises entirely, then the error may be estimated to be ± 0.002 ohm at the most. This value is obviously within the error allowed for their resistances. Otherwise, an uncertainty involved in the pressure coefficient of the gauge coil used must also be considered, but perhaps such a small difference between the pressure dependences of the e.m.f. is predominantly due to the former cause rather than to the latter.

The linearity of the manganin pressure gauge has been well verified from these results; hence, of course, it may undoubtedly be regarded as being established more exactly in a small range of pressure changes (usually below 100 atm) during the actual measurement of the reaction. The potentiometer employed in the present work can be easily read to 0.1 μV, so it is possible to measure the pressure change to 0.08 atm, at least over the pressure range up to a few thousand atmospheres, as was predicted from Eq. (6). Therefore, it is evident that one can determine the reaction rate with a reasonable accuracy by following the e.m.f. change consequent on the pressure change with the progress of the reaction in a closed system.

If a much greater sensitivity is desired in the measurement of the pressure, it may be convenient to place, on opposite sides of the bridge, two gauge coils exposed to the same pressure. When the coils, R_1 and R_4, in the arrangement shown in Fig. 2 are made up of the same material and are both equally subjected to the pressure being measured, one obtains the following approximate equation instead of Eq. (3):

$$E_p = E_1 + \frac{(\alpha_1+\alpha_4)R_1 \cdot R_4 \cdot I_b \cdot P}{R_1+R_2+R_3+R_4}, \quad (7)$$

where α_1 and α_4 are the pressure coefficients of the active coils, R_1 and R_4, respectively. Further, if their coefficients can be taken to be approximately equal to α, then it may be represented by:

$$E_p = E_1 + \frac{2\alpha R_1 \cdot R_4 \cdot I_b \cdot P}{R_1+R_2+R_3+R_4}. \quad (8)$$

Therefore, it follows that the sensitivity in the measurement can be enhanced to 2 times that in the present case when one active coil is used, as is clear from a comparison with Eq. (3).

In the practical measurement of the pressure, it is also necessary to take into account the effect due to the heat of reaction. If the heat evolved by the reaction could not be transferred to the surroundings, the reverse of when it is absorbed, fast enough to retain the isothermal condition, then the temperature of the reaction mixture varies; therefore, the crresponding pressure change must lead to a significant error in the measurement of the reaction rate. Although a theoretical analysis of the thermal effect has been pronounced by Withey and Whalley,[3] it is difficult in general to estimate to what extent the rate constant may be affected because there is no available information on the heat transfer between the reaction mixture and the thermostat in the system concerned. Because such an undesirable effect is essentially dependent upon the amount of conversion in a unit of time under given conditions, it can be experimentally eliminated by seeing whether or not the actually measured rate constants are appreciably affected by varying the concentrations of the reactant and the catalyst or the volume of the reaction mixture, *etc.*

Operation and Determination of the Rate

The reaction mixture, after being prepared, was readily preheated to a temperature somewhat higher than that of the thermostat in order to remove some dissolved air; then it was quietly poured into a glass syringe, from which air had been carefully expelled before it was stoppered with a Teflon plug. The syringe was put into the pressure vessel immersed in the thermostat, and then the vessel was quickly assembled and brought up to the desired pressure by means of the pressure pump. After about 40 min had been allowed for thermal equilibrium and the pressure had been finely adjusted to the required value on the Bourdon gauge, the valve was shut; then the unbalanced e.m.f. across the bridge, through which a constant current was passed, was potentiometrically measured at suitable time intervals. In all runs, an interval of about 2 half-lives of the reaction was taken between the first measuring set and the second one; thus, the obtained e.m.f. data were conveniently analyzed according to the Guggenheim equation:[8]

$$k_1 t + \ln(E_{t+\Delta t} - E_t) = \ln[(E_\infty - E_0)(1 - e^{-k_1 \Delta t})] = \text{constant}, \quad (9)$$

where E's are the observed e.m.f.'s, t is the reaction time and Δt is the time interval. The subscripts 0 and ∞ refer to the start and the equilibrium for reaction respectively. From Eq. (9), the first-order rate constants, k_1, were graphically obtained by plotting $\log(E_{t+\Delta t} - E_t)$ against t. The second-order rate constants, k_a, were calculated by dividing the first-order constants by the concentration of the catalyst used.

Results and Discussion

In order to test the usefulness of this apparatus in the measurement of the reaction rate, two kinds of reactions were chosen. One was the acid-catalyzed inversion of sucrose with a contraction of the volume, and the other was the base-catalyzed decomposition

of diacetone alcohol with, on the contrary, an expansion of the volume.

First, the inversion of sucrose was measured at 25.00°C in aqueous dilute hydrochloric acid which contained initially about 0.5 mol/l of the reactant; here, the total pressure change during the kinetic measurements was in the range of from 9 to 20 atm. A typical curve obtained is shown in Fig. 4, while its Guggenheim plot is shown in Fig. 5. The first-order rate constants, as calculated from similar plots obtained at various pressures, are listed in Table 1, together with the second-order constants.

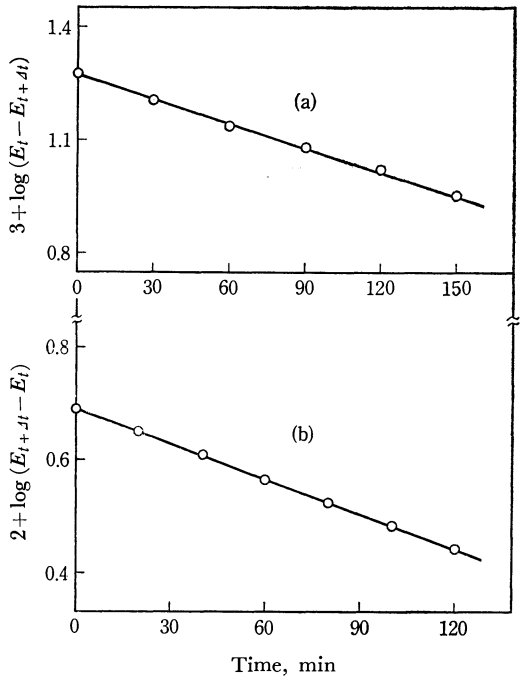

Fig. 5. Guggenheim plots for two e.m.f. data.
(a): Inversion of sucrose.
(b): Decomposition of diacetone alcohol.

The second-order rate constants as a function of the pressure are graphically shown in Fig. 6, together with those calculated from the data of Cohen and de Boer,[10] which were obtained by measurement with a polarimeter. The piezometrically-determined values are less than these by about 15 to 21 per cent, but it is not determined whether such a discrepanct results from the differences in the method of measurement or in the concentration of the acid used (their reaction mixtures were 0.0625 N in hydrochloric acid), or from other causes. The volumes of activation, $\Delta V^{\neq}$, were calculated from the slopes at 1 atm using the usual equation:

$$\left(\frac{\partial \ln k_a}{\partial T}\right)_T = -\frac{\Delta V^{\neq}}{RT}, \qquad (10)$$

where R is the gas constant and T is the absolute temperature. The value determined from the observed data is 6.0 cm³/mol; this is in good agreement with the 5.0 cm³/mol value from the data of Cohen and de Boer and also with the 6.0±~0.3 cm³/mol obtained by Whalley[11] from the same data.

The decomposition of diacetone alcohol as another reaction was measured in an aqueous solution involving initially about 0.4 mol/kg of the reactant and an appropriate amount of sodium hydroxide as a catalyst at 30.00°C and at various pressures. There was a pressure change of from 14 to 40 atm during the kinetic measurements. The results for this reaction are shown, along with those of sucrose, in Figs. 4 and 5. For purposes of comparison, the rates of the same reaction were also measured separately using an analytical method based on the oximation of the carbonyl group with hydroxylamine hydrochloride.[12] Both

rate constants obtained are listed in Table 2; the agreement between them is very satisfactory. The volume of activation obtained from Fig. 7 was almost the same, -6.6 cm^3/ mol, in both cases, and no appreciable difference could be found graphically. The mechanistic consideration of the observed value of $\Delta V^{\neq}$ for this reaction has not been made here, for it is beyond the present purposes, but it will be reported elsewhere. In addition, the rate of the depolymerization of paraldehyde catalyzed by 0.0991 mol/l perchloric acid was found in the same way to be 7.36×10^{-4} l/mol·sec at 35.00°C and 500 atm; this is in good agreement with the 7.12×10^{-4} l/mol·sec obtained by the piezometric measurements of Withey and Whalley.[4]

From some preliminary measurements for each reaction, it might be presumed that all of the results mentioned above were not significantly affected by the heat of reaction during the measurements.

Consequently, it may be concluded that the apparatus and the technique employed in the present work are sufficiently applicable to the rate measurements of any other reaction with a change in volume.

The author should like to thank Mr. H. Ōto for his help in the construction of the high-pressure apparatus and Mr. J. Ōtsubo for his help in the kinetic measurements.

An MO Interpretation of the Chemical Shifts of Inner-shell Electrons

Hiroshi KATO, Kazuhiro A. ISHIDA,* Hiroshi NAKATSUJI,* and Teijiro YONEZAWA*

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

** Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto*

(Received December 31, 1970)

A correlation formula between the chemical shifts of inner-shell electrons and molecular-charge distributions is derived by an MO scheme with CNDO-type approximations. Errors imposed in these schemes are discussed. Reorganization energy terms are briefly discussed in the same level of approximations.

The chemical shifts of inner-shell electrons have been studied in a wide variety of organic and inorganic compounds.[1,2] One interesting feature of the problem is that the chemical shifts change linearly with the charges on the atoms considered. These charges have been estimated by several methods-i.e., methods with using the oxidation number and Pauling's electronegativity differences,[1,3] an iterative extended Hückel method,[4] CNDO method,[5] and several types of non-empirical calculations.[6-11]

In this report, an MO interpretation of the correlation between the chemical shifts of the binding energies of inner-shell electrons in certain molecules and the atomic charges is given by introducing some approximations, and the limitations of these relations are briefly discussed.

Theoretical

By Roothaan's SCF treatment for closed-shell systems, the orbital energy of ith MO, ε_i, is given by:

$$\varepsilon_i = F_{ii} = \sum_{r,t} C_r{}^i C_t{}^i F_{rt} \qquad (1)$$

Where C_r^i and F_{rs} are the rth AO coefficient of the ith MO and the F_{rs}-element of the Fock operator respectively.

Suppose that the ith MO is mainly constructed by inner-shell AO's; the following derivation can then be easily carried out with considerable accuracy, since the diagonal elements of the Fock operator for inner-shell AO's, F_{ss}, is very large compared with that of the off-diagonal ones F_{rs}:[12,13]

$$\varepsilon_i \simeq \varepsilon_s = F_{ss}, \qquad C_s^i \simeq 1.0, \tag{2}$$

$$F_{ss} = \left(s\left|-\frac{1}{2}\Delta-\frac{Z_A}{r_A}\right|s\right) + \left(s\left|-\sum_{B\neq A}\frac{Z_B}{r_B}\right|s\right) + \sum_{r,t} P_{rt}\left\{(ss/rt)-\frac{1}{2}(sr/st)\right\}. \tag{3}$$

In Eq. (3), the first term is the self-core integral, while the second is the nuclear attraction by the other nuclei and the third consists of electronic repulsions. Throughout this report, r, s, t, and u denote atomic orbitals; especially, s denotes the inner-shell AO in question belonging to the A atom. The i and j notations represent occupied MO's, and k and l, vacant ones. The P_{rt} notation is the bond order between r and t AO's.

To connect the orbital energies with the atomic charges, we use the following approximation, using the same notations as in Refs. 14 and 17:

(A), The self-core integral:

$$\left(s\left|-\frac{1}{2}\Delta-\frac{Z_A}{r_A}\right|s\right) = -I_s - (N_s-1)(ss/ss) - \sum_{r}^{\text{on A}} N_r\left\{(ss/rr)-\frac{1}{2}(rs/rs)\right\} \tag{4}$$

and the nuclear attraction:

$$\left(s\left|-\frac{Z_B}{r_B}\right|s\right) = -Z_B(ss/ns_Bns_B) = -Z_B\gamma_{AB}. \tag{5}[15]$$

The above formulae have already been given in a previous paper.[14] (B), The electronic repulsion integrals can be estimated by a CNDO-type approximation[17]:

Thus, Eq. (3) can be re-written as:

$$F_{ss} = -I_s + (P_{AA}-Z_A^{\,v})\gamma_{AA} + \sum_{A\neq B}(P_{BB}-Z_B^{\,v})\gamma_{AB}, \tag{6}$$

where the average Coulomb integrals are:

$$\gamma_{AA} = (ss/ns_Ans_A), \qquad \gamma_{AB} = (ss/ns_Bns_B), \tag{7}$$

and where $Z_A^{\,v}$ denotes the number of valence electrons on the A atom and ns_A denotes valence s-type AO on the A atom.

When a Mulliken approximation with in Eq. (7) is used instead of the above CNDO-type one, and only the term of S(overlap) is considered, an expression similar to that in Eq. (6) is obtained, but in this case the P_{AA}'s in Eq. (6) become atomic populations.

From Eq. (6), the following simplified relation can be obtained by denoting $(P_{AA}-Z_A^{\,v})=-Q_A$ (Q_A is the net charge of atom A):

$$\Delta\varepsilon_s = \varepsilon_s + I_s = -Q_A\gamma_{AA} - \sum_{B\neq A} Q_B\gamma_{AB}. \tag{8}[18]$$

That is, the shift of the inner-shell binding energy from the atomic ionization energy in certain valence state is correlated with the molecular-charge distribution. The shift of the $\Delta\varepsilon_s$ for the A atom in different chemical environments, which are denoted as X and Y, is:

$$\delta\Delta\varepsilon_s(X,Y) = \{Q_A(X)-Q_A(Y)\}\gamma_{AA} - \sum_{B\neq A}^{\text{in Y}} Q_B(Y)\gamma_{AB}(Y) + \sum_{B\neq A}^{\text{in X}} Q_B(X)\gamma_{AB}(X). \tag{9}$$

Eq. (9) indicates that the chemical shifts depend not only on the atomic-charge differences of the A atom in different molecules, but also on the sum of the charges over the other parts of the molecules, since the γ_{AB}/γ_{AA} ratio is not negligibly small. For diatomic molecules of the first-row elements, AB and A_2, $\delta\Delta\varepsilon_s$-(AB, A_2)=0.5, if $Q_A(AB)=-Q_B(AB)=1.0$, $\gamma_{AA}(AB)=1.0$, and $\gamma_{AB}(AB)=0.5$ (in a.u.).[20] The change in the inner-shell binding energy between the molecules is about 14 eV per unit charge. This is in agreement with the previous results.[19]

Results and Discussion

Tables 1 and 2 summarize the values of some atomic integrals involving the $1S_C$ AO of formaldehyde (in a.u.). By means of these tables we can examine the approximations Eq. (5), and (B). Minimal Slater bases with Slater-rule exponents, except for that of 1.2 for hydrogen, are used throughout the calculations in the present paper. The integrals are evaluated by means of the 4-term Gaussian expansion method.[20]

As shown in Table 1, the approximation introduced

a) The z axis is taken to be paralled with the C-O bond.

in Eq. (5) is good. Table 2 indicates that the "average Coulomb" approximation is excellent for one-center integrals and is only correct to within about a 10% error for two-center ones. The two-center Coulomb and hybrid integrels, $(1s_A1s_A/2s_B2p_B)$ and $(1s_A1s_A/2s_A2p_B)$ types, however, are not negligible; therefore, the (B) approximation, *i.e.*, the CNDO-type integal which neglects the above type of integrals, may be bad in certain cases where the corresponding off-diagonal elements of the bond-order matrix are not negligible.

a), b), c) They are the same as in Table 3.
d) Calculated as anion.
e) The values in parenthesis are evaluated by non-empirical gross atomic charges in stead of CNDO/2 net charges in Eq. (9). These gross charges have been given in references; R. Bonaccorsi, C. Petorngolo, E. Scrocco, and J. Tomasi, *J. Chem. Phys.*, **48**, 1497, 1500 (1968); E. Clementi, *ibid.*, **46**, 4731 (1967); W. E. Palke and N. N. Lipscomb, *J. Amer. Chem. Soc.*, **88**, 2384 (1966).

The results calculated by means of Eq. (9) are collected in Tables 3 and 4 for carbon 1s and nitrogen 1s electrons respectively; they are all shown in Figs. 1 and 2 except for anions. Figures 1 and 2 indicate a rather satisfactory correlation between the observed chemical shifts and the values of $\delta\Delta\varepsilon_s$. The solid lines in Figs. 1 and 2 are inclined about 45°; therefore, it seems that the chemical shifts can be evaluated semi-quantitatively in terms of the $\delta\Delta\varepsilon_s$ in neutral molecules, and that a relation between the molecular-charge distributions and the observed shifts may be in the form of $(Q_A\gamma_{AA}+\sum_{B\neq A}Q_B\gamma_{AB})$. For the anious containing

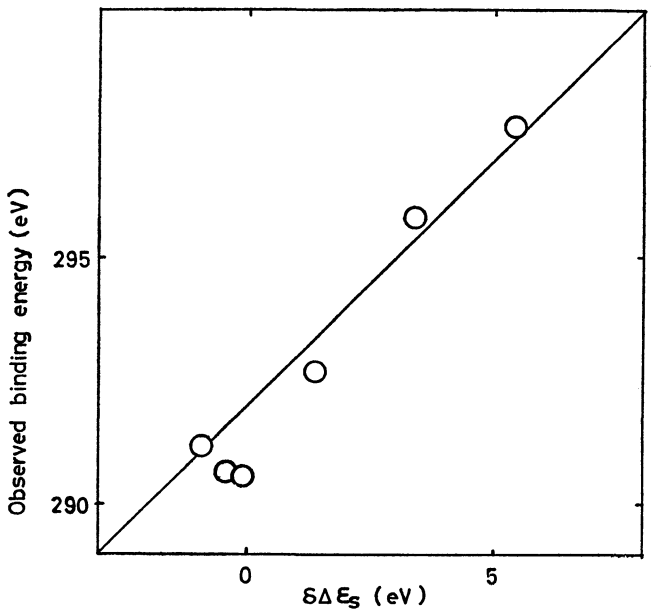

Fig. 1. The observed binding energies of carbon 1s electron plotted against the $\delta\Delta\delta_s$'s.

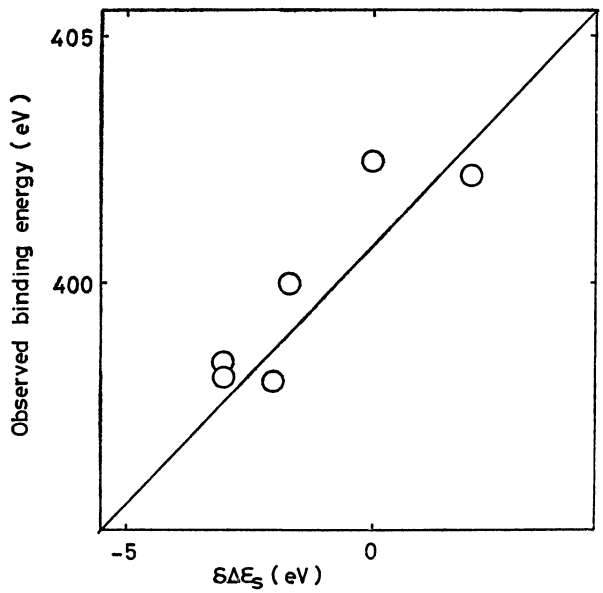

Fig. 2. The observed binding energies of nitrogen 1s electrons plotted against the $\delta\Delta\varepsilon_s$'s.

nitrogen atoms, the above rather good correlation is not observed; that is in these charged species, the crystal effects may be considerable.[5]

It is noticed that the values of ε_s obtained by Roothaan's closed-shell treatment are generally larger than those of the binding energy observed at about 10—20%, and open-shell SCF calculations give better results, as has been pointed out by several authors[7-11,13,21,22]. Further it has been suggested that the main effects of these discrepancies depend on the reorganization energy.[19]

Now, let me examine the reorganization energy in the above approximation scheme. Suppose that MO's i and j are given by Roothaan's closed-shell treatment. Using these MO's, an open-shell wave function with an s hole ($S_z=1/2$), is obtained approximately by a CI scheme;

$$\begin{aligned}\Phi_s{}^0 = {} & |si\bar{i}\cdots jj\bar{j}| + \sum_{j(\neq s)}^{\text{occ.}} \lambda_{is}|s\bar{s}i\bar{i}\cdots j| + \sum_{k}^{\text{vac}} \lambda_{sk}|ki\bar{i}\cdots jj\bar{j}| \\ & + \sum_{j(\neq s)}^{\text{occ}} \sum_{k}^{\text{vac}} \lambda_{jk}(1)\{|si\bar{i}\cdots jk\bar{k}| - |s\bar{i}i\cdots jk\bar{k}|\} \\ & + \sum_{j(\neq s)}^{\text{occ}} \sum_{k}^{\text{vac}} \lambda_{jk}(2)\{2|\bar{s}ii\cdots jk| - |si\bar{i}\cdots j\bar{k}| - |s\bar{i}i\cdots \bar{j}k|\}. \end{aligned} \tag{10}$$ [23]

That is, $\Phi_s{}^0$ is an approximate open SCF function[24] and λ_x is the coefficient of a related configuration, x. By perturbation treatment, these are[25];

$$\begin{aligned} \lambda_{js} &= F_{js}/E_{js} = 0, \qquad \lambda_{sk} = \frac{(ks/ss)}{E_{sk}}, \\ \lambda_{ik}(1) &= \frac{\sqrt{2}\{(ik/ss) - (1/2)(is/ks)\}}{E_{ik}(1)}, \\ \lambda_{ik}(2) &= \frac{-\sqrt{3/2}(is/sk)}{E_{ik}(2)}. \end{aligned} \tag{11}$$

Where E_{sk} is the energy difference between the energy of the $s\rightarrow k$ excited configuration, as shown in Eq. (10), and the ground-state configuration, and so on.

Then, the energy, $E_s{}^0$ becomes;

$$\begin{aligned} E_s{}^0 = (E_0 - \varepsilon_s) + \sum_k \frac{(ks/ss)^2}{E_{sk}} + \sum_{k,i\neq s} \frac{2\{(ik/ss) - (1/2)(is/ks)\}^2}{E_{ik}(1)} \\ + \sum_{k,i\neq s} \frac{\{-\sqrt{3/2}(is/ks)\}^2}{E_{ik}(2)} + \cdots \end{aligned} \tag{12}$$

That is, the reorganization energy is $E_s{}^0 - (E_0 - \varepsilon_s)$, and the dominant contribution comes from the third term, since $E_{sk} \sim \varepsilon_k - \varepsilon_s$(large), $E_{ik}(1) \sim {}^1E_{ik}$ (valence shell $i\rightarrow k$ singlet excitation energy for a closed-shell system, small), and $(ik/ss) \simeq C_r{}^i C_r{}^k (rr/ss)$ is large, and (is/ks) is small as is shown in Table 2.

The magnitude of the third term can be roughly estimated as; E_{sk} (1) $\sim$0.5 a.u., (rr/ss) $\sim$1 a.u., and $\varepsilon_s \sim$10 a.u.; hence, (the third term)$/\varepsilon_s$ $\sim 10^{-1}$ [26]. This order is reasonable when it is compared with the previous results, 10$\sim$20%.[10,13,19,27]

These results indicate that the third part is the most important in reorganization energy. Further, this third term can be approximated:

$$\sum_i \sum_k \frac{2\{\sum_r C_r{}^i C_r{}^k (rr/ss)\}^2}{E_{ik}(1)} \sim \sum_{\text{B}}^{\text{all on B}} \sum_r p_{rr}(2 - p_{rr}) \frac{(\gamma_{\text{AB}})^2}{2E_{\text{aV}}}$$

Where E_{aV} is the average excitation energy.

That is, the reorganization energy is not a linear function for the atomic charges.

As to the other corrections for inner electron binding energies, that is, the correlation correction,[13,28] the relativistic correction[29] and the crystal correction,[3,30] it can be pointed out that these are negligible or are proportional to the charges.

As has been shown in the above discussion, the linear relation between the charges and the inner-shell binding energy is restricted within the imposed approximations; thus, in some cases, this linearities may depend on the cancellations of various effects. We hope this point will be reexamined in the future.

The calculations have been carried out on the FACOM 230—60 Computer of Kyoto University.

Stochastic Formulation of Entropy Production due to Second-Order Reaction

Kenji ISHIDA

Department of Applied Chemistry, Ibaraki University, Hitachi, Ibaraki

(Received January 11, 1971)

Entropy production, originated from an ideal gas second-order reaction taking place in a closed system, has been stochastically formulated by defining the entropy in a form similar to the conditional entropy used in the theory of information. The entropy is introduced in the natural way as a result of the partial factorization of joint probability for reaction states devised for the approximate solution of the stochastic process of the second-order reaction. The entropy production has also been discussed in comparison with the usual one.

The stochastic nonequilibrium thermodynamics of reaction systems can be studied by the correlation of probability to entropy on the proposition that chemical reaction is a random process. The author has stochastically discussed the nonequilibrium thermodynamics for first-order reactions in closed and open systems.[1] It has been assumed that the entropy change $\Delta_i S$ due to a chemical reaction is of Gibbsian type, *viz.*,

$$\Delta_i S = -k \sum_{\boldsymbol{n}} P(\boldsymbol{n};\ t)\ln[P(\boldsymbol{n};\ t)/P(\boldsymbol{n};\ \infty)] \qquad (1)$$

or

$$S = -k\langle \ln[P(\boldsymbol{n};\ t)/P(\boldsymbol{n};\ \infty)]\rangle + S_e, \qquad (1')$$

where k is Boltzmann's constant, $P(\boldsymbol{n};\ t)$ the probability distribution for the set $\boldsymbol{n}=\{n_\gamma\}$ of all the numbers of molecules of reacting species γ's at time t, $P(\boldsymbol{n};\ \infty)$ the corresponding equilibrium probability distribution, $\Delta_i S=S-S_e$ (S_e is the entropy for the equilibrium probability distribution) and the angular brackets denote the average over all possible reaction states.

As an example, we consider the reaction A⇆B. The probability distribution for reaction states is given by the binomial distribution $P(\boldsymbol{n};\ t)=(n!/\prod_\gamma n_\gamma!)\prod_\gamma \{p_\gamma(t)\}^{n_\gamma}$, in which $n=\sum_\gamma n_\gamma$ (γ=A, B) is the total number of molecules and $p_\gamma(t)$ the probability for a molecule of reacting species γ to be found in the reaction system. According to Eq. (1), the entropy change can be written as

$$\begin{aligned}\Delta_i S &= -k \sum_\gamma \langle n_\gamma\rangle \ln[p_\gamma(t)/q_\gamma] \\ &= -k \sum_\gamma \langle n_\gamma\rangle \ln[\langle n_\gamma\rangle/\langle n_\gamma\rangle_e],\end{aligned} \qquad (2)$$

where q_γ is the probability corresponding to $p_\gamma(t)$ in equilibrium state. This is identified with the result from the usual nonequilibrium thermodynamics, in which the hypothesis of local equilibrium[2] plays an important role. It should be stressed, here, that the hypothesis of local equilibrium is also implicitly involved in Eq. (1), since the equilibrium probability distribution $P(\boldsymbol{n};\ \infty)$ is assumed to be retained throughout the reaction time.

For the system in which a second-order reaction occurs, however, the stochastic formulation of nonequilibrium thermodynamics remains unsettled. This may well be due to the difficulty in finding the probability distribution to facilitate the evaluation of stochastic entropy. When the probability distribution, even though it is approximate, is found at all, the entropy change can be calculated by Eq. (1). The plan of this paper is as follows. We describe a second-order reaction by the stochastic process linearized with the transition probability variable with time on the assumption of the partial factorization of the joint probability distribution for reaction states, and at the same time we define the stochastic entropy in a form similar to the conditional entropy in the theory of information.[3]

Stochastic Model for Second-Order Reaction

For the sake of simplicity, we consider a second-order reaction in ideal gases

$$\mathrm{A} + \mathrm{B} \rightleftarrows \mathrm{C}. \qquad (\mathrm{I})$$

Letting the random variables $X_A(t)$, $X_B(t)$, and $X_C(t)$ represent the numbers of molecules of reacting species A, B, and C at time t, respectively, the stochastic process is then described by the differential-difference equation,

$$\begin{aligned}&\frac{\mathrm{d}}{\mathrm{d}t}P(n_A,\ n_B,\ n_C;\ t) \\ &= \lambda(n_A+1)(n_B+1)P(n_A+1,\ n_B+1,\ n_C-1;\ t) \\ &- (\lambda n_A n_B+\lambda' n_C)P(n_A,\ n_B,\ n_C;\ t) \\ &+ \lambda'(n_C+1)P(n_A-1,\ n_B-1,\ n_C+1;\ t)\end{aligned} \qquad (3)$$

where $P(n_A,\ n_B,\ n_C;\ t)=\mathrm{Prob.}\{X_A(t)=n_A,\ X_B(t)=n_B,\ X_C(t)=n_C\}$ denotes the joint probability that there are n_A, n_B, and n_C molecules of reacting species A, B, and C in the reaction system at time t, respectively, and λ and λ' are the rate constants defined on the assumption that the transition probabilities of reaction processes of A+B→C and A+B←C in the time interval $(t,\ t+\mathrm{d}t)$ are given by $\lambda\, n_A n_B \mathrm{d}t$ and $\lambda' n_C \mathrm{d}t$, respectively.

It is a complicated problem, soluble in principle, to find the probability distribution $P(n_A,\ n_B,\ n_C;\ t)$ from Eq. (3), which is nonlinear with respect to the numbers of molecules. In order to obtain its approximate solution, however, we attempt to reform Eq. (3) into the linear equation of only the number of molecules of reacting species C, n_C. If the reaction system is in the thermodynamic limit such that the total number of molecules taking part in reaction is sufficiently large,

2) S. R. de Groot and P. Mazur, "Non-Equilibrium Thermodynamics," North-Holland Publishing Co., Amsterdam (1962), p. 23.

3) A. I. Khinchin, "Mathematical Foundations of Information Theory," Dover Publications Inc., New York (1957), p. 35.

it is possible to assume the partial factorization of the joint probability[4]

$$P(n_A, n_B, n_C; t) = P(n_A; t)P(n_B, n_C; t) \quad (4, A)$$

or

$$P(n_A, n_B, n_C; t) = P(n_B; t)P(n_A, n_C; t). \quad (4, B)$$

Such a factorization, as will be shown later, is made to preserve at least the stochastic process of the reaction. Applying the factorization (4, A) to Eq. (3) and taking the summation over all possible values of random variable $X_A(t)$, we obtain

$$\begin{aligned}\frac{d}{dt}P(n_B, n_C; t) &= \lambda\langle n_A\rangle(n_B+1)P(n_B+1, n_C-1; t) \\ &- (\lambda\langle n_A\rangle n_B+\lambda' n_C)P(n_B, n_C; t) \\ &+ \lambda'(n_C+1)P(n_B-1, n_C+1; t). \end{aligned} \quad (5)$$

From Eq. (5), we can easily derive the rate equation with respect to the mean $\langle n_C\rangle$,

$$\frac{d}{dt}\langle n_C\rangle = \lambda\langle n_A\rangle\langle n_B\rangle-\lambda'\langle n_C\rangle. \quad (6)$$

This is of the uncorrelated form of the alternative rate equation derived directly from Eq. (3),

$$\frac{d}{dt}\langle n_C\rangle = \lambda\langle n_A n_B\rangle-\lambda'\langle n_C\rangle, \quad (7)$$

which, in the thermodynamic limit, is practically equivalent to Eq. (6). If the initial numbers of molecules of reacting species A and B are denoted by $n_A^{(0)}$ and $n_B^{(0)}$, respectively, equation (6) is written as

$$\frac{d}{dt}\langle n_C\rangle = \lambda(n_A^{(0)}-\langle n_C\rangle)(n_B^{(0)}-\langle n_C\rangle)-\lambda'\langle n_C\rangle. \quad (6')$$

Solving this differential equation, we obtain, in agreement with the deterministic theory,

$$\langle n_C\rangle = \frac{\alpha\beta(1-\exp[-\lambda(\alpha-\beta)t])}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]}, \quad (8)$$

where α and β are the roots of

$$\langle n_C\rangle^2 - (n_A^{(0)}+n_B^{(0)}+\lambda'/\lambda)\langle n_C\rangle + n_A^{(0)}n_B^{(0)} = 0. \quad (9)$$

Let us return to Eq. (5). If the transition probability variable with time is defined by

$$\lambda_A(t) = \lambda\langle n_A\rangle, \quad (10)$$

where

$$\langle n_A\rangle = n_A^{(0)} - \frac{\alpha\beta(1-\exp[-\lambda(\alpha-\beta)t])}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]}, \quad (11)$$

equation (5) becames

$$\begin{aligned}\frac{d}{dt}P(n_B, n_C; t) &= \lambda_A(t)(n_B+1)P(n_B+1, n_C-1; t) \\ &- (\lambda_A(t)n_B+\lambda' n_C)P(n_B, n_C; t) \\ &+ \lambda'(n_C+1)P(n_B-1, n_C+1; t) \end{aligned} \quad (5')$$

or

$$\begin{aligned}\frac{d}{dt}P(n_C; t) &= \lambda_A(t)\{n_B^{(0)}-(n_C-1)\}P(n_C-1; t) \\ &- \{\lambda_A(t)(n_B^{(0)}-n_C)+\lambda' n_C\}P(n_C; t) \\ &+ \lambda'(n_C+1)P(n_C+1; t), \end{aligned} \quad (5'')$$

which is just the same because of Prob. $\{X_B(t)=n_B,\ X_C(t)=n_C\}$=Prob.$\{X_B(t)=n_B^{(0)}-n_C,\ X_C(t)=n_C\}$= Prob. $\{X_C(t)=n_C\}$ on the basis of the introduction of the transition probability $\lambda_A(t)$.

To solve Eq. (5''), let us define the generating function

$$G(z_C; t) = \sum_{n_C} z_C^{n_C}P(n_C; t), \quad 0<|z_C|\leq 1. \quad (12)$$

From Eq. (5''), then, we obtain the partial differential equation

$$\frac{\partial G}{\partial t} = \{\lambda_A(t)+\lambda'\}(1-z_C)\frac{\partial G}{\partial z_C} - n_B^{(0)}\lambda_A(t)(1-z_C)G, \quad (13)$$

where the initial condition is given by $G(z_C; 0)=1$, which corresponds to the initial condition for Eq. (5''), $P(n_C; 0)=\delta_{n_C,0}$. After rather lengthy algebraic manipulations, it can be found that the solution of Eq. (13) is of the form

$$G(z_C; t) = \left\{\frac{\alpha-n_A^{(0)}-(\beta-n_A^{(0)})\exp[-\lambda(\alpha-\beta)t]}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]} + \frac{n_A^{(0)}(1-\exp[-\lambda(\alpha-\beta)t])}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]}z_C\right\}^{n_B^{(0)}}. \quad (14)$$

Performing the binomial expansion of the right-hand side of this equation, we have, according to Eq. (12),

$$P(n_C; t) = \binom{n_B^{(0)}}{n_C}\left\{\frac{n_A^{(0)}(1-\exp[-\lambda(\alpha-\beta)t])}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]}\right\}^{n_C} \times \left\{\frac{\alpha-n_A^{(0)}-(\beta-n_A^{(0)})\exp[-\lambda(\alpha-\beta)t]}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]}\right\}^{n_B^{(0)}-n_C}. \quad (15)$$

This is the probability distribution on the understanding that the reacting species A takes part in the reaction through the mean number of molecules, $\langle n_A\rangle$. Of course, from the probability distribution (15), we obtain the mean $\langle n_C\rangle$ consistent with Eq. (8).

Let us find the probability $P(n_A; t)$. For this purpose, we introduce again the generating function defined by

$$g(z_A; t) = \sum_{n_A} z_A^{n_A}\{\sum_{n_B, n_C} P(n_A, n_B, n_C; t)\}, \quad 0<|z_A|\leq 1 \quad (16)$$

which may be called a reduced one. Thus, we have from Eq. (3),

$$\frac{\partial g}{\partial t} = (1-z_A)\left\{\lambda\langle n_B\rangle\frac{\partial g}{\partial z_A}-\lambda'\langle n_C\rangle g\right\}, \quad (17)$$

where the factorization (4, A) has been taken into account. Since $\lambda'\langle n_C\rangle_e/\lambda\langle n_B\rangle_e=\langle n_A\rangle_e$ at equilibrium, we find straight from Eq. (17)

$$g(z_A: \infty) = \exp[(z_A-1)\langle n_A\rangle_e]. \quad (18)$$

This shows that the equilibrium probability distribution is Poissonian;

$$P(n_A; \infty) = \exp(-\langle n_A\rangle_e)\langle n_A\rangle_e^{n_A}/n_A!. \quad (19)$$

The time-dependent solution of Eq. (17) is of the same form as Eq. (18),

$$g(z_A; t) = \exp[(z_A-1)\langle n_A\rangle] \quad (20)$$

obtained by means of the initial condition, $g(z_A; 0)=\exp[(z_A-1)n_A^{(0)}]$, in which we have assumed

4) I. Oppenheim, K. E. Shuler, and G. H. Weiss, *J. Chem. Phys.*, **50**, 460 (1969).

$\langle n_A\rangle_{initial}=n_A^{(0)}$. To this generating function corresponds the Poisson distribution,

$$P(n_A;\ t) = \exp(-\langle n_A\rangle)\langle n_A\rangle^{n_A}/n_A!, \tag{21}$$

where the mean $\langle n_A\rangle$ is consistent with the value given by Eq. (11).

It should be mentioned that Eq. (5′) or (5″) describes the stochastic process of the modified second-order reaction as follows:

$$B(\langle A\rangle) \rightleftarrows C, \tag{II, A}$$

where the symbol $\langle A\rangle$ in parentheses indictes the hypothesis that the average change of the number of A molecules is incorporated beforehand in the transition probability $\lambda_A(t)$ at an arbitrarily fixed time t. On the other hand, assuming the factorization (4, B), we may similarly consider the other modified second-order reaction

$$A(\langle B\rangle) \rightleftarrows C. \tag{II, B}$$

Thus, we can symbolically express the probability for the required reaction (I), $\mathcal{P}(A+B\rightleftarrows C)$, by

$$\mathcal{P}(A+B\rightleftarrows C) = \mathcal{P}(A)\,\mathcal{P}(B(\langle A\rangle)\rightleftarrows C) \tag{22, A}$$

or

$$\mathcal{P}(A+B\rightleftarrows C) = \mathcal{P}(B)\,\mathcal{P}(A(\langle B\rangle)\rightleftarrows C). \tag{22, B}$$

In Eq. (22, A), the probability $\mathcal{P}(B(\langle A\rangle)\rightleftarrows C)$ for the modified reaction (II, A) may be regarded as a conditional probability, calculated on the assumption that the average change of the number of A molecules is realized beforehand with the probability $\mathcal{P}(A)$. Equation (22, A) or (22, B), together with the Gibbs entropy postulate (1) or (1′), forms the basis of the stochastic formulation of nonequilibrium thermodynamics of reaction (I).

Stochastic Entropy

Following the Gibbs entropy postulate (1′), we have, as the stochastic entropy for the probability $\mathcal{P}(A+B\rightleftarrows C)$,

$$S(A+B\rightleftarrows C) = -k\langle\ln[\mathcal{P}(A+B\rightleftarrows C)/\mathcal{P}_e(A+B\rightleftarrows C)]\rangle + S_e(A+B\rightleftarrows C). \tag{23}$$

As an example, if we apply the relation (22, A) to Eq. (23), we can write the stochastic entropy $S(A+B\rightleftarrows C)$ in the form

$$\begin{aligned}S(A+B\rightleftarrows C) &= -k\{\sum_A \mathcal{P}(A)\ln[\mathcal{P}(A)/\mathcal{P}_e(A)]\sum_C \mathcal{P}(B(\langle A\rangle)\rightleftarrows C)\\ &\quad + \sum_A \mathcal{P}(A)\sum_C \mathcal{P}(B(\langle A\rangle)\rightleftarrows C)\ln[\mathcal{P}(B(\langle A\rangle)\rightleftarrows C)/\mathcal{P}_e(B(\langle A\rangle)\rightleftarrows C)]\} + S_e(A+B\rightleftarrows C).\end{aligned} \tag{24}$$

However, owing to the normalizations $\sum_A \mathcal{P}(A)=1$ and $\sum_C \mathcal{P}(B(\langle A\rangle)\rightleftarrows C)=1$, this equation now becomes

$$\begin{aligned}S(A+B\rightleftarrows C) &= -k\{\langle\ln[\mathcal{P}(A)/\mathcal{P}_e(A)]\rangle\\ &\quad + \langle\ln[\mathcal{P}(B(\langle A\rangle)\rightleftarrows C)/\mathcal{P}_e(B(\langle A\rangle)\rightleftarrows C)]\rangle\}\\ &\quad + S_e(A+B\rightleftarrows C).\end{aligned} \tag{25}$$

If we furthermore decompose the entropy $S_e(A+B\rightleftarrows C)$ for the equilibrium probability distribution $\mathcal{P}_e(A+B\rightleftarrows C)$ into the two parts, $S_e(A)$ and $S_e(B(\langle A\rangle)\rightleftarrows C)$, we have consequently

$$S(A+B\rightleftarrows C) = S(A) + S(B(\langle A\rangle)\rightleftarrows C), \tag{26, A}$$

which is in a form similar to the conditional entropy in the theory of information. In writing the above equation, we have defined

$$S(A) = -k\langle\ln[\mathcal{P}(A)/\mathcal{P}_e(A)]\rangle + S_e(A) \tag{27}$$

and

$$\begin{aligned}S(B(\langle A\rangle)\rightleftarrows C) &= -k\langle\ln[\mathcal{P}(B(\langle A\rangle)\rightleftarrows C)/\mathcal{P}_e(B(\langle A\rangle)\rightleftarrows C)]\rangle\\ &\quad + S_e(B(\langle A\rangle)\rightleftarrows C).\end{aligned} \tag{28}$$

Proceeding in the same manner, we get also for the relation (22, B),

$$S(A+B\rightleftarrows C) = S(B) + S(A(\langle B\rangle)\rightleftarrows C). \tag{26, B}$$

In order to express explicitly the stochastic entropy (26, A), we start with the evaluation of Eq. (28). Since the probability $\mathcal{P}(B(\langle A\rangle)\rightleftarrows C)$ is given by Eq. (15) and it follows that

$$\mathcal{P}_e(B(\langle A\rangle)\rightleftarrows C) = \binom{n_B^{(0)}}{n_C}(n_A^{(0)}/\alpha)^{n_C}\{(\alpha-n_A^{(0)})/\alpha\}^{n^{(0)}{}_B-n_C}, \tag{29}$$

the stochastic entropy $S(B(\langle A\rangle)\rightleftarrows C)$ takes the form

$$\begin{aligned}S(B(\langle A\rangle)\rightleftarrows C) &= -k\Big\{\langle n_C\rangle\ln\frac{n_A^{(0)}(1-\exp[-\lambda(\alpha-\beta)t])}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]}\\ &\quad + (n_B^{(0)}-\langle n_C\rangle)\\ &\quad \times\ln\frac{\alpha-n_A^{(0)}-(\beta-n_A^{(0)})\exp[-\lambda(\alpha-\beta)t]}{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]}\\ &\quad - \langle n_C\rangle\ln(n_A^{(0)}/\alpha) - (n_B^{(0)}-\langle n_C\rangle)\\ &\quad \times\ln[(\alpha-n_A^{(0)})/\alpha]\Big\} + S_e(B(\langle A\rangle)\rightleftarrows C).\end{aligned} \tag{30}$$

With the aid of the relations, $\alpha\beta=n_A^{(0)}n_B^{(0)}$, $\beta=\langle n_C\rangle_e$ and $\{\alpha+n_A^{(0)}-(\beta-n_A^{(0)})\exp[-\lambda(\alpha-\beta)t]\}/\{\alpha-\beta\exp[-\lambda(\alpha-\beta)t]\}=n_A^{(0)}(n_A^{(0)}-\langle n_C\rangle)/\alpha\beta$, the above equation is reduced to

$$\begin{aligned}S(B(\langle A\rangle)\rightleftarrows C) &= -k\{\langle n_C\rangle\ln(\langle n_C\rangle/\langle n_C\rangle_e)\\ &\quad + (n_B^{(0)}-\langle n_C\rangle)\ln[(n_B^{(0)}-\langle n_C\rangle)/(n_B^{(0)}-\langle n_C\rangle_e)]\}\\ &\quad + S_e(B(\langle A\rangle)\rightleftarrows C).\end{aligned} \tag{31, A}$$

Similarly, for the modified second-order reaction (II, B), we have

$$\begin{aligned}S(A(\langle B\rangle)\rightleftarrows C) &= -k\{\langle n_C\rangle\ln(\langle n_C\rangle/\langle n_C\rangle_e)\\ &\quad + (n_A^{(0)}-\langle n_C\rangle)\ln[(n_A^{(0)}-\langle n_C\rangle)/(n_A^{(0)}-\langle n_C\rangle_e)]\}\\ &\quad + S_e(A(\langle B\rangle)\rightleftarrows C).\end{aligned} \tag{31, B}$$

Since Eqs. (21) and (19) correspond to the probabilities $\mathcal{P}(A)$ and $\mathcal{P}_e(A)$, respectively, we obtain from Eq. (27)

$$\begin{aligned}S(A) &= -k\{\langle n_A\rangle\ln(\langle n_A\rangle/\langle n_A\rangle_e)\\ &\quad - (\langle n_A\rangle-\langle n_A\rangle_e)\} + S_e(A).\end{aligned} \tag{32, A}$$

Similarly, we have for the probability $\rho(B)$

$$S(\mathrm{B}) = -k\{\langle n_\mathrm{B}\rangle \ln(\langle n_\mathrm{B}\rangle/\langle n_\mathrm{B}\rangle_e) - (\langle n_\mathrm{B}\rangle - \langle n_\mathrm{B}\rangle_e)\} + S_e(\mathrm{B}). \quad (32,\ \mathrm{B})$$

In the final analysis, the substitution of Eqs. (31, A) and (32, A) into Eq. (26, A) leads to

$$\begin{aligned} &S(\mathrm{A}+\mathrm{B} \rightleftarrows \mathrm{C}) \\ &= -k\{\langle n_\mathrm{A}\rangle \ln(\langle n_\mathrm{A}\rangle/\langle n_\mathrm{A}\rangle_e) + \langle n_\mathrm{B}\rangle \ln(\langle n_\mathrm{B}\rangle/\langle n_\mathrm{B}\rangle_e) \\ &\quad + \langle n_\mathrm{C}\rangle \ln(\langle n_\mathrm{C}\rangle/\langle n_\mathrm{C}\rangle_e) + (\langle n_\mathrm{C}\rangle - \langle n_\mathrm{C}\rangle_e)\} \\ &\quad + S_e(\mathrm{A}+\mathrm{B} \rightleftarrows \mathrm{C}), \end{aligned} \quad (33)$$

or by setting $\Delta_i S(\mathrm{A}+\mathrm{B}\rightleftarrows\mathrm{C}) = S(\mathrm{A}+\mathrm{B}\rightleftarrows\mathrm{C}) - S_e(\mathrm{A}+\mathrm{B}\rightleftarrows\mathrm{C})$,

$$\begin{aligned} &\Delta_i S(\mathrm{A}+\mathrm{B} \rightleftarrows \mathrm{C}) \\ &= -k\{\langle n_\mathrm{A}\rangle \ln(\langle n_\mathrm{A}\rangle/\langle n_\mathrm{A}\rangle_e) + \langle n_\mathrm{B}\rangle \ln(\langle n_\mathrm{B}\rangle/\langle n_\mathrm{B}\rangle_e) \\ &\quad + \langle n_\mathrm{C}\rangle \ln(\langle n_\mathrm{C}\rangle/\langle n_\mathrm{C}\rangle_e) + (\langle n_\mathrm{C}\rangle - \langle n_\mathrm{C}\rangle_e)\}, \end{aligned} \quad (33')$$

where $\langle n_\mathrm{A}\rangle = n_\mathrm{A}^{(0)} - \langle n_\mathrm{C}\rangle$ and $\langle n_\mathrm{B}\rangle = n_\mathrm{A}^{(0)} - \langle n_\mathrm{C}\rangle$ have been used. Following the same argument closely we can again find Eq. (33) from Eqs. (26, B), (31, B), and (32, B). We have therefore the symmetrization

$$\begin{aligned} &S(\mathrm{A}+\mathrm{B} \rightleftarrows \mathrm{C}) \\ &= \frac{1}{2}\{[S(\mathrm{A}) + S(\mathrm{B}(\langle \mathrm{A}\rangle) \rightleftarrows \mathrm{C})] \\ &\quad + [S(\mathrm{B}) + S(\mathrm{A}(\langle \mathrm{B}\rangle) \rightleftarrows \mathrm{C})]\} \\ &= \text{r. h. s. of Eq. (33).} \end{aligned} \quad (34)$$

From Eq. (33), the stochastic entropy production $\sigma = \mathrm{d}S(\mathrm{A}+\mathrm{B}\rightleftarrows\mathrm{C})/\mathrm{d}t$ can be readily obtained as

$$\sigma = k(\mathrm{d}\langle n_\mathrm{C}\rangle/\mathrm{d}t)\ln\left(\frac{\langle n_\mathrm{C}\rangle_e}{\langle n_\mathrm{A}\rangle_e\langle n_\mathrm{B}\rangle_e} \Big/ \frac{\langle n_\mathrm{C}\rangle}{\langle n_\mathrm{A}\rangle\langle n_\mathrm{B}\rangle}\right). \quad (35)$$

If it is assumed that temperature T is uniform throughout the reaction system, the chemical affinity a is expressed by

$$a = kT\{\ln(\langle n_\mathrm{A}\rangle/\langle n_\mathrm{A}\rangle_e) + \ln(\langle n_\mathrm{B}\rangle/\langle n_\mathrm{B}\rangle_e) - \ln(\langle n_\mathrm{C}\rangle/\langle n_\mathrm{C}\rangle_e)\} \quad (36)$$

and the reaction velocity by $v = \mathrm{d}\langle n_\mathrm{C}\rangle/\mathrm{d}t$. The stochastic entropy production (35) is reduced to

$$\sigma = (a/T)v \quad (37)$$

a form convenient for comparison with the entropy production in the usual nonequilibrium thermodynamics.[5]

It is instructive to compare the stochastic theory with the usual one. In the latter, the entropy change due to a chemical reaction $\sum_{i=1}^{r} \nu_i \mathrm{A}_i \rightleftarrows \sum_{j=1}^{p} \nu_j' \mathrm{A}_j'$ in ideal gases can be written as

$$\Delta_i S = \int_{\text{arbitrary reaction state}}^{\text{equilibrium state}} (a/T)\mathrm{d}\xi, \quad (38)$$

where the degree of advancement ξ is defined by $-\mathrm{d}\langle n_{\mathrm{A}_i}\rangle/\nu_i = \mathrm{d}\langle n_{\mathrm{A}_j}'\rangle/\nu_j' = \mathrm{d}\xi$ and the chemical affinity a is given by

$$\begin{aligned} a &= \sum_{i=1}^{r} \nu_i \mu_{\mathrm{A}_i} - \sum_{j=1}^{p} \nu_j' \mu_{\mathrm{A}_j'} \\ &= kT\left\{\sum_{i=1}^{r} \nu_i \ln(\langle n_{\mathrm{A}_i}\rangle/\langle n_{\mathrm{A}_i}\rangle_e) - \sum_{j=1}^{p} \nu_j' \ln(\langle n_{\mathrm{A}_j'}\rangle/\langle n_{\mathrm{A}_j'}\rangle_e)\right\}. \end{aligned} \quad (39)$$

In this equation, we have used as the chemical potential of component γ,

$$\mu_\gamma = kT \ln\langle n_\gamma\rangle + \eta_\gamma(T, V),$$

where $\langle n_\gamma\rangle$ is the mean number of molecules of reacting species γ and $\eta_\gamma(T, V)$ a function of volume V and temperature T only. After integration, we obtain

$$\begin{aligned} \Delta_i S = -k\Big\{ &\sum_{i=1}^{r} [\langle n_{\mathrm{A}_i}\rangle \ln(\langle n_{\mathrm{A}_i}\rangle/\langle n_{\mathrm{A}_i}\rangle) - \langle n_{\mathrm{A}_i}\rangle + \langle n_{\mathrm{A}_i}\rangle_e] \\ &+ \sum_{i=1}^{p} [\langle n_{\mathrm{A}'_j}\rangle \ln(\langle n_{\mathrm{A}'_j}\rangle/\langle n_{\mathrm{A}'_j}\rangle_e) \\ &- \langle n_{\mathrm{A}'_j}\rangle + \langle n_{\mathrm{A}'_j}\rangle_e]\Big\}. \end{aligned} \quad (40)$$

In the case of reaction (I), for instance, we have Eq. (33') by using the relation $-(\langle n_\mathrm{A}\rangle - \langle n_\mathrm{A}\rangle_e) = -(\langle n_\mathrm{B}\rangle - \langle n_\mathrm{B}\rangle_e) = \langle n_\mathrm{C}\rangle - \langle n_\mathrm{C}\rangle_e$. Reflecting upon the requirement that the mean numbers of molecules, $\langle n_{\mathrm{A}_i}\rangle$ and $\langle n_{\mathrm{A}'_j}\rangle$, have to be taken with respect to a probability distribution governing the reaction system, we may reform Eq. (40) into

$$\begin{aligned} \Delta_i S = -k\Big\langle \ln\Big\{ &\prod_{i=1}^{r}\left(\frac{\exp(-\langle n_{\mathrm{A}_i}\rangle)\langle n_{\mathrm{A}_i}\rangle^{n_{\mathrm{A}_i}}}{n_{\mathrm{A}_i}!}\right. \\ &\left.\Big/\frac{\exp(-\langle n_{\mathrm{A}_i}\rangle_e)\langle n_{\mathrm{A}_i}\rangle_e^{n_{\mathrm{A}_i}}}{n_{\mathrm{A}_i}!}\right) \\ &\times \prod_{j=1}^{p}\left(\frac{\exp(-\langle n_{\mathrm{A}'_j}\rangle)\langle n_{\mathrm{A}'_j}\rangle^{n_{\mathrm{A}'_j}}}{n_{\mathrm{A}'_j}!}\right. \\ &\left.\Big/\frac{\exp(-\langle n_{\mathrm{A}'_j}\rangle_e)\langle n_{\mathrm{A}'_j}\rangle_e^{n_{\mathrm{A}'_j}}}{n_{\mathrm{A}'_j}!}\right)\Big\}\Big\rangle. \end{aligned} \quad (41)$$

Thus, it turns out that Poisson distribution holds for each reacting species and that it is maintained invariant throughout the reaction process in local equilibrium, which is also assumed in Eq. (38). If we set

$$p(n_\gamma) = \exp(-\langle n_\gamma\rangle)\langle n_\gamma\rangle^{n_\gamma}/n_\gamma! \quad (42)$$

and

$$p_e(n_\gamma) = \exp(-\langle n_\gamma\rangle_e)\langle n_\gamma\rangle_e^{n_\gamma}/n_\gamma! \quad (43)$$

and take the average with respect to the probability distribution $\prod_\gamma p(n_\gamma)$, we can rewrite Eq. (41) in the form

$$\begin{aligned} \Delta_i S &= -k\sum_{\boldsymbol{n}} \prod_\gamma p(n_\gamma)\ln\left(\prod_\gamma [p(n_\gamma)/p_e(n_\gamma)]\right) \\ &= -k\sum_\gamma \sum_{n_\gamma} p(n_\gamma)\ln[p(n_\gamma)/p_e(n_\gamma)]. \end{aligned} \quad (44)$$

If, furthermore, we set $\prod_\gamma p(n_\gamma) = P(\boldsymbol{n})$, we obtain from Eq. (44) the Gibbs entropy postulate

$$\Delta_i S = -k\sum_{\boldsymbol{n}} P(\boldsymbol{n})\ln[P(\boldsymbol{n})/P_e(\boldsymbol{n})] \quad (45)$$

in agreement with Eq. (1). We can therefore conclude that for the entropy change due to a chemical reaction in ideal gases the thermodynamic expression (38) is equivalent to the stochastic one (1).

We can rewrite Eq. (44) corresponding to Eq. (1') as

5) I. Prigogine, "Introduction to Thermodynamics of Irreversible Processes," 3rd ed., Interscience Publishers, New York (1967), p. 23.

$$S = -k \sum_{\gamma} \sum_{n_\gamma} p(n_\gamma) \ln[p(n_\gamma)/p_e(n_\gamma)] + S_e. \quad (44')$$

Assuming $S_e = \sum_{\gamma} S_e(\gamma)$, where $S_e(\gamma)$ denotes the entropy for the equilibrium probability distribution of reacting species γ, we obtain from Eq. (44')

$$S = \sum_{\gamma} S(\gamma), \quad (46)$$

where

$$S(\gamma) = -k \sum_{n_\gamma} p(n_\gamma) \ln[p(n_\gamma)/p_e(n_\gamma)] + S_e(\gamma). \quad (47)$$

This has its origin in the factorization $P(\boldsymbol{n}) = \prod_{\gamma} p(n_\gamma)$. In other words, we can say that the joint probability distribution $P(\boldsymbol{n}; t)$ for reaction states, at all times $0 \leq t \leq \infty$, is factorized as $P(\boldsymbol{n}; t) = \prod_{\gamma} P(n; t)$ in thermodynamic limit. However, so far as thermodynamic considerations are concerned, the probability distribution of reaction states can not be explicitly found through the reaction kinetics. The reason why we have presumed to use the factorization such as Eq. (22, A) or (22, B) is to formulate stochastically the nonequilibrium thermodynamics by considering at least the stochastic process of the modified reaction (II, A) or (II, B), which is of an advantage to the approximate solution of the stochastic process of reaction (I). We emphasize finally that such a theory can systematically deal with the nonequilibrium thermodynamics of chemical reaction together with its stochastic process.

The stochastic theory presented in this paper can be applied to other reactions, *e.g.*, $A+B \rightleftarrows C+D$. The stochastic entropy is given by $S(A+B \rightleftarrows C+D) = S(B(\langle A \rangle) \rightleftarrows C(\langle D \rangle)) + S(A(\langle B \rangle) \rightleftarrows D(\langle C \rangle))$ or $S(A+B \rightleftarrows C+D) = 1/2\{[S(A) + S(D) + S(B(\langle A \rangle) \rightleftarrows C(\langle D \rangle))] + [S(B) + S(C) + S(A(\langle B \rangle) \rightleftarrows D(\langle C \rangle))]\}$. Of course, the former agrees with the latter, assuming the relation (46).

Catalytic Oxidation over Molecular Sieves Ion-exchanged with Transition Metal Ions. IV. The Oxidative Dehydrogenation of Cyclohexane

Isao MOCHIDA, Tetsuji JITSUMATSU, Akio KATO, and Tetsuro SEIYAMA

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received February 1, 1971)

The oxidative dehydrogenation of cyclohexane over molecular sieves ion-exchanged with cupric ion (Cu(II)-Y) was investigated by means of an ordinary flow reactor with a reactant gas composed of 1.0% cyclohexane, 50% oxygen, and 49% nitrogen. The reaction was studied at temperatures between 210—350°C; here, carbon dioxide and benzene were the main products. The Cu(II)-Y was found to be a very active catalyst for the oxidation of cyclohexane as well as for that of olefins, in comparison with an ordinary cupric oxide catalyst supported on silica gel; the selectivity for benzene formation was as high as 80% below 10% conversion. Both products were found to be formed in competitive reactions. The catalytic activities were also studied on molecular sieves ion-exchanged with other transition metal ions, such as palladium (II), silver (I), and zinc (II). The relations between the catalytic activities and the heats of formation of the corresponding metal oxides per g-atom oxygen were examined; volcano-shaped correlations were observed for both benzene and carbon-dioxide formations for these catalysts. The most active catalyst was Cu(II)-Y for benzene formation, whereas it was Pd (II)-Y for the carbon dioxide formation. The meaning of the correlations was discussed according to Balandin's explanation, based on thermochemistry, although no satisfying explanation was found. The compensation effects were observed between the activation energies and the frequency factors in these oxidations.

In previous papers, it was reported that the molecular sieves ion-exchanged with transition metal ions have very high catalytic activities for the oxidation of olefins.[1-3] It may be interesting to investigate the catalytic activities of these catalysts for the saturated hydrocarbons. Agudo *et al.*[4] reported the oxidations of heptanes on Na-X, Ca-X, and Mn-X, but homogeneous processes were predominant, so the character of the transition metal on the molecular sieve appeared only obscurely.

In the present work, the oxidative dehydrogenation of cyclohexane was studied over molecular sieves ion-exchanged with several transition-metal ions. Although the dehydroisomerization (reforming, in other words) of saturated hydrocarbons by Pd- or Pt-molecular sieves has been reported and applied in industrial processes,[5] regarding oxidative dehydrogenation only a few works have been reported, those using alcohols and alkylbenzenes as the reactants.[6,7]

Cyclohexane can be thought to be transformed easily into benzene, and the benzene thus produced is relatively stable against further oxidations, so the oxidative dehydrogenation of cyclohexane can be expected to occur with a high activity and selectivity over molecular sieves ion-exchanged with transition-metal ions, since high activities of these catalysts were found with regard to the oxidation of olefinic hydrocarbons.[1,3]

Experimental

Catalyst. The ion-exchanged molecular-sieve catalysts were prepared by the ion-exchange of the Y-molecular sieve (Linde), Na–Y, with an aqueous solution of metal sulfates or nitrate except for the cases of cupric and palladium ions, for which amine complexes were used. A sufficient amount of the metal ion was passed through a cylindrically-shaped column of Na–Y. The ion-exchanged sieves were then washed thoroughly with decationized water, dried at 100°C, and calcined at 400°C for 7 hr in the air. The amount of metal ion-exchanged onto the sieve was determined by extraction with nitric acid and by the titration of the solution. 80—90% of the sodium ions were exchanged. The cupric oxide catalyst supported by silica gel was described in a previous paper.[1]

Reagent. The cyclohexane used was of a G. R. grade and was obtained from the Wako Junyaku Co. It was used without further purification. No benzene or cyclohexene was detected by the gas chromatography.

Apparatus and Procedure The oxidative dehydrogenation was studied by the ordinary flow method, with a fixed catalyst bed diluted with 1% cyclohexane, 50% oxygen, and 49% nitrogen. Cyclohexane was fed by means of a nitrogen flow passed through an alumina bed impregnated with a sufficient amount of cyclohexane kept at 0°C. The cyclohexane, cyclohexene, benzene, and carbon dioxide were analyzed by means of chromatography. For the first three, 2 m TCP (Japan Gaschro Co.) and 1 m PEG (Japan Gaschro Co.) columns were used at 80°C, and for the last, a Porapak Q (Waters Associates, Inc.) column of 2 m was used at room temperature. The conversions and the selectivity were calculated in the following ways:

$$\text{Conversion for carbon dioxide} = \frac{(1/6)\ \text{carbon dioxide}}{\text{cyclohexane fed}}$$

$$\text{Conversion for benzene} = \frac{\text{benzene}}{\text{cyclohexane fed}}$$

$$\text{Selectivity for benzene} = \frac{\text{benzene}}{\text{benzene} + (1/6)\ \text{carbon dioxide}}$$

The activity of the catalyst was corrected to that on a fixed amount of the metal ion.

Results

Oxidation of Cyclohexane on a Y Molecular Sieve Ion-exchanged with Cupric Ions (Cu(II)-Y). The oxidation of cyclohexane over Cu(II)–Y of 300 mg began to occur at 210°C under a flow rate of 50 ml/min. Up to 350°C, benzene and carbon dioxide were the main products, plus a small amount of cyclohexene. The carbon balance was better than 95% (on an inlet cyclohexane basis) after 2 hours' reaction, although a carbon deposit was observed on the catalyst. The catalyst recovered its original color of light blue when the carbon deposited on the catalyst was burned in the air. This means that the cupric ions maintain the ionic state on the molecular sieve during the oxidation reaction, as was previously observed in the oxidation of propylene.[1,2]

Above 350°C, products other than carbon dioxide and benzene were observed. Acetic acid and propionic acid were detected in the products. However, a detailed analysis was not made.

The reactant gas composition; 1% cyclohexane, 50% oxygen, 49% nitrogen.
○: benzene formation, ●: carbon dioxide formation,
△: selectivity of benzene formation.

The oxidation at 260°C is shown in Fig. 1 as a function of the contact time. Benzene and carbon dioxide were formed in linear relations with the contact time below a 10% conversion. Above this conversion, however, the carbon dioxide formation increased rapidly and the benzene formation was surpressed. The former fact may suggest the competitive formations of these products below a 10% conversion, while the latter may do the successive oxidation of benzene into carbon dioxide above a 10% conversion. The selectivity of the benzene formation was as high as 80% in the competitive region. The selectivity in the region of the competitive reactions varied little with the reaction temperature between 210 and 350°C, although the rates increased considerably.

A Comparison of Cu(II)–Y with Cupric Oxide Supported on Silica Gel in the Oxidative Dehydrogenation of Cyclohexane. The catalytic activity of Cu(II)–Y was compared with that of the ordinary cupric oxide mounted on silica gel (Cu(II)–S). The two catalysts had nearly equal surface areas.[1] The reactions on these catalysts in the competitive region at 310°C are shown in Fig. 2 as a function of the contact time. The catalytic

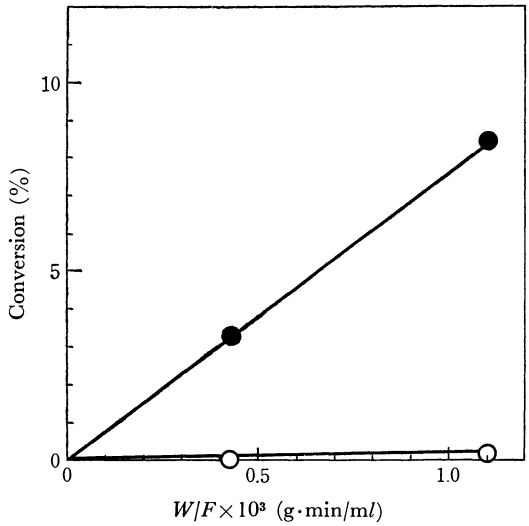

Fig. 4. The oxidation of cyclohexane on Pd(II)-Y at 230°C.
○: benzene formation, ●: carbon dioxide formation.

activity of Cu(II)-Y was much larger than that of Cu(II)-S, being fifteen times as much for the benzene formation and four times as much for the carbon-dioxide formation. The selectivity for the benzene formation in the competitive reactions was also better (80% for Cu(II)-Y, but 60% for Cu(II)-S). The activation energies and frequency factors of these two catalysts are shown in Table 1. It is interesting that Cu(II)-Y had a very high catalytic activity for the oxidations of saturated hydrocarbon as well as of olefinic hydrocarbons at such temperatures.[1-3]

The Oxidations of Cyclohexane over Molecular Sieves Ion-exchanged with Other Transition-metal Ions. The catalytic activities of molecular sieves ion-exchanged with five kinds of transition-metal ions other than the cupric ion were also studied in order to investigate the roles of metal ions in the oxidative dehydrogenation based on the δ_C LFER approach.[8] The reactions over Cr(III)-Y at 290°C and over Pd(II)-Y at 230°C are shown in Figs. 3 and 4 respectively as examples. It should be mentioned that the selectivities for the benzene formation of such sieves were much smaller than that of Cu(II)-Y, although the reactions also seemed competitive on these catalysts below a 10% conversion, as was shown by the linearity of the con-

8) I. Mochida and Y. Yoneda, *J. Catalysis*, **7**, 386 393, **8**, 223 (1967).

version plotted against the contact time. On Pd(II)–Y, the benzene formation was too small to be detected at low conversions, as is shown in Fig. 4, but it became measurable beyond a 10% conversion. This mean that the small value of the selectivity cannot be ascribed to the occurrence of the successive reaction at these conversion levels because of the high activity of this catalyst, and that the formations of benzene and carbon dioxide also take place competitively on Pd(II)–Y.

In Table 1, the rate data of the catalysts used are summarized; the activation energies and frequency factors here were calculated from the rates at reaction temperatures between 230 and 350°C, except for the case of Pd(II)–Y, which was too active for the oxidation rates to be observed in this temperature range, so the observation was made between 200 and 260°C. The catalytic activities of these catalysts at 290°C were in the following orders: Pd>Cu>Cr>Ni>Zn>Ag for the carbon dioxide formation, and Cu>Pd>Cr>Ni>Zn>Ag for the benzene formation (the activity of Pd(II)–Y at this temperature was extrapolated in the Arrhenius plots). The former activity order was analogous to that observed in the deep oxidations of olefins except for the small activity of Ag(I)–Y.[3]

Discussion

The Correlation of the Catalytic Activities with the Heats of Formation of the Corresponding Metal Oxides. The correlation of the catalytic activities for the oxidation of the metal oxides with their heats of formation per oxygen atom was reported on by Moro-oka and Ozaki, Seiyama *et al.*, Komuro *et al.*, and Boreskov and Balandin.[9] Recently, Aonuma and Nakada discussed such a correlation in the oxidative dehydrogenation of cyclohexene on the oxide catalyst.[10] A similar examination of the activities of molecular-sieve catalysts may be of value. In a previous paper,[3] volcano-shaped correlations were found in the oxidations of propylene and ethylene on the molecular-sieve catalysts. Such plots are made for the carbon dioxide and benzene formations in Fig.5, where volcano-shaped correlations were observed for both formations, showing the maximum activity at the palladium ion for carbon dioxide and at the cupric ion for benzene. It is interesting that the heat of the formation of the metal oxide could also be a parameter describing the catalytic activity in the present oxidation.

According to Balandin's explanation of such relations, the most active catalyst can be predicted on the basis of the thermochemical data on the reaction.[11] If the oxidation reaction of cyclohexane can be assumed to proceed through the following two steps, which consist of the dissociative adsorption of oxygen on the metal ion and the successive oxidation of cyclohexane by this adsorbed oxygen, the formation rate of carbon dioxide or benzene is at a maximum when ΔH_1 is equal to ΔH_2 or to ΔH_3 respectively:

$$\mathrm{Me} + 1/2\,\mathrm{O_2} = \mathrm{Me\text{-}O},\ \Delta H_1 \quad (1)$$

$$\mathrm{Me\text{-}O} + 1/24\,\mathrm{C_6H_{12}} = \mathrm{Me} + 1/4\,\mathrm{CO_2} + 1/2\,\mathrm{H_2O},\ \Delta H_2 \quad (2)$$

$$\mathrm{Me\text{-}O} + 1/2\,\mathrm{C_6H_{12}} = \mathrm{Me} + 1/3\,\mathrm{C_6H_6} + \mathrm{H_2O},\ \Delta H_3 \quad (3)$$

(ΔH_1, ΔH_2, and ΔH_3 are the heats of Reactions (1), (2), and (3) respectively.)

Since the sum of ΔH_1 and ΔH_2 or of ΔH_1 and ΔH_3 is equal to the heat of carbon-dioxide formation per g-atom oxygen (ΔH_{CO_2}) or that of benzene formation ($\Delta H_{C_6H_6}$) respectively, the above rule means that the formation rate is at a maximum at $\Delta H_1 = 1/2\,\Delta H_{CO_2}$ for carbon dioxide or at $\Delta H_1 = 1/2\,\Delta H_{C_6H_6}$ for benzene. The values of the heats of oxidation per g-atom oxygen are −42 kcal/mol for the benzene formation and −49 kcal/mol for the carbon-dioxide formation respectively. If the heat of adsorption of oxygen on the metal ion of the molecular sieve, ΔH_1, can be assumed to be equal to that of the formation of the metal oxide, ΔH_f°, the most active catalyst is the one whose ΔH_f° is −21 kcal/mol for the benzene formation and −24.5 kcal/mol for the carbon-dioxide formation respectively. Thus, if the assumptions are appropriate, Pd(II)–Y should be the most active for both formations among the catalysts examined here. The results for the carbon—dioxide formation support the above discussion. However, the cupric ion, not the palladium ion, was most active for the benzene formation. Even if the cyclohexyl radical rather than benzene is considered to be the intermediate product in Eq. (3), the situation is not improved. Other reaction schemes such as dehydrogenation in the first step, followed by the oxidation of the hydrogen with oxygen, may also be considered. However, sufficient thermodynamic data are lacking for further discussion.

Correlation as for Activation energies and Frequency Factors. The reaction rate should be connected with the thermochemical data of the reaction through its activation energy, according to Balandin's explanation.[11] The relations of the activation energies to the parameters used above are shown in Fig. 6 for both formations in order to make possible a discussion of the relations shown in Fig. 5 from another point of view. Similar volcano-shaped correlations were observed for the reaction rates in both formations. Such correlations for activation energies, however, were contradictory to those observed in the usual cases, where the most active catalyst has the smallest value of activation energy.[8,12] The frequency factors are often constant when a linear relation holds between the reaction rate and the thermochemical data.[8] The values of the present case, however, varied considerably from one to another. They were also correlated with the present parameter, as is shown in Fig. 7 for both for-

mations. The relations were in volcano shapes similar to those observed in the activation energies, so that the most active catalyst had the largest frequency factor. This situation was defined as frequency-factor-controlling.[12]

The analogous relations of the activation energy

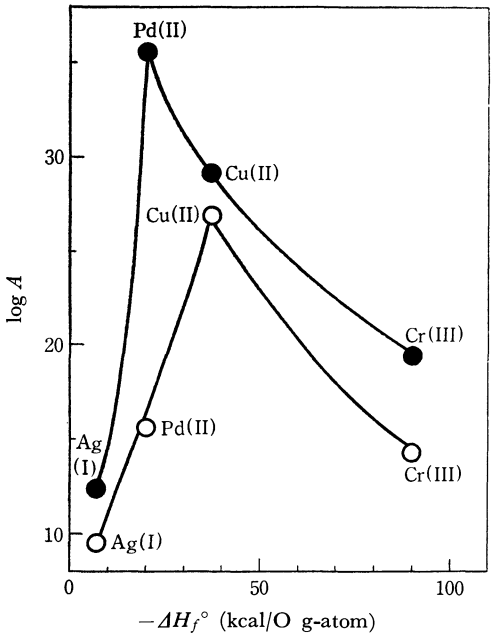

Fig. 7. Correlations of frequency factors of the carbon dioxide and benzene formations with the heats of formation of metal oxides per g-atom oxygen.

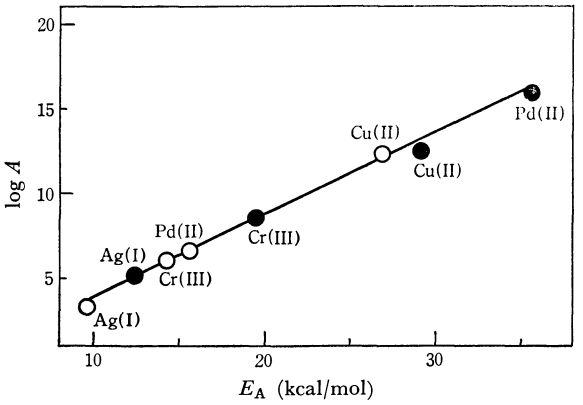

Fig. 8. Compensation effects observed between activation energies and frequency factors in the oxidations of cyclohexane on molecular sieves ion-exchanged with transition metal ions.
○: benzene formation, ●: carbon dioxide formation.

and the frequency factor with the same heat of formation suggest the existence of compensation effects in this oxidation. In fact, the compensation effects in the formations of both carbon dioxide and benzene are shown in Fig. 8. Thus, the frequency-factor-controlling mentioned above implies that the oxidation reaction was observed above the isokinetic temperature.[12]

In a previous paper,[3] the reaction orders as well as the catalytic activity of the ion-exchanged molecular-sieve catalysts for olefin oxidations were reasonably correlated with the parameter of Y,[13] which is thought to represent the softness of the metal ion, but no reasonable relation was found in the present oxidation of

13) M. Misono, E. Ochiai, and Y. Yoneda, *J. Inorg. Nucl. Chem.* **29**, 2685 (1967).

cyclohexane by the use of such a parameter.

In conclusion, the catalytic activities of ion-exchanged molecular-sieve catalysts for the oxidation of cyclohexane into benzene and carbon dioxide can be correlated with the heats of the formation of the corresponding metal oxides per g-atom oxygen at any of the reaction temperatures examined in the present study, because the compensation effects were present. Therefore, the activity of the ion-exchanged molecular sieve can be well estimated from the table values of the metal oxides, although the meaning of such a correlation is yet in question with regard to the reaction mechanism.

We should also mention the possibility of improving the selectivity for the benzene formation, even at the high conversion level, by adopting a better gas-composition of the reactant.

Our thanks are due to Mr. Shinji Hayata for his experimental assistance.

Oxidation of *s*-Butyl Alcohol by Cerium(IV)

D. L. MATHUR and G. V. BAKORE*

Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received October 5, 1970)

The oxidation of *s*-butyl alcohol by Ce(IV) in dilute nitric acid medium has been studied. The reaction is of first order with respect to Ce(IV)but of fractional order with respect to *s*-butyl alcohol. A plot of inverse of alcohol concentration against inverse of observed first order rate constant gave a straight line which did not pass through the origin. This suggests an intermediate Ce(IV)-alcohol complex formation. By repeating this procedure at different temperatures the formation constants of the complex and the thermodynamic parameters for the complex formation process have been evaluated. Hydrogen, nitrate, and sulphate ions decrease the rate of oxidation. The results have been explained on the basis of equilibrium $Ce^{4+}+H_2O \overset{K_h}{\rightleftarrows} Ce(OH)^{3+}+H^+$ and assuming $Ce(OH)^{3+}$ as the reactive species of Ce(IV). From the slope-intercept of straight line obtained between inverse of observed rate constant and $[H^+]$, value of $K_h=6.19$ at 35°C has been evaluated in dilute nitric acid at $\mu=2.55$ M. A mechanism in which the first step is the rapid reversible formation of a complex between Ce(IV) and Substrate followed by α–C–H bond rupture in the rate determining step has been suggested.

The oxidation of *s*-butyl alcohol by ceric salts in dilute nitric acid has been examined by Sethuram and Muhammad.[1] The present paper reports some additional data on the oxidation of *s*-butyl alcohol by cerium(IV) in nitric acid to elucidate the mechanism of oxidation.

Experimental

Material. B.D.H. "Analar" *s*-butyl alcohol was used after distillation. Ceric ammonium nitrate A.R. (Atomic Energy Commission, India) and Nitric acid A.R. (Oster, India) were used. All other chemicals used were of analytical grade. All solutions for kinetic studies were prepared in doubly distilled water.

Kinetic Measurements. The reactions were carried out at constant temperature (±0.05°C) with the reaction vessel covered with black paint. The reaction system consisted of ceric ammonium nitrate [$\sim 4.0\times10^{-3}$ M], alcohol [$\sim 5.0\times10^{-2}$ M] and nitric acid [~ 1.08 M] with a total volume of 100 m*l* and at an ionic strength $\mu=1.13$. The ionic strength was kept constant by the addition of sodium perchlorate. It was found that the change in ionic strength (~ 1.13 to 2.63) does not appreciably change the rate of oxidation. Nitric acid was used as a source of hydrogen ions and nitrate ion concentration was adjusted with potassium nitrate solution.

The rate of oxidation was followed by withdrawing aliquots at appropriate intervals of time and quenching the latter in known excess of ferrous ammonium sulphate, back titrating the excess of the latter by standard ceric sulphate using ferroin as an indicator. Reactions were usually conducted for 50—60% conversion of ceric ion.

Results and Discussion

Rate Laws. When *s*-butyl alcohol was in excess, the rate at which cerium(IV) disappears followed the first order rate law, agreeing with the findings of Sethuram and Muhammad.[1] The graphical method was generally used to derive the rate constants.

TABLE 1. VARIATION OF RATE WITH CONCENTRATION OF *s*-BUTYL ALCOHOL

$[Ce(IV)]: 4.0\times10^{-3}$ M; $[HNO_3]: 1.08$ M; Temp.: 25°C. $\mu=1.13$ M

$[Alcohol]\times10^2$ mol/*l*	5.0	10.0	15.00	20.0	25.0
$k_1\times10^3$ min^{-1}	2.23	4.06	5.15	6.66	7.69

In a constant cerium(IV) concentration, it was found that the rate of oxidation rises with increase in alcohol concentration but tends to reach a limiting value at high concentrations of alcohol (Table 1). A plot of the inverse of alcohol concentration against that of observed rate constants gave a straight line. The result suggests that the oxidation proceeds through

* Present address: Department of Chemistry, University of Udaipur, UDAIPUR (India).

1) B. Sethuram and S. S. Muhammad, *Acta Chim. Hung.*, **46**, 115, 125 (1965).

the complex between the alcohol and cerium(IV) as has been suggested by Ardon.[2]

$$\text{Cerium(IV)} + s\text{-butyl alcohol} \overset{K}{\rightleftarrows} \text{complex}$$

$$\text{Complex} \xrightarrow[\text{slow}]{k_s} \text{Cerium(III)} + \text{Free radical} + H^+$$

$$\text{Free radical} + \text{Cerium(IV)} \xrightarrow{\text{fast}} \text{Ketone} + \text{Cerium(III)} + H^+$$

The variation of rate of oxidation with concentration of alcohol is given by the expression

$$-\frac{d[Ce(IV)]}{dt} = \frac{k_s[\text{Alcohol}][Ce(IV)]}{1/K + [\text{Alcohol}]}$$

From the slope-intercept ratio, $K=2.50$ and $K_s = 3.34\times10^{-4}$ sec^{-1} at 25°C have been obtained.

By repeating the procedure at various temperatures, the formation constants (K) have been calculated at different temperatures (Table 2). The thermodynamic data on the cerium(IV)-alcohol complex are listed in Table 3.

Table 2. Effect of temperature on formation of cerium(IV)-*s*-butyl complex

[Ce(IV)]: 4.0×10^{-3} M; [HNO_3]: 1.08 M, $\mu=1.13$ M

Temp., °K	298	303	308
K, l/mol	2.50	1.97	1.62

Table 3. Thermodynamic constants of the cerium(IV) - *s*-butyl alcohol complex

Property	By Sethuran and Muhammad[1] at 22°C	Present work at 25°C and [H^+]: 1.08, μ: 1.13 M
K l/mol	2.213	2.50
$-\Delta H$ kcal/mol	6.75	7.66
$-\Delta F$ cal/mol	465.8	540.8
$-\Delta S$ e. u.	−23.06	−23.90

The difference in the values reported by Sethuram and Muhammad[1] and those obtained in the present investigation might be due to different experimental conditions. The value of the formation constant of the Ce(IV) -alcohol complex probably depends upon hydrogen ion concentration used. The authors[1] gave no idea of the hydrogen ion concentration used by them.

The variation of rate constants with temperature is shown in Table 4.

Table 4. Effect of temperature on the rate of reaction

[Ce(IV)]: 4.0×10^{-3} M: [Alcohol]: 5.0×10^{-2} M; [HNO_3]=1.08 M

Temp., °K	298	303	308	313
$k_1\times10^5$ sec^{-1}	3.71	6.83	10.4	21.6

The apparent energy of activation E was calculated to be 22.0±1.0 kcal by plotting $\log k_1$ *vs.* $1/T$.

2) M. Ardon, *J. Chem. Soc.*, **1957**, 1811.

At constant nitrate ion concentration increase in hydrogen ion concentration causes a slight but distinct decrease in the rate of oxidation. (Table 5).

Table 5. Variation of rate with concentration of hydrogen ions

[Ce(IV)]: 4.0×10^{-3} M, [Alcohol]: 5.0×10^{-2} M; Temp.: 35°C; [NO_3^-]: 2.5 M; $\mu=2.55$ M

[H^+] mol/l	0.50	0.90	1.50	2.0	2.5
$k_1\times10^3$ min^{-1}	7.17	6.76	6.07	5.81	5.48

The effect of hydrogen ion concentration may be explained on the basis of the equilibrium

$$Ce^{4+} + H_2O \rightleftharpoons Ce(OH)^{3+} + H^+ \quad (1)$$

If it is assumed that $Ce(OH)^{3+}$ is a more powerful oxidant than Ce^{4+}, then an increase in the concentration of hydrogen ions should decrease the concentration of $Ce(OH)^{3+}$ and hence the rate of oxidation. The small effect of the concentration of hydrogen ions on the rate of oxidation suggests that the value of the equilibrium constant for reaction (1) is small. At the total concentration of cerium(IV) used, cerium exists mostly as $Ce(OH)^{3+}$ or Ce^{4+}, concentration of the dimer $(Ce\text{–}O\text{–}Ce)^{6+}$ being negligibly small.

If reaction (1) is valid and [Ce(IV)] represents the total concentration of cerium(IV), we have

$$[Ce(OH)^{3+}] + [Ce^{4+}] = [Ce(IV)]$$

$$\text{and} \quad K_h = \frac{[Ce(OH)^{3+}][H^+]}{[Ce^{4+}]} = \frac{[Ce(OH)^{3+}][H^+]}{[Ce(IV)]-[Ce(OH)^{3+}]}$$

$$\text{or} \quad K_h[Ce(IV)] = [Ce(OH)^{3+}]\{[H^+]+K_h\}$$

$$\text{or} \quad [Ce(OH)^{3+}] = \frac{K_h[Ce(IV)]}{[H^+]+K_h}$$

The rate of oxidation will be given by the equation

$$\frac{-d[Ce(IV)]}{dt} = K'\frac{K_h}{[H^+]+K_h}\cdot[Ce(IV)] = k_1[Ce(IV)]$$

$$\text{hence} \quad k_1 = \frac{K'K_h}{[H^+]+K_h}$$

where K_h is the equilibrium constant for reaction (1), k_1 is the observed first order rate constant, and K' is a constant which includes the concentration of alcohol (which is kept constant). Hence we have

$$\frac{1}{k_1} = \frac{1}{K'K_h}\cdot[H^+] + \frac{1}{K'}$$

A plot of $1/k_1$ against [H^+] gave a straight line in the case of *s*-butyl alcohol. The value of K_h was found to be 6.19 at 35°C. The value of K_h found spectrophotometrically by Hardwick and Robertson[3] in $HClO_4$ for reaction (1) was 5.2 at 25°C. This supports the view that in the present investigation $Ce(OH)^{3+}$ may probably be the active species.

It may, however, be pointed out that Sethuram and Muhammad[1] observed that at constant nitrate

3) T. J. Hardwick and E. Robertson, *Can. J. Chem.*, **29**, 818 (1951).

ion concentration, the increase in the H^+ ion concentration was found to accelerate the rate of oxidation. They suggested $[Ce(H_2O)_2(NO_3)_4]$ as the neutral active species. We have not been able to confirm this result.

Table 6. Effect of nitrate ion on the rate of oxidation

[Ce(IV)]: 4.0×10^{-3} M; [Alcohol]: 5.0×10^{-2} M; [HNO]: 0.50 M; Temp.: 35°C.

$[KNO_3]$ mol/l	0.00	0.20	0.40	0.60	0.80	1.00
$k_1\times10^4$ min^{-1}	7.13	6.98	6.71	6.58	6.20	6.01

The nitrate ion was found to inhibit oxidation to a small extent (Table 6). The retardation caused by nitrate ions has also been indicated by Sethuram and Muhammad[1] who observed a linear relationship between observed rate constant and the square of the nitrate ion concentration. The retardation caused by nitrate ions is not so strong as indicated by them. The small retarding effect observed by us can not be attributed to the effect of the ionic strength as well. Shorter[4] explains this inhibiting action of nitrate ions during the oxidation of acetone by ceric ammonium nitrate in nitric acid, by conversion of $Ce(OH)^{3+}$ into a much less reactive species $[Ce(OH)NO_3]^{2+}$:

$$Ce(OH)^{3+} + NO_3^- \rightleftharpoons [Ce(OH)NO_3]^{2+} \quad (2)$$

Addition of sulphate ion retarded the rate of oxidation considerably. The results on the effect of addition of sulphate ions on the rate of oxidation are given in Table 7.

Table 7. Effects of sulphate ions on the rate of oxidation

[Ce(IV)]: 4.0×10^{-3} M; [Alcohol]: 10.0×10^{-2} M [HNO_3]: 1.08 M; Temp.: 25°C.

$[Na_2SO_4]\times10^3$ mol/l	0.00	5.0	10.0	15.0	20.0	25.0
$k_1\times10^3$ min^{-1}	4.06	2.88	2.30	1.92	1.60	1.40

A plot of $1/k_1$ against $[SO_4^{2-}]$ gave a straight line.

The results find an explanation on the assumption that $Ce(OH)^{3+}$ forms complexes with SO_4^{2-} of the type (*cf.* Hargreaves and Sutcliff[5]),

$$Ce(OH)^{3+} + SO_4^{2-} \overset{k_b}{\rightleftharpoons} [Ce(OH)SO_4]^+ \quad (3)$$

and that the complex $[Ce(OH)SO_4]^+$ is a poor oxidant as compared with $Ce(OH)^{3+}$.

If reaction (3) is valid, $[Ce(IV)]=[Ce(OH)^{3+}]+[Ce(OH)SO_4^+]$, the observed rate constant will be related to the concentration of sulphate ions by the expression

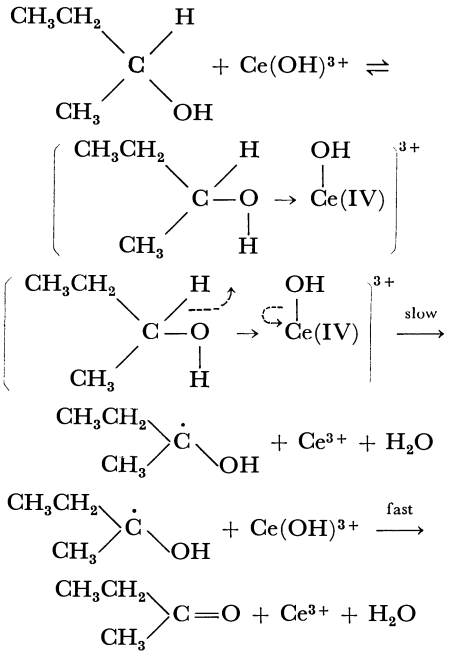
$$k_1 = \frac{K''}{1+K_b[SO_4^{2-}]}$$

$$\text{or} \quad \frac{1}{k_1} = \frac{K_b}{K''}\cdot[SO_4^{2-}] + \frac{1}{K''}$$

where k_1 is the observed rate constant and K'' is a constant which includes the concentration of alcohol. From the above relationship, the inverse of the observed rate constant plotted against concentration of sulphate ions should be a straight line as has been observed.

Our results suggest $Ce(OH)^{3+}$ as the reactive species. The colour change of the ceric solution from yellow to reddish brown when alcohol was added indicates the formation of an intermediate complex which has also been established spectrophotometrically.[1]

On the basis of the low value of $k_{CH}/k_{CD}=1.9$ for α-deuterioalcohol during the oxidation of deuterated cyclohexanol by ceric sulphate and $k_{OH}/k_{OD}=1.0$ for oxygen deuterium alcohol, Littler and Waters[6] and Littler[7] suggested that the α-carbon hydrogen fission might be preponderant, though Littler[8] suggested that a concerted mechanism involving both C–H and O–H fissions can not be ruled out. Thus, the mechanism for the oxidation of *s*-butyl alcohol by cerium (IV) in nitric acid may be written as



$Ce(OH)^{3+}$ is written as an oxidising species. The ligand groups like NO_3^-, H_2O, *etc.* have not been indicated for the sake of simplicity.

Charge-Transfer Interaction and Fluorescence in Some Tetracyanobenzene Complexes

Takayoshi KOBAYASHI, Keitaro YOSHIHARA,* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received February 15, 1971)

Fluorescence lifetimes and quantum yields were measured for some tetracyanobenzene complexes with benzene and its methyl derivatives, and the radiative and nonradiative rate constants were determined under various conditions. The results show that the low fluorescence intensities of the complexes in nonpolar fluid media are due to small radiative rate constants and that nonradiative processes become important for the complexes in polar fluid media. From the theoretical consideration of the observed radiative transition probability, it is found that the geometry and the charge distribution in the excited equilibrium state are greatly different from those in the excited Franck-Condon state for the complexes in fluid media at room temperature and that the degree of the charge-transfer in the former state amounts to 96—100%, while it is only 12—45% in the latter state. The stabilization energy due to the reorientation was obtained from the temperature dependence of the fluorescence spectrum.

The fluorescence spectra measured for charge-transfer (hereafter abbreviated to CT) complexes, though rather scanty,[1-9] have the following two characteristics: (1) their Stokes shifts in solution lie between 3500 cm^{-1} and 8500 cm^{-1} at low temperature (−190°C),[1,2] and (2) fluorescence has been observed for only a few CT complexes in solution at room temperature,[3-7] and its intensity is very weak even if it is observed.[10]

Short and Parker[4] determined the quantum yield of fluorescence at room temperature to be ~0.01 or less for the tetrachlorophthalic anhydride and pyromellitic dianhydride complexes with hexamethylbenzene and naphthalene in several solvents. Prochorow and Siegoczyński[5] also measured their fluorescence quantum yields and lifetimes in several solvents and obtained low quantum yields of less than 0.017. Mataga *et al.*[6,7] explained the decrease in the quantum yield with the solvent polarity as due to the decrease in the radiative transition probability. However, Prochorow and Siegoczyński[5] showed that the radiative transition probability might be constant for a series of solvents and that the radiationless transition probability increased with their dielectric constants, though they could not exclude the possibility that, in highly polar solvents, the radiative transition probability might diminish.

It must be emphasized that non-fluorescent CT complexes in fluid solutions at room temperature have fluorescence in the rigid phase.[1,2,11]

In order to explain the above-mentioned characters of CT complexes, we measured the fluorescence lifetimes and quantum yields of tetracyanobenzene complexes with benzene and its methyl derivatives, and determined the radiative and nonradiative rate constants under several conditions. On the basis of the observed results and the theoretical consideration of the radiative rate constants, we interpreted the low quantum yield and the large Stokes shift of CT fluorescence in terms of the reorientation of solvent molecules and the change in the geometry of the complex itself.

Experimental

Materials. Tetracyanobenzene (abbreviated hereafter to TCNB) used as an electron acceptor was purified by recrystallization from ethanol. Dotite spectrograde benzene and toluene were used as donors and solvents without further purification.[12] Commercially-available mesitylene and *m*- and *p*-xylene were purified by distillation. Durene was purified by repeated recrystallizations from benzene and by repeating zone refining about 50 times. Hexamethylbenzene (abbreviated hereafter to HMB) was purified by repeated recrystallizations from ethanol and thereafter by sublimation *in vacuo*.

Ethyl ether was shaken with a 10% aqueous sodium sulfite solution, washed with a saturated aqueous sodium chloride solution containing sodium hydroxide, dried over calcium chloride, and finally distilled over metallic sodium. Cyclo-

12) We checked, in the initial stage of our experiment, the effect of the purification of benzene and toluene upon fluorescence by comparing the results obtained by the use of the untreated materials with those obtained by the use of the materials purified by shaking with concentrated sulfuric acid, by washing, by drying, and finally by distillation. We could observe no significant effect of purification on the observed results.

hexane was shaken with fuming sulfuric acid, washed with water and aqueous sodium hydroxide, boiled with a mixture of fuming nitric acid and concentrated sulfuric acid, washed with the mixture more than three times, distilled with hydrochloric acid, washed with water, and dried with calcium chloride. After being passed through a newly activated silica gel column, it was finally distilled over metallic sodium.

Methyl methacrylate (MMA) was shaken with 5% aqueous sodium hydroxide several times until no color developed, washed with water more than five times, dried overnight with anhydrous magnesium oxide, and distilled under *ca.* 100 mmHg with nitrogen ebullition. Immediately after the distillation, it was passed through a column of activated silica gel covered with aluminum foil, and redistilled under reduced pressure with nitrogen ebullition. The purified MMA was stored at *ca.* −5°C and was used as a solvent and also as a material for the preparation of a polymer matrix as soon as possible after the above-mentioned purification.

Preparation of Polymer Rigid Solutions Containing Complexes. The rigid solutions of TCNB complexes in polymethyl methacrylate (PMMA) were prepared by polymerizing the MMA solutions in the following way. The MMA solution in a sample tube was deaerated carefully until no bubbling could be detected; then it was polymerized by being kept at 64°C in the dark for about 3 days, and finally slowly cooled to room temperature. No chemical change occurred during the polymerization in the electron donors and acceptors under consideration. We used transparent and completely polymerized rigid solutions with no crack at 77°K.[13] We carefully treated the polymerized samples in order not to expose them to light before measurements.

Measurements. The absorption spectra of TCNB complexes under various conditions were measured by a Cary recording spectrophotometer, Model 14 M. Emission spectra were measured by a JASCO CT-50 grating monochromator with a 100-W high-pressure mercury lamp at a light source, and by an Aminco-Bowman spectrophotofluorometer with a xenon or a mercury-xenon lamp. The emission was detected with an RCA 1P28, an RCA 1P21, or an EMI 9529A photomultiplier. The correct quantum spectra of the complexes were obtained by measuring the sensitivity spectrum of an optical system consisting of lenses, a monochromator, and a photomultiplier by the aid of a standard tungsten filament lamp. Fluorescence quantum yields, η_F's, were measured in the way described by Parker and Rees.[14] The fluorescence quantum yield of the tetrachlorophthalic anhydride-HMB complex was measured by taking the solution of quinine bisulphate in 0.1 N sulfuric acid as the standard. The value thus obtained is in good agreement with that measured by Prochorow and Siegoczyński[5] by using quinine bisulphate or trypaflavine as the standard. For the sake of convenience, the tetrachlorophthalic anhydride-HMB complex was adopted as the secondary standard in determining the quantum yields of the TCNB complexes under consideration, since its fluorescence and absorption are similar to those of the latter complexes in intensity, band shape, and position.

A nitrogen gas laser with a repetition rate of *ca.* 20 Hz, a peak power of ~20 kW, and a pulse width of ~3 nsec was used as the light source for the fluorescence-decay measurements.

Experimental Results

Absorption Spectra and Natural Lifetimes. Absorption spectra were measured for binary solutions containing TCNB in pure benzene, toluene, xylenes, and mesitylene, and also for MMA solutions containing TCNB as an electron acceptor and durene or HMB as an electron donor. The peak wave numbers (ν^A_{max}) and molar extinction coefficients (ε) for the observed CT bands are given in Table 1, together with the ionization potentials of the donors.[15] The natural lifetimes, τ_0's, and the corresponding radiative rate constants, k's, of the complexes were determined by the aid of Eq. (1) presented by Strickler and Berg[16]:

$$k(\mathrm{SB}) = \tau_0^{-1}(\mathrm{SB}) = 2.880 \times 10^{-9} n^2 \langle \nu^{F-3} \rangle_{Av}^{-1} \frac{g_l}{g_u} \int \varepsilon \, d\ln \nu^A \quad (1)$$

Here g_l and g_u represent the degeneracies of the lower and upper states, respectively; ν^A and ν^F are the wave numbers of the absorption and fluorescence spectra, respectively, and n is the refractive index of the solution. In actuality, k(SB) was obtained by the use of the refractive index of the solvent, n_0 instead of that of the solution. This may be expected to have no serious effect to the result, since the concentration of the solution is very small. The evaluated k(SB) values are given in Table 1.

Fluorescence Spectra, Stokes Shifts, Lifetimes, Quantum Yields, and Their Temperature Dependencies. Fluorescence spectra were measured under various conditions for the systems used for the absorption measurements. The total emission spectra are shown in Figs. 1 and 2. As clearly seen in Fig. 1, the fluorescence spectra measured at room temperature for the binary systems containing TCNB in benzene, toluene, *m*-

Table 1. The absorption peak wave number (ν^A_{max}), molar extinction coefficient (ε), and radiative rate constant (k) of TCNB complexes with various electron donors

Donor[a]	I[b] (eV)	n[c]	ν^A_{max} (10^3 cm^{-1})	ε (M^{-1} cm^{-1})	k(SB) (10^7 sec^{-1})
Benzene	9.245	1.5016	32.5	2200	3.8_4
Toluene	8.82	1.4893	31.8	1800	2.3_8

HMB	7.85	1.5015	24.6	880	0.80_0

a) The measurements were made for the binary systems including a small amount of TCNB in each donor except for the durene-TCNB and HMB-TCNB systems for which the MMA solutions were used.
b) The ionization potential of donor.
c) The refractive index of solvent.
d) The absorption spectrum of the TCNB-durene complex in MMA has no peak but a shoulder. The peak position was estimated by separating the absorption intensity in the concerned wavelength region into the two parts belonging to the strong and weak bands.

13) The incompletely polymerized solution was cracked at the liquid nitrogen temperature.
14) C. A. Parker and W. T. Rees, *Analyst*, **85**, 587 (1960).
15) The equilibrium constants for the CT complex formation were determined to be 0.79 and 2.8 ($l \cdot \mathrm{mol}^{-1}$) by the aid of the usual Stern-Volmer plot for the TCNB complexes with durene and HMB in MMA, respectively.
16) S. J. Strickler and R. A. Berg, *J. Chem. Phys.*, **37**, 814 (1962).

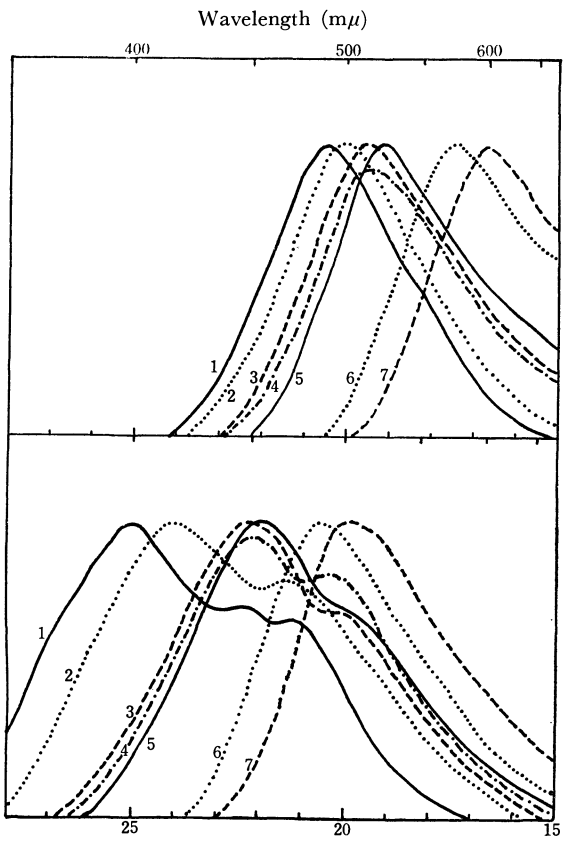

Fig. 1. The total emission spectra of TCNB complexes at room temperature (upper) and at 77°K (lower).

Curve	Donor	Solvent
1	benzene	benzene
2	toluene	toluene
3	*m*-xylene	*m*-xylene
4	*p*-xylene	*p*-xylene
5	mesitylene	mesitylene
6	durene	MMA
7	HMB	MMA

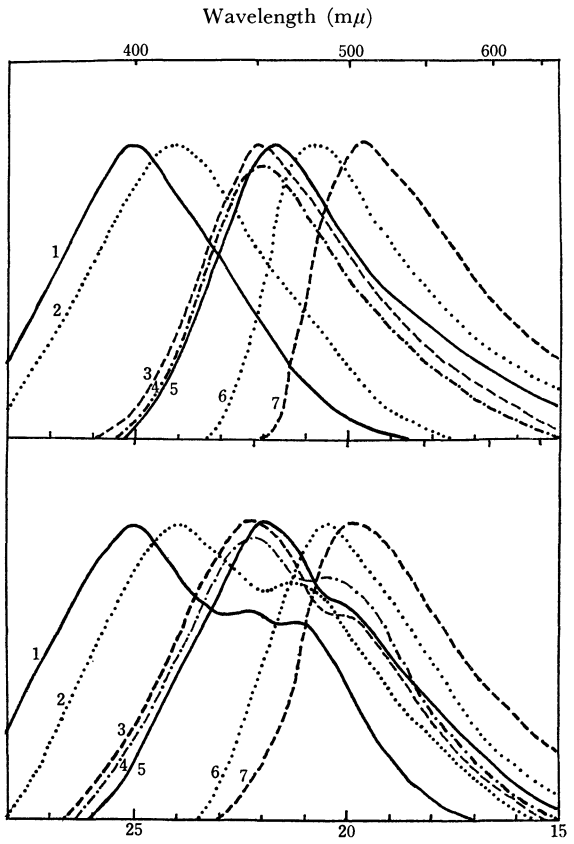

Fig. 2. The total emission spectra of TCNB complexes in PMMA solid solution at room temperature (upper) and at 77°K (lower). The numbering of the curves is the same as in Fig. 1.

xylene, *p*-xylene, and mesitylene (group I) and for the ternary systems of TCNB-durene-MMA and TCNB-HMB-MMA (group II) are different from those at the liquid nitrogen temperature. On the other hand, Fig. 2 shows that the fluorescence spectra of complexes in the PMMA rigid solution (group III) are essentially independent of the temperature, except for the fact that the CT phosphorescence appears at 77°K.

Tables 2 and 3 show the Stokes shifts observed for the TCNB complexes at room temperature and at 77°K, respectively. The observed values at 77°K lie between 8300 cm^{-1} for TCNB-*p*-xylene and 4500 cm^{-1} for TCNB-HMB-MMA, and are close to those previously observed for the other complexes *i.e.*, 8500 cm^{-1} for chloranil-1,2-benzanthracene and 3500 cm^{-1} for 1,3,5-trinitrobenzene-durene.[1,2] At room temperature, however, they are extraordinarily large; that is to say, they are 12000 cm^{-1} for TCNB-benzene

and 7900 cm^{-1} for TCNB-HMB-MMA. These facts suggest that the equilibrium state of the lowest excited state is very different from the Franck-Condon state.

The quantum yields were determined at room temperature for the complexes of groups I and II, but at the liquid nitrogen temperature they could not be measured because all the samples except for the TCNB-toluene system became opaque. Therefore, the quantum yields of the complexes of groups I and II at the liquid nitrogen temperature are assumed to be equal to the value of the corresponding TCNB complexes of group III at the same temperature. The validity of this assumption was checked by comparing the fluorescence intensity at 77°K measured for the TCNB-toluene-PMMA system with that for the TCNB-toluene system, which vitrifies in a thin glass tube. The quantum yields derived from the integrated fluorescence intensities observed for the TCNB-toluene and TCNB-toluene-PMMA systems deviate from each other by only 15%. Radiative and nonradiative rate constants were obtained from the quantum yields and lifetimes measured at room temperature and at 77°K; they are listed in Tables 2 and 3.

The fluorescence lifetimes and quantum yields were measured at various temperatures between 77°K and 300°K for the TCNB-toluene and TCNB-HMB-PMMA systems, and their radiative and nonradiative rate constants were obtained; the results are shown in Figs. 3 and 4, together with the temperature dependencies of the wave numbers of the fluorescence maxima, the lifetimes, and the quantum yields. According to Figs. 3 and 4, TCNB-toluene and TCNB-HMB-PMMA show greatly different temperature dependencies of the fluorescence maxima, lifetimes, quantum yields, and radiative rate constants. These quantities change abruptly at about 140°K for the former, while for the latter they vary continuously and the change is small in the whole temperature range.

	Ethyl ether	23	16.7	∼0.0001	5	∼0.2	20

Tables 2, 3, and 4 show that the lifetime of the TCNB-*p*-xylene system at the dry ice-ethanol temperature (−72°C) is close to that at 77°K, while in the TCNB-*m*-xylene system the values at both temperatures are different. This is related to the difference in the rigidity of the solutions. At both temperatures, the TCNB-*p*-xylene system is in a rigid state and has a similar lifetime. The TCNB-*m*-xylene system is fluid at dry ice-ethanol temperature and the lifetime at this temperature is shorter than that at 77°K.

Fluorescence Lifetime and Quantum Yield in Polar Solvents. The fluorescence maxima, lifetimes, and quantum yields of several TCNB complexes were measured in various solvents; the results for the TCNB-durene and TCNB-HMB systems are shown in Table 4. This table shows that the fluorescence lifetimes τ_F's, are shorter in polar solvents than in nonpolar solvents. However, the radiative rate constant, $k_F=\eta_F/\tau_F$, for each complex is nearly independent of the solvents used. The situation is the same for the other complexes, though the details will not be presented here.

CT Complexes in the Crystalline State. The fluorescence maximum wave numbers, lifetimes, and relative intensities, I_F's for the TCNB-durene and TCNB-HMB complexes in the crystalline state are given in Table 5. The fluorescence maximum wave numbers and lifetimes given in this table are similar to those of the corresponding complexes in PMMA or in solution at 77°K. The slight difference in the fluorescence maximum wave number between room temperature and 77°K was found by careful measurements to be due to the enhancement of the reabsorption at the higher temperature. The τ_F/I_F values are almost constant between room temperature and 77°K; therefore, the radiative rate constants are almost independent of the temperature.

Table 5. Fluorescence maximum wave numbers (ν^F_{max}), lifetimes (τ_F), and relative intensities (I_F) of the TCNB complexes with durene and hexamethylbenzene in crystalline state

	77°K	19.0	40	1.5

Theoretical Consideration and Discussion

The Possibility of 1 : m Complexes in the Excited State. The large Stokes shift observed for the complexes in the fluid state may be explained by the reorientation of the solvent and solute molecules or by $1:m$ ($m\geq 2$) complex (AD_m) formation in the excited state. According to Table 4, the binary system, for example, TCNB-durene at 80°C, has the fluorescence peak at 19.0×10^3 cm^{-1}. This position is almost the same for the solution containing TCNB-durene in an inert solvent like cyclohexane. This seems to mean that the large Stokes shift for this system in fluid media is not due to the $1:m$ complex formation in the excited state. The situation is the same for the other systems showing a large Stokes shift in fluid media.

Dependence of the Fluorescence Spectrum on the Rigidity of the Medium. The large Stokes shifts observed for fluorescence spectra in fluid solutions are conceivably caused by the stabilization due to the interaction of the excited CT complex with a large dipole moment with the surrounding solvent molecules.[17]

According to Bakshiev, with a decrease in the temperature the fluorescence spectra of polyatomic molecules shift first toward the longer wavelengths and thereafter toward the shorter wavelength as the solvent viscosity increases.[17] Accordingly, a turning point is expected to be observed for the ν^F_{max} *versus* temperature curve. This effect was in fact observed with the TCNB-toluene system, as is shown in Fig. 3. The turning point at ∼140°K is close to the melting point of the toluene solution containing 10^{-3} M of TCNB. This tendency has been found for several systems with intramolecular CT interaction, such as biphenyl, stilbene, and fluorene derivatives in various

solvents.[18]

From Eq. (4) in Reference (17b) and the fluorescence and absorption maxima observed by us and in the literature,[7] we estimate the dipole moment in the excited state of the TCNB-HMB complex to be 8.34 D, by assuming the Onsager radius to be 5.81 Å.[19] This value is rather small compared with 14(±3)D or 10(±1.5)D of the tetrachlorophthalic anhydride-HMB complex.[9,20]

We can now roughly estimate the stabilization energy due to the reorientation of the solute and solvent molecules in the excited state (E_R), the Franck-Condon energies in the ground state before and after reorientation (E_{gb}^{FC} and E_{ga}^{FC}, respectively), and the Franck-Condon energy in the excited state (E_e^{FC}). Their definitions and relations to the wave numbers of the absorption and fluorescence maxima are shown in Fig. 5, while their values are listed in Table 6.

The potential energy curves of the ground and excited states before and after reorientation are shown in Fig. 5, where q means a set of the coordinates which indicates the positions and orientations of the solvent molecules near the solute CT complex. All the q_G's and q_E's adjust themselves to minimize the energies of the ground state, $E_G(R, Q, q)$, and the lowest excited state, $E_E(R, Q, q)$, respectively. Fluorescences in rigid and fluid media take place from the lowest point of the

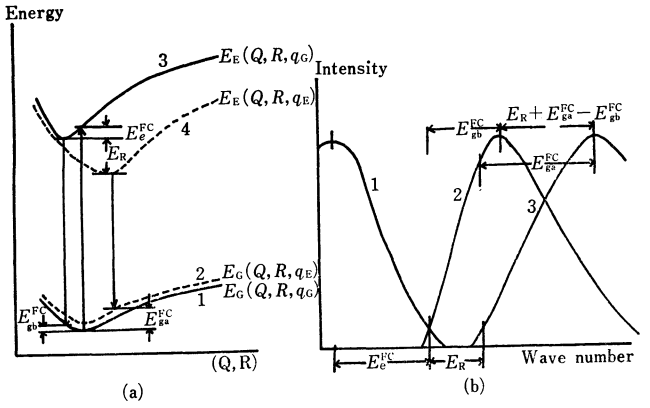

Fig. 5. (a) The potential energy curves of CT complexes. The curves are drawn by plotting the energies *versus* the internal coordinates of the component molecules, Q's and the coordinates concerning the intermolecular distance and orientation, R's. Coordinates of surrounding solvent molecules, q's are determined in such a way as to minimize the energy for a fixed point of the abscissa. 1, ground state before reorientation; 2, ground state after reorientation; 3, first excited singlet state before reorientation; 4, first excited singlet state after reorientation.

$E_E(R, Q, q_G)$ and $E_E(R, Q, q_E)$, respectively. The stabilization energy due to the reorientation, E_R, is defined as the energy difference between the two lowest points of the two potential energy curves.

As is shown in this table, the E_R value increases with an increase in the ionization potentials of donors. This may be related to the experimental fact that the difference in the radiative rate constant between room temperature and 77°K increases with the increase in the ionization potential of the donor.

Radiative and Nonradiative Rate Constants. The complexes in a rigid solution, in a nonpolar fluid medium, and in a polar fluid medium are denoted as the complexes in the A, B, and C states, respectively. According to Tables 2, 3, and 4, the radiative rate constants are 10^{6-7} sec^{-1} and 10^{4-5} sec^{-1} for the complexes in the A and B states, respectively. Furthermore, these tables show that the nonradiative rate constants of complexes in the A and B states are 10^{6-7} sec^{-1}, while those in the C state are about 10^8 sec^{-1}. From these facts, it can be concluded that the low fluorescence intensity of the CT complexes in a nonpolar fluid medium is due to the small radiative rate constant and that, for the CT complexes in a polar fluid medium, the nonradiative quenching effect becomes important in addition to the above-mentioned effect. Therefore, it may be said that the discussions made by Mataga and Murata[7] and by Prochorow and Siegoczyński[5] concerning the low fluorescence intensity are correct for the CT complexes in nonpolar and polar media, respectively.

When we compare the radiative rate constant, k(SB), in Table 1, obtained from the absorption intensity, with the rate constant, k^F, in Tables 2 and 3, we can see that the former is larger than the latter for each complex, both at room temperature and at the liquid nitrogen temperature.[21] In particular, the value of k^F at room temperature is extraordinarily small compared with k(SB). This fact, as will be described below, can be explained by considering the great differences in the electron distribution and in the

18) E. Lippert, W. Luder, and F. Moll, *Spectrochim. Acta*, **10**, 585 (1959).

19) The value is given by $(\sqrt{1.7^2+3.96^2}+1.5)$ Å, where 1.7 Å, 3.96 Å, and 1.5 Å are a half of the intermolecular distance, the distance between the center of the TCNB molecule and one of its nitrogen atoms, and the van der Waals radius of nitrogen, respectively.

20) J. Czekalla, *Z. Elektrochem.*, **64**, 1221 (1960); *Chimia* (Switz.), **15**, 26 (1961).

21) Mataga and Murata[7] obtained larger natural lifetimes, 50 and 60 nsec for TCNB-benzene and TCNB-toluene, respectively, than the corresponding values obtained by us, 26 and 43 nsec, respectively. According to our opinion, their values are too great because they disregarded the n^2 in Eq. (1) in their evaluation.

geometrical configuration between the Franck-Condon state and the excited equilibrium state.

The Calculations of the Radiative Rate Constants and the Contribution of the CT Configuration to the Excited State. The wave functions and energies of the ground and excited states of the complex were calculated by considering the configuration interaction among the ground, CT, and locally-excited (abbreviated hereafter to LE) configurations[22,23] constructed by putting electrons into the SCF of MO's of TCNB and benzene. The actual calculations were made by an electronic computer, FACOM 270—30.

The calculations for the system in the rigid solvent were made for the geometrical structure shown in Fig. 6(a), the most stable geometry in the ground state,[24] the ionization potential of the electron donor, I, being taken as a parameter and the electron affinity of the electron acceptor, A, being fixed at 0.4 eV.[25]

By evaluating the matrix element of the dipole moment by the aid of the Mulliken approximation and by taking the diagonal element concerning the CT configuration and the off-diagonal element between the ground and LE configurations to be 3.4 Å and 0.3 Å, respectively, we calculated the transition moment and the natural radiative rate constant, k, which corresponds to k(SB) in Table 1. The results are shown in Table 7. For purposes of comparison, k(SB) and k^F at 77°K ($k^F_{77°K}$) are also tabulated in this table. The k values calculated for the complexes under consideration lie intermediate between the corresponding k(SB) and $k^F_{77°K}$ values. Generally speaking, the calculated k value agrees well with the observed k(SB) or $k^F_{77°K}$ value for each complex. The contribution of the CT configuration to the excited Franck-Condon state changes from 12.4% for the TCNB-benzene complex to 44.6% for the TCNB-HMB complex.

Now let us consider the energy of the lowest excited singlet state in its potential energy minimum. There is no available data on the most stable configuration in the excited state, so we calculated its energy by the method described in the previous paper[23] for various geometrical configurations; the results are shown in Fig. 7. The energy contour map for the lowest excited state shown in this figure was obtained by locating the plane of TCNB parallel to that of benzene with a distance of 3.4 Å and by setting, as is shown in Fig. 6, the a axis of the TCNB molecule parallel to the x axis. It may be worth noting that the main feature in the

23) T. Kobayashi, S. Iwata, and S. Nagakura, This Bulletin, **43**, 713 (1970).
24) The geometry shown in Fig. 6(a) is very similar to that determined for the TCNB-durene and TCNB-HMB crystals by the X-ray diffraction technique (TCNB-durene: H. Tsuchiya, N. Niimura, and Y. Saito, private communication; TCNB-HMB; N. Niimura, Y. Ohashi, and Y. Saito, This Bulletin, **41**, 1815 (1968)).
25) G. Briegleb, *Angew. Chem. Intern. Ed. Engl.*, **3**, 617 (1964).

energy contour map is common for all the TCNB complexes examined and that in the most stable configuration, the component molecules are located with their centers on the z axis, as is shown in Fig. 6(b).

From the above-mentioned facts, it may be expected that, in fluid media, the component molecules reorient to a great extent and take the geometrical configuration shown in Fig. 6(b). Furthermore, there occur reorientations of the surrounding solvent molecules[26] in addition to those of the electron donor and acceptor molecules. Next, we will describe the wave functions of the ground and excited states of the reoriented system in general forms.

$$\theta_{re}^{G} = a_0^{re}\theta_0(AD)_{re} + \sum_i a_i^{re}\theta_i(A^-D^+)_{re} + \sum_j a_j^{re}\theta_j(A^*D)_{re} \quad (2)$$

$$\theta_{re}^{E} = b_0^{re}\theta_0(AD)_{re} + \sum_i b_i^{re}\theta_i(A^-D^+)_{re} + \sum_j b_j^{re}\theta_j(A^*D)_{re} \quad (3)$$

where θ_0, θ_i's, and θ_j's are the wave functions of the ground, CT, and LE (in acceptor) configurations, respectively, where a_m's and b_m's are the coefficients of the corresponding configurations in the ground and excited states, respectively, and where the superscript or subscript "re" means that the wave function or coefficient is connected with the reoriented system.

In the geometry shown in Fig. 6(b), the overlap integral between electron-donating and -accepting orbitals is equal to zero because of the high symmetricity of the system.[27] This means that the a_i^{re}, a_j^{re}, and b_0^{re} coefficients are nearly equal to zero[28] and that the matrix element, $\langle\theta_i(A^-D^+)_{re}|\vec{er}|\theta_0(AD)_{re}\rangle$, is very small. Here, r represents the coordinate of an electron. Thus, only the following term contributes to k_{RT}^{F};

$$\sum_j a_0^{re}b_j^{re}\langle\theta_0(AD)_{re}|\vec{er}|\theta_j(A^*D)_{re}\rangle \quad (4)$$

where $a_0^{re}\cong 1$. The transition-moment integral in Eq. (4) can be estimated by the aid of the observed absorption spectrum of TCNB itself.

From the observed k^F values at room temperature (k_{RT}^{F}) given in Table 2 and the matrix element shown by Eq. (4), we can obtain the coefficient of the lowest LE (in the acceptor), b_1, which is dominant among b_j's; therefore, we can evaluate the contributions of the LE and CT configurations to the fluorescent state after reorientation. The evaluated values for the CT configuration are given in Table 7. This table shows that, even for the TCNB-benzene and TCNB-toluene complexes, for which the contributions of the CT configuration are less than twenty percent in the Franck-Condon states, they exceed 95% in the excited equilibrium state after reorientation at room temperature. This conclusion as to the TCNB-toluene system is consistent with the result obtained by Masuhara and Mataga from the measurement of the absorption due to the transition from the first excited singlet state to the higher excited state.[29] It is worthy of notice that the degree of the CT between electron donor and acceptor changes greatly upon the reorientation of the component molecules of the complex and of the solvent molecules.

The experimental results given in Table 4 show that the decrease in the fluorescence intensity in a polar solvent is due to the increase in the nonradiative decay. This seems to mean that the scarcity of fluorescence at room temperature for the CT complex in a polar solvent may be due to the rapid nonradiative decay. In view of the great contribution of the CT configuration to the excited equilibrium state after reorientation, the rapid nonradiative process in a polar solvent may be the dissociation process into ions. On the other hand, the scarcity of fluorescence at room temperature for the CT complex in a nonpolar solvent can be mainly due to the small radiative rate constant, as has been described above.

26) In actuality, it is difficult to evaluate the wave functions including surrounding solvent molecules. Therefore, we do not intend to obtain the actual forms of the wave functions from theoretical calculations, alone.

27) The overlap integral between electron-donating and accepting orbitals may be small even when the geometrical configuration of the reoriented system deviates slightly from that shown in Fig. 6(b). This is because the distance between the two component molecules is increased by the increase in the solution energy caused by the reorientation of the solvent molecules.

28) Since $\theta_j(A^*D)_{re}$'s and $\theta_0(AD)_{re}$ mix only through $\theta_i(A^-D^+)_{re}$'s, a_j's are also equal to zero when a_i's vanish.

A Theoretical Consideration of the Electron-scavenging Process in Liquid Hydrocarbons. II. Pulse Irradiation

Hideo YAMAZAKI and Kyoji SHINSAKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received February 15, 1971)

A mathematical treatment of the electron recombination process is presented on the basis of the extended Smoluchowski equation, which includes the effects of several positive ions as ion cores in a spur and of a scavenger. The equation is reduced to the usual Smoluchowski equation for the geminate recombination in a special case. The time dependence of the electron concentration is obtained using a successive approximation. The results of numerical calculations for various reaction parameters are presented.

The geminate recombination of the electrons with the parent ions in the primary process in the radiolysis of the liquid phase has been discussed on the basis of a statistical treatment[1-5] and of the basis of the Smoluchowski equation,[6-11] using different approaches. The second method, used by Monchick,[6] Mozumder,[7] and Hummel[8] is based on the approximation of the prescribed diffusion of the Smoluchowski equation. The presence of a singularity at the point of origin in this equation makes it difficult to solve analytically. Numerical calculations using an electronic computer were attempted by Ludwig.[9] In spite of the difficulty of obtaining an accurate solution, the various experimental results, namely, the scavenging effect on the reaction products, the measurement of the electric conduction during irradiation, and the recent development of the spectroscopic tracing of the electron concestration after pulse irradiation, can be interpreted on this theoretical base. However, no unified theory based on a fundamental equation seems to have been proposed in explanation of the various experimental facts. In a previous paper the scavenger effect on the G value of electron recombination has been discussed.[12]

In the present paper, the recombination of the electrons with parent ions after pulse irradiation will be treated by considering the character of a spur and the effect of the scavenger as an extended form of the Smoluchowski equation,[12] which can be reduced to the usual Smoluchowski equation in the absence of a scavenger and in the presence of a single ion in the ion core. The successive approximation was applied to solve the extended form of the Smoluchowski equation, using two extreme cases, namely, the potential-control and diffusion-control cases. To solve the recombination relaxation of the electrons, the determination of the initial distribution of the electrons is important, so various initial distributions were tested in the numerical calculation. Inversely, the initial distribution can be obtained by the inverse Laplace transform from the analysis of the recombination process. In the ion-core model, an ion cluster at the center of the spur and the surrounding electrons are considered. The value of the central ion charge gradually decreases as the neutralization process progresses. The solution can be synthesized by the connection of the solutions for various effective charges in the ion core.

Theory

A) Fundamental Equation and Its Approximations. The fundamental equation for the electron recombination is based on the following form of the extended Smoluchowski equation, (I-12),[13] in a spherical coordinate:

$$\frac{\partial c(r,t)}{\partial t} = D\frac{\partial^2 c(r,t)}{\partial r^2} + \left(\frac{2D}{r} + \frac{\alpha}{r^2}\right)\frac{\partial c(r,t)}{\partial r} - \beta c(r,t) \quad (1)$$

where $C(r, t)$ is the concentration of electrons at a distance r from the center of the ion core and at a time t after the ionization of the central ions. D is the diffusion constant, α is determined by the Coulomb attraction, and β is the rate constant of the scavenger reaction. α decreases with an increase in t by the neutralization of the central ions, and also decreases with an increase in r by means of the screening effect of the electrons outside the ion core, as is shown by Eq. (2):

$$\alpha = N^+(t)eu/\varepsilon \quad (2)$$

where $N^+(t)$ is the number of ions in the ion core, e is the electron charge, u is the mobility of the electrons, and ε is the dielectric constant. However, for the sake of simplicity, α is assumed to be a constant or a step function of time during the neutralization process.

A successive approximation has been used to solve the fundamental equation. An analytical expression of the solution can be obtained in the absence of either the diffusion term or the term of the Coulomb attraction. Therefore, the solutions in which these terms are absent can be used as the zero-th order approximation. For example, in the absence of diffusion term, Eq. (3) is given for the zero-th-order approximation of the potential-control case:

$$\frac{\partial \chi_0(r,t)}{\partial t} = \frac{\alpha}{r^2}\frac{\partial \chi_0(r,t)}{\partial r} - \beta\chi_0(r,t) \tag{3}$$

In the absence of the Coulomb interaction, Eq. (4) is obtained as a diffusion-control case:

$$\frac{\partial \omega_0(r,t)}{\partial t} = D\frac{\partial^2\omega_0(r,t)}{\partial r^2} + \frac{2D}{r}\frac{\partial \omega_0(r,t)}{\partial r} - \beta\omega_0(r,t) \tag{4}$$

or:

$$\frac{\partial r\omega_0(r,t)}{\partial t} = D\frac{\partial^2 r\omega_0(r,t)}{\partial r^2} - \beta r\omega_0(r,t) \tag{4'}$$

The solution for the s-th order approximation can be obtained by means of Eqs. (5) and (6) for the potential control and the diffusion control respectively:

$$\frac{\partial \chi_s(r,t)}{\partial t} = \frac{\alpha}{r^2}\frac{\partial \chi_s(r,t)}{\partial r} + D\frac{\partial^2\chi_{s-1}(r,t)}{\partial r^2} + \frac{2D}{r}\frac{\partial \chi_{s-1}(r,t)}{\partial r} - \beta\chi_s(r,t) \tag{5}$$

and

$$\frac{\partial r\omega_s(r,t)}{\partial t} = D\frac{\partial^2 r\omega_s(r,t)}{\partial r^2} + \frac{\alpha}{r}\frac{\partial \omega_{s-1}(r,t)}{\partial r} - \beta r\omega_s(r,t) \tag{6}$$

By the use of these recurrent equations, the higher-order solutions can be obtained.[14] The zero-th-order solutions are given by Eqs. (7), (8), and (9).[15]

$$\chi_0(r,t) = f(\alpha t + r^3/3)\exp(-\beta t) \tag{7}$$

where f stands for an arbitrary function. Equation (7) is expressed by the integral representation:

$$\chi_0(r,t) = \int_0^\infty K_0(n)\exp(-\beta t - n\alpha t - nr^3/3)\mathrm{d}n \tag{8}$$

where $K_0(n)$ is an arbitrary function of n, which is determined by the initial distribution of electrons. The zero-th-order solution in the diffusion-control case can be written by Eq. (9):

$$\omega_0(r,t) = \frac{\exp(-\beta t)}{2r\sqrt{\pi Dt}}\int_0^\infty \xi\varphi(\xi)[\exp\{-(r-\xi-R_0)^2/4Dt\} - \exp\{-(r+\xi-R_0)^2/4Dt\}]\mathrm{d}\xi \tag{9}$$

where $\varphi(\xi)$ is the initial distribution of the electrons and where R_0 is the radius of the central-ion core. The first- and second-order approximations, χ_1 and χ_2, are given by Eq. (10) and Eq. (11) respectively:

$$\chi_1(r,t) = \int_0^\infty K_1(n)(1+nDr^4/\alpha - n^2Dr^7/7\alpha) \times \exp\{-(\beta+n\alpha)t - nr^3/3\}\mathrm{d}n \tag{10}$$

and

$$\chi_2(r,t) = \int_0^\infty K_2(n)(1+nDr^4/\alpha - n^2Dr^7/7\alpha - 4nD^2r^5/\alpha^2 + 5n^2D^2r^8/2\alpha^2 - 24n^3D^2r^{11}/77\alpha^2 + n^4D^2r^{14}/98\alpha^2) \times \exp\{-(\beta+n\alpha)t - nr^3\}\mathrm{d}n \tag{11}$$

Generally, the s-th order of approximation can be written by:

$$\chi_s(r,r) = \int_0^\infty K_s(n)H_s(n,\alpha,D,r)\exp(-\beta t - n\alpha t - nt^3/3)\mathrm{d}n \tag{12}$$

where H_s is a function of n, α, D, and r. When an approximate electron concentration in the system is expressed as N_s, the approximate electron concentration as a function of the time is given by Eq. (13):

$$\begin{aligned} N_s(t) &= 4\pi\int_{R_0}^\infty r^2\chi_s(r,t)\mathrm{d}r \\ &= 4\pi\int_0^\infty K_s(n)\exp(-\beta t - n\alpha t) \times\left[\int_{R_0{}^3/3}^\infty H_s(n,\alpha,D,\xi)\exp(-n\xi)\mathrm{d}\xi\right]\mathrm{d}n \\ &= 4\pi\int_0^\infty K_s(n)\exp(-\beta t - n\alpha t)G_s(n,\alpha,D,R_0)\mathrm{d}n \end{aligned} \tag{13}$$

where $G_s(n,\alpha,D,R_0)$ is the integral in the brackets, [ ] and is a function of n, α, D, and R_0. The approximate value of $N(t)$ and the time dependence of the electron concentration can be evaluated by using the approximate solutions of $C(r,t)$. Thus, the initial distribution of the electron and the time dependence of the electron concentration in the system are connected by the Smoluchowski equation. The initial distribution of electrons can be estimated from the time behavior of the electron concentration, which is itself determined by the pulse experiment. Therefore, the initial distribution can be expressed by the use of the inverse Laplace transforms[16] of the time dependence of the electron concentration in the system, as is shown in Eq. (14):

$$K_s(n)G_s(n,\alpha,D,R_0) = \frac{1}{8\pi^2 i}\int_{c-i\infty}^{c+i\infty} N_s(p/\alpha) \times \exp\{(\beta/\alpha+n)p\}\mathrm{d}p \tag{14}$$

where the c in the integral is a constant. $G_0(n,R_0)$, $G_1(n,\alpha,D,R_0)$, and $G_2(n,\alpha,D,R_0)$, corresponding to these solutions χ_0, χ_1, and χ_2, are given by Eqs. (15),

---

13) Ref. 12 will be referred to as I, while equations that appear in it will be referred to (I-—).

14) Equation (5) and (6) are solved by the following recurrent equations:

$$\chi_s(r,t) = \exp(-\beta t)\Big[f(t+r^3/3\alpha D) - \frac{D}{\alpha}\int_0^r \exp(-\beta t)\Big\{2r\frac{\partial\chi_{s-1}(r,t)}{\partial r} + r^2\frac{\partial^2\chi_{s-1}(r,t)}{\partial r^2}\Big\}\mathrm{d}r\Big]_{t=c_1-r^3/3\alpha}$$

Where C_1 is a constant, where f is an arbitrary function, and where

$$\omega_s(r,t) = \frac{\exp(-\beta t)}{2r\sqrt{\pi Dt}}\int_0^\infty \xi\varphi(\xi) \times [\exp\{-(r-\xi-R_0)^2/4Dt\} - \exp\{-(r+\xi-R_0)^2/4Dt\}]\mathrm{d}\xi + \frac{\exp(-\beta t)}{2r\sqrt{\pi Dt}}\int_0^t \frac{\exp(\beta\tau)}{\sqrt{t-\tau}}\int_0^\infty \frac{\alpha}{\xi}\frac{\partial\omega_{s-1}(\xi,t)}{\partial\xi} \times [\exp\{-(r-\xi-R_0)^2/4D(t-\tau)\} - \exp\{-(r+\xi-R_0)^2/4D(t-\tau)\}]\mathrm{d}\xi\mathrm{d}\tau$$

Where $\varphi(\xi)$ is the initial distribution of the electrons and where R_0 means the radius of the central-ion core.

15) In the approximation by prescribed diffusion,[7] the product of $\omega_0(r,t)$ and $N^+(t)$ is used for the $C(r,t)$ solution.

16) for example, I. N. Sneddon, "Fourier Transforms," McGrow-Hill Book Co, Inc., New York (1951), p. 30.

(16), and (17) respectively.

$$G_0(n, R_0) = \int_{R_0^3/3}^{\infty} \exp(-n\xi)\mathrm{d}\xi = \exp(-nR_0^3/3)/n \quad (15)$$

$$G_1(n, \alpha, D, R_0) = \int_{R_0^3/3}^{\infty} (1+nD(3\xi)^{4/3}/\alpha - n^2D(3\xi)^{7/3}/7\alpha)\exp(-n\xi)\mathrm{d}\xi \quad (16)$$

$$G_2(n, \alpha, D, R_0) = \int_{R_0^3/3}^{\infty} (1+nD(3\xi)^{4/3}/\alpha - n^2D(3\xi)^{7/3}/7\alpha - 4nD^2(3\xi)^{5/3}/\alpha^2 + 5n^2D^2(3\xi)^{8/3}/2\alpha^2 - 24n^3D^2(3\xi)^{11/3}/77\alpha + n^4D^2(3\xi)^{14/3}/98\alpha^2) \times \exp(-n\xi)\mathrm{d}\xi \quad (17)$$

B) Initial Conditions and Approximate Expressions of the Electron Concentration. From Eqs. (8)-(12) the various types of approximate solutions of electron concentrations can be obtained as a function of the time if the initial distribution of the electrons is given. One of the simplest examples of the initial distribution is the δ-function representation for the weight function, $K_s(n)$. When $K_0(n)$ is expressed by the δ-function in Eq. (8), $K_0(n)=\delta(n\text{-}n_0)$, where n_0 means a positive constant, the solution for the zero-th order approximation in the potential control case can be written as:

$$\chi_0(r, t) = \exp\{-(\beta+n_0\alpha)t - n_0r^3/3\} \quad (18)$$

n_0 can be represented by $2/r_{\max}^3$, where $r_{\max}$ is the distance at the maximum value of initial distribution.[12] Then, the electron concentration normalized by the initial value is given by Eq. (19):

$$N_0(t)/N_0(0) = \exp(-\beta t - n_0\alpha t) \quad (19)$$

Similarly, for the first-order approximation in the case of potential control, the distribution, $\chi_1(r, t)$, is:

$$\chi_1(r, t) = (1+n_0Dr^4/\alpha - n_0^2Dr^7/7\alpha) \times \exp\{-(\beta+n_0\alpha)t - n_0r^3/3\} \quad (20)$$

Then, $N_1(t)/N_1(0)$ is expressed by Eq. (21):

$$N_1(t)/N_1(0) = \exp(-\beta t - n_0\alpha t) \quad (21)$$

The same expression is obtained for the higher-order approximation for the distribution determined by $K_s(n)=\delta(n\text{-}n_0)$. The distribution determined by the superposition of the δ-function can also be considered:

$$K_0(n) = A\delta(n-n_1) + B\delta(n-n_2) \quad (22)$$

where n_1 and n_2 are positive constants and where A and B are constants for superposition. In this case, $N_0(t)/N_0(0)$ is given by Eq. (23):

$$\frac{N_0(t)}{N_0(0)} = \frac{\left(An_2\exp(-\beta t - n_1\alpha t - n_1R_0^3/3) + Bn_1\exp(-\beta t - n_2\alpha t - n_2R_0^3/3)\right)}{An_2\exp(-n_1R_0^3/3) + Bn_1\exp(-n_2R_0^3/3)} \quad (23)$$

Similarly, $N(t)/N(0)$ is expressed by Eq. (24):

$$\frac{N_s(t)}{N_s(0)} = \frac{\left(A\exp(-\beta t - n_1\alpha t)G_s(n_1, \alpha, D, R_0) + B\exp(-\beta t - n_2\alpha t)G_s(n_2, \alpha, D, R_0)\right)}{AG_s(n_1, \alpha, D, R_0) + BG_s(n_2, \alpha, D, R_0)} \quad (24)$$

The same quantities were evaluate for the diffusion-control equation. For the initial distribution, $\varphi(\xi) = \delta(\xi\text{-}r_{\max})/4\pi r_{\max}^2$, the zero-th order approximation solution is:

$$\omega_0(r, t) = \frac{\exp(-\beta t)}{8\pi r_{\max}r\sqrt{\pi Dt}}[\exp\{-(r-r_{\max}R_0)^2/4Dt\} - \exp\{-(r+r_{\max}-R_0)^2/4Dt\} \quad r>R_0 \quad (25)$$

where $r_{\max}$ is the distance between the electron and the ion for maximum distribution. $N_0(t)/N_0(0)$ is given by Eq. (26):[17]

$$N_0(t)/N_0(0) = \exp(-\beta t)\{1+(R_0/r_{\max})\mathrm{Erf}(r_{\max}/\sqrt{4Dt})\}/(1+R_0/r_{\max}) \quad (26)$$

Results and Discussion

The results of numerical calculation using various paremeters are shown in Figs. 1a and 1b and in Fig.

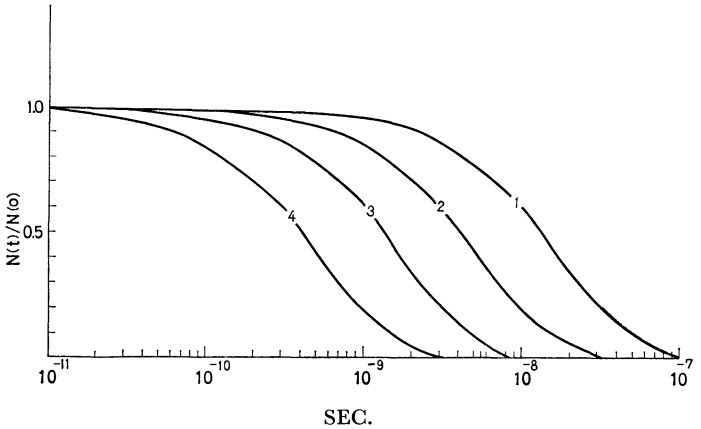

Fig. 1a. Number of electrons in a spur plotted as a function of time in the case of potential control, where the initial value was normalized to be unity. The numerical calculation was carried out using Eq. (23) and the following parameters in CGS unit without scavenger, $\beta=0$.

Curve 1: $A=0.0$, $B=1.0$, $n_1=3.9\times10^{18}$, $n_2=1.2\times10^{18}$, $\alpha=4.3\times10^{-11}$
Curve 2: $A=1.0$, $B=0.0$, $n_1=3.9\times10^{18}$, $n_2=1.2\times10^{18}$, $\alpha=4.3\times10^{-11}$
Curve 3: $A=0.0$, $B=1.0$, $n_1=3.9\times10^{18}$, $n_2=1.2\times10^{18}$, $\alpha=4.3\times10^{-10}$
Curve 4: $A=1.0$, $B=0.0$, $n_1=3.9\times10^{18}$, $n_2=1.2\times10^{18}$, $\alpha=4.3\times10^{-10}$

17) The error function, $\mathrm{Erf}(x)$, is defined by:
$\mathrm{Erf}(x) = \frac{2}{\sqrt{\pi}}\int_0^x \exp(-z^2)\mathrm{d}z$

Curve 7: $D=5\times10^{-5}$, $R_0=2\times10^{-7}$, $r_{max}=4\times10^{-7}\sim8\times10^{-7}$, $\beta=1.0\times10^{10}$
Curve 8: $D=5\times10^{-5}$, $R_0=2\times10^{-7}$, $r_{max}=4\times10^{-7}\sim8\times10^{-7}$, $\beta=2.0\times10^{10}$

2 for the potential-control process and the diffusion-control process respectively. In Fig. 1a, the time dependence of the electron concentration showed sigmoidal curves. The results of numerical calculation in the scavenger-free case are that the relaxation time of electron recombination is in the range of 10^{-10}—10^{-8} sec, depending mainly on the initial distribution of electron. If the scavenger is present in the system, the value of the relaxation time of the electron disappearance becomes much shorter, as is shown in Fig. 1b.

The case of diffusion control is shown in Fig. 2; here the geminate recombination partially took place, in contrast with the complete recombination in the case of potential control,(Fig. 1a). For the large value of scavenger concentration, the time dependence becomes almost equivalent in the diffusion-control and potential-control processes. Therefore, either method offers a reasonable approximation for the concentrated solution of the scavenger. In these calculations, the value of α was assumed to be constant. In the neutralization process, however, the value should be a step function. If $N^+(t)$ in Eq. (2) decreases from four to one by a step function during the successive neutralization, the time dependence of $N^+(t)/N(0)$ is shown in Fig. 3 with the curves for the fixed values of four and one in $N^+(t)$ in Eq. (2). The relaxation time decreased slightly with an increase in the effective charge of the ion core. The effect of the successive neutralization of the effective charge of the ion core from four to one decreases the rate of the electron recombination, (Fig. 3, Curve 4). The half-life of the electron recombination of the successive neutralization, (Curve 4) showed a intermediate value between that of the effective charge of one (Curve 3) and that of the effective charge of four, (Curve 5). Other calculations, *e.g.*, Mozumder's[7], Ludwig's[9],

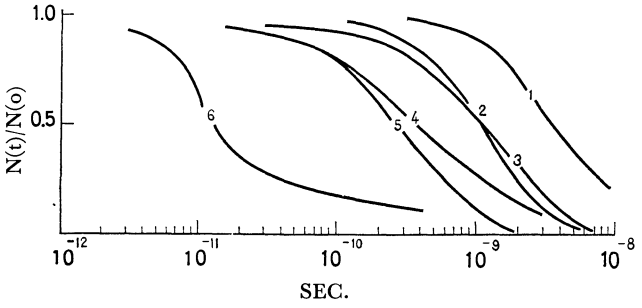

Fig. 3. The electron concentration as a function of time in the various methods of calculation without scavenger.
Curve 1: by Mozumder, (room temperature)
Curve 2: by Ludwig,
Curve 3: core charge to be constants, $N=1$, other parameters are corresponding to the case of curve 3 in Fig. 1a,
Curve 4: core charge to be changed, $N=4\sim1$,
Curve 5: core charge to be constant, $N=4$,
Curve 6: by Freeman

and Freeman's calculations,[5] are also quoted in Fig. 3. The relaxation times of electron recombination are 6×10^{-9}, 1×10^{-9}, 1×10^{-11}, and $4—10\times10^{-10}$ sec for Mozumder, Ludwig, Freeman, and the present calculations respectively, while the corresponding values of r_{max} are 80, 80—112, 20, and 80—120 Å. Thus, the relaxation time of electron recombination largely depends on r_{max}. The relaxation times evaluated by Ludwig, Mozumder, and the present methods are within the same order of magnitude. The slight difference in the relaxation time is due to the difference in the r_{max} and $N^+(t)$ values used in these calculations. The shorter relaxation time in the case of Freeman corresponds to the smaller value of r_{max}. Some examples of these initial distributions were illustrated in a previous paper.[12] The real solution, $C(r, t)$, may be somewhere between the potential-control and diffusion-control cases, it is quite similar to $\chi_s(r, t)$ at the smaller distance of r and can be well approximated by $\omega_s(r, t)$ for a large r distance. Therefore, a linear combination of $\chi_s(r, t)$ and $\omega_s(r, t)$ by using a slowly-changing function of distance will provide a better approximation.

In the numerical calculation, the estimation of the various parameters involved in the theory is important in relative the theory to the experimental results. In this work, the main parameters are n, α, β, and R_0. The value of n is expressed in terms of the distance of the maximum distribution, namely, $n=2/r_{max}^3$. The value of r_{max} can be determined by the thermalization length of the electron ejected from the parent ion by the primary act of radiation. According to Mozumder and Magee,[18] the value of the effective thermalization length is 80 Å. In this work, two values ($r_{max}=80$ Å, 120 Å) are used.

The parameter, $\alpha(=N^+(t)eu/\varepsilon)$, of electron recombination can be estimated from the number of ions in the ion core in a spur, $N^+(t)$, and from the mobility of the electron, u. The fixed values of $N^+(t)(=4, 3, 2, 1)$ and the variable value of $N^+(t)$ from four to one, decreasing with time as a step function, are considered in this work. The value of the mobility of the electron of $2\times10^{-3-4}$ cm^2 v^{-1} sec^{-1} [19] was used in estimating α. The β parameter is defined as the product of the rate constant and the concetration of the scavenger. The rate constants of most scavengers have an order of magnitude of 10^{10} M^{-1} sec^{-1}, and usually an appreciable effect of the scavenger is observed in the concentrations of the scavenger beginning from 10^{-1} M, so the value of β used in this calculation is in the range of $1.0\times10^{9-10}$ in terms of the scavenger effect. The reaction radius of the recombination of the electron and ions is in the range of 10 Å—20 Å, where the electron escape from the recombination seems to be negligible.

The authors wish to thank Professor S. Shida and Dr. S. Sato of the Tokyo Institute of Technology and Dr. K. Fueki of Nagoya University for reading the preliminary manuscript of this paper and for many helpful discussions. They also wish to thank Dr. A. Imamura and Miss H. Fujita of the National Cancer Center Research Institute for their assistance in the computer work.

19) This value has been used in most calculations. Recently, quite a large value of u ($=2\times10^{-1}$ cm^2 V^{-1} sec^{-1}) was reported by Conrad and Silverman.[20] If this value had been used in the present calculation, Curves 3,4, and 5 in Fig. 3 would have shifted to shorter life times, thus coming to have the same order of magnitude as in Freeman's data, (Curve 6). On the contrary, a small value of u ($\approx1\times10^{-5}$ cm^2 V^{-1} sec^{-1}) can be expected from the experimental results of the pulse radiolysis of viscous squalane[21] at a low temperature and with a lifetime of over 10^{-6} sec, where bound and unbound states of electrons may be in equilibrium.

The Estimation of the Surface Properties of Metal Oxides by the Use of TCNQ Adsorption

Hiroshi Hosaka, Takao Fujiwara, and Kenjiro Meguro

Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 1, 1971)

The electron-donor properties of metal oxides (magnesia, alumina, silica, titania, zinc oxide, and nickel oxide) were investigated by means of TCNQ adsorption. When TCNQ was adsorbed on the surfaces of the metal oxides from its acetonitrile solution, the surfaces of the metal oxides acquired the colorations characteristic of each oxide. The coloration was caused by the formation of TCNQ anion radicals on the metal oxide surfaces. The presence of the TCNQ anion radicals on the colored metal oxide surfaces was confirmed by studying the ESR absorption and electronic spectra. The radicals were formed as a result of electron transfer to TCNQ from the metal oxide surfaces. The order of the radical-forming activity, determined by ESR, was as follows: magnesia> zinc oxide>alumina>titania>silica>nickel oxide. The electron-donor property of the metal oxide surfaces might be dependent on the natures of the semiconductor and the surface hydroxyl ion.

During the past decade, there has been much discussion about the natures of the acid and base present on metal oxide surfaces, and their relevance in catalysis has been extensively investigated. Spectroscopic studies have established the existence of strong electrophilic centers on the silica-alumina surface and the formation of cation radical from hydrocarbons at the same centers.[1-3] On the assumption that cation radicals are formed on Lewis-acid sites, the formation of radical ions at the surface of the silica-alumina catalyst, *i.e.*, the electron-accepting property of the silica-alumina surface, has been widely studied.[1-3] The nature of the site responsible for the electron transfer process is of wide interest. Recently, Flockhart *et al.*[4] studied the formation of the TCNE anion radical at alumina surfaces, *i.e.*, the electron-donor properties of aluminas; however, there have been few reports about the electron-donor properties of metal oxides. In this work, it was demonstrated that when 7,7,8,8-tetracyanoquinodimethan (TCNQ), which was one of the strongest electron acceptors, was adsorbed onto magnesia, alumina, silica, titania, zinc oxide, and nickel oxide, TCNQ anion radicals were formed as a result of electron transfer to TCNQ from the metal oxide surfaces. Comparing the radical-forming activity of the metal oxides, we revealed the electron-donor properties of the metal oxides.

Experimental

Materials. The titania, alumina, and silica were prepared by the hydrolysis of titanium tetra-butoxide, aluminium *s*-butoxide, and silicon ethoxide, purified by distillation. Excess aqueous ethanol was vigorously stirred into the alcoholic solution of alkoxide. Stirring was continued for 10 hr at a temperature near the boiling point. The precipitate was then separated by centrifuging, thoroughly washed with alcohol, finely ground, and then evacuated at 100°C until the residual pressure was less than 10^{-5} Torr. The complete hydrolysis of these alkoxides was confirmed by infrared spectra. The dried products were calcined for 2 hr at 500°C.

The magnesia, zinc oxide, and nickel oxide were obtained by the thermal decomposition of their carbonates (G. R.) at 500°C for 2 hr in an electric furnace.

The crystal structures of the metal oxides, as determined by X-ray diffractometry, were as follows: the titania, anatase; the alumina, γ-alumina; the silica, amorphous. The X-ray diffraction patterns of the magnesia, zinc oxide, and nickel oxide showed typical lines.

The surface areas of the metal oxides, as determined by nitrogen adsorption, were as follows: the titania, 64; the alumina, 263; the silica, 600; the magnesia, 134; the zinc oxide, 7.10 m^2/g.

TCNQ was synthesized from the condensation product of 1,4-cyclohexanedione and malononitrile.[5] This was the purified by repeated recrystallization. The purity was checked by elemental analysis (Found: C, 70.22; H, 2.60; N, 27.8%, Calcd.: C, 70.59; H, 1.97; N, 27.42%), measurement of the melting point (280.0—283.0°C), and spectrophotometry.

Apparatus and Procedure. The metal oxide was placed in a flask which was attached directly to a high-vacuum line and outgassed at 10^{-5} Torr for 1 hr at 100°C, and then cooled to 25°C *in vacuo* prior to the TCNQ adsorption. A solution of TCNQ in acetonitrile (10 mM) was then poured into the flask through a stop cock. Subsequently, the content in the flask was transferred into an L-type test tube and then shaken for 2 hr at 25°C. After shaking, the metal oxide was collected by centrifuging and dried at room temperature *in vacuo*. The dried sample was used for the measurement of the electronic spectrum and was evacuated at 10^{-5} Torr for the ESR measurement.

The ESR spectra were measured by means of a Japan Electrons Optics Laboratory JES-3BS-X-type ESR spectrometer operating at a cavity resonance frequency of 9400 Hz with 100 kHz modulation. The *g*-value was obtained by comparison with the value for Mn^{2+}. The radical concentration (spin conc.) were estimated by comparing the peak-to-peak heights on the first derivative curves with those of an internal-standard Mn^{2+} sample.

The electronic spectra of the metal oxides were measured by means of a diffuse-reflectance spectrophotometer.

Results and Discussion

When TCNQ was adsorbed on the surfaces of the magnesia, alumina, silica, titania, and zinc oxide

from its acetonitrile solution at room temperature, the surfaces of the metal oxides acquired the coloration characteristic of each oxide. The colors were as follows: magnesia, blue green; alumina, blue green; silica, yellow; titania, violet; zinc oxide, greyish green. The same colorations were observed when the metal oxides were ground with TCNQ crystal. The colorations of the metal oxide surfaces suggest that new adsorbed species are formed on the surfaces. This suggestion was confirmed by the evidence that the colored metal oxides show ESR absorptions, indicating the presence of free radical species. The spectra are unresolved (Figs. 1—5; *g*-values, 2.011); this can be explained by the fact that the anisotropy of the hyperfine structure arises from the lack of motional degrees of freedom. The state of the adsorbed species was studied by means of the electronic spectra in addition to the ESR spectra. The electronic spectra of the colored samples are illustrated in Figs. 1—5. The bands appearing below 400 mμ are common to all the oxides and may be supposed to correspond to the physically-adsorbed state of neutral TCNQ, which has the absorption band at 395 mμ.[5] In the cases of titania and zinc oxide, this assignment does not hold completely because the titania

Table 1. Summary of the TCNQ adsorption

	Type of semiconductor	The color of the metal oxide surface after TCNQ adsorption	The relative radical concentration (radical conc./m^2)
MgO	insulator	blue green	100
Al_2O_3	insulator	blue green	38
SiO_2	insulator	yellow	0.11
TiO_2	*n*-type semiconductor	violet	1.6
ZnO	*n*-type semiconductor	greyish green	47
NiO	*p*-type semiconductor		0.00

and zinc oxide have characteristic bands in the same region. The absorption bands in the visible region observed in the cases of magnesia, alumina, silica, titania, and zinc oxide can be attributed to neither TCNQ nor the metal oxides. The bands near 600 mμ probably stem from the dimer TCNQ anion radical, which absorbs light at 643 mμ.[6] They are very broad and have not been assigned with certainty, but this tentative attribution is supported by the characteristic features that neutral TCNQ absorbs only at 395 mμ, that TCNQ has a high electron affinity, and that the TCNQ anion radical derivatives are stable even at room temperature.[7-10] The ESR and the electronic spectra confirm that radical ions are formed as a result of electron transfer to TCNQ from the metal-oxide surfaces.

The radical-forming activities of the metal oxide surfaces, estimated by means of the relative radical concentration (spin number/m^2), are as follows: magnesia, 100; zinc oxide, 47; alumina, 38: titania, 1.6; silica, 0.11; nickel oxide, 0.00. The nature of the site responsible for the electron-transfer process is not well understood. However, it may be suggested that two types of active sites exist on the surfaces. One of these has an anion deficiency (*n*-type semiconductor), and the other has a hydroxyl ion on the oxide surface.

The type of surface complex by the mechanism of electron transfer from a semiconductor was found in titania, zinc oxide, and nickel oxide. A major way of introducing donors and acceptors into semiconductors arises from the nonstoichiometry in compounds.[11] The nonstoichiometry can arise either by virtue of vacant lattice sites for one component of the compound, or because of an excess of one component located in interstitial sites. A donor center can result from the trapping of one or more electrons in an anion vacancy. Semiconductors which have an excess of conduction electrons over holes are normally called "*n*-type", because their conductivity arises from negative-current carriers. Those with an excess of holes are called "*p*-type," as the carriers are positive. *n*-Type semiconductors have anion deficiencies (or cation excesses), while *p*-type semiconductors have anion excesses (or cation deficiencies). For example, zinc oxide,[12,13] titania,[14] and nickel oxide are as follows;

$$ZnO \rightleftarrows O_v^{+} + \ominus + 1/2\, O_2(g)$$
$$ZnO \rightleftarrows O_v^{2+} + 2\ominus + 1/2\, O_2(g)$$

where O_v is an O vacancy and where $\ominus$ is a free electron. An O_v in zinc oxide is a donor.

$$2TiO_2 \rightleftarrows Ti_2O_3 + (O_v^{2+}\cdot 2\ominus)^{\circ} + 1/2\, O_2(g)$$
$$(O_v^{2+}\cdot 2\ominus)^{\circ} \rightleftarrows (O_v^{2+}\cdot\ominus)^{+} + \ominus$$

where $(O_v^{2+}\cdot 2\ominus)^{\circ}$ is a neutral, charged O vacancy.

$$1/2\, O_2(g) \rightleftarrows NiO + Ni_{(v)}^{2-} + 2\oplus$$
$$1/2\, O_2(g) \rightleftarrows NiO + Ni_{(v)}^{2-}\cdot\oplus + \oplus$$

where $Ni_{(v)}$ is a Ni vacancy and where $\oplus$ is a positive hole. A Ni vacancy in nickel oxide is an acceptor. From this fact, it is reasonable that nickel oxide has no radical-forming activity. If TCNQ radical ions are formed by interaction with free electrons derived from the intrinsic or extrinsic defects present on the surface or in the bulk of the solid, magnesia, alumina, and silica, which are insulators, they would not normally be expected to participate in a charge-transfer adsorption process because of the lack of a free electron. Flockhart *et al.*[4] have suggested that the electron-donor defect site on the surface of alumina was created at activation temperatures of above 500°C.

The second active site may be the surface hydroxyl ion. Surface hydroxyl groups can be expected on all metal oxides.[15] The ionization potential of hydroxyl ions is comparatively small ($\sim$2.6 eV in the gas phase[16]); therefore, the possibility of its participation in oxidation-reduction processes of the type:

$$OH^{-} + A \rightarrow OH + A^{-}$$

where A is an electron-acceptor, can not be excluded. Indeed, Fomin *et al.*[17] have shown that electron

transfer from the hydroxyl ion can and does occur in certain solvent systems provided a suitable acceptor molecule is present. Flockhart *et al.*[4] have reported that the electron-donor site on the alumina surface might be associated with the presence on the surface of unsolvated hydroxyl ions. As alumina, magnesia, and silica surfaces are usually covered with hydroxyl groups,[18] the charge-transfer adsorptions of TCNQ on alumina, magnesia, and silica may result from the electron-transfer from surface hydroxyl. Stöber[15] found that, even after thorough outgassing at 100°C, one molecule of externally tightly adsorbed water is retained for each two silanol groups in the amorphous silica. This surprising result was confirmed by Boehm *et al.*[19] using chemical reactions as well as deuterium exchange. Lee and Weller[20] confirmed the existence of surface hydroxyl groups on alumina which had been dehydrated at 500°C. It is reasonable to assume that these electron-transfer from hydroxyl ions on the metal oxides which have been calcined at a high temperature such as 500°C. Surface hydroxyls may exist on all of the samples. However, surface hydroxyls on metal oxides are shown to differ in chemical properties. Surface silanol groups are much more stable than Al–OH groups.[18] Differences in acidity among the hydroxyl groups of several oxide surfaces have been reported.[21] These results suggest that the hydroxyl ions of the metal oxide surfaces have different electron-donor properties (radical-forming activities).

The radical-forming activity, *i.e.*, the electron-donor property of the metal oxide surfaces, may be associated with the natures of the semiconductor and the surface hydroxyl ion. The radical-forming activity determined by TCNQ adsorption is a new convenient method of estimating the electron-donor property of metal oxide surfaces.

We wish to thank Miss Y. Matsumura, National Institute of Industrial Health, for her kindly advice on the measurement of the ESR spectra, and Mr. T. Sekine Government Chemical Industrial Research Institute, Tokyo, for his helpful advice on the measurement of the electronic spectra.

Effect of Phase on Hot Hydrogen Atom Abstraction Reaction with Solid Isobutane as Studied by Electron Spin Resonance Spectroscopy

Terunobu WAKAYAMA, Tetsuo MIYAZAKI, Kenji FUEKI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 10, 1971)

The effect of phase on the hot-hydrogen-atom abstraction reaction with isobutane at 77°K has been studied by electron spin resonance spectroscopy in the photolysis and the radiolysis of solid isobutane containing hydrogen iodide. While only the isobutyl radical is formed by the UV-illumination of isobutane–hydrogen iodide systems in the polycrystalline state, the tertiary butyl radical, accompanied with a small amount of isobutyl radicals, is produced from isobutane-methylcyclohexane-hydrogen iodide systems in the glassy state. The hot hydrogen atom produced by dissociative electron attachment to hydrogen iodide abstracts the tertiary hydrogen atom from isobutane at 77°K, independent of whether the matrix is polycrystalline or glassy. It appears that the H-abstraction reaction from isobutane by hot hydrogen atoms depends upon the energy of the hot hydrogen atoms.

The familiar atomic hydrogen-saturated hydrocarbon abstraction reaction has been extensively investigated at thermal energies under equilibrium conditions,[1] at very high kinetic energies in recoil media,[2] and at intermediate energies in photolytic systems.[3]

In the photolytic technique, hydrogen atoms of different known initial kinetic energies (7—92 kcal/mol) may be selectively generated by the photodissociation of hydrogen iodide (HI) in the presence of a reactant. For example, when activation is induced by a 2537 Å light, the kinetic energy of the hydrogen atom produced is 20 kcal/mol if the iodine atom is produced in the $^2P_{1/2}$ excited state and 41 kcal/mol if it is produced in the $^2P_{3/2}$ ground state.[4] The hot hydrogen atom produced by dissociative electron attachment to HI may have an energy of *ca.* 5—6 kcal/mol.

Although hot atom reactions have been investigated in detail in the gas phase, such reactions in condensed phases[5] are much less well understood. One of the complications in the hot atom reaction in condensed

phases is in the possible existence of the cage effect, which is absent in the gas phase. The cage effect explains the characteristically low quantum yield of primary dissociation in a condensed medium.[6] It was found in previous studies that the fragmentation of the excited molecule is an important process in the radiolysis of saturated hydrocarbons in the solid state at 77°K.[7] We reported in a previous paper that different radicals are formed in the radiolysis of solid isobutane at 77°K, depending on whether it is in the glassy or polycrystalline state.[8] In a recent stupy with isobutane-2-d_1 we concluded that such a phase effect cannot be attributed to the isomerization of butyl radicals, such as i-$C_4H_9 \rightleftarrows t$-$C_4H_9$, but must be attributed to the primary process of the C–H bond rupture.[9]

In the present work, we shall examine, by ESR measurements, the phase effect on the hydrogen atom abstraction reaction in the photolysis and the radiolysis of isobutane-HI systems at 77°K, and shall attempt to compare these results with those of hot-hydrogen-atom reaction in the radiolysis of pure isobutane at 77°K.

In this paper, emphasis will be placed on our experimental findings rather than on their interpretation.

Experimental

The isobutane, methylcyclohexane(MCH), and 3-methylpentane (3MP) were more than 99.9%pure. Gas-chromatographic analysis did not show any detectable impurities. They were purified by distillation on a vacuum line and were dried over a sodium mirror. Isobutane-2-d_1, synthesized by the Grignard reaction, was purified by passing it through a column of freshly-activated alumina and then through a column of fresh soda lime. The xenon was used as received, the stated purity being 99.9%.

The hydrogen iodide was prepared from Katayama Chemical reagent-grade aqueous HI by removing the iodine by shaking it with red phosphorus and by then allowing the frozen solution to warm twice in the presence of excess P_2O_5 on the vacuum line.

The samples, prepared on the vacuum line, were sealed in 4.3-mm o.d. Suprasil tubes. They were illuminated by ultraviolet light or γ-rays at 77°K, and then ESR measurements were made by means of a JES-3BX ESR spectrometer.

γ-Irradiation was provided by ^{60}Co at a dose rate of 1.0×10^6 rads/hr, and UV-illumination, by a filtered end-window Toshiba medium-pressure mercury lamp. A Toshiba UV-25 filter was used; it cut off UV-light of wavelengths shorter than 2500 Å.

Results and Discussion

Effects of Phase on Hydrogen-atom Abstraction in the Photolysis of Solid Isobutane Containing HI. Figure 1A shows the ESR spectrum of 0.2 mol% HI in isobutane at 77°K obtained after a 10-min illumination with a medium-pressure mercury lamp. The prolonged photolysis of isobutane without HI produced

no detectable radicals. A spectrum identical to Fig. 1A was obtained by the γ-irradiation of the isobutane. This indicates H-abstraction from the primary position in isobutane at 77°K by the photochemically-produced hot H atoms to form the isobutyl radical.

As the HI concentration in an isobutane matrix is increased, the yield of the isobutyl radical increases; it reaches a maximum at *ca.* 0.1 mol% HI concentration, and then decreases (Fig. 2). This result may

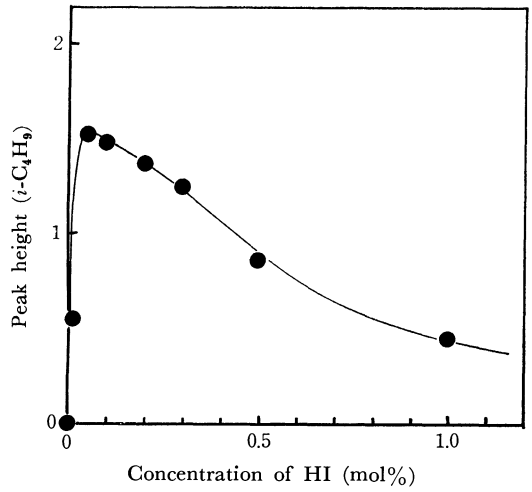

Fig. 2. Effect of HI concentration on the amounts of isobutyl radicals produced in UV-illuminated i-C_4H_{10} at 77°K. UV-illumination time: 10 min.
●—●: i-C_4H_9

be explained in terms of the competitive reactions between HI and isobutane for hot H atoms. A possible kinetic scheme is as follows:

$$HI \xrightarrow{\Phi I_{abs}} H_{hot} + I \quad (1)$$

$$i\text{-}C_4H_{10} + H_{hot} \xrightarrow{k_2} i\text{-}C_4H_9 + H_2 \quad (2)$$

$$i\text{-}C_4H_{10} + H_{hot} \xrightarrow{k_3} i\text{-}C_4H_{10} + H \quad (3)$$

$$HI + H_{hot} \xrightarrow{k_4} H_2 + I \quad (4)$$

where I_{abs} is the rate of light absorption by HI, Φ is the quantum yield of the photodissociation of HI, and k is the rate constant. From these equations we can derive the following kinetic equation:

$$\frac{\Phi I_{abs}\tau}{(R\cdot)} = \left(1 + \frac{k_3}{k_2}\right) + \frac{k_4(HI)}{k_2(RH)} \quad (5)$$

where (R·), (RH), and (HI) are the concentrations of isobutyl radicals, isobutane, and HI respectively. τ is the time of light illumination. (R·) is measured by ESR, and I_{abs} is calculated as a function of (HI), using a value of 75[10] for the molar extinction coefficient of HI and taking the geometrical factor of the sample into account. Since Φ is constant, it can be expected from Eq. (5) that the relative value of $\Phi I_{abs}\tau/(R\cdot)$ also increases linearly with an increase in (HI)/(RH). Figure 3 shows the relative value of $\Phi I_{abs}\tau/(R\cdot)$ *vs.* the value of (HI)/(RH). It can be seem from Fig. 3 that several of the points tested fall on a straight line. This supports our interpretation presented above.

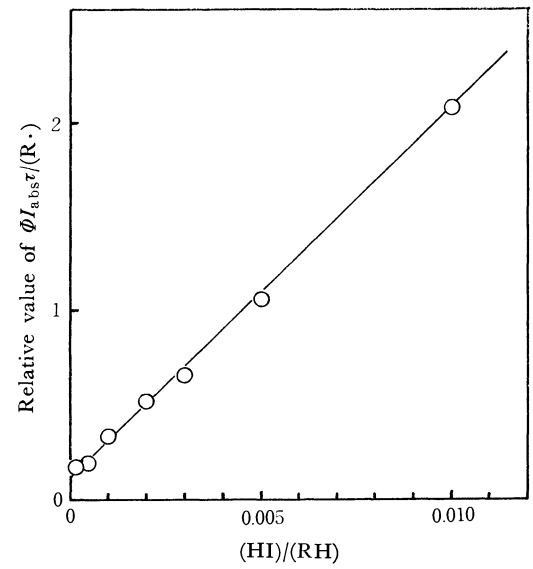

Fig. 3. Relation between $\Phi I_{abs}\tau/(R\cdot)$ and (HI)/(RH).

Pure isobutane is polycrystalline at 77°K, while isobutane containing 3.8 mol% MCH is glassy at 77°K. A quite different ESR spectrum was obtained by the 2.5-min photolysis of an isobutane-MCH mixture containing 0.2 mol%HI in the glassy state (Fig. 1B). This spectrum is identical with that of tertiary butyl radicals produced in γ-irradiated isobutane-3.8 mol% MCH in the glassy state at 77°K. This result indicates that the hot H atoms produced by the photolysis of isobutane-3.8 mol% MCH abstract the tertiary H atoms of isobutane to form tertiary butyl radicals.

The effect of the MCH concentration in an isobutane-0.2 mol% HI solution on the formation of radicals is shown in Fig. 4. Here, the remarkable point is the rapid increase in the yield of the tertiary butyl

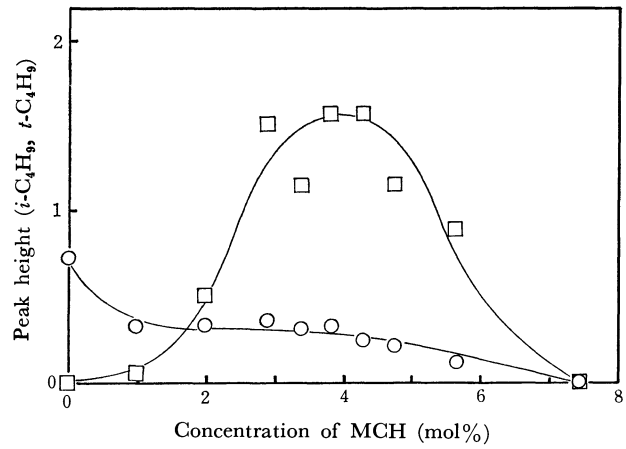

Fig. 4. Effect of MCH concentration on the amounts of butyl radicals produced in UV-illuminated i-C_4H_{10}-HI (0.2 mol%) at 77°K. UV-illumination time: 2.5 min.

radical, reaching a maximum at *ca.* 4 mol% MCH concentration. The yield of the isobutyl radical, however, does not change as much as that of the tertiary butyl radical. This result may be interpreted in terms of the following effects. As the concentration of MCH is increased, the matrix becomes glassy, so that the tertiary butyl radical is primarily produced by the hot-H-atom abstraction, while the isobutyl radical is secondarily produced by the photo-induced isomerization, $t\text{-}C_4H_9 \xrightarrow{h\nu} i\text{-}C_4H_9$. The yields of both isobutyl and tertiary butyl radicals decrease in the range of MCH concentration above *ca.* 4 mol%, where the matrix becomes so soft that the radicals are trapped less efficiently in the matrix.[11]

Figure 5 shows the dependence of the yields of butyl radicals on the UV-illumination time. As the illumination time is increased, the yield of the isobutyl radical increases almost linearly, while that of the tertiary butyl radical initially increases and then reaches a plateau after a 40-min illumination. This result indicates that the tertiary butyl radical is produced by the hot-H-atom abstraction reaction with isobutane, while the isobutyl radical arises from a secondary process, *i.e.*, the photoisomerization of the tertiary butyl radical to the isobutyl radical upon prolonged UV-illumination,[12] in an isobutane-3.8 mol% MCH solution containing 0.2 mol% HI at 77°K.

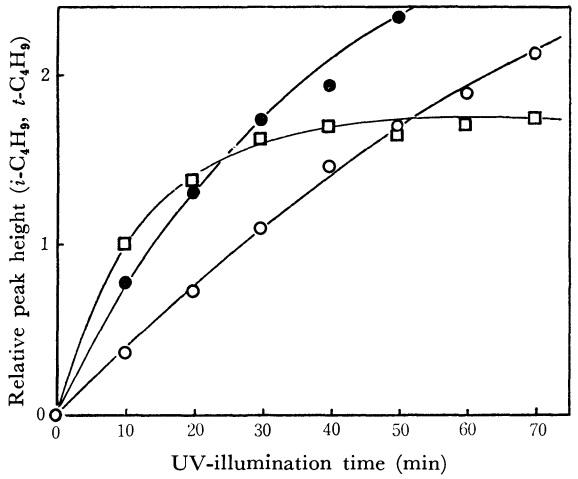

Fig. 5. Effect of UV-illumination time on the amounts of butyl radicals produced in UV-illuminated i-C_4H_{10}-HI (0.2 mol%) and i-C_4H_{10}-MCH (3.8 mol%)-HI (0.2 mol%) at 77°K.
●—●: i-C_4H_9 in an i-C_4H_{10} matrix.

Table I shows the butyl radicals produced by the hot-H-atom abstraction from isobutane in various UV-illuminated systems containing HI. Since the isobutyl-2-d_1 radical is produced in the photolysis of isobutane-2-d_1-HI (Fig. 1C), reactions (6) and (7) can be ruled out and reaction (8) occurs predominantly to form the isobutyl-2-d_1 radical:

$$i\text{-}C_4H_9D\text{-}2\text{-}d_1 + H_{hot} \rightarrow t\text{-}C_4H_9 + HD \quad (6)$$

$$t\text{-}C_4H_9 \rightarrow i\text{-}C_4H_9 \quad (7)$$

$$t\text{-}C_4H_9D\text{-}2\text{-}d_1 + H_{hot} \rightarrow i\text{-}C_4H_8D\text{-}2\text{-}d_1 + H_2 \quad (8)$$

In order to investigate the phase effect on the hot-H-atom abstraction reaction with isobutane, we have examined both the thermal isomerization and the decay of radicals. Ayscough and Evans[12] and Iwasaki and Toriyama[13] reported that isobutyl radicals produced in γ-irradiated alkyl halides, on standing at 77°K, isomerize thermally to tertiary butyl radicals. When the isobutyl radical was produced from dissociative electron attachment to i-C_4H_9Cl in the γ-irradiated i-C_4H_{10}-3.8 mol% MCH-1 mol% i-C_4H_9Cl system, the i-$C_4H_9 \rightarrow t$-C_4H_9 isomerization could be observed when it stood in the dark at 77°K for 15 hr.[8b] When an isobutane-3.8 mol% MCH solution containing 0.2 mol% HI is UV-illuminated for 30 min, the isobutyl radical is produced in addition to the tertiary butyl radical. When this sample was stored in the dark at 77°K for about 30 hr, the isomerization of the isobutyl radical could not be observed at all, but both isobutyl and tertiary butyl radicals decayed. The isobutyl radical produced by the photolysis of isobutane containing HI neither isomerizes to the tertiary butyl radical nor decays at all at 77°K (Fig. 6). The same phenomena were observed in γ-irradiated glassy isobutane-3.8 mol% MCH and in polycrystalline isobutane at 77°K.[8b]

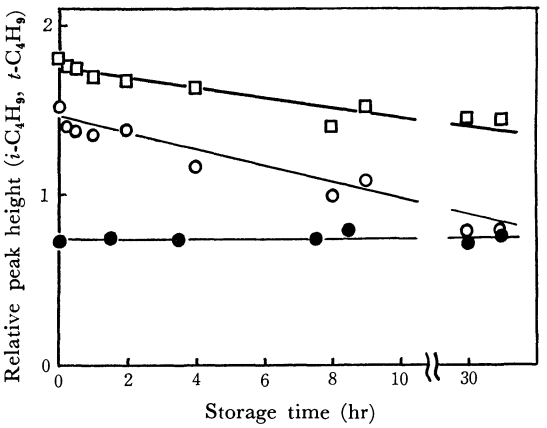

Fig. 6. Effect of storage time on the amounts of butyl radicals produced in UV-illuminated i-C_4H_{10}-HI (0.2 mol%) and i-C_4H_{10}-MCH (3.8 mol%) - HI (0.2 mol%) at 77°K. UV-illumination time: 30 min.

An ESR spectrum was obtained for the radicals produced in the radiolysis of a Xe-3.8 mol% isobutane mixture at 77°K; these radicals are identified as tertiary butyl radicals, presumably produced by energy transfer from Xe to isobutane. These tertiary butyl radicals isomerize to isobutyl radicals upon UV-

illlumination. When this sample was stored in the dark at 77°K for *ca.* 30 hr, both the isobutyl and the tertiary butyl radicals decayed. These results indicate that the physical state of a Xe-3.8 mol% isobutane mixture at 77°K is rather more similar to the glassy state of an isobutane-MCH mixture than to the polycrystalline state of pure isobutane. This is also consistent with the fact that the primary radicals produced from isobutane in the photolysis and radiolysis are isobutyl radicals in the polycrystalline matrix and tertiary butyl radicals in the glassy matrix at 77°K (Tables 1 and 2). Accordingly, the thermal isomerzation from the isobutyl to the tertiary butyl radical seems to be a phenomenon characteristic of the isobutyl radical produced from alkyl halides. The decay of butyl radicals seems to be related to the physical state of the matrix.

Figure 1D shows the ESR spectrum of radicals produced by the photolysis of 0.2 mol% in Xe-4.6 mol% isobutane at 77°K.

Kagiya *et al.* reported an empirical method of evaluating the activation energies for radical substitution reactions in the gas phase.[14)] Using their method, we have calculated the activation energies for such thermal radical substitution reactions as:

$$H_{thermal} + i\text{-}C_4H_{10} \rightarrow H_2 + t\text{-}C_4H_9 \text{ (or } i\text{-}C_4H_9) \quad (9)$$

and

$$H_{thermal} + i\text{-}C_4H_9D\text{-}2\text{-}d_1 \rightarrow HD \text{ (or } H_2) + t\text{-}C_4H_9 \text{ (or } i\text{-}C_4H_8D\text{-}2\text{-}d_1) \quad (10)$$

The calculated activation energies are shown in Table 3. If we assume that the activation energies for the thermal radical substitution reactions are independent of the temperature, we can say, on the basis of the

Table 3. The calculated activation energies of H atom abstraction reactions with isobutanes in the gas phase

Isobutane	Type of the bond	D_i[a)] (kcal/mol)	E_a[b)] (kcal/mol)
Isobutane	t-C-H	85	6.8
Isobutane	i-C-H	89	7.7
Isobutane-2-d_1	t-C-D	85.9	6.6
Isobutane-2-d_1	i-C-H	89	7.7

a) The bond dissociation energy of the initial bond. The C-D bond strength is taken to be 0.9 kcal/mol greater than that of C-H: S. W. Benson, "Foundations of Chemical Kinetics," McGraw-Hill Book Co., Inc., New York, N. Y. (1960), p. 666.
b) The activation energy.

activation energies estimated above, that the tertiary hydrogen atom of isobutane should be abstracted much more easily than the primary one at 77°K. However, this is inconsistent with observations on the polycrystalline samples, indicating that the hot hydrogen atom must be involved in the abstraction reaction in these systems.

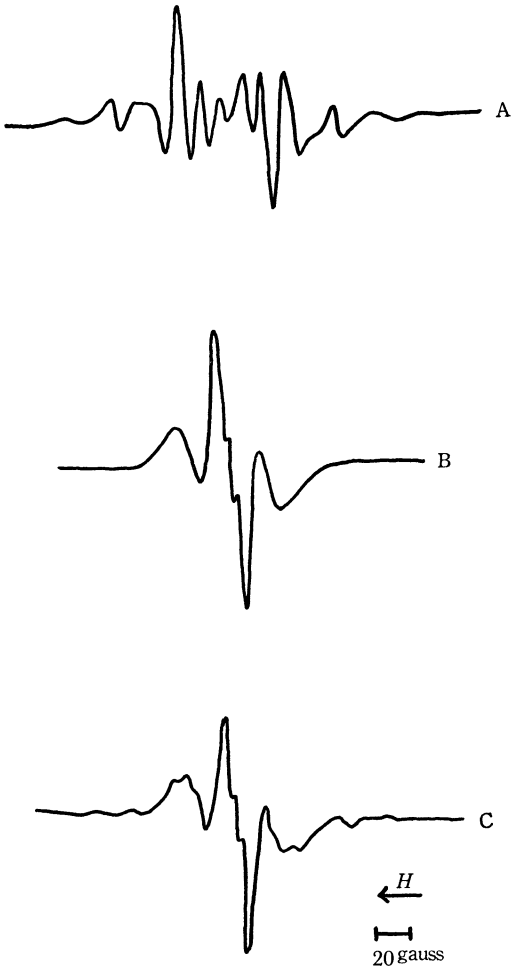

Fig. 7. (A) ESR spectrum of γ-irradiated i-C_4H_{10}-HI (1.0 mol%) at 77°K.
(B) ESR spectrum of γ-irradiated i-C_4H_9D-2-d_1 at 77°K.
(C) ESR spectrum of γ-irradiated i-C_4H_9D-2-d_1-HI (1.0 mol%) at 77°K. Irradiation dose: 2.22×10^5 rad.

Effects of Phase on Hydrogen-atom Abstraction in the Radiolysis of Solid Isobutane Containing HI. γ-Irradiated pure isobutane at 77°K displays a five-line ESR spectrum with a hyperfine coupling constant of $a_{av}=20.7$ G, which can be attributed to the isobutyl radical[15] (Table 2). A quite different ESR spectrum, however, is obtained for radicals produced in the radiolysis of isobutane containing 1.0 mol% HI. This spectrum consists of two components which may be assigned to the tertiary butyl radical (a ten-line spectrum with $a_{av}=22.3$ G)[16] and the isobutyl radical (Fig. 7A) respectively.

Figure 8 shows the dependence of the peak heights

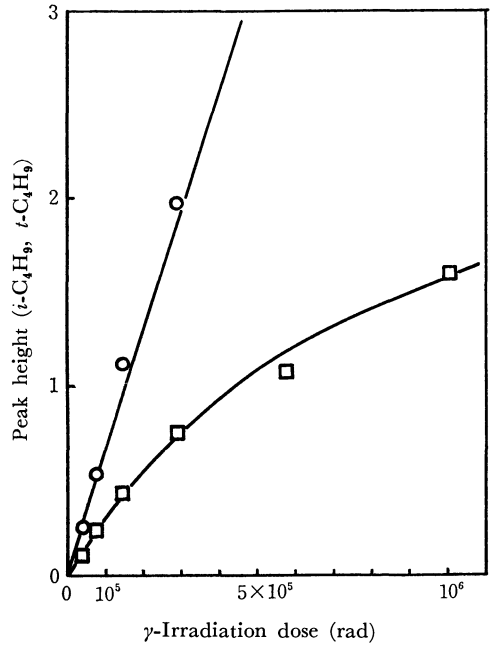

Fig. 8. Effect of dose on the amounts of butyl radicals produced in γ-irradiated t-C_4H_{10}-HI (2.0 mol%) at 77°K.
○—○: i-C_4H_9
□—□: t-C_4H_9

of trapped radicals on the dose in γ-irradiated isobutane containing 2.0 mol% HI at 77°K. The peak intensity of isobutyl radicals is linear in doses over the entire range studied, while that of tertiary butyl radicals is linear in doses up to 1.5×10^5 rad, but deviates from the straight line with doses beyond it. This result can be interpreted in terms of the following reactions:

$$i\text{-}C_4H_{10} \text{ -}\!\!\wedge\!\!\vee\!\!\wedge\text{- } i\text{-}C_4H_{10}^*,\ i\text{-}C_4H_{10}^+ + e^- \quad (11)$$

$$i\text{-}C_4H_{10}^* \rightarrow i\text{-}C_4H_9 + H \quad (12)$$

$$HI + e^- \rightarrow H_{hot} + I^- \quad (13)$$

$$H_{hot} + i\text{-}C_4H_{10} \rightarrow H_2 + t\text{-}C_4H_9 \quad (14)$$

The isobutyl radical is produced by the decomposition of the excited isobutane molecule (reaction (12)),[7] while the tertiary butyl radical is produced in the H-abstraction by the hot H atom which is formed in the dissociative electron attachment (reaction (13)) and has an energy of *ca.* 5—6 kcal/mol.

As the HI concentration in an isobutane matrix is increased, the yield of the isobutyl radical produced in the radiolysis decreases initially and reaches a plateau value at *ca.* a 1.0 mol% HI concentration, while that of the tertiary butyl radical increases rapidly initially and then gradually (Fig. 9). Figure 10

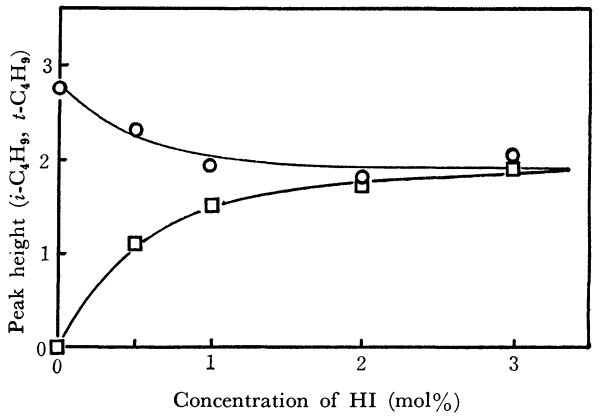

Fig. 9. Effect of HI concentration on the amounts of butyl radicals produced in γ-irradiated i-C_4H_{10} at 77°K. Irradiation dose: 8.9×10^4 rad.

□—□: t-C_4H_9

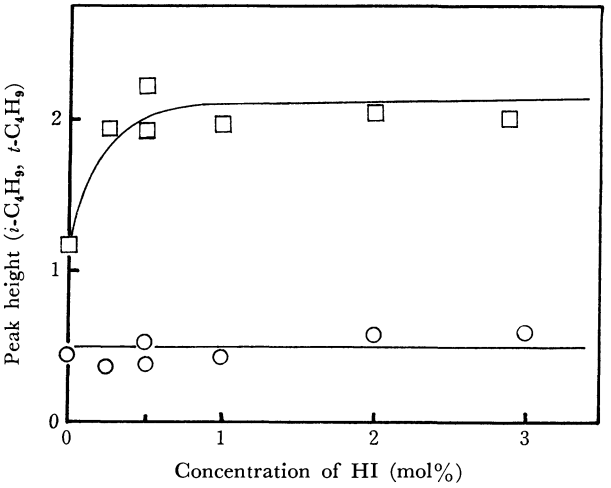

Fig. 10. Effect of HI concentration on the amounts of butyl radicals produced in γ-irradiated t-C_4H_{10}-MCH (3.8 mol%) at 77°K. Irradiation dose: 8.9×10^4 rad.
○—○: i-C_4H_9
□—□: t-C_4H_9

shows the dependence of the yields of trapped radicals on the concentration of HI in a γ-irradiated isobutane-3.8 mol% MCH matrix at 77°K. The yield of the tertiary butyl radical increases with the concentration of HI up to *ca.* 0.5 mol% and reaches a plateau value, while that of the isobutyl radical is constant over the entire range of HI concentrations studied. These results may be interpreted in terms of the energy dependence of the hot-H-atom reaction and on the basis of the electron yield in γ-irradiated hydrocarbons in the solid state; the hot H atom produced from HI by the dissociative electron attachment (reaction

15) J. Lin and F. Williams, *J. Phys. Chem.*, **72**, 3707 (1968).

(13)) abstracts an H atom from the tertiary position more easily than from the primary position in isobutane at 77°K, since the hot H atom thus produced has an energy of *ca.* 5—6 kcal/mol, which is much lower than that produced by the photolysis of HI. Such an argument holds for both polycrystalline isobutane and glassy isobutane-MCH matrices (Table 4). The

Table 4. Butyl radicals produced in the radiolysis of HI in various matrices at 77°K[a)]

System	Phase	Radical

a) Concentration of HI: 1.0 mol%; γ-irradiation dose: 2.22×10^5 rad

yield of the tertiary butyl radical produced by reaction (14) increases with HI concentration up to *ca.* 1.0 mol%, above which it remains constant, because the yield of electrons which escape from recombination with the parent positive ions in the radiolysis of condensed systems is limited and its maximum value in solid hydrocarbon matrices is $G(e^-)=2$.[17)] The yield of the isobutyl radical is rather insensitive to the concentration of HI, since the isobutyl radical is produced by the decomposition of the excited isobutane molecule.

Figure 7B shows the ESR spectrum of radicals produced in the radiolysis of pure isobutane-2-d_1 at 77°K, which can be attributed to the isobutyl-2-d_1 radical.[9)] In γ-irradiated 1 mol% HI in isobutane-2-d_1, the tertiary butyl radical is produced in addition to the isobutyl-2-d_1 radical (Fig. 7C). The tertiary butyl radical may arise from D-atom abstraction from isobutane-2-d_1 by the hot H atom produced from HI.

Cause of Phase Effect on H-atom-abstraction Reaction by Hot H Atoms. When a diatomic molecule such as HI dissociated by absorbing light with more energy than the dissociation energy of the bond, the atoms produced will be hot. The main advantage of utilizing photochemically-produced hot atoms is that their initial kinetic energy is well known. In the 2537 Å photolysis of HI, hot H atoms have 20 kcal/mol or 41 kcal/mol, depending on whether the iodine atom is produced in the excited state or in the ground state. Since the first excited-state energy of the H atom is about 237 kcal/mol, the energy given to the H atom produced photochemically is the kinetic energy.

The phase effect can be discussed from the following two points of view: (i) whether the phase change affects such primary processes as the fragmentation of the excited HI molecule in the photolysis of solid isobutane containing HI at 77°K, and (ii) whether the phase change affects such secondary processes as the hot-hydrogen-atom abstraction reaction with isobutane. In a diatomic molecule such as HI, the H–I bond rupture of the excited HI molecule (HI*) may occur repulsively in the period of one vibration (less than 10^{-13} sec). Therefore, the phase effect has no important influence upon the primary process of the HI* fragmentation.

One plausible explanation is given by the cage effect on the radiolysis of organic solids, which was reviewed by Willard.[18)] Since the C–C bond of the stable tertiary butyl radical is formed by sp^2-hybrid orbitals, three methyl groups construct a planar structure. Therefore, the structural rearrangement of the C–C bonds would be necessary for the formation of the stable tertiary butyl radical from the isobutane molecule, which such a rearrangement would be unnecessary for the formation of the isobutyl radical. In the radiolysis of isobutane in the polycrystalline state, the formation of the tertiary butyl radical, accompanied by the structural rearrangement of the C–C bonds, may be suppressed in the rigid crystal, and only the primary C–H bond, which is stronger than the tertiary C–H bond, may be ruptured. The effect of the matrix rigidity was observed both in the abstraction of H atom from isobutane by hot H atoms produced from the photolysis of HI and in the decomposition of the excited isobutane molecule produced by the radiolysis of isobutane (Tables 1 and 2). In the radiolysis of the polycrystalline isobutane-HI or isobutane-2-d_1-HI, however, it was found that the hot H atom, which is produced by dissociative attachment to HI, abstracts the tertiary H atom from isobutane or isobutane-2-d_1 (Table 4). Thus, only the cage effect does not explain satisfactorily this H-abstraction reaction in solid hydrocarbons at 77°K. The energy dependence of the hot-H-atom abstraction reaction must be invoked to interpret this observation.

Another effect of the hot-atom reaction is the moderator effect, which was discussed by Hamill,[19)] in the photolysis of HI. On this model, hot H atoms are formed with 20 or 41 kcal/mol of translational energy, which they can lose in the subsequent moderating collisions with an inert gas. Typically, these are rare gases such as He and Ne, but such substances as A, Kr, Xe, and H_2 may act as moderators. We may interpret the present results for a moderator matrix, Xe (Tables 1 and 2), as follows. The hot H atoms (H**) in a Xe matrix may lose translational energy by collisions with the moderator, Xe, and then they may abstract the tertiary H atoms of isobutane to form tertiary butyl radicals (reactions (15), (16), and (17)). This interpretation is consistent with the findings on the radiolysis of isobutane-HI, where hot H atoms have only 5—6 kcal/mol and preferentially abstract the tertiary H atoms. In summary, the H-abstraction reaction by hot H atoms depends upon the energy of the hot H atoms:

18) J. E. Willard, "Fundamental Processes in Radiation Chemistry," P. Ausloos, Ed., Interscience, New York, N. Y. (1968), p. 599.

19) H. A. Schwarz, R. R. Williams, Jr., and W. H. Hamill, *J. Amer. Chem. Soc.*, **74**, 6007 (1952).

$$HI \xrightarrow{h\nu} H^{**} + I \quad (15)$$

$$H^{**} + M \rightarrow H^{*} + M \quad (16)$$

$$H^{*} + i\text{-}C_4H_{10} \rightarrow H_2 + t\text{-}C_4H_9 \quad (17)$$

In reactions (15)—(17) H** and H* represent hot atoms with higher and lower kinetic energies respectively, and M represents a moderator such as Xe. It should be stressed that, although the efficiency of Xe as a moderator is probably lower than that of hydrocarbons, the contribution of H-abstraction by very hot atoms is more greatly reduced in a Xe matrix than in a hydrocarbon matrix, in which H-abstraction by hot atoms inevitably competes with hot-atom moderation.

The Reactions of Mobile Electrons in the Frozen Solution of Ethylene Glycol-Water at 77°K

Teikichi SASAKI and Shin-ichi OHNO

Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki-ken

(Received March 11, 1971)

The yield of trapped electrons produced in ethylene glycol-water glass at 77°K increased linearly with the gamma dose up to 1.5×10^{20} eV/g, and the G value was estimated to be 2.8 ± 0.2. The relative reaction rates of mobile electrons with various inorganic ions at 77°K were determined by competition kinetics. The observed relative reaction rates with simple inorganic ions corresponded to those of hydrated electrons obtained at room temperature. For complex ions, however, the reactivities of the mobile electrons were larger than those of hydrated electrons. The reaction products, such as bromine dioxide, Cr(V) species, and the pentacyano Co(II) ion, all of which are unstable at room temperature, could be detected by optical and ESR spectroscopies at 77°K.

A large number of rate constants for the reaction of the hydrated electron, e_{aq}^-, with solutes have been determined by competition kinetics and pulse-radiolysis techniques.[1] For the mobile electron, e_m^-, produced in acidic or alkaline ices at 77°K, some investigators[2-4] have determined the relative rates of reaction with metal cations and oxyanions. The results observed have shown that the relative reactivity of e_m^- with a solute is quantitatively similar to that of e_{aq}^- with the same solute. Based on these correlations, Kevan has postulated e_m^- as a mobile solvated electron in ice.[2] This preposition also implies that the structure of e_m^- at the time of reaction is similar to that of e_{aq}^-.

Dainton and his co-workers[4,5] have demonstrated that, in 5.4 M sulfuric acid at 77°K, an e_m^- can reduce solutes such as transition metal cations and nitrous oxide. The reaction products of lower valency states are trapped in the matrix; they have been studied by both optical and ESR spectroscopies. However, it is difficult to study the reactivity of e_m^- with solutes which are subject to decomposition in concentrated acid or alkaline solutions.

In the present paper, a study on the rate of the reaction of e_m^- with electron scavengers such as simple inorganic and complex ions was made by employing a neutral solution of an ethylene glycol-water mixture as the solvent matrix. The trapped electron, e_t^-, produced in this matrix by gamma irradiation is indefinitely stable in dark at 77°K and has an absorption band in the visible region which can be readily photobleached by exposure to the visible light. It is well-known[6,7] that the G value of the e_t^- produced at 77°K is comparatively high and reaches its maximum in the region of 50—65 vol% ethylene glycol, which is suitable for quantitative investigations of the reactivity of e_m^-. The products resulting from the e_m^- reactions could also detected by optical and ESR spectroscopies. In some cases, the results were correlated with the data obtained by pulse-radiolysis and flash photolysis.

Experimental

Sample Preparation. Water was distilled three times, and ethylene glycol from the Kanto Kagaku Co., Ltd., was fractionally distilled. All of the other chemicals were of analytical reagent grade and were used without further purification. As the solvent matrix, 67 vol% ethylene glycol diluted with pure water was used. Each sample contained 10^{-3}—5×10^{-2} M metal sulphate or potassium salt as an electron scavenger. The solution was degassed and made into the glassy state by the freeze-pump-thaw technique at 77°K.

The cells for the spectrophotometric measurement were made of quartz with rectangular cross-sections and with overall dimensions of $0.10\times1.2\times3.5$ cm. For the ESR study, Spectrosil tubings of 0.45 cm i.d. were used.

Irradiation and Measurement. Gamma irradiations by a ^{60}Co source were carried out in the dark at 77°K. The dose rate was 4.0×10^{18} eV g^{-1} hr^{-1} except where otherwise described.

The optical absorption spectra were obtained with a Shimadzu QV-50-type spectrophotometer by the use of a Dewar flask with quartz windows. The yield of e_t^- was determined from the decrease in the optical density at 530 nm after the photobleaching procedure. The photobleaching of e_t^- was performed with a 400-W tungsten lamp whose UV light of wavelengths shorter than 350 nm was cut off with a Toshiba color filter.

The ESR spectra were scanned on an X-band ESR spectrometer (Japan Electron Optics Laboratory Co., Ltd., JEP-1) operating at ~9.3 kMc/s and employing 100 kc/s magnetic-field modulation and phase-sensitive detection. The gamma-irradiated samples were first transferred into a quartz Dewar flask of the temperature of liquid nitrogen. Then the vessel was placed inside the cavity of ESR spectrometer equipped with a dry N_2 gas-flow system. The *g*-factors were determined by employing nitrogen oxide radicals trapped in 0.6M $NaNO_3$ ice as a standard. Its isotropic splitting constant was taken to be 54.7 *G*, with a *g*-factor of 2.001.[8]

Results and Discussion

Yield of e_t^- in the Ethylene Glycol-Water Mixture. After gamma irradiation in the dark at 77°K, ethylene glycol-water glass developed a deep blue color. The color readily decayed, however, upon exposure to the visible light ($\lambda>350$ nm). The optical absorption spectra were essentially identical with those of e_t^- reported by Ershov *et al.*[9]

A signal due to e_t^- was also detected by ESR measurement, together with those of hydrogen atoms and some different organic radicals. One of the spectra

(a) before photobleaching, (b) after photobleaching

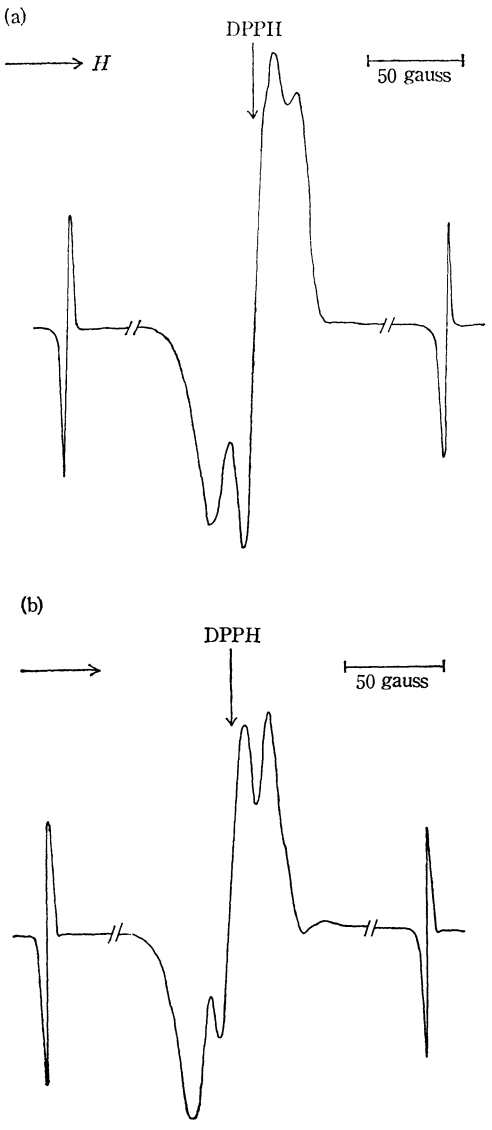

Fig. 2. ESR spectra of ethylene glycol-water glasses irradiated with gamma rays to a dose of 7.3×10^{20} eV/g at 77°K.
(a) before photobleaching, (b) after photobleaching

observed at 77°K is displayed in Fig. 1(a). Besides an H-atom doublet with a splitting of 510 *G*, a signal attributable to e_t^- superimposed by those of the organic

8) L. Kevan, *J. Phys. Chem.*, **68**, 2590 (1964).

radicals was observed in the central part of the spectrum. The line shape was changed by the photobleaching of e_t^- with the visible light, and the signals due to the organic radicals which have been assigned to the $HOCH_2CH_2\dot{O}$ and $HOCH_2\dot{C}HOH$ radicals[7] clearly appeared, as is shown in Fig. 1(b). For the samples irradiated with gamma doses higher than about 1.5×10^{20} eV/g, a decrease in the ratio of the signal intensity of e_t^- to that of hydrogen atoms was observed. The central part of the spectrum was also changed, as may be seen in Fig. 2.

The yield of e_t^- in the ethylene glycol-water glass increases linearly up to a dose of about 1.5×10^{20} eV/g. Assuming that the extinction coefficient of e_t^- produced in the matrix at 77°K is identical with that of e_t^- in the irradiated alkaline glass, 1.37×10^4 M^{-1} cm^{-1} at 530 nm,[10] the G value of e_t^- can be estimated to be 2.8±0.2. It is noteworthy that this value agrees well with the maximum G value of e_t^- produced in the alkaline glasses (3.0 in 10 M KOH glass[10]). The yield of e_t^- reaches its maximum at *ca.* 1×10^{21} eV/g and then decreases, while those of the hydrogen atoms and organic radicals increase with the absorbed dose, as is shown in Fig. 3. Such a dose dependence of e_t^- is identical with the observations for the 10 M NaOH frozen solutions irradiated with gamma rays of doses higher than *ca.* 2.5×10^{20} eV/g.[11] The characteristics observed may arise from di-electron formation and the disappearance due to the recombination reaction of e_t^- with the positive-ion radicals.

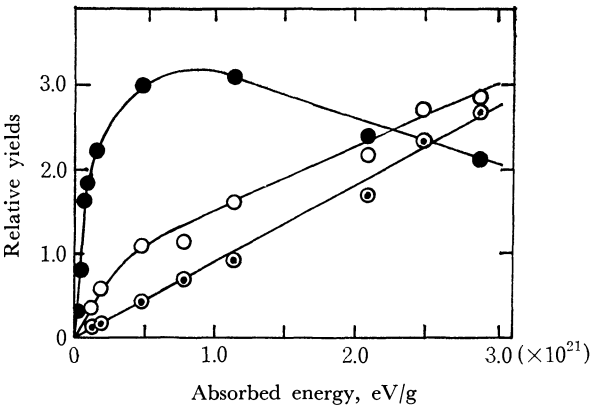

Fig. 3. Relative yields *vs.* absorbed energy of gamma irradiation. In the region of the dose higher than 1.1×10^{21} eV/g, the samples were irradiated at the dose rate of 2.4×10^{19} eV/ghr.

Reaction Rates of e_m^- with Electron Scavengers. The relative reaction rates of e_m^- can be determined by a competition reaction, such as:

$$e_m^- + T \xrightarrow{k_1} e_t^- \qquad (1)$$

$$e_m^- + S \xrightarrow{k_2} S^- \qquad (2)$$

where T and S are the electron trap and the electron scavenger respectively. Competition kinetics applied to the e_m^- reaction in the system yields the following expression:

$$\frac{C_o(e_t^-)}{C(e_t^-)} - 1 = \frac{k_2[S]}{k_1[T]} \qquad (3)$$

where $C_o(e_t^-)$ and $C(e_t^-)$ are the e_t^- concentrations in the absence and in the presence of the scavenger. Because the optical density at 530 nm, $D(e_t^-)$, is proportional to the e_t^- concentration, the relative value of k_2 is obtained from the slope of the straight line by plotting $\{D_o(e_t^-)/D(e_t^-)-1\}$ against [S].

The results for NO_3^-, $[Fe(CN)_6]^{3-}$, and $[Co(CN)_6]^{3-}$ ions, corrected for the absorption of the solvent matrix and quartz cell, are shown in Fig. 4. The ordinate values increases linearly with the scavenger concentration, and no effect on the electron-trap concentration was observed upon the addition of the electron scavenger. The relative rates for the e_m^- reactions with various inorganic ions are summarised in Table

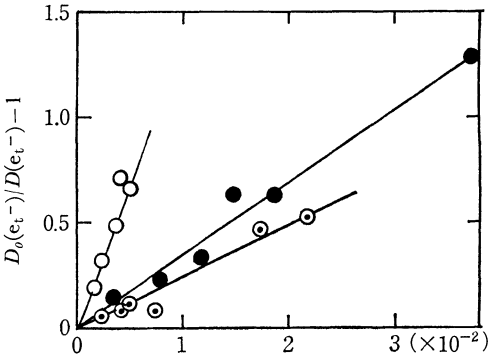

Fig. 4. Relationships between $\{D_o(e_t^-)/D(e_t^-)-1\}$ and scavenger concentration. All samples were irradiated to a gamma dose of 4.0×10^{18} eV/g at 77°K.

11) L. Kevan, D. Renneke, and R. J. Friauf, *Solid State Commun.*, **6**, 469 (1968); H. Hase and L. Kevan, *J. Phys. Chem.*, **73**, 3290 (1969).

1; those for the e_m^- reaction obtained at pH 7.0 are also presented for comparison.

In the case of all inorganic ions except the complex ion, the relative values of the e_m^- rates agree with those of the e_{aq}^- rates. The correlations seem to support Kevan's postulations[2,12] that e_m^- in ice acts as a mobile solvated electron and that the entropic effects of the scavenger ions are responsible for the rate differences between the different solutes. On the other hand, the e_m^- rates for complex ions are usually larger than the e_{aq}^- rates for the corresponding ions. This finding is unexpected, and it seems that more experimental data are neccessary to give a definite explanation of the reactivity of e_m^- with complex ions.

Spectra of Reaction Products. After the photobleaching of e_t^-, the irradiated glass containing the bromate ion gave an optical absorption spectra with a tail in the UV region and a peak at 475 nm, as is shown in Fig. 5. This absorption band disappeared

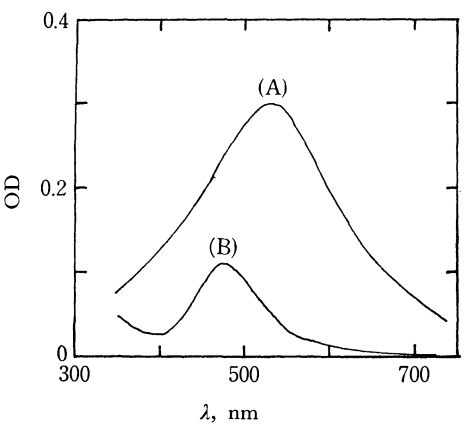

Fig. 5. Optical absorption spectra for glassy specimens irradiated gamma rays at 77°K.
(A): Ethylene glycol-water glass irradiated to a dose of 3.8×10^{18} eV/g (before photobleaching).
(B): Ethylene glycol-water glass containing 0.05 M $KBrO_3$ irradiated to a dose of 5.6×10^{19} eV/g (after photobleaching).

upon thermal annealing at *ca.* 140°K. The peak position is in good agreement with that of the transient species observed in the pulse-radiolysis experiment at room temperature;[13] therefore, it may be thought to be due to the bromine dioxide (BrO_2) which is produced in the reaction:

$$e_m^- + BrO_3^- \rightarrow BrO_2 + O^{2-} \quad (4)$$

An analogous reaction scheme was proposed for the reduction of the bromate ion with e_{aq}^- by flash photolysis.[14] In the irradiated solution containing the iodate ion, however, the clear optical spectrum of dioxide species could not be observed because it was superimposed by a tail of a stronger absorption of the iodine trioxide radical.[15]

The extinction coefficient of the bromine dioxide observed can be determined from the optical density in Fig. 5, assuming that Eq. (3) is correct up to the solute concentration of the order of 0.05 M. Since the bromine dioxide concentration, $C(BrO_2)$, is equal to $C_o(e_t^-)-C(e_t^-)$, it can be expressed as follows:

$$C(BrO_2) = \frac{K[S]C_o(e_t^-)}{1+K[S]} \quad (5)$$

where K is $k_2/(k_1[T])$. Therefore, the extinction coefficient, $\varepsilon(BrO_2)$, is related with the reaction rate of bromate ion by the following expression:

$$\varepsilon(BrO_2) = \frac{D(BrO_2)}{C(BrO_2)\cdot l} = \frac{(1+K[S])\,D(BrO_2)}{K[S]C_o(e_t^-)\cdot l} \quad (6)$$

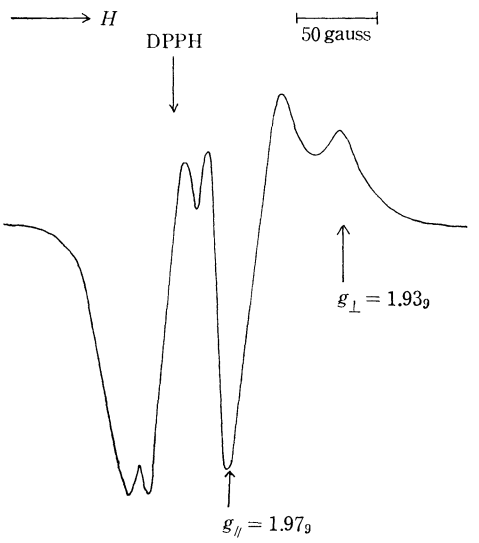

Fig. 6. ESR spectrum of 0.1 M K_2CrO_4 solution irradiated with gamma rays to a dose of 5.0×10^{19} eV/g and photobleached at 77°K.

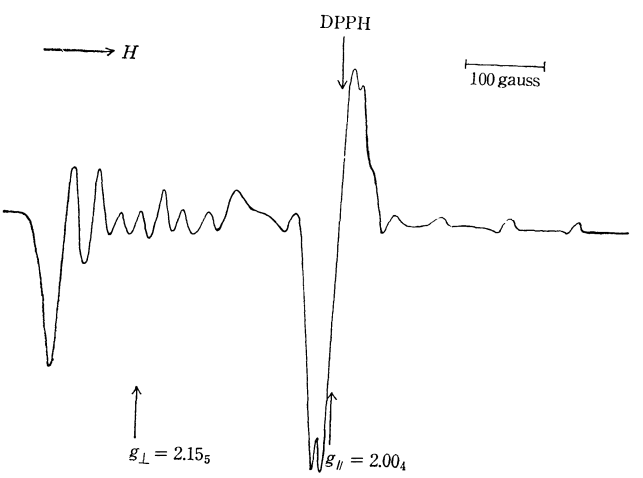

Fig. 7. ESR spectrum of 0.07 M $K_3[Co(CN)_6]$ solution irradiated with gamma rays to a dose of 5.0×10^{19} eV/g and photobleached at 77°K.

14) O. Amichai, G. Czapski, and A. Treinin, *Isr. J. Chem.*, **7**, 351 (1969).
15) The trioxide species might be produced in consequence of the following hole reaction:
$M \rightsquigarrow M^+ + e_m^-$
$M^+ + IO_3^- \longrightarrow M + IO_3$
where M denotes the solvent matrix.

where D is the optical density and l is the optical path. The value of K is determined to be 6.5 M^{-1} from the slope of the scavenger curve, and $C_0(e_t^-)$ is 3.2×10^{-3} M in the ethylene glycol-water glass irradiated with a dose of 5.6×10^{19} eV/g. Thus, $\varepsilon(BrO_2)$ can be estimated to be approximately 1.4×10^3 M^{-1} cm^{-1} at 475 nm.

In the presence of the chromate ion as an electron scavenger, an intermediate species was also detected by ESR spectroscopy. The spectrum recorded at 77°K is shown in Fig. 6. An anisotropic signal on the low g-factor side of the free-electron position, which was also observed in the 6 M sulfuric acid matrix, indicates the formation of an electron-rich center. The line shape and the principal g-factors are characteristic of the Cr(V) species formed in the frozen solutions[16] as a result of the electron capture of the chromate ion.

Figure 7 shows the ESR spectrum of a gamma-irradiated glassy specimen containing the 0.07 M hexacyano cobaltate ion. In addition to the central signals resulting from the organic radicals, the specimen gives two eight-line hyperfine patterns. The spectrum is interpreted as consisting of superimposed parallel and perpendicular absorptions; each splits into eight lines, with coupling constants of 30 and 91 G respectively, by means of ^{59}Co ($I=7/2$) nuclear interactions. The respective g-factors and the hyperfine constants are characteristic of those observed for the penta-coordinated Co(II) complex ion rather than the hexa-coordinated Co(II) complex ion in frozen solutions at 77°K by Kataoka and Kon.[17] Therefore, the spectrum obtained strongly suggests the formation of the pentacyano Co(II) ion in consequence of the reaction associated with e_m^-:

$$[Co(CN)_6]^{3-} + e_m^- \rightarrow [Co(CN)_5]^{3-} + CN^- \qquad (7)$$

Gel Filtration of Aqueous Sodium Dodecyl Sulfate

Hitoshi SUZUKI and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Tokyo, Japan

(Received March 17, 1971)

Gel filtration of an aqueous solution of sodium dodecylsulfate (SDS) was carried out using Sephadex G-50 as a gel column, and the overall elution rate (R_f) of SDS was measured. The value of R_f was found to be independent of the concentration C of SDS below a certain point, above which it increased with increasing C. A sharp break point observed coincided with the critical micelle concentration (CMC) of SDS. The intermicellar concentration of SDS was estimated from the shape of the elution curve for the solutions beyond CMC, and shown independent of the total concentration C. The value of R_f for the micelle was further determined by direct measurement. The value was found to increase slightly with C above CMC, becoming practically constant above about 1.4×10^{-2} mol/l. It was concluded from the results that the size of the micelle also increase with the concentration above CMC. Theoretical equations were derived for the relation between R_f and C below and above CMC. Observed R_f *vs.* C relation fitted the equations satisfactorily, from which CMC was calculated. A rapid equilibrium between micelles and monomer ions and the independence of intermicellar concentration on C were also confirmed.

A study on the dissolved state of sodium dodecyl sulfate (SDS) by the gel filtration method using Sephadex G-50 was reported in a previous paper.[1] Equations were proposed which predict a relation between a relative elution rate and the concentration of SDS solution. The observed data fitted the equation from which a rapid equilibrium between micelles and monomer ions, uniformity of micellar size and the independency of intermicellar concentration on the total concentration were concluded.

Further studies made on the direct measurement of the relative elution rate of micelles suggested a slight increase of the micellar size above CMC. This made it necessary to re-examine the former plots. We have derived a revised equation for gel filtration which involves a well defined parameter for the rate of micelle decomposition. Verification was carried out without the method of trial and error which was adopted in the previous case.[1] Constancy of the intermiceller concentration of SDS was also checked experimentally.

Experimental

Materials. Sodium dodecyl sulfate (SDS) was synthesized from dodecyl alcohol and chlorosulfonic acid by the usual method[2] and was purified by solvent extraction using ethyl ether and recrystallization from ethanol. Purity was checked by the absence of a minimum in the surface tension-concentration curve.

2) S. J. Rehfeld, *J. Phys. Chem.*, **71**, 738 (1967).

Sodium chloride was purified by recrystallization of the reagent grade product.

The gel used for packing the column was Sephadex G-50[3] fine, manufactured by Pharmacia, Uppsala, Sweden.

Apparatus. The apparatus used for gel filtration is schematically shown in Fig. 1. The main parts of the apparatus consisted of a gel column G prepared in the usual manner[3,4] (diameter 1.2 cm and gel height 32.5 cm), a conductance cell D, a conductometer C and a recorder R. The conductance cell D for detecting SDS recorded the conductance against the elution volume. All experiments were carried out at 30±1°C.

Fig. 1. Arrangement for gel filtration.

Methods. To measure the retention volume of SDS, the gel column was previously equilibrated with distilled water and 25.0 m*l* of SDS solutions of varying concentration (C) were put on the gel column. Elution was then started using distilled water at a flow rate of 20 m*l*/hr, and the retention volume (V) was determined from the conductance curve recorded. The results were conventionally expressed as the relative elution rate

$$R_f = V_0/V \qquad (1)$$

where V_0 denotes the retention volume of solvent water.

To measure R_f value of the micelles in the aqueous solution of SDS above CMC, the gel was previously equilibrated with SDS solution of concentration C larger than CMC (C_m), and SDS solution with concentration C' larger than C was added to the gel column. The solution was then eluted with water. From the elution volume $V_m(C')$ thus obtained for the SDS solution of concentration C', the relative elution rate of the micelle $R_f^m(C') = V_0/V_m(C')$ was calculated. $R_f^m(C')$ was then plotted against C' and the value $R_f^m(C)$ was estimated by extrapolating C' to C. The value $R_f^m(C)$ can be considered as the relative elution rate of the micelle flowing through its own intermiceller solution of concentration C without decomposition.

Results and Discussion

Intermiceller concentration of SDS. Figure 2 shows two typical elution curves of SDS solution of concentrations below and above CMC, through the gel column filled with water. We see that the curve of SDS solution of the concentration below CMC shows one plateau and that above CMC two. The higher one corresponds to concentration C of the solution eluted. The lower one might be considered to be the concentration of the intermicellar SDS left after the fast flowing micelles have been eluted, provided that the plateau is sufficiently horizontal and the change between the two plateaus is fairly sharp. Figure 3 shows the plots of the conductance and concentration corresponding to one (solid circles) or two plateaus (open circles and triangles) of the elution curves against the analytical concentration of SDS. We see a straight line passing through the origin and a horizontal straight line starting from CMC. The latter might indicate constant intermicellar concentration which is independent of the SDS concentration and is equal to C_m.

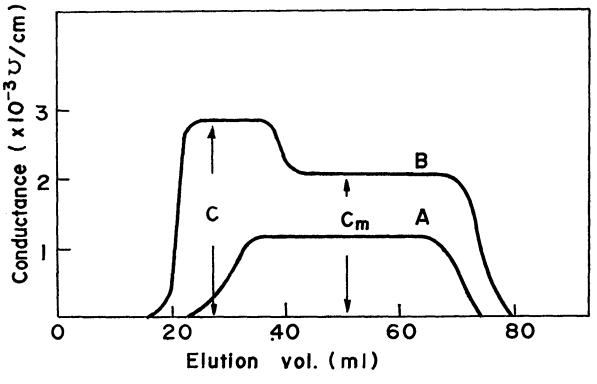

Fig. 2. Elution curve of SDS solution.

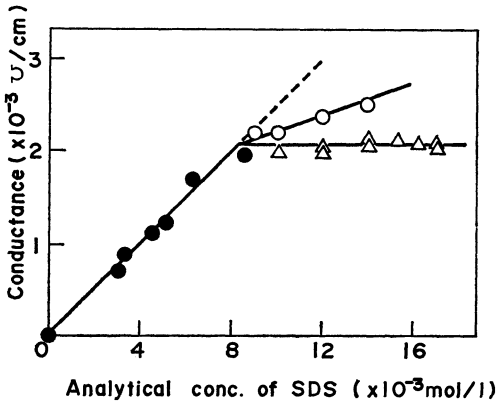

Fig. 3. Conductance of SDS solution.
Conductance of the solution below CMC(●) and above CMC(○); conductance of intermicellar solution(△)

R_f vs. C relation. The observed values of R_f for the aqueous solution of SDS below and above CMC are plotted against the concentration as shown in Fig. 4. Since V_s, the retention volume of the lower concentration region of SDS, was found practically independent of SDS concentration,[1,5,6] its mean value $\bar{V}_s$ was calculated, and $R_f = \bar{V}_s/V$ instead of $R_f = V_0/V$ was used as a relative elution rate. The relative

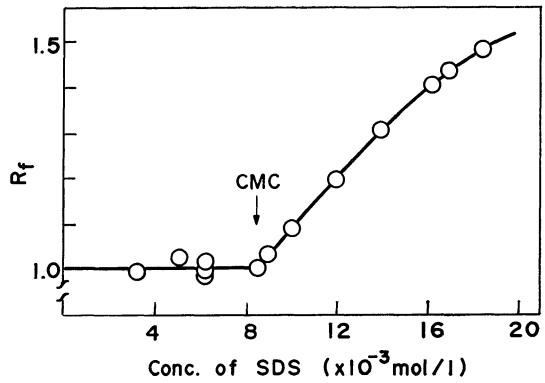

Fig. 4. R_f *vs.* concentration of SDS.

elution rate of monomer ion R_f^s is therefore expressed as

$$R_f^s = \bar{V}_s/V_s \fallingdotseq 1$$

It is evident from Fig. 4 that R_f *vs.* C curve consists of a horizontal straight line $R_f=R_f^s \fallingdotseq 1$ in the lower concentration region and a curve in the higher concentration region, with a break point between them corresponding to the CMC of SDS (8.5×10^{-3} mol/l). The constancy of R_f^s value in the lower concentration region might indicate the presence mainly of monomer molecule of SDS in this region.

The results of the direct measurement of $R_f^m(C')$ together with the process of extrapolation are shown in Fig. 5. The extrapolated $R_f^m(C)$ value (solid circles) increases from about 2.2 near CMC with increasing SDS concentration until it becomes constant, 2.54 above 1.4×10^{-2} mol/l SDS. It is worthy to note that the change in R_f^m is exclusively ascribed to the change in size of solute particle, since the effect of adsorption and other conceivable factors can be excluded from the present experimental conditions, and there is the possibility for a slight increase of micellar size with concentration above CMC.

Let us discuss the relation between R_f and SDS concentration for the solution especially above CMC. For this purpose, it is convenient to use such a diagram as shown in Fig. 6a,[5] for the elucidation of the mechanism of gel filtration and the calculation of R_f as a function of the concentration above CMC. In this diagram, the effective cross sectional area A_m of a packed gel column through which micelles can flow (total cross-section of interspace of gel particles), and a similar area A_s for the passage of sufficiently small molecules (monomer surfactant molecules and solvent water molecules), are taken on OY axis. The distance travelled by the monomer molecules and the micelles during the flow of a solution is taken on OX axis. Thus, the vertical line RS indicates the front of the micelles in sample solution (large circles) just reaching the lower end of the gel column while the solution is continuously supplied and flows down, assuming no decomposition into monomer takes place. The vertical line PQ indicates the front of monomer molecules (small circles) when the front of the micelles reaches RS. Since the volumes occupied by these solute components are equal, we have

$$\square A_sOPQ = \square A_mORS \qquad (3)$$

where □ denotes the area of the square specified which actually expresses the volume. A simple geometry shows that the intersection M of the two straight lines A_mS and PQ lies on the diagonal OU. The micelles in □ MPRS are unstable since they are isolated from monomer molecules which should exist in equilibrium with them. Therefore, such micelles as in □ RR'S'S actually decompose into monomer molecules to fill the space □ QPR'U' with the concentration C_m' ($C_m' \leqq C_m$) as shown by the small circles in this area (Fig. 6b). For further calculation, we put OR=t

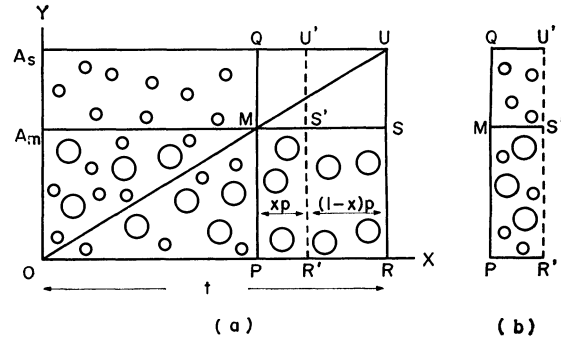

Fig. 6. Mechanism of gel filtration.
○; monomer molecule, ○; micelle

which represents the total length of the gel column, PR'=xp, RR'=$(1-x)p$ as shown in Fig. 6. Then we obtain the relation

$$A_m p(1-x)(C-C_m) = A_s pxC_m' = A_s pxC_m\alpha$$

or

$$A_m(1-x)(C-C_m) = A_s xC_m\alpha \qquad (4)$$

Here α, being equal to C_m'/C_m, denotes a parameter of the rate of micelle decomposition or the rate of equilibration between micelles and monomer. Namely, the decomposition is instantaneous when $\alpha=1$ and no decomposition occurs when $\alpha=0$. Further, the actual retention volume V of the solute is given by

$$tA_m : V = [t-(1-x)p] : t$$

or

$$V[t-(1-x)p] = t^2A_m \tag{5}$$

Eq. (3) is rewritten as

$$(t-p)A_s = tA_m \tag{6}$$

From Eqs. (4), (5), and (6), we obtain

$$\frac{V}{V-tA_m} = \frac{A_mC}{(A_s-A_m)C_m\alpha} + \frac{A_s\alpha-A_m}{(A_s-A_m)\alpha} \tag{7}$$

It can be understood from Fig. 6 that $A_st=V_s$ and $A_mt=V_m$ represent the retention volumes of monomer molecule and micelle (assumed to flow without decomposition), respectively, and the relations

$$R_f = \bar{V}_s/V,\ R_f{}^m = \bar{V}_s/A_mt,\ R_f{}^s = \bar{V}_s/A_st$$

express the relative elution rates of solution and micelle, and mean relative elution rate of monomer molecule, respectively.

Substituting V, A_s, and A_m in Eq. (7) by R_f's, we obtain

$$\frac{R_f{}^m-R_f{}^s}{R_f{}^s}\cdot\frac{R_f}{R_f{}^m-R_f} = \frac{C}{C_m\alpha} - \frac{1-\alpha}{\alpha} \tag{8}$$

Eq. (8) predicts a linear relationship between $\frac{R_f{}^m-R_f{}^s}{R_f{}^s}\cdot\frac{R_f}{R_f{}^m-R_f}$ and C above CMC, from which α and C_m can be calculated. Below CMC we can also express the R_f term in a form similar to Eq. (8) for comparison:

$$\frac{R_f{}^m-R_f{}^s}{R_f{}^s}\cdot\frac{R_f}{R_f{}^m-R_f} = \frac{R_f{}^m-R_f{}^s}{R_f{}^s}\cdot\frac{R_f{}^s}{R_f{}^m-R_f{}^s} \fallingdotseq 1 \tag{9}$$

To verify Eqs. (8) and (9), $\frac{R_f{}^m-R_f{}^s}{R_f{}^s}\cdot\frac{R_f}{R_f{}^m-R_f}$ was plotted against C, using the observed data of $R_f{}^m(C)$, $R_f(C)$, and $R_f{}^s$ (Fig. 7).

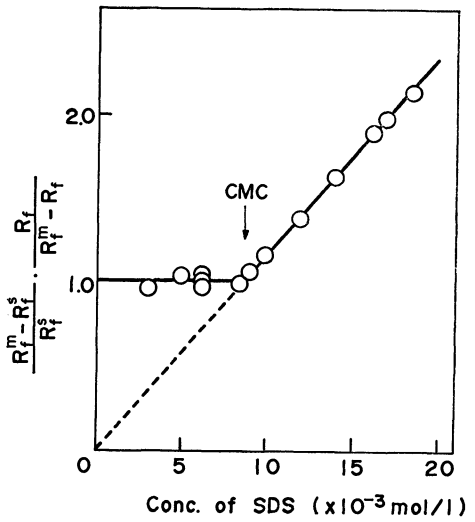

Fig. 7. Concentration dependence of R_f.

We see two straight lines corresponding to Eqs. (8) and (9) with a sharp break point between them which again gives the CMC of SDS. The fact that the plots corresponding to Eq. (8) show a straight line which passes through the origin ($\alpha=1$) indicates the constancy of the intermicellar concentration and a rapid equilibrium between micelles and monomer molecules, at least under the present conditions of the experiment. The value of CMC obtained from the break point was 8.6×10^{-3} mol/l, and the same value was obtained from the inclination of Eq. (8). These values are compared with similar values in literature.[7]

In the above study, the elution volume of SDS monomer molecule was used in place of V_0, the elution volume of solvent water or such a simple substance as sodium chloride. This may be justified since the molecular weight of SDS (about 500) is well below the lower limit of the fractionation range of Sephadex

Table 1. Gel chromatography of SDS and NaCl on sephadex gel

G-50. In a separate experiment, however, the elution volumes of urea, NaCl, and dodecylpyridinium bromide have been measured under the same conditions as for SDS. The retention volumes for urea and NaCl found were 29.1 m*l* and 28.8 m*l*, respectively, while the retention volumes of SDS and dodecylpyridinium bromide obtained were 31.0 m*l* and 30.9 m*l*, respectively, the latter two being slightly but distinctly larger. This presents another problem since an elution volume not larger than 28.8 m*l* is expected for SDS. Various factors can be pointed out to explain the anomalies, such as adsorption of SDS by the gel matrix,[8] swelling or syneresis of the gel by SDS or NaCl respectively, so-called ion exclusion effect,[9] and the effect due to the amphipathic nature of the internal surface of gel matrix.[10] In the present study, however, the effect of adsorption need not be considered since in the measurements above CMC the elution of the solution was made into the gel previously equilibrated with the solution of the same concentration. Elution of the solutions below CMC was also carried out under similar conditions and the possibility of adsorption was also confirmed to be excluded. In order to confirm the effects, if any, of syneresis and swelling, elution volumes of aqueous NaCl and SDS solutions into the gels previously equilibrated with SDS and NaCl, respectively, were measured for comparison with the untreated gels as shown in Table 1. However, the elution volumes were not affected by this gel-treatment. Thus these factors are considered to be insignificant. The possibility of ion exclusion effect which had been expected was also excluded, since the elution volume was independent of the concentration of the electrolyte in the present study. Further study is required concerning the effect of amphipathic nature of the gel matrix as a cause of the anomalies.[10] It may be inferred further that the micelles are uniform in size, since the conductance rise in the elution curve indicating the micellar front is as sharp as that for single ions below CMC.

Electron Spin-Spin Interaction in the Multiplet Ground State of Non-planar Methylene Derivatives

Jiro HIGUCHI

Department of Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

(Received March 20, 1971)

The effect of deviation from the planar structure in electron spin-spin interaction has been semiempirically investigated for spin multiplet ground state of radicals with methylene bonds. If these bonds are not coplanar, a significant influence occasionally appears on the values of D and E, while the influence is very small if the relative orientation among the methylene bonds still does not change.

In previous papers,[1-3] the electron spin-spin interaction of the methylene derivatives was investigated by assuming coplanar methylene bonds with the central benzene ring. From the non-planar structure of the benzophenone molecule (the dihedral angle between the plane of the carbonyl bond [C–(C=O)–C] and that of the phenyl group (α) is 30°, and the bond angle at the carbonyl carbon atom (θ) is 122°),[4] the above assumption does not seem always adequate for higher molecular spin multiplet radicals with several phenyl groups. In the present paper, a semiquantitative study will be reported on the relation between the electron spin-spin interaction and the molecular structure, especially concerning the influence on the deviation from the planar structure.

The ratio of E/D is used for a measure which can be compared with the observed value, since this ratio may be largely affected by the molecular structure but subject to minor influence on the spin density at the methylene carbon –C–. The values of D and E were evaluated according to the formulas

$$D = \left(\frac{3e^2\hbar^2}{4m^2c^2}\right)\frac{2!(2S-2)!}{(2S)}\sum_{i,j}\left\langle \phi_i(1)\phi_j(2) - \phi_j(1)\phi_i(2)\left|\frac{r_{12}^2-3z_{12}^2}{r_{12}^5}\right|\phi_i(1)\phi_j(2)\right\rangle \quad (1)$$

and

$$E = \left(\frac{3e^2\hbar^2}{4m^2c^2}\right)\frac{2!(2S-2)!}{(2S)!}\sum_{i,j}\left\langle \phi_i(1)\phi_j(2) - \phi_j(1)\phi_i(2)\left|\frac{y_{12}^2-x_{12}^2}{r_{12}^5}\right|\phi_i(1)\phi_j(2)\right\rangle \quad (2)$$

where ϕ_i's are the unpaired orbitals. Details of the

calculation are the same as those in previous papers.[5]

Radicals with Only One Methylene Bond

Diphenylmethylene $(C_6H_5)_2C$ is taken as the simplest example of non-planar triplet radicals with only one methylene bond assuming the symmetry of C_2. In this case, the unpaired orbitals may be expressed as

$$\phi_1 = (4-6\sin^2\alpha\cos\theta)^{-1/2}[2\chi_{l0}-\sin\alpha\,(-\cos\theta)^{1/2} \times(\chi_2-\chi_4+\chi_6-\chi_{2'}+\chi_{4'}-\chi_{6'})] \quad (3)$$

and

$$\phi_2 = (4+6\cos^2\alpha)^{-1/2} \times[2\chi_{\pi 0}-\cos\alpha(\chi_2-\chi_4+\chi_6+\chi_{2'}-\chi_{4'}+\chi_{6'})]. \quad (4)$$

Here, θ and α are, respectively, the –C– bond angle and the dihedral angle between the plane of the –C– bond and that of the phenyl group, χ_{l0} is the s–p hybridized orbital of the –C– atom (0):

$$\chi_{l0} = [(1+\cos\theta)/(1-\cos\theta)]^{1/2}\chi_{2s0} + [-2\cos\theta/(1-\cos\theta)]^{1/2}\chi_{2px0} \quad (5)$$

(x is the symmetry axis of the molecule),

$\chi_{\pi 0}$ is the p orbital of the –C– atom which is perpendicular to the –C– bond plane, and χ_i's ($i\neq 0$) are the p orbitals of atom C_i's which are perpendicular to the phenyl plane concerned.

Figure 1 shows the calculated D and E values of diphenylmethylene as a function of the –C– bond angle (θ) assuming the planar structure ($\alpha=0°$) and the structure with the two phenyl groups to be perpendicular to the plane of the –C– bond ($\alpha=90°$). Similar calculations were carried out at various dihedral angles of α. The deviation of D and E values from those of the planar structure with the same –C– angle is fairly small at angles of α within 60°. In these calculations, we obtain various sets of angles, θ and α, where the ratio of E/D coincides with the observed value of 0.04735 [$D/\boldsymbol{hc}=\pm 0.40505\ \mathrm{cm}^{-1}$, $E/\boldsymbol{hc}=\pm 0.01918\ \mathrm{cm}^{-1}$][6] as shown in Fig. 2. As a result, the probable –C– bond angles are found over a range between 144° and 150°. It should be noted here that the electron spin resonance experiment of diphenylmethylene by Brandon *et al.*[6] was carried out using a host crystal of benzophenone molecule. From the dihedral angle of $\alpha=30°$ in the host molecule with $\theta=122°$, the value of α in the diphenylmethylene might be slightly smaller than 30°, since the steric

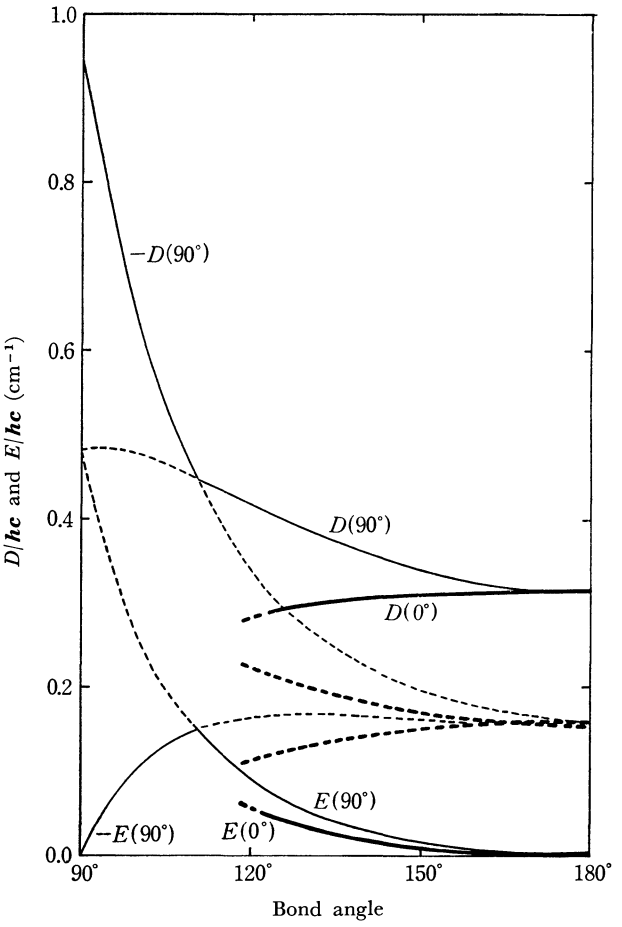

Fig. 1. D and E values of diphenylmethylene with planar structure ($\alpha=0°$) (bold lines) and that with the two phenyl groups perpendicular to the plane of the –C– bond ($\alpha=90°$) (fine lines). For large (small) –C– bond angles, the principal axes of fine-structure tensor [or Eqs. (1) and (2)] are as follows: the x axis is the symmetry axis of the molecule, the y (z) axis is perpendicular to the plane of the –C– bond, and the z (y) axis is perpendicular to the other axis. Fine dotted lines are the extensions in the case of $\alpha=90°$. Bold dotted lines correspond to the case where the z axis in Eq. (1) is taken to be perpendicular to the molecular plane ($\alpha=0°$).

hindrance is expected to be smaller than that of the benzophenone because of its larger θ value. In view of these facts, the most probable –C– bond angle can be estimated to be 145°±1° as in the phenylmethylene (see Appendix). In this case, the influence of non-planar structure does not appear remarkably, although the D and E values increase with increasing dihedral angle of α. This is apparently due to the fact that the terms with α almost cancel each other in the ratio of E/D, since the atomic contribution in D is approximatley proportional to that of E. Similarly, the influence of non-planar structure on the ratio of E/D is expected to be very small for other triplet radicals with only one methylene bond, because of the slight change of their atomic term which has a large contribution to the energy. This is similar to the case of *m*-phenylene-*bis*-phenylmethylene where the change in the orientation of only the side phenyl groups does not significantly affect the relative values of D and E[3].

5) The one-center integrals were those calculated from the self-consistent field atomic orbitals. The two-center integrals were approximately evaluated as follows: the 2*s* electron was replaced by a unit point charge at the nucleus, the 2*p* electron was two half-unit charges located to give the same quadrupole moment, and the atomic dipole effect was added. All the C–C distances were taken to be 1.393 Å as in benzene molecule. Simple LCAO-MO's were used for the π-orbitals. The unpaired σ orbitals were assumed to be hybridized ones located at each –C– atom and directed along the bisector of the –C– bond angle. For the sake of simplicity, configuration interaction was disregarded. [Refs. 2 and 3].

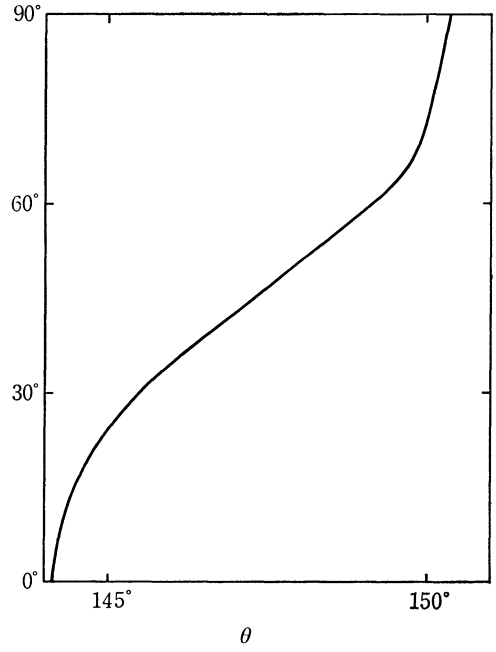

Fig. 2. The -C- bond angle (θ) and the dihedral angle between the plane of the -C- bond and that of the phenyl groups (α) in the diphenylmethylene with the structure where E/D coincides with the experimental value.

Radicals with Several Methylene Bonds

For spin multiplet radicals with more than one methylene bond such as *m*-phenylene-dimethylene, the approximation of the planar structure might not always be adequate for discussing the spin-spin interaction, since the relative orientation of these bonds is expected to have a great influence on the ratio of E/D. In the spin quintet radicals with coplanar methylene bonds, the bond angular dependence of D and E does not differ much between the calculation with all the spin-spin interactions and that with only the atomic contribution.[7] This means that approximation without interatomic interactions might be used for knowing the general tendency of *m*-phenylene-dimethylene radicals, because the main contribution of the D and the E values is due to the atomic term. In view of these facts, a simplified calculation of the D and the E values for only the atomic contribution is carried out by changing dihedral angles between the plane of the central phenylene group and that of each side methylene bond. Hereafter, such angles are denoted by α_1 and α_2, corresponding to the methylene bond with C_7 and that with C_8, respectively. (Fig. 3).

The result obtained for *m*-phenylene-dimethylene shows that the relative orientation of two methylene bonds has a significant influence on the D and E values. In some sets of the –C– bond angles, all the possible values of $|E|/|D|$ appear by changing α_1 and α_2 [*e.g.* in the case of $\theta_1=\theta_2=210°$, the $|E|/|D|$ changes from 0 to 1/3 by varying α_i ($\alpha_1=\alpha_2$) from 0° to 60°]. In such cases, one cannot estimate the –C– bond angles from only the absolute value of E/D, although the possibility of α_i values larger than 45° may be very small. On the other hand, it is not always very easy to calculate the D and E values which can be compared with the experimental values in a quantitative sense. A similar result is obtained for the septet ground state of 1,3,5-$C_6H_3(CX)_3$ without a C_3 axis.

As an example, Figs. 4 and 5 show the ratio of $|E|/|D|$ thus obtained for *m*-phenylene-dimethylene at the dihedral angles of $\alpha_1=30°$ and $\alpha_2=\pm30°$ in the cases of $\theta_1=\theta_2$ and $\theta_1+\theta_2=360°$, respectively. Such dihedral angles might have probable values when the host crystal used is the benzophenone (with $\alpha=30°$). We see that the uncertainty of the –C– bond angles due to the change of $\Delta\alpha_i=\pm30°$ is larger than 10° for some values of E/D. For *m*-phenylene-*bis*-phenylmethylene and *m*-phenylene-*bis*-methylene, however, the direction of principal axes in the fine-structure tensor [or those in Eqs. (1) and (2)] differ from those of the cases where all the possible values

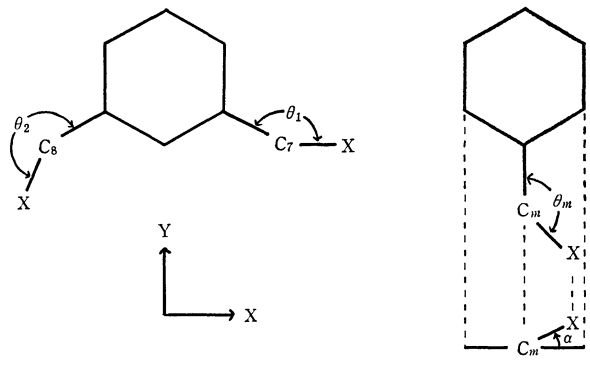

Fig. 3. Coordinate system (right-handed system), the methylene bond angles (θ_i's), and the dihedral angles between the central phenylene group and that of a side methylene bond (α_i's) in *m*-$C_6H_4(CX)_2$.

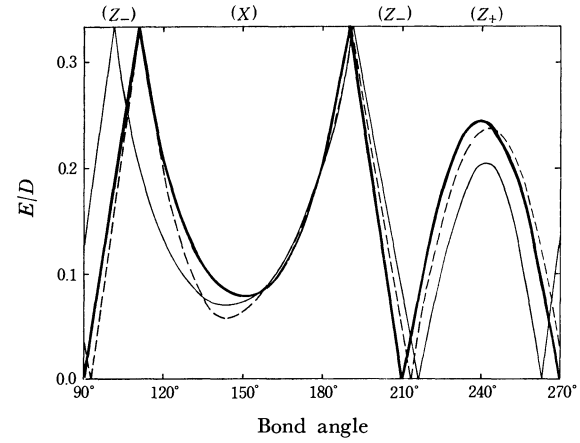

Fig. 4. The ratio of E/D of *m*-$C_6H_4(CX)_2$ calculated with only the intratomic interaction with $\theta_1=\theta_2$ in the cases of $\alpha_1=\alpha_2=0°$ (bold full line), $\alpha_1=\alpha_2=30°$ (fine full line), and $\alpha_1=-\alpha_2=30°$ (fine broken line). The letters X, Z_+, and Z_- on the top of the figure imply that the set of axes (x, y, z) in Eqs. (1) and (2) should take the sets of directions, respectively, (Y, Z, X), (X, Y, Z), and (Y, X, Z) shown in Fig. 3.

7) For example, compare Figs. 4 and 5 of Ref. 3 with the bold lines in Figs. 4 and 5 of this paper.

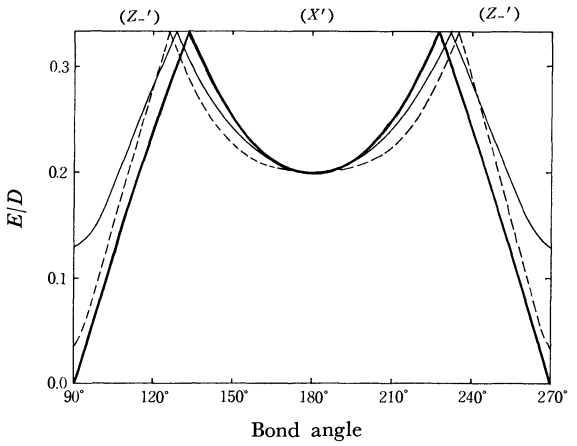

Fig. 5. The ratio of E/D of m-$C_6H_4(CX)_2$ calculated with only the intratomic interaction when $\theta_1+\theta_2=360°$ in the cases of $\alpha_1=\alpha_2=0°$ (bold full line), $\alpha_1=\alpha_2=30°$ (fine full line), and $\alpha_1=-\alpha_2=30°$ (fine broken line). The letters X' and Z_-' on the top of the figure imply that the set of axes (x, y, z) in Eqs. (1) and (2) are close to the sets of directions, (Y, Z, X) and (Y, X, Z) respectively, shown in Fig. 3. In the case of $\alpha_1=\alpha_2=0°$, the z axis ($\theta_1\geq 129°$) or the x axis ($\theta_1<129°$) makes angle of $90°-\theta_1/2$ counterclockwise with the X axis in Fig. 3.

of $|E|/|D|$ appear by changing α_1 and α_2 under the conditions of $|D|\geq 3|E|$ and $E/D\geq 0$. In these cases, the uncertainty is not large near the observed ratio of E/D ($\simeq 0.275$) [*i.e.* $\theta_1=\theta_2\simeq 185°$ and $\theta_1\simeq 140°$, $\theta_2\simeq 220°$]. This might show that the conclusion obtained in the previous work[3] on the spin quintet radicals is fairly reasonable. In general, however, one should take the influence of the relative orientation among methylene bonds into consideration for discussing the electron spin-spin interaction in molecular multiplets with several methylene bonds.

Some Remarks

Recently, Bernheim *et al.*[8] reported values of D and E for the methylene radical (CH_2) in matrix [$|D|/\boldsymbol{hc}=0.69$ cm^{-1}, $|E|/\boldsymbol{hc}=0.003$ cm^{-1}]. A similar result was also obtained by Wasserman *et al.*[9] If the present procedure is applied to these values, the –C– bond angle may be near 170° which is much larger than the estimated values of the triplet ground states of phenylmethylene and diphenylmethylene ($\sim$145°) and the quintet ground states of *m*-phenylene-*bis*-methylene and *m*-phenylene-*bis*-phenylmethylene ($\sim$140°). Wasserman *et al.*[9] showed that if the effect of the partial rotation in the matrix is included the –C– bond angle is 136° which is fairly close to that of these radicals. Further, they reported that the D and especially the E value considerably decrease by such a partial rotation and that the extrapolated $D/\boldsymbol{hc}$ value yields 0.93 cm^{-1} for an immobile methylene radicals. These evidences do not contradict the results we obtained, and suggest the necessity of further investigations of spin multiplet radicals with methylene bonds.

Most of the numerical calculations were carried out on HITAC 5020E at the Computer Centre, The University of Tokyo.

Appendix

Spin-Spin Interaction in Phenylmethylene. There were some numerical errors in the calculation of planar phenylmethylene in a previous paper.[2] The revised result given herewith is closely connected with the present work on diphenylmethylene. As can be seen in Fig. 6, the general

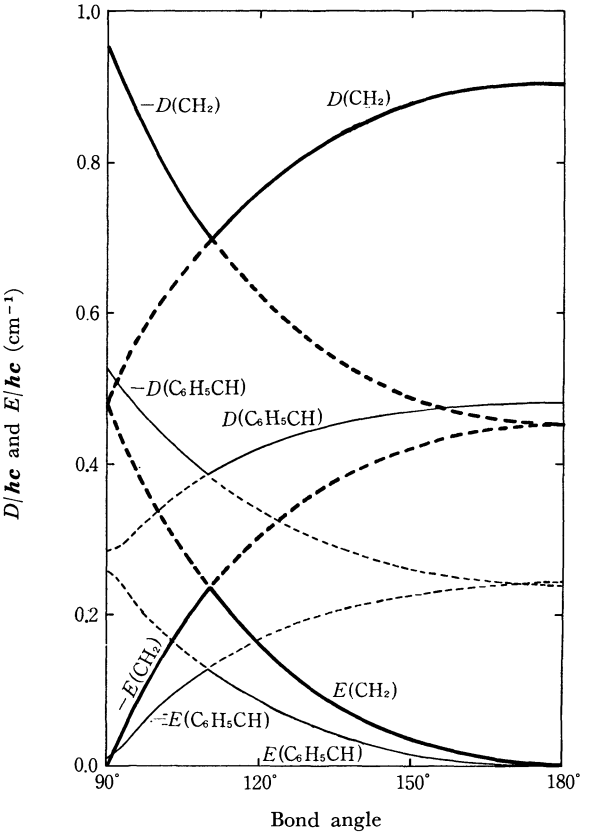

Fig. 6. D and E values of methylene (bold lines) and of phenylmethylene (fine lines). For large (small) –C– bond angles, the y (z) axis of fine-structure tensor [or Eqs. (1) and (2)] is perpendicular to the molecular plane. Dotted lines show their extensions [the revised figure of Fig. 1 in Ref. 2].

tendency of the angular dependence of D and E values does not differ much from the previous result. However, the most possible –C– bond angle is obtained near $\theta=145°$ where the calculated E/D value coincides with the observed ratio of $|E|/|D|=0.046$.[10] For large (small) –C– bond angles, the principal axes of fine-structure tensor [or those in Eqs. (1) and (2)] are as follows: the x axis is closely directed to the bisector of the –C– bond angle, the y (z) axis is perpendicular to the molecular plane, and the z (y) axis is perpendicular to the other axes. The deviation from the z (y) axis from the symmetry axis of the carbon skeleton in the phenylmethylene is given in Table 1.

Molecular Structure and Phase-shift of Tetramethyllead as Studied by Gas Electron Diffraction

Takeo OYAMADA*, Takao IIJIMA, and Masao KIMURA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received March 25, 1971)

The molecular structure of tetramethyllead has been determined by the sector-microphotometer method of gas-phase electron diffraction. The structure parameters determined by a least-squares analysis on molecular intensities are, with estimated limits of error, as follows; r_g(Pb–C)=2.238±0.009 Å, r_g(Pb···H)=2.72±0.06 Å, r_g(C···C)=3.66±0.07 Å, and r_g(C–H)=1.08±0.02 Å. The experimental cut-off point was nearly 37 in q value for the 42.0 keV electrons; this was not in sufficient agreement with the theoretical value as calculated from the Thomas-Fermi-Dirac potential for Pb and from the Hartree-Fock potential for C. Moreover, the experimental background showed a significant deviation from its theoretical counterpart in the region of small q values. This discrepancy has not been accounted for even by the use of scattering factors based on a relativistic SCF calculation, or by the correction for the polarization effect available at present.

The electron diffraction study of tetramethyllead (abbreviated to TML) was previously carried out by Wong and Schomaker[1] by use of the visual technique. They pointed out that the use of the complex atomic scattering factors of Ibers and Hoerni,[2] instead of the first Born scattering factors, was essential to the interpretation of the electron-diffraction pattern of TML, which contains both heavy (Pb) and light (C, H) atoms. The effect of the phase-angle difference of the atomic scattering factors, occasionally called the phase-shift, had already been elucidated by Schomaker and Glauber.[3] Wong and Schomaker attempted the first experimental test of the then newly-calculated table of Ibers and Hoerni. They determined the molecular structure of TML to be r(Pb–C)=2.20_3±0.01_0 Å and r(Pb–H)=2.79±0.01 Å. The first cut-off point was determined as q^c_{Pb-C}=38.5±1.5 for the 39.7 keV electrons; they remarked that this was slightly larger than the theoretical value 35.8 obtained from the table of Ibers and Hoerni, which was based on the Thomas-Fermi potential. When the present study was initiated, it was anticipated that the use of the phase angles calculated by the Thomas-Fermi-Dirac (TFD) potential instead of by the Thomas-Fermi potential would improve the consistency between the experimental and theoretical cut-off points. Thus, the present investigation has the purpose of performing a more quantitative examination of the phase-effect as well as making a more precise determination of the structure parameters, which became possible by the use of a modern diffraction unit and by means of the microphotometric processing of the photographic plates.

Experimental

The sample of TML was kindly supplied by Mr. Y. Fujiwara of the Central Technical Research Laboratory, Nippon Oil Co., Ltd., in the form of toluene blend. (Blending with toluene is necessary in order to stabilize the TML. The rate of the blending of TML and toluene was about 2 to 3). The separation of toluene (mp −95°C) from TML was achieved by utilizing the higher melting point of TML (mp −30°C) as follows. In order to protect TML from oxidation by air, the blend was placed in a flask purged with a flow of dry nitrogen gas. It was then slowly cooled in a dry ice-acetone bath under gentle stirring in order to avoid rapid crystallization. This cooling process was continued for about three hours until nearly two-thirds of the total content had solidified. Then the liquid part (toluene) was removed by decantation. This process of separation was repeated three times. The sample thus obtained was then assumed to have sufficient purity, since it has been reported that a series of several freezings and decantations raises the purity of TML to above 99%.[4]

The separated TML was transferred into a glass sample holder in a dry box filled with nitrogen gas. The whole

procedure of separation and purification was carried out just before taking photographs. Since TML is a strong toxicant, full caution was used during the experimental procedures by following the advice in the Manual prepared by Ethyl Corporation.

Diffraction patterns were taken by means of a unit reported elsewhere,[5] with an r^3-sector at the camera length of 24.43 cm. The experimental conditions were as follows; accelerating voltage, ~42.0 kV; sample pressure, ~17.5 Torr; exposure time, 40~50 sec; electron-beam current, ~0.2 μA; and room temperature, 18°C. In order to make the calibration of the accelerating voltage, the diffraction patterns of carbon disulfide were taken just before taking those of the sample in the same sequence of exposures.

The optical densities of the diffraction photagraphs were measured by means of a double-beam microphotometer connected to an integral digital voltmeter. The data covered the range of $q=12$—62.

Analysis

The optical densities (0.25—0.50) were converted to the total intensities by assuming the proportionality between density and electron intensity. After the correction for the imperfection of the sector shape had been applied, the total intensities were interpolated at integral q values by Lagrange's method of three-point interpolation and were leveled by the theoretical background function. The experimental backgrounds and molecular intensities were determined by the calculation of the radial distribution curve and its inverse Fourier trans formation in the range of $r \leqq 0.8$ Å. In the calculation of the radial distribution curves, Bartell's correction for non-nuclear scattering[6] was modified in order to avoid difficulty arising from the large phase-angle difference. The method follows that of our previous paper.[7] The factors $\chi_{tj}=\mu_{tj}\cos\Delta\eta_{tj}$ were replaced by the following approximate functions:

$$\chi_{Pb,C} = 1.527 \cos\left\{0.1251\left(\frac{\pi}{10}q\right)\right\}$$

$$\chi_{Pb,H} = 1.933 \cos\left\{0.1488\left(\frac{\pi}{10}q\right)\right\}$$

$$\chi_{C,C} = 4.247 \exp\left\{-0.0143\left(\frac{\pi}{10}q\right)^2\right\}$$

$$\chi_{C,H} = 6.302 \exp\left\{-0.0135\left(\frac{\pi}{10}q\right)^2\right\}$$

$$\chi_{H,H} = 8.569 \exp\left\{-0.0133\left(\frac{\pi}{10}q\right)^2\right\}$$

The b value in the damping factor $\exp(-bq^2)$ was taken to be 0.00065.

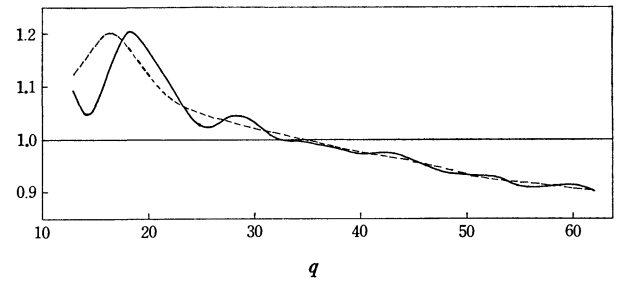

Fig. 1. Total intensity and experimental background of TML leveled by the theoretical background based on the TFD potential for Pb.

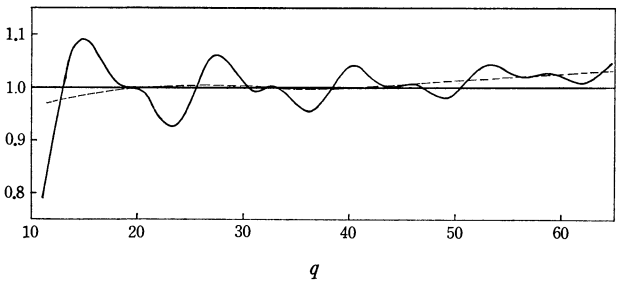

Fig. 2. Total intensity and experimental background of carbon disulfide leveled by the theoretical background.

One of the leveled total intensities and its background thus obtained are shown in Fig. 1 for TML[8] and in Fig. 2 for carbon disulfide, the reference molecule. The theoretical backgrounds were calculated by the use of elastic and inelastic scattering factors taken from the literature.[9-11] As is shown in Fig. 1, the background of TML rises sharply in the region of q values less than 19; this tendency is different from that of the theoretical value, which is a straight horizontal line at 1.00. On the other hand, the background of carbon disulfide, shown in Fig. 2, is not so different from its theoretical counterpart, except for the tailing up at large q values. This discrepancy in the background will be discussed in the next section.

The experimental molecular intensities obtained from the three best plates were analysed by the standard least-squares method.[12] The theoretical molecular intensity was calculated by the following equation, in which the notations have the usual significance:

$$qM(q) = k\sum_{ij}{}' A_{tj}\mu_{tj}\cos\Delta\eta_{tj}\exp\left\{-\frac{1}{2}\left(\frac{\pi}{10}q\right)^2 l_{tj}^2\right\} \times \sin\left[\frac{\pi}{10}q\left\{r_{atj}-\left(\frac{\pi}{10}q\right)^2\kappa_{tj}\right\}\right]$$

The index of resolution k, the distance r_a and the mean amplitude l were determined by the least-squares fitting of the theoretical expression to the experimental intensities. The nine parameters, the index of resolu-

tion, the distances and the mean amplitudes of Pb–C, Pb···H, C···C, and C–H atom pairs were adjusted without any constraint among them. All the non-bonded C···H and H···H pairs were ignored because of the negligibly small contribution of these terms. The asymmetry parameters κ for bonded pairs were fixed at the values estimated by the diatomic approximation:[13]

$$\kappa = \frac{1}{6}al^4\left\{1+\frac{8\varepsilon}{(1+\varepsilon)^2}\right\}, \quad \varepsilon = \exp\left(-\frac{h\nu}{kT}\right).$$

The Morse anharmonicity parameters, a, were assumed to be 1.7 Å^{-1} for the Pb–C atom pair and 2.0 Å^{-1} for the C–H atom pair.[14] The characteristic frequencies ν were taken to be 475 and 2998 cm^{-1} for Pb–C and C–H, respectively.[15] The estimated values were 49×10^{-7} Å^3 for κ_{Pb-C} and 123×10^{-7} Å^3 for κ_{C-H}. The parameters κ for the non-bonded pairs were assumed to be zero.

The results of the least-squares adjustment for the three plates were in excellent consistency with one another, as is shown in Table 1. The error matrix is shown in Table 2. The final values of the interatomic distances r_g and mean amplitudes are given in Table 3. The total limits of error were estimated by following the procedure described in previous papers.[7,16] The experimental molecular intensity and the theoretical one calculated by the best-fit parameters are shown in Figs. 3 and 4.

Table 3. Distances and mean amplitudes of TML with estimated limits of error (in Å)

	r_g	l
Pb-C	2.238±0.009	0.055±0.012
Pb···H	2.721±0.058	0.174±0.045
C···C	3.656±0.066	0.173±0.055
C—H	1.083±0.020	0.087±0.025

A remarkable result seen in Fig. 3 is that the general features of the experimental molecular intensity are rather different from those of the theoretical curve in the region of q=35—44. This was systematically reproduced in each of the molecular intensities from the three plates. The reproducibility is demonstrated by the vertical bars in Fig. 3(b). Thus, the deviation has been considered to be significant, although its amount at each observed point is roughly twice the random scattering of data observed in current studies of other molecules using the same apparatus and analytical procedure. The cut-off points for the Pb–C and Pb···H bond pairs lie in this region. However, the contributions of the Pb···H and other terms to the molecular intensity are smaller in this region than that of the Pb–C term. The theoretical value for the first cut-off point, q^c_{Pb-C}, defined by $\Delta\eta_{Pb-C}=\pi/2$ at q^c_{Pb-C}, is 39.8 for the 42.0 keV electrons, according to the calculation based on the TFD potential for Pb and the Hartree-Fock potential for C.

Discussion

Structure. The bond angles, θ(CPbC) and θ(PbCH), calculated by use of the final values of the r_g distances are 109.5°±3.6° and 104.6°±5.4° respectively. Although the θ angle does not necessarily correspond to the geometrical conformation,[17] no further refinement was attempted on account of the large uncertainties of the non-bonded distances. The obtained θ(CPbC) value merely indicates the overall consistency of the present results with the symmetry of the molecule.

Mean Amplitudes. The vibrational mean amplitudes of TML were calculated by the following two simplified models: (a) A five-atom molecule with *Td* symmetry, where the methyl group was replaced by a point of mass; (b) A five-atom molecule, $PbCH_3$, with C_{3v} symmetry. In each of these models, a simple Urey-Bradley force field was determined from the normal frequencies observed by Jackson and Nielsen.[15] For the *Td*-model, the skeletal normal modes were selected from the observed frequencies. For the C_{3v}-model, the observed frequencies were assessed by considering the correlation between *Td* and C_{3v}. If nearly equivalent frequencies were found in the A_1 and F_2 species in the original assignment by Jackson and Nielsen, an average of them was taken; it was assumed to be an A_1 mode in the local C_{3v} molecule. Similarly, those found in both E and F_2 were assessed to be E-mode frequencies in the C_{3v}-model.

The values of these *observed* frequencies and those calculated by the use of the determined force constants are listed in Table 4. The calculated values of the mean amplitudes are shown in Table 5. In spite of the above simplification, the calculated values have sufficient accuracy because of the heavy central atom in TML. By comparing Tables 5 and 3, it may be seen that the observed mean amplitudes are in fair agreement with the calculated values.

Scattering Factors and Phase-angles. It has been found that the discrepancy in the molecular intensity shown in Fig. 3 can be alleviated if the cut-off point of the Pb–C term is moved to q=37, which is indicated by a heavy bar in Fig. 3. The phase-angle η of the Pb atom was modified in such a way as to make $\Delta\eta_{Pb-C}=\pi/2$ at q=37 by simply shifting the whole η *vs.* q curve slightly upwards. As is shown in Fig. 4, the general features of the theoretical intensity as calculated from the modified phase-angles are in better agreement with those of the experimental intensity in the region of q=35—44. This suggests that the phase-angles of Pb as calculated from the TFD potential are slightly smaller than the exact values.

In Table 6 are listed the structure parameters obtained by a least-squares fitting of the theoretical expression by the use of the modified phase-angles. The r_a distances are in agreement with the previous values given in Column II within their standard deviations.

Table 6. Results of the least-squares analysis of plate 3 (r_a and l in Å)

	I[a]	II[b]
k	0.992	0.961
r_a(Pb-C)	2.2368	2.2372
r_a(Pb···H)	2.735	2.720
r_a(C···C)	3.637	3.625
r_a(C-H)	1.077	1.081
l(Pb-C)	0.068	0.055
l(Pb···H)	0.182	0.158
l(C···C)	0.171	0.180
l(C-H)	0.091	0.089

a) By use of modified phase angles (see Text).
b) Previous results by use of unmodified phase angles.

17) K. Kuchitsu, *ibid.*, **44**, 96 (1971).

The mean amplitudes are slightly larger, but they are consistent within the total limits of error.

In the hope of accounting for the discrepancy in the background and the cut-off point, the scattering factors based on the relativistic SCF calculation and the correction for the polarization effect were employed. The background of TML was calculated by the use of the relativistic scattering factor for Pb, which was computed by Schäffer, Yates, and Bonham[18] from Liberman's Dirac-Slater atomic potentials. The phase-angles η taken from their table are graphically shown in Fig. 5. The background is shown in Fig. 6. The original values for the 40 keV electrons were converted to those for 42 keV by assuming that the $|f|$ and η curves, regarded as functions of the scattering angle, show no significant difference between 40 and 42 keV. Therefore, only the scaling of abscissa was corrected for the voltage difference in getting the $|f|$ and η *vs.* q curves for 42 keV. The validity of this assumption was confirmed by comparing the TFD scattering factors for 40 and 42 keV.

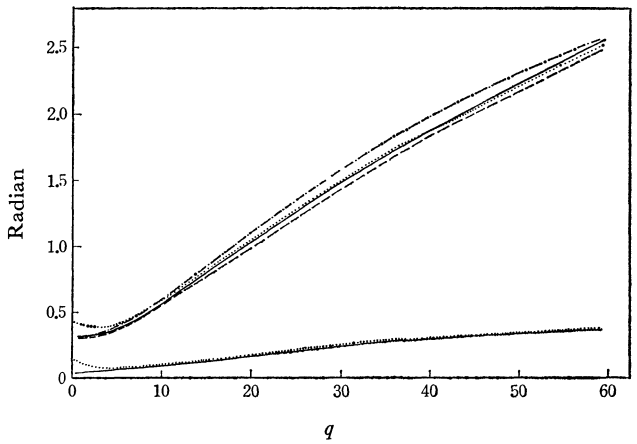

Fig. 5. Comparison of phase-angles; —— TFD for Pb and Hartree-Fock for C, ····· TFD corrected for the polarization effect for Pb and Hartree-Fock corrected for the polarization effect for C, ---- Dirac-Slater for Pb, —·—· modified phase-angle for Pb.

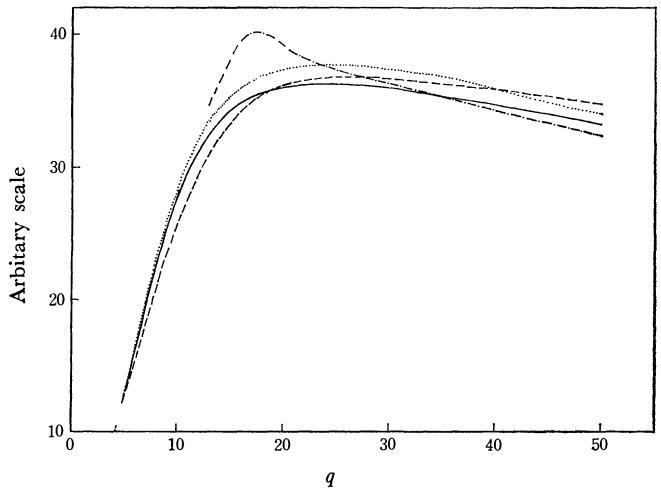

Fig. 6. Comparison of the background functions of TML. The elastic scattering factor of Pb is based on the atomic potential of TFD (——), TFD corrected for the polarization (·····), and Dirac-Slater (----). The observed background normalized to TFD at $q=35$ is shown by (—·—·).

18) L. Schäffer, A. C. Yates, and R. A. Bonham, *J. Chem. Phys.* to be published.

The correction for the polarization effect was computed by a program kindly offered by Professor Bonham.[19] As the numerical parameters for the computation, the following values of the total inelastic scattering cross sections σ_{inel} were employed, namely, $\sigma_{inel}(\mathrm{Pb})=0.2684$ Å^2 and $\sigma_{inel}(\mathrm{C})=0.0531$ Å^2. By this program, the corrections for the real part ΔR^{pol} and the imaginary part ΔIm^{pol} due to the polarization effect were computed. For the Pb atom, these values were added to the real part R^{TFD} and the imaginary part Im^{TFD} of the TFD scattering factors, and the magnitude $|f|$ and the phase angle η of the corrected scattering factors were obtained by:

$$|f| = \{(R^{\mathrm{TFD}}+\Delta R^{\mathrm{pol}})^2 + (Im^{\mathrm{TFD}}+\Delta Im^{\mathrm{pol}})^2\}^{1/2}$$

$$\eta = \tan^{-1}\{Im^{\mathrm{TFD}}+\Delta Im^{\mathrm{pol}})/(R^{\mathrm{TFD}}+\Delta R^{\mathrm{pol}})\}.$$

For the C atom, the same procedure was applied to the Hartree-Fock scattering factors.

The phase-angles and the backgrounds are compared in Figs. 5 and 6. It can be seen from these figures that the theoretical improvement by the use of relativistic scattering factors and the polarization correction is too small to account for the experimental results. The deviation in the background is too large in amount and opposite in direction to be interpreted in terms of the effect of chemical-bond formation.[20] In the diffraction studies of $HgCl_2$[21] and $BiCl_3$[22], however, the experimental results showed no discrepancy from the TFD-based theoretical values in either the cut-off points or the backgrounds. Thus, the possibility that this discrepancy is common in heavy atoms seems to have been excluded. Should the discrepancy observed in the present study be in fact real, then it must presumably be due to something specific to the lead atom. A future investigation of this matter in both experimental and theoretical aspects is to be hoped for.

The authors wish to thank Mr. Yasuo Fujiwara of Central Technical Research Laboratory, Nippon Oil Co., Ltd. for his kind supply of the sample and information on safe handling of the material. They also thank Professor Russell A. Bonham, Indiana University, for his allowing them to use his program and numerical results before publication. The authors are indebted to Dr. Shigehiro Konaka for his helpful discussions, Mr. Koji Igarashi for his help in the early stage of this work and Miss H. Hayasaka for her typing the manuscript. Numerical computations were performed on a FACOM 230—60 of the Hokkaido University Computing Center and also on a FACOM 270—20 of Professor Kimio Ohno's laboratory, Hokkaido University, to whom the authors' thanks are also due.

Molecular Structure of Dimethyltin Dichloride as Studied by Gas-electron Diffraction

Hideji Fujii[1] and Masao Kimura

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received March 25, 1971)

The molecular structure of dimethyltin dichloride was determined by the sector-microphotometer method of electron diffraction to be as follows: r_g(Sn-Cl)=2.327±0.003 Å, r_g(Sn-C)=2.108±0.007 Å, and r_g(C-H)=1.113±0.020 Å, and all the valency angles were near 109.5°. In comparison with the Sn-Cl distances in the series of $Sn(CH_3)_{4-n}Cl_n$, as determined previously by the same method, a regular bond contraction in going from $Sn(CH_3)_3Cl$ to $SnCl_4$, as pointed out previously by Skinner and Sutton, was ascertained.

Many structural studies have recently been published of a series of molecules, $Sn(CH_3)_{4-n}Cl_n$(n=0, 1, 2, 3, 4), by various experimental techniques, *e.g.*, dipole moment measurements,[2,3] NMR,[2,4] Mössbauer effects,[5] NQR,[6] X-ray crystal analysis,[7] and studies of the vibrational spectra[8-11] and electron diffraction.[12-14] In these studies, relations between bond lengths and other physical quantities have often been discussed.

As for the interatomic distances in these molecules in the gaseous state, Skinner and Sutton once determined tin-chlorine bond lengths by the visual method and found that the magnitude of bond contraction from the sum of the covalent radii increased with an increase in the number of halogen atoms.[12] However, these data involve large uncertainties inherent in the visual method and may even be incorrect owing to the ignorance of phase differences between Sn and Cl, and Sn and C, atoms.[15]

In order to get a more profound insight into the molecular structures of this series of molecules, it is essential to have more precise, up-to-date information regarding the bond lengths in free molecules. Recently, the present authors have determined the Sn-Cl bond length in $SnCl_4$ to be 2.281±0.004 Å,[13] a value which was 0.03 Å shorter than the value determined by the visual method.[14] In the present paper we will report on the bond lengths of dimethyltin dichloride as determined by the sector-microphotometer method.

Experimental

A pure sample of dimethyltin dichloride (mp 108°C) was kindly provided by Professor Toshio Tanaka of the Osaka University. Photographs were taken by the apparatus in our laboratory equipped with an r^3-sector[16] and a high-temperature nozzle[17] at two camera lengths, 258.90 cm (long camera length) and 123.90 cm (short camera length). The accelerating voltage was about 42.25 kV. The sample was sublimed by maintaining the nozzle temperature at 85—88°C. The scale factors were determined by reference to the diffraction patterns of carbon disulfide taken under the same experimental conditions.[13] The photographs were recorded on Fuji Process Hard Plates with exposure times of 40 to 70 sec and a beam current of 0.3 μA, and were developed at 20°C for 5 min with a FD-131 developer diluted twice. Seven plates from the long camera length and four plates from the short camera length were selected, and their optical densities were measured as reported previously;[13] the observed points covered the range of q=8—60 and q=25—110 for the respective camera lengths. Because of the damping effects due to intramolecular vibrations and the phase differences of scattered beams from the Sn, Cl, and C atoms, the molecular scattering in a range of q beyond about 80 falls in amplitude down to the order of random fluctuations of the observed total intensities. Therefore, the structure parameters were determined by employing the optical densities of the plates from the long camera length.

Analysis and Results

The reductions of the molecular intensities, $qM(q)^{exptl}$, were done following the method described in our previous paper, unless otherwise stated.[13] The experimental leveled intensity, I_T, and the experimental background, I_B, curve, the $qM(q)^{exptl}$ and the difference curve of the experimental and theore-

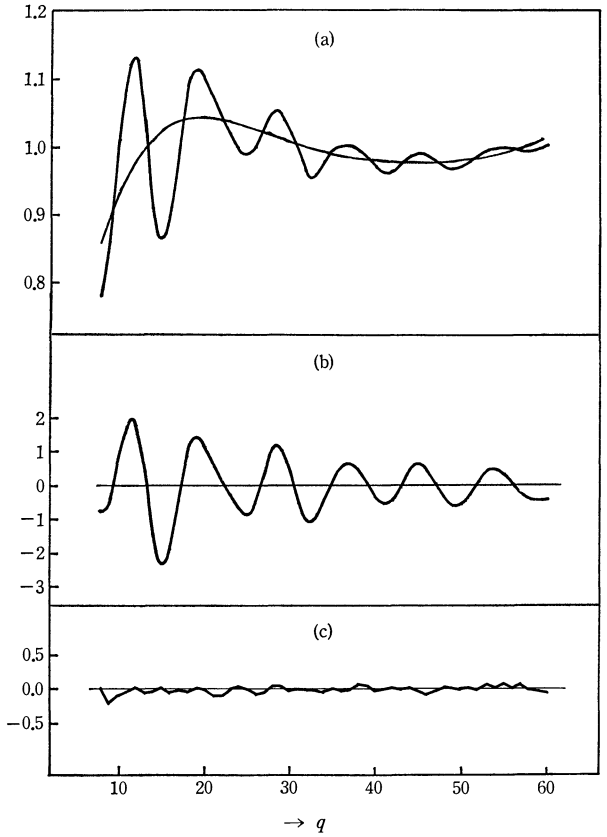

Fig. 1. (a) The experimental leveled intensity and the background curve; (b) The observed molecular intensities $qM(q)^{exptl}$; and (c) The difference curve of the experimental and theoretical molecular intensities.

tical $qM(q)$ values for an arbitrarily selected plate are shown in Figs. 1(a), (b), and (c) respectively.[18] The elastic and inelastic scattering factors used were taken from the references.[19-23]

The radial distributions, $f(r)$, were calculated by the use of the correction term for the non-nuclear scattering:[13]

$$\Delta qM(q) = \sum_{i,j}{}' A_{ij} \sin\left(\frac{\pi}{10} q r_{ij}\right) \exp(-a_{ij}q^2) \times \{\chi_{ij} - \mu_{ij} \cos(\Delta\eta_{ij})\},$$

with the following correction functions, χ_{ij}:

$$\chi_{HH} = 1.20 + 1.65 \exp(-0.00017\, q^2) + 3.1 \exp(-0.0015\, q^2),$$

$$\chi_{HC} = 1.08 + 1.10 \exp(-0.00013\, q^2) + 2.5 \exp(-0.0020\, q^2),$$

$$\chi_{HCl} = 0.20 + 2.80 \exp(-0.0002\, q^2),$$

$$\chi_{HSn} = 0.88 \cos(0.3206\, q) + 0.8 \exp(-0.0020\, q^2),$$

$$\chi_{CC} = 1.32 + 1.78 \exp(-0.0006\, q^2),$$

$$\chi_{CCl} = 0.90 + 1.40 \exp(-0.00034\, q^2)$$

$$\chi_{CSn} = 0.90 \cos(0.02523\, q) + 0.5 \exp(-0.0014\, q^2),$$

$$\chi_{ClCl} = 1.40$$

and

$$\chi_{ClSn} = \cos(0.01415\, q).$$

A trial background was revised after Karles' non-negativity criterion by the Fourier inverse transformation of the difference between the observed and calculated radial distributions, $\Delta f(r)$, below $r=1.10$ Å. In these calculations, it was assumed that the molecule has C_{2v} symmetry, that each methyl group has a three-

23) Elastic scattering factors have been calculated by Cox and Bonham on the bases of relativistic wave functions (*J. Chem. Phys.*, **47**, 2599 (1967)). As far as the Sn atom is concerned, these scattering factors are significantly larger than those used by us[19] and also by the Manchester group, and consequently, give a larger phase difference for the Sn–Cl atom pair. However, new scattering factors based upon relativistic wave functions, which are to be published by Schäffer, Yates, and Bonham in the Journal of Chemical Physics. The authors are indebted to Professor Bonham for making use of their table for a comparative purpose.

fold symmetry about the bond joining the methyl group to the Sn atom and is staggered to the opposite Sn–Cl bond, and that all the valence angles are 109.5°. On these assumptions, the molecular parameters were evaluated appropriately from the observed $f(r)$ curve and the results of the least-squares adjustments. The final $f(r)$ and $\Delta f(r)$ values obtained from the I_T's shown in Fig. 1 are depicted in Fig. 2.

The structural parameters were determined by the least-squares method applied to the observed molecular intensities with a diagonal weight matrix (Fig. 3). The asymmetry parameters, κ, for the H···H, C···H, and Cl···H pairs were set equal to zero, while the others were fixed at the following values:

κ_{CH}	122,	κ_{ClCl}	178,
κ_{SnC}	26,	κ_{ClC}	257,
κ_{SnCl}	18,	κ_{SnH}	313, (in 10^{-7} Å^3);
κ_{CC}	281,		

These values were estimated by the method applied to $SiCl_4$ by Morino and Murata.[24,25] The interatomic distances for the non-bonded H···H, C···H, Cl···H, and C···C pairs, which make very little contributions to the scattering intensity, were constrained in the r_a structure, and their mean amplitudes were fixed at values roughly estimated from those in analogous compounds. Least-squares adjustments were then performed for the thirteen parameters listed in Table 1. The fluctuations of the adjusted values during least-squares iterations were the largest for r(Cl···Cl) or l(Cl···Cl). Therefore, the iterations were terminated when the fluctuations of the adjusted r(Cl···Cl) and l(Cl···Cl) values became less than 1.5 percent and when the parameter values for the C–H, Sn–C, and Sn–Cl atom pairs converged within 10, 4, and 1×10^{-4} Å respectively.

The value for each parameter was obtained by averaging the results from the seven plates. The parameter values thus obtained and their estimated standard deviations, σ_1 and σ_2, are shown in Table 1, where the interatomic distances are given in terms of r_g and where the σ_1 and σ_2 have the same significances as in our previous paper.[13]

As may be seen in Table 1, the non-bonded interatomic distances could not be determined with satisfactory accuracy. If the valence angles are evaluated from the r_g values in Table 1, we get the values of 107.5±3.9° for ∠ClSnCl and 109.8±1.2° for ∠ClSnC; hence, they are indistinguishable from the tetrahedral angle. The most probable bonded interatomic distances and mean amplitudes are reproduced in Table 2, together with their limits of error, which include the random errors and the errors due to the uncertainty of the scale factor. The former errors were taken as 2.5 times the larger of σ_1 and σ_2, while the latter were estimated to be 0.1% of the interatomic distances.

Table 1. Results of the least-squares adjustments[a]

Calculation of the Mean-square Amplitudes

Since the low-lying fundamental frequencies and their assignments were uncertain,[8–11] the Nujol-mull spectra were measured in the region below 400 cm^{-1}. Some of them are reproduced in Table 3. Edgell and Ward[8] assigned the Raman lines at 344 cm^{-1} and 135 cm^{-1} to accidentally degenerate Sn–Cl stretching modes and skeletal bending modes respectively. However, such degeneracies seem unlikely. Taimsalu and Wood[9b] studied the effect of the environment on the vibrational frequencies of the $Sn(CH_3)_{4-n}Cl_n$ series and concluded that dimethyltin dichloride associated strongly in the solid state and that its Sn–Cl stretching frequencies shifted markedly towards the lower-frequency side. On the contrary, our solid spectra in this range displayed an intense band at 357 cm^{-1} with a shoulder near 349 cm^{-1} and broad, weak bands at 306 and 325 cm^{-1}. It seems that the strong band and its shoulder at 357 and 349 cm^{-1} are to be assigned to the Sn–Cl stretching frequencies, and that the two weak bands at the lower frequencies are overtone and combination bands. The assignment of the $SnCl_2$ deformation mode is also ambiguous. Taimsalu and Wood assigned bands at 124 cm^{-1} and 129 cm^{-1} to the bending and rocking modes respectively,[9a] whereas Butcher *et al.* assigned a band at 121 cm^{-1} to the bending mode.[10] If one follows the assignment made by Taimsalu and Wood, the observed frequencies in our spectra may be assigned as is shown in the last column of Table 3. The general

pattern of our frequencies is similar to that assigned by Clark *et al.*[11b] Although the frequencies and their assignments of the low-lying fundamental vibrations remain questionable, the mean-square amplitudes were calculated with rigid CH_3 groups and by the use of the Urey-Bradley force field. The results are listed in Table 4. It was necessary to introduce a non-zero force constant, G(SnC.SnC), in order to fit the calculated Sn-C stretching frequencies to the observed ones to the extent shown in Table 4. In spite of some uncertainties in the vibrational spectra and in spite of the approximations involved in the present calculations, the mean amplitudes thus obtained may be considered to have sufficient accuracy for comparative use. The experimental and theoretical values listed in Table 2 and 4 have similar orders of magnitude.

Table 4. The Urey-Bradley force constants, the calculated skeletal vibrational frequencies and the calculated mean amplitudes

Contraction of the Sn–Cl Bonds

Table 5 presents the molecular structures of the $Sn(CH_3)_{4-n}Cl_n$ series (n=0,1,2,3,4) as determined by electron diffraction.

It is evident in Table 5 that there is a regular contraction of Sn-Cl bond lengths from $Sn(CH_3)_3Cl$ to $SnCl_4$; that is, the magnitudes of the contractions of r(Sn-Cl) from the sum of the single-bond covalent radii, 2.39 Å, are 0.04, 0.06, 0.09, and 0.11 Å for the molecules of n=1,2,3, and 4 respectively. The values of the Sn-C distances, except for $Sn(CH_3)_4$, are equal in their marginal errors, while the Sn-C distance in $Sn(CH_3)_4$ is close to those in methyl stannanes, *e.g.*, r_g(Sn-C)=2.150±0.003 Å for $Sn(CH_3)_2H_2$ and 2.147±0.004 Å for $Sn(CH_3)_3H$.[26] The relations between the bond lengths and other physical properties for these compounds present interesting problems which will have to be solved in the future.

Table 5. The bond distances of $Sn(CH_3)_{4-n}Cl_n$ as determined by electron diffraction

Compound	Visual method			Sector-microphotometer method		
	Sn-C (Å)	Sn-Cl (Å)	Ref.	Sn-C (Å)	Sn-Cl (Å)	Ref.

A New Method of Solubility Determination of Hydrolyzing Solute — Solubility of Benzyl Chloride in Water

Ryuichiro Ohnishi and Kozo Tanabe

Research Institute for Catalysis and Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 1, 1971)

A method of determining the solubility of a solute with a considerable rate of hydrolysis and small solubility in water was devised. The method consists of measurements of the hydrolysis rate below or at saturation solubility, the rate constants and order of reaction, and analysis of kinetic data. The solubility of benzyl chloride in water was found to be 33.1 mg/100 m*l* at 4.5°C, 49.3 at 20°C, and 55.5 at 30°C. Solubility of benzal chloride and benzotrichloride was calculated to be 25 mg/100 m*l* at 30°C and 5.3 at 5°C, respectively, by utilizing the kinetic data given in literature

In a course of a study on the relative reactivity of benzyl chloride, benzal chloride and benzotrichloride,[1] it became necessary to obtain the solubility of the compounds in water. The only datum is the solubility of benzyl chloride at 30°C obtained by means of extraction with ether from the saturated aqueous solution.[2] However, since chlorine compounds having small solubility in water hydrolyze fairly fast during extraction, the extraction method does not seem to be reliable. We therefore attempted to determine the solubility by analyzing the kinetic data of hydrolysis. The rate, the rate constant, and the order of the hydrolysis reaction of benzyl chloride were measured at 4.5, 20, and 30°C and the solubility was determined by a new method. The solubility of benzal chloride and benzotrichloride determined by the same method using known kinetic data is also reported.

Principle of Kinetic Determination of Solubility

Let us express the rate V of a hydrolysis reaction by the equation

$$V = \sum_i k_i[S]^i \qquad (1)$$

where i is the order of reaction, k_i the rate constant of ith order reaction, and $[S]$ the concentration of a solute.

First, a sufficiently large amount of a solute is dissolved in water forming a liquid phase of a solute, the concentration of the solute in water being kept constant at constant temperature with the saturation solubility S_s. The rate V_s at saturation solubility can be measured keeping the solute concentration constant during the rate measurement. The rate V is then measured at various solute concentrations below saturation solubility, and k_i and i are determined from the data by the usual method. Saturation solubility S_s is now obtained from the observed V_s, k_i, and i by the following equation.

$$V_s = \sum_i k_i[S_s]^i \qquad (2)$$

The principle of this method is simple and can be applied to the solubility measurement of a solute whose solubility is so small and solvolysis rate so great that the application of usual methods is difficult. However, there are several restrictions for the measurement. 1) The solubility of a solute must be so small that the phase of the solute can exist together with the solvent phase. 2) The rate of dissolution of a solute into a solvent must be sufficiently fast in comparison with that of solvolysis. 3) The solubility or the rate of solvolysis must not be influenced by any product of solvolysis. If the influence cannot be neglected, correction of the influence should be made. 4) The rate of solvolysis in solute phase must be negligibly small compared with that in solvent phase. If not, correction should be made.

Experimental

Since benzyl chloride decomposes in water to form benzyl alcohol and hydrogen chloride,[1,2] the reaction was followed by observing the increase in proton concentration.

As soon as benzyl chloride was added to water in a glass reaction vessel equipped with a tefron-coated magnetic stirrer and placed in a water bath, the mixture was vigorously stirred in order to dissolve the benzyl chloride and start the reaction immediately. The pH change of the solution due to hydrolysis was measured with a Hitachi-Horiba M-5 type pH meter (accuracy: 0.03 pH) whose glass electrode was dipped in the solution. The temperature of the reaction mixture was maintained at 20±0.01°C, 30±0.01°C, and 4.5±0.2°C. In the measurement of V, the amount of benzyl chloride

1) K. Tanabe, *Nippon Kagaku Zasshi*, **87**, 629 (1966).

which is smaller than that of the saturation solubility was used for the reaction, while a sufficiently large amount above S_s was used for the measurement of V_s.

An approximate value of the saturation solubility necessary to undertake experiments at solute concentration below saturation solubility was obtained by the following method. A certain amount (a mg) of benzyl chloride is dissolved in a certain amount (b ml) of acetone which can dissolve both benzyl chloride and water and in which benzyl chloride does not solvolyze. Some amount (c ml) of water is then added dropwise from a burette into the solution until the solution shows white turbidity. An approximate value of the solubility in acetone-water is thus calculated by the equation, $a/(b+c)\times 100$ (mg/100 ml). An approximate solubility in pure water is obtained by extrapolating the plots of $a/(b+c)\times 100$ against the volume %, $(c/b+c)\times 100$, of added water.

Benzyl chloride (extra pure reagent of Wako Junyaku Co., Ltd.) was distilled in a vacuum. Deionized water was used.

Results and Discussion

Rate V_s at Saturation Solubility. The pH change due to the hydrolysis of benzyl chloride in the saturated aqueous solution plotted against reaction time is shown in Fig. 1. The change is fast in the initial stage of the reaction but slow later. Since the increase in the amount of added benzyl chloride above saturation solubility value caused an increase in the amount of the first sharp pH change but did not change the inclination of the straight line at the later stage, the sharp pH change is considered to be due to the hydrolysis of impurities such as benzal chloride and benzotrichloride whose rate constants,[3] $(292\pm2)\times 10^{-5}$ sec^{-1} at 30°C and $(387\pm5)\times 10^{-5}$ sec^{-1} at 5°C, are much larger than that of benzyl chloride, $(58.3\pm 0.1)\times 10^{-5}$ sec^{-1} at 60°C. The amount of impurities was estimated to be 0.1 mol% from the amount of the sharp pH change. The rate V_s was thus obtained from the inclination of the straight line appearing later, the values being listed in Table 1. The fact that V_s was almost constant independent of the amount of added benzyl chloride indicates that the hydrolysis in the phase of benzyl chloride can be neglected. All calculations were made by employing the method of least square.

-●- 1 ml/300 ml -△- 2 ml/300 ml

Rate Constant k_i and Order of Reaction i. An approximate value of the solubility of benzyl chloride was 15 mg/100 ml of water at room temperature (Experimental). The reactions were carried out at several concentrations of benzyl chloride below the approximate solubility, and the initial rates $(dx/dt)_0$ were calculated from the curves obtained by plotting proton concentration against reaction time, where x is the concentration of proton formed by the hydrolysis at time t. The initial rates thus obtained at various initial concentrations a and at several temperatures are given in Table 2.

By plotting $\log(dx/dt)_0$ against $\log a$, the order of reaction was obtained to be 1.00 at 30°C, 1.11 at 20°C, and 1.17 at 4.5°C. At 20 and 4.5°C, second order reaction seems to take place together with first order reaction as represented by the equation

$$\left(\frac{dx}{dt}\right)_0 = k_1 a + k_2 a^2 \qquad (3)$$

where k_1 and k_2 are the rate constants of the first and second order reactions, respectively. Eq. (3) was justified by the fact that the plot of $(dx/dt)_0/a$ *vs.* a gave straight lines as shown in Fig. 2. The values of k_1 and

Determination of Solubility. Solubility S_s of benzyl chloride is now calculated from the values of V_s, k_1, and k_2 according to the following equation.

Table 3. k_1 and k_2 and activation parameter

Temp. (°C)	k_1, (min^{-1})	k_2, ($M^{-1}\,min^{-1}$)
4.5	$(3.98\pm0.17)\times10^{-5}$	$(8.9\pm2.5\ )\times10^{-3}$
20	$(2.90\pm0.02)\times10^{-4}$	$(3.6\pm0.10)\times10^{-2}$
30	$(1.16\pm0.09)\times10^{-3}$	$(2.7\pm7.1\ )\times10^{-2}$
Activation energy (kcal/mol)	21.2±1.1	14.6±1.3
Frequency factor (sec^{-1})	12.2±0.8	9.4±1.0

Table 4. Solubility of benzyl chloride

Temp. (°C)	Solubility	
	M	mg/100 m*l*
4.5	$(2.61\pm0.09)\times10^{-3}$	33.1
20	$(3.89\pm0.08)\times10^{-3}$	49.3
30	$(4.4\ \pm1.0\ )\times10^{-3}$	55.5

$$V_s = k_1S_s + k_2S_s^2 \qquad (4)$$

The results are given in Table 4. The solubility value at 30°C is a little larger than 46.5 mg/100 m*l* obtained by Olivier.[2] The heat of dissolution calculated from the data in Table 4 was 4.05±0.44 kcal/mol.

Equation (4) allows us to calculate the degree of contribution of second order reaction to total hydrolysis reaction. The fractions of second order reaction, $k_2S_s^2/(k_1S_s+k_2S_s^2)$, are 36.9% at 4.5°C, 32.6 at 20°C, and 9.25 at 30°C, the values being higher at lower temperature.

The solubility of benzal chloride and benzotrichloride was calculated similarly by the present method, utilizing the kinetic data obtained by Ohnishi,[4] Tanabe and Sano,[5] and Laughton and Robertson,[3] and is shown in Table 5. Tables 4 and 5 reveal that with the increase of the number of chlorines of chlorinated phenylmethanes, their hydrolysis rate increases, but solubility decreases.

Table 5. Solubility of benzal chloride and benzotrichloride

A Further Study of the Scavengeable Electron Yield in the Radiolysis of Hydrocarbon Glasses at −196°C

Toyoaki KIMURA, Kenji FUEKI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 8, 1971)

The yield of scavengeable electrons produced by γ-irradiation in mixtures of cyclopentane and methylcyclohexane at −196°C has been determined by electron-scavenging experiments with bromobenzene. It has been found that the maximum yield of scavengeable electrons in these mixture glasses increases with an increase in the cyclopentane concentration and that it reaches the total ionization yield in a liquid hydrocarbon. The implication of these results for the yield of radiation-induced ionization in condensed systems is discussed.

In order to determine the yield of electrons produced by ionizing radiations in nonpolar condensed systems, we must reply upon electron-scavenging experiments with some electron scavenger, because in such systems any direct method of observing solvent-trapped electrons, such as ESR and optical absorption, can only provide information about a small fraction of the electrons produced.

In a previous study[1] we have shown that bromobenzene can be used as an electron scavenger in hydrocarbons and have measured the yield of scavengeable electrons in methylcyclohexane(MCH), 3-methylpentane, cumene, and *t*-butylbenzene in the liquid state at 20°C and in the glassy state at −196°C. In that study it was found that the yield of scavengeable electrons in glassy hydrocarbons is much lower than that in liquid hydrocarbons. The possible causes for this difference in the electron yield were discussed in some detail. In the experiments with mixtures of isopentane and MCH at −196°C, we have shown that the yield of scavengeable electrons depends on the viscosity of the system, and suggested that the electron-solvent interaction would affect the yield of scavengeable electrons. However, because of the limitation of the solubility of bromobenzene in these mixtures, we could not determine the maximum yield of scavengeable electrons in isopentane-MCH glasses.

In this work we will extend such a study to mixtures of cyclopentane and MCH, where bromobenzene dissolves to a higher concentration, and will determine from the Schuler plot the maximum yield of scavengeable electrons in these mixture glasses.

Experimental

Materials. The methylcyclohexane was a product of Tokyo Kagaku Seiki (99.9%) and was used as received. The cyclopentane (a Nakarai Kagaku guaranteed reagent) was shaken with concentrated sulfuric acid in a separating flask, washed with distilled water, and then dried with sodium sulfate. After passage through a silica gel column, the cyclopentane was fractionally distilled before use. The bromobenzene (a Nakarai Kagaku guaranteed reagent) was passed through an activated alumina column and then fractionally distilled.

Sample Preparation. Each sample was degassed in a 10-mm glass tube by the freeze-pump-thaw technique and then sealed off.

Irradiation. Irradiation was performed with γ-rays from a ^{60}Co source. The dose delivered to the sample was 3.6×10^{19} eV/g.

Analysis. The yield of benzene produced was determined by means of a Hitachi K53 gas chromatograph with a flame ionization detector. The column used was *n*-hexatriacontane (4 mm×4 m).

Results and Discussion

A fraction of the electrons produced by γ-irradiation in liquid or glassy hydrocarbons containing bromobenzene are captured by bromobenzene to yield bromide anions and phenyl radicals. The phenyl radical thus produced immediately abstracts a hydrogen atom from a solvent molecule, even at −196°C, to form a benzene molecule and a solvent radical.[2]

$$RH \rightsquigarrow RH^+ + e^- \quad (1)$$

$$e^- + C_6H_5Br \rightarrow C_6H_5 + Br^- \quad (2)$$

$$C_6H_5 + RH \rightarrow C_6H_6 + R \quad (3)$$

It can be seen from Eqs. (2) and (3) that the yield of benzene produced corresponds to that of the electrons scavenged. It has been shown that the abstraction of a bromine atom by the hydrogen atom from bromobenzene does not occur to any appreciable extent.[3] The contribution to benzene formation of the neutralization reaction of the bromobenzene cation with a negative species can also be excluded at bromobenzene concentrations below about 0.1 M.[1]

In the present study we have measured the yield of benzene produced from bromobenzene in mixtures of cyclopentane (CP) and MCH γ-irradiated at −196°C as a function of the bromobenzene concentration. The compositions of these mixtures were varied over a wide range from pure MCH to a volume ratio of CP to MCH=7/4. Such a variation in the composition results in a substantial change in the viscosity of the system, although the viscosity is not known quantitatively. We have also measured the yield of benzene from bromobenzene in MCH at 20°C for comparison with the results obtained at −196°C.

These results are presented in Figs. 1 and 2 in a converted form to be described below. It can be seen from Fig. 1 that the yield of benzene at −196°C increase with an increase in the CP concentration at a

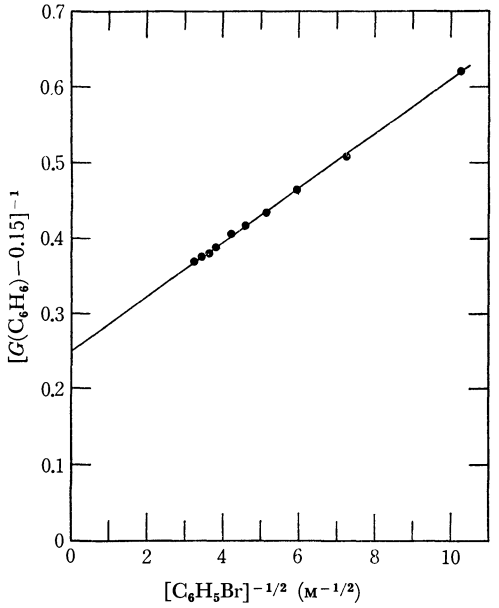

Fig. 2. Plot of $[G(C_6H_6)-0.15]^{-1}$ as a function of $[C_6H_5Br]^{-1/2}$ in MCH containing bromobenzene at 20°C.

specified concentration of bromobenzene. Here we have applied the semiempirical equation developed by Schuler and his coworkers[3] to our data on electron scavenging. The maximum yield of scavengeable electrons can be determined by using the following equation:

$$\frac{1}{G(C_6H_6)-G_{fi}}=\frac{1}{G_{gi}}+\frac{1}{G_{gi}\alpha_s^{1/2}}\frac{1}{[S]^{1/2}} \quad (4)$$

where G_{fi} and G_{gi} are the yield of free electrons and that of electrons which undergo geminate recombination respectively, where α_s is an empirical parameter, and where [S] is the molarity of the scavenger. Taking $G_{fi}=0.15$,[4] the values of $[G(C_6H_6)-0.15]^{-1}$ are plotted against $[C_6H_5Br]^{-1/2}$ in Figs. 1 and 2. The experimental data at both −196°C and 20°C fit straight lines well, as was to be expected from Eq. (4). From the intercepts of the straight lines, the maximum yields (G_m) of scavengeable electrons are determined as $G_m=G_{fi}+G_{gi}$. The values of α_s are obtained from the slopes of the straight lines. These values are listed in Table 1. The value of G_m in the CP-MCH mixtures at −196°C increases with an increase in the CP concentration or with a decrease in the matrix viscosity, reaching 4.28 for the mixtures with volume ratios of CP to MCH>1. This limiting value of G_m at −196°C is in agreement with the value of G_m in MCH at 20°C (4.15 G) within the limits of experimental error. The principal source of error in G_m at −196°C is perhaps in the dosimetry at this temperature.

Table 1. Scavengeable electron yields in CP-MCH mixtures at −196°C and MCH at 20°C

Irradiation temperature	Volume ratio of CP : MCH	G_m	α_s (M^{-1})
−196°C	pure MCH	2.65	18
−196°C	1 : 10	2.69	42
−196°C	2 : 9	2.73	69
−196°C	3 : 8	3.23	59[a]
−196°C	4 : 7	3.41	98
−196°C	5 : 6	3.72	110
−196°C	6 : 5	4.28	140
−196°C	7 : 4	4.28	190
20°C	pure MCH	4.15	48

a) This value is probably underestimated.

Recently, Shida[6] has reported the yields of radiation-induced ionization in a variety of organic systems at −196°C. He measured by optical absorption spectroscopy the disulfide anion produced on scavenging electrons in mixture glasses containing disulfide, obtaining $G=2.10$ for the yield of scavengeable electrons in aliphatic hydrocarbons. This value of 2.10 is compared with our value of 2.65 for MCH at −196°C. It is possible that this discrepancy arises partly from the different methods of extrapolating the experimental data adopted by the two studies. Nevertheless, both of these results indicate that the yield of scavengeable electrons produced in hard hydrocarbon glasses at −196°C is significantly lower than that in liquid hydrocarbons.

As may be seen in Table 1, the value of α_s at −196°C

4) The yield of free electrons was determined by the clearing-field method to be 0.155 for CP and 0.148 for cyclohexane at 23°C.[5]

5) W. F. Schmidt and A. O. Allen, *J. Phys. Chem.*, **72**, 3730 (1968).

6) T. Shida, *ibid.*, **74**, 3055 (1970).

increases with an increase in the CP concentration or a decrease in the matrix viscosity. The parameter, α_s, is given by the ratio of the second-order rate constant, k_s, for the electron scavenging process to the parameter, λ:[7]

$$\alpha_s = \frac{k_s}{\lambda} \tag{5}$$

λ is proportional to $D=D_+ + D_-$, where D_+ and D_- are the diffusion coefficients of the positive ion and the electron respectively. Since D_- is generally much greater than D_+, λ is approximately proportional to the diffusion coefficient of the electron, which is itself related to the electron mobility by the relation:

$$D_- = \frac{kT}{e} u_- \tag{6}$$

where u_- is the mobility of the electron; e, the electronic charge; k, the Boltzmann constant; and T, the absolute temperature. Thus, if k_s is nearly constant in these systems, the variation in values of α_s at -196°C may be ascribed to the change in the electron mobility; *i. e.*, the harder the matrix, the greater the mobility of the electron. We are tempted to state that, in the harder hydrocarbon glasses, the electrons behave more like "quasi-free" electrons, while in the softer glasses the electrons behave more like "solvated" electrons. This might be further related to the rate of molecular relaxation in the matrix, but our present knowledge on this problem is too little to provide any satisfactory explanation for this.

It may also be seen in Table 1 that the α_s for the softer glasses at -196°C is much greater than that for liquid MCH at 20°C. It should be noted, however, that the temperature can affect the diffusion coefficient, given by Eq. (6), if the mobility is kept constant, and can then affect α_s through Eq. (5). Thus, the value of α_s at -196°C is reduced by a factor of 4 for a constant mobility when the temperature is raised to 20°C. For example, a value of $\alpha_s=190$ for the softest glass at -196°C is reduced to 47 at 20°C, which is very close to the α_s for MCH at 20°C. This may indicate that the mobility of the electron in the softest glass studied almost reaches that in liquid MCH.

Such a consideration of α_s may be relevant to the interpretation of the yield of scavengeable electrons. The smaller value of α_s at a specified temperature implies a faster geminate recombination between positive ions and electrons at that temperature. Thus, it is likely that, in hard hydrocarbon glasses at -196°C, a substantial fraction of the electrons recombine with the geminate positive ions too fast to be captured by any electron scavengers, and that the Schuler plot is not necessarily applicable over a wide range of solute concentrations and that its simple extrapolation does not provide the total ionization yield in these systems. It should be noted, however, that the present results do not exclude the possibility that the initial ionization yield is substantially lower in hard hydrocarbon glasses at -196°C than in liquid hydrocarbons.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2652—2660 (1971)

The Crystal Structure of Ascochlorin *p*-Bromobenzenesulfonate[1)]

Yoshiharu NAWATA* and Yoichi IITAKA

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo, Tokyo

**Research Laboratories, Chugai Pharmaceutical Co., Ltd., Takada, Toshima, Tokyo*

(Received April 20, 1971)

The structure of ascochlorin, $C_{23}H_{29}O_4Cl$, has been determined by the three-dimensional X-ray crystal structure analysis of ascochlorin *p*-bromobenzenesulfonate. The crystal is orthorhombic, space group $P2_12_12_1$, with four molecules in a unit cell of dimensions, $a=13.86$, $b=30.04$, and $c=6.82$ Å. The structure was solved by the heavy atom method and refined by the method of block-matrix least-squares. The final R value was 0.102 for 1627 independent reflexions. Ascochlorin consists of (3-chloro) orcylic aldehyde and (2,3,4-trimethyl) cyclohexanone moieties which are connected with each other through a zigzag chain of *trans*-(3-methyl)penta(2,4) diene. The cyclohexanone ring takes a typical chair form, and the intramolecular hydrogen bond exists in the orcylic aldehyde residue. The absolute configuration was determined by the anomalous dispersion method.

Ascochlorin is a new antibiotics obtained from the filter cake of fermented broth of Ascochyte viciae Libert,[2)] which exhibits significant inhibitory effect on the viral growth in cultured cells.[3)] Since the molecular structure of ascochlorin had not been known, the present X-ray analysis was undertaken. The terpenoid metabolite (named LL-Z1272-γ) with the same chemical structure as ascochlorin has been isolated from an unclassified Fusarium species.[4)] The crude products of ascochlorin containing both α and β forms are easily divided into each component by silica gel column chromatography. While the β form is syrup, the α form crystallizes as extremely fine

TABLE 1. THE FINAL ATOMIC PARAMETERS AND THEIR STANDARD DEVIATIONS

x, y, and z are the fractional coordinates. The temperature factors are expressed in the form

$$T=\exp[-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+2\beta_{12}hk+2\beta_{13}hl+2\beta_{23}kl)].$$

The e.s.d.'s given in parentheses are in the units of the least significant digits given for the correponding parameters. To represent the correct absolute configuration, the parameters should be referred to a right handed set of axes.

TABLE 2. (Continued)

needles from methanol solution. Thus, the *p*-bromobenzenesulfonyl derivative of the α form was subjected to the crystal structure analysis. A preliminary report has already been published.[5]

Experimental

The *p*-bromobenzenesulfonyl derivative of ascochlorin was prepared by the esterification of the phenolic hydroxyl group with *p*-bromobenzenesulfonyl chloride in pyridine (heating for 30 min on boiling water bath). The reaction mixture was poured into cold water, and the product was extracted with ether. The crystals obtained from acetone solution were needles developed along the *c*-axis. Two single crystals of 0.20×0.12 and 0.15×0.05 mm in cross section, measured along the diagonal lines, were used for the intensity data collection around the *c*- and *a*-axes, respectively. Precession photographs of (0*kl*) and (*hk*0) were used for the measurements of cell parameters, and the higher layer line spectra of Weissenberg photographs were also used for the determination of the space group.

Crystal data. Ascochlorin-*p*-bromobenzenesulfonate, $C_{29}H_{33}O_6SClBr$, mol wt, 624.4.

Orthorhombic,

$a=13.86\pm0.03$, $b=30.04\pm0.03$, $c=6.82\pm0.01$ Å;

$U=2839.5$ Å^3, $Z=4$, $Dx=1.460$ g.cm^{-3}.

μ(Cu $K\alpha$)$=41.2$ cm^{-1}, F(000)$=1160$.

Absent spectra, *h*00 when *h* is odd, 0*k*0 when *k* is odd, 00*l* when *l* is odd.

Space group, D_2^4—$P2_12_12_1$.

Intensity data were collected with Cu$K\alpha$ radiation on the multiple film packs of Weissenberg photographs with the use of equi-inclination method. Layers from 0th to 5th around the *c*-axis and from 0th to 6th around the *a*-axis were recorded. Intensities were measured visually by comparison with the standard intensity scale. These data were then corrected for Lorentz, polarization and spot elongation factors but not for absorption. The derived structure factors on different layers were correlated and scaled in a common base by comparing the common reflexions. The total number of independent reflexions was 1627.

Determination of the Crystal Structure

The crystal structure was elucidated by the heavy atom method. The positional parameters of bromine atom were determined from the three Harker sections of $P(0.5, v, w)$, $P(u, 0.5, w)$, and $P(u, v, 0.5)$, sharpened to correspond to the atoms at rest. The structure factor calculated for the bromine atom alone gave the *R* value of 0.44. The coordinates of the atoms in

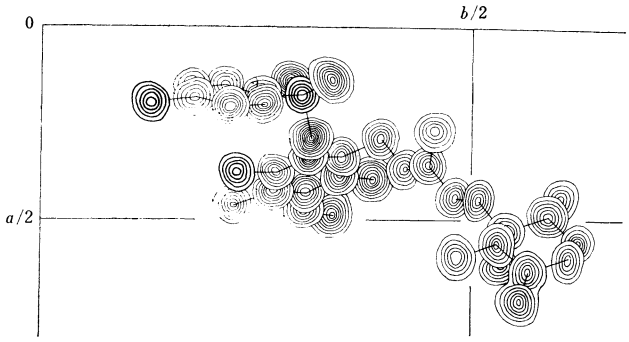

Fig. 1(a). Composite drawing of the final electron density map viewed along the *c*-axis. Contours for carbon and oxygen atoms are drawn at intervals of 1 e.Å^{-3} starting at 1 e.Å^{-3}, and for sulfur and chlorine atoms are at intervals of 3 e.Å^{-3} starting at 3 e.Å^{-3}. Those for bromine atom are drawn by arbitrary scale.

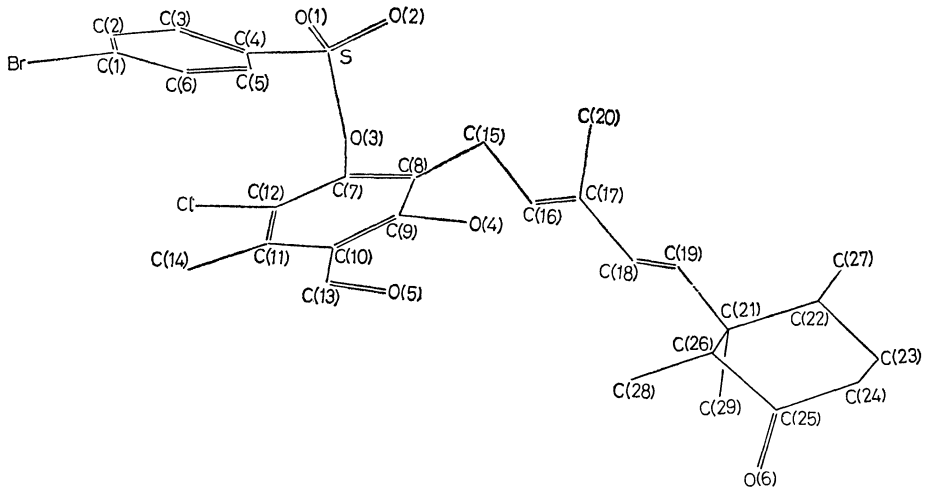

Fig. 1(b). The molecular structure viewed along the *c*-axis.

the *p*-bromobenzenesulfonyl group and the chlorine atom were determined on the Fourier map and used for the next structure factor Fourier calculations. The *R* value for the structure factors of these twelve atoms was 0.34. The subsequent Fourier and difference Fourier syntheses revealed all the positions of the atoms at the stage where the *R* value reached 0.24. The four oxygen atoms of the ascochlorin molecule were distinguished easily from the carbon atoms on the difference Fourier map. The molecular structure of ascochlorin elucidated in this way consisted of (3-chloro)orcylic aldehyde and (2,3,4-trimethyl)cyclohexanone moieties linked together through the zigzag chain of *trans*-(3-methyl)penta(2,4)diene. Further refinement of the parameters was carried out by the least-squares method of block matrix approximation with the use of the program HBLS.[6] Anisotropic thermal motions were considered only for bromine atom. The *R* value dropped to 0.123 after four cycles of refinement, and the positions of single and double bonds in the molecule were confirmed. The characters of the four oxygen atoms of ascochlorin molecule were made clear at this stage; one was of keto group in the cyclohexanone moiety, and the others were of two hydroxyl and one aldehyde groups in the orcylic aldehyde moiety. Finally, the least-squares refinement was carried out with the anisotropic temperature factors for all atoms. The *R* value was converged to 0.102 after three cycles of calculations. In these calculations all reflexions were treated with equal weight. Atomic scattering factors used were those given in *International Tables for X-ray Crystallography*.[7] Final values of atomic parameters and anisotropic temperature factors are given in Table 1. Figure 1(a) shows the final three-dimensional Fourier map.

Absolute Configuration

The absolute configuration of ascochlorin-*p*-bromobenzenesulfonate molecule was determined by Bijovet's method with the use of anomalous dispersion of Cu$K\alpha$ radiation by bromine, sulfur, and chlorine atoms. Dispersion corrections of the scattering factors used were those given by Dauben and Templeton.[8] The values of $\Delta f'$ and $\Delta f''$ are as follows:

Br	$\Delta f' = -1.0$	$\Delta f'' = 1.4$
S	0.3	0.7
Cl	0.3	0.6

The structure factors for both hkl and $h\bar{k}l$ were calculated with final atomic parameters. If one takes the left-handed coordinate system, the observed and calculated values of the ratios of the intensities $I(hkl)/I(h\bar{k}l)$ are not coincident for all pairs, as shown in Table 3, and the assumed configuration proves to be reversed. In this report, the molecules are shown by the correct absolute configuration.

Discussion of the Structure

The molecular structure of ascochlorin-*p*-bromobenzenesulfonate is illustrated in Fig. 1(b), in which the numbers and symbols of the atoms are also given. Ascochlorin is built up of chloroorcylic aldehyde residue, trimethylcyclohexanone ring and the zigzag chain of *trans*-methylpentadiene. As shown in Table 5, all atoms of chloroorcylic aldehyde residue lie approximately on a plane. Of these, the six carbon atoms of the benzene ring lie on an almost complete plane, the average deviation from the least-squares plane being only 0.009 Å. Chlorine atom and its adjacent methyl group(C(14)), which are separated only by 3.03 Å, deviate by −0.124 and +0.134 Å from the benzene ring in order to balance the repulsive forces between the *ortho*-substituents. The short distance(2.57 Å) between the two oxygen atoms of hydroxyl(O(4)) and aldehyde group (O(5)), indicates the existence of an intramolecular hydrogen bond between them, in consistence with the spectral data of proton magnetic resonance.[5] The four oxygen atoms of the sulfonyl group are arranged in a distorted tetrahedral configuration around the central sulfur atom, and O(1) lies nearly on the plane passing through the benzene ring(perpendicular distance to the plane is +0.027 Å), O(2) lies above the plane(+0.795 Å) and O(3) below the plane(−1.540 Å). As the conformation of O(1)—S—O(3)—C(7) bonds at the ester linkage

is *cis* form, the chlorine atom of the chloroorcylic aldehyde residue comes at a position close to the benzene ring of the *p*-bromobenzenesulfonyl residue. The perpendicular line from the chlorine atom to the latter benzene ring drops inside the ring(distance 3.22 Å). This conformation is thus stabilized by the interaction between the benzene ring and the chlorine atom which has a larger electron affinity than the other atoms. These two benzene planes of the same molecule make an angle of 133°25′. In the case of siccanin-*p*-bromobenzenesulfonate,[9] the conformation of O–S–O–C bonds(at the ester linkage) is *trans* form and the ether oxygen atom in *D*-ring of siccanin comes above the benzene ring of *p*-bromobenzenesulfonyl residue.

The zigzag chain of the methylpentadiene residue takes all *trans* conformations, and the internal rotation angle[10] around the C(17)—C(18) bond is 175.9°. The bond lengths of C(17)—C(18) and C(19)—C(21), 1.47 and 1.48 Å, respectively, suggest that the π electrons in the methylpentadiene residue is delocalized.

The cyclohexanone ring adopts a typical chair form. As shown in Table 5, the two carbon atoms,

9) K. Hirai, S. Okuda, S. Nozoe, and Y. Iitaka, *Acta Cryst.*, **B25**, 2630 (1969).

10) The internal rotation angle around the B—C bond of A—B—C—D is defined as the angle between projection of A—B and that of C—D, when the projection is taken along the B—C bond. The positive value is taken in the same sense as that of the turning direction of a right handed screw advancing along the B—C bond.

where X, Y, Z are taken along the crystallographic a, b, and c axes, respectively, and measured in Å units.

C(25) and C(22), deviate by +0.64 and −0.70 Å, respectively, from the plane(A) formed by the four carbon atoms of C(21), C(23), C(24), and C(26). The two planes formed by C(21), C(22), and C(23), and by C(24), C(25), C(26), and O(6), intersect with the plane (A) at angles of 126.6° and 128.5°, respectively. Of the three methyl groups attached to the cyclohexanone ring, two are in equatorial (C(27), C(28)) and the other in axial position (C(29)). The same conclusion was deduced for the terpenoid metabolite (LL-Z1272-γ) from the NMR spectral data.[4]

The structures of the crystal projected along the c and a axes are shown in Figs. 4 and 5, respectively. As is clear from Fig. 5, the orcylic aldehyde and *p*-bromobenzenesulfonyl residues are stacked to construct the columns of aromatic rings along the a-axis and form the layers parallel to the (010) plane. The stacking of the two phenyl groups is such that the Br-ϕ and Cl-ϕ groups are arranged in anti-parallel fashion with respect to the halogen position. The cyclohexanone and the methylpentadiene residues are extended from the aromatic layers and fill up the spaces between them. The shortest intermolecular distances less than 3.8 Å are shown in Fig. 4, in which the molecules are designated by the molecular number I to IV as follows:

I at (x, y, z)
II at $(0.5+x, 0.5-y, 1-z)$
III at $(0.5-x, 1-y, -0.5+z)$
IV at $(1-x, -0.5+y, 2.5-z)$

The distance between the oxygen atom O(6) of keto group (IV) and the bromine atom (I) (3.33 Å) suggests the existence of rather strong van der Waals interaction between them (the sum of the van der Waals radii=3.35 Å).

Electrochemiluminescence of Aromatics in *N,N*-Dimethylformamide

Kenji MORI, Naoto YAMAMOTO, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received April 22, 1971)

Electrochemiluminescence (ECL) of aromatics was studied in dimethylformamide. The solutions were electrolyzed with square-wave voltage at various frequencies. For anthracene, emission from species produced by electrochemical reaction was observed together with anthracene fluorescence. These emissions were quenched when water was added to the solution. For rubrene and perylene, fluorescence from the molecules was observed. For phenanthrene, emission differing from phenanthrene fluorescence was observed at 515 mμ.

Many investigations have shown that alternating current electrolysis of aromatics hydrocarbons in conducting fluid media produces chemiluminescence.[1-6] The spectrum of this electrochemiluminescence (ECL) comprises, in most cases, normal or excimer fluorescences of the aromatics,[3] though spectra of different origin have sometimes been observed.[7]

The mechanism of the appearance of normal and excimer fluorescence in the ECL processes is generally recognized to be as follows.

Production of cation and anion

$$A - e^- \rightarrow A^+ \quad (1)$$

$$A + e^- \rightarrow A^- \quad (1)'$$

Combination of the ions yielding singlet or triplet excited states

$$A^+ + A^- \rightarrow {}^1A^* \text{ (or } {}^3A^*) + A \quad (2)$$

Triplet annihilation process

$$2\,{}^3A^* \rightarrow {}^1A^* + A \quad (3)$$

Emission of fluorescence

$${}^1A^* \rightarrow A + h\nu_F \quad (4)$$

Production of excimer

$$A^+ + A^- \rightarrow ({}^1A^*\cdots A) \quad (5)$$

Emission from excimer

$$({}^1A^*\cdots A) \rightarrow 2A + h\nu_{F'} \quad (6)$$

It has been suggested on the basis of energetics[2] that the fluorescent singlet state is generally formed rather from processes (3) and (4) via the triplet state than from the direct combination of cation and anion. To explain the ECL emission band at longer wavelengths than the normal fluorescence, the excimer fluorescence mechanisms (5) and (6) were proposed as well.[3] In some cases, the contribution from species electrochemically formed or from the impurities in the solution cannot be ignored.

In this paper, we report the studies on the ECL emission obtained for anthracence rubrene, perylene phenanthrene and pyrene in dimethylformamide (DMF), applying square-wave voltage at various frequencies.

Experimental

Anthracene and phenanthrene were recrystalized from benzene after passing through a column of silica gel and then sublimed in a vacuum. Commercially obtained rubrene and pyrene were sublimed in a vacuum. Perylene was recrystalized from toluene and then sublimed in a vacuum. Tetra-*n*-butylammonium perchlorate (TBAP) used as a supporting electrolyte was prepared from an aqueous solution of sodium perchlorate and tetra-*n*-butylammonium iodide and repeatedly recrystalized from aqueous solutions. DMF used as solvent was distilled at reduced pressure after standing for two days over potassium carbonate or magnesium sulfate. The distillate was stored in a vacuum desiccator. Acetonitrile was purified in the same way as described elswhere.[8]

The cell used is made of quartz, 30 mm in diameter, and has two platinum electrodes shown in Fig. 1, namely, a slightly curved plate (20×20 mm) and a rod 3 mm in diameter. The electrodes were 5 mm apart.

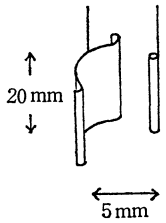

Fig. 1. The shape and arrangement of electrodes.

The solutions containing 10^{-3}—10^{-2} M aromatics and 5×10^{-1} M TBAP in DMF or acetonitrile were deaerated by bubbling with nitrogen gas before electrolysis. All solutions except for the cases of phenanthrene and pyrene were electrolyzed by applying voltage of the square-wave type generated from a transistor switching circuit shown in Fig. 2. Switching was controlled with a signal from a National VP-702B low frequency oscillator. The frequency was varied from 20 to 2×10^5 cps. ECL emission spectra were recorded in most cases using a Nalumi RM 23 monochrometer, an RCA 1P28 photomultiplier tube and a pen recorder. Response of the ECL emission was measured with a photomultiplier tube placed near the cell and a synchroscope (National VP 511B). Frequency dependence of the emission

intensity was also recorded on the pen recorder through an AC-DC converter(Yokogawa 3142). During electrolysis, the ECL emission changed with time owing to irreversible electrochemical reactions. Measurements were, therefore, carried out immediately after the start of electrolysis. When acetonitrile was used as a solvent, the ECL intensity was found to be weaker than that for DMF. Detailed experiments were performed only for DMF solutions.

Results and Discussion

Anthracene. The ECL of anthracene was reported by two groups. Chandross *et al.* reported a broad spectrum with maximum at 450 mμ,[3,9] while Faulkner and Bard obtained a quite different spectrum having a rather sharp maximum at 400 mμ and another one at 460 mμ.[7] The ECL spectrum of anthracene in DMF we obtained is shown in Fig. 3, where the solution was electrolyzed at a frequency of 20 cps. The broken line shows an ECL spectrum for the applied voltage of 2.5 V.[10] The emission appearing at a wavelength shorter than 470 mμ has a shape similar to that of the normal fluorescence of anthracene and

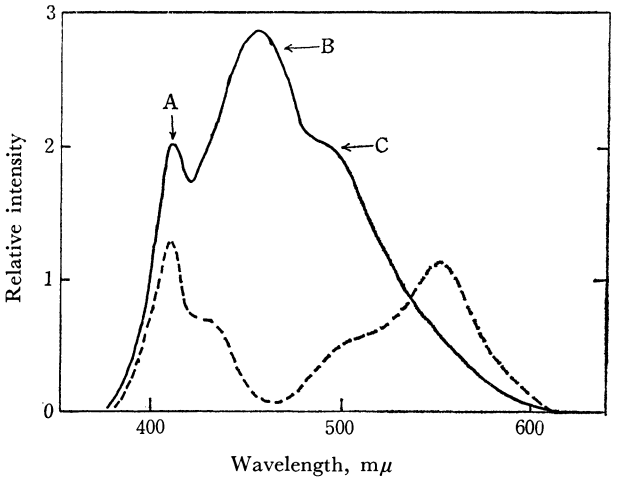

Fig. 3. Emission spectra of anthracence solution electrolyzed at 20 cps. --- at 2.5 V; —— at 3.6 V

9) R. E. Visco and E. A. Chandross, *J. Amer. Chem. Soc.*, **86**, 5350 (1964).

may be assigned to it. It is difficult to determine the species relevant to the 470—600 mμ emission from its spectral shape. The ECL emission spectra obtained at voltages lower than 3.0 V stayed essentially the same as the broken line in Fig. 3. Above 3.0 V, the spectrum changed very much. A typical example is shown by the solid line in Fig. 3 obtained at 3.6 V. The spectrum seems to consist of three components, (A) the fluorescence of anthracence, (B) a strong emission centered at 455 mμ, and (C) a shoulder at 500 mμ. The B band is similar to that previously obtained by Faulkner and Bard[7] who asigned it to the fluorescence of anthranol. When the applied voltage was varied in the range 3.0—6.0 V, the spectral feature did not change. It was found that the intensity ratio of the B band to the A band decreased with increase in the frequency of the applied voltage.

The total ECL response on the photomultiplier was traced with a synchroscope, and is shown in Fig. 4 together with the wave form of the applied voltage. It was confirmed from visual observation that the emission near the earthed electrode was so weak that its contribution to the wave form is negligible. Figure 4a shows a wave form of the ECL intensity obtained

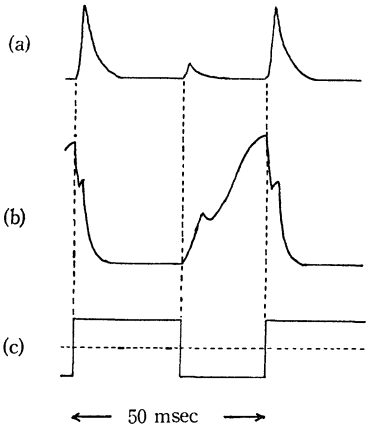

Fig. 4. Wave form of ECL intensity of anthracene solution,
(a) electrolyzed at 2.5 V.
(b) electrolyzed at 3.5 V.
(c) Wave form of the applied voltage.

at 2.5 V. There is a strong peak appearing immediately after the begining of each positive-half cycle, while the peak appearing at the negative-half cycle was very weak. It can be suggested that the emission results, for the most part, from an annihilation reaction of the cation and anion radicals of anthracence, and the marked difference between peak heights at positive- and negative-half cycles is explained by assuming that the cation radical is much more short-lived than the anion radical.[11] It is then expected that as the frequency is increased until its reciprocal is equal to the life-time of the cation radical or less,

10) In this paper, a rod-like electrode was earthed, and positive and negative voltages were alternately applied to the other electrode. The voltage given in the text indicates the absolute value of the voltage applied to the latter.

11) M. E. Peover and B. S. White, *J. Electroanal. Chem.*, **13**, 93 (1967).

the magnitudes of the two peaks should become alike. It was, in fact, found that the two peaks were equal in magnitude at 100 cps. When the solution was electrolyzed at 3.0 V, the ECL intensity increased but the wave form was identical with that obtained at 2.5 V.

At a voltage higher than 3.0 V, the ECL emission had a wave form as shown in Fig. 4b. There is a new strong peak at the negative-half cycle in addition to the peak described before. It can be easily deduced that this peak corresponds to the B band shown in Fig. 3 which appears only at a higher voltage. Since the peak has a long rise time and appears only at the negative-half cycle, it may be concluded that the B band is due to a species formed secondarily from the ionic species. As mentioned before, the higher the frequency, the smaller the intensity of the B band. This tendency may be explained very well by the results obtained in Fig. 4.

Frequency dependence of the ECL intensity was measured at 6.0 V (Fig. 5). Curve a shows a typical result obtained at wavelengths shorter than 405 mμ corresponding to the normal fluorescence of anthracence. The curve is nearly flat in the region up to 150 cps and quickly drops at higher frequencies. The drop at high frequency might be explained by the change of bulk impedance. Curve b in Fig. 5 shows a typical curve for the emission at longer wavelengths than 440 mμ. The curve decreases rapidly with frequency even in the range where curve a is flat. The result confirms also that the slow-rising component in Fig. 4b corresponds to the B band. Addition of water to the same solution as used above was found to quench the ECL emission.

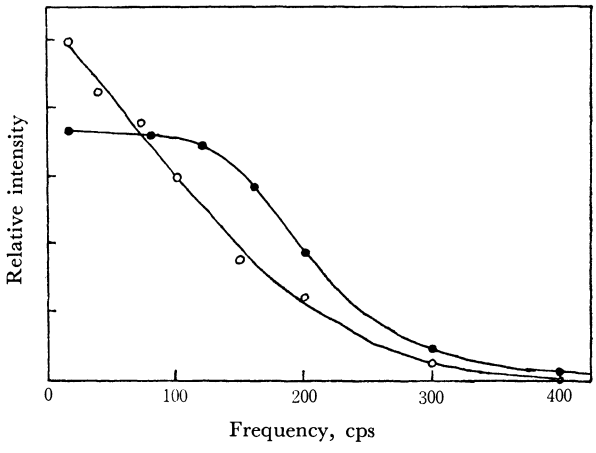

Fig. 5. Frequency dependence of ECL intensity of anthracene solution electrolyzed at 6.0 V. Curve a, emissions at wavelengths longer that 440 mμ (●), curve b, emissions in wavelengths shorter than 405 mμ (○).

From the position and shape of the spectrum, it seems reasonable to assign the B band at 455 mμ in Fig. 3 to the fluorescence of anthranol. As this band has a threshold voltage higher than that yielding the anthracene fluorescence and is observed as a slow-rising peak only at negative-half cycle (Fig. 5b), it may be suggested that anthracene dinegative ion participates in the mechanism yielding the anthranol fluorescence. At present, however, it is difficult to explain details of the anthranol emission process.

With the continuation of electrolysis, the ECL emission gradually changed its intensity as shown in Fig. 6. Here, the electrolysis was performed at an

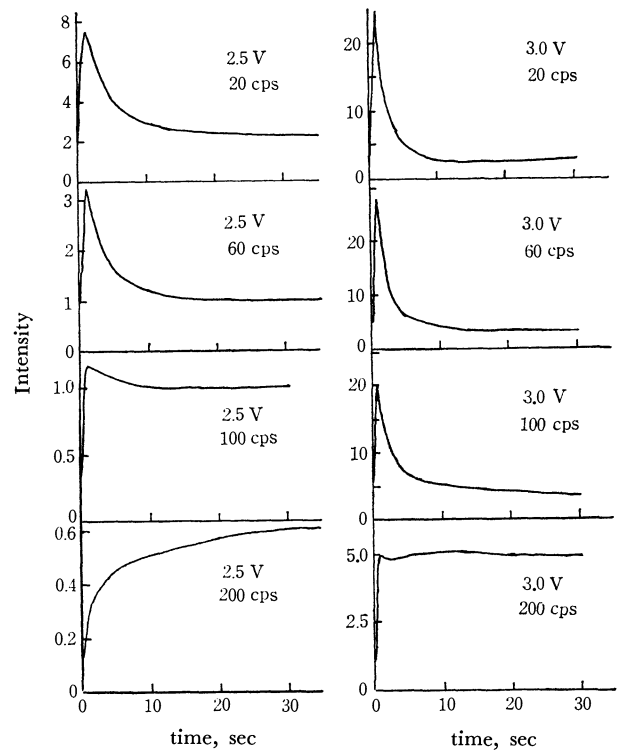

Fig. 6. Time dependence of ECL intensity of anthracene solution.

applied voltage below 3.0 V, and no emission band at 455 mμ appeared. From the curves shown in Fig. 8, the following relationships are derived.

(1) At a given frequency, the higher the voltage, the quicker the decay of emission.

(2) At a constant voltage, the greater the frequency, the slower the decay of emission.

Since the electric current increases with the applied voltage, it is reasonable to consider that irreversible chemical change of anthracene is promoted by increasing the voltage. Relation (1) seems to be based on it. It is expected that if the frequency is high enough, the cation radical formed on a positive-half cycle reacts efficiently with the anion radical and disappears. The annihilation of the cation may decrease the decomposition rate of anthracene. Relation (2) seems to be due to this.

Rubrene. The intense ECL emission of rubrene has been assigned to the normal fluorescence of rubrene.[12,13] All the ECL spectra we obtained at 1.8, and 3.6 V at the frequency of 20 cps had a peak identical with that of the normal fluorescence of rubrene. The wave form was also measured at various voltages. By the electrolysis of solution at 2.0 V, a strong peak

12) D. M. Hercules, R. C. Lansbury, and D. K. Roe, *J. Amer. Chem. Soc.*, **88**, 4578 (1966).

13) D. L. Maricle and A. H. Maurer, *ibid.*, **89**, 188 (1967).

appeared at the positive-half cycle and a weak peak at the negative-half cycle. Their average lifetimes were found to be about 2.5 msec. At 3.0 V, a slow-rising peak appeared at the positive-half cycle as well as sharp-rising peaks. The peak increased with time. It may be suggested that the sharp-rising peaks are the emission due to the annihilation between the cation and the anion radicals of rubrene, while the slow-rising peak is the emission originated from the reaction product from rubrene. In spite of the change of the wave form with the voltage, the spectrum did not change. It is possible that, even if the reaction product participates in the ECL emission, the excited singlet state of rubrene is finally formed by charge transfer process or by energy transfer process.

Perylene. The ECL-intensity of perylene was weak compared with that of anthracence and rubrene. The solution was electrolyzed at 2.5, 3.0, and 3.6 V at 50 cps. Concentration of TBAP was 5.6×10^{-2} M. The solid line in Fig. 7 shows a spectrum obtained at 3.0 V. The broken line shows the spectrum obtained by Chandross *et al.* who assigned it to the excimer fluorescence of perylene.[3] The spectrum we obtained is similar to that of the normal fluorescence of perylene. Wave form of the ECL intensity was also measured at various voltages (Fig. 8). It differs largely from that observed for anthracene or for rubrene. By increasing the voltage, the time lag for the sharp-rising on a negative-half cycle was found to become longer. In addition to the peak, there was a slow-rising peak in the positive-half cycle and even in the negative-half cycle at a higher voltage. Assuming that the ECL emssion is assigned only to the normal fluorescence, these results suggest that there is, in addition to the annihilation reaction, an other one producing the excited singlet state of perylene.

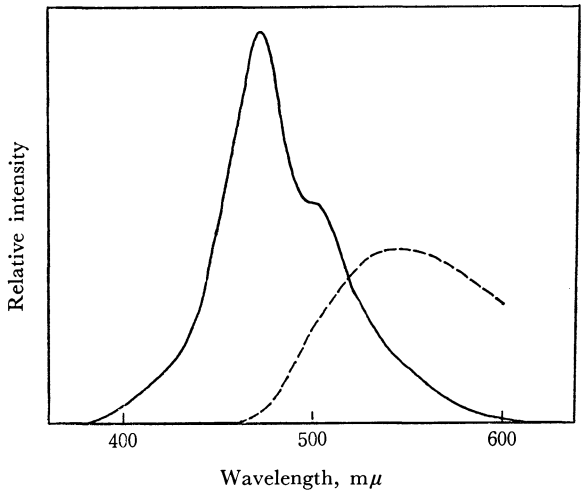

Fig. 7. Emission spectrum obtained from perylene solution electrolyzed at 3.0 V at 50 cps (solid line).
Broken line indicates ECL spectrum from a pyrene solution reported by Chandross *et al.*[3]

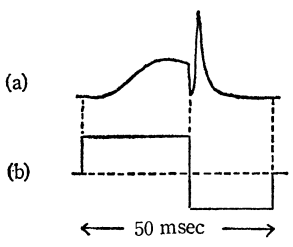

Fig. 8. Curve a, wave form of the ECL intensity of perylene solution electrolyzed at 2.5 V. Curve b, that of the applied voltage.

Frequency dependence of the ECL emission was measured at various voltages. Concentration of TBAP was 2.66×10^{-2} M. Curves (a) and (b) in Fig. 9 obtained at 3.0 and 4.0 V, respectively, decline monotonically with the frequency. Curves (c) and (d) at 5.0 and 6.0 V, respectively, have maxima. As the voltage increases, the maxima tend to shift toward the high frequency side. The shift seems to be related with the slow-rising peak.

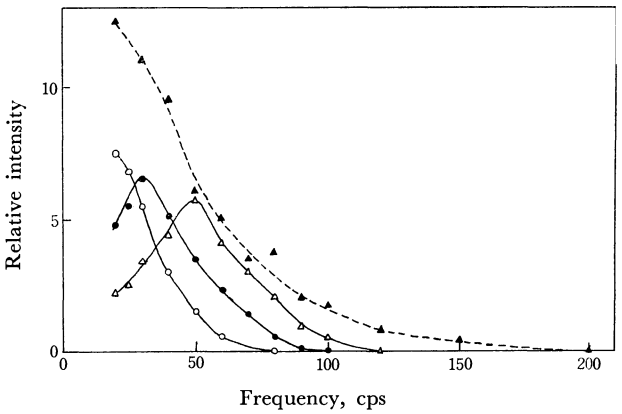

Fig. 9. Frequency dependence of the ECL emission from perylene solution, electrolyzed.

(d) △, at 6.0 V, 2.3×10^{-2} M TBAP.

Phenanthrene. ECL emission spectrum from phenanthrene solution in DMF is shown in Fig. 10. Electrolysis was carried out with the sinusoidally alternating voltage of 60 cps. The spectrum obtained resembles that of the phosphorescence of phenanthrene. However, it seems unreasonable that the phosphorescence of phenanthrene should be observed so strongly in a solution at room temperature. Therefore, the

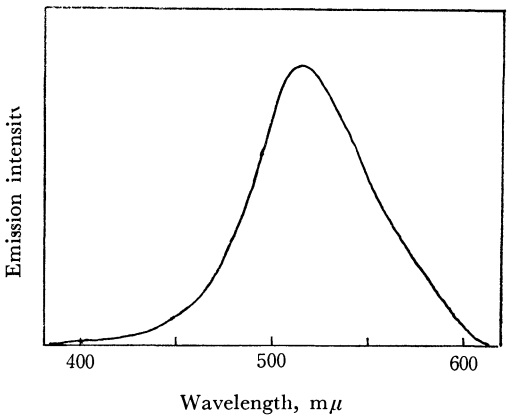

Fig. 10. Emission spectrum from phenanthrene solution.

possibility of an impurity luminescence cannot entirely be neglected.

Pyrene. When pyrene in DMF was electrolyzed with a DC voltage at 6.0 V, white-blue emission was observed at the anodic surface together with gas evolution. The emission intensity was so weak that we could not measure the spectrum.

Concluding Remark. There have been a few studies on the ECL imposing square wave voltage.[14] It may be emphasized that the observation of the wave form of the ECL-intensity as described in this paper is a useful method to study the mechanism of emission and the assignments of the emitting species. Measurement of the frequency dependence of the ECL emission bands may also give valuable information on the electrolytic reaction mechanisms.

(Received April 26, 1971)

The crystal structure of 3-(10,11-dihydro-5H-dibenzo[*a*,*d*]cyclohepten-5-ylidene)-1-ethyl-2-methylpyrrolidine hydrobromide, $C_{22}H_{26}NBr$, has been determined. The crystal is monoclinic with space group $P2_1/a$; the unit-cell dimensions are: $a=30.16$, $b=18.78$, $c=7.048$ Å, $\beta=90.53°$. The asymmetric unit contains two molecules. The intensities were estimated visually from the multiple-film equi-inclination Weissenberg photographs. The structure was solved by the heavy atom method. The atomic parameters were refined by the block-diagonal least-squares method, and final R index was reduced to 0.147. It is concluded that the overall geometry of the two independent molecules is similar in every detail The pyrrolidine ring is puckered. The 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene part consists of three planes. The dihedral angles between the planes are 63° for the benzene planes I and II, 59° for the benzene plane I and the ylidene plane, and 76° for the benzene plane II and the ylidene plane.

3-(10,11-dihydro-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)-1-ethyl-2-methylpyrrolidine hydrochloride (piroheptine hydrochloride) has been found to show antagonism of tremorine tremor by S. Kumada *et al.*[1] S. Umio *et al.*[2] have suggested that both piroheptine hydrochloride and piroheptine hydrobromide seemed to have more than two conformations in the solution on the basis of interpretation of NMR spectra.

From our interest in the relation[3] between structure and drug action, we undertook X-ray determination of the crystal structure of piroheptine hydrobromide in order to obtain useful information on its conformation in the solution.

As a result, conformation in the crystal seems to correspond to the most stable conformation in the solution suggested by NMR study.

Experimental

The crystal of piroheptine hydrobromide was obtained from a methanol-ether solution in the form of colorless prism elongated along the c axis.

Unit-cell dimensions were determined by the least-squares calculation, using 19 $hk0$ and 20 $0kl$ reflections whose Bragg angles were measured on zero-layer Weissenberg photographs taken with Cu$K\alpha$ radiation and calibrated with aluminum powder lines. The density was measured by flotation in a benzene-carbon tetrachloride mixture.

Crystal data:

Piroheptine hydrobromide, $C_{22}H_{26}NBr$; M=384.4; mp=237—240°C

Monoclinic, $a=30.16\pm0.008$, $b=18.78\pm0.014$, $c=7.048\pm0.003$ Å, $\beta=90.53\pm0.03°$, V=3992.0 Å^3

$D_m=1.28$, Z=8, $D_x=1.279$ g/cm^3

Absorption of X-ray, $\lambda=1.5418$ Å (Cu$K\alpha$); $\mu=31.3$ cm^{-1}.

$F(000)=1608$

Absent spectra: $h0l$ when h is odd, $0k0$ when k is odd. Space group is $P2_1/a$.

Since a unit-cell contains eight molecules, an asymmetric unit contains two crystallographically independent molecules.

The three dimensional intensity data of nickel-filtered Cu$K\alpha$ radiation were collected from the multiple-film equi-inclination Weissenberg photographs for the layer line 0—5 about the c axis and 0—2 about the b axis. The intensities of reflections out to spacings of 1 Å were visually estimated by comparison with a standard scale. The values of intensity ranged from 1 to 10,000. They were corrected for Lorentz and polarization factors; no absorption or extinction corrections were applied. Corrections for variation in spot-size on higher-layer photographs were made by the method of Phillips.[4] The intensity data from the b axis photographs were used only for layer scale adjustment of the a axis photo-

graphs. 3797 intensity data were obtained of which 800 were too weak to be observed.

Structure Determination

The coordinates of two bromine ions in an asymmetric unit were deduced from the Patterson function. A Fourier synthesis based on the coordinates of the two bromine ions clearly revealed all 46 light atoms. Succesive Fourier synthesis showed no spurious peak except for a few peaks about the bromine ions.

The positional and thermal parameters of the atoms were refined by the block-diagonal least-squares method minimizing $\sum w(|F_o|-|F_c|)^2$. The weighting scheme

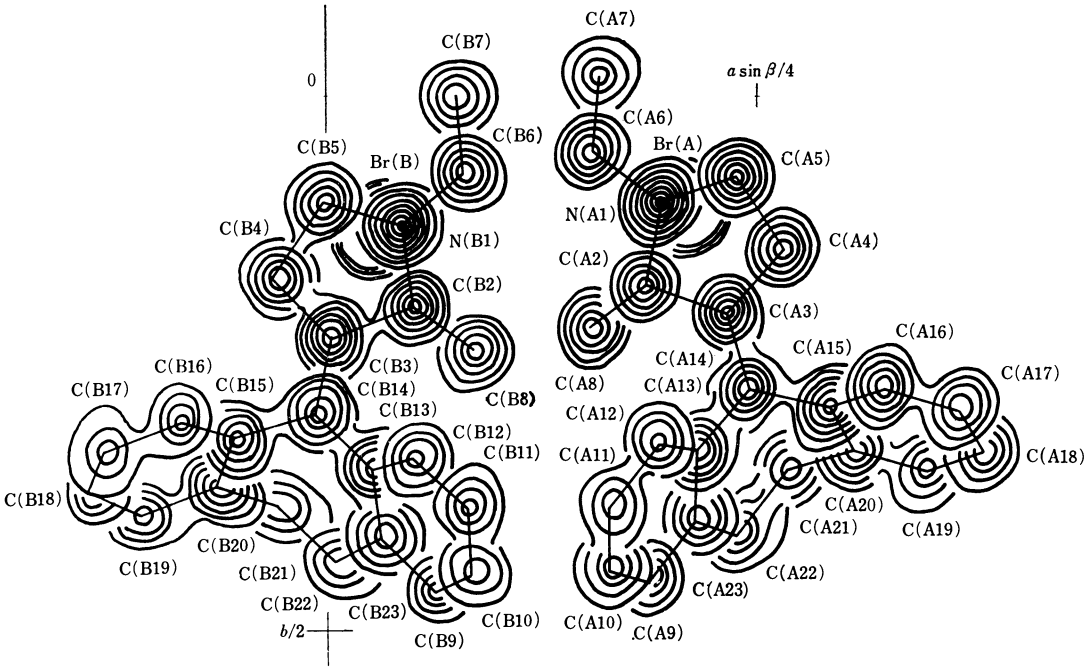

Fig. 1. A composite drawing of the final electron density map, viewed along the c axis. Contours are drawn at 1.5, 2.5, 3.5 e.Å^{-3}...for the light atoms. Contours for the bromide ions are omitted.

was; $w=0.3$ when $|F_o|=0$ and $w=1$ when $|F_o|\neq 0$. The scattering factors for H, C, N, and Br^- were taken from International Tables.[5] Two cycles of the least-squares refinement were carried out, assigning isotropic temperature factors to all atoms and ions. These two cycles decreased the reliability index R to 0.192. Four more cycles of the refinement were performed, assigning anisotropic temperature factors to two bromine ions. The R index was reduced to 0.147, excluding non-observed reflections ($R=0.188$, for all 3797 reflections).

The final atomic coordinates and isotropic temperature factors are given in Table 1, and the anisotropic temperature factors for the bromine ions in Table 2. The two independent molecules are denoted by symbols A and B. A composite drawing of the final electron density map is shown in Fig. 1.

All the numerical computations were carried out on a CDC 3600, C. Itoh Electronic Computing Service Co., Ltd. and a HITAC 8400, Fujisawa Pharmaceutical Co., Ltd. Most computing programs used were the application programs of C. Itoh Electronic Computing Service Co., Ltd.

5) "International Tables for X-ray Crystallography," Vol. III, Kynoch Press, Birmingham (1962), p. 202.

Discussion

Geometry of the molecule. Comparison of the corresponding bond lengths and angles in the two independent molecules are given in Table 3 and 4, and the average values of the corresponding bond lengths and angles in the two independent molecules are shown in Fig. 2. The bond lesgths and angles in the two molecules agree closely with each other, with a few exceptions. The root mean square deviations between the two molecules are 0.052 Å for the bond lengths and 4.0° for the bond angles. The C(3)–C(14) bond length 1.33 Å agrees with the standard C–C double bond length 1.34 Å.

The conformation of the pyrrolidine rings is shown in Fig. 3. Arabic numerals denote the displacements (in Å) of the atoms from the best plane of the pyrrolidine ring. The pyrrolidine rings are puckered. The conformation about the C(2)–N(1) bond by stereographic projection is shown in Fig. 4.

The 10,11-dihydro-5H-dibenzo[*a*,*d*]cyclohepten-5-ylidene part consists of the three planes. The first is benzene plane I through the C(9), C(10), C(11), C(12), C(13), C(23), C(14), and C(22) atom. The second is benzene plane II through the C(15), C(16),

			A	B	Average
Benzene plane I	and	Benzene plane II	64°	62°	63°
Benzene plane I		Ylidene plane	60	59	59
Benzene plane II		Ylidene plane	76	76	76

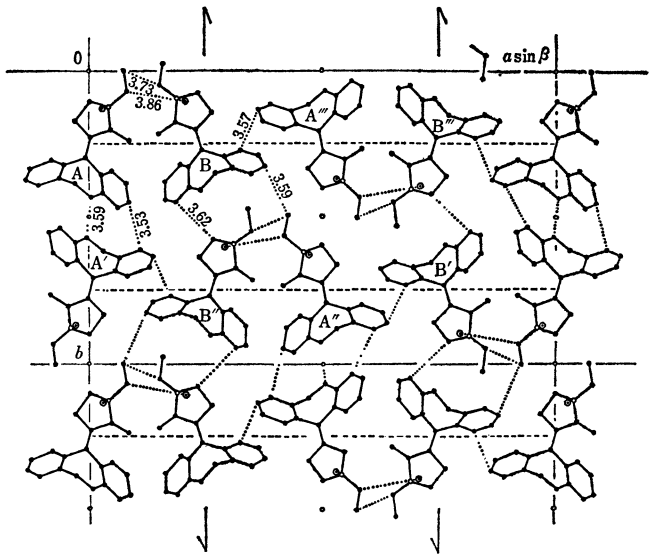

Fig. 5. A drawing of the structure viewed along the *c* axis. Some of the van der Waals contacts are indicated by dotted lines.

Br^- distances are 3.12 Å in the A molecule and 3.13 Å in the B molecule. In both A and B molecules, the C(2), C(5), C(6) atom, and the Br^- ion are approximately on the four vertices of a tetrahedron centered at the N(1) atom. The bond angles involving the N(1) atom and the Br^- ion are:

	A molecule	B molecule
$Br^-\cdots N(1)$-C(2)	111°	115°
$Br^-\cdots N(1)$-C(5)	101	99
$Br^-\cdots N(1)$-C(6)	119	116

The evidence thus obtained suggests that $N(1)\cdots Br^-$ form $N\text{–}H\cdots Br^-$ hydrogen bondings. They are indicated by the broken lines in Fig. 6.

Some shorter intermolecular distances are indicated by dotted lines in Figs. 5 and 6. No unusually short contact is found in this crystal structure.

The complete data of the F_o–F_c table are kept at the office of the Bulletin of the Chemical Society of Japan.[6]

The authors thank Miss Kazuko Nakayama for her assistance in the intensity measurement. They are also indebted to Professor Masao Kakudo and Dr. Tamaichi Ashida for discussions and suggestions.

The Decomposition of Energized Ethylene Formed in the Photolyses of Alkanes

Yuji OGATA, Kinichi OBI, Hajime AKIMOTO, and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received May 4, 1971)

The decomposition and the collisional deactivation of energized ethylene formed in the photolyses of ethane, propane, *n*-butane, and cyclobutane at 1470 Å have been studied from the change in ethylene and acetylene yields with varying pressures of alkane or nitrogen added as a deactivator. The rate constants of the collisional deactivation and decomposition of energized ethylene were determined from the experimental data. The unimolecular decomposition theory has been applied to energized ethylene, and the results compared with the experimental rate constants.

In recent years, several studies of the Photolyses of simple alkanes, such as ethane,[1-5] propane,[6-9] *n*-butane,[9-11] and cyclobutane,[12] have been reported in respect of the primary processes. On the other hand, some studies of the photolyses of ethane[13,14] and propane[15] at 1470 Å have been undertaken in order to obtain insight into the nature of intermediate energized ethylene. These works have made it clear that two kinds of energized ethylene should be yielded through the molecular elimination of hydrogen from ethane or that of methane from propane; one undergoes unimolecular decomposition into acetylene and hydrogen, competing with collisional stabilization to ethylene, while the other can not decompose more. In the photolyses of ethane and propane, the following reaction schemes with respect to the ethylene- and acetylene-forming reactions have been proposed:[14,15]

$$C_2H_6 + h\nu \xrightarrow{\phi_{1a}} H_2 + C_2H_4^{**} \xrightarrow{k_d} C_2H_2 + H_2 \quad (1)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad \searrow^{k_s^M[M]} \quad (2)$$
$$\xrightarrow{\phi_{1b}} H_2 + C_2H_4^{*} \longrightarrow C_2H_4$$
$$\xrightarrow{\phi_2} 2H + C_2H_4 \quad (3)$$
$$C_3H_8 + h\nu \xrightarrow{\phi_{1a}} CH_4 + C_2H_4^{**} \xrightarrow{k_d} C_2H_2 + H_2 \quad (4)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad \searrow^{k_s^M[M]} \quad (5)$$
$$\xrightarrow{\phi_{1b}} CH_4 + C_2H_4^{*} \longrightarrow C_2H_4$$
$$\xrightarrow{\phi_2} H + CH_3 + C_2H_4 \quad (6)$$

The k_s^M/k_d values should depend on the energy retained in energized ethylene and the relative deactivation efficiencies of the deactivators. In order to determine the relative deactivation efficiency of energized ethylene, nitrogen was added as a common deactivator to a fixed amount of alkane and the change in the product distribution was studied by means of the change in the pressure of added nitrogen.

Recently, the nonequilibrium decomposition of ethylene has been discussed theoretically using a simple RRKM treatment, especially in the photolysis of 3-methyldiazirine.[16] In this paper, the average rate constants for the decomposition of ethylene produced in the photolyses of several alkanes will be calculated using the unimolecular decomposition theory. The experimental results are compared with the values obtained on a theoretical model for the relative deactivation rates, and a good agreement was found.

Experimental

The experimental procedures used in these experiments were almost the same as have been described previously.[15] A reaction cell with a magnetic circulator was used to prevent the accumulation of the products near the window. C_2H_6, C_3H_8, and *n*-C_4H_{10} were obtained from the Takachiho Chem. Ind. Co., and cyclo-C_4H_8 from Merck, Sharp, & Dohme, Ltd. Samples were purified by means of a gas chromatograph with a silica gel column. A 3 m activated charcoal column was used to detect ethylene and acetylene in a huge amount of unreacted ethane or propane. In the photolysis of *n*-C_4H_{10} or cyclo-C_4H_8, products were analyzed on a 2 m silica gel column with 5% squalane. In order to eliminate radical reactions, experiments were always carried out in the presence of nitric oxide (5—10% of alkanes).

Results and Discussion

A) Experimental Average Rate Constants. The reaction scheme previously established in the photolyses of ethane and propane,[14,15] in which the energized ethylene in two excited states is formed, may be similarly adopted in the photolyses of *n*-butane and cyclobutane:

$$n\text{-}C_4H_{10} + h\nu \xrightarrow{\phi_{1a}} C_2H_6 + C_2H_4^{**} \xrightarrow{k_d} C_2H_2 + H_2 \quad (7)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad \searrow^{k_s^M[M]} \quad (8)$$
$$\xrightarrow{\phi_{1b}} C_2H_6 + C_2H_4^{*} \longrightarrow C_2H_4$$
$$\xrightarrow{\phi_2} H + C_2H_5 + C_2H_4 \quad (\text{and/or } 2CH_3 + C_2H_4) \quad (9)$$

$$\text{cyclo-}C_4H_8 + h\nu \xrightarrow{\phi_{1a}} C_2H_4 + C_2H_4^{**} \xrightarrow{k_d} C_2H_2 + H_2$$
$$\xrightarrow{k_s^M[M]} \quad (10)$$
$$\xrightarrow{\phi_{1b}} C_2H_4 + C_2H_4^{*} \longrightarrow C_2H_4 \quad (11)$$

In the case of cyclobutane, the primary process of radical splitting is not observed.[17]

In the presence of nitrogen, the energized ethylene is deactivated upon collision with alkane itself or nitrogen. Thus, assuming the reaction schemes described above, and neglecting the internal scavenging reaction of hydrogen atoms by products at a very low conversion, the following equations are obtained for ethane, propane, and *n*-butane:

$$\frac{\phi(C_2H_4)}{\phi(C_2H_2)} = \frac{\phi_2+\phi_{1b}}{\phi_{1a}} + \frac{k_s^M}{k_d}\left(1+\frac{\phi_2+\phi_{1b}}{\phi_{1a}}\right)[M] + \frac{k_s^{N_2}}{k_d}\left(1+\frac{\phi_2+\phi_{1b}}{\phi_{1a}}\right)[N_2] \quad (12)$$

and for cyclo-C_4H_8:

$$\frac{\phi(C_2H_4)}{\phi(C_2H_2)} = \frac{\phi_{1a}+2\phi_{1b}}{\phi_{1a}} + \frac{2k_s^M}{k_d}\left(1+\frac{\phi_{1b}}{\phi_{1a}}\right)[M] + \frac{2k_s^{N_2}}{k_d}\left(1+\frac{\phi_{1b}}{\phi_{1a}}\right)[N_2] \quad (13)$$

where $\phi(C_2H_4)$ and $\phi(C_2H_2)$ are the relative yields of ethylene and acetylene respectively, and M is C_2H_6, C_3H_8, or *n*-C_4H_{10} for Eq. (12) and cyclo-C_4H_8 for Eq. (13).

Figure 1 shows the ratios of C_2H_4 to C_2H_2 in the photolyses of pure C_2H_6, C_3H_8, *n*-C_4H_{10}, and cyclo-C_4H_8 as a function of the alkane pressure. Also, varying amounts of nitrogen were added to a fixed amount of alkane (28 Torr), and the ratios were measured as a function of the N_2 pressure, as is shown in Fig. 2. These results show that Eqs. (12) and (13) are satisfied.

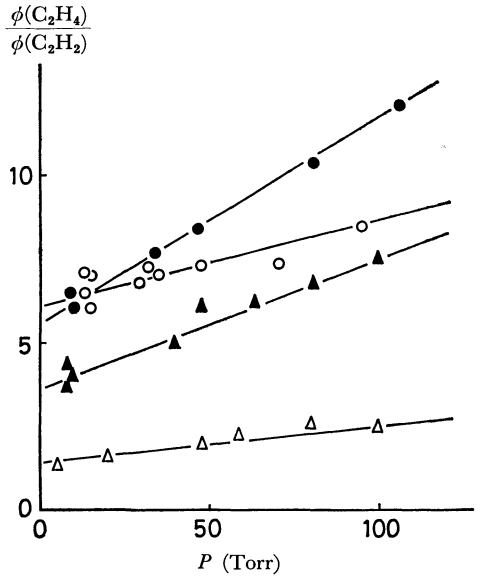

Fig. 1. Ethylene to acetylene ratio *vs.* alkane pressure. C_2H_6 (△), C_3H_8 (▲), *n*-C_4H_{10} (●), and cyclo-C_4H_8 (○)

17) K. Obi, Y. Ogata, H. Akimoto, and I. Tanaka, *J. Chem. Phys.*, in press.

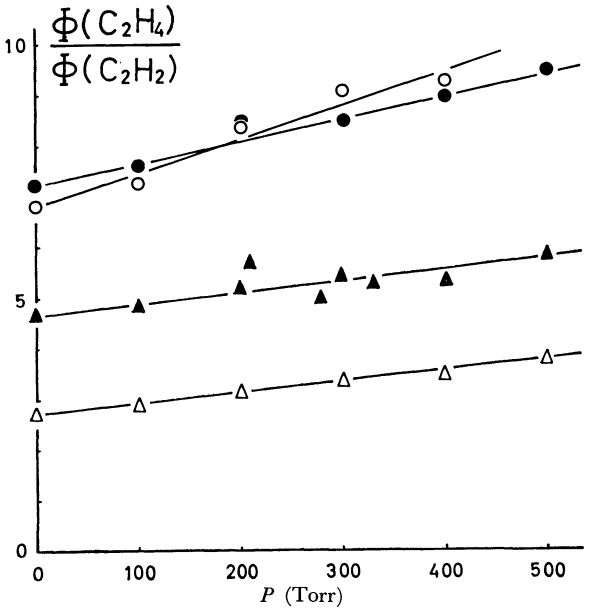

Fig. 2. Ethylene to acetylene ratio *vs.* added nitrogen pressure in the photolyses of alkanes. C_2H_6 (△), C_3H_8 (▲), *n*-C_4H_{10} (●), and cyclo-C_4H_8 (○)

The values of ϕ_2 were determined from the relative yields of methane and ethane in the photolyses of propane and *n*-butane respectively; this will be discussed elsewhere.[17] From the intercepts and the slopes of the plots in Figs. 1 and 2, the values of ϕ_{1a}, ϕ_{1b}, k_s^M/k_d and $k_s^{N_2}/k_d$ can be determined. The results are summarized in Table 1.

Table 1. The relative yields of the primary processes and the ratios of rate constants in the photolyses of alkanes at 1470 Å

	ϕ_{1a}	ϕ_{1b}	ϕ_2	k_s^M/k_d (Torr^{-1})	$k_s^{N_2}/k_d$ (Torr^{-1})
C_2H_6	0.39	0.46	0.15	0.0047	0.00088
C_3H_8	0.20	0.20	0.60	0.0089	0.00051
n-C_4H_{10}	0.15	0.19	0.66	0.0095	0.00064
cyclo-C_4H_8	0.28	0.72		0.0039	0.00097

Since the rate of deactivation would not be equal to the strong collision frequency, the rate constant of deactivation, k_s^M, is written as follows:

$$k_s^M = \frac{\beta Z^{C_2H_4-M}}{[M]} \quad (14)$$

where β is the collisional deactivation probability and $Z^{C_2H_4-M}$ is the collision frequency between the energized ethylene and the deactivator, M. The latter was calculated by means of the gas kinetic theory.

If the unit probability of energy transfer per collision is assumed for propane, the experimental values of k_s^M/k_d and $k_s^{N_2}/k_d$ and the collision frequencies yield values of β for the other deactivators. The values of β and k_s^M are summarized, together with the collision diameters, in Table 2.

The value of β is supposed to be affected by the nature and the degree of internal freedom of the deactivators. It can easily be understood that β increases with the complexity of the molecule from nitrogen to propane. A small decline from propane to *n*-butane would result from the experimental error. An unexpected lower value is found for cyclobutane. This lower value probably cames from the different character of the internal modes of vibrations compared with those of other paraffins or from the formation of energized ethylene with a different nature. The energized ethylene formed from chain alkanes results from the isomerization of the ethylidene produced in the primary processes, while that from cyclobutane is formed directly. The different nature of the energized ethylene can, therefore, be expected to be formed in the case of cyclobutane. If this is the case, it would be reasonable to obtain the lower value of β.

The experimental average rate constants for the decomposition of energized ethylene can be obtained by using the values of k_s^M (in Table 2) and k_s^M/k_d (in Table 1).

Table 2. The collisional diameters, the collisional deactivation probabilities and the rate constants of deactivation

	σ_{M-M} [a] (A)	β	k_s^M (Torr^{-1} sec^{-1})
N_2	3.85	0.063	8.03×10^5
C_2H_6	4.38	0.33	4.77×10^6
C_3H_8	5.24	1	1.58×10^7
n-C_4H_{10}	5.87	0.78	1.34×10^7
cyclo-C_4H_8	5.0	0.25	3.60×10^6
C_2H_4	4.07		

a) Values are taken from J. O. Hirschfelder, C. F. Curtis, and R. P. Bird, "Molecular Theory of Gases and Liquids," John Wiley & Sons, Inc., New York, N. Y. (1964), p. 1214, or are reasonable estimates based on data given in this reference.

B) Calculated Average Rate Constants. It was assumed in this treatment that the energized ethylene molecules decomposing to acetylene and hydrogen were composed of highly vibrational-excited ground-state ethylene.[13] The energized ethylene produced in the photolyses of alkanes may not be monoenergetic. If the energy distribution function of energized ethylene is expressed as $f(E)$, the average rate constant for the decomposition of ethylene is written as follows:[18]

$$k_d = \frac{\int \frac{k_E}{k_E+\omega} f(E)\,dE}{\int \frac{1}{k_E+\omega} f(E)\,dE} \tag{15}$$

where k_E is the specific rate constant for the decomposition of ethylene at energy E (which can be calculated from the RRKM theory), and ω is the rate of the deactivation of energized ethylene (assumed to be independent of the energy), which is equal to $k_s^M[M]$.

18) B. S. Rabinovitch and D. W. Setser, *Advan. Photochem.*, **3**, 1 (1964).

Calculations of the Specific Rate Constant, k_E: The specific rate constant for the decomposition of ethylene at energy E is given by the RRKM theory as follows:[19,20]

$$k_E = \frac{1}{h}\frac{\sigma}{\sigma^+}\left(\frac{I_A{}^+ I_B{}^+ I_C{}^+}{I_A I_B I_C}\right)^{1/2} \frac{\sum P(E-E_0)}{N(E)} \tag{16}$$

where σ and σ^+ are the symmetric numbers of the active molecule and the activated complex, I_i and $I_i{}^+$ are the moments of inertia of the active molecule and the activated complex respectively, and E_0 is the critical energy for the decomposition of ethylene to acetylene and hydrogen.

$N(E)$ is the energy level density for the active molecule at energy E. If there is no active internal free rotation for the active molecule, the expression for $N(E)$ is:

$$N(E) = \frac{(E+aE_z)^{s-1}}{\Gamma(s)\prod_i h\nu_i} \tag{17}$$

which is given by Rabinovitch and Setser,[18] where a is a correcting factor, s is the number of the degrees of freedom for the vibration, and E_z is the zero-point energy (*i.e.* $1/2\sum_i h\nu_i$).

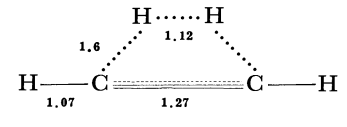
$\sum P(E-E_0)$ is the sum of the energy levels for the activated complex, and in the absence of an active internal free rotation for the activated complex, it is written as follows:[21]

$$\sum P(E-E_0) = \frac{(E-E_0+a^+E_z{}^+)^{s^+}}{\Gamma(s^++1)\prod_i h\nu_i{}^+} \tag{18}$$

Thus, the expression for k_E (*i.e.* Eq. (16)) is:

$$k_E = \frac{1}{h}\frac{\sigma}{\sigma^+}\left(\frac{I_A{}^+ I_B{}^+ I_C{}^+}{I_A I_B I_C}\right)^{1/2} \times \frac{\Gamma(s)\prod h\nu_i}{\Gamma(s^++1)\prod h\nu_i{}^+} \frac{(E-E_0+a^+E_z{}^+)^{s^+}}{(E+aE_z)^{s-1}} \tag{19}$$

In this paper, the rigid and semirigid models were considered as an activated complex. The structure of the activated complex was assumed to be as follows:



(unit; Å)

The fundamental frequencies and the moments of inertia for the active molecule and activated complexes are given in Table 3. The correlation between the fundamental frequencies is also shown. The frequencies of the fundamental modes of the activated complexes leading to the vibrational modes of products were estimated roughly from the average values of the initial and final systems. The vibrations leading to the free rotation in the final system were taken to have

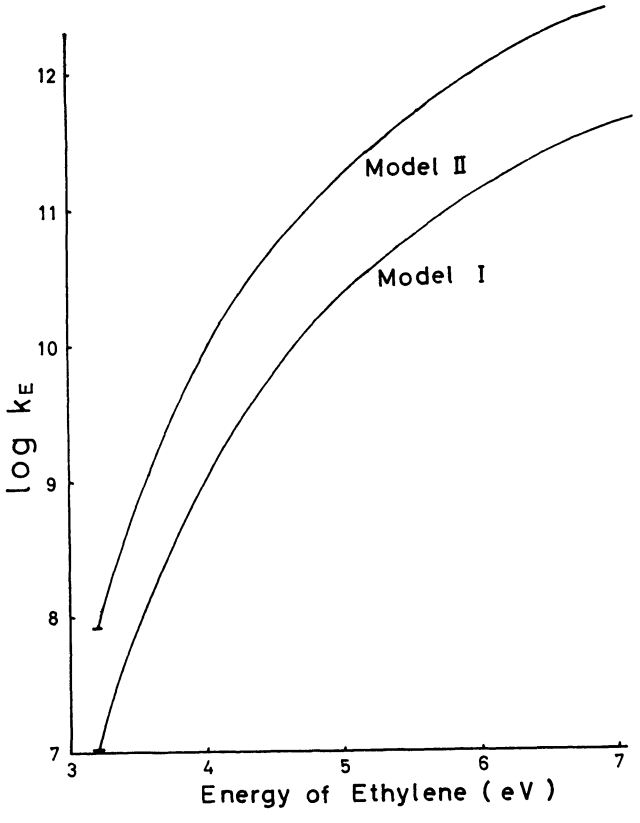

Fig. 3. Variation of the specific rate constant with energy of ethylene.

the same values in the initial system for the rigid model, but were lowered to half those values for the semirigid model.

E_0 was assumed to be 74 kcal/mol (3.2 eV).[22] The correcting factor has a value of 0.7—0.8 when the energy is small, rising to unity at a sufficiently high energy.[18] Since the decomposition reaction would occur near the critical energy, we assumed that $a=1$ and $a^+=0.8$.

Figure 3 shows the plots of log k_E as a function of energy E. The specific rate constant calculated using Model I is rather claser to that obtained by Kirk and Tschuikow-Roux[16] than that calculated using Model II. The difference in the specific rate constants is mainly due to the values of E_0 and the frequencies of the activated complex. These values make it possible to make an arbitrary choice, while there has not previously been any reliable value in the literature.

Calculation of the Energy Distribution Function, $f(E)$: It can be expected that the energized ethylene molecules produced in the photolyses of various alkanes will have energy spreads. However, at present there exists no *a priori* method to determine the energy distribution of the products of the reaction. A simple statistical distribution was used in this paper. If all the internal degrees of freedom for alkane are in an energy equilibrium everwhere on the reaction surface, one can determine the relative concentration of products with energy E simply from the phase-space consideration. The fraction of energized ethylene molecules which have an energy E out of the total available energy, E_t, can be written[23,24] as:

$$f(E)=\frac{N_{C_2H_4}(E)\cdot N_R(E_t-E)}{\sum N_{C_2H_4}(E_i)\cdot N_R(E_t-E_i)} \qquad (20)$$

where $N_{C_2H_4}(E)$ is the energy-level density of the ethylene part of alkane, $N_R(E_t-E)$ is that of the remaining degrees of freedom of alkane, and E_t is the total available energy. The energy-level densities were calculated by means of Eq. (17).

The total available energy is written as follows:

$$E_t = E(\text{h}\nu) + E(\text{thermal}) - \Delta H \qquad (21)$$

where $E(\text{h}\nu)$ is the photon energy of the exciting wavelength, which is equal to 8.4 eV at 1470 Å, E(thermal) is the thermal energy of the active molecule at the initial temperature (neglected in this paper), and ΔH is the heat of the reaction. The total available energies are 6.99, 7.57, 7.44, and 7.60 eV for ethane, propane, n-butane, and cyclobutane respectively.

The energy distribution function of the energized ethylene calculated from Eq. (20) is shown in Fig. 4(a), with ethane as the example. As C_2H_4* is thought to have a smaller energy than the critical energy,[16,25] the fraction of C_2H_4* can be estimated from Fig. 4(a). As may be seen in Table 4, the estimated values differ from the experimental values. Therefore, the correcting parameter, A, was introduced into Eq. (20) as follows:

$$f(E) = \frac{N_{C_2H_4}(E)N_R(E_t-A-E)}{\sum N_{C_2H_4}(E_i)N_R(E_t-A-E_i)} \qquad (22)$$

The correcting parameter was determined so that the fractions of C_2H_4* calculated from the energy distribution functions of Eq. (22) were nearly equal to the experimental fractions of C_2H_4*. The experimental fractions, the calculated fractions, and the correcting parameter are summarized in Table 4. The corrected energy distribution of energized ethylene is shown in Fig. 4(b), with ethane as the example.

The correcting parameter expresses the difference between the simple statistical distribution as calculated by Eq. (20), and the real energy distribution of energized ethylene. The correcting parameter is larger than zero in the photolysis of ethane, propane, or cyclobutane, while it is negative for n-butane. It is interpreted that energized ethylene would have a smaller vibrational energy than that to be expected from the simple statistical distribution for the positive A value, in other words, that the relative translation

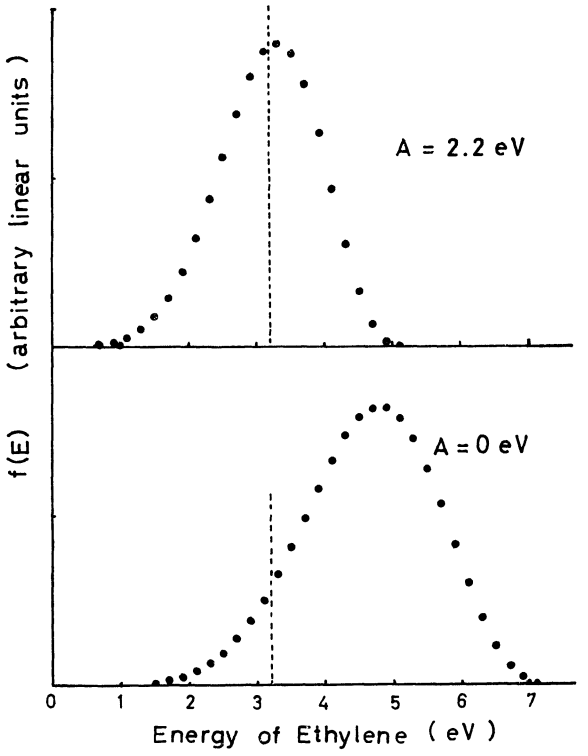

Fig. 4. Energy distributions of ethylene formed in the photolysis of ethane. (a) is calculated without a correcting parameter A; (b) is calculated with a correcting parameter A=2.2 eV.

or rotation of the products would take away a larger energy than that to be expected from Eq. (20). In particular, the correcting parameter is fairly large in the case of ethane. According to the Monte Carlo calculations,[26] this may be explained by the large energy transfer into the relative translational mode, since the hydrogen molecule in the products is quite light.

Calculation of the Average Rate Constants, k_d: A graphical integration procedure consists of approximating the energy distribution above E_0 to a histogram of regular energy intervals (ΔE=0.2 eV). The average rate constants for the decomposition can be calculated by means of Eq. (15) using the values of k_E, $f(E)$ and k_s^M. When the pressure of alkane is 100 Torr, the experimental rate constants and the calculated

ones for the two kinds of the activated complex are summarized in Table 4.

In spite of the fairly simple estimation of the vibrational frequencies of the activated complexes, the calculated rate constants show good agreement with the experimental ones. Although it is not possible to choose between the two model, these simple models yield satisfactory results.

Nuclear Quadrupole Resonance Study of Charge Transfer Complexes: Chloranil Complexes

Hideaki CHIHARA and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 4, 1971)

^{35}Cl nuclear quadrupole resonance frequencies were measured in electron donor-acceptor complexes between chloranil (tetrachloro-*p*-benzoquinone) and such donors as aromatic hydrocarbons, polyaromatics and amines. Some correlations between the resonance frequencies and infrared spectra were found and discussed in a qualitative way in terms of the π-electron transfer between donors and the chloranil molecule as acceptor. A Zeeman effect experiment was carried out on a single crystal of the 1:2 chloranil-8-hydroxyquinoline complex. The direction of one of the two non-equivalent C–Cl bonds obtained slightly differs from that determined by an X-ray diffraction study. Possible effects of the charge transfer on the resonance frequency and the asymmetry parameter are discussed according to the Mulliken theory of 'weak' charge-transfer complex. No simple relations could be found between the experimental resonance frequencies and the ionization potential of the donor. This suggests that crystal field effects are rather large in comparison with the effect of charge transfer interaction.

A great number of experimental works have been carried out on various charge transfer (CT) complexes. Most of the data on the electronic and infrared spectra, dipole moments, and electron spin resonances were successfully interpreted by Mulliken's theory of the electron donor-acceptor complexes.[1)]

Recently some questions have been raised about the role of the CT forces in the formation of the CT complexes.[2–4)] Moreover, the extent to which the CT forces contribute to the stability of the CT complexes has not been settled.[5)]

As the electric field gradient (EFG) at a nucleus is a quantity sensitive to a small intermolecular perturbation in a crystal,[6)] one should be able to obtain some information about the existence and/or the degree of charge transfer from the donor (D) to the acceptor (A), by applying the nuclear quadrupole resonance (NQR) method to the CT complexes in a coordinated way. Hooper found that the shift in the NQR frequencies upon the complex formation was so slight that it could reasonably be concluded that there was virtually no CT in the ground state.[7)] On the other hand, Read and others have found that the NQR frequencies both of Br_2 and of C_6H_5Br are influenced when they form a CT complex.[8)]

Gilson and O'Konski pointed out that an NQR frequency at a temperature other than 0°K can not be directly correlated with the CT force because the frequency changes with temperature.[9)] The controversial situation as to whether the charge transfer is in fact responsible for the formation of such complexes seems to arise from differences in the nature of interactions between a particular pair of the donor and the acceptor molecules.

The complexes studied are so called σ-π complexes and analysis of the NQR data may be complicated by a variety of donor-acceptor interactions. The π-π complexes, on the other hand, usually assume rather simple crystal structures in which D and A molecules stack alternately and can be treated as approximately rigid molecules.[10)] Thus information concerning CT interaction could be obtained from the NQR data of weak CT complexes containing one specified acceptor and various donors, since the crystal field effect is not expected to change seriously.

We chose chloranil (CA) as an acceptor and measured the NQR frequencies in its CT complexes. While our work was in progress several authors reported on

NQR studies on organic CT complexes.[11–13]

Semin and others found that in picryl chloride complexes the ^{35}Cl NQR frequencies can be correlated with the ionization potential of D's.[13]

This paper presents NQR frequencies of CA complexes with aromatic hydrocarbons and amines and gives discussion on the relation of NQR parameters to other quantities pertaining to the CT interactions in the light of Mulliken's CT theory. The result of the Zeeman effect experiment on CA-8-hydroxyquinoline complexes is compared with that of X-ray analysis.[14]

Experimental

Chloranil was purified by recrystallization from a benzene solution. The *N,N*-dimethylaniline complex was obtained by mixing solid chloranil and *N,N*-dimethylaniline directly under stirring followed by washing with ether. Bis-8-hydroxyquinolinatocopper(II) complex was prepared after the method in literature.[15] Other complexes were prepared by mixing the warm benzene solutions of the D- and A-components.

The ^{35}Cl NQR was observed at liquid nitrogen temperature with a Dean-type super-regenerative detector.[16] The resonace frequencies (ν_Q) were determined on an oscilloscope by use of a VHF signal generator (Yokogawa-Hewlett-Packard Model 608C) and a frequency counter (Takeda Riken TR-5578). The error in the frequency measurement was about 1 kHz except for the case of *p*-phenylenediamine complex for which the resonance line was very weak and broad, the uncertainty being about 5 kHz. The Zeeman effect study was carried out at liquid nitrogen temperature with Helmholtz coils and a goniometer designed for low temperature studies.[17] The zero-splitting loci for the ^{35}Cl reosnance lines were determined on an oscilloscope by rotating the sample and the magnetic field about mutually orthogonal axes. A magnetic field strength between 150 and 300 gauss was used.

Unsuccessful attempts were made to find the ^{35}Cl resonance lines in the frequency range 25—42 MHz in the chloranil complexes with the following donors: phenothiazine, *p*-anisidine, benzidine, tetramethyl-*p*-phenylenediamine, *p*-aminodiphenylamine, 1,8-diaminonaphthalene, and K^+-(chloranil)$^-$. Absence of the resonance lines is probably

due either to some imperfections in the complex or to the effect of the occlusion of the solvent. It is also possible that delocalized unpaired electrons prevent the observation of the NQR lines in the case of the radical salts.

Results and Discussion

The ^{35}Cl NQR frequencies of chloranil in the complexes together with those in the pure chloranil crystal are listed in Table 1. The resonance frequencies in CA-hexamethylbenzene complex slightly differ from those in literature.[18] The number of resonance lines in 8-hydroxyquinoline, hexamethylbenzene, and pyrene complexes coincides with that of the non-equivalent chlorine atoms in these complexes.[14,19,20]

It is to be noted that the resonance signals have been observed in freshly prepared specimens of *N,N,N',N'*-tetramethylbenzidine, 1,5-diaminonaphthalene and *p*-phenylenediamine complexes but they faded out in about a week. This phenomenon is perhaps due to decomposition of the complexes. On the other hand, in hexamethylbenzene, pyrene and perylene complexes the resonance lines became progressively sharper during several months. This might be due to the relaxation of the lattice strain produced in the preparation process.

In Table 1, C–Cl b_{2u} and C=O stretching frequencies are also recorded. They were measured for solid complexes in nujol mull and were assigned according to Prichard[21] and Yamada and Kawamori.[22]

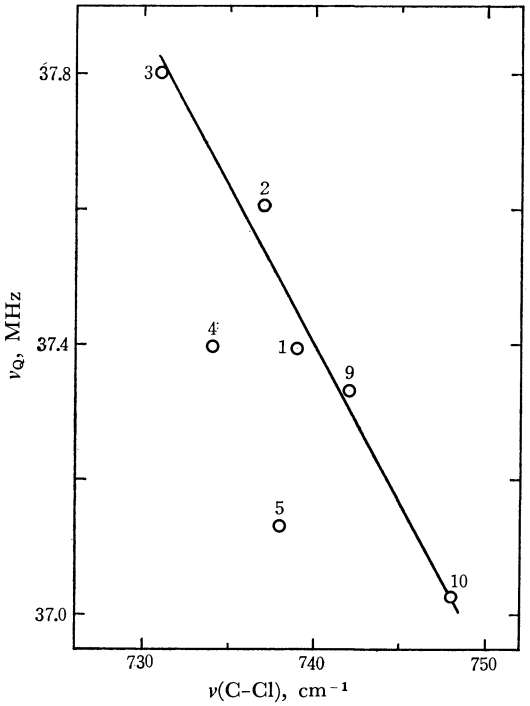

Fig. 1. The average nuclear quadrupole resonance frequency plotted against the C–Cl b_{2u} stretching frequency. For the numbers expressing the complexes cf. Table 1.

Correlation between the Quadrupole Resonance Frequencies and Infrared Spectra. In Figs. 1 and 2 the average NQR frequency ν_Q is plotted against the average C–Cl b_{2u} and C=O stretching frequencies for each complex, respectively. Although almost linear relationship between ν_Q and C–Cl b_{2u} mode holds in Fig. 1, the slope inclined in the opposite direction to that found experimentally[23] or predicted theoretically[24] for simple σ-bonded molecules. We see from Fig. 2 that ν_Q changes more rapidly than the C=O stretching frequency in the same direction.

These facts can be interpreted qualitatively as follows: The large inductive effect of an oxygen atom, making its π-electron density increase, increases the partial π-bond character between the carbon and the chlorine atoms in a free CA molecule to make the bond stronger than those in chlorobenzenes. Now, if a charge transfer complex is formed between CA and a molecule acting as an electron donor, the π-electron density on the CA molecule increases. This seems to make the two C=O bonds stronger,[25] whereas the π-bond character in the four C–Cl bonds decreases in

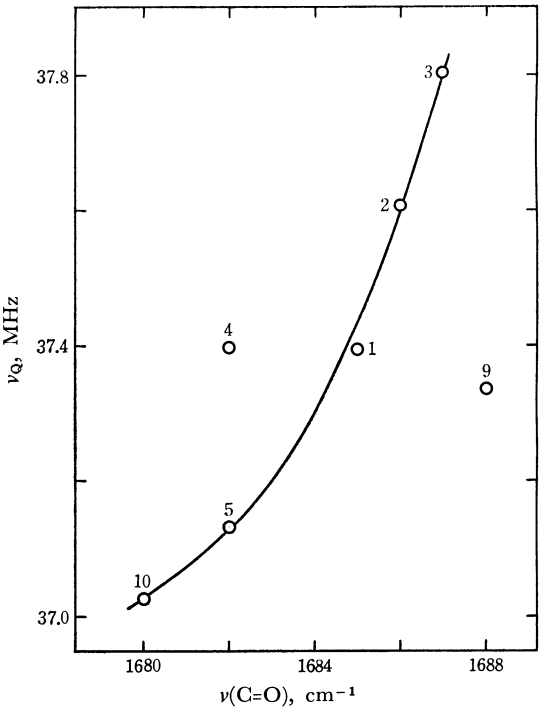

Fig. 2. The average nuclear quadrupole resonance frequency plotted against the C=O stretching frequency. For the numbers expressing the complexes, cf. Table 1.

24) A. B. Anderson, N. C. Handy, and R. G. Parr, *J. Chem. Phys.*, **50**, 3634 (1969).
25) In view of the very narrow range in which ν(C=O) changes its frequency, the trend appearing in Fig. 2 may not be significant enough for us to state that the charge transfer increases the C=O bond order (strength). In fact, ν(C=O) is displaced to a *lower* frequency by a radical ion formation (*cf.* Y. Matsunaga, *Can. J. Chem.*, **38**, 1172 (1960); Y. Iida, This Bulletin, **43**, 345 (1970); M. A. Slifkin, *Phys. Lett.*, **7**, 195 (1970)). Perhaps in the limit of weak complexes, the transfer of minute quantity of electronic charge might affect the C=O and C–Cl bonds in a different way from that in the case of strong complexes.

comparison with that in the bonds in a free CA molecule. Therefore, ν(C=O) shifts to a higher frequency and ν(C–Cl) to a lower with an increase in the effective number of π-electrons on CA due to the complex formation. ν_Q is expected to increase in such a situation as will be discussed in the next section. Then it seems reasonable to consider that the correlations between ν_Q and infrared frequencies in Figs. 1 and 2 originate from the charge transfer.

Predictions by Theory of Charge Transfer and Comparison with Experiments. The ground state wave function of a CT complex may be given after Mulliken[1b] by

$$\Psi_N = a\psi_0 + b\psi_1 \quad (1)$$

where ψ_0 and ψ_1 are the wave functions for the no-bond and the CT structures, respectively, and both are assumed to have been normalized.

We are interested in the electric field gradient (EFG) q at a chlorine nucleus in the acceptor molecule, which is given by

$$q = \sum_i e_i \int \Psi_N (3\cos^2\theta_i - 1)/r_i^3) \Psi_N d\tau + q_{ex} \quad (2)$$

In this equation the resonant ^{35}Cl nucleus is assumed to be at the origin; the sum represents the contributions to q from the nuclear or the electronic charges e_i at the position r_i and θ_i in the molecule. The summation in Eq. (2) must be carried out over all the nuclei and the electrons in the molecule. The second term q_{ex} is the EFG which comes from all molecules in the crystal except for the acceptor under consideration. Substituting Eq. (1) into Eq. (2), q is written as

$$q = a^2 q_0 + 2abq' + b^2 q_{CT} + q_{ex} \quad (3)$$

where

$$q_0 = \sum_i e_i \int \psi_0 (3\cos^2\theta_i - 1)/(r_i^3)\psi_0 d\tau$$

$$q' = \sum_i e_i \int \psi_0 (3\cos^2\theta_i - 1)/(r_i^3)\psi_1 d\tau$$

and

$$q_{CT} = \sum_i e_i \int \psi_1 (3\cos^2\theta_i - 1)/(r_i^3)\psi_1 d\tau$$

q_0 is the EFG in the no-bond structure and is thought to be approximately equal to that in a free acceptor molecule. q' is the EFG connecting the no-bond and the CT states. It will be roughly proportional to the overlap integral between the donor and the acceptor $S = \int \psi_0 \psi_1 d\tau$. q_{CT} represents the EFG in the CT state where one π-electron has been transfered from the donor to the acceptor.

By using the normalization condition on Ψ_N,

$$a^2 + 2abS + b^2 = 1$$

Eq. (3) can be rewritten as follows.

$$q = q_0 + 2ab(q' - Sq_0) + b^2(q_{CT} - q_0) + q_{ex} \quad (4)$$

If it is assumed that the second term on the right hand side of Eq. (4) is small in comparison with the other terms, and that q_{ex} varies only slightly from one donor to another, we can expect that the EFG is linearly dependent on the amount of contribution of the CT state b^2 to the ground state of the complex. Then it follows that

$$q \fallingdotseq q_0' + b^2 \Delta q_{CT} \quad (5)$$

where $q_0' = q_0 + q_{ex}$ and $\Delta q_{CT} = q_{CT} - q_0$ or in terms or the resonance frequencies

$$\nu_Q \fallingdotseq \nu_0' + b^2 \Delta \nu_{CT} \quad (6)$$

The contribution of the CT structure b^2 can also be related to the ionization potential I_p of a donor through the formula

$$b/a \fallingdotseq cS/(I_p - A) \quad (7)$$

where c and A are constants. Since $a \approx 1$ for a weak complex, it follows that

$$\nu_Q \fallingdotseq \nu_0' + \Delta \nu_{CT}(cS)^2/(I_p - A)^2 \quad (8)$$

A comparison of the experimental results with theoretical predictions is a very crucial matter.

Equation (6) states that ν_Q should increase when chloranil forms a CT complex. However, Table 1 shows that the resonance frequencies for some of the complexes are lower than the frequency for chloranil itself, whereas those for other complexes are higher. This fact may be an indication of the relieved strain of chloranil molecules upon complex formation. Therefore comparison among a family of donors seems more practical. Hydrocarbon donors give higher ν_Q than do the nitrogen- or oxygen-containing donors. Reliable values of b^2 have not been obtained except for hexamethylbenzene[26] and durene[27] complexes which b^2 of the order of 0.04 has been assigned.

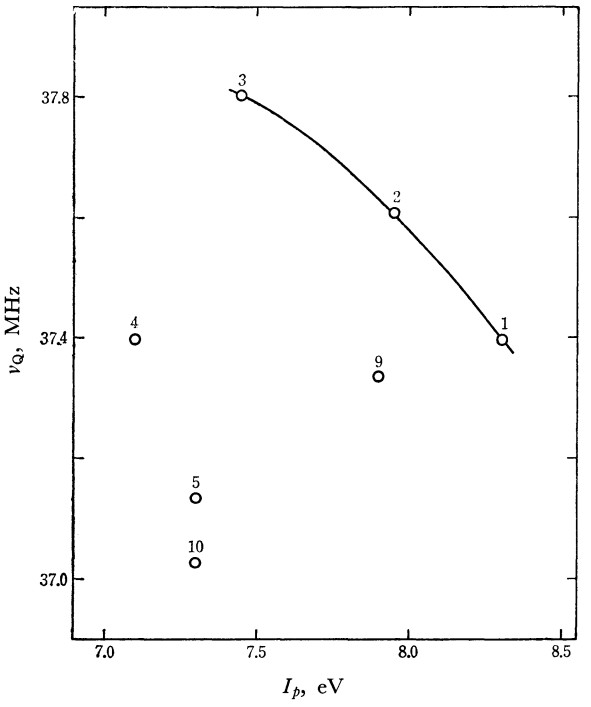

Fig. 3. The average nuclear quadrupole resonance frequency ν_Q *vs.* the ionization potential of the complex.
For the numbers expressing the complexes cf. Table 1.

26) G. Briegleb, J. Czekalla, and G. Reuss, *Z. Phys. Chem.*, **30**, 333 (1961).
27) G. Briegleb and J. Czekalla, *Angew. Chem.*, **72**, 401 (1960).

Correlation of ν_Q with I_p or the CT absorption bands is also very poor as seen in Fig. 3.

The reason for the poor correlation between the quadrupole resonance and the available CT properties is probably twofold. One is that for weak complexes the crystalline field effect (q_{ex}) is often as large as the CT effect. This is shown by the fact that *N,N*-dimethylaniline, for example, gives three resonance lines between 36.9 and 37.4 MHz. The other reason would be that the charge transfer is mainly responsible for the appearance of the so-called CT band but may not be so for the intermolecular interaction. In other words the field of force in which the acceptor molecule is placed consists not merely of the charge transfer interaction but also of other contributions. One evidence of the latter is found in the good relationship between ν_Q and vibrational frequencies as depicted in Figs. 1 and 2.

Zeeman Effect on Chloranil-8-Hydroxyquinoline Complex (1 : 2). Electrons transferred from the donor molecule will enter a π-orbital of the acceptor molecule which will then migrate to some extent to the *p*-orbital of the chlorine atom. Such an effect will cause a change in the asymmetry parameter of the EFG. We have grown a large single crystal of CA-8-hydroxy quinoline complex and carried out a Zeeman effect experiment of the ^{35}Cl resonance lines at room temperature. This crystal belongs to the triclinic space group $P\bar{1}$ and contains one formula unit in the unit cell: There are two crystallographically non-equivalent chlorine atoms and only one equivalent direction exists for each C-Cl bond.[14]

The zero-splitting loci were determined for the two ^{35}Cl lines, ν_1 and ν_2. The directions of the principal axes (X, Y, Z) of the EFG tensor in the laboratory-fixed coordinate system were determined and were transformed to X_c, Y_c, and Z_c in the crystal-fixed coordinate system. Calculation of the directions of X,Y, and Z was carried out by the least squares method programmed for the NEAC-2200 digital computer.

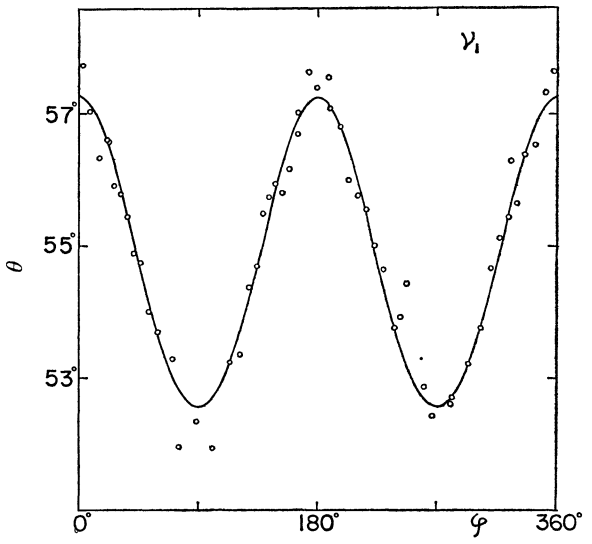

Fig. 4. The zero-splitting locus of ν_1 in 8-hydroxyquinoline complex in the principal axes system of the electric field gradient tensor.

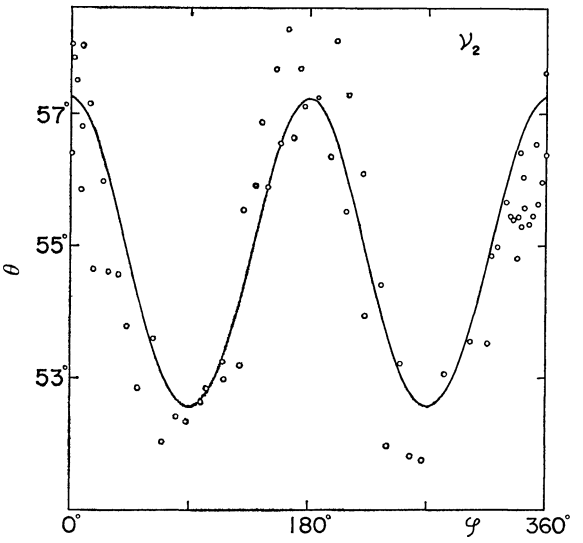

Fig. 5. The zero-splitting locus of ν_2 in 8-hydroxyquinoline complex in the principal axes system of the electric field gradient tensor.

The numbers of the data employed were 55 and 70 for ν_1 and ν_2, respectively.

The results are shown in Figs. 4 and 5. In these figures θ and φ express the direction of the zero splitting locus in the principal axes system of the EFG tensor. The solid curve in each figure corresponds to the theoretical relation[28]

$$\sin^2\theta = 2/(3-\eta\cos^2\varphi) \tag{9}$$

where η was chosen so as to obtain the best fit between experimental data and the theoretical curve.

The direction cosines in the crystal fixed coordinate system are given in Table 2, where the X-axes of the EFG are taken to be perpendicular to the quinone ring. The direction cosines of the Z-axes of the EFG's can be compared with the C-Cl bond directions determined by X-ray analysis.[14] Although the principal Z-axis of the EFG for ν_2 coincides with the direction of the C_2-Cl_{12} bond,[29] that for ν_1 differs from the direction of the C_1-Cl_{11} bond by about 17°. The reason for this discrepancy is not obvious.

η is thus given, in terms of the number of unbalanced *p*-electrons U_X, Y_Y, and U_Z, by the formula[6a]

$$\eta = (3/2)(U_X - U_Y)q_{at}/q \tag{10}$$

where q_{at} is the EFG in an atomic chlorine. If it is assumed that the charge transfer is accompanied only by an increase in the π-electron density of the acceptor molecule, U_Y can be put equal to U_Y^0 corresponding to the free acceptor molecule whereas U_X can be expressed as $U_X = U_X + \delta$, where δ expresses the increase in the excess electrons in the p_X- or the π-orbital of the chlorine. Then, Eq. (10) can be written as

$$\eta = (3/2)(U_X^\circ - U_Y^\circ)q_{at}/q + (3/2)\delta q_{at}/q \tag{11}$$
$$\fallingdotseq \eta_0 + (3/2)\delta q_{at}/q$$

Table 2. Nuclear quadrupole coupling constants, asymmetry parameters, and the direction cosines of the principal Z-axes of the electric field gradient tensors

The direction cosines are compared with the direction of the C-Cl bond determined by X-ray analysis (Ref. 14).

Bond	Method	R (A)	e^2Qq/h (MHz)	η %	X_c (a^*)	Y_c (b)	Z_c (c')
C_{11}-Cl_1	NQR	—	74.191	17.3	−0.5182	−0.5251	0.6752
	X-ray	1.77	—	—	−0.5680	−0.5448	0.5556
C_{12}-Cl_2	NQR	—	74.416	17.2	0.5420	−0.5591	−0.6274
	X-ray	1.70	—	—	0.5504	−0.5062	−0.6639

	NQR	X-ray
Angle between Cl_1 σ bond and Cl_2 σ bond	65°43′	66°04′
Cl_1 π bond and Cl_2 π bond	2°25′	—

where η_0 is the asymmetry parameter in the free acceptor.

On the other hand, the EFG q is expressed by using the unbalanced electron numbers as

$$q = \left(U_Z - \frac{(U_X + U_Y)}{2}\right)q_{at} + q_{ex}$$
$$= q_0' - (\delta/2)q_{at}$$

By comparing this equation with Eq. (5), we get

$$(\delta/2)q_{at} \fallingdotseq -b^2\Delta q_{CT}$$

and therefore

$$\eta \fallingdotseq \eta_0 - 3b^2\Delta q_{CT}/q$$

Since $\Delta q_{CT} > 0$, η should decrease with an increase in CT. As shown in Table 3, η's in CA-8-hydroxy quinoline complex are significantly small in comparison with those in pure chloranil crystal for which η is about 0.21:[30] and this is consistent qualitatively with Eq. (12). However a quantitative comparison does not seem of any value for reason given in the preceding Section.

Thanks are due to Profs. Haruo Kuroda and Yoshihiko Saito, University of Tokyo, for their valuable discussions. We are also indebted to Prof. Haruka Yamada, Kwansei Gakuin University, for kindly showing us the manuscript of her paper prior to publication.

Correlation between the Transition Temperature and the Rotational Potential Barrier in Plastic Crystals

Hideaki CHIHARA and Yoshikata KOGA*

Department of Chemistry, Osaka University, Toyonaka

* *Department of Chemistry, University of British Columbia, Vancouver 8, B. C., Canada*

(Received May 10, 1971)

A linear retationship was found between the transition temperature of plastic crystals and potential energy barrier hindering molecular rotation determined below or above the transition point, with the slope of the line 7.5 R and 4.1 R, respectively, where R is the gas constant. Consideration of the distribution of molecules between the librational and the rotational states showed that the transition starts to occur cooperatively when the fraction of the rotating molecules reaches a value of 1/60 and concludes with a value of 1/3. The model gives the entropies of transition which reasonably agree with the observed values.

Many of the phase transitions in molecular solids are the result of a further acquisition of the degree or degrees of freedom of motion at the transition point. In the case of globular molecules, the additional degrees of freedom are considered to be of rotational or orientational origin.[1] In fact, a previous paper[2] demonstrated an approximately linear relationship between the transition temperature and the height of the potential barrier hindering the molecular rotation in a few molecular crystals of this type. There, the values of the hindering potential was derived from the entropy evaluation and its procedure was subject to an assumption based on the corresponding state principle.

Meanwhile, more reliable values of the hindering potential barrier height have been accumulated by application of the nuclear magnetic resonance techniques; In particular the measurements of the spin-lattice relaxation time by the pulsed NMR methods have proved to give the more meaningful values for such a quantity than does the indirect thermodynamic reasoning.

In the present paper, we will put forward a revised relationship between the transition temperature and the potential barrier hindering the molecular rotation in solids and also discuss some of its ramifications which will help to understand the nature of the cooperative phenomena.

Potential Energy Barrier and Fraction of Rotating Molecules. Table 1 is a compilation of the experimental values of the barrier height for a number of plastic crystals. Where available, the value for both the high temperature phase and the low temperature phase are given. These barrier values are plotted against the transition temperatures in Fig. 1. Inert gas crystals, Ar and Kr, are also listed at the bottom of the Table, which are the plastic crystals that have no transition points; Their values refer to the triple points and the heats of vacancy formation.[3] The significance of these two points will be discussed in a later Section.

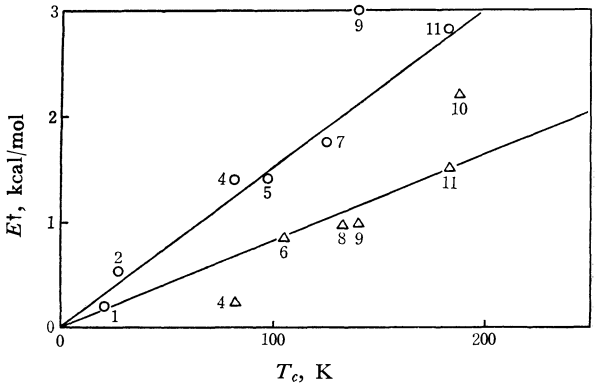

Fig. 1. Linear relationship between the transition temperature (T_c) and the potential energy barrier ($E^\dagger$) hindering molecular rotation: ○ Phase B, △ phase A. Numbers in the figure correspond to those given in Table 1.

It is seem from Fig. 1 that the points corresponding to the high-temperature phase (phase A) and those corresponding to the low-temperature phase (phase B) lie on the two separate straight lines. Both lines pass through the origin as pointed out earlier[2] and the lines are represented by the formula

$$E^\dagger = \alpha R T_c \qquad \begin{matrix} \alpha = 4.1 \text{ for phase A} \\ \alpha = 7.5 \text{ for phase B} \end{matrix} \qquad (1)$$

These relationships may be interpreted as showing that the phase transition takes place when the average thermal energy reaches a certain fraction of the potential barrier and the factor α at which it occurs does not depend on a particular compound.[4] However α depends on the direction in which the transition point is approached and there is a jump in its value at T_c. The jump occurs in a cooperative way but we shall focus our attention on its difference between the two

phases. Although the cooperative effect does not abruptly come into play at T_c, the transitions under consideration are very close to those of the first order. Therefore, we may extrapolate the properties of the phases A and B to T_c to examine what triggers the cooperative transition.

To evaluate the significance of Eq. (1), we shall take a simplified classical picture. It will be assumed that a crystal consists of two different species of molecules, 'rotational' and 'librational' (abbreviated as R and L, respectively), and that a quasi-chemical equilibrium

$$\mathrm{L} \rightleftarrows \mathrm{R} \tag{2}$$

is established between the two species, with the Helmholtz energy difference $A^\dagger$ given by

$$A^\dagger = E^\dagger - TS^\dagger . \tag{3}$$

$E^\dagger$ will be taken as the potential barrier height and

$$S^\dagger = S_\mathrm{R} - S_\mathrm{L} \tag{4}$$

The transition may now be looked upon as an abrupt displacement of the equilibrium (2) toward the right as T_c is approached from Phase B. This may be achieved by an increase in $S^\dagger$ and/or a decrease in $E^\dagger$ in a cooperative way.

In the present treatment, S_R was calculated in a conventional way from the knowledge of the geometry of molecules and S_L was obtained in the harmonic oscillator approximation from the appropriate values of $E^\dagger$ and the appropriate number of minima ($=4$) of the potential function for both Phases A and B.

Such calculations yielded $S^\dagger/R=3.2\pm0.6$, except for methanes, with a surprisingly small scatter from compound to compound and between the two phases. Therefore, the transitions are associated with a decrease in $E^\dagger$ (as shown in Eq. (1)) rather than with an increase in $S^\dagger$.

The fraction of rotating molecules or the equilibrium constant of the reaction (2) may be written as

$$N_\mathrm{R}/N_\mathrm{L} = \exp(-A^\dagger/\boldsymbol{R}T) = \exp(S^\dagger/\boldsymbol{R})\exp(-E^\dagger/\boldsymbol{R}T) \tag{5}$$

where N_R and N_L denote the number of 'rotational' and 'librational' molecules. Thus at $T=T_c$, Eq. (5) reads

$$N_\mathrm{R}{}^\mathrm{B}/N_\mathrm{L}{}^\mathrm{B} = (30\pm20)\exp(-7.5) \fallingdotseq 1/60 \tag{6}$$

for Phase B and

$$N_\mathrm{R}{}^\mathrm{A}/N_\mathrm{L}{}^\mathrm{A} = (30\pm20)\exp(-4.1) \fallingdotseq 1/2 \tag{7}$$

for Phase A.

This means that only one molecule out of 60 is 'rotating' in phase B, whereas as many as one-third of the molecules are in the 'rotational' state in Phase A at the transition temperature, *i.e.* the transition would be triggered by the fraction of molecules that amounts to 1.7% of the total or one-quarter $(1/60)^{1/3}$ of a one-dimensional extention of the molecular array.

Entropy of Transition

We shall now attempt to calculate the entropy of transition by use of Eqs. (6) and (7).

The entropy of either phase S is given by

$$S = \boldsymbol{k}T\left(\frac{\partial \ln Q}{\partial T}\right)_{V,N} + \boldsymbol{k}\ln Q \tag{8}$$

where Q is the partition function of the phase, which may be written, aside from the configurational part, as

$$Q = q^N \tag{9}$$

q being the molecular partition function,

$$q = \sum_{i=1}^{\infty} \exp(-E_i/\boldsymbol{k}T) = \sum_{i}^{E_i \le E^\dagger} \exp(-E_i/\boldsymbol{k}T) + \sum_{i}^{E_i > E^\dagger} \exp(-E_i/\boldsymbol{k}T) \tag{10}$$

the first sum in Eq. (8) corresponds to the 'librational' state and the second corresponds to the 'rotational' state. If q_L and q_R denote the corresponding partition functions, Eq. (8) can be rewritten as

$$q \fallingdotseq q_\mathrm{L} + [\exp(-E^\dagger/\boldsymbol{k}T)]q_\mathrm{R}. \tag{11}$$

The entropy of the molecules in the two states is given by

$$S_\mathrm{L} = \boldsymbol{R}T\left(\frac{\partial \ln q_\mathrm{L}}{\partial T}\right)_{V,N} + \boldsymbol{R}\ln q_\mathrm{L} \tag{12}$$

and

$$S_\mathrm{R} = \boldsymbol{R}T\left(\frac{\partial \ln q_\mathrm{R}}{\partial T}\right)_{V,N} + \boldsymbol{R}\ln q_\mathrm{R} \tag{13}$$

Therefore,

$$\frac{N_\mathrm{L}S_\mathrm{L}+N_\mathrm{R}S_\mathrm{R}}{N} = \frac{\boldsymbol{R}T}{N}\left[N_\mathrm{L}\left(\frac{\partial \ln q_\mathrm{L}}{\partial T}\right)_{V,N} + N_\mathrm{R}\left(\frac{\partial \ln q_\mathrm{R}}{\partial T}\right)_{V,N}\right] + \frac{\boldsymbol{R}}{N}N_\mathrm{L}\ln q_\mathrm{L} + N_\mathrm{R}\ln q_\mathrm{R}) \tag{14}$$

Now, since

$$\frac{q_\mathrm{L}}{q} = \frac{N_\mathrm{L}}{N} \quad \text{and} \quad \frac{q_\mathrm{R}\exp(-E^\dagger/\boldsymbol{k}T)}{q} = \frac{N_\mathrm{R}}{N} \tag{15}$$

we have

$$\begin{aligned} \ln q_\mathrm{L} &= \ln\frac{N_\mathrm{L}}{N} + \ln q \\ \ln q_\mathrm{R} &= \ln\frac{N_\mathrm{R}}{N} + \ln q + E^\dagger/\boldsymbol{k}T \end{aligned} \tag{16}$$

From Eqs. (8), (9), (14), and (16), the total entropy S is given by

$$S = \frac{N_\mathrm{L}}{N}S_\mathrm{L} + \frac{N_\mathrm{R}}{N}S_\mathrm{R} - \boldsymbol{R}\left(\frac{N_\mathrm{L}}{N}\ln\frac{N_\mathrm{L}}{N} + \frac{N_\mathrm{R}}{N}\ln\frac{N_\mathrm{R}}{N}\right) \tag{17}$$

The entropy of transition ΔS_c is defined by

$$\Delta S_c = S^\mathrm{A} - S^\mathrm{B} \tag{18}$$

where S^A and S^B desote the total entropies of the Phases A and B. $N_\mathrm{R}/N_\mathrm{L}$ values are given by Eqs. (6) and (7). Therefore the entropy of transition may be obtained simply from the knowledge of T_c and the geometry of molecules. The result is given in the last column of Table 1. General agreement with the observed entropy changes is satisfactory except for CH_4 and CD_4.

Discussion

It has been shown that the fraction of rotating molecules changes in a cooperative way from 1/61 in phase B to 1/3 in phase A at least in a class of compounds that undergoes 'rotational' transition. Further experimental evidence may be required to establish this as an empirical rule but it does seem that the intermolecular interaction of the cooperative nature extends as far as the second neighbors in phase B where the crystal field is rather 'hard,' whereas it extends only to the nearest neighbors in phase A in which the crystal field is rather 'soft' because of the large kinetic energy.

It is interesting in this connection to note that the fusion of argon and krypton is governed by the same principle; *i.e.* melting occurs when the fraction of vacancies reaches the same number 1/61, This equality in the number, however, may only be a fortuitous one in the sense that $S^{\dagger}/R$ for both cases happened to be the same and this may have brought about the equality in $E^{\dagger}/RT_c$. Therefore it seems extremely interesting to analyze various kind of phase changes in terms of such two-species model as is developed in the present treatment.

The molecular model adopted here is a crude one which neglects the detailed configurational considerations and deals with a uniform phase as a mixture of the two molecular species, nevertheless the good agreement of the calculated and observed entropies of transition suggests that it should serve a useful picture of such solids. It is certainly more realistic than interpreting the entropy in terms of increased uniform orientational degrees in phase A.[5]

The authors would like to thank Dr. P. S. Allen (University of Nottingham) for stimulating discussions.

ESR Studies of Methyl Radicals Stabilized on Silica-gel Surfaces

Shozo KUBOTA, Masamoto IWAIZUMI, and Taro ISOBE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-nichome, Sendai

(Received May 14, 1971)

The methyl radicals produced on silica-gel surfaces by the photolysis of methyl iodide or methane have been investigated by ESR. When the silica gel is preheated at high temperatures (above *ca.* 300°C), two methyl radicals which have abnormally small hfs constants are trapped on the surfaces. In the case of the photolysis of methyl iodide, these two radicals disappear by continuing uv-irradiation, and instead an ordinary type of methyl radical is produced. The former two radicals have nearly isotropic *g*-values, and these values are approximately equal to that of a free electron and are considered to have a non-planar structure. The adsorption sites for these radicals were estimated to be siloxane groups. On the other hand, when the silica gel is preheated at low temperatures (below *ca.* 300°C) the methyl radicals produced have hfs constants of the same magnitude as that of the ordinary type of methyl radical, but each proton line of the radicals is accompanied by four satellite lines. The outer satellite lines have been confirmed by measurements of the X- and K-band spectra to be a concurrent spin-flip transition of an odd electron and a nearby proton of the silica-gel surface. The models of the adsorption state of the radicals are considered.

Since Kazanskii's work,[1] several interesting investigations[2-7] have been reported on the ESR of methyl radicals stabilized on solid surfaces. As the methyl radical shows a well-resolved hyperfine structure, even in the adsorbed state, it is possible to detect a small perturbation of the methyl radical caused by the interaction with solid surfaces. The studies of the methyl radical, therefore, seem of interest and seem to be useful from the point of view of studies of the nature of radical-solid surface interaction and also studies of the surface structure.

In this work, methyl radicals trapped on silica-gel surfaces were studied by ESR. The methyl radicals on the silica-gel surfaces show characteristics similar in several points to those trapped on porous Vycor glass.[6,7] In this paper, the characteristics of the ESR of the radicals and of radical-surface interactions observed in silica-gel systems pretreated at different temperatures, the effect of the irradiation time on radical formation by the photolysis of methyl iodide, and the satellite lines in the ESR will be presented. Some of our results may be useful in understanding problems of the methyl radicals in the porous Vycor glass system already reported.

Experimental

Methyl radicals were produced by the photolysis of methyl iodide or methane adsorbed on silica-gel surfaces at the temperature of liquid nitrogen. The methyl iodide was ob-

tained from the Koso Chemical Co., Ltd., and purified according to the procedure used by Cowley and Partington.[8] The purified methyl iodide was degassed in a vacuum line and stored over P_2O_5. The methane was obtained from the Takachiho Co. and was used after drying over P_2O_5. The silica gel obtained from the Kanto Chemical Co., Ltd., (60—80 mesh for chromatography) was heated in oxygen at 300°C to remove organic impurities and then stored in a glass bottle. Prior to the adsorption of methyl iodide or methane, this silica gel was heated *in vacuo* to dehydrate the surface. To see the effect of the dehydration on the methyl-radical formation, the silica gel was heated at various temperatures from room temperature to 700°C. After the methyl iodide or methane had adsorbed on the silica gels, the resulting samples were irradiated with the light of a mercury lamp. An Ushio 6-w low-pressure mercury lamp and a Hitachi ultra-high pressure mercury lamp were used as the light sources. The measurements of ESR spectra were carried out with a Hitachi 771 X-band spectrometer. For the measurements of the satellite lines, a Hitachi MES 4001 K-band spectrometer was used as well as the X-band spectrometer. The magnetic field was calibrated with an aqueous solution of potassium nitrosodisulfonate and DPPH powder for the determination of the *g*-values.

Results and Discussion

The Methyl Radicals Stabilized on Silica Gel Preheated at High Temperatures. The ESR spectra for the methyl radicals trapped on the silica-gel surfaces depend on the dehydration temperature of the silica gel. Figure 1 shows the ESR spectra obtained from the methyl radicals produced by the photolysis of methyl iodide when the silica gel was preheated at 600°C *in vacuo* for 5 hr. The spectra obviously show marked changes with the uv-irradiation time. In an early stage of the irradiation, two sets of quartet splittings due to two methyl radicals, $Me(a_1)$ and $Me(a_2)$, are observed. The intensities of these two methyl radicals increase with the progress of the irradiation until about 90 sec.[9] However, upon further irradiation the intensities of the radicals begin to decrease and another quartet ($Me(n_1)$) appears. The intensity of this latter quartet increases as the first two decrease with the continuation of the photolysis, until only the latter radical, $Me(n_1)$, remains. For heating the samples, the former two methyl radicals, $Me(a_1)$ and $Me(a_2)$, are very unstable, but the latter one, $Me(n_1)$, is stable and can be observed even at room temperature. The radical existing at the final stage of irradiation, $Me(n_1)$, has about the same hfs constant and amplitude distribution for the quartet as those already reported by Kazanskii *et al.*[1] On the other hand, $Me(a_1)$ and $Me(a_2)$ radicals have abnormally small hfs constants compared to that of the ordinary methyl radical and have *g*-values close to that of a free electron (see Table 1). The line broadening for the quartets of these methyl radicals, $Me(a_1)$ and $Me(a_2)$, are approximately symmetric

	Hfs constants (in gauss)	*g*-values
$Me(a_1)$	20.7	2.0024
$Me(a_2)$	21.2	2.0023
$Me(n_1)$	23.0	2.0027

to the center of the spectrum, showing a marked contrast to the line-broadening effect in the $Me(n_1)$ radical or the previously-reported normal methyl radicals, which reveal unsymmetric line broadening to the center of the spectrum (see Fig. 2).

Recently Fujimoto,[3] and also Shimamoto,[6] found in the porous Vycor glass system a methyl radical with an abnormally small hfs constant. Shimamoto *et al.* pointed out that this new type of methyl radical shows an inverse line-broadening effect compared to that of the normal methyl radical; that is, in the normal methyl radical the low-field lines are broader than the high-field lines, but in the new methyl radical the higher-field lines are broader than the low-field lines. In the present case, if a large amplitude of

9) The time is not strict because it changes somewhat with sample.

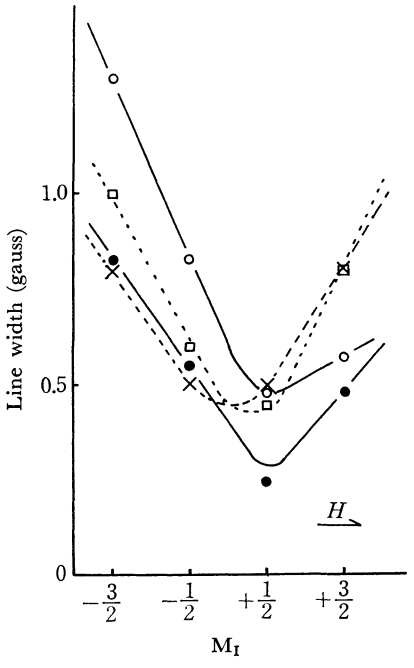

Fig. 2. Line width as a function of M_I at 77°K. X: $Me(a_1)$, □: $Me(a_2)$, ●: $Me(n_1)$, ○: Main proton lines for $Me(n_2)$. The line widths for $Me(a_1)$ and $Me(a_2)$ are evaluated by computer simulation.

field modulation is used for the measurements of ESR, the absorptions for $Me(a_1)$ and $Me(a_2)$ can not be distinguished as two species any more, but shows a hyperfine pattern quite similar to that observed in the porous Vycor glass system. This fact implies that the quartet splitting for the new type of methyl radical observed in the porous Vycor glass system may consist of two overlapped quartets which are due to two species of methyl radicals.

According to the electron-spin-relaxation theory,[10-12] the fact that the line-width-broadening effect is symmetric to the center of the spectra in the $Me(a_1)$ and $Me(a_2)$ radicals implies that the *g*-values of the radicals are nearly isotropic. In the present case, as is indicated in Table 1, the *g*-values for the $Me(a_1)$ and $Me(a_2)$ radicals are also almost equal to the value for a free electron. The *g*-value of the $Me(n_1)$ radical is larger than the value of a free electron and is estimated to be anisotropic from the line-width-broadening effect in the spectrum. From the changes in the *g*-values of the free radicals, it may be estimated that the structures of the new types of methyl radicals, $Me(a_1)$ and $Me(a_2)$, are different from that of the normal type, $Me(n_1)$; *i.e.*, the new one probably has a non-planar structure. The deformation from a planar structure corresponds to the increase in the *s*-character in an odd electron orbital; this in turn leads to a *g*-value close to that of a free electron. The facts that the proton hfs constants of the $Me(a_1)$ and $Me(a_2)$ radicals are smaller than that of the normal methyl radical is also a good indication of the non-planar structure. Although there may be some effect due to charge transfer to the surface sites, the contribution of the charge transfer to the decrease in hfs constants is probably small. If there is any appreciable effect of charge transfer to the surface sites, such as the boroxane groups suggested by Garbutt *et al*,[7] the *g*-value would probably deviate more from the value of a free electron because of the larger effect of spin-orbit coupling at the adsorption sites.

The formation of the nonplanar methyl radicals can be attributed to the strong interaction with the silica-gel surface. The formation of such radicals could not be observed when the silica gel was preheated at low temperatures. This fact suggests that the adsorption sites for the non-planar methyl radicals are siloxane groups formed by the dehydration of surface silanol groups. In the study of methyl radicals in the porous Vycor glass system, Garbutt *et al*, proposed that boroxane groups are adsorption sites for the methyl radical, which has an abnormally small hfs constant. Their conclusion was based on Zammit's experiment, which reported that this new type of methyl radical could not be observed on the pure (boron-free) silica gel. The present result using silica gel implies that siloxane groups are adsorption sites for this new type of methyl radical in the porous Vycor glass system, too. It seems interesting that there are two different adsorption states for the non-planar methyl radicals. From the intensity ratio of the two radicals, $Me(a_1)$ and $Me(a_2)$, it can be estimated that the populations of the two strong adsorption sites on the silica-gel surface are approximately the same.

As has been mentioned above, in the photolysis of the methyl iodide the new methyl radicals, $Me(a_1)$ and $Me(a_2)$, appear at the early stage of irradiation, but as the photolysis continues the intensities of the radicals decrease, and instead an ordinal methyl radical, $Me(n_1)$, appears. In the photolysis of methane, the observed spectra (Fig.3) did not show such a change, indicating that the iodine produced in the photolysis of methyl iodide disturbs the stabilization of the non-planar form of the methyl radical by covering the active sites for adsorption.

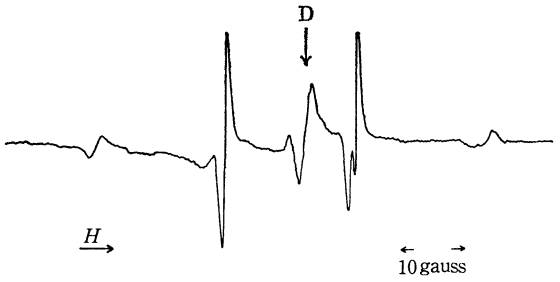

Fig. 3. ESR spectrum of the methyl radicals produced from methane at 77°K. The silica gel was preheated at 600°C *in vacuo* for 5 hr. D: Defect signal.

The Methyl Radical Formed on the Silica Gel Preheated at Low Temperatures, and the Satellite Lines about the Four Proton Lines. When the silica gel is preheated at temperatures below about 300°C, the methyl radicals with abnormally small hfs constants are not ob-

served. The observed quartet for the methyl radical has about the same splitting and amplitude distributions as those of the ordinary methyl radical (Fig.4). In this case, however, each proton hyperfine line is accompanied by four satellite lines, as is shown in Fig. 5. Such satellite lines were not observed when the silica gel was preheated at high temperatures, implying that they are related to the interaction with the proton of the silanol groups on the silica-gel surface. By measurements of both the X- and K-band spectra, it has been found that the outer satellite lines are affected by the magnetic field, although the inner satellite lines are not affected (see Figs. 5 and 6). The separations between the two outer satellite lines were 11.5 and 26.2 gauss at the X- and K-band spectra respectively; the spectra were approximately equal to $2g_N \cdot \beta_N I \cdot H$. That is, the values calculated by the use of $2g_N\beta_N I \cdot H$ are 10.9 and 25.8 gauss respectively and

Fig. 4. ESR spectrum of the methyl radical on the silica gel surface at 77°K. The silica gel was pretreated by evacuating for 15 hr without heating.

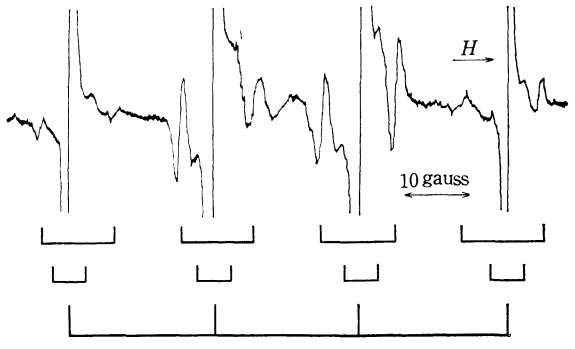

Fig. 5. ESR spectrum showing the satellite lines at X-band. Temp: 77°K.

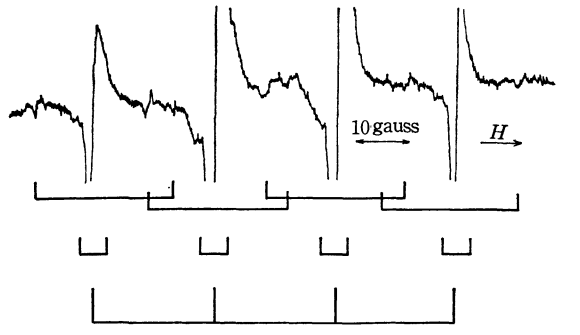

Fig. 6. ESR spectrum showing the satellite lines at K-band. Temp: 77°K.

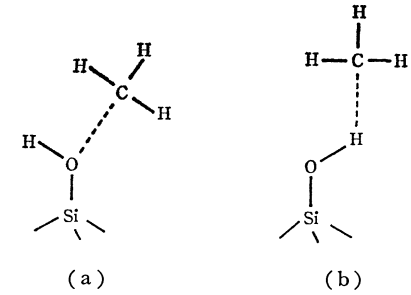
are in good agreement with the observed values.

Previously Rogers *et al.*[13] explained the two satellite lines observed for the methyl radicals in irradiated single crystals of sodium acetate trihydrate as arising from the concurrent spin flip of the electron of the methyl radical and the proton of the water of crystallization. They showed in their study that the separation of the satellite lines is close to $2g_N\beta_N I \cdot H$, which is to be expected from the theory that there is some second-order effect in the hyperfine interaction.[14,15] In such concurrent spin flip-type transitions of the unpaired electron and a nearby proton, if it is assumed that the central line is associated with satellite lines, as in the above example, the ratio of the intensity of either satellite line, T_1, to that of the central line, $2T_2$, is given by:

$$T_1/2T_2 = (3g^2\beta^2/20\,H^2)\,\langle r^{-6}\rangle \qquad (1)$$

This equation indicates that the $T_1/2T_2$ ratio is inversely proportional to the square of the external field. The $T_1/2T_2$ ratio in the K-band spectrum can, therefore, be expected to be about 1/6 for the case of the X-band spectrum. In the present case, the ratio of the intensity of the outer satellite lines to that of the central line, $T_1/2T_2$, in the K-band spectrum was about 1/3—1/6 of the value in the X-band spectrum, in good agreement with the expectation from Eq. (1).

It may be concluded, therefore, that the outer satellite lines are due to the spin flip-type transition of the unpaired electron and a nearby silanol proton coupled by dipole-dipole interaction. As has been mentioned above, the central line can probably be associated with the outer satellite lines (the Me(n_2) radical), and so the inner satellite lines may be attributed to the other species of methyl radical, which has Fermi-type interaction with protons on the silica-gel surface (the Me(n_3) radical). It seems interesting that in this case, too, there are two different adsorption states for the methyl radicals. Figure 7 is one possible model for Me(n_2) and Me(n_3). By using the $T_1/2T_2$ intensity ratio for the outer satellite lines, the mean distance, $\langle r\rangle$, for the Me(n_2) methyl radical is calculated to be 2 Å from Eq. (1).



(a) (b)

As has been shown, the methyl radicals show well-resolved ESR spectra even in the adsorbed state, although the hyperifine interaction between the $2p_z$ unpaired electron and a α proton has a large anisotropy. This can be well explained by the rapid rotation of the molecules around the three-fold axis. However, the tumbling of the molecules should be greatly restricted by the interaction with solid surfaces, as may be seen from the line-width broadening, showing the deviation of the amplitude distribution from the binomial law. The observation of the satellite lines due to the magnetic dipole-dipole interaction between the electron spin and a neighboring surface proton gives useful information about the lifetime of adsorbed states or the tumbling of the molecules. That is, the tumbling frequency of the $Me(n_2)$ radical was estimated to be lower than 2×10^8 Hz from the relation:

$$\tau_c \gg 1/2\pi\Delta\nu \qquad (2)$$

where τ_c is the correlation time for fluctuation in the interaction between the electron and the proton or a reciprocal of the tumbling frequency, and where $\Delta\nu$ is the separation of the doublet.

Gas Chromatography of Aluminum, Gallium, and Indium β-Diketone Chelates

Kei UTSUNOMIYA

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received November 30, 1970)

The gas-chromatographic behavior of aluminum(III), gallium(III), and indium(III) chelates with various β-diketones was investigated. The β-diketones studied were acetylacetone and 8 synthesized, alkyl-substituted acetylacetones, benzoylacetone, dibenzoylmethane, trifluoroacetylacetone and its 5 synthesized alkyl derivatives, hexafluoroacetylacetone, benzoyltrifluoroacetone, furoyltrifluoroacetone, and thenoyltrifluoroacetone. The trifluoromethyl group increases the volatility of the chelates, while the aromatic group tends to decrease the volatility. In the alkyl-substituted acetylacetone series, the retention time of the chelates increases with an increase in the molecular weight, but it does not depend upon the volatility. On the other hand, the retention of the chelates containing the trifluoromethyl group is almost inversely correlated with the volatility.

During the past decade, the gas chromatography of volatile metal chelates has attracted much attention; many works were summarized in a monograph[1] in 1965. Beryllium(II) and aluminum(III) chelates with acetylaceton,[2-4] trifluoroacetylacetone,[2-11] and hexafluoroacetylacetone[4,12,13] have been most extensively investigated. The results indicated that the substitution of fluorine for the hydrogen of the methyl group in the ligand increased the volatility and also sometimes the thermal stability of metal chelates.

Other tervalent metals, chromium(III),[3,4,6,7,14,15] gallium(III),[16,17] indium(III),[16,17] and iron(III)[9-11,18] chelates, were well studied, and the separation of these metal ions by means of gas chromatography was also examined using trifluoroacetylacetone[16,17] or hexafluoroacetylacetone.[12] However, little has been published on systematic investigations with various β-diketones which have different terminal groups, except for Tanaka and his co-workers, study[19] of the gas chromatography of some copper β-diketones chelates and Eisentraut and Sievers's study[20] of the thermogravimetry of aluminum, chromium(III), iron(III), and rhodium(III) chelates.

The present investigation was undertaken in order to evaluate the effect of the substitution of acetylacetone for methyl groups on the volatility, the thermal stability, and the gas chromatographic behavior of metal chelates. Aluminum, gallium, and indium were chosen as the central metals so that the present results could be readily compared with the results already reported. As the ligands, 21 β-diketones, acetylacetone and its alkyl derivatives, benzoylacetone dibenzoylmethane, trifluoroacetylacetone and its

alkyl derivatives, hexafluoroacetylacetone, benzoyltrifluoroacetone, furoyltrifluoroacetone, and thenoyltrifluoroacetone were compared.

Experimental

Preparation of β-Diketones. The β-diketones were prepared by Claisen condensation, except for eight β-diketones—acetylacetone, benzoylacetone, dibenzoylmethane, trifluoroacetylacetone, furoyltrifluoroacetone, thenoyltrifluoroacetone, benzoyltrifluoroacetone, and hexafluoroacetylacetone—which were obtained from the Dojindo Co., Ltd., Research Laboratories. The alkyl-substituted β-diketones, propionylacetone, isobutyrylacetone, pivaloylacetone, diisobutyrylmethane,[21] isobutyrylpivaloylmethane, dipivaloylmethane, dipropionylmethane, and pivaloylpropionylmethane, were prepared by the condensation of the corresponding esters and ketones in the presence of sodium amide,[22] while the fluorinated β-diketones, trifluoroacetylpropionylmethane, trifluoroacetylisobutyrylmethane, trifluoroacetylpivaloylmethane,[23] trifluoroacetyl-α-methylbutyrylmethane, and trifluoroacetylisovalerylmethane, were prepared from ethyl trifluoroacetate and the corresponding ketones in the presence of sodium methoxide.[24] The crude products were converted to the copper chelates by treatment with a solution of cupric acetate in hot aqueous methanol. After recrystallization from benzene, the copper chelates were dissolved in ether and decomposed with 10% sulfuric acid. The boiling points of these β-diketones are given in Table 1, along with the symbols used in this paper.

Preparation of Aluminum(III), Gallium(III), and Indium(III) Chelates. The β-diketonates were prepared by adding a stoichiometric quantity of β-diketone, dissolved in ethanol or methanol, to an aqueous solution of the metal nitrate. The solution was either buffered with sodium acetate or adjusted to pH 6 with a 1 M ammonia solution. The metal chelate thus precipitated was filtered off, dried, recrystallized from benzene, and then dried in a vacuum desiccator over phosphorus pentoxide. Attempts to synthesize the metal chelates with HPrA, HDPrM and HPiPrM by the same procedure failed. The melting points of the chelates thus prepared are shown in Table 2; the results of the elemental analyses of the alkyl substituted β-diketonates are in good agreement with the values calculated for the (1 : 3) chelate.

The thermogravimetric analysis of metal chelates was made with a Shimadzu thermo-balance. About 20 mg of a sample placed in a platinum dish were heated at a rate of 10°C/min in a nitrogen atmosphere and at a flow rate of 50 ml/min. The gas chromatograms were obtained with a Yanagimoto gas chromatograph GCD-5DH equipped with a thermal conductivity detectar. The column, 75 cm × 3 mm i.d., stainless steel, was packed with 5% (by weight) Dow Corning high-vacuum silicone grease on Chromosorb W AW DMCS (80—100 mesh). Helium was used as the carrier gas. Sample solutions, prepared by dissolving the chelates in benzene, were injected at the optimum column temperature for the chelates. The injection-port temperature was maintained at 30°C above the column temperature.

Results and Discussion

Thermogravimetric Analysis. Thermogravimetric analysis is a well-established technique for surveying the volatility of various metal chelates. It presents information on whether the chelates in question are sufficiently volatile and thermally stable to give

good gas chromatograms. The TGA curves of aluminum, gallium, and indium β-diketonates are shown in Figs. 1 to 3.

The aluminum β-diketonates are volatile and are thermally stable, except for $Al(BzA)_3$ and $Al(DBM)_3$, which decompose over 200°C instead undergoing sublimation. The volatility increases in the following order: for alkyl-substituted acetylacetone chelates,

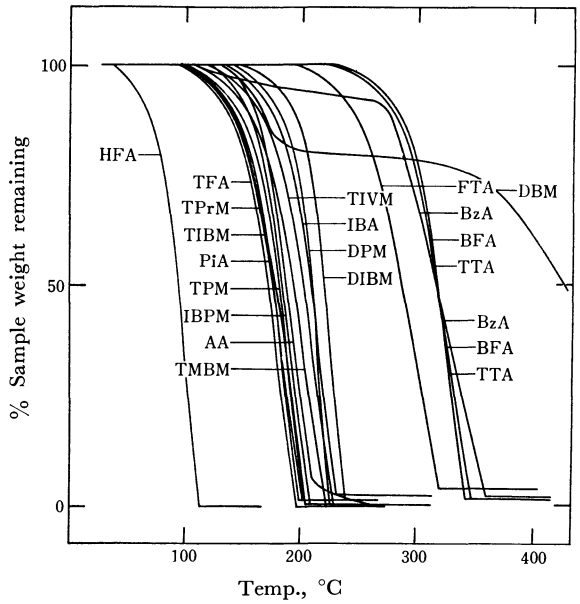

Fig. 1. Thermogravimetric curves of aluminum β-diketonates.

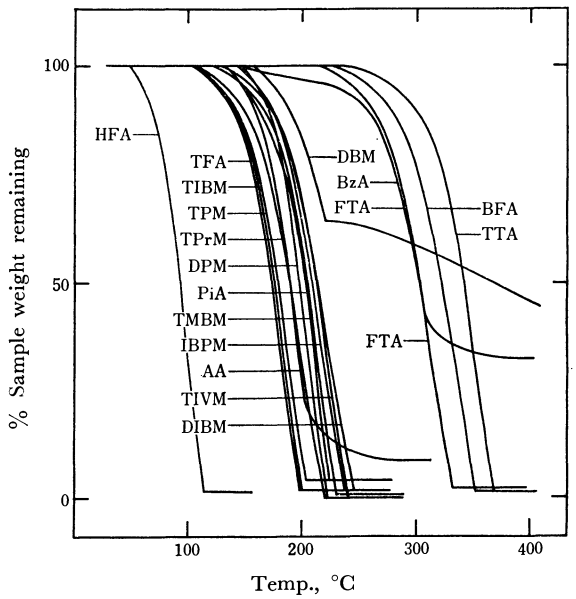

Fig. 2. Thermogravimetric curves of gallium β-diketonates.

$Al(DIBM)_3 < Al(DPM)_3 \leq Al(IBA)_3 < Al(AA)_3 < Al(IBPM)_3 < Al(PiA)_3$; for fluorinated β-diketone chelates, $Al(TTA)_3 \leq Al(BFA)_3 < Al(FTA)_3 \ll Al(TIVM)_3 < Al(TMBM)_3 < Al(TPM)_3 < Al(TIBM)_3 \leq Al(TPrM)_3 < Al(TFA)_3 \ll Al(HFA)_3$ (Fig. 1). Gallium(III) acetylacetonate does not completely sublime, and $Ga(BzA)_3$ and $Ga(DBM)_3$ decompose. The volatility increases in this order: $Ga(DIBM)_3 < Ga(IBPM)_3 < Ga(PiA)_3 < Ga(DPM)_3 < Ga(AA)_3$; $Ga(TTA)_3 < Ga(BFA)_3 < Ga(FTA)_3 \ll Ga(TIVM)_3 < Ga(TMBM)_3 < Ga(TPrM)_3 < Ga(TPM)_3 < Ga(TIBM)_3 < Ga(TFA)_3 \ll Ga(HFA)_3$ (Fig. 2). Many of the indium(III) chelates do not quantitatively sublimate, and $In(AA)_3$, $In(BzA)_3$, $In(DMB)_3$, and $In(HFA)_3$ decompose. The increasing order of the volatility is as follows: $In(DIBM)_3 < In(IBPM)_3 < In(DPM)_3$; $In(TTA)_3 < In(BFA)_3 < In(FTA)_3 \ll In(TIVM)_3 < In-$

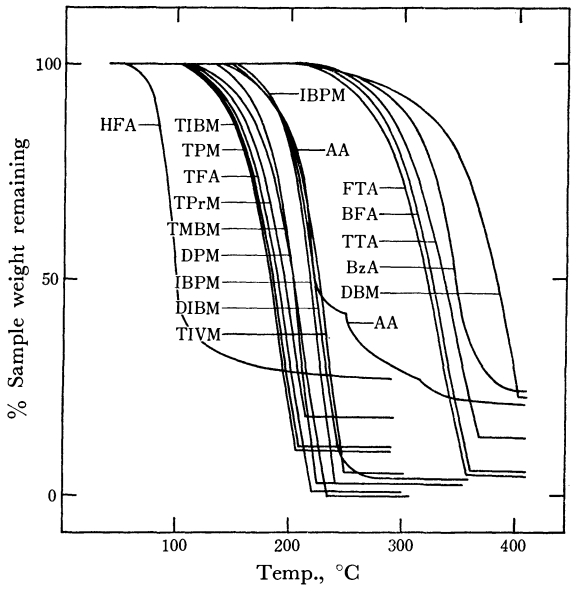

Fig. 3. Thermogravimetric curves of indium β-diketonates.

$(TMBM)_3 < In(TPrM)_3 < In(TFA)_3 < In(TPM)_3 < In(TIBM)_3$ (Fig. 3).

Usually, the substitution of the fluoromethyl group increases the volatility of the chelates, while an aryl group, such as a furyl, phenyl, or thienyl group, tends to decrease the volatility. Accordingly, FTA, BFA, and TTA chelates are less volatile, in spite of the presence of a trifluoromethyl group, and BzA and DBM chelates decompose without sublimation. However, there is no general correlation between the volatility of alkyl-substituted chelates and their substituted groups, except in the one case of indium(III) chelates, where the volatility does seem to increase in the order of substitution: $CH_3- < (CH_3)_2CH- < (CH_3)_3C-$.

Gas Chromatography of Alkyl-substituted β-Diketonates. Figure 4 shows gas chromatograms of the aluminum, gallium, and indium chelates of some β-diketones. The elution is strongly temperature-dependent. Aluminum chelates give optimal chromatograms at a column temperature of 200°C, but at this temperature the peaks of gallium and indium chelates are broad and tailed. The peak sharpens at a higher column temperature. Gallium chelates show good chromatograms at 212°C, and indium chelates, at 220°C. As may be seen in the chromatograms of $Ga(AA)_3$ and $Ga(PiA)_3$ (Fig. 5(a), (b)), a small peak or a shoulder is observed prior to the main peak. Such a confusing peak can not be removed by varying the temperature or by employing another kind of column; it might arise from a thermally-decomposed impurity.

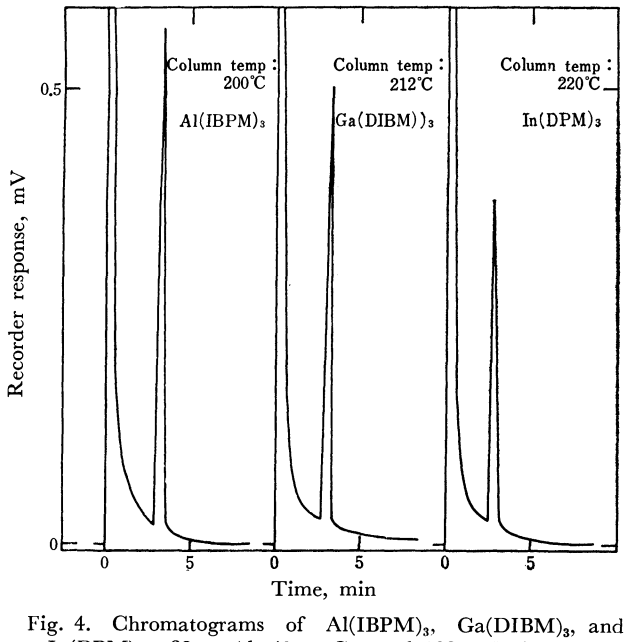

Fig. 4. Chromatograms of $Al(IBPM)_3$, $Ga(DIBM)_3$, and $In(DPM)_3$. 28 μg Al, 49 μg Ga, and 102 μg In in benzene (10 μl).

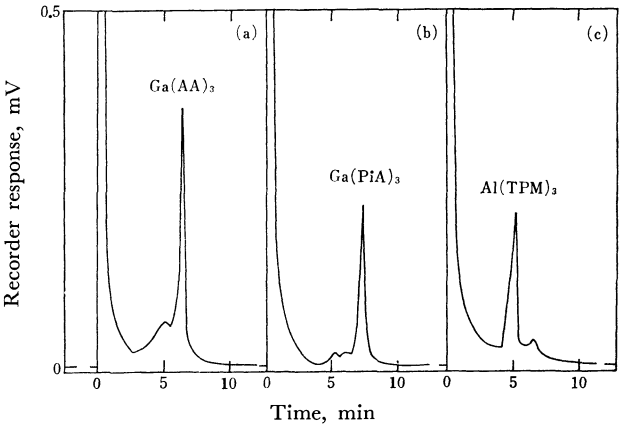

Fig. 5. Chromatograms of $Ga(AA)_3$, $Ga(PiA)_3$, and $Al(TPM)_3$. (a) 120 μg $Ga(AA)_3$, and (b) 152 μg $Ga(PiA)_3$ in benzene (20 μl). Column temperature: programmed from 100 to 250°C at 20°C/min. Helium flow rate: 95 ml/min. (c) 231 μg $Al(TPM)_3$ in benzene (10 μl). Column temperature: 178°C. Helium flow rate: 81 ml/min.

The retention data of the metal chelates with alkyl substituted β-diketones are summarized in Table 3. The retention times of the chelates increase in the following order: $Al(AA)_3 < Al(IBA)_3 < Al(PiA)_3 \approx Al(DIBM)_3 < Al(IBPM)_3 < Al(DPM)_3$, $Ga(AA)_3 < Ga(PiA)_3 < Ga(DIBM)_3 \approx Ga(IBPM)_3 < Ga(DPM)_3$, $In(DIBM)_3 < In(IBPM)_3 < In(DPM)_3$. This order is in good agreement with an empirical rule of gas chromatography that the retention time of organic compounds increases with an increase in the molecular weight. However, no correlation is obtained between the elution behavior and the volatility of the chelates observed in the TGA curve. For the separation of aluminum, gallium, and indium, DIBM, IBPM, and DPM chelates are suitable, but AA, BzA, and DBM chelates can not be used because of their smaller volatility.

Gas Chromatography of Fluorinated β-Diketonates. Aluminum, gallium, and indium chelates with TFA, TPrM, TIBM, TPM, TMBM, and TIVM are eluted at a column temperature between 120 and 200°C. For FTA, BFA, and TTA chelates, the column temperature must rise about 100°C higher than for the above β-diketonates: $Al(FTA)_3$ and $Al(BFA)_3$ are eluted at 230°C, while $Al(TTA)_3$, $Ga(TTA)_3$, and $In(FTA)_3$ are eluted at 250°C with decomposed products. The TGA curves predict that the column temperature for $In(BFA)_3$ and $In(TTA)_3$ will be 300°C or more.

Indium	ne	2.5	4.2	4.6	5.3	6.0	9.5	3.2[b] / 3.6	ne	ne
Operating conditions	column temp.: 90°C Helium flow rate: 47 ml/min.			For Al and Ga chelates, column temp.: 138°C, Helium flow rate: 67 ml/min. For In chelates, column temp.; 154°C Helium flow rate: 50 ml/min.				column temp.: 250°C Helium flow rate: 45 ml/min.		
Order of elution	← fast elution						late elution →			

a) partly decomposed. b) decomposed products. ne: chelates were not eluted.

Therefore a column coated with 3% (by weight) silicone gum SE-30 on Chromosorb W AW DMCS (80—100 mesh) was used for these indium chelates; nevertheless, the chelates were not eluted even at a column temperature between 300 and 340°C. In the chromatograms of $Al(TPrM)_3$, $Al(TIBM)_3$, and $Al(TPM)_3$, a main peak is followed by a smaller peak (Fig. 5(c)); although no detailed study was carried out, this phenomenon might result from the *cis* and *trans* isomers, as has been reported for $Cr(TFA)_3$.[3]

The retention data of fluorinated β-diketone chelates are listed in Table 4. The table indicates that HTFA, HTPrM, HTIBM, HTPM, HTMBM, and HTIVM can be used for the separation of aluminum, gallium, and indium. An example using HTPrM is presented in Fig. 6. The retention time of fluorinated β-diketonates increases in this order: $M(HFA)_3 \ll M(TFA)_3 < M(TPrM)_3 < M(TIBM)_3 < M(TPM)_3 < M(TMBM)_3 < M(TIVM)_3 \ll M(FTA)_3 < M(BFA)_3 < M(TTA)_3$; in contrast with the alkyl-substituted acetylacetonates series, it evidently depends upon the volatility of the chelates. The increasing order of the retention time is quite the same as the decreasing order of the volatility of aluminum chelates; a similar relationship is observed for gallium chelates except for the position of TPrM and for indium chelates except for the position of TFA and TPrM.

In the present research, the substitution on the γ-position of β-diketonates was not investigated, because it had previously been reported that substitution on this position with bromine,[20] methyl,[31] or isopropyl[31] group reduced the volatility of the metal chelates.

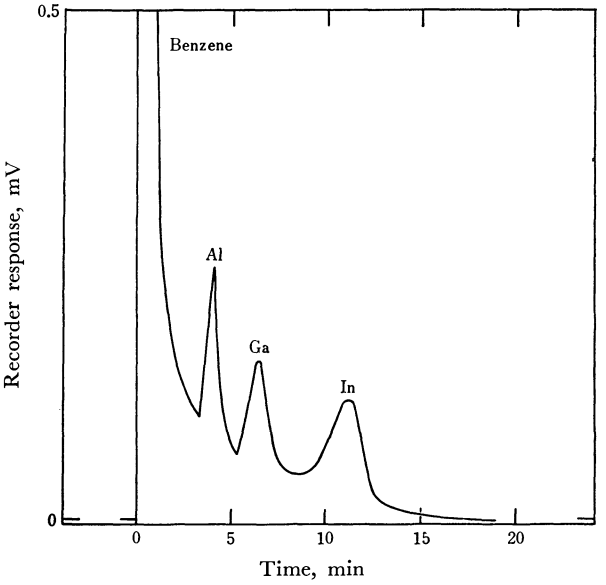

Fig. 6. Separation of aluminum, gallium, and indium TPrM chelates. 29 μg Al, 72 μg Ga, and 230 μg In in benzene (25 μl). Column temperature: 128°C. Helium flow rate: 81 ml/min.

The author wishes to express his thanks to Professor Tsunenobu Shigematsu for his guidance throughout this study. Thanks are also due to Drs. Masayuki Tabushi and Masakazu Matsui for their helpful advice and discussions.

The Separation of Aluminum from Iron by the Zone-melting of Their Complexes

Michio MASHIMA and Kazuo MARUYAMA

Faculty of Engineering, Niigata University, Nagaoka

(Received December 16, 1970)

The separation of Al from Fe was attempted as a first step in the chromatographic application of the zone-melting method to metal complexes. *N,N'*-ethylenedianthranilic acid and benzoic acid complexes, and various organic solid solvents were prepared. The experiment was carried out with a zone speed of 6 cm/hr and a molten-zone length of 0.6—1.0 cm at 75°C. When stearic acid was used as the solvent, the recovery percentage of Al was about 75% with the benzoic acid complex and about 99% with the *N'N'*-ethylenedianthranilic acid complex. Furthermore, the effective distribution coefficient and phase diagram supported due idea of the behavior of the complexes.

It has widely been known that pure germanium may be prepared by a zone-melting method.[1] Nowadays, it is used in various fields.[2,3] There are two methods of zone-melting for the separation and condensation of metals. One is used for the metallic state, and the other is used for the metal chelate state. Though the latter is easier than the former, because metal chelates have relatively low melting points and various organic characteristics, good results seem not yet to have been obtained.[4]

In this study, in order to separate one metal from other, the chromatographic development[5] by the zone-melting method was carried out with the metal chelates of benzoic acid[6] and *N,N'*-ethylenedianthranilic acid (NEA)[7] as solutes, and with stearic acid, benzoic acid, and naphthalene as their solvents. When stearic acid was used as the solvent, good results in the separation of aluminum from iron were obtained. Furthermore, the effective distribution coefficient[8] and the phase diagram were examined, so that the operation of this method could be discussed.

Experimental

Zone-melting Procedure. A vertical type zone-melting apparatus was used, by which a sample in a glass tube was zone-melted. The apparatus had several ring heaters, and it was cooled with water or air. The apparatus was of our own making. Long glass tubes 5 mm in inner diameter were used as the sample columns. As Fig. 1 shows, about 0.1 mg of the complex with about 250 times as much solid solvent was melted into the bottom of the glass tube and then cooled to solidify it, then the pure solvent was placed on it. Finally, the column length was 20 cm. When a 30-cm column was used, it took very long to zone-melt, and the results were similar to those obtained with the 20-cm column. Therefore, the 20-cm column was mainly used in this experiment. Besides it, the 10-cm column was also used for the sake of comparison. The experiment was carried out at a rate of zone travel of 6 cm/hr. The width of the molten zone was 1 cm in the apparatus with air cooling and 0.6 cm in the one with water cooling. The temperature of the molten zone was about 75°C. At temperatures higher than 75°C, the molten zone became wider and it became unstable at the solid-liquid intersurface.

Preparation of Metal Complexes. A metal ion solution was adjusted to pH 4—5 with ammonium acetate; then a 50 : 50 water-alcohol solution which contained a little more excess ligand than the calculated quantity of a solution of NEA[9] or benzoic acid was added to the solution. A precipitate was formed immediately; it was then collected in a suction filter. It was washed with water and sucked to dryness. These precipitates were determined photometrically. In both the benzoic acid complexes and the NEA complexes, we found a 1 : 3 rate of metal to ligand.[6,7] These metal complexes and such organic compounds as stearic acid, benzoic acid, naphthalene, and acetoanilide were solutes and solid solvents respectively.

Analysis of Zone-melted Samples. Zone-melted samples were cut, weighed, and dissolved in chloroform; after these complexes had then been decomposed with 6 N HCl, aluminum and iron ions were removed into the HCl phase. The HCl phase separated from chloroform phase was added to a 1% oxine acetic acid solution, and the solution was adjusted to pH 4.8—5.2 with 2 N ammonia water and ammonium acetate. The oxinates were extracted with 10 m*l* of chloroform. The aluminum and iron were then determined photometrically.[10]

Results and Discussion

At first, the NEA complex in stearic acid solvent was zone-melted with an air-cooling apparatus. The molten zone traveled upwards. The Al and Fe complexes contained 0.3 and 0.6 mg of metal respectively. The zone passes were done 12 and 15 times. One of these chromatograms is shown in Fig. 2. The metal concentration (%), the quantity of metal (mg) per

gram of the solvent is plotted as the ordinate, and the length from the bottom to the center of a piece of the sample is plotted as the abscissa. Though the Al-complex moved toward the upper end with an increase in the number of zone passes, the Fe-complex moved only to the center of the column even after zone passes. Therefore, it may be possible to separate Al from Fe. If the column was cut at the point where Fe was absent, 40 and 51% of the total Al could be separated with 12 and 15 zone passes respectively. This was defined as the "recovery percentage." As a large quantity of the Al-complex was still present at the bottom in the above case, the experiments were carried out with a smaller amount of complexes later.

Figure 3 shows a chromatogram when 0.02 mg of Al and 0.03 mg of Fe were used. Most of the Al-complex moved to the upper end, while the Fe-complex could not be found more than 9 cm from the bottom; thus, the Al-complex was separated efficiently.

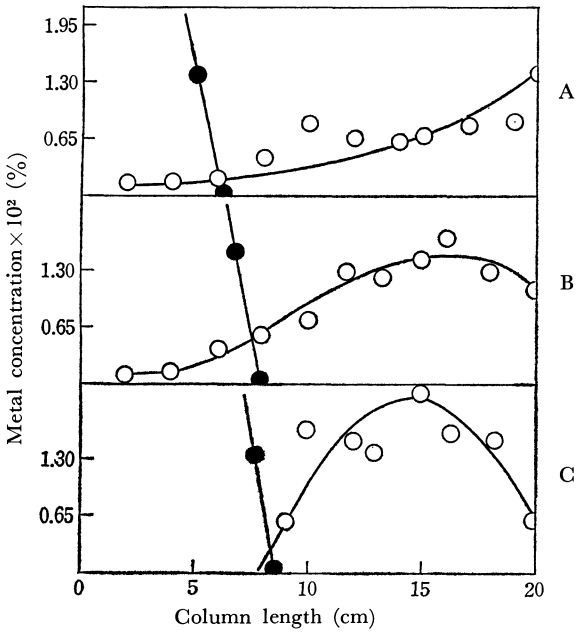

Fig. 3. Distribution of NEA-complex in stearic acid after zone melting process, using 2.0×10^{-2} mg of Al(○) and 3.0×10^{-2} mg of Fe(●).
A: 12 zone passes, B: 16 zone passes,
C: 18 zone passes

Table 1. Recovery percentage of Al as NEA complex

Exp. No.	Column length (cm)	Rate of zone travel (cm/hr)	No. of zone passes	Weight of Al (cm)	Weight of Fe (mg)	Recovery percent (%)
1	10	6	10	1.05	0.47	17
2	10	6	12	1.15	0.54	17
3	10	6	10	1.07	1.09	16
4	10	6	12	1.11	1.09	20
5	20	6	10	1.16	0.62	17
6	20	6	12	1.16	0.62	25
7	20	6	5	3.36	7.15	55
8	20	3	5	2.36	5.21	56
9	20	6	12	0.013	0.025	88
10	20	6	16	0.022	0.041	89
11	20	6	18	0.021	0.038	99

The recovery percentages of Al were 88, 89, and 99% with 12, 16, and 18 zone passes respectively; Al was thus almost completely separated from Fe with 18 zone passes. In Figs. 3B and C, the decrease in the Al concentration at the top of the chromatogram may be attributed to the following cause. Stearic acid evaporated from the top of the charge and condensed on the inner wall of the glass tube, and then this stearic acid was present in the top section of the sample during the analysis.

Table 1 shows the recovery percentage for the quantity of the complexes used, the column length, and the rate of zone travel. A comparison of No.1 with No. 3 reveals that the recovery percentage was not affected by the quantity of the Fe-complex; the recovery percentages were 17 and 16% for about 0.5—1 mg of Fe. Furthermore, a comparison of No. 2 with No. 6 reveals that the recovery percentage increased with the column length; the recovery percentages were 17 and 25% for the column lengths of 10 and 20 cm respectively.

No. 7 and No. 8 show the variation with the rate of zone travel. The recovery percentages were 55 and 57% in 6 and 3 cm/hr respectively.

Figure 4 shows a chromatogram of the Al and Fe complexes of benzoic acid in a stearic acid solvent obtained by the use of the apparatus with water-cooling. Here, the solubility of the benzoic acid complexes in stearic acid was about 2.5%, the same

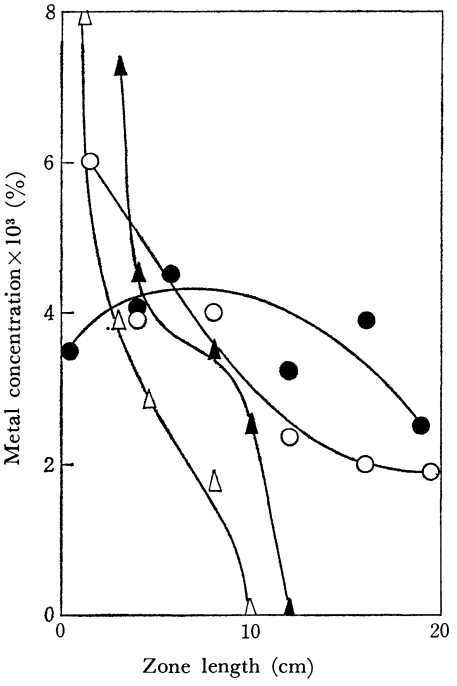

Fig. 4. Distribution of benzoic acid-complex. with 4 and 8 zone passes.
Al {○ 4 zone passes ● 8 zone passes Fe {△ 4 zone passes ▲ 8 zone passes

Table 2. Recovery percentage of Al as benzoic acid complex

Exp. No.	Column length (cm)	Rate of zone travel (cm/hr)	No. of zone passes	Weight of Al $\times 10^2$ mg	Weight of Fe $\times 10^2$mg	Recovery percent (%)
1	20	6	8	7.49	7.22	49
2	20	6	12	9.90	7.16	46
3	20	6	10	8.86	4.75	49
4	20	6	14	7.54	3.82	58
5	20	6	5	2.88	1.77	44
6	20	6	9	3.26	2.03	63
7	10	6	9	2.55	1.47	58
8	10	6	12	2.50	1.86	75

as that of the NEA complex in stearic acid. In this case also, the results obtained were similar to those obtained with the NEA complex. The recovery percentages were 25 and 49% in 4 and 8 zone passes respectively; the percentage thus increased with the number of zone passes.

Table 2 shows the recovery percentage for the Al-complex of benzoic acid, obtained in the same manner as in Table 1. The separation of Al from Fe seems to be efficient in No. 4, 6, 7, and 8.

The normal freezing equation has also been derived theoretically and experimentally by Mcfee *et al.*[2,8] Thus;

$$\log [C_s(x)/C_0] = \log K + (K-1) \log[1-(x/L)]$$

where C_0 is an initial concentration. Both the slope and the intercept at $x=0$ provided a measure of the effective distribution coefficient, K. Figure 5 shows the relationship between $\log C_s(x)$ and $\log[1-(x/L)]$ with the complexes in stearic acid. The initial concentrations were all 0.2%. The effective distribution coefficient was obtained from the slope of the linear line; in normal freezing, the column of the complex and stearic acid mixture was melted, then it was frozen from the bottom by means of a cooler, and the frozen sample was analyzed by the above-mentioned method. The concentration of the complex, $C_s(x)$, at any distance, x, from the bottom along a frozen column with a total length of L was obtained from the normal freezing. The effective distribution coefficients of NEA and benzoic acid complexes of Fe were 1.08 and 1.01, while those of the Al-complex were 0.61 and 0.89 respectively. These results suggest that only the Al-complexes travel to the upper end, while Fe-complexes do not; the results presuppose the possibility of the separation of Al from Fe.

Table 3 shows the effective distribution coefficients of these complexes in other solvents. From the table, it seems that benzoic acid could also be used as a solvent in this method, but it was not used because the column of the benzoic acid solvent was easily broken when several zones were passed.

Figure 6 shows the phase diagrams of these complexes in stearic acid; the concentration of the complex in stearic acid was less than 3%. A Coblle automatic thermoanalyzer was used in this experiment. These results suggest that the tendency of the NEA-complex

Table 3. Effective distribution coefficient

was different from that of the benzoic acid complex, and each complex may not change its ligand in this zone-melting method. Here, the difference in temperature is based on the melting point of stearic acid. In each figure 6A, B, and C, the upper curve and lower curve were liquidus and solidus lines respectively. In Fig. 6A, the liquidus curve of Al-complex is not horizontal; it may decrease slightly with the concentration. A more detailed analysis of these phase diagrams will be reported latter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2697—2702 (1971)

Studies of Aliphatic Hydroxycarboxylic Acids as Antioxidant. V. Complexes of Copper(II) with *erythro*- and *threo*-2-Methyltartaric, and *meso*- and *threo*-2,3-Dimethyltartaric Acids

Kazuo Horikawa and Shinroku Masuyama
The Osaka Municipal Technical Research Institute, Kita-ku, Osaka

(Received December 21, 1970)

The dissociation constants of *erythro*- and *threo*-2-methyltartaric and *meso*- and *threo*-2,3-dimethyltartaric acids were determined by the potentiometric titration method at the ionic strength of $\mu=0.1$ and at 22°C. The values of the dissociation constants were $pK_1=3.54$ and $pK_2=5.03$ for *erythro*-2-methyltartaric acid, and $pK_1=3.28$ and $pK_2=4.70$ for the *threo*-form. For *meso*-2,3-dimethyltartaric acid, the corresponding values were 3.52 and 4.98, while the *threo*-form had values of 3.04 and 5.30. The complex formation of copper(II) with these acids has been investigated using Job's method of continuous variations at the ionic strength of $\mu=0.2$ and at 22°C. Copper-(II) and *erythro*-2-methyltartaric acid react in a 1 : 1 ratio at pH 2.40 and in a 3 : 2 ratio at pH 5.00. On the other hand, the *threo*-form does not combine with copper(II) at pH 2.40, though it does react at pH 5.00 in a 1 : 1 ratio. As for *meso*-2,3-dimethyltartaric acid, the complex formation in a 3 : 2 ratio was observed at pH 5.00. However, the *threo*-form and copper(II) react in a 1 : 2 ratio at pH 5.00. The equilibrium constants (apparent stability constants) were calculated by the method of Turner and Anderson. The values of the equilibrium constant were $\log K=9.71$ (pH 5.00) and $\log K=2.02$ (pH 2.40) for *erythro*-2-methyltartaric acid, $\log K=3.78$ (pH 5.00) for the *threo*-form, $\log K=9.70$ (pH 5.00) for *meso*-2,3-dimethyltartaric acid, and $\log K=5.19$ (pH 5.00) for the *threo*- form. On the basis of these data, the structures of these complexes are discussed.

It is a well-known fact that small quantities of heavy metals have a deteriorating effect on the stability of oils. Especially, copper and iron have long been known to be detrimental to the stability of vegetable oils. Chelating agents, citric or tartaric acids, was added in order to decrease the influence of these metals. In order to study the influence of metal traces on the behaviour and the efficiency of these hydroxycarboxylic acids against the autoxidation of oils, we carried out experiments with a pure substrate, diethyl linoleate, and with soybean oil. These results have been published previously.[1] In a continuation of our study of hydroxycarboxylic acids as antioxidants, the present paper will report the determination of the dissociation constants on methyl derivatives of tartaric acid and of the equilibrium constants with copper(II). It seemed worthwhile to study the stability constants of these methyl derivatives with copper(II), since the composition of the complexes and the stability constants of these chelate compounds might be related to the stabilizing effect on the vegetable oils as antioxidants. Although a great deal of work has been done in the preparation of chelate compounds, for example, copper(II) or iron(III) tartrate and citrate, and upon their structures and formation constants,[2-5] no attempt has yet been made to determine the dissociation constants of methyl derivatives of tartaric acid and the stability constants with copper(II).

In this paper, *erythro*- and *threo*-2-methyltartaric acids were synthesized by the oxidation of diethyl-citraconate and diethylmesaconate respectively with permanganate. *Meso*- and *threo*-2,3-dimethyltartaric acids were prepared according to the procedure of Izumi *et al.*[6] The dissociation constants of these acids was determined by means of the potentiometric titration method. In order to calculate the equilibrium constants (apparent stability constants), we used the Turner and Anderson dilution method.[7] The composition of the complexes was studied Job's method of continuous variation.[8,9]

Experimental

All the melting points are uncorrected. The infrared spectra were determined in Nujol mull using a Shimadzu IR-27 spectrometer in the 2—15 μ region. The potentiometric titrations were made with a Metrohm Herisau Potentiograph, E 336. Optical density measurements from 600 to 800 mμ were made on a Hitachi 139 spectrophotometer. The pH of the reaction mixture was measured by means of a Yanagimoto Model 42-A pH-meter. During potentiometric titrations and spectro photometric measurements, constant ionic strenghts of 0.1 and 0.2 respectively were maintained by adding the requisite amount of a sodium perchlorate solution. Buffer solutions were prepared by adding the proper amount of 0.1 N acetic acid to a 0.1 N solution of sodium acetate. Standard copper(II) perchlorate (commercial reagent) in demetalized water and copper(II) was estimated spectrophotometrically (JIS-H-1101—1961). A sodium perchlorate solution was prepared in a concentration of 1 M. The dissociation constants of these acids were determined by the potentiometric titration of 10^{-3} M solutions, while the equilibrium constants of the copper(II) complexes were obtained spectrophotometrically.

Preparation of Ligands. The Preparation of erythro-*2-Methyltartaric Acid* (erythro-*MTA*): A solution of diethylcitraconate (40 g) dissolved in 200 m*l* of ethanol was oxidized with 2% aqueous potassium permanganate for 5 hr from −20 to −5°C. The reaction solution was then allowed to stand at room temperature overnight. The precipitated inorganic salt was removed by filtration; the filtrate was concentrated *in vacuo* to a syrup, which was then extracted with ether. After the evaporation of the solvent *in vacuo*, the residue was refluxed for 8 hr with 3 N hydrochloric acid. The hydrolysate was then evaporated to dryness *in vacuo*. The residue was dissolved in ethylacetate and was crystallized by the addition of a small amount of petroleum ether. Recrystallization from ethylacetate gave *erythro*-MTA. Mp 144—145°C. IR: 2.92, 2.99 μ. Paper chromatography R_f: 0.37 (*n*-BuOH-HCO_2H-H_2O, 4 : 1 : 2)

The Preparation of threo-2-*Methyltartaric Acid* (threo-*MTA*): The *threo*-form was similarly prepared by the oxidation of diethylmesaconate and by subsequent hydrolysis. Recrystallization from ethylacetate gave *threo*-MTA. Mp 159—160°C. IR: 2.89, 2.91 μ. R_f: 0.44.

The Preparation of meso- (meso-*DMT*) *and* threo-2,3-*Dimethyl tartaric Acids* (threo-*DMT*): *meso*-DMT and *threo*-DMT were prepared according to the method described by Izumi *et al.*; that is, these acids were prepared from diacetyl and hydrogen cyanide, and their barium salts were separated by solubility difference in water. *meso*-DMT: mp 179—180°C. *threo*-DMT: mp 187°C.

The Determination of the Dissociation Constants of These Acids. The dissociation constants were determined as follows: about a 100-mg portion of acid was dissolved in 25 m*l* of water. A mixture of the acid solution (5 m*l*) and 1 M sodium perchlorate (5 m*l*) was diluted to 50 m*l* with demetalized water (ionic strength 0.1) and then titrated at 22°C with a 0.1 N sodium hydroxide solution, using a Metrohm Herisau Potentiograph, E 336. The dissociation constants were calculated by the procedure of Speakman;[10] that is, the dissociation constants of a dibasic acid, H_2A, may be difined by the equations:

$$K_1 = a_{H^+}[HA^-]y_1/[H_2A]y_0,\quad K_2 = a_{H^+}[A^{2-}]y_2/[HA^-]y_1$$

where a_{H^+} signifies the activity of hydrogen ions and where y_0, y_1, and y_2 are the activity coefficients of the H_2A, HA^-, and A^{2-} species respectively. In a solution with a total acid concentration of a (molar):

$$a = [H_2A] + [HA^-] + [A^{2-}]$$

and when a strong monoacid base, which may be taken as completely dissociated, has been added to give a molar concentration of b, electrical neutrality requires that:

$$b + [H^+] = [HA^-] + 2[A^{2-}] + [OH^-]$$

If we define L, M, and N by these equations:

$$L = b + [H^+] - [OH^-]$$

$$M = a - b - [H^+] + [OH^-]$$

$$N = 2a - b - [H^+] + [OH^-]$$

it can be shown that:

$$Ly_2[H^+]^2/Ny_0 = My_2[H^+]K_1/Ny_1 + K_1K_2 \qquad (1)$$

where $\log y_1 = -0.5\sqrt{I}$ and $\log y_2 = -2.0\sqrt{I}$, $y_0 = 1$. (I signifies the ionic strength). Therefore, in the case of an ionic strength of 0.1, Eq. (1) may be written as:

$$0.233L[H^+]^2/N = 0.233M[H^+]K_1/0.695N + K_1K_2 \qquad (2)$$

When L, M, and N can be evaluated from the experimental data, the plot of the $(0.233L[H^+]^2/N)$ term against the $(0.233M[H^+]/0.695N)$ term should give a straight line, the slope of which equals K_1, while the intercept on the Y axis should equal K_1K_2.

The Determination of the Equilibrium Constants of the Copper-(II) Complexes. The equilibrium constants (apparent stability constants) of copper(II) with these acids were determined as follows: calculated volumes of copper(II) perchlorate (1.536×10^{-2} mol/*l*) and acid solutions (1.536×10^{-2} mol/*l*) were mixed, and then we added the proper amount of sodium perchlorate (1 mol/*l*) to maintain a constant ionic strength $\mu=0.2$; the whole was diluted to the proper volume (*e.g.*, 25 m*l*, 10 m*l*) by adding a buffer solution and allowed to stand 1 hr at 22°C. The optical density was then measured. The absorption cell was not thermostated, but all the solutions were brought to a constant temperature before measurements were made. Preliminary experiments showed that the copper(II)-acid solutions reached equilibrium within 1 hr and showed no measurable variation thereafter for a period of less than 24 hr. In order to calculate the equilibrium constants, we used the Turner and Anderson dilution method; *i.e.*, complex formation proceeds by this pathway:

$$nM + mA \rightleftarrows M_nA_m \qquad (3)$$

in which M is a metallic ion, and A, an organic molecule or an anion. If a and b are the initial concentrations of M and A respectively and if x is the equilibrium concentration of the chelate complex, then the equilibrium constant:

$$K = x/(a-nx)^n(b-mx)^m \qquad (4)$$

To determine the value of x, Job's method of continuous variations is employed, with different initial concentrations of the reactants. n and m can be determined from the experimental data by means of Job's method. If two concentrations (a_1+b_1) and (a_2+b_2) of the reactants have the same optical density, then the equilibrium constant:

$$K = x/(a_1-nx)^n(b_1-mx)^m = x/(a_2-nx)^n(b_2-mx)^m \qquad (5)$$

This equation can be solved for x. Thus, knowing the value of x, at a known concentration of reactants K can be calculated.

Results and Discussion

The Dissociation Constants of Ligands. erythro-2-*Methyltartaric Acid*: Table 1 represents the titration of *erythro*-MTA (1.881×10^{-2} mol/*l*, 10 ml) with 0.1081 N sodium hydroxide. The plot of the ($Ly_2[H^+]^2/Ny_0$) term against ($My_2[H^+]/Ny_1$) is shown in Fig. 1; the points lie very close to the straight line, from which pK_1 and pK_2 were calculated to be 3.54 and 5.03 respectively at μ=0.1.

threo-2-*Methyltartaric Acid*: The dissociation constants, pK_1 and pK_2, were similarly calculated to be 3.28 and 4.70 respectively. For *meso*-2,3-*dimethyltartaric acid*, the corresponding values were 3.52 and 4.98 (Fig. 2), on the other hand, for the *threo*-form the corresponding values were 3.04 and 5.30 (Fig. 2).

The Equilibrium Constants of Copper(II) Complexes. Complex with erythro-*MTA, at pH* 2.40: Calculated volumes of copper(II) perchlorate (3.840×10^{-2} M) and this acid (3.840×10^{-2} M) solution were mixed; then a sodium perchlorate solution (1 M, 5 ml) was added, and the whole was diluted to 25 ml by adding a buffer solution and was allowed to stand 1 hr at 22°C. The optical density was then measured at 760 mμ. The results are shown in Fig. 3A, where

the difference in optical density (ΔOD) of the complex and copper(II) perchlorate is plotted against the concentration of the reactants. Maxima are obtained at a mole fraction (copper) value of 0.5 with this acid and indicate a 1 : 1 combination. In order to calculate the eqilibrium constant, therefore, Eq. (4) should become:

$$K = x/(a-x)(b-x) \tag{6}$$

To determine the value of x, Job's method is again employed, but with a different initial concentration of the reactants. That is, an appropriate amount of copper(II) perchlorate (3.840×10^{-2} M) and this acid (3.840×10^{-2} M) solution were mixed; then we added the sodium perchlorate solution (1 M, 2 ml), and the whole was diluted to 10 ml by adding a buffer solution. The optical density was measured at the same wave length (760 mμ). The results are shown in Fig. 3B. From this curve and the data of Fig. 3A, a series of pairs of solutions can be selected with equal optical densities (and thus essentially equal concentrations of the complex), but with different concentrations of reactants. Therefore, Eq. (5) becomes:

$$K = x/(a_1-x)(b_1-x) = x/(a_2-x)(b_2-x) \tag{7}$$

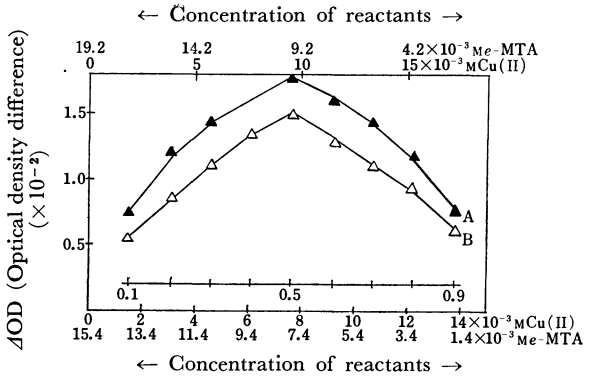

Fig. 3. Variation of ΔOD with varying concentration of Cu(II) and *erythro*-MTA, at pH 2.40, 760 mμ. Upper scale for curve A and lower scale for curve B. (ionic strength μ=0.2)

This equation could be solved for x as follows:

$$x = (a_1b_1 - a_2b_2)/\{(a_1+b_1)-(a_2+b_2)\} \quad (8)$$

In this case, a line at an optical density difference of 0.011 was drawn parallel to the concentration axis which intersects the curves, A and B. A point corresponding to the intersection at curve A gives a_1 and b_1 on the concentration axis, while the point on curve B gives a_2 and b_2 (on the right side of the peak). Similarly, other pairs, a_1 and b_1, and a_2 and b_2, can be selected on the left side of the peak, and x and also the log K value may be calculated for the complex. The results are shown in Table 3.

At pH 5.00: Copper(II) perchlorate (1.464×10^{-2} M) and this acid (1.464×10^{-2} M) solution were mixed similarly, and the optical density was measured. Maxima are obtained at a mole fraction value of 0.6, indicating that copper(II) and this acid react in a 3 : 2 ratio. Therefore, Eq. (4) becomes:

$$K = x/(a-3x)^3(b-2x)^2,$$

Then,

$$x = (a_1^3b_1^2 - a_2^3b_2^2)/\{(9a_1^2b_1^2+4a_1^3b_1)-(9a_2^2b_2^2+4a_2^3b_2)\}$$

The results are shown in Figs. 4A and 4B and in Table 3.

It would be reasonable to assume that these hydroxycarboxylic acids function as quadridentate chelating agents, and that both carboxyl and adjacent hydroxyl groups are involved in bond formation, and a tentative structure could be presumed for them (Fig. 8). The most stable conformations in *threo*-MTA and *erythro*-MTA would, respectively, be 1 and 2, where the two carboxyl groups are in anti positions (Fig. 9). Five- and six-membered rings are by far the most common among metal chelates. In *threo*-MTA, if the complex formation with copper(II) occurred at the carboxyl and hydroxyl groups in the vicinal position, as is shown in Fig. 9, the combination ratio would be the same as in the *erythro*-MTA-copper(II). Hence, the chelate formation in this manner does not explain the observed difference in the combination ratio between *threo* and *erythro* forms. Accordingly, it seemed to

Fig. 9.

be reasonable to assume that the copper(II) complexes have a 5-membered ring and that copper(II) attaches to geminally-situated carboxyl and hydroxyl groups. In *erythro*-MTA, both sets of carboxyl and hydroxyl groups are set in opposite directions, thus forming the complex in a 2 : 3 ratio. The chelate from *threo*-MTA in this ratio is unstable. Among the equilibrium constants of the acid-copper(II) complexes, the *erythro*-form ligands have larger values, $\log K=9.71$ for *erythro*-MTA and $\log K=9.70$ for *meso*-DMT. It is known that the stability constant difference is correlated with the dissociation constant of the ligand.[11] Strictly speaking, the stability constant does not agree with the equilibrium constant, but the equilibrium constant can be regarded as the apparent stability constant.[7,9] A close parallelism between the equilibrium constant and the dissociation constant is observed also in our case. When comparing the pK values of *threo*-form ligands with those of *erythro*-form ligands, the former are found to have lower values of pK. The pK values of the *erythro*-form are similar to each other, while there is a remarkable difference in the *threo*-form ligands. These tendencies also reflect the values of the equilibrium constants of *erythro*-form ligands; that is, the $\log K$ values of *erythro*-form ligand-copper(II) are also similar to each other.

The stabilizing effect of the substituted tartaric acids, *erythro*- and *threo*-MTA, and *meso*- and *threo*-DMT, on the vegetable oil as antioxidants in o/w-type emulsion has been evaluated in our previous work.[1] The influence of the metallic ion and the effect of these acids as antioxidants on the dissolved oxygen in o/w-type emulsion was investigated by employing a polarographic Beckman Oxygen Analyzer, Model 777. Soybean oil with different P.O.V.'s (peroxide values) and water were emulsified into o/w-type emulsions using Tween-40 as the emulsifiser, and the absorption of dissolved oxygen was measured in the presence of the Cu(II) ion. In order to evaluate the effect of these acids, an acid solution (10^{-1} mol/l, 1 ml) was added to the emulsion. Then, the metallic solution (0.5×10^{-1} mol/l, 1 ml) was added to the same emulsion, and the variation in the dissolved oxygen was measured. The results of these measurements revealed that the oxygen absorption increased in the presence of Cu(II) and, that the deteriorating effect was suppressed by the addition of these acids. When comparing the stabilizing effect of *erythro*-form acid with those of *threo*-form ligands, the former is clearly seen to function as a more effective antioxidant. Moreover, in the test for antioxidant activity by means of AOM (Active Oxygen Method) and the Shaal Oven Test, the results similarly revealed that *erythro*-form acid functions as a more effective antioxidant. On the basis of these data, it cab be concluded that the stabilizing effect on the oil as antioxidant can be attributed to the equilibrium constants of these acid-metal complexes. Detailed results will be published later.

The Electronic Character of the π-Allylic Group of π-Allylic Palladium Complexes

Yasutaka TAKAHASHI, Hiroyuki AKAHORI, Shizuyoshi SAKAI, and Yoshio ISHII

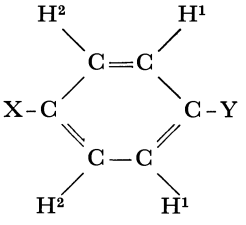
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya

(Received January 7, 1971)

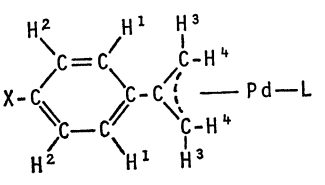
The substituent constants of the 2- and 1-positions of the π-allylic group of acetylacetonato (a) and cyclopentadienyl (b) derivatives of π-[2-(*p*-substituted phenyl)allyl]-(I) and π-(*p*-substituted cinnamyl)-palladium complexes(II) were estimated from their NMR spectra. The differences in the chemical shift ($\Delta\nu$, Hz) between the *p*-phenylene ring protons H^1 and H^2 of the complexes was found to be dependent upon the ligand and the substituent X. The plot of $\Delta\nu$ against the substituent constant σ_p^+, of X gave a fairly good linear relationship, and from the intercept of the straight line at $\Delta\nu=0$, the substituent constants of the 1-and 2-positions of the π-allylic group in the IIa or IIb complex and the Ia or Ib complex were estimated: σ_p: at the 1-position, 0.27 (IIa) or 0.24 (IIb), and at the 2-position, 0.21 (Ia) or 0.03 (Ib).

Up to now, little evidence suggesting the electronic character of the π-allylic group in π-allylic palladium complexes has been reported. Robinson and Shaw[1] found that 4-methoxy-substituted π-allylic palladium complexes were converted to the corresponding 4-ethoxy derivatives by ethanolysis, in which a carbonium-ion intermediate stabilized with the π-allylic group was assumed. This result suggests that the π-allylic group has an olefinic character even after coordinating with the metal ion. Nesmeyanov and Gubin,[2] on the other hand, suggested that the palladium ion in π-cyclopentadienyl-π-allylpalladium was to be regarded as an electron-attracting atom from an investigation of the electrophilic reaction and from the polarographic study. Bis(π-allylpalladium chloride) is also known to react with a nucleophilic reagent such as alkoxide, acetate, and the malonate anion.[3] The latter two results are evidence that the electron density of the π-allylic group is rather poor. These apparently contradictory observations stimulated us to estimate the electronic character of the π-allylic group.

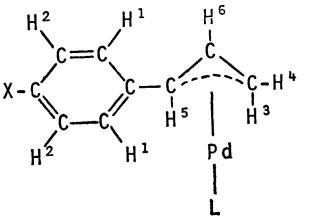
In the NMR spectra of *p,p'*-disubstituted benzene derivatives, the differences in the chemical shifts, $\Delta\nu$, of *p*-phenylene-group protons depend upon the electronic characters of the X and Y substituents, becoming zero when they are equal.



If Y is a π-allylic palladium moiety, its electronic character may be determined from the relation of $\Delta\nu$ to a substituent constant of X. Furthermore, the electron-donating or -withdrawing character of another ligand bonded to a metal may be evaluated at the same time. From this point of view, the NMR spectra of I and II complexes were measured. The results will be presented and discussed in this paper.



(I)



(II)

[L=acac (a), Cp (b), Cl (C); X=Br, Cl, H, CH_3, and CH_3O]

Experimental

The acetylacetonato and cyclopentadienyl derivatives of π-(*p*-substituted cinnamyl)palladium complexes (IIa and IIb) were prepared by the reaction of bis[π-(*p*-substituted cinnamyl)palladium chloride] with thallium acetylacetonate and cyclopentadienide[4] respectively, according to the methods in the literature.[5,6] Bis[π-{2-(*p*-substituted phenyl)-allyl}palladium chloride] complexes were prepared by the reaction of sodium chloropalladite and *p*-substituted α-methylstyrenes in the presence of cupric acetate in acetic acid. The complexes prepared are summarized as follows:

Substituent	Yield (%)	Mp(°C)		Analysis C(%)	H(%)	Pd(%)

These complexes were converted to acetylacetonato (Ia) or cyclopentadienyl derivatives (Ib) by treatment with thallium acetylacetonate or cyclopentadienide respectively.

The NMR spectra were measured on JEOL, MH-60 in $CDCl_3$ (or CCl_4), using TMS as the internal standard, and were calibrated by the signal due to $CHCl_3$ contaminated in $CDCl_3$. The $\Delta\nu$ values observed in chloroform were consistent with those observed in carbon tetrachloride.

Results and Discussion

Acetylacetonato (Ia or IIa) and π-cyclopentadienyl derivatives (Ib or IIb) were prepared from the reactions of the corresponding chloro-bridged complexes (Ic or IIc) with thallium cyclopentadienide and acetylacetonate in benzene, and their NMR spectra were measured in $CDCl_3$ except for the case of IIb (CCl_4). The observed spectra of two representative complexes Ib (X=Cl) and IIa (X=Cl) are shown in Figs. 1 and 2 respectively. The spectral data for Ia and Ib are summarized in Tables 1 and 2. In the case of complex IIa, the resonance of the methyl group in the acetylacetonato-ligand appeared as two singlets because of the anisotropic effect of the phenyl ring in the π-cinnamyl moiety.[5] Allylic protons were observed distinctly as three doublets and a multiplet assignable to H^{3-5} and H^6 respectively; these results are consistent with the general features of the NMR spectra for a rigid π-allyl complex. In the case of complex IIb, the NMR spectra for the rigid π-allyl structure were also observed. These observations seem, therefore, to support the assumption that there is no fluxinal behaviour including the Pd-

ligand bond dissociation or the σ-π interconversion of the π-allylic moiety in the solution of complex IIa.

The chemical-shift difference between H^1 and H^2, $\Delta\nu$, decreased in the order of the *p*-substituent, X: $CH_3O > CH_3 > H > Cl > Br$. The plot of $\Delta\nu$ against the substituent constant, σ_p^+, of X gave a moderately good linear relationship, as is shown in Fig. 3, but the constant other than σ_p^+ did not. The intercept of the straight lines at the axis, $\Delta\nu=0$, were designated as 0.21 (Ia) and 0.03 (Ib). In *p*-substituted toluenes and acetophenones, an analogous correlation between $\Delta\nu$ and σ_p^+ was also found,[9] as is shown in Figs. 4 and 3 respectively. The intercept (−0.30) of the straight line for toluenes at $\Delta\nu=0$, which might be the substituent-constant of the methyl group, was consistent with its σ_p^+ value as it appeared in the literature.[10] Therefore, the results obtained for complex Ia or Ib might be considered to indicate the substituent constant of the 2-position of the π-allylic group of complex Ia or Ib respectively. These results suggest that the substituent constant of the 2-position of the π-allylic group varies with other ligand bonded to the palladium ion, and that cyclopentadienyl group gave a smaller σ_p^+ value than the acetylacetonato group, indicating that the former is a better electron donor than the latter. These results are in accordance with the fact that the $CpRh(CH_2{=}CH_2)_2$ complex is more basic than the $(acac)Rh(CH_2{=}CH_2)_2$.[11]

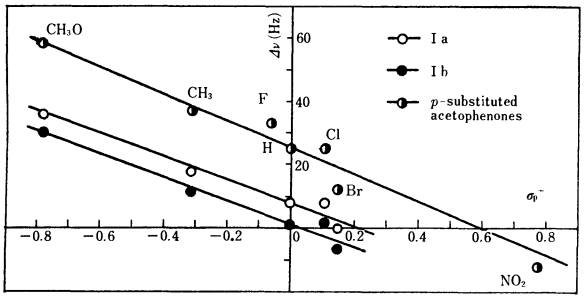

Fig. 3. The relation of $\Delta\nu$ of *p*-phenylene group of complexes Ia and Ib, and of *p*-substituted acetophenones.

In the cases of π-(*p*-substituted cinnamyl)palladium acetylacetonate (IIa) and cyclopentadienide (IIb), linear relationship between $\Delta\nu$ and σ_p^+ of X were also found; the results are illustrated in Fig. 4. The intercepts of the straight lines (σ_p^+ values of the 1-position of the π-allylic group) at $\Delta\nu=0$ were independent of the ligand; 0.27 (IIa) and 0.24 (IIb), unlike as in the observations in the case of I complexes. The relatively large σ_p^+ values estimated for the complexes II indicate that the 1-position of the π-allylic group is so electron-poor to be susceptible to nucleophilic reactions.

In the NMR spectrum of *p*-methoxy- and *p*-methyl-substituted α-methylstyrenes, $\Delta\nu$ was found to be 32.0 or 13.5 Hz respectively. The line through the points

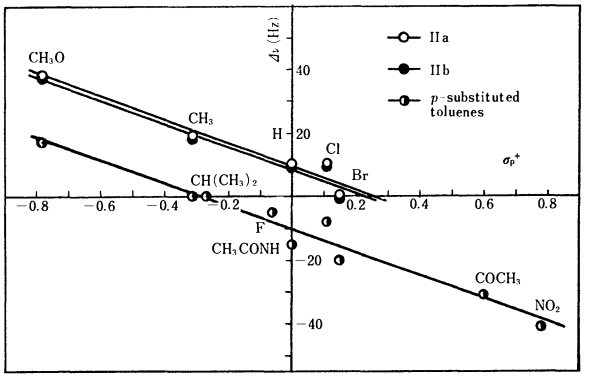

Fig. 4. The relation of $\Delta\nu$ of *p*-phenylene group of complexes IIa and IIb, and of *p*-substituted toluenes to substituent constant σ_p^+.
The σ_p^+ value of acetyl group was eastimated from the result of Fig. 1.

for the methoxy and methyl groups was assumed (parallel with other lines), and the σ_p^+ value for the isopropenyl group was evaluated as 0.05, smaller than that for Ia, IIa, and IIb, and nearly equal to that of Ib. Therefore, except for complex Ib, π-allylic palladium group may be concluded to behave as an electron-attracting substituent, consistent with the qualitative observations of Nesmeyanov and Gubin.[2]

The different dependences of the σ_p^+ of the 1- and 2-position of the π-allylic group on the ligand are closely related to the bonding nature of the π-allylic ligand to the metal ion. Kettle and Mason[12] reported from their theoretical calculations that two lower levels of the molecular orbital (ϕ_1 and ϕ_2) of the allylic radical could be more strongly overlapped with the atomic orbital of palladium than its highest orbital ϕ_3. It may be assumed that ϕ_1 is overlapped with the metal orbital with bonding-manner, and ϕ_2 with backbonding-manner. The bonding of the 1-position of allylic radical with metal is governed by both ϕ_1 (donation) and ϕ_2 (backdonation), but that of the 2-position is governed only by ϕ_1, indicating that the 1-position of the allylic group in the complex is "softer" than the 2-position. Therefore, the substituent constant of the 2-position might be directly reflected by the electron density of the metal atom, that is, the ligand on it, but that of the 1-position is independent of it as a result of compensation between ϕ_1 and ϕ_2.

Throughout, the anisotropic effects of the π-allylic and other ligands have been ignored. Furthermore, the effect of the solvent is very important. The $\Delta\nu$ value of complex IIb (X=Cl) was observed to be 10.5 Hz in CCl_4, but changed to zero Hz in hexadeuterobenzene. In our previous paper[5] concerning the NMR spectra of a substituted π-cinnamylpalladium complex, the specific solvation of benzene molecules to palladium atom had been suggested. However the above observation can not be explained as a result of such a solvation of benzene; a different kind of factor have to account for it. We can not, at present, give a clear explanation.

9) The $\Delta\nu$ values for *p*-substituted toluenes and acetophenones in the literature "NMR Data Tables for Organic Compound," Vol. 1, by F. A. Bovey, Interscience Publishers (1967) and of our measurement were used ignoring the solvent effect.

The Determination of the Amount of Oxygen in Molten Copper-Nickel and Copper-Silver Alloys by the EMF Method

Iwao TSUKAHARA

Furukawa Electric Co., Ltd., Central Research Laboratory, Futaba, Shinagawa-ku, Tokyo

(Received January 28, 1971)

Using the following solid oxide-electrolyte galvanic cells, Pt/air//ZrO_2 (+CaO) O//(in Cu–Ni alloy)/Mo and Pt/air//ZrO_2 (+CaO) O//(in Cu–Ag alloy)/Mo, the electromotive forces of the cells have been measured as a function of the oxygen concentration in copper-nickel or -silver alloys at oxygen concentrations ranging from several ppm to 1000 ppm, at 1210°C for copper-nickel alloys and at 1100°C or 1200°C for copper-silver alloys respectively. The activity coefficient of oxygen has been determined from the electromotive force for the alloy systems investigated. In the case of copper-nickel, the activity coefficient of oxygen decreases with an increase in the nickel concentration and also with a decrease in the oxygen concentration. The solubility of oxygen in the copper-nickel alloy has also been measured at 1210°C by the use of the following galvanic cell, Pt/air//ZrO_2 (+CaO)//O(in Cu–Ni alloy), NiO/Mo.

The determination of the amount of oxygen in molten metals and alloys is of great importance in the metallurgical process or in controlling the quality of products. In recent years, there have been many studies concerning the direct electrochemical measurement of the oxygen content in molten iron[1–9] or copper.[10–14] These investigations have employed galvanic cells, the electrolytes in which are various solid mixed-oxides which conduct the current through the migration of oxide ion vacancies. Since the work of Kiukkola and Wagner[15] was reported, such electrolytes have been used in numerous cell studies in order to determine the thermodynamic properties of metallic oxides, the partial pressure of oxygen in various atmospheres, and the properties of oxygen dissolved in metals and alloys. The advantage of this electrochemical method is that it make possible the fast, direct, and continuous determination of oxygen.

In a previous paper,[16] the determination of the amount of oxygen in molten copper and copper-tin alloys by the EMF method using lime-stabilized zirconia as the solid electrolyte was reported by the author. In this investigation, a study of the determination of the amount of oxygen in molten copper-nickel and copper-silver alloys has been made by the same method. The main objects of this investigation are to determine the relationship between the electromotive forces of the following cells and the oxygen contents in copper-nickel and copper-silver alloys and to determine the activity coefficients of the oxygen in these alloys.

$$\text{Pt/air//}ZrO_2\text{(+CaO)//O(in Cu-Ni alloy)/Mo} \quad (1)$$

$$\text{Pt/air//}ZrO_2\text{(+CaO)//O(in Cu-Ag alloy)/Mo} \quad (2)$$

Since the transference number of oxide ion in stabilized zirconia is regarded as unity under the experimental conditions of this work,[9,17–19] the electromotive force (E) of the cell, (1) or (2), is:

$$E = (2.303\boldsymbol{R}T/4\boldsymbol{F}) \log (0.21/P_{O_2}) - E_{th}$$
$$= (2.303\boldsymbol{R}T/4\boldsymbol{F}) \log (0.21/a_O^2) - E_{th} \quad (3)$$

where $\boldsymbol{F}$ is the Faraday constant, where P_{O_2} and a_O are the partial pressure and the activity of oxygen in the liquid alloys with respect to a reference state of pure oxygen gas at 1 atmospheric pressure respectively, and where E_{th} is the thermoelectromotive force of the Pt–Mo thermocouple, which has been measured previously and expressed by Eq. (4),[16] where molybdenum is positive and where t is the temperature in °C:

$$E_{th}(\text{in mV}) = 406.3/t^{1/2} + 0.04352t - 29.09 \quad (4)$$

At a given temperature, all the terms of Eq. (3) are constants except E and a_O. Thus, a_O can be determined by the measurement of the electromotive force.

The electromotive force is also related to the mole fraction of oxygen (N_O) by Eq. (5) in the oxygen concentration range over which the activity of oxygen obeys Henry's law:

$$E = (2.303\boldsymbol{R}T/4\boldsymbol{F}) \log 0.21K$$
$$- E_{th} - (2.303\boldsymbol{R}T/2\boldsymbol{F}) \log N_O \quad (5)$$

where K is the equilibrium constant for the reaction:

$$O_2(g) = 2O \text{ (in alloy, liq.)} \quad (6)$$

At a given temperature, the electromotive force of the cell, (1) or (2), is a linear function of $\log N_O$.

Experimental

An internal cell arrangement is shown in Fig. 1. About 600 g of molten Cu–Ni or Cu–Ag alloy was placed in the alumina crucible (66 mm i.d., 100 mm height), in which a stabilized zirconia in the form of a closed-end tube (500 mm long, 13 mm o.d., 8 mm i.d.) and a Pt–Pt/13% Rh thermocouple in an alumina sheath were immersed. A platinum contact wire was pressed (with a spring mechanism) against the inside bottom wall of the electrolyte tube, which was flushed continuously with a stream of air *via* an alumina tube inserted inside the electrolyte tube. The platinum contact wire acted as the reference electrode ($P_{O_2}=0.21$ atm.). A molybdenum contact wire was immersed in the alloy melt only at the times when the measurements were taken, because dissolved oxygen attacked molybdenum and eventually broke the electrical contact if the molybdenum wire was immersed continuously in the melt with a high oxygen content. A radiation shield of inconel or of alundum was placed on the alumina crucible. The whole of the cell was enclosed in an alumina outer tube which was closed gas-tight at the top with a water-cooled brass head.

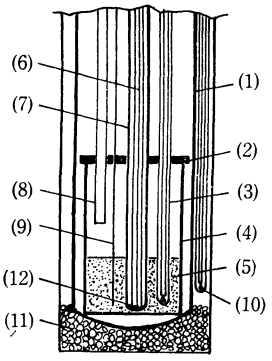

Fig. 1. Experimental cell.
(1) quartz tube, (2) inconel or alundum radiation shield, (3) Pt-Pt/13%Rh thermocouple in alumina tube, (4) alumina crucible, (5) Cu-Ni or Cu-Ag alloy melt, (6) Pt lead in alumina tube, (7) ZrO_2(+CaO) tube, (8) quartz sampling guide and addition tube, (9) Mo lead, (10) thermocouple for temperature control, (11) alumina, (12) Pt electrode

After the system had been evacuated and then filled with purified argon, the entire cell unit was heated in a resistance furnace to the desired temperature. The temperature was controlled by means of a Chino E-500 Controller using a Pt–Pt/13% Rh thermocouple with an accuracy of ±2.5°C. The cell potential was measured with a Yokogawa Electric P-1 Electrometer with an accuracy of ±0.5 mV. Oxygen was added to the melt by dropping reagent-grade copper oxide (CuO) chips through the sampling guide tube. After waiting for equilibrium, as evidenced by a steady cell potential with the time, electromotive force measurements were taken for each oxygen concentration: a sample of about 20 g was taken from the alloy melt by suction into the quartz tube (4 mm i.d.) which was guided through the sampling guide tube. The quartz tube was then immediately removed from the melt and quenched in distilled water. The sample was analyzed for oxygen by the vacuum-fusion method.

The measurements were carried out for the Cu–Ni alloy containing up to 0.22 mole fraction of nickel at 1210°C and for the Cu–Ag alloy containing up to 0.031 mole fraction of silver at 1100°C and 1200°C. The oxygen concentration was changed from several ppm to 1000 ppm.

Table 1. Chemical composition of stabilized zirconia (in wt%)

ZrO_2	CaO	MgO	SiO_2	Al_2O_3	Fe_2O_3	TiO_2
90.98	5.93	0.67	1.59	0.46	0.20	0.14

The stabilized zirconia used was a commercial zirconia tube, ZR-11, of the Nippon Kagaku Kogyo Co., Ltd.; its chemical composition is listed in Table 1.

Results and Discussion

1) Relation between Electromotive Force and Oxygen Content. The relations between the oxygen concentrations in the alloy melts and the electromotive forces measured are shown in Fig. 2—Fig. 4, where N_O, N_{Ni}, and N_{Ag} are the mole fractions of oxygen, nickel, and silver respectively. The relations have also been expressed in the form of Eq. (7), and the values of A and B have been calculated by the least-squares method and are listed in Tables 2 and 3.

0.0029	0.041	−0.136	0.010	−0.146
0.0059	0.041	−0.136	0.007	−0.146
0.031	0.039	−0.136	0.010	−0.146

$$E = A + B \log N_O \quad (7)$$

As is shown in the results, in the cases of both Cu-Ag and Cu-Ni alloys containing not more than 0.0053 mole fraction of nickel, the relation between the electromotive force and log N_O is shown by a straight line over the oxygen concentration range investigated. On the other hand, in the case of the Cu-Ni alloy containing 0.011 mole fraction of nickel or more, the relation is divided into two regions, lower and higher concentration regions of oxygen, and is shown by a straight line in each region. In the latter case, the majority of the B values in Eq. (7) exhibit deviations from the Nernstian slope (−0.147 at 1210°C). These deviations are due to the lowering of the activity coefficient of oxygen with a decrease in the oxygen concentration as will be discussed later. Phenomena similar to those discussed above were also observed in the Cu-Sn alloy system.[16]

In any case, we can use the relations shown in Fig. 2—Fig. 4 as calibration curves for the determination of the amount of oxygen in molten Cu-Ni and Cu-Ag alloys.

2) Activity of Oxygen. The activity coefficient of oxygen (γ_O), as defined by Eq. (8), has been determined. From Eqs. (8) and (3), we obtain Eq. (9). By substituting E and E_{th}, which have been already given by Eqs. (7) and (4) respectively, into Eq. (9), we can obtain the activity coefficient of oxygen as a function of the mole fraction of oxygen at each temperature

$$a_O = \gamma_O \cdot N_O \quad (8)$$

$$\log \gamma_O = (1/2) \log (0.21/N_O^2) - 2\boldsymbol{F}(E+E_{th})/2.303\boldsymbol{RT} \quad (9)$$

and at each concentration of nickel or silver. The activity coefficient of oxygen thus obtained has been expressed in the form of Eq. (10); the values of A and B in Eq. (10) are listed in Tables 4 and 5. From the results listed in those tables, it can be seen that: (1) in cases of both Cu-Ag and Cu-Ni alloys containing not more than 0.0053 mole fraction of nickel, the activity coefficient of oxygen is independent of the oxygen concentration and the activity of oxygen follows Henry's law. (2) in the Cu-Ni alloy containing 0.011 mole fraction of nickel, the decrease in the activity coefficient of oxygen with a decrease in the oxygen concentration is seen in the lower oxygen concentration region, while in the higher oxygen concentration region, the activity of oxygen follows Henry's law. (3) in Cu-Ni alloys containing 0.056, 0.10, and 0.22 mole fractions of nickel, the activity coefficient of oxygen decreases with a decrease in the oxygen concentration and the activity of oxygen no longer follows Henry's law over the whole oxygen concentration region investigated. Similar phenomena in the activity coefficient of oxygen were also observed in the Cu-Sn-O system.[16] It is worth noting that the lowering of the activity coefficient of oxygen with a decrease in the oxygen concentration was observed in copper alloy with nickel or tin, but not in the case of copper[16] or copper-silver alloy. The origin of these phenomena is not obvious. However, in view of the fact that the affinity of nickel or tin for oxygen is stronger than that of copper or silver, it probably depends on the affinity of the atoms of alloying elements for oxygen atoms, or it may be due to the formation of the molecular species or the dipoles between oxygen atoms and the atoms of the alloying elements, the oxygen atoms in which may be bonded more tightly to nickel or tin atoms as the concentration of oxygen decreases. Kozuka *et al.*[14] have noted that phenomena similar to those described above which were also observed by them in the Cu-O system are probably

$$\log \gamma_O = A + B \log N_O \quad (10)$$

Table 4. The values of A and B in Eq. (10) at 1210°C, Cu-Ni alloy

N_{Ni}	A	B
0.0015	−0.660	0
0.0053	−0.660	0
0.011	$N_O \leqq 7.7\times10^{-5}$: −0.197	0.129
	$N_O \geqq 7.7\times10^{-5}$: −0.728	0

	$N_O \geqq 8.3\times10^{-5}$: −0.646	0.041
0.10	$N_O \leqq 3.0\times10^{-4}$: 0.082	0.286
	$N_O \geqq 3.0\times10^{-4}$: −0.775	0.041
0.22	$N_O \leqq 5.2\times10^{-4}$: 0.191	0.401
	$N_O \geqq 5.2\times10^{-4}$: −0.347	0.238

Table 5. The values of A and B in Eq. (10) at 1100°C and 1200°C, Cu-Ag alloy

N_{Ag}	1100°C		1200°C	
	A	B	A	B
0	−0.863	0	−0.654	0
0.00089	−0.863	0	−0.649	0
0.0029	−0.870	0	−0.649	0
0.0059	−0.874	0	−0.672	0
0.031	−0.865	0	−0.649	0

due to impurities in the copper. If this is so, it is probably that the impurities are elements which have a strong affinity for oxygen.

On the other hand, as is shown in Tables 4 and 5, the activity coefficient of oxygen in the Cu–Ni alloy is also affected by the addition of nickel and decreases with an increase in the nickel concentration. This decrease in the activity coefficient of oxygen, as expressed by Eq. (11) in both the nickel concentration range of not more than 0.011 mole fraction and the oxygen concentration range over which the activity coefficient of oxygen is independent of the oxygen concentration, is due to the interaction between oxygen and nickel atoms. The usual way of expressing this

$$\log \gamma_O = -8.06N_{Ni} - 0.636 \quad (11)$$

interaction is in terms of the interaction coefficient, $\varepsilon_O^{(Ni)}$, derived by Wagner.[20] The value of $\varepsilon_O^{(Ni)}$ obtained from the present work, −8.06, that is, the slope of function (11), is in near agreement with the value determined by Oishi *et al.*, −7.00.[21]

3) Solubility of Oxygen. The solubility of oxygen in Cu–Ni melts containing 0.056, 0.10, and 0.22 mole fractions of nickel has been measured at 1210°C. By substituting E_s, which is the electromotive force of Cell (12) measured at 1210°C in a fixed mole fraction of nickel under the equilibrium conditions of Reaction (13), into E in Eq. (7), we can obtain the solubility (in mole fraction) of oxygen in the Cu–Ni melt. The solubilities thus obtained are listed in Table 6.

$$Pt/air//ZrO_2(+CaO)//O(\text{in Cu-Ni, liq.}), NiO/Mo \quad (12)$$

$$Ni(\text{in Cu-Ni, liq.}) + O(\text{in Cu-Ni, liq.}) = NiO(s) \quad (13)$$

The experiments were carried out as follows: after assembling the cell as has been described above, the cell system was evacuated, filled with purified argon, and then heated to 1210°C. Oxygen was added to the Cu–Ni melt until the oxygen concentration near the solubility of oxygen was reached, and then nickel oxide (NiO) powder was added to the melt. After the equilibrium has been reached, the potential (E_s) was measured, at the same time, a sample for oxygen analysis was taken. The oxygen content of the sample taken, that is, the solubility of oxygen, was determined by the vacuum-fusion method; these values are listed in Table 6 and compared with those calculated from E_s and Eq. (7).

The solubility of oxygen, as calculated from E_s and Eq. (7), is in good agreement with that determined by the analysis of oxygen; the solubility of oxygen decreases with an increase in the nickel concentration in the nickel concentration range investigated.

Table 6. Solubility of oxygen in Cu-Ni alloy at 1210°C

N_{Ni}	Solubility (mole fraction)	
	Calculated[a]	Analyzed[b]
0.056	0.00482	0.00478
0.10	0.00392	0.00387

The Chelating Behavior of 1-(2-Phosphonophenylazo)-2-hydroxynaphthalene-3,6-disulfonic Acid with Alkaline Earth Metals

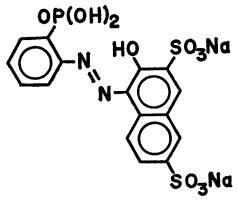
Kenyu KINA, Haruo MIYATA, and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received March 19, 1971)

A new chelating agent, *o*-phosphonophenylazo-2-hydroxynaphthalene-3,6-disulfonic acid, has been synthesized. The acid dissociation constants of this ligand and the chelate stability constants with alkaline earth metals have been measured by the pH titration method at an ionic strengh of 0.10 and at 25.0±0.1°C. This ligand forms the acido complex, MHL, in the pH 5—7 region. The stability constants of the acido complex decrease in this order: $\log K_{SrHL} \approx \log K_{CaHL} > \log K_{MgHL}$; whereas the decreasing order of the stability constants, $\log K_{ML}$, is as follows: $\log K_{MgL} > \log K_{CaL} > \log K_{SrL}$.

As a link in the chain of the studies of the *o*-substituted phenylazo compound, the present authors have attempted to introduce the phosphonate group into the *o*-position of the azo compound. For this purpose, it is necessary to prepare *o*-aminophenylphosphonic acid, which is produced by the reduction of *o*-nitrophenylphosphonic acid; however, it seemed difficult to introduce the phosphonate group into the *ortho* position of the nitro group. Recently Cadogan *et al.* presented a new method of synthesizing diethyl *o*-nitrophenylphosphonate;[1] the difficulty of the substitution is overcome by this synthetic manner, that is, *o*-nitrophenylphosphonic acid is obtained by the hydrolysis of diethyl *o*-nitrophenylphosphonate. The structural formula for *o*-phosphonophenylazo-2-hydroxynaphthalene-3,6-disulfonic acid disodium salt is:



The present paper will describe a method of synthesizing *o*-phosphonophenylazo-2-hydroxylnaphthalene-3,6-disulfonic acid disodium salt and the chelating behavior of this compound.

Experimental

Synthesis of o-*Phosphonophenylazo-2-hydroxynaphthalene-3,6-disulfonic Acid Disodium Salt.* The reagent was obtained by the coupling reaction of diazotized *o*-aminophenylphosphonic acid with the R acid [2-hydroxynaphthalene-3,6-disulfonic acid]. This reaction mixture was allowed to stand overnight, and then it was added, drop by drop to well-chilled concentrated hydrochloric acid. A reddish precipitate was obtained by this procedure. The azo compound thus obtained was recrystallized several times from an acidic solution by the salting-out method. The reagent, which is obtained as disodium salt, consists of fine, reddish needles. *o*-Aminophenylphosphonic acid was synthesized by using *o*-dinitrobenzene as the starting material; the procedure has been described in detail in a previous paper.[2]

Reagent Solutions. The stock solution of the ligand was prepared by dissolving it in distilled water; the concentration, 1.5×10^{-3} M, was standardized by potentiometric titration with standard 0.10 N potassium hydroxide before use. A carbonate-free potassium hydroxide solution was prepared by the method of ion exchange and was standardized titrimetrically by potassium hydrogen phthalate. The concentrations of the Mg(II) and Ca(II) solutions were determined by chelatometric titration, while the concentration of the Sr(II) solution was determined by the usual gravimetric method.

pH Titration Method. All the measurements were carried out by the use of a micro-titration vessel, the volume of which was 5 m*l*. The temperature was kept at 25.0± 0.1°C during the titration by the circulation of water through the jacketed titration vessel; the ionic strength of the solution was adjusted to 0.10 with potassium nitrate. Alkali was added from a calibrated 0.50-m*l* micrometer syringe to the solution in an atmosphere of carbon dioxide-free nitrogen. Potentiometric measurements were performed by using an HRL-Model P pH meter (made by Horiba instruments, Inc., Kyoto), with a combined glass electrode (Metrohm, EA-125 U-type, Herisaw, Switzerland). Further details of the titration have been presented in the previous paper.[2]

Results and Discussion

Titration Curves. The titration curves are illustrated in Fig. 1 for the ligand in the presence and in the absence of alkaline-earth metal ions. The acid-dissociation constants of this ligand can be calculated by the use of the titration curve in the absence of alkaline earth metal ions. As can be seen from Fig. 1, the "ligand only" titration curve shows well-defined inflections at $a=1$ and at $a=2$, where a is equal to the number of moles of bases added per mole of the ligand. Since each of the dissociation steps is separated by such well-defined inflection points, the calculation of the acid dissociation constants can be performed separately, as in the case of monoprotic acid. The calculation formula is as follows:

$$(T_L - T_{OH} - [H] + [OH])/(T_{OH} + [H] - [OH])[H] = 1/K_a$$

where T_L represents the total concentration of the ligand species and where T_{OH} represents the total concentration of the base added to the system. The acid dissociation constants of the reagent are defined as follows:

$$K_{a1} = [H][H_2L]/[H_3L],\ K_{a2} = [H][HL]/[H_2L],$$
$$K_{a3} = [H][L]/[HL],$$

1) J. I. G. Cadogan, D. J. Sears, and D. M. Smith, *Chem. Commun.*, **1966**, 491.

2) K. Kina, H. Miyata, and K. Tôei, This Bulletin, **44**, 1855 (1971).

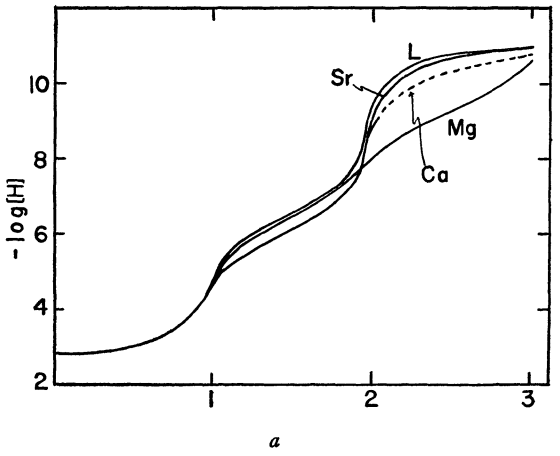


Fig. 1. Titration of 1-(2-phosphonophenylazo)-2-hydroxy-naphthalene-3,6-disulfonic acid disodium salt and its chelate system at 25°C, $\mu=0.10$; L, Ligand only, [Ligand]$=1.555\times10^{-3}$ M, [Mg]$=2.216\times10^{-3}$ M, [Ca]$=2.256\times10^{-3}$ M, [Sr]$=2.078\times10^{-3}$ M,
a=moles of base added per mole of ligand

where the ionic charge is omitted for the sake of convenience. The first and the second steps of the titration curve correspond to the two phosphonic protons, while the third step corresponds to the naphtholic proton. Therefore, the pK_{a1} and the pK_{a2} values were assigned to the phosphonic group; the pK_{a3} value was assigned to the naphtholic hydroxyl group.

The titration curves in the presence of alkaline earth metal ions show a clear pH depression caused by the chelation; the chelate stability constants can be obtained from these curves by the algebraic method. No precipitates, except for the barium chelate system, were found throughout the titration. The calcium and the strontium chelate systems present the same degree of pH depression in the region of $a=1$—2, while this titration curve splits into two lines at $a=2$; the dotted and the solid lines indicate the titrations of the calcium and strontium chelate systems respectively. These chelate systems give well-defined inflections at $a=1$ and at $a=2$ similar to that of the ligand only. This indicates that different reactions occur in the two pH regions separated by such well-defined inflections. In the region of $a=1$—2, the metal-ligand equilibria may be expressed by:

$$M + HL \rightleftarrows MHL, \quad K_{MHL} = [MHL]/[M][HL].$$

That is to say, the acido complex exists in this region; after $a=2$, the reaction may be expressed as:

$$MHL \rightleftarrows H + ML, \quad K_a' = [H][ML]/[MHL],$$

where the dissociation of the complex is observed. The order of the stability constant can be judged roughly by the extent of the pH depression. It is obvious that calcium and strontium ions form more stable acido complexes than does the magnesium ion; their values, $\log K_{SrHL}$ and $\log K_{CaHL}$, may be of much the same magnitude. The decreasing order of the stability constant, K_{ML}, with respect to the metal ions may be as follows: Mg(II)>Ca(II)>Sr(II). The titration curves of the calcium and strontium chelate systems show a clear inflection at $a=2$ similar to that of the ligand only. From this, it can be expected that the pK_a' values of the acido complex will differ little from the pK_{a3} value of the ligand.

Stability Constants. The chelating reaction is separated into two steps; the calculation of the equilibrium constants, except for the case of the magnesium chelate system, can be treated separately as two steps, that is, the acido complex formation and the acid dissociation of this complex. The stability constant of the barium chelate system was not obtained because of the precipitation. At the formation step of the acido complex in the region of $a=1$—2, the calculation formula of the acido complex stability constant is:

$$K_{MHL} = (T_L-F)/[HL](F+T_M-T_L),$$

where $$[HL] = K_{a3}/[H](T_L - T_{OH} - [H] + [OH]),$$

$$F = (1+K_{a2}/[H])(T_L-T_{OH}-[H]+[OH]).$$

The acid dissociation constant of the acido complex was then obtained by the following equation:

$$1/K_a' = (T_{MHL}-A)/[H]A, \quad \text{here } A=T_{OH}+[H]-[OH],$$

where T_{MHL} represents the total concentration of the acido complex species, which is almost equal to T_L when there is an excess of the metal ion. In addition, the following simple relationship holds among the equilibrium constants:

$$K_{MHL}\cdot K_a'/K_{a3} = K_{ML}.$$

Therefore, $\log K_{MHL} - pK_a' + pK_{a3} = \log K_{ML}$

The stability constant, $\log K_{ML}$, of the calcium or strontium chelate system was obtained by the use of the above relationship. The results of these calculations are shown in Table 1. When we suppose the structural formula of the acido complex, first we consider that the metal ion makes a coordination bond with the phosphonate group alone; however, neither phenylphosphonic acid nor the *p*-isomer of the ligand showed a remarkable pH depression such as did the ligand in the region of $a=1$—2. As can be seen from this result, the metal ions form a coordination bond not only with the phosphonate group, but also with the azo group. The naphtholic hydroxyl group of the azo compound is known to make a hydrogen bond with the azo link;[3] the structural formula for the acido complex, therefore, may be represented by Structure I. The magnesium ion forms an unstable chelate, MgHL, therefore, the calculation of the K_{ML} can be adequately approximated by the following equation:

$$K_{ML} = (T_L-F)/[L](F+T_M-T_L)$$

where $$[L] = (2T_L-T_{OH}-[H]+[OH])/([H]/K_{a3} + 2[H]^2/K_{a3}K_{a2})$$

$$F = [L](1+[H]/K_{a3}+[H]^2/K_{a3}K_{a2})$$

In this manner, the stability constant of the magnesium chelate, $\log K_{MgL}$, was obtained; it is also shown in Table 1. As can be seen from the titration curves and Table 1, the acido complex of the magnesium ion has a smaller pK_a' value than the other pK_a' values; it is considered that the acido complex of the magnesium ion, MgHL, has a tendency to become the stable

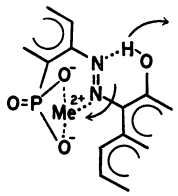
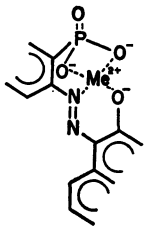
chelate form, MgL, through its own acid dissociation. In other words, since the electron-withdrawing tendency of the magnesium ion is larger than that of the calcium or strontium ion, the basicity of the naphtholic hydroxyl group was lowered by the magnesium ion which was coordinated to the azo link. This relation may be illustrated by Structure I.





Me^{2+} = Metal Ion

Structure I. MHL Structure II. ML

The decreasing order of the pK_a' values with respect to the metal ions is as follows: Sr(II)>Ca(II)>Mg(II); that is, the electron-withdrawing tendency of the metal ions increases in this order: Sr(II)<Ca(II)<Mg(II). It seems reasonable that the metal ion forms a coordination bond with the dissociated naphtholic hydroxyl group after the dissociation of the acido complex (Structure II).

The Chelate Formation of (*o*-Substituted Phenylazo)chromotropic Acids with Alkaline Earth Metals. II

Takeshi KATAYAMA, Haruo MIYATA, and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received April 20, 1971)

The acid dissociation constants of phenylazochromotropic acid and its *o*-substituted derivatives with $-CH_3$, $-OCH_3$, $-COCH_3$, -COOH, $-CH_2COOH$, -COCOOH, $-OCH_2COOH$, and -CH(OH)COOH in the *ortho* position to the azo group, and the stability constants of their 1 : 1 metal chelates with alkaline earth metals have been measured by potentiometric titation. The measurements have been carried out at 25°C and at $\mu=0.10$ with KNO_3. The effects of these substituents on the acid dissociation constants of the reagents and on the stability constants of these chelates were discussed. The pK_a value for the naphtholic proton of the *o*-substituted reagents was larger than that of phenylazochromotropic acid, and the stability constants of these chelates with alkaline earth metals decreased as follows: Mg>Ca>Sr>Ba, while for the chelates of the *o*-OCH_2COOH reagent the order was Ca>Mg>Sr>Ba, and for the *o*-CH(OH)COOH reagent it was Mg≈Ca>Sr>Ba. The plots of the stability constants, $\log K_1$, against the sum of the acid dissociation constants, $pK_A(=pK_{a1}+pK_{a2})$, were approximately linear except for the above two reagents with calcium, strontium, and barium. From the results obtained, the *o*-OCH_2COOH reagent that behaves as a quadridentate ligand forms a more stable chelate with calcium, strontium, and barium, and the effect of the $-OCH_2COOH$ group, especially that of the coordination of the -O- atom, is remarkable in its calcium chelate.

Many of the (*o*-substituted phenylazo)chromotropic acids are well known as colorimetric reagents and as metal indicators in chelatometry. In a previous paper,[1] the effects of various substituents on the acid dissociation of the reagents and also on the chelate formation with alkaline earth metals were discussed. The present authors have now extended the studies to alkaline earth metal chelates with the eight (*o*-substituted phenylazo)chromotropic acids shown in Fig. 1, and have investigated the effect of the substituents on the dissociation constants and the stability constants by means of the potentiometric-titration method.

Experimental

Reagents. The o-H reagent [phenylazochromotropic acid, 2-(phenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid],[2] the o-CH_3 reagent [2-(o-tolylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid], the o-OCH_3 reagent [2-(o-anisolazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid],[3] the o-$COCH_3$ reagent [2-(o-methylbenzoylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid,[4] the o-COOH reagent [2-(o-carboxyphenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid],[5] the o-CH_2COOH reagent[2-(o-phenylacetic acidazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid],[6] the o-COCOOH reagent [2-(o-oxalophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid],[7] the o-OCH_2COOH reagent [2-(o-phenoxyacetic acidazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid],[8] and the o-CH(OH)COOH reagent [2-(o-mandelic acidazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid][9] were synthesized by the coupling reaction of chromotropic acid with the corresponding diazonium compounds. The disodium salt of the reagents was obtained by the salting-out of purified azo sulfonic acids. These reagents are all fine crystals. They are dried at 60°C in a vacuum and stored in a calcium chloride desiccator. The stock solutions of these reagents were standardized by potentiometric titration with a standard 0.10 M potassium hydroxide solution.

Analytical-grade $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, $Sr(NO_3)_2$, and $Ba(NO_3)_2$ were used to make the stock solutions, and these solutions were standardized by chelatometric titration or gravimetric analysis.

Potentiometric titration. The apparatus and the procedure for the potentiometric titration were presented in a previous paper[1]; the temperature and ionic strength of a solution were maintained, respectively, at 25°C and at 0.10 with potassium nitrate.

Calculations of Acid Dissociation Constants and Stability Constants. The o-H, o-CH_3, o-OCH_3, and o-$COCH_3$ reagents are considered to be monobasic acids, while the o-COOH, o-CH_2COOH, o-COCOOH, o-OCH_2COOH, and o-CH(OH)COOH reagents are considered to be dibasic acids. The acid dissociation constants, K_{a_1} and K_{a_2}, and the stability constant, K_1, can be calculated by equations similar to those reported by Murakami *et al.*[10] K_{a_1}, K_{a_2} and K_1 are expressed as follows:

$$K_{a1} = \frac{[H][HL]}{[H_2L]}, \quad K_{a2} = \frac{[H][L]}{[HL]}$$

$$K_1 = \frac{[ML]}{[M][L]}$$

where the ionic charge was neglected for the sake of convenience

Results and Discussion

Titration Curves. The potentiometric titration curves for phenylazochromotropic acid (the o-H reagent) chelate system are illustrated in Fig. 2, while those for the o-COOH reagent chelate system are shown in Fig. 3. The clear inflection at $a=1$ in the titration curve of the ligand in Fig. 3 shows the dissociation of the carboxyl proton of the reagent. No inflection was observed at all on the neutralization of the naphtholic hydroxyl proton. The titration curves of the o-CH_3, o-OCH_3, and o-$COCH_3$ reagents were similar to that of the o-H reagent in Fig. 2, while those of the o-CH_2COOH, o-COCOOH, o-OCH_2COOH, and o-CH(OH)COOH reagents resemble the curve in Fig. 3.

Acid Dissociation Constants. The acid dissociation constants of the reagents were calculated from the titration curves and are summarized in Table 1.

$-OCH_3$		9.92	3.95	3.25	2.40	2.08
$-COCH_3$		9.65	3.66	2.95	2.35	
-COOH	3.60	10.00	4.53	3.37	2.82	2.81
$-CH_2COOH$	3.77	9.64	4.00	3.50	2.75	2.43
-COCOOH	3.54	9.96	4.55	3.41	2.88	2.73
$-OCH_2COOH$	2.84	9.83	4.31	5.13	3.65	3.00
-CH(OH)COOH	3.03	9.39	3.96	3.92	3.40	3.12

The pK_{a1} and pK_{a2} values correspond to the dissociation of the carboxyl group and one of the naphtholic hydroxyl groups respectively. The other naphtholic hydroxyl group is not dissociated under ordinary experimental conditions because of a strong hydrogen bridge between two oxygen atoms of chromotropic acid, as is shown in Fig. 1. The pK_a value of the *o*-H reagent is 9.19. It is suggested that pK_a values of the *o*-CH_3 and *o*-OCH_3 reagents are larger than that of the *o*-H reagent, because the methyl and methoxy groups are *ortho*- and *para*-directing and electron-donating. Because of the effects of these groups, the N···H hydrogen bond should become stronger, as is shown in Fig. 1; in fact, the pK_a values for the *o*-CH_3 and the *o*-OCH_3 reagents are 9.60 and 9.92 respectively. In the case of the *o*-$COCH_3$ reagent, the value is 9.65 in spite of its electron-withdrawing effect. However, the value of the *p*-$COCH_3$ reagent is 9.08 because of this effect. The same phenomenon appears in the case of the *o*- and the *p*-sulfophenylazochromotropic acids, where the pK_a of the *o*-reagent is 9.35, whereas that of the *p*-reagent is 8.95.[1] Thus, the introduction of such electron-withdrawing groups into the *para*-position results in a lowering of the pK_a value, while their introduction into the *ortho*-position leads to a rise in the value. This is due to the *ortho* effect which inhibits the dissociation of the naphtholic proton.

In the *o*-COOH reagent, the resonance of the carboxyl group is so inhibited by the six-membered ring, which contains the N···H hydrogen bond, that the carboxyl group and benzene ring cannot exist on the same plane. The carboxyl proton tends to be dissociated easily for this reason.

The pK_{a1} values of the five reagents which have a carboxyl group are compared with those of the aromatic acids in Table 2. The pK_{a1} values of all the reagents except the *o*-COCOOH reagent are smaller than those of the aromatic acids. This exception is also dependent on the *ortho* effect.

Stability Constants. The stability constants of their 1 : 1 chelates with alkaline earth metals are also tabulated in Table 1. The *o*-H, *o*-CH_3, *o*-OCH_3, and *o*-$COCH_3$ reagents are considered to form a bidentate ligand, the *o*-COOH, *o*-CH_2COOH, and *o*-COCOOH reagents are terdentate, and the *o*-OCH_2-COOH and the *o*-CH(OH)COOH reagents are quadridentate for alkaline earth metal ions.

The strontium and barium chelates of the *o*-CH_3 reagent were so unstable that their stability constants could not be determined. The barium chelate of the *o*-$COCH_3$ reagent also could not be obtained because of its precipitation.

The relation between the stability constants, log K_1, and the reciprocal of alkaline earth metal ionic radii,[16] $1/r$, is given in Fig. 4. The log K_1 values of most metal chelates decrease as follows: magnesium >calcium>strontium>barium, with an increase in

the ionic crystal radii. However, in the o-OCH_2-COOH and the o-CH(OH)COOH chelates, the order of decreasing stability is calcium≳magnesium> strontium>barium. The values of the o-COOH chelates with strontium and barium are nearly equal, because the chelation in the o-COOH reagent is suitable for the barium ionic radius.

As the relation between metal ions and these ligands is regarded as a Lewis acid-base reaction, the log K_1 value is plotted against the sum of the dissociation constants, pK_A ($=pK_{a_1}+pK_{a_2}$), in Fig. 5. The log K_1 values are nearly proportional to the pK_A values. This implies that the stability of these chelates is mainly dependent upon the basicity, *i.e.*, the pK_A value, of the ligands, except for the calcium, strontium, and barium chelates of the o-OCH_2COOH and the o-CH(OH)COOH reagents.

As for the reagents behaving as monobasic acid, the plots of the log K_1 values of the o-H chelates against

those of the o-OCH_3 or o-$COCH_3$ chelates are shown in Fig. 6(a). These reagents may form a bidentate ligand, and a good linear relation sphip is obtained among the reagents. This suggests that these chelate structures are similar to each other, as is shown in the structural formula (1). The chelate structure of the o-H reagent with an alkaline earth metal ion forms a stable six-membered ring. The bulky methyl group of the o-CH_3 reagent disturbs the chelate formation. Especially, these chelates with strontium and barium are very unstable because of these large ionic radii. The small stable deviation of the o-OCH_3 reagent with calcium is due to the coordination of the oxygen atom of the methoxy group, but those of the acetyl group scarcely coordinate at all with the metal ion.

The same relationship is obtained for the dibasic acid system, as is shown in Fig. 6(b) and (c); these structures are shown in structural formulas (2), (3), and (4). That is to say, the structure of the o-COOH chelate has two chelate rings as a terdentate ligand, but those of the o-OCH_2COOH and the o-CH(OH)-COOH chelates probably have three chelate rings.

Thus, the reagents may behave as a quadridentate ligand. As is shown in Fig. 5, the positive deviation from the straight line for the log K_1 values of these calcium, strontium, and barium chelates is considered to result from this cause. This tendency is so remarkable in the *o*-OCH_2COOH chelate with calcium that the order of the stability is calcium>magnesium. On the other hand, on the magnesium chelates of these reagents, the plots in Fig. 5 lie on or under the straight line. This means that their oxygen atom (–O– or –OH) in the substituent scarcely contributes at all to the coordination, because the ionic radius of magnesium is much smaller than that of the other alkaline earth metals discussed before.

The Stability of Fused Rings in Metal Chelates. VIII. Solution Equilibria of the Copper(II) Complexes of Glycinamide and Related Compounds

Osamu YAMAUCHI, Hiroko MIYATA, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received May 14, 1971)

The aqueous solution equilibria of the systems containing copper(II) ion and glycinamide, β-alaninamide, glycine-*N*,*N*-diethylamide, or β-alanine-*N*,*N*-diethylamide have been investigated by potentiometric titration at 25°C (μ=0.1 (KNO_3)). The stability constants K_1 and K_2 and the constants of the deprotonation reactions K_1^H, K_{c1}, and K_{c2}, for the glycinamide-copper(II) systems, and K_1 and K_2 for the other ligand-copper(II) systems were calculated by the method of non-linear least-squares with the aid of a computer. The K_1 values were found to be in the order, glycine-*N*,*N*-diethylamide (6.17) > β-alanine-*N*,*N*-diethylamide (5.5) > glycinamide (5.30) > β-alaninamide (5.1). The sequence reveals that the five-membered chelates are more stable than the six-membered ones. The K_1 and K_{c1} values for glycylglycine and β-alanylglycine have been determined anew, and the structures of the chelates formed in acid solution have been discussed from comparative studies of the equilibrium constants, which suggest a tridentate nature of the dipeptides in the chelates of the type $Cu(HL)^+$ where HL denotes free dipeptide.

From comparative studies of the stability constants of various copper(II)-dipeptide chelates, Rabin[1] postulated that in acid solution glycylglycine (Gly·Gly) binds with copper(II) as bidentate ligand through the amino nitrogen and peptide oxygen as indicated by the structure Ia. Since then a considerable number of papers have appeared dealing with the nature of the copper(II)-peptide bonding in the chelates formed in acid solution.

Pagenkopf and Margerum[5] and Pasternack *et al.*[6] also obtained results supporting the view from kinetic studies. Kim and Martell,[7,8] on the other hand, favored the fused-ring structures like IIa from the potentiometric and spectral points of view.

We reported[9] the reactions of copper(II) with some dipeptides composed of glycine and/or β-alanine as studied from the viewpoint of the relative stability of fused-ring chelates, and interpreted the results as indicative of the coordination to copper(II) in acid solution by the amino nitrogen, amide nitrogen, and carboxyl oxygen of the dipeptides as shown by IIa and IIb.

The necessity for further information on the bonding modes in solution prompted us to carry out studies on the interactions of copper(II) with some amino acid amides as fundamental constituents of peptides. In this connection, it seemed significant to investigate comparatively the stabilities and structures of the copper(II) complexes of glycinamide, β-alaninamide, and the corresponding *N,N*-diethylamides in order to get information on the contribution of peptide oxygen and nitrogen atoms to coordination.

The solution equilbria of the copper(II)-glycinamide complexes have been reported by Datta and Rabin,[10] Li *et al.*,[11] and Sigel.[12] Regardh[13] carried out detailed studies on the equilibria involved in a 2 : 1 glycinamide-copper(II) mixture as well as the copper(II) ion-catalyzed hydrolysis of glycinamide, and obtained equilibrium constants by the method of Bjerrum. However, the equilibrium constants for glycinamide reported so far by these investigators were determined under different conditions and do not seem to be complete. It might be of value to reinvestigate the glycinamide-copper(II) systems along with the other amide-copper(II) systems.

This paper deals with the studies on the solution equilibria of the copper(II) complexes of glycinamide (GA), β-alaninamide (β-AA), glycine-*N,N*-diethylamide (GDA), and β-alanine-*N,N*-diethylamide (β-ADA), and a discussion on the structures and stabilities of the complexes.

Experimental

Reagents. GA hydrochloride was purchased from Nakarai Chemicals Co., Ltd., and used without further purification. β-AA hydrochloride,[14] GDA hydrochloride,[15] Gly·Gly,[16,17] and β-alanylglycine (β-Ala·Gly)[18] were prepared according to literature and checked by the melting point and elemental analysis.

*β-Alanine-*N,N*-diethylamide* (β-ADA). To a stirred solution of diethylamine (6.6 g, 90 mmol) in toluene (50 m*l*) was added, under cooling in ice water, carbobenzoxy-β-alanyl chloride[19] in toluene (50 m*l*) prepared from carbobenzoxy-β-alanine (10.0 g, 45 mmol), and the mixture was stirred for 2.5 hr at room temperature. The filtrate from diethylamine hydrochloride was washed successively with dilute aqueous sodium carbonate and water and dried over magnesium sulfate. The yellow oil obtained after evaporation of the solvent *in vacuo* was reduced with Pd-H_2 in methanol (250 m*l*) containing concentrated hydrochloric acid (2 m*l*). After removal of the catalyst and solvent, the oily residue was dried over P_2O_5 *in vacuo* and crystallized by washing with acetone. Yield, 3.0 g. Recrystallization from ethanol-acetone-ether gave the hydrochloride of β-ADA as very hygroscopic leaflets, mp 115—116°C (uncor.). Found: C, 46.38; H, 9.57; N, 15.51%. Calcd for $C_7H_{17}N_2OCl$: C, 46.53; H, 9.48; N, 15.51%.

0.1 N *Potassium Hydroxide.* Prepared according to Armstrong,[20] standardized against potassium hydrogen phthalate, and stored under a nitrogen atmosphere.

0.01 M *Copper(II) Nitrate.* Prepared by dissolving copper (II) nitrate trihydrate in water and standardized by chelatometric titrations.[21]

All the reagents used were of reagent grade and deionized water was used throughout.

pH Titrations. An aqueous solution of a ligand and copper(II) nitrate (0.002—0.008 M) was titrated with 0.1 N potassium hydroxide under a nitrogen atmosphere at 25°C (μ=0.1(KNO_3)). For the calculation of the acid dissociation constants, the ligands were titrated in the absence of copper(II) nitrate. The pH values were measured with a Radiometer PHM 4d pH meter equipped with a G202C glass electrode and a K401 saturated calomel electrode. The system was standardized with a Horiba and a Radiometer standard buffer solution (pH 4.01 and 6.48). Conversion of pH to $-\log[H^+]$, where $[H^+]$ refers to the hydrogen ion concentration, and determination of the apparent ion product of water pK_w' were made by titrating 0.01 N nitric acid with 0.1 N potassium hydroxide under the same conditions. The values $[H^+]=10^{-pH}/0.85$ and $pK_w'=13.88$ were used in the calculations.

Results and Discussion

Titration Curves. The titration curves of the amides both in the absence and presence of copper(II) are shown in Fig. 1. The curves for the GA-copper (II) systems reveal that two protons are liberated from a ligand in the presence of copper(II), whereas only one proton is liberated in the GDA-copper(II) system. The two protons undoubtedly can be ascribed

to the dissociation of the ammonium and amide groups of protonated GA. The titrations of the solutions containing copper(II) and the β-alaninamides at various ratios resulted in the precipitations of the hydrolyzed species of copper(II). No sufficient data were obtained. This might indicate that the β-alanine derivatives, in sharp contrast to the glycine derivatives, form unstable complexes with copper(II), where the copper(II)-ligand bonds are susceptible to hydrolytic cleavage.

Calculation of the Equilibrium Constants. We see from the titration curves that the equilibria for the GA-copper(II) systems are somewhat complicated, and the usual Bjerrum method, which is effective for the *N*,*N*-diethylamides, does not seem to be suitable for calculating the constants appearing in these systems. Various computer programs for the non-linear least-squares treatment of data have hitherto been proposed and applied to such complex systems. Recently Sayce[22] reported a general program SCOGS, which evaluates data by this method based on the minimization of the sum of the squares of the residuals in the titer of base, in contrast to the earlier programs which seek to minimize the sum of the squares of the residuals in the analytical hydrogen ion concentrations.

Since the former apparently seems to be easier in the weighing procedure, we also attempted the least-squares refinements as suggested by Sayce. Our program is in principle analogous to SCOGS and earlier programs and consists of the Newton-Raphson iterations, which calculate from the initial estimates of the constants the free ligand and free metal ion concentrations, using the mole balance equations for the total ligand and total metal ion concentrations, the setting up of the matrix for the least-squares treatment, which gives the shifts in the constants by matrix inversion, and the output of the refined constants and their estimated standard deviations. The output also includes the calculated concentration of alkali, the difference of the calculated titer from the experimental, the free ligand and free metal concentrations, and the individual amounts of coordinated species relative to the total metal ion concentration, for each data point. In the present version of the program, partial derivatives were obtained arithmetically for each system, and the calculated shifts in the constants were in the form of the constants and not in their logarithms. The residuals in the concentrations of alkali were calculated from the equation for the electroneutrality of solution. Initial estimates of the constants were obtained by some other methods or taken from literature, and the program accepted up to ten sets of such estimates for a system. The standard deviations of the constants were estimated from the elements of the inverted matrix and the assumed error in the titer of alkali. The subroutine for matrix inversion is conventional and that for least-squares treatment is described elsewhere.[23]

The reaction sequences expected from the titration curves of the 1 : 1 and 2 : 1 GA-copper(II) systems can be expressed by the following equlibria (1) through (5) with the relevant equilibrium constants K_1, K_1^H, K_2, K_{c_1}, and K_{c_2} defined by Eqs. (6) through (10):

$$Cu^{2+} + HL \overset{K_1}{\rightleftharpoons} Cu(HL)^{2+} \quad (1)$$

$$Cu(HL)^{2+} \overset{K_1^H}{\rightleftharpoons} CuL^{+} + H^{+} \quad (2)$$

$$Cu(HL)^{2+} + HL \overset{K_2}{\rightleftharpoons} Cu(HL)_2^{2+} \quad (3)$$

$$Cu(HL)_2^{2+} \overset{K_{c_1}}{\rightleftharpoons} Cu(HL\cdot L)^{+} + H^{+} \quad (4)$$

$$Cu(HL\cdot L)^{+} \overset{K_{c_2}}{\rightleftharpoons} CuL_2 + H^{+} \quad (5)$$

$$K_1 = \frac{[Cu(HL)^{2+}]}{[Cu^{2+}][HL]} \quad (6)$$

$$K_1^H = \frac{[CuL^{+}][H^{+}]}{[Cu(HL)^{2+}]} \quad (7)$$

$$K_2 = \frac{[Cu(HL)_2^{2+}]}{[Cu(HL)^{2+}][HL]} \quad (8)$$

$$K_{c_1} = \frac{[Cu(HL\cdot L)^{+}][H^{+}]}{[Cu(HL)_2^{2+}]} \quad (9)$$

$$K_{c_2} = \frac{[CuL_2][H^{+}]}{[Cu(HL\cdot L)^{+}]} \quad (10)$$

			5.50[f]			4.10[f]	
β-Ala·Gly	3.22±0.009	9.45±0.009	5.45±0.001			4.09±0.001	
			5.45[f]			4.08[f]	
Glycine[g]	2.41	9.63	8.20[e]		6.90[e]		
β-Alanine[g]	3.55	10.15	6.99[e]		5.55[e]		

a) Variances are expressed in standard deviations. For all the data used for calculation, the differences between the observed and calculated titers of 0.1 N potassium hydroxide were within 0.02 m*l* for the titers ranging from 0 to 2.5 m*l*.
b) The following values have been reported:
$pK_{a_{NH_3^+}}$=8.04±0.02; log K_1=5.40±0.04; pK_1^H=7.01±0.04 (25°C; μ=0.1 ($NaClO_4$))[12]
$pK_{a_{NH_3^+}}$=8.19±0.01; log K_1=5.4; log K_2=4.4; pK_{c_1}=7.7; pK_{c_2}=8.6 (25°C; μ=1.0 ($NaClO_4$)).[13]
c) Calculated from the data obtained by titrating a 1 : 1 GA-copper(II) system.
d) The log K_1 and log K_2 values are inaccurate owing to precipitation.
e) Calculated from the $\bar{n}$ values.[24]
f) Calculated by the method of Datta and Rabin.[10]
g) Constants included for comparison and are taken from our previous studies[9] and unpublished results.

where HL and L refer to GA and GA deprotonated from the amide nitrogen atom, respectively. Least-squares adjustment taking the equlibria (1), (3), (4), and (5) into account was satisfactory for the 2 : 1 ligand-copper(II) system over the pH range 4—9. Attempts to include the equilibrium (2) were not successful, indicating that this process is negligible if not improbable in this system. Constant K_1^H was obtained from the titration of a 1 : 1 ligand-copper(II) mixture.

For the β-AA-copper(II) system, evaluation of the data may be inaccurate because of the precipitate formation at a very early stage of titration. Considering the pH range of the data and the expected stability of the complex, deprotonation reactions (2), (4), and (5) seemed to be negligible, and only the calculation of the constants K_1 and K_2 for the equilibria (1) and (3) was attempted. On the other hand, the *N,N*-diethylamides have no dissociable amide hydrogens and form complexes of the types CuL^{2+} and CuL_2^{2+}, where L refers to free ligand, according to equlibria similar to (1) and (3). Thus, the stability constants K_1 and K_2 were calculated by the Bjerrum and the least-squares methods. The amide β-ADA was similar in behavior to β-AA and did not afford sufficient data owing to precipitation.

Interpretation of the Equilibrium Constants. The calculated constants for the amides are shown in Table 1 along with the values for Gly·Gly, β-Ala·Gly, glycine, and β-alanine. The dipeptide-copper(II) systems were titrated under the same conditions, and the K_1 and K_{c_1} values, which describe the reactions analogous to (1) and (2), were calculated by the method of Datta and Rabin[10] and by the present method.

The stability constants log K_1 and log K_2 for GDA and β-ADA calculated by the present method agreed with those obtained by the method of Irving and Rossotti[24] from the $\bar{n}$ values (average number of ligand molecules bound to a metal ion) within 0.1 log unit.

Also, the constants log K_1 and $-\log K_c$ (pK_{c_1}) for the dipetides calculated by the present treatment were in excellent agreement with those obtained by the method of Datta and Rabin.

As regards the GA-copper(II) systems, Regardh[13] obtained the four constants K_1, K_2, K_{c_1}, and K_{c_2} according to the method of Bjerrum by titrating a 2 : 1 ligand-copper(II) system at 25°C (μ=1.0($NaClO_4$)). Considering the differences in the conditions and the method of calculation, they are in good agreement with the present values. As Regardh remarked, however, serious deviations were observed between the calculated and the experimental values in the

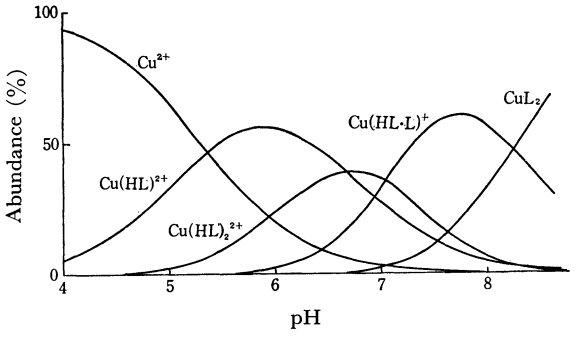

Fig. 2. Abundances of coordinated species in the 2 : 1 GA-copper(II) system; calculated from the constants listed in Table 1.

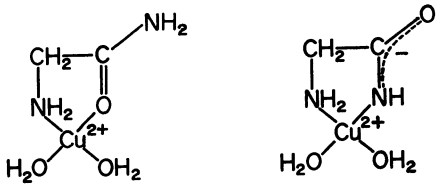
24) H. Irving and H. S. Rossotti, *J. Chem. Soc.*, **1953**, 3397.

pH region where two or more concomitant reactions take place, because only a limited number of reactions were taken into consideration. According to the least-squares treatment of data, a better fit to the experimental curve could be obtained over the entire pH range in question. The relative amounts of the coordinated species present in a 2 : 1 ligand-copper (II) system at various pH values are shown in Fig. 2. We see that in the pH range 6.2—8.0 at least three of the four species exist in considerable amounts. Constant K_1^H for the equlibrium (2) could not be obtained from the titration of a 2 : 1 ligand-copper(II) system, which indicates the predominance of the formation of the 2 : 1 chelate over that of the deprotonated 1 : 1 chelate.

Stability constants for the β-alaninamides were calculated from a very small number of data as compared with those for the glycinamides and are less reliable. For the β-AA-copper(II) system, the stability constants can be influenced by the probable errors due to hydrolysis reactions.

Komorita *et al.*[25] inferred from the spectral studies that the preferred coordination sites of α-amino acid amides in acid solution are the amino nitrogen and the carbonyl oxygen as shown by structure III and that in alkaline solution the amide nitrogen replaces oxygen (IV). Figure 2 indicates that in the pH range 4—7 the complexes $Cu(HL)^{2+}$ and $Cu(HL)_2^{2+}$ predominate, whereas at higher pH values the amounts of the deprotonated species $Cu(HL\cdot L)^+$ and CuL_2 exceed the amount of $Cu(HL)_2^{2+}$. The finding is consistent with that from the spectral studies.



III IV

When compared with the dipeptide-copper(II) chelates, the 1 : 1 GA-copper(II) chelate exhibits a remarkable difference in the pK_{c_1} value (6.95) which is more than 2.8 log units higher than the values for the dipeptides. Therefore, the deprotonated chelates CuL of Gly·Gly and β-Ala·Gly predominate over $Cu(HL)^+$ in wide pH ranges as demonstrated in Figs. 3 and 4. The fact probably points to the difference in stability of the deprotonated chelates.

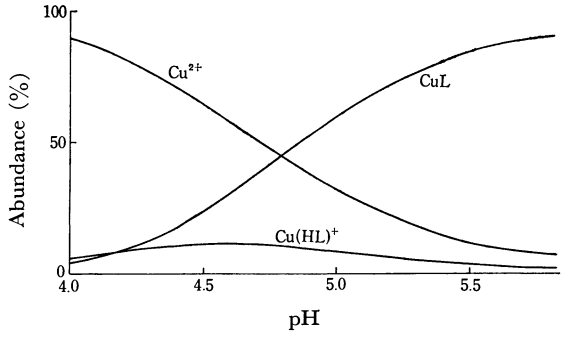


Fig. 3. Abundances of coordinated species in the 1 : 1 Gly·Gly-copper(II) system; calculated from the constants listed in Table 1. Similar curves were reported by Kim and Martell.[7]

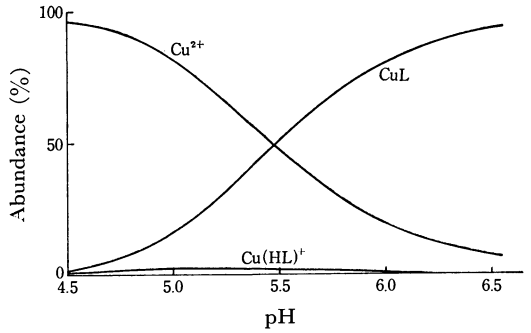

Fig. 4. Abundances of coordinated species in the 1 : 1 β-Ala·Gly-copper(II) system; calculated from the constants listed in Table 1.

Stability constants log K_1 for the glycinamides are now found to be greater than those for the corresponding β-alaninamides. Although the values for β-AA may not be reliable, the hydrolysis reactions observed during the titrations manifest that β-AA-copper(II) chelates are less stable than the GA-copper-(II) chelates. On the other hand, there is practically no difference between the log K_1 values of the Gly·Gly-and β-Ala·Gly-copper(II) chelates in spite of the large difference between those of the glycine- and β-alanine-copper(II) chelates. We explained the fact as due to the formation of the fused-ring structures, IIa and IIb,[9] where the steric requirements of the individual rings might be cancelled or dispersed over the chelate system as a whole to give chelates of equal stability. The present results indicate that the ring size produces a decisive effect on the chelate stability when the substituents on the amide nitrogen do not take part in chelation. Hence, the equal stability of the Gly·Gly- and β-Ala·Gly-copper(II) chelates appears to be better explained by the structures IIa and IIb rather than by Ia and Ib. As suggested by Tanaka *et al.*,[26] there seems to be a linear relationship between the differences in the pK_a values of the amino groups of the glycine derivatives and of the corresponding β-alanine derivatives investigated and the differences in the log K_1 values. Although the small difference observed for the dipeptides can be explained according to this relationship by the Rabin models Ia and Ib as well, we are more inclined to favor the fused-ring structures for the charged dipeptide-copper(II) chelates formed in acid solution, from the findings described above. Very recently Barnet *et al.*[27] determined the crystal structures of cobalt(III) complexes of Gly·Gly, of which bis(glycylglycinato)cobalt(III) perchlorate was shown to have

two Gly·Gly ions coordinating to cobalt(III) through the amino nitrogen, peptide nitrogen, and carboxyl oxygen with the hydrogen of the peptide group attached to the peptide oxygen. This seems to strongly support our view.

The situation would be somewhat different in the longer peptides, because the carboxyl group is quite apart from the strongly coordinating amino residue, so that it would be rather difficult to arrange the intervening peptide nitrogens around the coordination sphere of copper(II) without dissociation of the peptide hydrogens.

The authors wish to thank the members of the Osaka University Computation Center for the computations. The investigation was supported in part by a grant of the Japanese Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2721—2724 (1971)

The Crystal Structure of $(+)_{589}$-Dicyanobis(ethylenediamine)cobalt(III) Chloride Monohydrate

Keiji MATSUMOTO, Shun'ichiro OOI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City Univetsity, Sumiyoshi-ku, Osaka

(Received May 17, 1971)

The crystal structure of $(+)_{589}$-$[Co(CN)_2en_2]Cl \cdot H_2O$ has been determined from three-dimensional X-ray photographic data. The crystals are monoclinic, with the lattice constants of $a=8.15(1)$, $b=11.69(2)$, $c=6.61(1)$Å, and $\beta=107.1(2)°$, and with the space group of $P2_1$, containing two formula units in the cell. The structure was solved by a conventional Fourier technique and was refined by the least-squares method to an R factor of 0.114. The absolute configuration of the complex ion can be denoted as $\Lambda(\lambda\lambda)$; this is in accordance with the assignment made by Mason *et al.* The complex ion has an approximately two-fold axis, and both of the ethylenediamine chelate rings are of the *ob*-conformation.

The absolute configurations of the several bisethylenediamine cobalt(III) complexes with C_2-symmetry have been studied on the basis of the optical properties, such as CD or ORD spectra.[1-4] However, since no X-ray diffraction study had been made on the bisdiamine complexes, we carried out the direct determination of the absolute structure of $(+)_{589}$-$[Co(CN)_2en_2]Cl \cdot H_2O$ by the X-ray method. The preliminary results of this work have been reported previously.[5,6] In this paper, the complete crystal structure, as refined by the use of the three-dimensional reflection data, will be described.

Experimental

The plate-like, yellow crysatls of $(+)_{589}$-$[Co(CN)_2en_2]Cl \cdot H_2O$ were kindly supplied by Ohkawa and Fujita.[7] Lattice constants were determined by the least-squares refinement of the twenty-eight θ values from the $h0l$ and $hk0$ Weissenberg photographs, on which aluminum-powder diffraction lines were superimposed for calibration.

The observed systematic absences ($0k0$, $k=2n+1$) indicate two possible space groups, $P2_1$ and $P2_1/m$; however, the latter can be excluded, because the compound is optically active, including only the dextrorotatory enantiomer of the complex ions. The crystal data are shown in Table 1.

$Z=2$ ($D_m=1.56$, $D_c=1.57$ g·cm^{-3})
$\mu=51.3$ cm^{-1} (for Ni$K\alpha$, $\lambda=1.6591$ Å)

Multiple-film, equi-inclination Weissenberg photographs, $h0l$ through $h6l$, and $hk0$ through $hk3$, were taken with Ni$K\alpha$ radiation. The intensities were estimated by visual comparison with the calibrated intensity scale and were corrected for the Lp factor and spot-shape.[8] Since the crystal specimens used were sufficiently small ($\sim 0.10 \times 0.03 \times 0.4$ mm), the absorption correction was not applied. A total of 860 independent reflections were collected. However, 163 of these were too weak to be measured and so their intensities were assumed to be zero.

Determination of the Crystal Structure

At the early stages of this work, the electronic computer available to us was OKITAC 5090D, with which it was difficult to deal with the three-dimensional data; hence, we started on the structure analysis

by the two-dimensional method. The positions of the cobalt and chlorine atoms were found from the Patterson functions, $P(UW)$ and $P(UV)$. The remaining atroms were difficult to locate on the Fourier map $\rho(xz)$ phased by the heavy atoms, because of the poor resolution of the atomic peaks. Subsequently, the minimum function, $M(xy)$, was synthesized graphically[9] utilizing the coordinates of the Co and Cl atoms. The x and y coordinates of all the non-hydrogen atoms but the oxygen atom of the water molecule were found on the $M(xy)$ by the use of the scaled model of the complex ion. The oxygen atom could be located on the subsequent Fourier map, $\rho(xy)$. The crystal structure was refined to an R factor of 0.13 for the $hk0$ data by a diagonal least-squares method. At this stage, the z coordinate of each atom was readily obtained from the $\rho(xz)$. The R value for $h0l$ data was reduced to 0.14 by successive difference syntheses.

Further refinements were made by the block-diagonal least-squares method using the three-dimensional reflection data. The weighting scheme employed was as follows:

$$w=0.4 \text{ for } F_o<5.3$$
$$w=1.0 \text{ for } 5.3\leq F_o\leq 40.0$$
$$w=40.0/F_o \text{ for } F_o>40.0$$

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[10] The real part of the anomalous dispersion correction for Co was taken into account.[11] After four cycles of the refinement with an individual isotropic temperature factor, the R value was reduced to 0.114 for the 697 non-zero reflections. A subsequent refinement in which the Co and Cl atoms were allowed to vibrate anisotropically could improve neither the R factor nor the e.s.d.'s of the parameters. A difference Fourier map calculated at this point confirmed the crystal structure, but did not show peaks corresponding to any of the hydrogen atoms. The final atomic coordinates and temperature factors are listed in Table 2; a complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan.[12]

In order to determine the absolute configuration of the complex ion, the oscillation photographs were taken around the b axis with Cu$K\alpha$ radiation. The right-handed coordinate system was carefully used in the indexing of photographs throughout the present work. Some Bijvoet pairs are shown in Table 3, together with the observed inequality relationships. In the table, the intensities of the reflections, as calculated on the basis of the atomic coordinates in Table 2, are also listed. A comparison of the observed inequality relationships with the calculated ones indicates that the set of the atomic coordinates shown in Table 2 corresponds exactly to the absolute structure of the crystal.

Result and Discussion

The absolute crystal structures viewed along the c and b axes are shown in Figs. 1 and 2 respectively. The crystal is composed of $(+)_{589}$-$[Co(CN)_2en_2]^+$, Cl^- and H_2O, which are held together mainly by ionic forces. In order to find the hydrogen bonds, the positions of the hydrogen atoms in the NH_2 groups were calculated on the assumption that the N–H bond length is 1.03 Å.[13] The data for the N–H···B hydrogen bonds (B=N, O, and Cl) are summarized in Table 4a. In the chelate ring involving N_1 and N_2, all the hydrogen atoms linked to the nitrogen atoms participate in the hydrogen bonding, while in another ring only one hydrogen atom of the individual NH_2

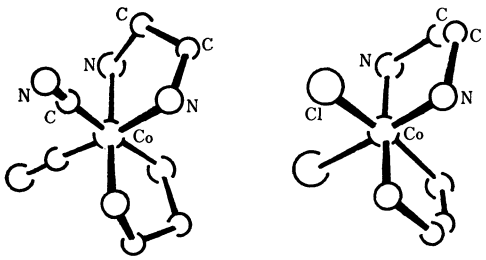
a) The atoms are labelled in the same way as in the previous paper.[15] There are two crystallographically-independent complex ions in the $(+)_{589}$-$[CoCl_2en_2]Cl \cdot H_2O$ crystal.

group takes part in the hydrogen bonding. The interatomic distance between $O(-x, 1/2+y, -z)$ and $N_5(x-1, y, z)$ is 3.08 Å, and that between $O(-x, 1/2+y, -z)$ and Cl is 3.27 Å, the Cl–O–N_5 angle being 102°. Thus, both of the hydrogen atoms of the water molecule seem to participate in the hydrogen bonding. The hydrogen bonds are shown in Fig.2 by the dashed lines.

The absolute configuration of $(+)_{589}$-$[Co(CN)_2en_2]^+$ is depicted in Fig. 3. This is in accordance with that proposed by Mason *et al.*[4] and can be denoted as $\Lambda(\lambda\lambda)$.[14] In the figure the absolute configuration of $(+)_{589}$-$[CoCl_2en_2]^+$ is also shown as a reference.[15] Both of the ethylenediamine molecules have the *ob* conformation in the present complex; thus, the complex cation can be described as having the *ob-ob* conformation. According to the conformational analysis made by Corey and Bailar,[16] the *ob-ob-ob* conformer is the least stable among the possible conformers of the trisethylenediamine complex. This probably holds true for the case of the *cis*-bisethylenediamine complex as well. As was stated in the previous paper,[15] however, the difference in the intramolecular potential energy between the most stable



$(+)_{589}$-$[Co(CN)_2en_2]^+$ $\Lambda(\lambda\lambda)$ $(+)_{589}$-$[CoCl_2en_2]^+$ $\Lambda(\delta\delta)$

16) E. J. Corey and J. C. Bailar, Jr., *J. Amer. Chem. Soc.*, **81**, 2620 (1959).

lel-lel conformer and the least stable *ob-ob* conformer is quite small in the bisethylenediamine complex, as compared with the case of the trisethylenediamine complex.

Ibers *et al.*[17] pointed out that the *lel-lel-lel* conformer of $[Cr\ en_3]^{3+}$ has fewer amine hydrogens which are free to form hydrogen bonds than does the *ob-ob-ob* conformer, and that the less stable latter conformer is favoured in the cases where strong hydrogen bonds can be formed. Though, in the bisethylenediamine complex, the situation is different from the case of the trisethylenediamine complex, their results seem also to be applicable to $(+)_{589}$-$[Co(CN)_2en_2]^+$ and $(+)_{589}$-$[CoCl_2en_2]^+$. In Fig. 4 are illustrated the hydrogen bonds coming out of the amine hydrogens of $(+)_{589}$-$[Co(CN)_2en_2]^+$ (*ob-ob*) and $(+)_{589}$-$[CoCl_2en_2]^+$(*lel-lel*), while the numerical data of the latter cation are listed in Table 4b. A comparison of these data with those of $(+)_{589}$-$[Co(CN)_2en_2]^+$ indicates that there are no appreciable differences in number and in length of the hydrogen bonds between these *lel-lel* and *ob-ob* conformers. Thus, the role of the hydrogen bonding in stabilizing the energetically-unfavourable *ob-ob* conformer does not seem so important in the bisethylenediamine complex as in the trisethylenediamine complex.

C_5-N_5	1.18 (4)		
C_6-N_6	1.19 (4)		

The bond distances and angles are given in Table 5. The Co–C bond is nearly collinear with the C–N bond. The average value of the Co–C bond length (1.87 Å) is in good agreement with that (1.869 Å) found in $[Cr\ en_3][Co(CN)_6]\cdot 6H_2O$,[18] but slightly less than the value (1.92 Å) in $(+)_{589}$-$[Co(C_{10}H_{28}N_6)][Co(CN)_6]\cdot 2H_2O$.[19] All the bond distances and angles in the chelate rings are normal.

The authors wish to express their thanks to Dr. K. Ohkawa and Dr. J. Fujita, who provided the crystals of $(+)_{589}$-$[Co(CN)_2en_2]Cl\cdot H_2O$. We are also indebted to Mr. K. Hirotsu, who adapted the HBLS-4 and the RSSFR-3 computer programs to the FACOM 270-30 computer at Osaka City University. This research was aided in part by a Scientific Research Grant from the Ministry of Education, to which the authors' thanks are due. Furthermore, one of authors (K. M.) gratefully acknowledges the financial support of the Matsunaga Science Foundation for his research.

The Polymerization of Silacyclopentene and -pentane Derivatives

Tsunao ARAKI, Daiyo TERUNUMA, Tamio SATO, Norio NAGAI, Mitsuharu FURUICHI, and Shigeyoshi NAKAMURA

Department of Applied Chemistry, Faculty of Science and Engineering, Saitama University, Urawa

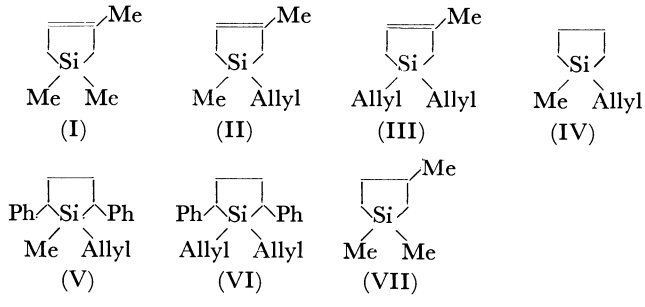
(Received September 11, 1970)

The polymerization of 1,1,3-trimethyl-1-silacyclopentene-3 (I), 1-methyl-, 1-allyl-1,1-diallyl-1-silacyclopentenes and -pentanes with aluminum chloride was carried out. By means of an IR spectroscopic analysis of the resulting polymers, it was established that not only ring opening but also vinyl polymerization due to the C–C double bond occur in this polymerization. Attempts to polymerize I with other catalysts, such as $BF_3 \cdot OEt_2$, AIBN, KOH, and a Ziegler catalyst, were unsuccessful.

Nametkin, Vdovin *et al.*[1] reported the aluminum chloride-catalyzed ring-opening polymerization of silaheterocylic compounds. We have been interested in studying the behavior of silacyclopentene derivatives toward aluminum chloride. Since 1,1,3-trimethyl-1-silacyclopentene-3 (I) contains an unsaturated bond in the ring, it is expected that I can be polymerized either at the C–C double bond or with the opening of the ring. The polymerization of I and its derivatives has been studied in order to obtain some information about the polymerizability of the silacyclo compounds.

Results and Discussion

The silacyclo compounds synthesized in the present work are 1,1,3-trimethyl-1-silacyclopentene-3 (I),[2] 1,3-dimethyl-1-allyl-1-silacyclopentene-3 (II),[3] 1,1-diallyl-3-methyl-1-silacyclopentene-3 (III),[3] 1-methyl-1-allyl-1-silacyclopentane (IV),[3] 1-methyl-1-allyl-2,5-diphenyl-1-silacyclopentane (V),[3] 1,1-diallyl-2,5-diphenyl-1-silacyclopentane (VI), and 1,1,3-trimethyl-1-silacyclopentane (VII).[3]



These silacyclopentenes and -pentanes were polymerized in the presence of aluminum chloride under various conditions, and studies of the solubilities and IR absorption spectra were carried out with all the polymers obtained. The IR spectrum of VII (Fig. 1) shows three absorption bands, at 1020, 1030, and 1070 cm^{-1}, attributable to a silicon-containing five-membered ring,[4] whereas polymers obtained from VII exhibit an absorption band only at 1070 cm^{-1} in the above region. The disappearance of the absorption bands at 1020 and 1030 cm^{-1} may be taken as an indication of the occurrence of ring-opening polymerization. Consequently, we used these bands for detecting the presence of the five-membered ring in the polymerization products.

4) V. M. Vdovin, K. S. Pushchevaya, N. A. Belikova, and R. Syltanov, *Dokl. Akad. Nauk SSSR.*, **136**, 96 (1961).

The IR spectrum of the polymer prepared from I at 21°C showed somewhat weakened absorption bands at 1020 and 1030 cm^{-1}, while the polymer prepared at 120°C showed no absorption band in this region. (Fig. 2) A similar correlation was found between the temperature of polymerization and the intensity of the IR absorption band of the C–C double bond which appears in the 1600 cm^{-1} region in the spectrum. These observations indicate that I, upon treatment with aluminum chloride at a high temperature, polymerized at the C–C double bond as well as by ring opening. On the other hand, as is shown in Table 1, the yield of the polymer obtained from I increased with an increase in the concentration of aluminum chloride in I up to 20%, beyond which the yield decreased instead. Moreover, the addition of a small amount of water to aluminum chloride was found to have no influence on the yield of polymers (Table 2). Attempts to polymerize I with radical, cationic, and anionic catalyst, such as AIBN, $BF_3 \cdot OEt_2$, and KOH, were unsuccessful (Table 4). Therefore, it is conceivable that the aluminum chloride-catalyzed polymerization of I must be explained in terms of a mechanism which is not involved in ordinary vinyl polymerization.

A mechanism of the ring-opening polymerization of five-membered saturated silaheterocyclic compounds was proposed by Nametkin *et al.*[1] on the base of a metal halide-catalyzed disproportionation.[5] This concept of coordinative attack on the α–C of silacyclopentane may also be applied to the polymerization of the unsaturated silaheterocyclic compound. Further, no noticiable polymerization occurred when I and II were treated with a Ziegler cata-

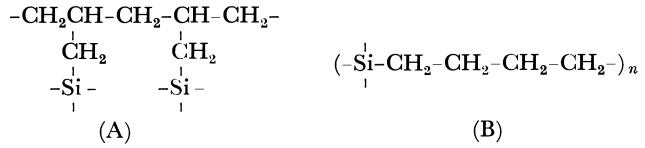
lyst at 60—85°C, although Murahashi *et al.* reported[6] the successful polymerization of allyl derivatives of methylsilanes with a Ziegler catalyst (Table 5). This difficulty in the polymerization of silacyclopentene derivatives may be attributed to the inactivity of the double bond in the ring toward Ziegler polymerization and to that of the allylic double bond resulting from the steric hindrance of the bulky silacyclopentene ring.

In addition, in order to examine the polymerizability of the allylic double bond in silacyclopentane and -pentene derivatives, the polymerizations of II, III, IV, V, and VI were undertaken and the IR spectra of the polymers were obtained. The results of the experiment (Table 6) show that allyl derivatives of silacyclopentane (IV, V, VI) undergo polymerization faster than their methyl derivatives to give insoluble polymers; this shows that they are crosslinked. In Fig. 3 it can be seen that an absorption band of the allylic double bond which would appear at 1640 cm^{-1} is scarcely observable in the IR spectra of the resulting polymers. These facts lead to the conclusions that polymerization occurs by the allylic double bond as well as by ring opening, and that the polymers are crosslinked through allylic linkages (A) and also by linkages produced by ring opening (B):



(A) (B)

Furthermore, II and III also undergo polymerization upon treatment with aluminum chloride, giving solid polymers even under such mild conditions where the analogous methyl derivative of silacyclopentene does not polymerize easily (Table 6). Moreover, a remarkable decrease in intensity of the absorption band at 1640 cm^{-1} was observed in the IR spectra of the resulting polymers. Since II and III contain two kinds of double bonds, allylic and endocyclic, the IR absorption bands of which appear in the same region, no decided conclusion about the predominance of allylic polymerization can be drawn from only these experimental data; yet, it may be considered from the foregoing discussion of the facility of the polymerization of allylic derivatives of silacyclopentane, that the allylic polymerization may also play an important role in the case of the polymerization of allyl derivatives of unsaturated silacyclic compounds.

Experimental

The infrared spectra were obtained on a Shimadzu IR 27 spectrophotometer.

Preparation of Monomers. Compounds I, II, III, V, and VI were synthesized by the method of Weyenberg *et al.*[2)] Olefins, such as isoprene and styrene, were treated with diorganodichlorosilane $R_1R_2SiCl_2$ (R_1=Me, Allyl; R_2=Me, Allyl) in tetrahydrofuran in the presence of sodium dispersion under a nitrogen atmosphere. After stirring for 20—25 hr at room temperature, filtration and distillation gave I in a 28.5% yield from isoprene and dimethyldichlorosilane, II in a 18.4% yield from isoprene and methylallyldichlorosilane, III in a 15.1% yield from isoprene and diallyldichlorosilane, V in a 25.2% yield from styrene and methylallyldichlorosilane, and VI from styrene and diallyldichlorosilane. IV was synthesized from 1-chloro-1-methyl-1-silacyclopentane, which had itself been synthesized from methyltrichlorosilane and the di-Grignard reagent of 1,4-dibromobutane, by treating it with allylmagnesium bromide in Et_2O. VII was prepared from I by hydrogenating it with hydrogen gas using a Pt–C catalyst in dry *n*-hexane. The yields and physical properties of the above monomers are summarized in Table 8.

Purification of Aluminum Chloride. The $AlCl_3$ catalyst used in this polymerization was obtained from commercial $AlCl_3$ by subliming it and sealing into a glass ampoule.

Polymerization of I and VII with $AlCl_3$. Polymerization was carried out in a three-necked flask equipped with a mechanical stirrer under a nitrogen atmosphere. A monomer and an ampoule containing a given amount of $AlCl_3$ were placed in the flask. Polymerization was started by breaking the ampoule and mixing the ampoule content-$AlCl_3$ with the monomer. After stirring for 4—48 hr at various temperature, polymerization was stopped by the addition of methanol. Dissolving the product in cyclohexane, followed by reprecipitation from a cyclohexane solution, gave a soluble polymer, while an insoluble polymer was obtained from the cyclohexane-insoluble part by washing it with methanol, chloroform, and with dilute alkali.

Polymerization of I and II with a Ziegler catalyst. The triethylaluminum used in this experiment was a product of the Mitsui Toatsu Kagaku Co. *n*-Hexane and *n*-heptane were purified by shaking them with concentrated sulfuric acid, washing them with water and aqueous sodium hydroxide and, after drying over sodium wire, redistilling them under a nitrogen atmosphere just before use. A solution of $AlEt_3$ in *n*-hexane or in *n*-heptane was slowly added, using an injector, to a solution of $TiCl_4$ contained in a flask. A monomer was then added, and polymerization was allowed to proceed for a given period of time. Polymerization was stopped by adding acidic methanol (10 vol. Methanol+1 vol. conc. HCl) to the reaction mixture in the flask. The isolation of the polymer was attempted by pouring the reaction product into a large amount of methanol.

Polymerization of II, III, IV, V, and VI with $AlCl_3$. In a three-necked flask equipped with a mechanical stirrer, aluminum chloride which had been sublimed just before use was placed, a monomer was then stirred into the aluminum chloride under a nitrogen atmosphere. After the reaction flask

had been kept at the polymerization temperature for a given period of time, the resulting product was purified by reprecipitation from a cyclohexane solution into methanol, in just the same manner as has been described before.

Polymerization of I with other than $AlCl_3$. Polymerization was carried out in the same manner as in the case of the polymerization of I and VII with $AlCl_3$ except for the use of catalysts other than $AlCl_3$.

The authors are indebted to Dr. H. Nohira for his valuable discussions, to the Shinetsu Kagaku Co. for providing the dimethyldichlorosilan, and to the Mitsui Toatsu Kagaku Co. for supplying the triethylaluminum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2729—2732 (1971)

Electrolyses of 2,2-Dichloro-3-phenylcyclopropanecarboxylic Acids in Hydroxylic Solvents with a Platinum Anode*

Akira TAKEDA, Satosi WADA, and Yasuo MURAKAMI

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tusima, Okayama

(Received October 27, 1970)

Electrolysis of 2,2-dichloro-3-phenylcyclopropanecarboxylic acid (**1a**) in hydroxylic solvents such as methanol and acetic acid, or in aqueous methanol with acetic acid in excess, was carried out with a platinum anode. Solvolysis rather than coupling was found to occur yielding 3,3-dichloro-1-phenylallyl methyl ether (**4a**) or 3,3-dichloro-1-phenylallyl acetate (**5a**), or both, depending on the solvent. Electrolysis of 2,2-dichloro-3-methyl-3-phenylcyclopropanecarboxylic acid (**1b**) in aqueous methanol gave ether **4b**. Structural characterization of the products was also discussed.

In the Kolbe reaction of carboxylic acids, alkyl-substitution at the α-position of the carboxyl group causes a decrease in the yield of the coupled product.[1] Similarly, the α-phenyl-substitution of acetic acid hinders the normal Kolbe coupling reaction and favors anodic reactions such as methoxylation in methanol and acetoxylation in acetic acid.[2] Wladislaw and Ayres[3] have found that the electrolysis of α-methoxyphenylacetic acid and α-methoxydiphenylacetic acid in methanol produces benzaldehyde dimethyl acetal and benzophenone dimethyl acetal in good yield. For these anodic reactions, a two electron discharge mechanism to generate carbonium ion, which in turn undergoes solvolysis, has been postulated.[4a] Formation of allylic products in the electrolysis of cyclopropanecarboxylate has been presented as a proof.[4b] We investigated the behavior of 3-substituted 2,2-dichlorocyclopropanecarboxylic acids (**1a**, R=H; **1b**, R=CH_3) in the Kolbe anodic reaction in different hydroxylic solvents to obtain more chemical evidences concerning the reaction mechanism.

Electrolysis of 46 g of **1a** conducted in aqueous methanolic solution of acetic acid partly neutralized with potassium hydroxide, with two platinum foils (1.5 cm×2 cm) as an electrode, gave 44 g of neutral oily product, whose composition obtained by gas chromatography (glc) is shown in Table 1 (Electrolysis-1).

The principal product collected by fractional distillation of the neutral product (97—120°C/2 mmHg, see Experimental) was further purified by preparative thin layer chromatography (tlc). The results (C, 55.25; H, 4.80%), correspond to the formula $C_{10}H_{10}OCl_2$. We suspected that this might be 2,2-dichloro-3-methoxycyclopropylbenzene (**2a**) ($C_{10}H_{10}OCl_2$), since the primary step of the reaction would allow the existence of both 2,2-dichloro-3-phenylcyclopropyl radical and methoxy radical. Attempted synthesis of **2a** by the addition of dichlorocarbene to β-methoxystyrene gave only α-chlorocinnamal-

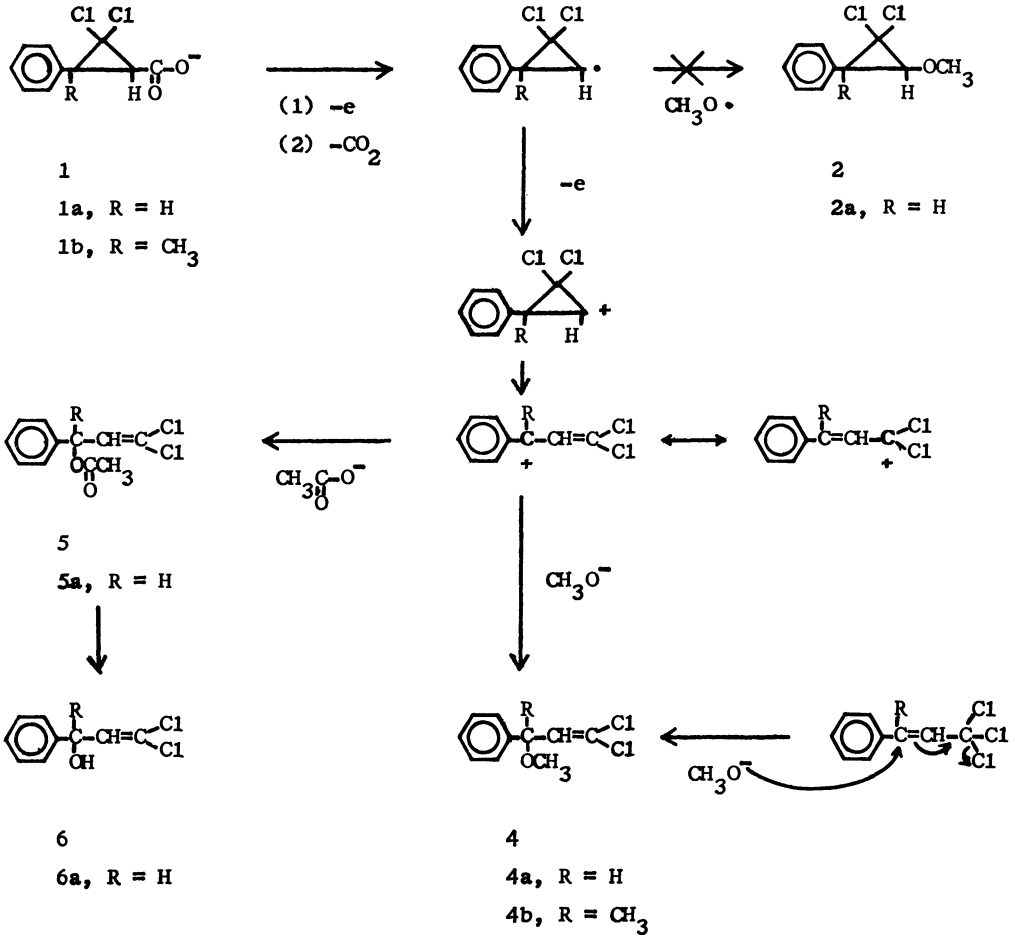
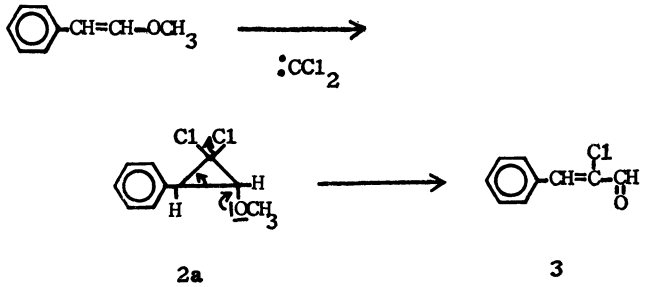


Scheme 1

dehyde (**3**).[14] Compound **3** was identified by its IR spectra, the IR spectra, melting point, and elementary analysis of its 2,4-dinitrophenylhydrazone. This suggests that compound **2a**, if its formation was possible in electrolysis, is so unstable to rearrange to **3** immediately. Actually, the presence of **3** in the electrolyte could not be detected. Thus, 3,3-dichloro-1-phenylallyl methyl ether (**4a**) was considered to be the possible structure of the principal product in Electrolysis-1. The structure has been verified by identity of its spectral data with those of the authentic sample, prepared in a different way. Preparation of 1,1-dichloro-3-methoxy-1-butene by the action of sodium methoxide to 1,1,1-trichloro-2-butene has been reported by Nesmeyanov *et al.*[5] The reaction



Scheme 2

of sodium methoxide with 1-phenyl-3,3,3-trichloropropene[6] afforded **4a** in 77% yield; IR (cm^{-1}, liquid) 2840 (OCH_3), 1615 (C=C), 765, and 705; NMR(τ, $CDCl_3$) 6.62 (s, 3H, $-OCH_3$), 4.95 (d, 1H, J= 8.2 Hz, C_6H_5-CH-OCH_3), 3.96(d, 1H, J=8.2 Hz, =CH–), and 2.63(s, 5H, C_6H_5–).

Identification of benzaldehyde, acetophenone, benzyl alcohol, methyl benzoate, and 3,3-dichloro-1-phenylallyl acetate (**5a**) present in the electrolyte was made by a comparison of the retention time in glc with that of the authentic sample. We failed to isolate **5a** either by preparative glc (TCD) or by tlc. However, its existence in the neutral product has been confirmed by the retention time of glc (FID), which was determined for the acetate **5a** obtained in Electrolysis-4 (see Experimental).

The anodic reaction of 2,2-dichloro-3-methyl-3-phenylcyclopropanecarboxylic acid (**1b**) carried out in a similar condition, gave products such as acetophenone, α-methylbenzyl alcohol, α-methylbenzyl acetate, and 3,3-dichloro-1-methyl-1-phenylallyl

methyl ether (**4b**) (Electrolysis-2). Compound **4b** was isolated by means of preparative tlc, and its structure has been elucidated by IR spectra, NMR spectra, and elementary analyses. Table 2 summarizes the compositions of the neutral product in Electrolysis-2, which were analyzed by glc (FID) at different reaction times (12 hr and 30 hr).

Table 2. Electrolytic products of 2,2-dichloro-3-methyl-3-phenylcyclopropanecarboxylic acid (**1b**)

Retention time[a] Min	Sec	Neutral portion Peak area (%) 12 hr	30 hr	Constituent

13	48	56.2	22.3	3,3-Dichloro-1-methyl-1-phenylallyl methyl ether (**4b**)
		14.6	22.9	Others

a) Hitachi F6-D gas chromatograph; column, 10% polyneopentyl glycol succinate, 4 m/m×1 m; column temp., 160°C; injection temp., 290°C; carrier gas, N_2 (0.5 kg/cm², 50 ml/min); detector, FID.

Formation of ether **4** and acetate **5** can be interpreted by assuming a two electron discharge mechanism of **1** to generate cyclopropyl cation as an intermediate, which undergoes ring opening followed by solvolysis to **4** and **5**. The reaction sequence is shown in Schemes 1 and 2. The pathway in which the carbonyl compounds such as benzaldehyde and acetophenone were formed could not be ascertained in detail. However, the fact that the content ratio of acetophenone to ether **4b** in the product of Electrolysis-2 was upset between the 12th hr and 30th hr of the reaction strongly supports the assumption that **4b** primarily produced is transformed to acetophenone during electrolysis. Accordingly, it seems reasonable to consider that methyl benzoate, acetophenone, and benzyl alcohol in Electrolysis-1 and α-methylbenzyl acetate and α-methylbenzyl alcohol in Electrolysis-2 are the secondary products from benzaldehyde in the former and from acetophenone in the latter.[7]

Electrolysis of **1a** in methanol gave **4a** in 81% yield, together with benzaldehyde in 5% yield. On the other hand, electrolysis of **1a** in acetic acid containing anhydrous sodium acetate afforded **5a** in 94% yield and benzaldehyde in 4% yield. Compound **5a** tends to be decomposed during distillation or by treatment with either tlc or glc. Therefore, the acetate **5a** was hydrolyzed to α-(2,2-dichlorovinyl) benzyl alcohol (**6a**)[8] with 1 N aqueous sodium hydroxide for structural confirmation.

Experimenal[9]

The melting points and boiling points are uncorrected. Thin layer chromatography was carried out on silica gel G (E. Merck AG, Darmstadt), where the spots of materials were detected by spraying with sulfuric acid solution of potassium permanganate (7 : 3 in wt.). Infrared spectra was determined on a Hitachi IR EPI-S2 spectrophotometer. The electrolysis was carried out using the apparatus described previously.[7b] Standard conditions of electrolysis are as follows [code number of electrolysis experiment, terminal voltage (V), current density (A/cm²), current efficiency (%)]: 1, 6—8, 0.8, 8; 2, 9—12, 0.8, 3; 3, 15, 0.4, 9; 4, 15, 0.2, 3.

Materials. Ethyl ester of **1a** was prepared from ethyl cinnamate and sodium trichloroacetate, bp 135—140°C/4 mmHg (lit. bp 103—106°C/0.3 mmHg).[10] Acid **1a** was obtained from the ester by hydrolysis, mp 101°C (lit. mp 101°C).[10] Ethyl ester of **1b** was prepared from ethyl β-methylcinnamate[11] and sodium trichloroacetate in 57% yield, bp 126—130°C/2 mmHg. Found: C, 57.05; H, 5.13%. Calcd for $C_{13}H_{14}O_2Cl_2$: C, 57.16; H, 5.17%. The acid **1b** was prepared from the ethyl ester by treatment with a mixture of fuming hydrochloric acid and acetic acid (1 : 1 V/V) in 53% yield, mp 136.5°C. Found: C, 53.67; H, 4.17%. Calcd for $C_{11}H_{10}O_2Cl_2$: C, 53.90; H, 4.11%.

Commercially available compounds were used as reference samples for tlc and glc. α-Methylbenzyl acetate was prepared, bp 103—104°C/17 mmHg.[12]

Electrolysis of 2,2-Dichloro-3-phenylcyclopropanecarboxylic Acid (1a) in Aqueous Acetic Acid-Methanol-Potassium Hydroxide Solution (Electrolysis-1). A mixture of **1a** (46.2 g, 0.2 mol) with acetic acid (120 g, 2 mol), methanol (60 ml), water (120 ml), and potassium hydroxide (16.8 g, 0.3 mol) was charged to the cell. Electrolysis was carried out for 58 hr at 30—33°C with magnetic stirring with terminal voltage 6—8 V and a current of 2.0—2.4 A. Platinum electrodes were cleaned every 5 hr to avoid deposition of resinous material on the surface until the electrolyte became weakly acidic (pH 5—6). The reaction mixture was diluted with 300 ml of water and taken up in ether. The extract was separated in the usual manner giving neutral component (43.7 g) and acidic component (0.8 g). The glc analysis of the neutral portion has been summarized in Table 1. It was fractionally distilled under reduced pressure as follows.

Fraction	Bp, °C/mmHg	Weight, g
1	50—97/2	3.5
2	97—110/2	7.9
3	110—120/2	2.1
4	120—145/2	1.3
5	Residue	5.7

By glc analysis each fraction was found to be a mixture but the principal constituent was present in fractions 2 and 3. Product identification was achieved by comparing retention times with those of authentic samples. The analytical sample of the principal constituent (**4a**) was isolated by preparative tlc,[13] bp 110—114°C (bath temp.)/4 mmHg, R_f 0.85, IR

(cm^{-1}, liquid) 2840 (-OCH_3), 1615 (C=C), 765, and 705; NMR (τ, $CDCl_3$) 6.62 (s, 3H, -OCH_3), 4.95 (d, 1H, J= 8.2 Hz, C_6H_5-CH-OCH_3), 3.96 (d, 1H, J=8.2 Hz, =CH-), and 2.68 (s, 1H, C_6H_5-).

Found: C, 55.25; H, 4.80%. Calcd for $C_{10}H_{10}OCl_2$: C, 55.32; H, 4.64%.

Alternative Synthesis of 3,3-Dichloro-1-phenylallyl Methyl Ether (4a). This compound was prepared in the same manner as in the synthesis of 1,1-dichloro-3-methoxy-1-butene.[5] To a sodium methoxide solution prepared by dissolving sodium (0.07 g, 0.003 g-atom) in methanol (5 m*l*) was added 1-phenyl-3,3,3-trichloropropene[6] (0.7 g, 0.003 mol). After refluxing for 150 min, the mixture was allowed to stand overnight. Water was added and the organic layer was extracted with ether, washed with water, and dried over anhydrous sodium sulfate. Removal of the solvent gave 0.5 g (77%) of the oily product, which was purified by preparative tlc; bp 110—115°C (bath temp.)/4 mmHg; IR (cm^{-1}, liquid) 2840 (-OCH_3), 1615 (C=C), 765, and 705.

Found: C, 55.51; H, 4.63%. Calcd for $C_{10}H_{10}OCl_2$: C, 55.32; H, 4.64%.

Attempted Reaction[14] of β-Methoxystyrene with Dichlorocarbene (α-Chlorocinnamaldehyde). To a stirred solution of β-methoxystyrene[15] (9.4 g, 0.07 mol) and chloroform (56.9 g, 0.48 mol) in petroleum ether (500 m*l*) was added powdered potassium *t*-butoxide (17.4 g, 0.18 mol) in small portions at −35—−40°C. Stirring was continued for additional 5 hr at room temperature. After being allowed to stand overnight, the reaction mixture was diluted with water. The organic layer was separated and washed with water several times, dried over anhydrous sodium sulfate, and concentrated. Distillation of the residue *in vacuo* gave 6.4 g (43%) of oily product boiling at 107—108°C/3 mmHg, which exhibited one large spot at R_f 0.41 and one very small spot at R_f 0.66. The constituent with the R_f value of 0.41 was purified by preparative tlc; IR (cm^{-1}, liquid) 1690 (C=O) and 1610 (C=C).

The oily product gave 2,4-dinitrophenylhydrazone quantitatively; mp 269—270°C (lit. mp 272—273°C);[16] IR (cm^{-1}, Nujol) 1620 (C=N), 1510 (NO_2), and 1340 (NO_2).

Found: C, 52.20; H, 3.44; N, 15.78%. Calcd for $C_{15}H_{11}O_4ClN_4$; C, 51.96; H, 3.20; N, 16.16%.

Electrolysis of 2,2-Dichloro-3-methyl-3-phenylcyclopropanecarboxylic Acid (1b) in Aqueous Acetic Acid-Methanol-Potassium Hydroxide Solution (Electrolysis-2). A mixture of **1b** (9.6 g, 0.04 mol) with acetic acid (24.0 g, 0.4 mol), methanol (40 m*l*), water (40 m*l*), and potassium hydroxide (3.4 g, 0.06 mol) was electrolyzed for 30 hr at 20—26°C with magnetic stirring, with terminal voltage 9—12 V and a current of 2.0—2.4 A. During the electrolysis, a 20 m*l* portion of acetic acid was added every 5 hr to the reaction mixture. It was worked up in a manner similar to that in Electrolysis-1, giving 5.4 g of the neutral portion and 0.3 g of the acidic portion. Glc analysis of the product is summarized in Table 2. Isolation of 3,3-dichloro-1-methyl-1-phenylallyl methyl ether (**4b**) from the non-ketone and non-aldehyde portion was achieved by preparative tlc;[13] bp 103—108°C (bath temp.)/2 mmHg; R_f 0.73; IR (cm^{-1}, liquid) 2840 (-OCH_3), 1610 (C=C), 767, and 705; NMR (τ, $CDCl_3$) 8.30 (s, 3H, CH_3-), 6.93 (s, 3H, -OCH_3), 3.76 (s, 1H, =CH-), and 2.75 (s, 5H, C_6H_5-).

Found: C, 56.87; H, 5.17%. Calcd for $C_{11}H_{12}OCl_2$: C, 57.16; H, 5.23%.

Electrolysis of 1a in Methanol (Electrolysis-3). To a solution of sodium methoxide (0.012 mol) in absolute methanol (200 m*l*) was added 13.8 g (0.06 mol) of **1a**. The mixture was electrolyzed at 30—31°C for 31 hr with magnetic stirring, with terminal voltage 15 V and a current of 0.9—1.2 A. After removal of the solvent under reduced pressure, the residue was dissolved in ether and separated into the neutral portion (12.4 g) and acidic portion (2.5 g) as usual. Glc analysis (FID) of the constituents of the neutral material indicated the presence of 3,3-dichloro-1-phenylallyl methyl ether (**4a**) (81.4%), benzaldehyde (4.9%), and unidentified materials (13.7%).

Electrolysis of 1a in Acetic Acid (Electrolysis-4). A solution of **1a** (4.6 g, 0.02 mol) and anhydrous sodium acetate (9.8 g, 0.12 mol) in acetic acid (144 g, 2.4 mol) was electrolyzed at 27—30°C for 55 hr with magnetic stirring, with terminal voltage 15 V and a current of 0.5—0.6 A. After working up in the usual manner, 3.3 g of neutral portion and 0.1 g of acidic portion were obtained. By glc analysis the neutral portion was found to contain **5a** (93.5%), benzaldehyde (4.3%), and a small amount (2.2%) of unidentified materials. Purification of **5a** by means of preparative tlc or glc was unsuccessful because of decomposition under such treatment. A crude sample of **5a** obtained by preparative tlc gave no correct analysis; IR (cm^{-1}, liquid) 1745 (acetate C=O), 1625 (C=C), and 1235 (ester C-O).

A mixture of 7.4 g (0.03 mol) of the crude ester and 60m*l* of 1 N aqueous sodium hydroxide was heated at 50°C for 42 hr. The hydrolysate was acidified and extracted with ether. The ethereal extract, after being washed with water, dried over anhydrous sodium sulfate, and removal of the solvent, gave 4.0 g (58%) of the crude product, which was distilled under reduced pressure to yield the following fractions.

Fraction	Bp, °C/mmHg	Weight, g
1	50—118/2.5	1.0
2	118—122/2.5	1.8
3	122—150/2.5	0.3
4	Residue	0.9

α-(2,2-Dichlorovinyl)benzyl alcohol (**6a**) was isolated from fraction 2 by preparative tlc;[13] mp 53—55°C (lit. mp 53—54°C);[8] R_f 0.58; IR (cm^{-1}, Nujol) 3200 (OH), 1615 (C=C), 1025, 760, and 705 (lit. IR 1621, 1026, 901, 895, 763, and 699);[8] NMR (τ, $CDCl_3$) 7.55 (s, 1H, -OH), 4.50 (d, 1H, J=8.2 Hz, C_6H_5-CH-OH), and 3.90 (d, 1H, J=8.2 Hz, =CH-).

Found: C, 53.13; H, 3.94%. Calcd for $C_9H_8OCl_2$: C, 53.23; H, 3.97%.

14) The synthesis of alkyl-substituted *gem*-dichlorocyclopropyl ethers has been reported by Skattebøl [L. Skattebøl, *J. Org. Chem.*, **31**, 1554 (1965)]. These ethers, when heated under reflux with an alcohol in the presence of a base, undergo ring opening with formation of acetals.

The 3020-cm^{-1} Band in the Infrared Absorption Spectra of Methyl Esters of Unsaturated Higher Fatty Acids

Yoshio HIRABAYASHI, Nobukatsu KATO, Masateru MIZUTA, and Hideharu ISHIHARA

Faculty of Engineering, Gifu University, Kakamigahara, Gifu

(Received November 13, 1970)

Studies were made of the infrared absorption spectra of methyl esters of oleic, elaidic, linoleic, linoelaidic, *trans*-10, *cis*-12-octadecadienoic, α-eleostearic, stearolic, stearic, 9,10-dideutero-oleic, and 9,10-dideutero-elaidic acids in the C–H stretching region. It was further confirmed that the prominent absorption bands at 3020 cm^{-1} occurring in the infrared absorption spectra of methyl esters of unsaturated higher fatty acids are assignable to the =C–H stretching vibrations of a *cis*-ethylenic double bond. The =C–D stretching vibrations of deutero-ethylenic double bonds (–CD=CD–) in methyl 9,10-dideutero-oleate and -elaidate occurred at 2250 and 2225 cm^{-1} respectively.

It is well known that, in the infrared absorption spectra of some unsaturated higher fatty acid methyl esters such as methyl oleate and methyl linoleate, a prominent absorption band occurs at 3020 cm^{-1}, which is on the higher-frequency side of the absorption bands attributable to the stretching vibrations of carbon-hydrogen bonds in the methylene and methyl groups.

Two explanations have been reported of the assignment of the absorption band at 3020 cm^{-1}. Sinclair *et al.*[1] assigned the absorption band at 3020 cm^{-1} to the =C–H stretching vibrations of an ethylenic double bond in their study of the infrared absorption spectra of oleic, linoleic, linolenic, arachidonic, and elaidic acids, and their methyl esters. On the other hand, Adams and Auxier[2] assigned the absorption band at 3020 cm^{-1} to the C–H stretching vibrations of alpha methylene groups adjacent to an ethylenic double bond on the basis of their observations that the intensity of this band diminished simultaneously with the oxidation of dipentaerythritol linoleate, and that the intensity of this band was very small in oleate, greater in linoleate, and still greater in linolenate. Privett *et al.*[3] supported the latter explanation on the basis of their observations that this band was much weaker in the conjugated peroxide-concentrate from autoxidized methyl linoleate than in oleate or in *cis-trans* conjugated linoleate; this is in accordance with the speculation that the expected structure of the peroxide, $-CH_2CH=CHCH=CHCH-$ (OOH), would have only one alpha methylene, compared to two for oleate or conjugated linoleate, and three for linoleate, and that this fact agreed best with the assignment of this band to the alpha methylene group. Fukuzumi and his collaborators[4-19] discussed, by employing this explanation, the infrared absorption spectra in liquids, methyl eicosapentaenoate, methyl docosahexaenoate, and methyl octadecatetraenoate, and further confirmed the assignment of the absorption band at 3020 cm^{-1} to the C–H stretching vibrations of alpha methylene groups adjacent to an ethylenic double bond; they did this on the basis of the observation that the intensity of this band was much smaller in conjugated methyl docosahexaenoate(with different *polytrans* conjugated polyene systems) than in non-conjugated methyl docosahexaenoate(with isolated *cis*-ethylenic double bonds only), in spite of the presence of the same number of ethylenic double bonds in both.[13]

Thus, the assignment of the absorption band at 3020 cm^{-1} seems to be not necessarily established in the field of fat and oil chemistry.

This paper will describe a study of the infrared absorption spectra of methyl esters of unsaturated higher fatty acids, such as oleic, elaidic, linoleic, linoelaidic, *trans*-10,*cis*-12-octadecadienoic, α-eleostearic, stearolic, 9,10-dideutero-oleic, and 9,10-dideutero-eladic acids, in the C–H stretching region; some information will be presented to facilitate a choice between these alternative explanations of the assignment of the absorption band at 3020 cm^{-1}.

Experimental

Materials. Each sample of the methyl esters used for the determinations of the infrared absorption spectra was prepared by the esterification of the corresponding acid (obtained by a process to be described later) with methanol by using *p*-toluenesulfonic acid as a catalyst. Its purity was estimated to be above 99%, except for methyl 9,10-dideutero-

oleate. The analysis was made by combinations of gas-liquid chromatography, infrared absorption spectrometry, and ultraviolet absorption spectrometry.

Methyl oleate was prepared from oleic acid ($n_D^{17.0}$ 1.4612) fractionated from olive oil fatty acids by the urea-adduct process: iodine value (I. V.) 85.6; $n_D^{14.4}$ 1.4543. The presence of the *trans*-isomer was not detected by means of the infrared absorption spectrum.

Methyl elaidate was prepared from elaidic acid (mp 44.5—45.0°C), which had itself been isolated by the recrystallization of an elaidinized matter obtained by the nitric acid-potassium nitrite isomerization of oleic acid: I. V. 85.6; $n_D^{16.2}$ 1.4529.

Methyl stearolate[20] was prepared from stearolic acid (mp 47.2—47.3°C), which had itself been isolated by the recrystallization of a crude product obtained by the dehydrobromination of dibromostearic acid (prepared by the bromination of oleic acid in ether) with isoamyl alcohol and potassium hydroxide: I. V. 85.7; $n_D^{17.9}$ 1.4578.

Methyl linoleate[21] was prepared from linoleic acid ($n_D^{16.3}$ 1.4711), which had itself been fractionated, by the urea-adduct process in a nitrogen atmosphere, from safflower-oil fatty acids free from unsaponifiable matter: I. V. 172.3; $n_D^{16.0}$ 1.4629. Its ultraviolet and infrared absorption spectra indicated that it contained trace amounts of the conjugated acid ester and of the *trans*-isomer.

Methyl linoelaidate[22] was prepared from linoelaidic acid (mp 27.7—28.1°C), which had itself been isolated by the recrystallization of an elaidinized matter obtained from linoleic acid by the selenium (1%) isomerization at 200—210°C for 6 hr in a nitrogen atmosphere: I. V. 172.4; $n_D^{15.0}$ 1.4620.

Methyl trans-10,cis-12-octadecadienoate[23] was prepared from *trans-10,cis-12*-octadecadienoic acid (mp 22.0—23.0°C), which had itself been isolated from a crude product obtained by the alkali isomerization of linoleic acid: $n_D^{16.0}$ 1.4750; K_{233} 92.6.

Methyl α-Eleostearate was prepared from α-eleostearic acid (mp 48.1—48.8°C) obtained by the crystallization of tung oil fatty acid: $n_D^{20.0}$ 1.5148.

Methyl 9,10-Dideutero-oleate was prepared by the partial deuteration of methyl stearolate with Lindlar's catalyst[24] in the presence of quinoline. A modified type of Herschberg's apparatus for catalytic hydrogenation was used for the deuteration. In a reduction flask were charged 0.522 g of methyl stearolate, 30 ml of cyclohexane, and 0.02 g of quinoline. The air in the apparatus was completely replaced with deuterium (purity: above 99.9 mol%, Showa Denko make). Then, 0.2 g of Lindlar's catalyst was added to the solution, and the deuterium was allowed to be absorbed at 16.5°C under atmospheric pressure with stirring. Deuteration was stopped when the uptake corresponded to one mole of deuterium per mole of methyl stearolate. The catalyst was then filtered off. The cyclohexane solution was washed with dilute hydrochloric acid (1 : 1), and the sample was obtained by distilling away the cyclohexane: I. V. 85.0; $n_D^{8.0}$ 1.4571. The presence of several per cent of *trans*-isomer was detected by studying the infrared absorption spectrum. No other impurities, such as methyl stearolate and methyl 9,9′,10,10′-tetradeutero-stearate, were detected by gas-liquid chromatography or by a study of the infrared absorption spectrum.

Methyl 9,10-Dideutero-elaidate. An elaidinized matter was obtained by the nitric acid-potassium nitrite isomerization of 9,10-dideutero-oleic acid itself prepared by the saponification of methyl 9,10-dideutero-oleate. (The process of the isomerization was the same as that of elaidic acid from oleic acid.) The elaidinized matter was recrystallized from methanol to give 9,10-dideutero-elaidic acid (mp 44.2—44.4°C), from which the sample itself was prepared: $n_D^{18.0}$ 1.4521.

Infrared Absorption Spectra. A JASCO Grating Infrared Spectrophotometer, Model IR-G, with 0.5-mm matched cells was used. The infrared absorption spectrum of each methyl ester was determined in a carbon tetrachloride solution at a concentration of 0.067 mol/l (approximately 2%) or in a liquid film at 20°C.

Results and Discussion

Table 1 shows the characteristics of the structural units possibly associated with the absorption at 3020 cm^{-1} of the methyl esters investigated. Figures 1

TABLE 1. INFRARED ABSORPTION OF UNSATURATED HIGHER FATTY ACID METHYL ESTERS AT 3020 cm^{-1}

and 2 show the infrared absorption spectra of the methyl esters in the C–H stretching region.

Among the methyl esters investigated, oleate, linoleate, *trans*-10,*cis*-12-octadecadienoate, and α-eleostearate possess prominent absorption bands at 3020 cm^{-1}.[25] The accurate determination of the optical densities of these esters at the 3020-cm^{-1} bands is difficult because the bands overlap with the C–H stretching bands of the methylene and methyl groups. However, the approximate values of the optical densities, as calculated from the transmittances obtained by the base–line method at the absorption maximum at 3020 cm^{-1} (I/I_0, see Fig. 1), were as follows (in the CCl_4 solution of 0.067 mol/l and with the cell of 0.5-mm thickness): oleate, 0.156; linoleate, 0.315; *trans*-10,*cis*-12-octadecadienoate, 0.160; α-eleostearate, 0.158.

The ratio between the optical densities, 1.00 : 2.02 : 1.03 : 1.01, is almost equal to the ratio of the numbers of the *cis*-ethylenic double bonds present in the molecules, 1 : 2 : 1 : 1; there is thus no difference between isolated and conjugated systems.

On the other hand, elaidate and linoelaidate,[26] in which the ethylenic double bonds are of the *trans*-structure, do not possess prominent absorption bands at 3020 cm^{-1}, though they, like oleate and linoleate, have alpha methylene groups adjacent to the ethylenic double bonds. In addition, stearolate, methyl 9,10-dideutero-oleate (d_2-O), and methyl 9,10-dideutero-elaidate (d_2-E), which all have alpha methylene groups adjacent to a triple bond or dideutero–ethylenic double bonds (–CD=CD–), do not possess an absorption band at 3020 cm^{-1}.

From the above facts, it seems most reasonable to conclude that the absorption bands at 3020 cm^{-1} evident in the absorption spectra of methyl esters of unsaturated higher fatty acids are attributable to the =C–H stretching vibrations of *cis*-ethylenic double bonds, and not to the C–H stretching vibrations of alpha methylene groups adjacent to ethylenic double bonds.

25) Sinclair *et al.*[1] reported that similar bands were observed in oleic, linoleic, linolenic, and arachidonic acids, and proposed the spectrographic method for the determination of the degree of the *cis*-unsaturated acids, basing the procedure on the optical densities of the absorption bands at 3020 and 2920 cm^{-1}.

26) Linoelaidate possesses only a very weak absorption band at about 3030 cm^{-1}; this absorption is not attributable to the trace of the *cis*-isomer in the sample methyl ester. At any rate, its intensity is much lower than that of the absorption band at 3020 cm^{-1} in linoleate.

The propriety of the above view can be more clearly explained by the following results.

Both d_2-O and d_2-E have two alpha methylene groups adjacent to a deutero-ethylenic double bond. The deutero-ethylenic double bond in d_2-O has the *cis*-structure, while that in d_2-E has the *trans*-structure. None of them shows an absorption band at 3020 cm^{-1}. However, the absorption band attributable to the =C-D stretching vibrations of the deutero-ethylenic double bond occurs at 2250 cm^{-1} in d_2-O and at 2225 cm^{-1} in d_2-E. A slight shoulder at 2225 cm^{-1} in d_2-O indicates the formation and mixing of several per cent of the *trans*-isomer after methyl stearolate was subjected to the partial deuteration with Lindlar's catalyst in the presence of quinoline.

If it is true that the absorption band at 3020 cm^{-1} is due to the =C–H stretching vibrations of the *cis*-ethylenic double bond, the absorption at 3020 cm^{-1} will not occur in d_2-O, but the absorption band attributable to the =C-D stretching vibrations of the *cis*-deutero-ethylenic double bond corresponding to the above band must occur in d_2-O. Fortunately, spectroscopic data by Hoffmann[27] are available in this case.

The =C–D stretching frequency of a *cis*-deutero-ethylenic double bond corresponding to 3020 cm^{-1} was calculated to be 2247 cm^{-1} from the ratio of 1.344 : 1 between the stretching frequencies of the =C–H(νC–H) and the =C–D(νC–D) of Hoffmann's data; this value agrees very well with the value of 2250 cm^{-1} for that of d_2-O.

Furthermore, the =C–H stretching frequency corresponding to the 2225 cm^{-1} in d_2-E was calculated in the same way to be 2990 cm^{-1}. Sinclair *et al.*[1] reported that weak bands appeared at 2995, 3015, and 3033 cm^{-1} in the infrared absorption spectrum of elaidic acid. According to the results of the present experiments, the absorption band at 2995 cm^{-1}, among the three bands, corresponds to the =C–H stretching band of a *trans*-ethylenic double bond.

It was, thus, further confirmed that the 3020 cm^{-1} absorption band occurring in the infrared absorption spectra of methyl esters of unsaturated higher fatty acids is due to the =C–H stretching vibrations of *cis*-ethylenic double bonds in the isolated or the conjugated system, and not to the C–H stretching vibrations of alpha methylene groups (including the group existing between the two double bonds, of course) adjacent to the ethylenic double bonds.

Some reports, mentioned in the preface of this paper, have stated that the diminution in intensity of the 3020 cm^{-1} absorption band coinciding with the oxidation of methyl esters of unsaturated higher fatty acids is to be attributed to the loss of alpha methylene groups adjacent to an ethylenic double bond as a result of the formation of a hydroperoxide ($-CH=CH-CH_2- \rightarrow -CH=CH-\underset{\underset{OOH}{|}}{CH}-$),[5-8,12,13,15] as a result of the formation of a conjugated system ($-CH=CH-CH_2-CH=CH- \rightarrow -CH=CH-CH=CH-CH_2-$),[9,12,14,15] or as a result of consumption for polymerization,[10] indicating that the expected structure of the hydroperoxide obtained has the $-CH=CH-CH=CH-\underset{\underset{OOH}{|}}{CH}-$ or the $-CH=CH-\underset{\underset{OOH}{|}}{CH}-CH=CH-$ group.[3,4,12]

However, it seems to be important to consider that the decrease in this band is due to the loss of *cis*-ethylenic double bonds, including that by isomerization to the *trans*-form coinciding with the maintenance of the intact position, with migration to a new position, or with the formation of a conjugated system.

The Stereochemistry of the Reduction of 2-Substituted Cyclopentanones with Complex Aluminum Hydrides

Yasuhisa SENDA, Sekio MITSUI, Ryuko ONO*, and Shizuo HOSOKAWA**

Department of Applied Science, Tohoku University, Sendai

**Department of Science, Miyagi University of Education, Sendai*

***Ichinoseki Technical College, Ichinoseki, Iwate*

(Received November 13, 1970)

Five different 2-substituted cyclopentanones have been reduced by complex aluminum hydrides in various solvents. In the lithium aluminum hydride reduction, the proportion of *cis* 2-substituted cyclopentanols tends to increase with the steric bulkiness of the substituent. The fact that the composition of the products changes with the sort of solvent is discussed in terms of the difference in the coordinating abilities of the solvents. More *cis* 2-substituted cyclopentanols are obtained by lithium trimethoxyaluminum hydride than by the other complex aluminum hydrides used in the present study. Lithium tri-*t*-butoxyaluminum hydride and lithium aluminum hydride-aluminum chloride reduction are also investigated.

Although the stereochemistry of the reduction of substituted cyclohexanones has been studied in detail,[1] there have been only a few investigations of that of simple cyclopentanone derivatives.[1a,2]

In order to ascertain the effects of the substituents, solvents, and complex metal hydrides on the stereochemistry in the reduction of five-membered ring compounds, the reduction of representative 2-substituted cyclopentanones with lithium aluminum hydride and some of its alkoxy derivatives was undertaken in various solvents. The cyclopentanones (2-methyl-, 2-ethyl-, 2-isopropyl-, 2-cyclopentyl-, and 2-phenylcyclopentanones) were reduced with lithium aluminum hydride in diethyl ether, tetrahydrofuran, dimethoxyethane, triethylamine or pyridine, lithium trimethoxyaluminum hydride in tetrahydrofuran, lithium tri-*t*-butoxyaluminum hydride in tetrahydrofuran, and lithium aluminum hydride-aluminum chloride mixture in diethyl ether. In order to confirm the accuracy of the data, experiments were repeated at least twice in all hydride reductions, and the isomeric ratios of the products were quantitatively analyzed by gas chromatography.

Results

Reduction with Lithium Aluminum Hydride. The reduction of 2-methylcyclopentanone(I) in diethyl ether yielded a mixture of *cis* and *trans* 2-methylcyclopentanol(VI) containing 74—78% of the *trans* isomer. This is in good agreement with the result reported by Umland and Jefraim.[2a] The proportion of *trans*-VI changed with the solvents and increased in the order of diethyl ether, tetrahydrofuran, and dimethoxyethane. A similar isomer distribution was obtained in the reduction of 2-ethylcyclopentanone(II). The reduction of 2-isopropylcyclopentanone (III), which is considered to be relatively hindered ketone, gave slightly more *cis* 2-isopropylcyclopentanol (VIII) than *trans* (55—57% of *cis*-VIII) in diethyl ether. Conversely, the formation of *trans*-VIII was preferred in tetrahydrofuran, and 70% of the *trans* isomer was yielded in dimethoxyethane. On the other hand, the reduction of 2-cyclopentylcyclopentanone (IV) proceeded to give slightly more *trans*-2-cyclopentylcyclopentanol (IX) than *cis* (54% of *trans*-IX) in diethyl ether; a similar solvent dependence in the case of III was observed. The reduction of 2-phenylcyclopentanone (V) afforded 61% of *trans* 2-phenylcyclopentanol (X) in diethyl ether, while no appreciable solvent dependence on the isomer distribution was observed.

When triethylamine was used as the solvent, less of the *trans* isomer was obtained than in the ether-type sovents. Compounds I, II, III, IV, and V gave 68, 67, 37, 45, and 44% of the *trans* isomers respectively.

Lansbury and Peterson[3] reported that the reaction of lithium aluminum hydride with excess pyridine fairly rapidly formed a complex, lithium tetrakis-(1,2-dihydropyridyl)aluminate. They also reported that the complex reacted sluggishly with aliphatic ketones. Actually, the reaction of the cyclopentanones which were used in the present study with the complex gave the corresponding cyclopentanols in a yield of less than 1% even after 24 hr. However, when lithium aluminum hydride was added to the ketone-pyridine mixtures at 0°C, cyclopentanols were obtained in a good yield, so the ketone might be reduced by lithium aluminum hydride itself. In this case, the isomer distribution was similar to that obtained in dimethoxyethane. In all cases, the reduction favored the formation of the *trans* isomer.

Reduction with Lithium Tri-t-butoxyaluminum Hydride. In this case, inverse addition method was employed

for all experiments. Compounds I and II gave results very similar to the isomer distribution realized with lithium aluminum hydride itself. Similar results have already been observed in the reduction of substituted cyclohexanones by Haubenstock and Eliel[4] and by Brown and Deck.[1a] In the cases of III and IV, a situation different from that of I and II prevailed and the proportion of the more stable isomer was larger than that realized with lithium aluminum hydride in diethyl ether, the predominant product being the *trans* isomer. The lithium tri-*t*-butoxyaluminum hydride reduction of V gave more of the *cis* isomer than that with the parent hydride, and the ratio of the *cis* to the *trans* isomer became almost unity. In the cases of III, IV, and V, the isomer distribution was not similar to that obtained from lithium aluminum hydride reduction in diethyl ether, but was rather close to that in tetrahydrofuran.

Reduction with Lithium Trimethoxyaluminum Hydride. The replacement of hydrogen in lithium aluminum hydride by methoxyl groups resulted in an isomer distribution of the reduction products different from that resulting from reduction by other reagents. In the case of I, the amount of the more stable isomer decreased as compared to the amounts with other metal hydride reagents, and the isomer ratio became 46% of *cis* and 54% of *trans*-VI. With the increase in the steric requirement of the substituent in the 2 position, in other words, the change in the methyl group into the ethyl group, the predominant product was no longer the *trans* isomer. The *trans* 2-ethylcyclopentanol (VII) thus obtained was 38—40%.

Reduction with Lithium Aluminum Hydride - Aluminum Chloride Mixture. The reduction with a lithium aluminum hydride - aluminum chloride mixture was also performed. Under the conditions of kinetic control (in the presence of excess hydride), the ratio of *trans* 2-substituted cyclopentanols to *cis* isomers was very close to that obtained in the reduction by lithium aluminum hydride alone. However, when acetone was added at the end of the reduction, and when the reaction mixture was then refluxed for 4 hr (in the presence of excess ketone), the products of thermodynamical control, *trans* 2-substituted cyclopentanols, were predominant, probably because equilibriation occurred.

The results of the reduction of 2-substituted cyclopentanones are summarized in Table 1.

Discussion

In 1956 Dauben, Fonken, and Noyce postulated that the steric course of complex metal hydride reduction was controlled by two factors, "product development control" and "steric approach control".[5] Alternative explanations have also been devised. Richer[6] seeks it in the steric interference of the approaching nucleophile with the axial hydrogens in the 2 and 6 positions, and Chêrest and Felkin[1c] ascribe the same interference to bond-eclipsing factors. Eliel and his coworkers deduce, from the kinetic data of the reduction of several cyclohexanones by lithium tri-*t*-butoxyaluminum hydride[1d] and from a competitive rate study of complex metal hydrides,[1f] that product development control plays, at best, a minor role especially in the reduction with aluminum hydrides.

Since it has been suggested[7] that the cyclopentanone exists in the half-chair form with the maximum puckering occurring at the 3 and 4 carbon atoms, the Dreiding model shows the steric environments above and below the plane of the carbonyl group in this molecule

to be identical. Consequently, it seems impossible to introduce the steric factors, for example, Felkin's eclipsing factor, to explain the prior formation of the more stable one of the two possible products. Our results indicate that, in contrast to six-membered cyclic ketones, the steric course in the resuction of relatively unhindered cyclopentanone reflects the relative stability of the two isomeric products.

As was pointed out previously, the rates of reaction of the simple cyclic model systems exhibit this order; cyclohexanone>cyclopentanone.[8] This typical I-strain order can be attributed to the influence of bond-opposition forces on the energetics of the initial and final states, reflected in the transition state.

Since it has been suggested that the complex metal hydride reduction of cyclohexanone has a reactant-like transition state,[1c,1g] the results obtained in the present study and the difference in reactivity between cyclohexanone and cyclopentanone implies that the complex aluminum hydride reduction of the latter has a product-like transition state. In the increase in the steric requirement of the substituent in the 2 position of cyclopentanone, steric approach control is also operative in the course of the reaction.

It is also evident from this study that lithium trimethoxyaluminum hydride reduction gives more of the *cis* isomer which is obtained by the hydride attack from the less-hindered side of the carbonyl group than either lithium aluminum hydride or lithium tri-*t*-butoxyaluminum hydride reduction, as has been observed previously.[1a,4] This may mean, of course, that steric approach control becomes important with the trimethoxyaluminum hydride, even in the reduction of II.

The solvent effect on the isomeric ratio of the products was observed in the lithium aluminum hydride reduction. Our results do not permit a definitive statement of the mechanism, but we have adopted the one presented below as a tentative postulate. The solvent effect on the stereochemistry of the reduction is examined in terms of steric approach control, which is the steric interference between the entering metal hydride and the substituent in the 2 position, and product development control, which is the steric interference between the developing alkoxyaluminum function and the substituent in the 2 position at the transition state. Geneste and Lamaty[9] have postulated a transition state for hydride reduction of the type shown in Fig. 1. For convenience, however, these two factors will be discussed separately.

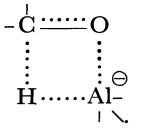

Fig. 1.

Steric Approach Control. Hydride transfer from aluminum to carbonyl carbon is facilitated by the coordination of aluminum with a Lewis base.[10] Since the greater the coordination, the more facile the hydride transfer, the ionic property of hydride may be accentuated and the distance between aluminum and hydride at the transition state seems to be longer in strongly-coordinating solvent than in a weakly-coordinating solvent. Consequently, the steric interaction of the entering hydride reagent with the substituent in the 2 position decreases with an increase in a Lewis base strength; in other words, more of the *trans* isomer will be afforded in a strongly-coordinating solvent than in a weakly-coordinating one.

Product Development Control. When the solvent coordinates on the aluminum atom of the OAl group in the 1 position, the steric strain between this OAl group and the substituent in the 2 position at the transition state may increase with the coordinating ability of the solvents; in other words, more of the *trans* isomer will be obtained in a strongly-coordinating solvent than in a weakly-coordinating one.

Jorgenson and Thacher[11] reported on the basis of a rate study of the reduction of cinnamyl alcohol with lithium aluminum hydride that tetrahydrofuran is more effective than diethyl ether as a solvent medium by a factor of 7.5, and that dimethoxyethane is better than tetrahydrofuran by a factor of 4—6.

Reportedly, the observed Lewis base strengths of the ether-type solvents used in the present study increase in the order: diethyl ether < tetrahydrofuran<dimethoxyethane,[12] an order which is identical with the coordinating ability.

Taking the above discussion of the coordinating ability of the solvents into account, the proportion of the *trans* isomer may increase in the order: diethyl ether<tetrahydrofuran<dimethoxyethane. Actually, the proportion of the *trans* isomers obtained from I, II, III, and IV agrees with the above prediction. Especially in the cases of III and IV, the solvent dependence is very significant.

Pyridine, whose base strength is stronger than that of an ether-type solvent, may behave as a solvent only under the experimental conditions employed. The isomer distributions of the products in pyridine are close to those in dimethoxyethane.

Wiberg and his coworkers[13] found that, when lithium aluminum hydride is treated with an excess of trimethylamine, the molecular compound $LiAlH_4 \cdot 2Me_3N$ is formed in the temperature range between $-40°$ to 0°C. Alternatively, Peters[14] reported that lithium aluminum hydride with one mole of trimethylamine forms $(Me_2N)_2AlH_3$. He observed, however, when an excess of trimethylamine was used, nearly all of the lithium aluminum hydride gave a compound containing lithium and aluminum in an approximately 1 to 1 molar ratio, hydrogen and loosely-bound trimethylamine. He considered that this compound may be the material that Wiberg

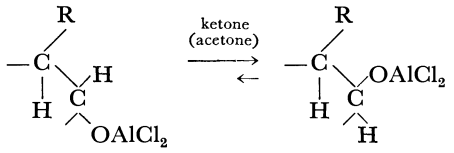
and his coworkers observed. However he did not reach any definite conclusion. The formation of the corresponding compound, $LiAlH_4 \cdot 2Et_3N$ or $(Et_2N)_2AlH_3$, can be expected when triethylamine is used instead of trimethylamine. Either way, although triethylamine is the strongest Lewis base among the solvents used in the present study, the molecular structure of lithium aluminum hydride in triethylamine seems to be a bulkier reagent than that in other solvents and so the steric interaction of the entering hydride reagent with the substituent in the 2 position will increase.

In the reduction of 2-substituted cyclopentanones with the lithium aluminum hydride-aluminum chloride mixture, the isomeric ratios differ according to the reaction conditions. In the presence of an excess of the hydride reagent, the isomer distribution is very close to that obtained in the reduction with lithium aluminum hydride. On the other hand, when excess ketone exists in the reaction system, *trans* isomers are yielded exclusively. Presumably the complex of the *trans* isomer is much more stable than that of the *cis* isomer because of the large bulk of the $-AlCl_2$ group, which is possibly swelled further by the solvation of the aluminum with ether. The equilibrium lies certainly very much more on the side of the *trans* isomer than the corresponding equilibrium of the free 2-substituted cyclopentanols.[15]



(*cis*) (*trans*)

It is also of interest to relate the conformational equilibrium constant with the steric course of metal hydride reduction. The equilibria of VI, VII, VIII, and IX were studied in dioxane with Raney nickel at 80°C. The composition of the equilibrium mixture is listed in Table 2. The equilibrium compositions of VI and VII are 76 and 75% of the *trans* isomer respectively. However, VIII whose substituent is expected to be of a larger effective size than that of the methyl or the ethyl group gives a proportion of 61% of the *trans* isomer at equilibrium, while IX yields a mixture containing 66% of the *trans* isomer.

Table 2. Equilibrium mixture of 2-substituted cyclopentanols

Cyclopentanol	*Trans* %
2-Methyl-	76[a]
2-Ethyl-	75
2-Isopropyl-	61[b]
2-Cyclopentyl-	66

a) Umland and Williams[16] reported 58% *trans* with aluminum isopropoxide-isopropanol system. b) Hückel and Näher[2a] reported more than 91% *trans* with aluminum isopropoxide-isopropanol system.

Experimental

Materials. The lithium aluminum hydride and the lithium tri-*t*-butoxyaluminum hydride were purchased from Metal Hydride Inc. The lithium trimethoxyaluminum hydride was prepared *in situ* by adding a calculated amount of anhydrous methanol solution to lithium aluminum hydride in tetrahydrofuran. The hydride solution was titrated with iodine and sodium thiosulfate. The 2-methylcyclopentanone (I) was prepared from 1-methylcyclopentene by the method of Brown and his coworkers.[17,18] The 2-ethylcyclopentanone (II) was prepared from 1-ethylcyclopentene as the above ketone (I). The 2-isopropylcyclopentanone (III) was prepared by the aldol-type condensation of cyclopentanone with acetone, followed by the hydrogenation over the palladium catalyst. The 2-cyclopentylcyclopentanone (IV) was prepared by the method reported by Hückel and his coworkers.[19] The 2-phenylcyclopentanone (V) was prepared by the rearrangement of 1-phenylcyclopentene oxide by sulfuric acid. The 1-phenylcyclopentene oxide was dissolved in ether with 5 micro drops of 6 N sulfuric acid, after which the mixture was refluxed for 32 hr.

Reduction Procedures. The gas-chromatographic analysis showed that the yields of isomeric cyclopentanols from the corresponding ketones were in the range between 75—100%.

Reduction with Lithium Aluminum Hydride or Its Alkoxy Derivatives. (*a*) *In the Ether-type Solvent*: Ketone (0.04 mol) which had been dissolved in 15 m*l* of a solvent and an equivalent amount of a hydride solution was mixed at 0°C over a period of 10—15 min. Two orders of addition, normal and inverse addition were employed. After the reaction mixture had been stirred for 30 min, water and crushed ice were added, followed by enough 10% sulfuric acid to dissolve the precipitate. The aqueous layer was extracted with ether which had been washed with saturated sodium hydrogen carbonate, and then by brine, and dried over sodium sulfate. The solution was concentrated, and the residual solution was subjected to gas chromatography.

(*b*) *In Pyridine*: Ketone (0.04 mol) was dissolved in 10 m*l* of pyridine. To this solution, maintained in an ice bath, we then added powdered lithium aluminum hydride (0.01 mol) over a period of 1—2 min. After the reaction mixture had been stirred for 30 min, water and crushed ice were added, followed by enough 10% sulfuric acid to acidify the solution. The solution was extracted with ether which had been washed with saturated sodium hydrogen carbonate, and then by brine, and dried over sodium sulfate. The solution was concentrated, and the residual solution was subjected to gas chromatography.

(*c*) *In Triethylamine*: Lithium aluminum hydride (0.01 mol) was dissolved in 15 m*l* of triethylamine. To this solution, maintained in an ice bath, we then added a ketone (0.04 mol) in 10 m*l* of triethylamine over a period of 10—15 min. After the reaction mixture had been stirred for 30 min, water and crushed ice were added, followed by enough 10% sulfuric acid to acidify the solution. The solution was

extracted with ether which had been washed with saturated sodium hydrogen carbonate, and then brine, and dried over sodium sulfate. The solution was concentrated, and the residual solution was subjected to gas chromatography.

Reduction with Lithium Aluminum Hydride - Aluminum Chloride.[20] (*a*) *Under Conditions of Kinetic Control*: To a solution of 0.050 mol of aluminum chloride in 50 m*l* of ether, we added 0.014 mol of lithium aluminum hydride in ether. After stirring the homogeneous solution for 30 min, a solution of ketone (0.050 mol) in 10 m*l* of ether was added, drop by drop, over a period of 30 min. The mixture was stirred for 30 min at 0°C; then the excess hydride was destroyed with water and crushed ice, followed by enough 10% sulfuric acid to dissolve the precipitate. The aqueous layer was extracted with ether which had been washed with saturated sodium hydrogen carbonate, and then by brine, and dried over sodium sulfate. The solution was concentrated, and the residual solution was subjected to gas chromatography.

(*b*) *Under Conditions of Thermodynamic Control*: The mixed hydride was prepared as in (a) from 0.050 mol of aluminum chloride and 0.014 mol of lithium aluminum hydride. A solution of 0.050 mol of ketone in 10 m*l* of ether was added, after which the mixture was stirred for 30 min at 0°C. To this reaction mixture we then added 0.010 mol of acetone and refluxed the mixture for 4 hr; then water and crushed ice were added, followed by enough 10% sulfuric acid to dissolve the precipitate. The aqueous layer was extracted with ether, which had been washed with saturated sodium hydrogen carbonate, and then by brine, and dried over sodium sulfate. The solution was concentrated, and the residual solution was subjected to gas chromatography.

Equilibrium. Raney nickel which had been prepared from the alloy was thoroughly washed with distilled water, absolute ethanol, and dioxane. For equilibriation 0.3 g of 2-substituted cyclopentanol was dissolved in 10 m*l* of the solvent. Raney nickel (*ca* 2 g) was added in the suspension and the mixture was heated at 80°C. From time to time, samples were withdrawn and analyzed by gas chromatography. Equilibrium was deemed to be reached when several consecutive samples gave identical analyses. In all cases, equilibrium was approached from both sides. Equilibriation was usually complete after 250—300 hr.

Gas Chromatography. Hitachi K-53 or F-6 equipped with 45 m PEG goley column (0.25 or 0.50 mm in diameter) was used along with a flame ionization detector.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2741—2744 (1971)

p-Nitrophenyl Phosphates as Phosphorylating Reagents of Alcohols

Kyu-Jang CHONG and Tsujiaki HATA

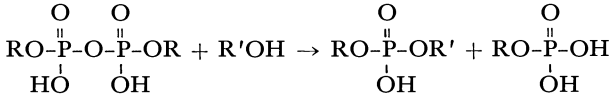
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 21, 1970)

Phosphorylation of alcohols by means of P^1,P^2-di-*p*-nitrophenyl pyrophosphate and *p*-nitrophenyl phosphate was investigated. Alcohols were phosphorylated in almost quantitative yields by use of P^1,P^2-di-*p*-nitrophenyl pyrophosphate. It was found that *p*-nitrophenyl phosphate acts as an effective phosphorylating reagent for alcohols in dry pyridine to give the corresponding alkyl phosphate.

It is known that tetra-substituted[1] and tri-substituted[2] pyrophosphates can be advantageously used for the syntheses of esters of phosphoric acid and nucleotides. However, P^1,P^2-di-substituted pyrophosphates are not suitable for the phosphorylation of alcohols except when the reaction is carried out in the presence of an activator such as trichloroacetonitrile[3] or dicyclohexylcarbodiimide.[4]

In the present experiment, we tested the phosphorylation of alcohol with various P^1,P^2-di-aryl substituted pyrophosphates with the expection that the usefulness of the method would considerably increase if a generally applicable reagent, P^1,P^2-di-substituted pyrophosphate, could be found. We found that P^1,P^2-di-*p*-nitrophenyl pyrophosphate (**1**) is effctive for the phosphorylation of alcohols without using any activating reagent. As an example, when **1** was treated with excess alcohol at 80°C for three hours, alkyl *p*-nitrophenyl phosphate (**2**) and *p*-nitrophenyl phosphate (**3**) were obtained in almost quantitative yields(Table 1).



(**1**) (**2**) (**3**)

R = *p*-nitrophenyl, R' = alkyl

In the course of the experiment, it was found that alkyl phosphate (**4**) and *p*-nitrophenol were unexpectedly obtained in high yields along with **2** when the reaction was carried out in dry pyridine.

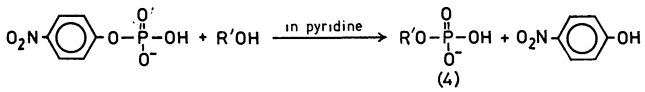
a) Monoanilinium salt
b) Solvent system used: *i*-propyl alcohol, concentrated ammonium hydroxide, water (7:1:2 v/v).
c) Monoammonium salt

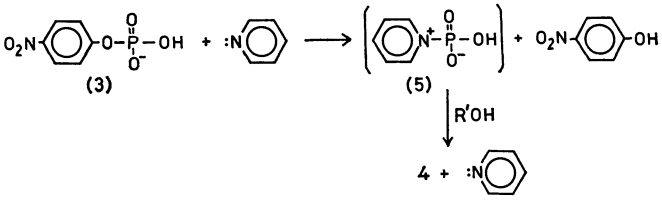
It seems that the formation of **4** and *p*-nitrophenol was caused by the subsequent reaction of alcohol and **3** which was initially formed. The reaction of **3** with alcohol in dry pyridine was tried separately in order to elucidate the mechanism of the formation of **4** and *p*-nitrophenol. When a mixture of **3** and excess ethanol in dry pyridine was heated at 110—120°C for two hours, ethyl phosphate and *p*-nitrophenol were obtained in high yields.



This indicates that *p*-nitrophenyl phosphate (**3**) could be successfully employed as an effective phosphorylating reagent for the synthesis of various alkyl phosphates (**4**). It was established that several alkyl phosphates (**4**) can be prepared in high yields by a simple procedure from **3** and alcohols.[5] The results are summarized in Table 2. In the above reactions, it was shown that the yields of **4** depend on the amount of alcohols. As an example, the yields of **4** remarkably decreased when one equivalent of alcohols was used.

Of various tertiary amines examined, it was shown that pyridine is superior to other amines[6] such as triethylamine, tri-*n*-butylamine and *N*-methylmorpholine. It was also found that *p*-nitrophenyl phosphate (**3**) is the most suitable reagent in comparison with other aryl phosphates such as phenyl-, *p*-tolyl-, and *o*-hydroxyphenyl phosphate.

The reaction seems to proceed through an intermediate, inner salt of *N*-phosphopyridinium hydroxide (**5**), formed from **3** and pyridine. The inner salt (**5**) in turn reacts with alcohol to give alkyl phosphate **4** as shown in the following scheme.



On the other hand, when *p*-nitrophenyl phosphate **3** was heated alone in pyridine, several *p*-nitrophenyl polyphosphates were obtained. These polyphosphates can be detected and determined by UV spectra and phosphorus analysis after being chromatographed on paper (Table 3).

TABLE 1. REACTION OF P^1,P^2-DI-*p*-NITROPHENYL PYROPHOSPHATE (**1**) WITH ALCOHOLS

Alcohol	Yield (%) of **2**	R_f value[a]	Yield (%) of **3**
Ethanol	60	0.83	68
n-Propanol	83	0.84	77
n-Butanol	96	0.86	94
s-Butyl alcohol	99	0.90	98
i-Pentanol	86	0.87	83
n-Octanol	96	0.89	70

a) Solvent system used: *i*-propyl alcohol, concentrated ammonium hydroxide, water (7:1:2 v/v).

5) The reason why 2 can not be used for this type of phosphorylation could not be explained.
6) In the cases of triethylamine and tri-*n*-butylamine, the reactions proceeded very sluggishly.

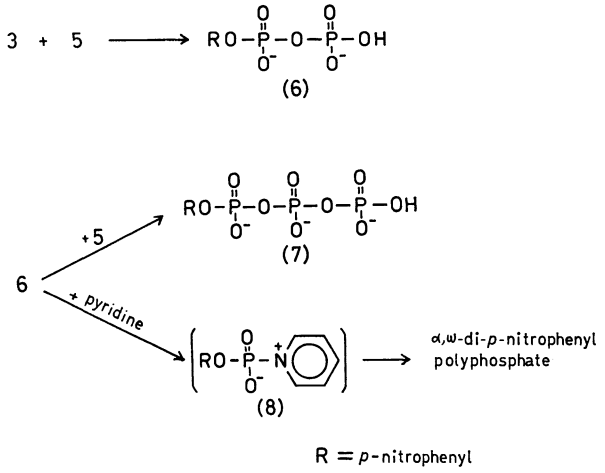
TABLE 3. REACTION OF *p*-NITROPHENYL PHOSPHATE (**3**) WITH PYRIDINE

(R = *p*-nitrophenyl)

Product	R_f value[a]	Yield[b] (%)	Phosphorus content[c]	$\lambda_{max}^{H_2O}$ (mμ)
Rp	0.36	15	1.00	309
Rp_2	0.24	7	2.01	292
Rp_3	0.12	0.8	3.21	289
Rp_4	0.08	0.7	4.97[d]	288
Rp_2R	0.73	4	1.00	288
Rp_3R	0.58	2	1.49	290
Rp_4R	0.47	0.6	1.90	288

a) Solvent system used: *i*-propyl alcohol, concentrated ammonium hydroxide, water, (7:1:2 v/v).
b) A remaining part was proved to be *p*-nitrophenol and inorganic phosphates.
c) Values are relative to *p*-nitrophenyl group.
d) The compound is contaminated with inorganic phosphate.

In this reaction, intermediate **5** would react with **3** to give *p*-nitrophenyl diphosphate (**6**). Compound **6** would further react with **5** to form *p*-nitrophenyl triphosphate (**7**), whereas inner salt of *p*-nitrophenylphosphopyridinium hydroxide (**8**) and inorganic phosphate would be produced by the immutability reaction of polyphosphates, reported by Moffatt.[7] Compound **8** thus successively reacts with **3**, **6**, or **7** to afford α,ω-di-*p*-nitrophenyl polyphosphates.



Experimental

General Procedure. Paper chromatography was performed by the descending technique using Toyo Roshi No.51 paper. Solvent system used was: isopropyl alcohol, concentrated ammonium hydroxide, water (7 : 1 : 2 v/v) (Solvent *A*). The phosphorus containing compounds were dected by means of a spray of Hanes-Isherwood reagent[8] on paper. The R_f values of all compounds described are given in Tables 1, 2, and 3. In all reactions, dried materials were employed. Pyridine was purified and dried by distillation over *p*-toluenesulfonyl chloride and stored over calcium hydride for several days. Evaporation was carried out using a rotatory evaporator under reduced pressure. *p*-Nitrophenyl phosphate was prepared by a modified procedure of Cramer[9] as described below. P^1,P^2-Di-*p*-nitrophenyl pyrophosphate was prepared according to a previous paper.[10]

p-Nitrophenyl Phosphate (3). *p*-Nitrophenyl phosphorodichloridate[11] (83.5 g) was added slowly in portions into 400 m*l* of water with vigorous stirring. The temperature was kept below 15°C during the reaction. Water was evaporated under reduced pressure at a temperature below 60°C. After addition of benzene (150 m*l*), the solution was concentrated under reduced pressure until some white crystals appeared and was allowed to stand in a refrigerator overnight. *p*-Nitrophenyl phosphate (40.0 g, 56%) was obtained as pale yellowish crystals. Recrystallization from benzene containing a trace of ether afforded white needles, mp 156—158°C. By recrystallization from the mother liquid, an additional product (14.3 g, 20%) was obtained.

Reaction of P¹,P²-*Di*-p-*nitrophenyl Pyrophosphate (1) with Alcohols.* A mixture of P^1,P^2-di-*p*-nitrophenyl pyrophosphate (**1**) (11.56 mg, 0.02 mmol) and alcohol (2.0 m*l*) was heated at 100°C for 3 hr. The mixture was then concentrated to dryness and the residue was dissolved in water (2.25 m*l*). Chromatography was performed on paper using Solvent *A* for development. Yields of the compounds, **2** and **3**, were determined spectrophotometrically using $\varepsilon_{291m\mu}=1\times10^4$ (pH 7) for alkyl *p*-nitrophenyl phosphate (**2**) and $\varepsilon_{307m\mu}=1\times10^4$ (pH 7) for *p*-nitrophenyl phosphate (**3**). The results are summarized in Table 1.

Reaction of P¹,P²-*Di*-p-*nitrophenyl Pyrophosphate (1) with Alcohols in pyridine. A Typical Procedure*: A solution of di-pyridinium salt of P^1, P^2-di-*p*-nitrophenyl pyrophosphate (**1**) (324 mg, 0.5 mmol) and *s*-butyl alcohol (3 m*l*) in dry pyridine (4 m*l*) was concentrated by heating at 100°C for 4 hr. Chromatography was performed on paper using Solvent *A*. Three products were detected: *s*-butyl *p*-nitrophenyl phosphate (R_f 0.85, 92%), *s*-butyl phosphate (R_f 0.43, 96%) and *p*-nitrophenol (R_f 0.77, 96%). The yields of the compounds were determined spectrophotometrically.

Isolation of s-*Butyl Phosphate.* The oily residue was dissolved in water (10 m*l*) and the solution was washed with three portions of ether (3×20 m*l*) for removal of *p*-nitrophenol. The aqueous layer was concentrated to dryness. The residue was dissolved in dry pyridine (5 m*l*) and pyridine was evaporated for complete removal of moisture. White precipitate was stored in desiccator over phosphorus pentoxide. The percipitate was poured into a solution of freshly distilled aniline (0.5 m*l*) in dry benzene (20 m*l*). The suspension was heated until it became clear. After cooling, the solution separated white crystals which were collected by filtration. Monoanilinium salt of *s*-butyl phosphate (102 mg) was obtained: mp 155.5—156°C. Found: C, 48.84; H, 7.91; N, 5.10%. Calcd for $C_{10}H_{18}O_4NP$: C, 48.55; H, 7.29; N, 5.66%. From the mother liquid, the salt (10 mg) was obtained. Total yield was 112 mg (92%).

Preparation of Alkyl Phosphates (3). To a solution of an anhydrous alcohol (4 m*l*) in dry pyridine (2 m*l*), *p*-nitrophenyl phosphate (438 mg, 2 mmol) was added. The mixture was heated at 120°C for 1.5 hr and then was concentrated under reduced pressure. The gummy residue was dissolved in water (50 m*l*) and washed with three portions of ether (3×10 m*l*). Ethyl, β-cyanoethyl, *n*-propyl, *n*-butyl and *i*-butyl phosphates were obtained according to method A and the other derivatives listed in Table 2 were isolated by method B.

Method A. The aqueous solution was concentrated to dryness under reduced pressure at a temperature below 15°C. The residue was dissolved in 10% of aqueous pyridine (10 m*l*) and 30% aqueous barium acetate solution was added with vigorous stirring. After 2 hr, the precipitate was collected by filtration and washed with ethyl alcohol. Amorphous barium salt of alkyl phosphate was isolated by centrifuging. The barium salt was further suspended in water and then Dowex 50W-X8 (pyridinium form) was added with stirring over a period of 2 hr. After filtration, the resin was washed with water. The filtrate and washings were combined and concentrated to dryness. The syrup was dissolved in dry pyridine and further concentrated to dryness. This was repeated three times for complete removal of moisture. After addition of freshly distilled aniline (0.4 m*l*), the precipitate was collected by filtration and recrystallization from benzene containing a small amount of ethyl alcohol gave a monoanilinium salt of alkyl phosphate (**4**). The yields and the physical properties are shown in Table 2.

Method B. The aqueous solution was concentrated to dryness. Pyridine (10 m*l*) was added and removed by evaporation. This was repeated three times for complete removal of moisture. The gummy residue was dissolved in dry chloroform (50 m*l*) and allowed to stand at room temperature for 6 hr. The pyridinium salt of inorganic phosphate was removed by filtration. After evaporation of chloroform, this procedure was repeated three times for complete removal of inorganic phosphate. The resulting residue was dissolved in chloroform and freshly distilled aniline (0.4 m*l*) was added. The precipitate was collected by filtration and recrystallization from benzene. A monoanilinium salt of alkyl phosphate (**4**) was obtained as shown in Table 2.

Reaction of p-*Nitrophenyl Phosphate (4) with Pyridine in the Absence of Alcohol.* *p*-Nitrophenyl phosphate (65.7 mg, 0.3 mmol) was dissolved in dry pyridine (0.1 m*l*). The solution was sealed and heated at 110°C for 1.5 hr. After cooling, water (3 m*l*) was added and the aqueous solution was washed with three portions of ether (3×10 m*l*). The aqueous solution was then concentrated to a small volume. Chromatography was performed on paper (Toyo Roshi No. 51) using Solvent *A* for development. The results are summarized in Table 3.

The authors heartily thank Professor Teruaki Mukaiyama for his encouragement and discussions throughout the investigation and also Mr. Masaru Koezuka for his help with elemental analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2744—2749 (1971)

Synthesis and Decomposition of Alkane- and Arenesulfonyl Aryl Disulfides

Yasuo ABE, Takeshige NAKABAYASHI, and Jitsuo TSURUGI

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

(Received December 12, 1970)

Pyridinium alkane- and arenethiolsulfonates were allowed to react with arenesulfenyl chlorides, ClSAr′, to yield sulfonyl disulfides in which R is *n*-dodecyl, benzyl, phenyl, or *p*-tolyl group, and Ar′ *o*-nitrophenyl or *o*-nitro-*p*-chlorophenyl. *p*-Toluenesulfonyl *p*-nitrophenyl disulfide was also prepared by this method. IR and UV spectra of these compounds were determined and compared with those of the corresponding thiolsulfonates. Decomposition of ^{35}S-labeled *p*-toluenesulfonyl *p*-nitrophenyl disulfide, *p*-$CH_3C_6H_4SO_2S^{35}SC_6H_4NO_2$-*p*, gave ^{35}S-labeled *p*-nitrophenyl *p*-toluenethiolsulfonate, *p*-$CH_3C_6H_4SO_2{}^{35}SC_6H_4NO_2$-*p*. Triphenylphosphine was found to attack two oxygen atoms and a sulfur atom of *p*-toluenesulfonyl *o*-nitrophenyl disulfide at the same rate. The reaction of triphenylphosphine with ^{35}S-labeled *p*-toluenesulfonyl *o*- and *p*-nitrophenyl disulfides revealed that the central sulfur atom of these sulfonyl disulfides was desulfurated. This result coincides with that of the decomposition mentioned above. The susceptibility of sulfonyl disulfides containing *p*-nitrophenyl group to the decomposition and the desulfuration of the central sulfur atom of sulfonyl disulfides in general are also discussed.

Very little work has been published on the synthesis and chemistry of organic sulfonyl disulfides (RSO_2SSR', sulfonyl sulfenyl thioanhydride in IUPAC) which are considered as partially oxidized compounds of organic trisulfides. Brooker *et al.*[1] reported synthesis of arenesulfonyl aryl disulfides by the reaction of finely powdered potassium arenethiolsulfonates with arenesulfenyl chlorides in ether. Uhlenbroek and Koopmans[2] examined fungitoxic activity of arenesulfonyl trichloromethyl disulfides which were prepared by the heterogeneous reaction of potassium arenethiolsulfonates in water with trichloromethanesulfenyl chloride.

$$ArSO_2SK + ClSAr' \rightarrow ArSO_2SSAr' + KCl$$

$$ArSO_2SK + ClSCCl_3 \rightarrow ArSO_2SSCCl_3 + KCl$$

In the present work we succeeded in the homogeneous synthetic reaction in organic solvents by using pyridinium alkane- or arenethiolsulfonates and arenesulfenyl chlorides. Since most sulfenyl chlorides are sensitive to hydrolysis, our method will promise synthesis of a variety of the entitled compounds.

Some types of organic sulfonyl disulfides including several novel compounds were successfully prepared by our method, but others were found to decompose during preparation process or recrystallization procedure to give the corresponding thiolsulfonates, RSO_2SAr'. So far as our experiments show, *p*-toluenesulfonyl *p*-nitrophenyl disulfide, was only one stable compound containing *p*-nitrophenyl group as Ar′ in RSO_2SSAr'. This compound specifically labeled with ^{35}S was utilized to confirm which sulfur atom was desulfurated on the spontaneous decomposition, $RSO_2SSAr' \rightarrow RSO_2SAr'$.

In order to obtain further knowledge on sulfonyl disulfides, we allowed nonlabeled and ^{35}S-labeled *p*-toluenesulfonyl *p*- or *o*-nitrophenyl disulfides to react with triphenylphosphine, which has been known to behave as both deoxygenating and desulfurating agents.

Results and Discussion

Synthesis of Alkane- and Arenesulfonyl Aryl Disulfides. A chloroform solution of arenesulfenyl chloride (9 mmol) was added to pyridinium alkane- or arene-

thiolsulfonate (10 mmol) in chloroform at room temperature. The mixture was allowed to stand overnight for completion of the reaction, and washed with water to remove the unchanged pyridinium thiolsulfonate and pyridinium hydrochloride produced. Our experience indicates that an excess

$$RSO_2S^-C_5H_5NH^+ + ClSAr' \rightarrow RSO_2SAr' + C_5H_5NH^+Cl^- \quad (1)$$

sulfenyl chloride should be avoided not to induce undesirable reaction between the sulfonyl disulfide produced and the excess sulfenyl chloride. The results are summarized in Table 1 together with the results of the corresponding thiolsulfonates for comparison. Table 1 clearly indicates that when Ar′ in RSO_2SAr' is o-nitrophenyl or o-nitro-p-chlorophenyl, the sulfonyl disulfides are stable enough to be isolated. With the exception of **9** in Table 1, synthesis of alkane- and arenesulfonyl p-nitrophenyl disulfides failed in spite of all our efforts.

Absorption Spectra of the Sulfonyl Disulfides. In Table 2 are summarized the spectral data of the sulfonyl disulfides together with those of the corresponding thiolsulfonates. As expected from the literatures on sulfones and thiolsulfonates,[4] IR bands of SO_2 group of the sulfonyl disulfides in Table 2 are in a range from 1117 to 1149 and a range from 1325 to 1338 cm^{-1}, respectively.

Leandri *et al.*[5] reported absorption spectra of some thiolsulfonates in near-UV range. The sulfonyl disulfides prepared by us are restricted to only the compounds containing nitro-aromatic rings attached to the thiol sulfur atom, because of the synthetic dif-

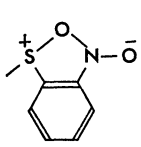
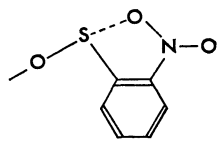
—— **9**, ---- **9a**

ficulty. Therefore, the discussion should be confined to only a limited type of the compounds. As to the UV spectra of thiolsulfonates, Leandri[5] noticed that substituent effects in benzene ring attached to sulfonyl group are comparatively small to affect the general character of the spectra. The same effect as Leandri noticed is observed in the UV spectra of the sulfonyl disulfides in Table 2. (Compare **3** with **4**, and **7** with **8** in Table 2.) Moreover, when the spectra of alkanesulfonyl aryl disulfides (**1**, **2**, **5**, and **6**) were compared with those of arenesulfonyl aryl disulfides (**3**, **4**, **7**, and **8**), prominent difference was not observed. However, the effect of a nitro-substituent in thiol-containing benzene ring is eminent depending on whether the nitro group is in *ortho* or *para* position.

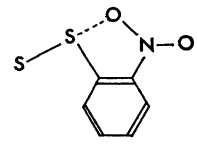
Figure 1 shows UV spectra of **4** and **4a**, and Fig. 2 those of **9** and **9a**. A band at 233 mμ and a shoulder at 269 mμ of **4** in Fig. 1 are attributed to the excitations of benzene ring attached to sulfonyl group as Leandri has assigned for thiolsulfonates. (Refer to those of **4a** in Fig. 1.) However, the broad but well defined band at 347 mμ is considered specific for **4**, because **4a** exhibits only smooth running in this range.[6] We[7] reported already that di-*o*-nitrophenyl sulfide and disulfide have a maximum near 350 mμ and that structure I might contribute to the excitation of these compounds. The specific band at 347 mμ of **4** may be rationalized by the contribution of the structure I,



I



II



III

in which N, O, and S atoms are coplanar with benzene ring. The similar specific bands are observed in UV spectra of **1**—**3** (sulfonyl *o*-nitrophenyl disulfides), and slight bathochromic shifts are also observed in **5**—**8** (sulfonyl *o*-nitro-*p*-chlorophenyl disulfides). The smooth running down of the spectrum of thiolsulfonate **4a** in this range suggests that coplanarity in structure I disappeared because of steric effect of adjacent SO_2 group or that the electrons of sulfur atom attached to nitrobenzene ring are intensively withdrawn by SO_2 group.

A shoulder near 310 mμ of **9** in Fig. 2 may be assigned to the excited structure of *p*-nitrobenzenesulfenyl group, because di-*p*-nitrophenyl disulfide was reported[8] to exhibit a maximum at 316 mμ. The similar shoulder of **9a** is shifted to shorter wavelength. This suggests that the excited state of *p*-nitrobenzenesulfenyl group is disturbed to some extent by the intensive electron-withdrawing effect of adjacent SO_2 group, while in **9** this effect is weakened to a greater extent by the intervening sulfur atom.

The stability of the sulfonyl disulfides containing *o*-nitrophenyl or *o*-nitro-*p*-chlorophenyl group (compounds **1**—**8**) may be explained as follows. Hamilton and La Placa[9] attributed the stability of *o*-nitrobenzenesulfenate to a resonance stability originated from the coplanarity as indicated in II and a specific nonbonding interaction of S and O atoms of sulfenic acid group with almost linear O—S···O configuration. The stability of the compounds **1**—**8** may be rationalized by the same argument mentioned above (III).

The Decomposition of ^{35}S*-labeled* p-*Toluenesulfonyl* p-*Nitrophenyl Disulfide (labeled* ***9****).* As stated above, **9** was obtained as only one stable compound among sulfonyl *p*-nitrophenyl disulfides. We examined the decomposition of the ^{35}S-labeled **9** by submitting to several recrystallizations from a polar solvent. This labeled compound was prepared as shown below.

$$p\text{-}NO_2C_6H_4{}^{35}S{}^{35}SC_6H_4NO_2\text{-}p + Cl_2 \rightarrow 2\,p\text{-}NO_2C_6H_4{}^{35}SCl$$

$$p\text{-}CH_3C_6H_4SO_2S^-C_5H_5NH^+ + p\text{-}NO_2C_6H_4{}^{35}SCl \rightarrow p\text{-}CH_3C_6H_4SO_2S{}^{35}SC_6H_4NO_2\text{-}p \quad \text{(labeled 9)}$$

This compound, after recrystallizations of more than ten times, was found to be converted into *p*-nitrophenyl *p*-toluenethiolsulfonate (labeled **9a**), of which specific activity was determined as 1,395 dpm/mg. The standard labeled **9a** for radioassay was prepared from the same *p*-nitrobenzenesulfenyl chloride as for the labeled **9**. The specific activity of the standard **9a** was found 1,427 dpm/mg and coincided with that (1,395 dpm/mg) of the decomposition product from the labeled **9** within experimental error. Therefore, we can conclude that the central sulfur atom of **9** is desulfurated on the spontaneous decomposition. This conclusion does not contradict with the explanation on the stability of compounds **1**—**8** mentioned above. The failure to synthesize other compounds than **9** which contain *p*-nitrophenyl as Ar′ in RSO_2-SSAr′ may be ascribed to the extreme susceptibility to spontaneous decomposition.[10]

$$p\text{-}CH_3C_6H_4SO_2S{}^{35}SC_6H_4NO_2\text{-}p \rightarrow p\text{-}CH_3C_6H_4SO_2{}^{35}SC_6H_4NO_2\text{-}p \quad (2)$$
(labeled **9**) (labeled **9a**)

The Reaction of Triphenylphosphine with p-*Toluenesulfonyl* o-*Nitrophenyl Disulfide (****4****).* Hayashi *et al.*[11] subjected thiolsulfonates and disulfonyl sulfides

6) Leandri *et al.*[5] reported that UV spectra of phenyl *o*- and *p*-nitrobenzenethiolsulfonates, when determined in ethanol, have each maximum at 400 and 340 mμ respectively, besides those determined in cyclohexane. They ascribed these additional bands to specific interaction between alcohol and the nitrobenzenethio-group. However, as shown in Figs. 1 and 2 (**4a** and **9a**), we could not observe such additional bands as they reported.

7) T. Nakabayashi and J. Tsurugi, *J. Org. Chem.*, **26**, 2482 (1961).

8) E. Campaigne, J. Tsurugi, and W. W. Meyer, *ibid.* **26**, 2486 (1961).

9) W. C. Hamilton and S. J. La Placa, *J. Amer. Chem. Soc.*, **86**, 2289 (1964).

10) We attempted to prepare also alkanesulfonyl alkyl disulfides like $C_6H_5CH_2SO_2SSCH_2C_6H_5$ and arenesulfonyl aryl disulfides such as $C_6H_5SO_2SSC_6H_5$, but failed in spite of all our efforts. The order of the susceptibility of sulfonyl disulfide to the decomposition to thiolsulfonate is estimated by the numbers of times of recrystallization (from ethanol) to be converted to the corresponding thiolsulfonate. The order is: alkanesulfonyl alkyl> arenesulfonyl aryl>arenesulfonyl *p*-nitrophenyl.

(RSO_2SSO_2R') to deoxygenation and desulfuration with triphenylphosphine and concluded as summarized below. It seems interesting to examine whether or

$$RSO_2SR' \xrightarrow[\text{reflux}]{Ph_3P} RSOSR' \xrightarrow[\text{reflux}]{Ph_3P} RSSR'$$

$$RSO_2SSO_2R' \xrightarrow[\text{reflux}]{4\ Ph_3P} RSSSR' \xrightarrow[\text{reflux}]{Ph_3P} RSSR'$$

not sulfonyl disulfide behaves similarly to thiolsulfonate or disulfonyl sulfide. Benzene solution of **4** (1 mmol) was added to equimolar amount of triphenylphosphine in ethanol. After the mixture was allowed to stand for one hour at room temperature, glc analysis indicated that 0.67 mmol of triphenylphosphine oxide and 0.33 mmol of triphenylphosphine sulfide were produced. This result shows that under these conditions two oxygen atoms of sulfonyl group and a sulfur atom were eliminated with triphenylphosphine, and makes a clear contrast to the stepwise deoxygenation and desulfuration of thiolsulfonate and disulfonyl sulfide.

The Reaction of Triphenylphosphine with ^{35}S-Labeled p-*Toluenesulfonyl* o- *and* p-*Nitrophenyl Disulfides (Labeled* ***4*** *and* ***9***). In order to confirm which sulfur atom of sulfonyl disulfide is desulfurated, we utilized ^{35}S-labeled **4**, which was prepared as shown below. The specific activity of the labeled **4** recrystallized from

$$p\text{-}CH_3C_6H_4SO_2^-C_5H_5NH^+ + {}^{35}S \rightarrow p\text{-}CH_3C_6H_4SO_2{}^{35}S^-C_5H_5NH^+$$

$$p\text{-}CH_3C_6H_4SO_2{}^{35}S^-C_5H_5NH^+ + o\text{-}NO_2C_6H_4SCl \rightarrow p\text{-}CH_3C_6H_4SO_2{}^{35}SSC_6H_4NO_2\text{-}o$$

(labeled **4**)

carbon tetrachloride was 25,634 dpm/mg. One mmol of the labeled **4** in benzene was allowed to react with three mmol of triphenylphosphine in ethanol at room temperature for one hour. An aliquot of the reaction mixture, when determined by GLC, showed 2 : 1 molar ratio of phosphine oxide and sulfide produced. Triphenylphosphine sulfide was separated from the mixture by recrystallization from ethanol. Specific activity of the sulfide obtained was 29,855 dpm/mg. The standard triphenylphosphine sulfide for radioassay was prepared from triphenylphosphine and the same radioactive sulfur as used for the labeled **4**. The specific activity of this standard was found 29,867 dpm/mg and coincided with that (29,855) of the desulfuration product from the labeled **4**. Therefore,

$$p\text{-}CH_3C_6H_4SO_2{}^{35}SSC_6H_4NO_2\text{-}o + 3(C_6H_5)_3P \rightarrow 2(C_6H_5)_3PO + (C_6H_5)_3P{}^{35}S + p\text{-}CH_3C_6H_4SSC_6H_4NO_2\text{-}o \quad (3)$$

The ^{35}S-labeled **9**, $p\text{-}CH_3C_6H_4SO_2S^{35}SC_6H_4NO_2\text{-}p$, which was utilized for the decomposition of sulfonyl disulfide as shown above, was also allowed to react with triphenylphosphine. Triphenylphosphine sulfide separated similarly to the case for the labeled **4** was found nonradioactive.

$$p\text{-}CH_3C_6H_4SO_2S^{35}SC_6H_4NO_2\text{-}p + 3(C_6H_5)_3P \rightarrow 2(C_6H_5)_3PO + (C_6H_5)_3PS + p\text{-}CH_3C_6H_4S^{35}SC_6H_4NO_2\text{-}p \quad (4)$$

Although Eqs. (3) and (4) predict the formation of the nonlabeled *p*-tolyl *o*-nitrophenyl disulfide and labeled *p*-tolyl *p*-nitrophenyl disulfide respectively, their isolation was not carried out, because our intention is to isolate and assay the radioactivity of phosphine sulfide produced. The formation of radioactive phosphine sulfide in Eq. (3) clearly indicates that the central sulfur atom of the sulfonyl disulfide is desulfurated. Eq. (4) also supports this conclusion. In the present paper we noticed that unstable sulfonyl disulfide decomposes into thiolsulfonate by recrystallization from ethanol. The decomposition results in the release of the central sulfur atom. (See Eq. (2).) This analogy suggests that the decomposition may arise from a nucleophilic attack by ethanol.

Experimental

All melting points are uncorrected. Infrared spectra were recorded on a JASCO IR-S spectrometer by KBr disk method and UV spectra were recorded on a Shimadzu RS-27 spectrometer in 99.5% ethanol. Triphenylphosphine oxide and sulfide were identified by comparison of their retention times with those of authentic specimens, and estimated by use of triphenylphosphorothionate as an internal standard, with a Yanagimoto GCG-5DH gas chromatograph using Silicone DC 200 column. Specific activities of all the labeled compounds, which were recrystallized until the respective constant specific activities attained, were counted with a Packard Tri-Carb Liquid Scintillation Spectrometer, Model 314, using a mixture of POPOP and PPO (0.1 g and 4 g in 1 *l* of toluene) as a scintillator.

Materials. Benzene- and *p*-toluenesulfinic acids were prepared by acidification of commercial sodium salts. *n*-Dodecanesulfinic acid was prepared from *n*-dodecylmagnesium bromide and sulfur dioxide.[12] ω-Toluenesulfinic acid was prepared from ω-toluenesulfonyl chloride by reduction with sodium sulfite.[13]

Pyridinium salts of alkane- and arenethiolsulfonic acids were prepared from the corresponding sulfinic acids and elemental sulfur in pyridine.[14] Mp and analysis of the compounds are summarized in Table 3.

Table 3. The Mp and analysis of the pyridinium thiolsulfonates

Pyridinium thiolsulfonate[b]	Mp (°C)	Anal, Found (Calcd)			
		C	H	N	S
n-Dodecane	65— 70	58.76 (59.07)	9.08 (9.06)	3.75 (4.05)	18.4 (18.56)
p-Toluene	88— 94	54.06 (53.91)	5.20 (4.90)	5.23 (5.24)	23.9 (23.98)
w-Toluene	129—131	53.69 (53.91)	4.85 (4.90)	5.08 (5.24)	24.13 (23.98)

b) Since benzenethiolsulfonate was obtained as an oily material, it was used for the succeeding synthesis without isolation.

Arenesulfenyl chlorides were prepared from the corresponding disulfides by chlorination.[15,16]

Thiolsulfonates. Compounds **1a**—**8a** were prepared from the arenesulfenyl chlorides and a slight excess of the sulfinic acids both in chloroform. Compound **9a** was prepared from pyridinium sulfinate by the same method as for **1a**—**8a**. Crude products were recrystallized from ethanol.

Alkane- and Arenesulfonyl Aryl Disulfides. To a solution of the pyridinium alkane- or arenethiolsulfonate (10 mmol) in 30 m*l* of chloroform, was added a solution of the arenesulfenyl chloride (9 mmol) in 30 m*l* of chloroform dropwise at room temperature. The mixture was allowed to stand overnight at the same temperature. The reaction mixture was thoroughly washed with water and then dried over anhydrous sodium sulfate. After the removal of the solvent under reduced pressure, the crude sulfonyl disulfide was recrystallized from ethanol. Only **9** was recrystallized from carbon tetrachloride for prevention of the decomposition.

Specifically ^{35}S*-Labeled* p-*Toluenesulfonyl* o-*Nitrophenyl Disulfide (**4**).* Radioactive sulfur (5 mCi) in benzene was diluted with 18 g of nonactive sulfur in 200 m*l* of carbon disulfide. After removal of the solvent under reduced pressure, crystals of elementary sulfur were recrystallized from benzene. The crystals had an appropriate specific activity for the further synthesis. To a solution of *p*-toluenesulfinic acid (7.1 g) in pyridine (50 m*l*) was added 1.5 g of the radioactive sulfur. The mixture was treated by the same method as for nonactive one to yield 8.2 g of pyridinium *p*-toluenethiolsulfonate. The radioactive sulfonyl disulfide was prepared from this compound and *o*-nitrobenzenesulfenyl chloride by the same method as for nonactive compound and recrystallized from carbon tetrachloride (25,634 dpm/mg).

Specifically ^{35}S*-Labeled* p-*Nitrophenyl Disulfide (**9**).* Radioactive sulfur (1 mCi) in benzene was diluted with 10 g of nonactive sulfur in 100 m*l* of carbon disulfide. The solvent was removed under reduced pressure. From the active sulfur was prepared radioactive sodium disulfide, which was allowed to react with *p*-nitrochlorobenzene to give radioactive *p,p'*-dinitrodiphenyl disulfide (12.7 g, mp 182—183°C). The latter compound (1.6 g) was converted to radioactive *p*-nitrobenzenesulfenyl chloride by chlorination. Radioactive **9** was prepared from the radioactive sulfenyl chloride and pyridinium *p*-toluenethiolsulfonate (2.7 g) as for nonlabeled **9**, and recrystallized from carbon tetrachloride (mp 105—106°C, 1,287 dpm/mg).

Specifically ^{35}S*-Labeled* p-*Nitrophenyl* p-*Toluenethiolsulfonate (**9a**).* Radioactive *p*-nitrobenzenesulfenyl chloride which was used for the preparation of the labeled **9** and pyridinium *p*-toluenesulfinate (2.64 g) in chloroform (100 m*l*) was allowed to stand overnight. The mixture was washed with water three times and dried over anhydrous sodium sulfate. Removal of chloroform by a rotary evaporator yielded crystals. After five recrystallizations from ethanol, constant specific activity (1,427 dpm/mg) was obtained.

Standard ^{35}S*-Labeled Triphenylphosphine Sulfide.* To a solution of radioactive sulfur (0.32 g) which was used for the preparation of labeled **4** in benzene was added triphenylphosphine (2.62 g) in ethanol. The mixture was allowed to stand for one hour at room temperature. The solvent was removed under reduced pressure. After four recrystallizations from ethanol, constant specific activity (29,867 dpm/mg) was obtained.

Reaction of p-*Toluenesulfonyl* p-*Nitrophenyl Disulfide (**4**) with Triphenylphosphine.* To a solution of nonactive sulfonyl disulfide (1 mmol) in 10 m*l* of benzene, was added a solution of triphenylphosphine (1 mmol) in 5 m*l* of ethanol.

*Reaction of the Labeled **4** with Triphenylphosphine.* To a solution of radioactive sulfonyl disulfide (1 mmol) in 20 m*l* of benzene, was added a solution of triphenylphosphine (3 mmol) in 15 m*l* of ethanol at room temperature. The mixture was allowed to stand for one hour. An aliquot was analyzed by GLC. The solvent of the remaining portion of the solution was evaporated under reduced pressure, the solid was washed with cold ethanol and then recrystallized from ethanol to constant mp (162.5—163°C) and specific activity (29,855 dpm/mg).

*Reaction of the Labeled **9** with Triphenylphosphine.* Reaction was carried out by the same method as for labeled **4**. Pure triphenylphosphine sulfide obtained indicated no radioactivity.

We wish to thank Mr. Ryuichi Akaki in this laboratory for elemental analysis.

Studies of Benzoylsulfene. IV.[1] The Cycloaddition Reactions of Benzoylsulfene with Cinnamylideneamines

Otohiko TSUGE and Sumio IWANAMI

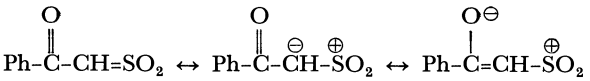
Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received February 2, 1971)

The reaction of benzoylmethanesulfonyl chloride with cinnamylideneamines in the presence of triethylamine has been investigated; the products were identified, by spectral studies as well as by chemical transformations, as the corresponding Diels-Alder adducts of benzoylsulfene as a dienophile to the α,β-unsaturated anils, 2-substituted 5*H*, 6*H*-6-benzoyl-5-phenyl-1,2-thiazine 1,1-dioxides, in which the phenyl and benzoyl groups are quasi-equatorial and quasi-axial respectively. The cycloadducts underwent inversion, on treatment with sodium methoxide in methanol or with silica gel in chloroform, to the corresponding epimers, in which both the phenyl and benzoyl groups are quasi-equatorial.

Recently, we found that benzoylsulfene PhCO-CH=SO_2), generated *in situ* from benzoylmethanesulfonyl chloride (I) and triethylamine (NEt_3), reacts with the C=N bonds of anils[2] and carbodiimides[3] to give the (2+2) and/or (4+2) cycloadducts, in spite of the fact that the usual sulfenes (RCH=SO_2) did not react with the C=N bond.[4]

This might indicate that the electron-attracting benzoyl group makes benzoylsulfene more reactive than the sulfenes (RCH=SO_2), and that benzoylsulfene behaves as a 1,2- and/or 1,4-dipole.



On the other hand, Sakamoto and Tomimatsu[5] found that the adduct obtained from the reaction of phenylketene with cinnamylideneaniline is not the Diels-Alder adduct, as proposed by Pfleger and Jäger,[6] but the corresponding (2+2) cycloadduct of ketene to the C=N bond.

In this connection, it seemed that it would be interesting to investigate the reaction of benzoylsulfene with α,β-unsaturated anils.

In the present paper, we wish to report on the formation of the Diels-Alder adducts by the reaction of benzoylsulfene with cinnamylideneamines.

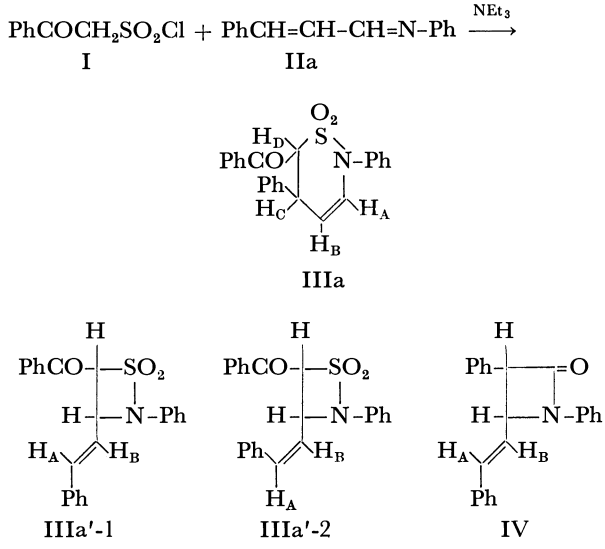
Results and Discussion

The reaction of benzoylmethanesulfonyl chloride (I) with equimolar amounts of cinnamylideneaniline (IIa) and NEt_3 in dioxane at room temperature for 1.5 hr gave a crystalline compound, IIIa, mp 159—160°C (decomp.), and triethylammonium chloride in 43% and quantitative yields respectively. The elemental analysis and the molecular weight (M^+ *m/e* 389) of IIIa were consistent with those of the expected 1 : 1 adduct of benzoylsulfene and IIa.

The Diels-Alder adduct of benzoylsulfene as a dienophile to IIa, and the (2+2) and (4+2) cycloadducts of benzoylsulfene to the C=C or C=N bond in IIa, are possible for the structure of IIIa.

The IR spectrum of IIIa showed characteristic band at 1686 (νC=O), 1655 (νC=C or νC=N), 1340, and 1140 cm^{-1} (νSO_2), while the PMR spectrum in deuteriochloroform ($CDCl_3$) exhibited the four signals (each 1H) shown in Fig. 1, and also multiplets around τ 2.2—3.1 (15H, aromatic protons). Moreover, a solution of IIIa in benzene absorbed an equimolar amount of bromine.

These observations suggest that the 1 : 1 adduct is either the Diels-Alder adduct (IIIa) or the (2+2) cycloadduct (IIIa′) to the C=N bond.



It is well known[7] that *trans* ethylenic coupling constants are always larger than *cis* ethylenic coupling constants for any pairs of 1,2-disubstituted ethylenes. The value of the ethylenic coupling constants, J_{AB} of the β-lactam IV obtained from phenylketene and IIa has been reported to be 17 Hz.[4] Also, the value of the ethylenic coupling constant of *trans*-cinnamaldehyde, the starting material of IIa, is 16.2 Hz.[8]

7) L. M. Jackman and S. Sternhell, "Application of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry," 2nd Ed., Pergamon Press, Oxford, London, Edinburgh, New York, Toronto, Sydney, Paris, Braunschweig (1969), p. 301.

The value of J_{AB} (8.6—8.8 Hz) in IIIa, as obtained its PMR spectrum (see Fig. 1 and Table 2), implies that H_A and H_B in IIIa are *cis*;[9,10] this observation excludes the possible formation of 4-benzoyl-2-phenyl-3-*trans*-styrylthiazetidine 1,1-dioxide (IIIa'-1).

It was very difficult to distinguish between the Diels-Alder adduct, 5*H*,6*H*-6-benzoyl-2,5-diphenyl-1,2-thiazine 1,1-dioxide (IIIa), and the (2+2) cycloadduct, 4-benzoyl-2-phenyl-3-*cis*-styrylthiazetidine 1,1-dioxide (IIIa'-2), on the basis of the spectral data. Since the olefinic hydrogens of IIa are *trans*, however, the predominant formation of the (2+2) cycloadduct with the *cis*-styryl group does not seem reasonable.

On the basis of the above observations and the chemical transformations, which will be discussed below, we can conclude that the most reasonable structure for the reaction product between benzoylsulfene and IIa is the Diels-Alder adduct IIIa.

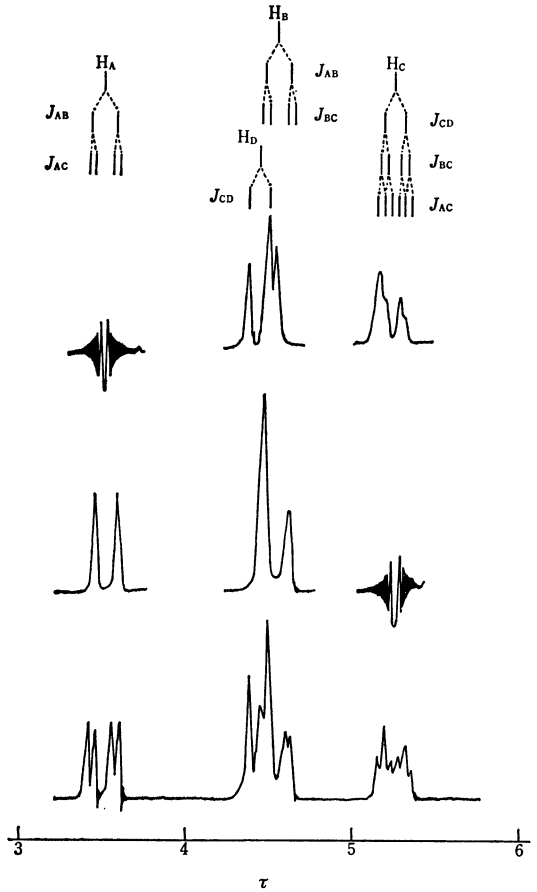

Fig. 1. PMR spectrum of IIIa in $CDCl_3$ at 60 MHz.

When a suspension of IIIa in methanol was treated with sodium methoxide at room temperature for 10 min, a compound Va, mp 175°C, was obtained as colorless needles in an exellent yield. The compound Va was also formed on treating IIIa with silica gel in chloroform.

The compound Va was proved, by the results of elemental analysis as well as by a study of its mass spectrum, to be an isomer of IIIa. The IR spectrum of Va showed characteristic bands at 1678 (νC=O), 1629 (νC=C), 1360, and 1160 cm^{-1} (νSO_2), while the PMR spectrum in $CDCl_3$ exhibited four signals (each 1H), as Fig. 2 shows, besides multiplets around τ 2.2—2.9 (15H, aromatic protons); the J_{AB} value between olefinic protons is 8.1 Hz.

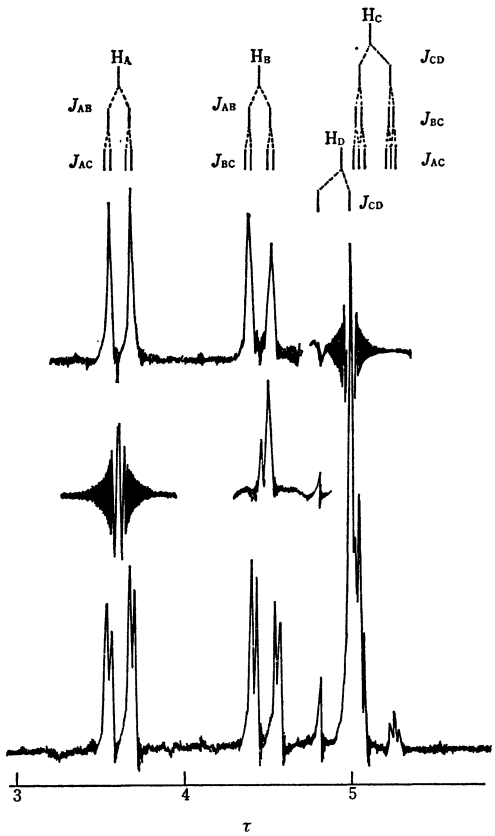

Fig. 2. PMR spectrum of Va in $CDCl_3$ at 60MHz.

From the above observations, it seems that the same ring structure as in IIIa might be involved in Va.

As is illustrated in Fig. 1, the allylic J_{AC} value between the olefinic and the allylic protons is almost equal to the vicinal J_{BC} value (2.5 Hz). This fact suggests that the hydrogen, H_C, in IIIa is quasi-axial.

An inspection of the Dreiding models indicates that the dihedral angle, θ_{CD} between H_C and H_D is about 40° if the benzoyl and phenyl groups in IIIa are *cis*. The observed J_{CD} value of 7.2 Hz is compatible with the value of 7.3 Hz calculated by a modified Karplus equation when θ=40°.[11]

On the other hand, in the PMR spectrum of Va (Fig. 2) the J_{AC} value is also almost equal to the J_{BC} value (1.8 Hz); consequently, the hydrogen, H_C, in Va is quasi-axial.

Furthermore, the observed J_{CD} value of 11.7 Hz implies that the benzoyl and phenyl groups in Va are *trans*-diquasi-equatorial.

8) The olefinic coupling constant of IIa could not be measured, because assignments of the olefinic protons could not be made. While, the olefinic coupling constant of IId was observed to be 16 Hz.

9) G. V. Smith and H. Krilof, *J. Amer. Chem. Soc.*, **85**, 2016 (1963).

10) R. Bramley and M. D. Johnson, *J. Chem. Soc.*, **1965**, 1372.

11) R. J. Abraham, *Mol. Phys.*, **1**, 513 (1962).

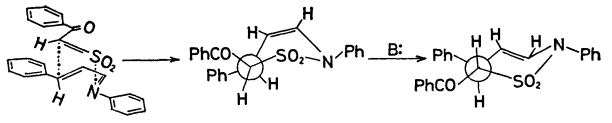
On the basis of the above observations, it is evident that IIIa is 5*H*,6*H*-6-benzoyl-2,5-diphenyl-1,2-thiazine 1,1-dioxide, in which the benzoyl and 5-phenyl groups are quasi-axial and quasi-equatorial (*cis*), while Va is its epimer, in which the benzoyl and 5-phenyl groups are both quasi-equatorial (*trans*).

It may be thought that IIIa is easily isomerized into the stable epimer, Va, under such mild conditions, because the hydrogen, H_D, in IIIa is highly activated by the neighboring electron-attracting benzoyl and sulfone groups. The treatment of IIIa with sodium methoxide in deuteriomethanol (CH_3OD) afforded the epimer-6-d (Va-d), mp 175°C, whose structure was established by a study of the PMR and mass spectra.

In general, the Diels-Alder reaction proceeds through the endo addition corresponding to the maximum accumulation of the double bond of the two reagents.

The favorable formation of IIIa can be reasonably explained in terms of the maximum accumulation of double bonds of benzoylsulfene and IIa with the *trans-s-cis-anti* configulation, as is illustrated in Scheme 1.

Furthermore, it may be considered that the active hydrogen, H_D, in IIIa is easily abstracted with a base, leading to the formation of the stable epimer, Va. However, the reaction course is not yet clear in detail.



IIa Va

Scheme 1

Both the cycloadducts, IIIa and Va, were hydrolyzed with aqueous sodium hydroxide in boiling methanol; both thus afforded the same compound, VI ($C_{16}H_{15}O_2NS$, M^+ *m/e* 285), mp 86—87°C (decomp.), as colorless plates, whose IR spectrum did not show any bands ascribable to the carbonyl and NH groups, but which did exhibit bands at 1645 (νC=C), 1350, and 1165 cm^{-1} (νSO_2).

The PMR spectrum of VI in $CDCl_3$ exhibited signals due to olefin-, methine- and methylene-protons, as is shown in Fig. 3, besides multiplets (10H, aromatic protons) around τ 2.5—2.9. The values of J_{AB}, J_{AC}, J_{BC}, J_{CD}, J_{CE}, and J_{BD} are found to be 8.3, 2.3, 2.2, 6.0, 12.5, and 1.2 Hz respectively. The long-range coupling (J_{BD}=1.2 Hz) may be due to the W-letter arrangement of H_B-C-C-C-H_D.[12] Furthermore, J_{DE} is 13.0 Hz.

The above observations indicate that the compound VI is 5*H*,6*H*-2,5-diphenyl-1,2-thiazine 1,1-dioxide, in which the 5-phenyl group and hydrogen H_D are both equatorial.

4-Benzoyl-2,3-diphenyl-1,2-thiazetidine 1,1-dioxide was hydrolyzed with aqueous sodium hydroxide as in the following equation,[2] while the ring skeltons

12) A. Rassat, C. W. Jefford, J. M. Lehn, and B. Waegell, *Tetrahedron Lett.*, **1964**, 1233; S. Sternhell, *Rev. Pure Appl. Chem.*, **14**, 15 (1964).

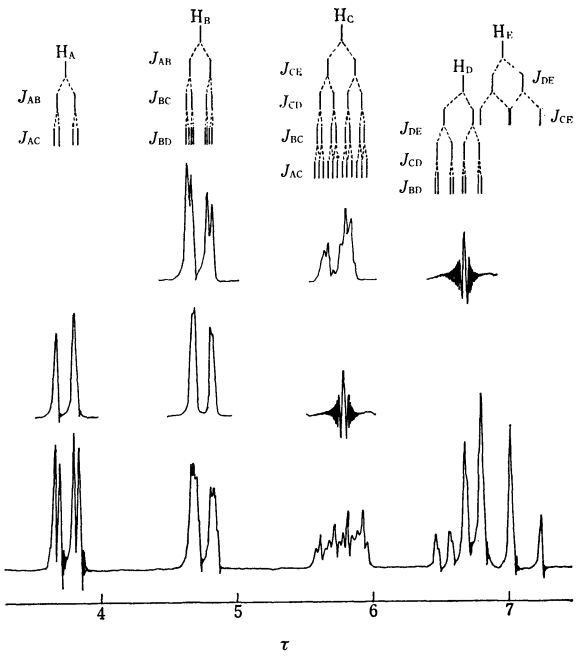


Fig. 3. PMR spectrum of VI in $CDCl_3$ at 60 MHz.

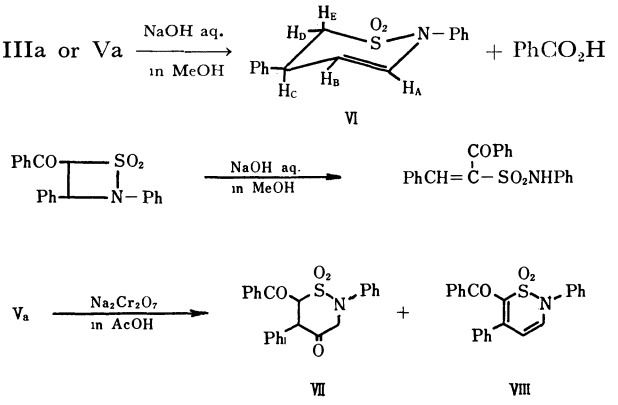
of IIIa and Va were retained under similar conditions. These facts also support the proposed structures for IIIa and Va.



Scheme 2

The following experiment offered additional evidence for the proposed structure for Va. The oxidation of Va with sodium dichromate in acetic acid afforded perhydro-6-benzoyl-2,5-diphenyl-1,2-thiazin-4-one 1,1-dioxide (VII), mp 239—240°C, and 6-benzoyl-2,5-diphenyl-1,2-thiazine 1,1-dioxide (VIII), mp 169—170°C, in 23 and 10% yields respectively. The structures of VII and VIII were confirmed by elemental analyses and spectral studies.

Similar reactions of I with cinnamylidene-*p*-anisidine (IIb), -*p*-chloroaniline (IIc), -*n*-propylamine (IId) and α-methylcinnamylideneaniline (IIe) were investigated in the presence of triethylamine the results are summarized in Table 1.

Althogh the reaction with IIa and IId afforded the initial Diels-Alder adducts, IIIa and IIId, as crystalline compounds, oily substances were formed in the reactions with IIb, IIc, and IIe. However,

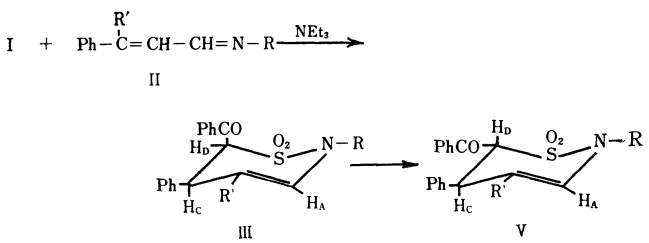
a) Coupling constant, *J*, was measured with an error of about ±0.3 Hz.
b) Chemical shift of methyl protons.
c) This value is uncorrect, since impurity of the solvent exhibits multiplets around τ 5.6—5.8.



b: R=*p*-$MeOC_6H_4$, R'=H_B; c: R=*p*-ClC_6H_4, R'=H_B; d: R=*n*-Pr, R'=H_B; e: R=Ph, R'=Me

oily substances were transformed, by chromatography on silica gel using chloroform as the eluent, to the corresponding epimers, V, as crystalline compounds. These results suggests that the oily substances contained considerable amounts of III, because IIIa and IIId were quantitatively transformed, as has been mentioned, to Va and Vd.

The structures of III and V were established by elemental analyses and by spectral studies. The yields, physical properties, elemental analyses, and spectral data are summarized in Tables 1 and 2.

Additional reactions of Va with hydrogen halides and bromine were also investigated.

When hydrogen bromide was passed through a solution of Va in benzene, and the resulting solution was then treated with methanol, perhydro-6-benzoyl-2,5-diphenyl-4-methoxy-1,2-thiazine 1,1-dioxide (IX), mp 175°C (decomp.), was obtained quantitatively. The structure of IX was confirmed by the results of the elemental analysis and by the spectral data.

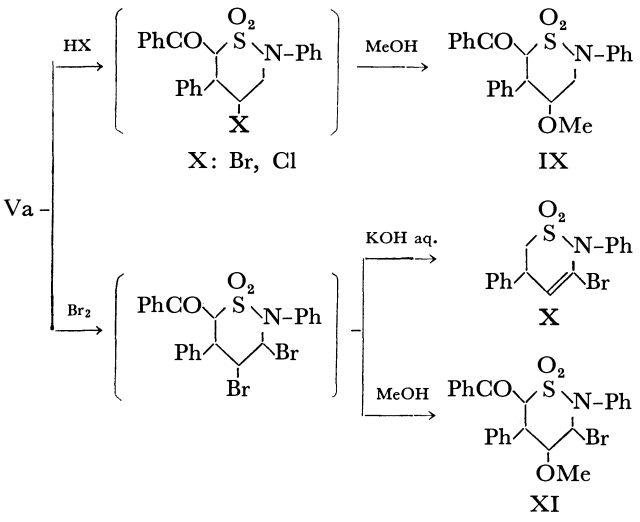
Also, the treatment of Va with concentrated hydrochloric acid in methanol at room temperature gave IX in a quantitative yield. Although an addition

product of hydrogen bromide to Va could not be in a pure form, it is evident that the products from hydrogen halides are the corresponding perhydro-4-halo-1,2-thiazine 1,1-dioxide (Scheme 3).

The bromination of Va, followed by the treatment of a resulting oily dibromo compound with aqueous potassium hydroxide, afforded a crystalline compound, X ($C_{16}H_{14}O_2NSBr$), mp 147°C, in a low yield. The IR spectrum of X showed bands at 1632 (νC=C), 1355, and 1160 cm^{-1} (νSO_2), but not any carbonyl bands. The PMR spectrum in $CDCl_3$ revealed signals at τ 6.15—6.95 (2H, multiplets, >C<u>H</u>$_2$), 5.4—5.9 (1H, multiplet, >C<u>H</u>), 3.32 (1H, doublet, -C<u>H</u>=, J=1.8 Hz), and 2.4—2.7 (10H, multiplets, aromatic protons).

The above observations indicate that the compound X is 5*H*,6*H*-3-bromo-2,4-diphenyl-1,2-thiazine 1,1-dioxide. The structure for X was also supported by the mass spectrum.

On the other hand, the treatment of the dibromo compound with methanol gave a crystalline compound XI, mp 170—171°C (decomp.), in a good yield. The compound XI ($C_{24}H_{22}O_4NSBr$) was assumed to be perhydro-6-benzoyl-3-bromo-2,5-diphenyl-4-methoxy-1,2-thiazine 1,1-dioxide on the basis of the following evidence.



Scheme 3

The IR spectrum of XI showed bands at 1685 (νC=O), 1336, and 1150 cm^{-1} (νSO_2), while the PMR spectrum in $CDCl_3$ revealed signals at τ5.47 (1H, two pairs of doublets, MeO-C<u>H</u><, each J= 2.5 Hz), 4.98 (1H, double doublets, Ph-C<u>H</u><, J= 11.8 and 2.5 Hz), 4.82 (1H, doublet, Br-C<u>H</u><, J= 2.5 Hz), 3.95 (1H, doublet, PhCO-C<u>H</u><, J=11.8 Hz), and 1.8—2.9 (15H, multiplets, aromatic protons). The 4-bromo-3-methoxy isomer is also possible for the structure of XI. However, it may be considered that the 3-bromo-4-methoxy compound is more probable than the isomer, because the 4-bromine is more reactive than 3-bromine in the dibromo compound, as was shown in the formation of X. From the vicinal $J_{4,5}$ and $J_{5,6}$ values, it is evident that the 5-phenyl and benzoyl groups are both equatorial, and that the methoxy group is axial in XI.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were measured in a KBr disk. The PMR spectra were taken on a Hitachi R-20 NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

Materials. Benzoylmethanesulfonyl chloride (I), mp 88°C (lit,[13] mp 87.5—88.2°C) was prepared according to the method of Truce and Vriesen.[13] α,β-Unsaturated anils were prepared from the corresponding cinnamaldehydes and amines: cinnamylideneaniline (IIa), mp 109°C (lit,[14] mp 109°C), -*p*-anisidine (IIb), mp 118—119°C (lit,[15] mp 119°C), and -*p*-chloroaniline (IIc), mp 106—107°C (lit[15] mp 107°C).

Cinnamylidene-*n*-propylamine (IId), bp 140—142°C/0.2 mmHg.

Found: C, 83.40; H, 8.66; N, 7.93%. Calcd for $C_{12}H_{15}N$: C, 83.19; H, 8.73; N, 8.09%. M^+: *m/e* 173.

β-Methylcinnamylideneaniline (IIe); bp 192°C/1.2 mmHg.

Found: C, 87.18; H, 6.79; N, 6.26%. Calcd for $C_{16}H_{15}N$: C, 86.84; H, 6.83; N, 6.33%. M^+: *m/e* 221.

General Procedure for the Reaction of I with II in the Presence of NEt_3. To a vigorously-stirred solution of 0.01 mol of II and 1.0 g (0.01 mol) of NEt_3 in 20 m*l* of dioxane, a solution of 2.2 g (0.01 mol) of I in 30 m*l* of dioxane was added, drop by drop, at room temperature over a period of 30 min. After the reaction mixture had been stirred at the same temperature for 1.5 hr, the triethylammonium chloride was removed by filtration. The filtrate was evaporated *in vacuo* at 40—50°C, leaving an oily substance. The oily substance obtained from the reaction with IIa or IId was triturated with methanol to give the 5*H*,6*H*-6-benzoyl-5-phenyl-1,2-thiazine 1,1-dioxide, IIIa or IIId, as crystals, but the thiazines, IIIb, IIIc, and IIIe, could not be isolated as crystals.

On the other hand, a chloroform solution of III was chromatographed over silica gel to give the epimer V.

The yields, physical properties, results of elemental analyses, and spectral data of III and V are summarized in Tables 1 and 2.

Inversion to V from III with Sodium Methoxide. A suspension of 0.5 g of IIIa in 5 m*l* of methanol was stirred with a few milligrams of metallic sodium at room temperature for 10 min. Subsequent filtration gave 0.49 g (98%) of colorless crystals, which were identical with the epimer, Va, obtained from the treatment of IIIa with silica gel described above. Similarly, IIId was transformed to the epimer Vd in a 97% yield.

A similar reaction of IIIa in deuteriomethanol (CH_3OD) gave the epimer-6-d (Va-d), mp 175°C, as colorless needles in a quantitative yield.

IR: 1673 (νC=O), 1625 (νC=C), 1354, 1158 cm^{-1} (νSO_2). PMR ($CDCl_3$): τ 3.62 (1H, double doublets, >N-C<u>H</u>=, J= 8.2 and 2.1 Hz), 4.49 (1H, double doublets, -C<u>H</u>=C<u>H</u>-N<, J=8.2 and 2.1 Hz), 5.10 (1H, multiplet, Ph-C<u>H</u><). Mass spectrum: M^+ *m/e* 390.

Hydrolysis of Va. A solution of 0.26 g of Va in 5 m*l* of 80% aqueous methanol, with 0.1 g of sodium hydroxide dissolved in it, was refluxed for 30 min. To the mixture was added 100 m*l* of water, and then the mixture was extracted with benzene. The benzene extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo* to give a viscous oil, which crystallized on trituration with petroleum benzine. Recrystallization from petroleum benzine (bp 45—60°C) gave 30 mg (16%) of 5*H*,6*H*-2,5-diphenyl-1,2-thiazine 1,1-dioxide (VI), mp 86—87°C, as colorless plates.

Found: C, 67.26; H, 5.16; N, 4.91%. Calcd for $C_{16}H_{15}O_2NS$: C, 67.36; H, 5.30; N, 4.91%. Mass spectrum: M^+ *m/e* 285.

The water layer was neutralized with concentrated hydrochloric acid to give 20 mg (24%) of benzoic acid.

Oxidation of Va. After a solution of 3.0 g of Va in 30 m*l* of acetic acid had been refluxed with 7.7 g of sodium dichromate dihydrate for 1 hr, the reaction mixture was cooled. To the mixture was added 100 m*l* of water, and then the mixture was extracted with chloroform. The chloroform extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was triturated with 10 m*l* of methanol to afford crystals. Subsequent filtration and recrystallization from a methanol-benzene mixture gave 0.72 g (23%) of perhydro-6-benzoyl-2,5-diphenyl-1,2-thiazin-4-one 1,1-dioxide (VII), mp 239—240°C, as colorless needles.

Found: C, 68.20; H, 4.66; N, 3.76%. Calcd for $C_{23}H_{19}O_4NS$: C, 68.14; H, 4.72; N, 3.46%. IR: 1710 (νC=O), 1672 (νC=O), 1325, 1143 cm^{-1} (νSO_2). Mass spectrum: *m/e* 405(M^+), 341(M^+-SO_2), 324(341^+-OH), 249(341^+-PhNH), 236(341^+-PhCO), 221(249^+-CO), 105($PhCO^+$).

The methanol filtrate was cooled at 0°C to give yellow crystals. Recrystallization from methanol gave 0.3 g (10%) of 6-benzoyl-2,5-diphenyl-1,2-thiazine 1,1-dioxide (VIII), mp 169—170°C, as yellow needles.

Found: C, 70.99; H, 4.27; N, 3.73%. Calcd for $C_{23}H_{17}O_3NS$: C, 71.31; H, 4.42; N, 3.62%. IR: 1640 (νC=O conjugated with C=C), 1340, 1160 cm^{-1} (νSO_2). PMR ($CDCl_3$): τ 3.12 (1H, doublet, olefinic protons). Mass spectrum: *m/e* 387(M^+), 323(M^+-SO_2), 322(323^+-H), 246(323^+-Ph), 230(322^+-PhNH), 217(322^+-PhCO), 105($PhCO^+$).

Perhydro-6-benzoyl-2,5-diphenyl-4-methoxy-1,2-thiazine 1,1-Dioxide (IX). After a suspension of 0.2 g of Va in 10 m*l* of methanol has been stirred with 2 m*l* of concentrated hydrochloric acid at room temperature for 5 hr, the mixture was evaporated *in vacuo* to leave 215 mg of crystals. Recrystallization from methanol gave IX, mp 175°C (decomp.), as colorless needles.

Found: C, 68.51; H, 5.45; N, 3.25%. Calcd for $C_{24}H_{23}O_4NS$: C, 68.40; H, 5.50; N, 3.33%. IR: 1670 (νC=O), 1340, 1148 cm^{-1} (νSO_2). PMR (deuteronitromethane): τ 7.4 (2H, multiplet, >N–C<u>H</u><), 6.49 (3H, singlet, OCH_3), 5.5 (1H, multiplet, Ph–C<u>H</u><), 4.92 (1H, multiplet, MeO–C<u>H</u><), 4.23 (1H, doublet, PhCO–C<u>H</u>–SO_2–, J=11.9 Hz), 1.9—2.9 (15H, multiplet, aromatic protons). Mass spectrum: *m/e* 421 (M^+), 389 (M^+—MeOH), 265 (M^+-SO_2-PhNH), 233 (265^+-MeOH), 147 ($Ph-N^+\equiv C-\dot{C}HOMe$), 115 ($147^+-MeOH$), 105 ($PhCO^+$).

After hydrogen bromide gas was passed through a solution of 0.39 g of Va in 50 m*l* of benzene at room temperature for 5 hr, the benzene was evaporated *in vacuo* to leave a pale red solid. A methanol solution of the solid was refluxed for 5 min to give 0.2 g of IX.

5H,6H-3-Bromo-2,4-diphenyl-1,2-thiazine 1,1-Dioxide (X). To a solution of 0.8 g of Va in 50 m*l* of benzene was added, drop by drop at room temperature, a solution of bromine in benzene until there was no further disappearance of the reddish color of the bromine. The reaction mixture was then evaporated *in vacuo*, leaving an oily substance. A mixture of the oily substance in 20 m*l* of 0.5 N aqueous potassium hydroxide was heated at 70—80°C for 1 hr, after which the mixture was cooled. After 30 m*l* of concentrated hydrochloric acid had then been added to the mixture, the mixture was extracted with benzene. The benzene extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo* to leave a residue. A benzene solution of it was chromatographed over alumina and then eluted using chloroform to give colorless crystals. Recrystallization from petroleum benzine (bp 45—60°C) gave 0.1 g (13%) of X, mp 147°C, as colorless needles.

Found: C, 52.36; H, 3.83; N, 3.82%. Calcd for $C_{16}H_{14}O_2NSBr$: C, 52.76; H, 3.87; N, 3.85%. Mass spectrum: *m/e* 365, 363 (M^+, relative intensity 1 : 1), 301, 299, (M^+-SO_2, relative intensity 1 : 1), 220 (301^+ and 299^+-Br).

Perhydro-6-benzoyl-3-bromo-2,5-diphenyl-4-methoxy-1,2-thiazine 1,1-Dioxide (XI). The oily substance obtained from the bromination of 193 mg of Va according to the above mentioned-method was triturated with 5 m*l* of methanol, thus affording colorless crystals. Recrystallization from methanol gave 0.2 g (81%) of XI, mp 170—171°C (decomp.), as colorless needles.

Found: C, 57.36; H, 4.60; N, 2.74%. Calcd for $C_{24}H_{22}O_4NSBr$: C, 57.65; H, 4.44; N, 2.80%. Mass spectrum: *m/e* 501, 499 (M^+, relative intensity 1 : 1), 369, 467 (M^+—MeOH, relative intensity 1 : 1), 420 (M^+-Br), 388 (420^+—MeOH), 356 (420^+-SO_2), 227, 225 (relative intensity 1 : 1).

Chemically Induced Dynamic Nuclear Polarization in the Photochemical Reaction of Phenanthraquinone with Hydrogen Donors. I. Kinetics of Nuclear Spin Polarization[1]

Kazuhiro MARUYAMA, Heisaburo SHINDO,* Tetsuo OTSUKI, and Tetsuo MARUYAMA*

Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Kyoto
**JEOL(USA) Inc., 235 Birchwood Avenue, Cranford, N.J. 07016, USA*

(Received February 23, 1971)

Strongly-enhanced NMR signals were observed in the photo-induced hydrogen abstraction reaction of phenanthraquinone with several hydrogen donors in benzene. Chemically-induced dynamic nuclear polarization was kinetically treated in the photochemical reaction during the course of irradiation by visible light and shut-off. It was found that the relaxation time of the nuclear-spin system under the irradiation is shorter by a factor of 2 to 4 than that in the black-out stage and that the enhancement factor for the methine proton of the 1,2-adduct of phenanthraquinone was evaluated as 1000—2000.

Of the products of the rapid radical reaction, their proton NMR spectra are often observed as an enhanced absorption and/or emission line during the course of the reaction.[2-11] This phenomenon is called "chemically-induced dynamic nuclear polarization (CIDNP)"[3]

Since the discovery of this phenomenon by Fischer and Bargon,[2,3] many kinds of radical reactions have been investigated by several workers from the standpoint of CIDNP.[4-9] Thus, Closs and his co-workers[10] and Kaptein and Oosterhoff[11] recently proposed a model of a radical pair as an intermediate of the reaction, and showed that the CIDNP phenomenon originates from the mixing between the electronic singlet and triplet states of the radical pair. Their theory (CKO theory)[10,11] seems to have been accepted as the explanation of CIDNP phenomenon.

CIDNP is dynamic in its nature; nevertheless, no phenomenological treatments have been made from the point of view of kinetics. For simplicity, we preferred the photo-induced chemical reaction to any other type of radical reaction, that is, the hydrogen abstraction reactions of phenanthraquinone with fluorene, xanthene, diphenylmethane, and 9,10-dihydroanthracene in benzene. In these reactions, the 1,2-type adduct[12] of phenanthraquinone with hydrogen donors mentioned above is known to be mainly produced.[13]

The NMR singlet spectrum of the methine proton of the adduct of each of hydrogen donors revealed a strongly-enhanced absorption; the nuclear-spin polarization of this methine proton will be kinetically discussed.

Experimental

Materials. Phenanthraquinone was prepared by oxidation of phenanthrene with pottassium dichromate and was repeatedly purified by the recrystallization method from its acetic acid solution. It has a mp of 202—206°C and λ_{max} =410—420 mμ in the UV spectrum. Commercially-available guaranteed-grade reagents, used as hydrogen donors to phenanthraquinone, were used without further purification. A benzene solution of 2.3×10^{-2} M of phenanthraquinone and 1.0M of the hydrogen donor was sufficiently degassed in vacuum and submitted to NMR measurements.

Apparatus. The NMR spectra were observed at 60 MHz by the use of a spectrometer of the C-60HL type (JEOL Co. Ltd.). A saw-tooth wave generator (JEOL. Co. Ltd.) was used to measure the variation in the spectrum intensity with the time.

In order to induce a photochemical reaction within the NMR probe, we modified the probe for introducing UV or visible light as follows. The light source (Ushio high-pressure Hg lamp, 500W) is placed above the magnet. The focused light from the source is guided into the probe through a hole, reflects once on the aluminum mirror attached within the probe, and then arrives at the sample. In order to be used effectively, the light is forced to pass to the sample again by means of a concave aluminum mirror.

Theory

Phenanthraquinone (PQ) I in benzene is photochemically excited to a triplet state, II, with a fairly long lifetime, τ; II returns to a singlet ground state with the emission of fluorescence.[14]

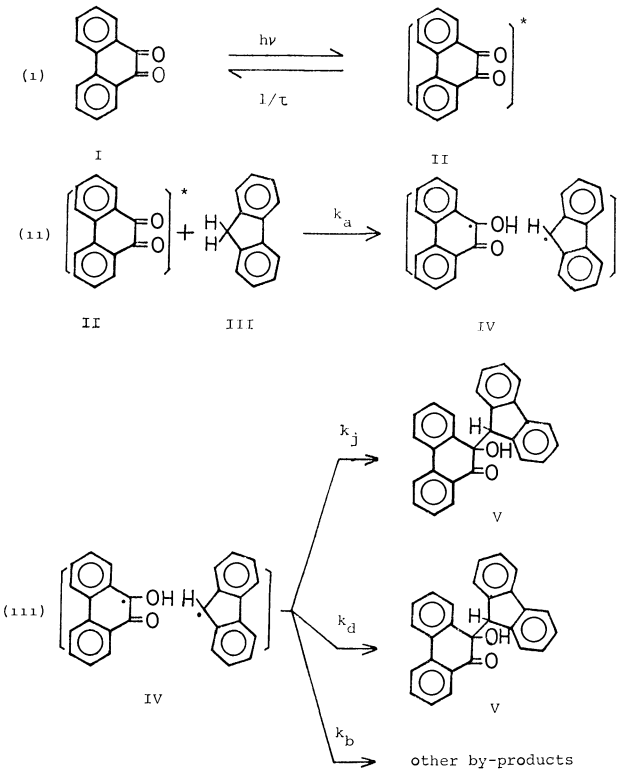
12) See structure V.
13) These reactions are, in general, very clean, and almost all of the products are 1,2-type adducts. The details of the structure of the photo-adduct will be reported in the near future.
14) Although PQ is activated to an excited singlet state at first through $n\rightarrow\pi^*$ excitation, the molecule is transformed to a triplet state by inter-system crossing.

When a hydrogen donor (III), for instance, fluorene, is present, hydrogen abstraction reaction easily proceeds with a specific rate constant of k_a, simultaneously, a radical pair, IV, may be formed, as was assumed in CKO theory.[10,11]



The radical pair, IV, was assumed to yield the products through three processes. One is the process producing the 1,2-adduct V directly from the radical pair. The specific rate constant of this process, k_j, is assumed to depend on the nuclear spin state of the 1,2-adduct, in accordance with the CKO theory. Thus, the nuclear-spin polarization occurring in the adduct is produced only through this process. The second process, occurring with a rate constant of k_d is related to the separation and recombination of the radical pair to give the 1,2-adduct. However, the nuclear-spin polarization of the adduct generated through this process is considered to be less important in our system.[15]

The last process of the three is assumed to be associated with the process giving other by-products.

For convenience, we may rewrite the reaction processes, (i), (ii), and (iii), as follows:

$$X \underset{1/\tau}{\overset{k_0}{\rightleftharpoons}} X^* \xrightarrow{k_a} Y \begin{cases} \xrightarrow{k_j} Z_j^* \\ \xrightarrow{k_d} Z_j' \\ \xrightarrow{k_b} \text{by-products} \end{cases}$$

Also, the nuclear-spin system polarized through the reaction process mentioned above will, with the relaxation time, T_1, approach the thermal equilibrium;

$$Z_j \underset{1/2T_1(k,j)}{\overset{1/2T_1(j,k)}{\rightleftharpoons}} Z_k$$

where the two suffixes, j and k, represent, respectively, jth and kth nuclear spin state of the 1,2-adduct, and where $T_1(j,k)$ is the relaxation time between jth and kth nuclear-spin states. The population of the jth nuclear spin state of the 1,2-adduct, $[Z_j^*]+[Z_j']$, is denoted by $[Z_j]$.

In the case of a sufficiently concentrated solution of PQ, the increase in the rate of X*, k_0, may be considered to be independent of the concentration of PQ, [X]. It depends only on the intensity of the light used; that is, this reaction process is of the zeroth order. The reaction process from X* to Y may be regarded as quasi-first order because of the large excess of the hydrogen donor compared with that of PQ. The other processes are first order in their natures. Thus, we may write the rate of chemical change during the course of the light irradiation as follows;

$$\frac{d[X^*]}{dt} = k_0 - (1/\tau + k_a)[X^*] \tag{1}$$

$$\frac{d[Y]}{dt} = k_a[X^*] - \sum_j (k_j + k_d + k_b)[Y] \tag{2}$$

$$\frac{d[Z_j]}{dt} = (k_d + k_j)[Y] - \sum_k 1/2T_1^*(j,k) \times (\langle [Z_j]-[Z_k]\rangle - \langle [Z_j]-[Z_k]\rangle_0) \tag{3}$$

where $\langle [Z_j]-[Z_k]\rangle_0$ is the difference in populations between the jth and kth energy levels in the thermal euilibrium; the use of T_1^* in place of T_1 indicates the relaxation time during irradiation.

As the signal of photo-adduct in the thermal equilibrium can not be observed even after the chemical change proceeded, the term $\langle [Z_j]-[Z_k]\rangle_0$ may be ignored in Eq. (3). In general, a solution of Eq. (3) can not be analytically obtained, so we will deal with the case of the single spin system alone. In such a case, we can replace Eq. (3) by;

$$\frac{d[Z_1]}{dt} = (k_d + k_1)[Y] - 1/2T_1^*\langle [Z_1]-[Z_2]\rangle \tag{4}$$

$$\frac{d[Z_2]}{dt} = (k_d + k_2)[Y] - 1/2T_1^*\langle [Z_1]-[Z_2]\rangle \tag{5}$$

From Eqs. (4) and (5), we obtain;

$$\frac{d\langle [Z_1]+[Z_2]\rangle}{dt} = \sum_{j=1}^{2} (k_j + k_d)[Y] \tag{6}$$

$$\frac{d\langle [Z_1]-[Z_2]\rangle}{dt} = (k_1 - k_2)[Y] - 1/T_1^*\langle [Z_1]-[Z_2]\rangle \tag{7}$$

On integrating Eqs. (1) and (2), and considering that X* and Y are zero when t is zero, the concentrations of PQ* and the radical pair are given by;

$$[X^*] = \frac{k_0}{1/\tau + k_a}(1 - e^{-t/\tau - k_a t}) \tag{8}$$

$$[Y] = \frac{k_0 k_a}{1/\tau + k_a}\left\{ \frac{1}{\sum(k_j + k_d + k_b)}(1 - e^{-\sum(k_j+k_d+k_b)t}) - \frac{1}{\sum(k_j + k_d + k_b) - 1/\tau - k_a}(e^{-t/\tau - k_a t} - e^{-\sum(k_j+k_d+k_b)t}) \right\} \tag{9}$$

15) This can be concluded from the following two experimental observations: i) the rate of hydrogen abstraction by phenanthraquinone and the successive recombination of radicals formed are usually too fast for intermediate radicals to be observed by the ESR technique, and ii) the fact described in footnote 13).

Since it is reasonable that $\sum(k_j+k_d+k_b) \gg 1/\tau+k_a$ and $1/T_1^*$, the solutions of Eqs. (6) and (7) can be approximated by;

$$\langle[Z_1]+[Z_2]\rangle = \frac{k_0k_d(k_j+k_d)}{(1/\tau+k_a)\sum(k_j+k_d+k_b)} \times \left(t+\frac{1}{1/\tau+k_a}e^{-t/\tau-k_at}\right) \quad (10)$$

$$\langle[Z_1]-[Z_2]\rangle = \frac{k_0k_a(k_1-k_2)T_1^*}{(1/\tau+k_a)\sum(k_j+k_d+k_b)}\left\{(1-e^{-t/T_1^*}) - \frac{1/T_1^*}{1/T_1^*-1/\tau-k_a}(e^{-t/\tau-k_at}-e^{-t/T_1^*})\right\} \quad (11)$$

by using Eq. (9).

Next, let us consider the case when the irradiation is shut off at a certain time, $t=t_0$, after the establishment of a steady-state nuclear polarization. The rate of the chemical reaction (1) is replaced by;

$$\frac{d[X^*]}{dt} = -(1/\tau+k_a)[X^*] \quad (12)$$

On integrating Eqs. (2), (9), and (12) under appropriate initial conditions,[16] the expression of $\langle[Z_1]-[Z_2]\rangle$ is given by Eq. (13);

$$\langle[Z_1]-[Z_2]\rangle = \frac{k_0k_a(k_1-k_2)T_1}{(1/\tau+k_a)\sum(k_j+k_d+k_b)} \times \left\{\frac{1/T_1}{1/T_1-1/\tau-k_a}e^{-(1/\tau+k_a)(t-t_0)} - \frac{1/\tau+k_a}{1/T_1-1/\tau-k_a}e^{-(t-t_0)/T_1}\right\} \quad (13)$$

after being approximated in the same manner as was done in Eqs. (10) and (11). The relaxation time under the off-irradiation is denoted by T_1 in order to distinguish it from the relaxation time under the irradiation, T_1^*.

If $1/T_1^*$ and $1/T_1 \ll 1/\tau+k_a$, the signal intensity in the irradiating stage increases in accordance with the following expression;

$$\langle[Z_1]-[Z_2]\rangle = \frac{k_0k_a(k_1-k_2)T_1^*}{(1/\tau+k_a)(k_1+k_2+2k_d+2k_b)}(1-e^{-t/T_1^*}) \quad (14)$$

as may be found from Eq. (11). On the other hand, the signal after blacking-out is diminished exponentially as follows;

$$\langle[Z_1]-[Z_2]\rangle = \frac{k_0k_a(k_1-k_2)T_1}{(1/\tau+k_a)(k_1+k_2+2k_d+2k_b)}e^{-(t-t_0)/T_1} \quad (15)$$

as may be seen from Eq. (13). We obtain the envelope curve depicted by signal peaks during the irradiation and black-out.

The enhancement factor is defined by;

$$P = \frac{\langle I\rangle-\langle I\rangle_0}{\langle I\rangle_0} \simeq \frac{\langle I\rangle}{\langle I\rangle_0} = \frac{\langle[Z_1]-[Z_2]\rangle}{\langle[Z_1]-[Z_2]\rangle_0} \quad (16)$$

16) The initial conditions, that is, the concentrations of X,* Y, and $\langle[Z_1]-[Z_2]\rangle$ at $t=t_0$ may be given by the respective values at $t=\infty$ in Eqs. (8), (9), and (11); $[X^*]=k_0/(1/\tau+k_a)$, $[Y]=k_0k_a/(1/\tau+k_a)\times\sum(k_j+k_d+k_b)$ and $\langle[Z_1]-[Z_2]\rangle = k_0k_a \times T_1^*/(1/\tau+k_a)\sum(k_j+k_d+k_b)$ were used.

where $\langle I\rangle_0$ is the expectation value of the spin-angular momentum in the thermal equilibrium. The value of $\langle[Z_1]-[Z_2]\rangle_0$ can be obtained from the value of $\langle[Z_1]+[Z_2]\rangle$ on the basis of Boltzmann's law. Thus, the enhancement factor at a certain time in a steady-state can easily be found from Eqs. (10) and (11);

$$P = \frac{(k_1-k_2)T_1^*}{(k_1+k_2+2k_d+2k_b)t}\cdot\frac{2kT}{\Delta E} \quad (17)$$

where ΔE is the energy difference between the two energy levels of the spin system; k, Boltzmann constant, and T, the absolute temperature.

Results

Phenanthraquinone (PQ) is photochemically induced to yield its 1,2-adducts in the presence of hydrogen donors. For example, when a solution of 2.3×10^{-2}M of PQ and 1.0M of fluorene in benzene was irradiated inside the probe, an enhanced singlet line of the methine proton of the 1,2-adduct was observed at a field lower by about 45 Hz from the chemical shift of the methylene protons of fluorene. This is shown for fluorene and xanthene in Fig. 1. That such an absorption line is strongly enhanced is shown by its collapse after the irradiation was shut off.

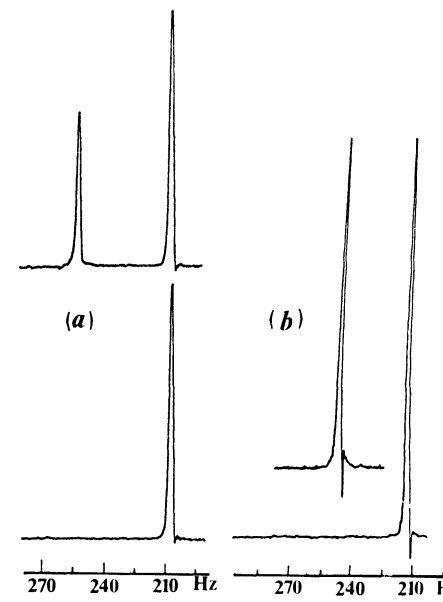


Fig. 1. Enhanced and normal NMR spectra in the photochemical reaction of phenanthraquinone (2.3×10^{-2}M) with hydrogen donor (1.0M) in benzene.

The envelope curves of the singlet lines in Figs. 2 and 3 were obtained at 70°C by field scanning repeated with a saw-tooth wave of 1 Hz for both fluorene and xanthene. Figures 4—6 show the envelope curves for the adducts of fluorene, xanthene, diphenylmethane, and 9,10-dihydroanthracene at 30° and 50°C. As can be seen from these figures, the signal intensity increases exponentially just after the application of light and then establishes its steady-state. When the irradiation is shut off at a certain time, $t=t_0$, signal is diminished exponentially. The values of the loga-

rithms of the signal intensities, $I_\infty - I_t$ and I_{t-t_0}, are plotted against the time (see Fig. 7). Here, I_∞ and I_t represent the signal intensities at the steady-state and at a certain time, t. As may be seen in Fig. 7, the fact that these plots fall on a straight line indicates an exponentially time-dependent nature of the signal intensity. Thus, it may be found that the relaxation times, T_1^* and T_1, in Eqs. (14) and (15) can be determined from the slopes of straight lines in Fig. 7. The values of T_1^* and T_1 are given in Table 1.

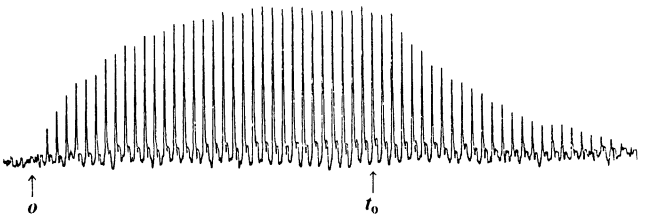

Fig. 2. Envelope curve of enhanced signals due to the methine proton of the adduct of fluorene (field-scanning with saw-tooth wave of 1 Hz, 70°C). Arrows in figure indicate a starting point of the irradiation, $t=0$ and a point of the black-out $t=t_o$.

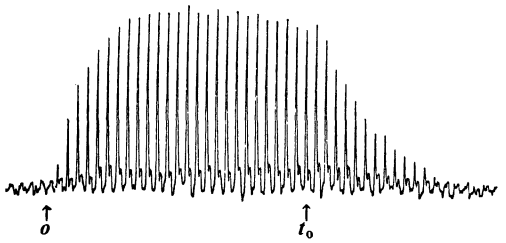

Fig. 3. Envelope curve of enhanced signals due to the methine proton of the adduct of xanthene at 70°C.

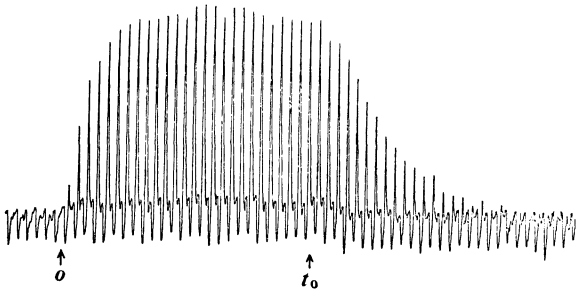

Fig. 4. Envelope curve of enhanced signals due to the methine proton of the adduct of fluorene at 50°C.

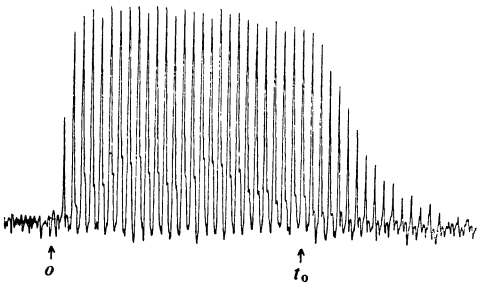

Fig. 5. Envelope curve of enhanced signals due to the methine proton of the adduct of xanthene at 50°C.

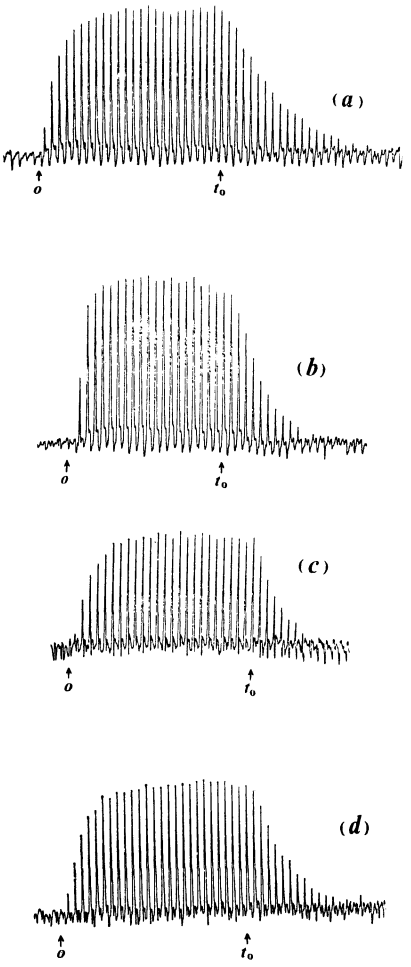

Fig. 6. Envelope curves of enhanced signals due to the methine proton of the adducts of fluorene (a) and xanthene (b) at 30°C, and those of diphenylmethane (c) and 9,10-dihydroanthracene (d) at 50°C.

TABLE 1. RELAXATION TIMES T_1^* AND T_1 EVALUATED FROM THE ENVELOPE CURVES OF THE ENHANCED SIGNALS

Hydrogen donors	Temperature(°C)	T^*_1 (sec)	T_1 (sec)	Signal intensity[a)]
Fluorene	30	2.1	6.8	
	50	2.6	7.0	2.0
	70	6.6	9.4	
Xanthene	30	1.0	3.6	
	50	0.9	4.3	2.3
	70	3.0	4.6	
Diphenylmethane	50	2.3	3.2	1.8
9,10-Dihydroanthracene	50	2.6	4.4	3.9

a) See the text.

Now, we are interested in the relative values of $\langle[Z_1]-[Z_2]\rangle$, which are proportional to the signal intensity. The intensity ratios of the enhanced signal to the intensity per proton of a methylene group of a given hydrogen donor (concentration; 1.0M) in a benzene solution were evaluated as shown in the last column in Table 1.

Discussion

The envelope curves of enhanced signals are shown in Figs. 2 to 6; the figures represent the typical nature of these photochemical reactions. Contrary to the usual conception of photochemical reactions, in the photo-induced CIDNP examined here the rate constants of nuclear polarization after the irradiation and black-out differed by a factor of about 2 to 4 (see Table 1). It was mentioned in the previous section that the rate constants for nuclear-spin polarization are controlled by the relaxation times of the nuclear-spin system.

For fluorene at 50°C, the relaxation time during the irradiation is 2.6 sec and that under the black-out is 7.0 sec. It is found that the value of T_1^* is generally smaller than that of T_1 and that the ratio of T_1^*/T_1 approaches a unit value with an increase in the temperature. These facts may be responsible for the presence of paramagnetic species during the irradiation, whose concentration must decrease with an increase in the temperature. This is because the relaxation time is inversely proportional to the concentration of paramagnetic species.[17] The steady-state concentration of PQ* is given by (see Eq. (4));

$$[X^*] = \frac{k_0}{1/\tau + k_a}$$

Since the specific rate, k_a, can be considered to increase with an increase in the temperature in the temperature range of 30° to 70°C, the steady-state concentration of PQ* decreases with an increase in the temperature, as may be seen from the last equation. On the other hand, the value of T_1 may well give the usual relaxation time because of the rapid collapse of PQ* just after blacking-out. The facts that the T_1^*/T_1 ratio is smaller than the unit value and that it increases with an increase in the temperature can reasonably be explained in terms of the presence of activated phenanthraquinone PQ* during the irradiation of light.

The enhancement factor, P, is defined as the expression (16); hence, it is experimentally determined from the ratio of the intensity of the enhanced signal to that of the standard solution as follows;

$$P = \frac{[Z]_s}{[Z]_p} \times \frac{I_p}{I_s} \tag{18}$$

where $[Z]_p$ and $[Z]_s$ are the concentration of the proton associated with the enhanced signal and that of the standard methylene protons of hydrogen donors respectively. I_p and I_s represent the signal intensity of the enhanced and that of the standard protons.

In our case, the increase in the rate of the adduct, $[Z]_p=[Z_1]+[Z_2]$, is given by Eq. (10). Since phenanthraquinone exclusively yields 1,2-adducts, $2k_b$ can be neglected compared with $(k_1+k_2+2k_d)$. Thus, one obtains the following expression for the increase in the rate of the 1,2-adduct in the steady-state polarization;

$$[Z]_p = k_0 t$$

The light was very difficult to apply uniformly over the whole of the sample; hence, the exact value of k_0 could not be determined. However, it may be roughly evaluated as below. When the irradiation was kept on continuously, the steady-state polarization was found to be suddenly broken at a certain time, t_b, which was about 100 sec or more at 50°C in all of our experiments. This is the time where the zeroth-order approximation can not hold any longer for the reaction process from X to X*; thus, the concentration of phenanthraquinone at t_b is found to be rather small. Thus, the ratio of the initial concentration of phenanthraquinone to the time, $[X]_0/t_b$, may be taken as the value of k_0. Remembering that $[X]_0=2.3\times10^{-2}$M, we find that $k_0 \gtrsim 2\times10^{-4}$ mol/l/sec.

The value of I_p/I_s is in the range of 2 to 4 (see Table 1). Since $[Z]_s$ is 1.0M, we find that the enhancement factor, P, should amount to the value of 1000—2000 at $t=10$ sec just after the irradiation.

The authors wish to thank Mr. Shozo Shimizu (JEOL (USA), Inc.) for his helpful suggestions for modifying the NMR probe for photochemical reactions.

Chemical Constituents of *Alnus sieboldiana* (BETULACEAE)[1] II. The Isolation and Structure of Flavonoids and Stilbenes

Yoshinori ASAKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received March 18, 1971)

Four new flavonoids with an unsubstituted B-ring, alnusin, alnetin, alnustin, and alnustinol, isolated from *Alnus sieboldiana* were established to be 3,5,7-trihydroxy-6-methoxyflavone (**1**), 5-hydroxy-6,7,8-trimethoxyflavone (**2**), 5-hydroxy-3,6,7-trimethoxyflavone (**3**), and 3,5,7-trihydroxy-6-methoxyflavanone (**15**) respectively. Some previously-known flavonoids, chrysin (**4**), izalpinin (**5**), tectochrysin (**6**), pinocembrin (**16**), pinobanksin (**17**), strobopinin (**19**) and naringenin (**20**), and some stilbenes, pinosylvin (**24**), pinosylvin monomethyl ether (**25**), and pinosylvin dimethyl ether (**26**), were identified along with the above new flavonoids.

In previous papers,[2] we have reported the isolation and the structure of two new hydroxyketones, *trans*-stilbene (**23**), pinostrobin (**18**), alpinetin (**21**), β-phenylethyl cinnamate, and cinnamic acid from the benzene extract of the male flower of *Alnus sieboldiana*. In the course of continuing the investigation on the viscous substance of the male flower, we further isolated four new flavonoids,[3] accompanied by some previously-known flavonoids and stilbenes. We now wish to report on the structural elucidation, and to present our supposition as to the biosynthetic pathway, of these compounds.

Results and Discussion

The isolation of flavonoids and stilbenes was performed by utilizing their solubility difference in ether and methanol, followed by a combination of column- and preparative thin-layer chromatography on silica gel.

Fig. 1

Alnusin (1). Alnusin, the main flavonoid of the plant, was crystallized as yellow plates, mp 239—241°C. Its elemental analysis and the mass spectrum indicated the formula $C_{16}H_{12}O_6$. The compound was shown to be a flavone by alcoholic ferric chloride and magnesium hydrochloric acid tests. The IR spectrum indicated the presence of an α,β-unsaturated carbonyl group (1640 cm^{-1}). The presence of hydroxyl groups were confirmed by the infrared absorption bands at 3350 and 3300 cm^{-1} and by the NMR signal of two singlets at 9.25 and 12.23 ppm. The signal in the far-down field showed the presence of a hydroxyl group which is hydrogen-bonded to the carbonyl group. The acetylation of **1** with acetic anhydride gave the triacetate (**7**), confirming the presence of three hydroxyl groups. The absence of *o*-dihydroxyl groups was indicated by the lack of any appreciable change in the UV spectrum of alnusin on the addition of boric acid-sodium acetate.[4] On the other hand, the presence of the C_7–OH group was suggested by the bathochromic shift on the addition of sodium acetate to the alcoholic solution of **1**.[4] The presence of C_5–OH group was shown by the bathochromic shift in the UV spectrum on the addition of aluminum chloride[4] and by the NMR spectrum of the triacetate, which showed the characteristic resonance of C_5–OAc as a singlet at 2.48 ppm, unlike those of other flavone acetyl groups.[5] The presence of a monosubstituted benzene-ring was shown by the infrared absorption bands at 762 and 680 cm^{-1} and by the A_2B_3 signals of the NMR spectrum at 7.60 and 8.20 ppm. The NMR spectrum of **1** showed a signal for one methoxy proton at 3.89 ppm. The position of the methoxy group was confirmed to be C_6 by the intense quinoid cation (M-15, *m/e* 285) of the mass spectrum, which is characteristic of flavones with the C_6–OMe group.[6] The one-proton singlet at 6.88 ppm was assinged to either the C_3- or the C_8-proton. The treatment of **1** with diazomethane gave trimethylether (**8**), while methylation with dimethyl sulfate resulted in 3,5,6,7-tetramethoxyflavone (**9**).[7] The oxygenation pattern was established by the alkaline degradation of **9** which gave 2-hydroxy-ω-4,5,6-

1) The plant name "*Alnus firma* Sieb. et Zucc." has been given in our previous papers.[2] However, we now wish to correct it to "*Alnus sieboldiana*," due to the identification of *Alnus* species by Professor Hyoji Suzuki of Hiroshima University.

tetramethoxyacetophenone (**12**) and benzoic acid (**14**). Thus, the structure of alnusin is undoubtedly 3,5,7-trihydroxy-6-methoxyflavone. The NMR solvent shift data[8] obtained on changing the solvent from deuteriochloroform to benzene for alnusin triethylether (**10**) offered further support for the structure of alnusin.

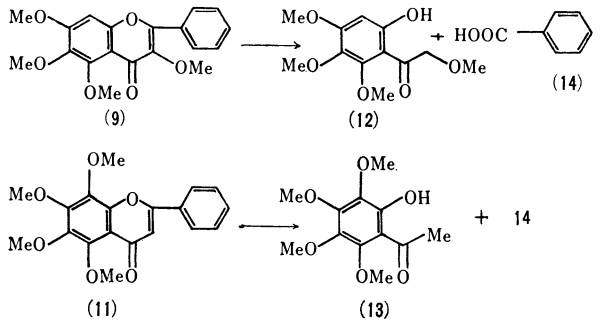

Fig 2.

Alnetin (2). Alnetin was obtained as pale yellow needles (mp 100—101°C). The elemental and mass spectral analyses supported the molecular formula of $C_{18}H_{16}O_6$ (M^+ 328). It showed a positive coloration with ferric chloride. The IR spectrum showed the presence of a hydroxyl group, an α,β-unsaturated carbonyl group, and a monosubstituted benzene-ring. The considerable bathochromic shift of the UV spectrum upon the addition of aluminum chloride to the alcoholic solution of **2** suggested the presence of the C_5–OH group, which was also supported by the NMR signal at 12.45 ppm (s, 1H). The absence of the C_7–OH and *o*-dihydroxyl groups was based on the lack of any appreciable change in the UV spectrum upon the addition of sodium acetate or boric acid-sodium acetate. The NMR spectrum indicated the presence of three methoxy groups (3.95, 3.97, 4.10 ppm, each s, 9H), one aromatic proton (6.69 ppm, s, 1H), monosubstituted benzene-ring protons (7.56, 7.95 ppm, m, 5H), and a chelated hydroxyl group (12.45 ppm, s, 1H). The methylation of **2** with dimethyl sulfate afforded a tetramethoxy derivative (**11**) which was identical with the 5,6,7,8-tetramethoxyflavone reported by Lee *et al.*[9] The hydrolysis of the tetramethoxy derivative (**11**) with aluminum chloride in ether gave the original compound. The treatment of **11** with a 50% potassium hydroxide solution gave 2-hydroxy-3,4,5,6-tetramethoxyacetophenone (**13**) and benzoic acid (**14**). Alnetin has thus been assinged the (**2**) structure. This compound has never been isolated from any natural source; it has been reported only as a synthetic product.[9]

Alnustin (3). Alnustin, $C_{18}H_{16}O_6$, mp 175—176°C, M^+ 328, was obtained as yellow plates. The compound showed a positive coloration with ferric chloride, and all of its spectra were typical of flavoniods. The IR spectum showed the presence of an α,β-unsaturated carbonyl group and a monosubstituted benzene-ring. The UV spectrum, upon the addition of sodium acetate, boric acid-sodium acetate, or aluminum chloride, showed that **3** contained no *o*-dihydroxyl groups and no C_7–OH, but it did contain the free C_5–OH group. The presence of the C_5–OH group was also indicated by the far-down signal at 12.58 ppm (s, 1H) in the NMR spectrum. The other signals in the spectrum were assigned to monosubstituted benzene-ring protons (7.56, 8.10 ppm, m, 5H), three methoxy groups (3.89, 3.94, 3.97 ppm, each s, 9H), and C_8–H (6.54 ppm, s, 1H). On methylation with dimethyl sulfate, Compound (**3**) gave a tetramethoxy derivative (**9**) which was identical with 3,5,6,7-tetramethoxyflavone. The demethylation of **9** with aluminum chloride in ether gave the original compound. Thus, the structure of alnustin was established as 5-hydroxy-3,6,7-trimethoxyflavone.

Fig 3.

Alnustinol (15).[10] Alnustinol was isolated in a minute quantity as colorless needles, mp 175—176°C, M^+ 302. The compound gave the characteristic coloration of flavanonols with ferric chloride, magnesium hydrochloric acid, and zinc hydrochloric acid and in Pachcós tests. The IR spectrum indicated the presence of hydroxyl groups, an α,β-unsaturated carbonyl group, and a monosubstituted benzene-ring. The lack of the bathochromic shift in the UV spectrum, on the addition of boric acid-sodium acetate, showed the absence of *o*-dihydroxy groups. On the other hand, the considerable bathochromic shift on the addition of aluminum chloride or sodium acetate indicated the presence of the C_7–OH and C_5–OH groups. The latter hydroxyl group was also confirmed by the NMR signal at 11.34 ppm (s, 1H). The NMR spectrum exhibited the signals at 3.86 ppm (s, 3H) assignable to a methoxy group, at 4.40 ppm and 4.97 ppm (typical AB doublet, J=12 Hz, 2H) assignable to the flavanonol structure, and at 5.99 ppm (s, 1H) to C_8–H, and at 7.33 ppm (s, 5H) assignable to monosubstituted benzene-ring protons. The presence of the C_3–OH group was supported by the fragment ions at *m/e* 273 (M–CHO) and 91 (120–CHO) which are characteristic of 3-hydroxyflavanone.[11] Chemical evidence in favor

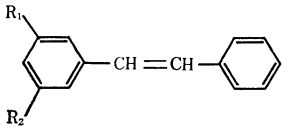
10) In the previous paper,[3] the structure of alnustinol has been given as 3,5,8-trihydroxy-7-methoxyflavanone. The author now wishes to correct it to 3,5,7-trihydroxy-6-methoxyflavanone from the results of the reexamination of the solvent shift in the UV spectrum and the chemical reactions.

11) H. Audier, *Bull. Soc. Chim. Fr.*, **1966**, 2892.

of the C_5–OH and C_3–OH groups in alnustinol was obtained by its reaction with diazomethane,[12] which gave only a monomethylated compound (**22**). Hence, the structure of 15 may be said to be 3,5,7-trihydroxy-6-methoxy- or 3,5,7-trihydroxy-8-methoxyflavanone. The dehydrogenation of **15** with palladium charcoal gave a flavonol which was shown to be identical with 3,5,7-trihydroxy-6-methoxyflavone (**1**). On the basis of the above chemical and spectral evidence, alnustinol was established to be 3,5,7-trihydroxy-6-methoxyflavanone (**15**). 3,5,6,7-Tetrasubstituted- and fully oxygenated A-ring flavonoids with an unsubstituted B-ring are rare in nature.

The Known Flavonoids and Stilbenes. Nine flavonoids, chrysin (**4**), izalpinin (**5**), tectochrysin (**6**), pinocembrin (**16**), pinobanksin (**17**), pinostrobin (**18**), strobopinin (**19**), naringenin (**20**), and alpinetin (**21**), were identified by the comparison of their physical and chemical properties with those of authentic samples



trans-Stilbene (23) $R_1=R_2=H$
Pinosylvin (24) $R_1=R_2=OH$
Pinosylvin monomethyl ether (25) $R_1=OH$ $R_2=OMe$
Pinosylvin dimethyl ether (26) $R_1=R_2=OMe$

Fig 4.

or with those reported previously. Also, three stilbenes, pinosylvin (**24**), pinosylvin monomethyl ether (**25**), and pinosylvin dimethyl ether (**26**), were confirmed by the same methods as above. In the mass spectrum of *trans*-stilbene (**23**), the loss of the methyl radical (M-15) from the molecular ion is observed; this fragmentation process has shown, by the deuterium labelling, that one of the central CH groups, together with an ortho-hydrogen atom from either ring, is eliminated.[13] Similar losses of a methyl radical are also observed in pinosylvin, pinosylvin monomethyl ether, and pinosylvin dimethyl ether. Except for the M-15 ion, all these stilbenes involve the strong fragment ion at *m/e* 165 which was determined to be $C_{13}H_9^+$ by high-resolution mass measurements. Thus, stilbenes isolated from natural source can be detected by the mass spectrum with characteristic fragment ions at *m/e* M-15, and *m/e* 165 ($C_{13}H_9^+$), and the molecular ion appears as a base peak. It is known that the stilbenes of the genus Pinus serve as chemotaxonomic tracers in the *Pinaceae*[14] and that pinosylvin and its monomethyl ether have biological activity and protect the heartwood from wood-rotting fungi and insects.[15] Stilbenes have been found in *Pinaceae*, *Moraceae*, *Saxifragaceae*, *Myrtaceae*, *Polygonaceae*, *Fagaceae*, *Liguminosae*, and *Liliaceae* as free and/or glycoside forms.[16] Hence, it is notable that this paper is reporting the first example of the isolation of the stilbenes (**23**, **24**, **25**, and **26**) from the *Betulaceae*.

Biogenesis. Flavonoids and stilbenes have been found to occur together in the heartwood of various pines,[14] *Morus bomycis*,[17] and *Eucalyptus* species.[18] Apparently, the co-existence of these compounds has never been found in *Betulaceae*. The coexistence of the flavonoids and stilbenes in the same plant and the analogy of the structure of the isolated compounds provide important clues for the elucidation of their biogenesis. Almost all the compounds isolated from *A. sieboldiana* possessed a monosubstisuted benzene-ring in the molecule; only naringenin (**20**) did not. The male flower of this plant contained a large quantity of free cinnamic acid. Accordingly, the above monosubstituted benzene-ring must arise from cinnamic acid. The route of synthesizing pinosylvin (**24**) has recently been established by the isolation of the enzyme, which catalyzes the cyclization of cinnamoyl triacetic acid to pinosylvin (**24**), from *Eucalyptus sideroxylon* leaves,[18] while the formation of various flavonoids from chalkone has been confirmed by means of a parallel competetive feeding experiment.[19]

The flavonoids and stilbenes isolated from *A. sieboldiana* may be formed by a combination of the shikimic acid and acetate (polyketide) pathways. We would like to propose the biosynthetic pathway of the flavonoids and stilbenes shown in Scheme 1.

Experimental

All the melting points are uncorrected. Analytical and preparative tlc were carried out using silica gel GF_{254} and $HF_{254+366}$ (Merck) using a solvent composed of benzene, dioxane, and acetic acid (90:25:4 vol%). The spot was detected by using the UV light (254 and 366 nm) and/or iodine vapor. The mass spectra were recorded on a Hitachi-RMU 6D Mass spectrometer under the following conditions: chamber volt, 70 V; vacuum, 3.0×10^7 mmHg; ion chamber temp., 250°C; direct sample-introduction system. The high-resolution mass spectra were measured on a MS 902 double-focusing instrument. The UV, IR, and NMR spectra were measured by the methods reported in a preceding paper.[2c]

Extraction and Isolation. The *Alnus sieboldiana* was collected near Hiroshima City in March, 1969. The male flower (95 kg) was extracted with benzene for three months. The benzene extract (780 g) was successively extracted with a 5% aqueous sodium bicarbonate solution (Fraction 1), a 5% aqueous sodium carbonate solution (Fraction 2), and a 5% sodium hydroxide solution (Fraction 3).

Alnustinol (15). The neutralization of Fraction 1 with dilute hydrochloric acid and extraction with ether yielded a brown slurry (8 g). It was triturated with ether to give alnustinol (**15**). The crystallization of **15** from *n*-hexane gave colorless needles (58 mg); mp 175—176°C; $FeCl_3$ (dark

green), Mg-HCl (yellow), Zn-HCl (yellow), Pachcós test (reddish brown); UV spectrum λ_{max}^{EtOH} 215 nm (log ε, 4.58), 226_{sh} (4.48), 295 (4.32), 340 (3.65), $\lambda_{max}^{EtOH+AlCl_3}$ 226 (4.36), 318 (4.48), 400 (3.55), $\nu_{max}^{EtOH+NaOAc}$ 216 (4.34), 300 (4.14), 335 (4.41), $\lambda_{max}^{EtOH+NaOEt}$ 215 (4.43), 245 (4.18), 333 (4.41); IR spectrum, λ_{max}^{Nujol} 3480, 3460, 3340 (OH), 1635—1654 (CO), 1588, 1498, 1358, 1298, 1175, 1164, 1126, 1086, 1000, 990, 963, 884, 838, 797, 752, 685 cm^{-1}; NMR signals ($CDCl_3$), δ=3.49 (s, C_3–OH), 3.86 (s, C_6–OMe), 4.40 (d, J=12 Hz, C_3–H), 4.97 (d, J=12 Hz, C_2–H), 5.99 (s, C_8–H), 7.33 (s, 5H, B-ring protons), 11.34 ppm (s, C_5–OH); mass spectrum (prominent) *m/e* 302 (M^+), 273, 195, 183 (base), 182, 167, 156, 120, 91, 77, 69.

Found: C, 63.95; H, 4.87%. Calcd for $C_{16}H_{14}O_6$; C, 63.57; H, 4.67%.

Chrysin (4), Pinocembrin (16), and *pinobanksin (17).* Fraction 2 was acidified with 5% hydrochloric acid and then extracted with chloroform. The refrigeration of the brown viscous material (0.85 g) dissolved in ether diposited a yellow mass. Subsequent crystallization from methanol gave chrysin (**4**) (40 mg); mp 275—277°C, lit,[20] 278—279°C; ν_{max}^{Nujol} 3350—3050 (OH), 1640 (CO), 795 cm^{-1}; *m/e* 254 (M^+, base), 226, 152, 124, 113, 77, 69. On the other hand, more cooling of the mother liquor gave another pale yellow mass. Subsequent crystallization from methanol afforded white needles of pinocembrin (**16**) (150 mg); mp 200—201°C, lit,[21] 193—194°C; ν_{max}^{Nujol} 3250—2500 (OH), 1623 (CO), 1155 cm^{-1}; *m/e* 256 (M^+, base), 179, 153, 152, 124, 104, 103, 96, 78, 77, 69, 51. When the combined mother liquor was subjected to preparative thin-layer chromatography, it yielded pinobanksin (**17**) (8 mg); mp 177—178°C, lit,[21] 177—178°C; ν_{max}^{Nujol} 3465 (OH), 1625 (CO), 815 cm^{-1}.

Alnusin (1), Alnetin (2), Alnustin (3), Tectochrysin (6), Izalpinin (5), Pinostrobin (18), Strobopinin (19), Naringenin (20), Alpinetin (21), Pinosylvin (24), and *Pinosylvin monomethyl ether (25).* Fraction 3 was extracted with chloroform after acidification with dilute hydrochloric acid. The removal of the solvent yielded a brown solid (8.45 g), which was then dissolved in ether and kept in a refrigerator. The major flavonol, alnusin (**1**), was thus deposited as yellow mass (2.85 g); mp 239—241°C (from methanol); $FeCl_3$ (dark green), Mg-HCl (pink); λ_{max}^{EtOH} 238 (3.91), 270 (4.25), 325 (4.26), 362_{sh} (4.20), $\lambda_{max}^{EtOH+AlCl_3}$ 251 (4.33), 278 (4.38), 350 (4.25), 415 (4.26), $\lambda_{max}^{EtOH+NaOAc}$ 271 (4.39), 328 (4.15), 368 (4.20), $\lambda_{max}^{EtOH+NaOEt}$ 212 (4.26), 234 (4.13), 281 (4.00), 347 (3.71), 413 (3.95); ν_{max}^{Nujol} 3350, 3300 (OH), 1640 (CO), 1615, 1590, 1548, 1490, 1480, 1387, 1318, 1295, 1260, 1215, 1200, 1170, 1155, 1098, 1073, 1065, 1033, 1020, 970, 883, 805, 789, 762, 735, 695, 680, 585 cm^{-1}; δ (CD_3COCD_3)=3.89 (s, 3H, C_6–OMe), 6.68 (s, 1H, C_8–H), 9.25 (s, C_3 or C_7–OH), 7.60 and 8.20 (m, 5H, B-ring protons), 12.23 ppm (s, 1H, C_5–OH); *m/e* 300 (M^+), 285 (M-15, 50%), 283 (M–OH), 282 ($M-H_2O$), 271, 257 (M–MeCO, base), 131, 105, 77, 69, 51, 39;

Found: C, 64.88; H, 4.29%. Calcd for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03%.

The removal of the solvent from the mother liquor affored a brown solid, which was then chromatographed on a silica-gel column using a mixture of ether and methanol, thus dividing it into four eluates. The first eluate was further chromatographed on a silica-gel column using chloroform to give pinostrobin (**18**) (0.87 g) and alnetin (**3**) (0.48 g) as yellow needles; mp 100—101°C (from *n*-hexane); $FeCl_3$ (dark green); λ_{max}^{EtOH} 207 (4.52), 282 (4.56), 320 (3.84), $\lambda_{max}^{EtOH+AlCl_3}$ 206 (4.35), 218 (4.29), 300 (4.33), 336 (3.88), 415 (3.14), $\lambda_{max}^{EtOH+NaOEt}$ 216 (4.20), 229 (4.04), 286 (4.37), 410 (3.46); ν_{max}^{Nujol} 3350 (OH), 1660 (CO), 760, 675 cm^{-1} (monosubst. benzene-ring); δ ($CDCl_3$)=3.95, 3.97, 4.10 (s, 9H, 3 OMe), 6.69 (s, 1H, C_3–H), 7.56 and 7.95 (m, 5H, B-ring protons), 12.45 ppm (s, 1H, C_5–OH), δ (benzene)=3.83, 3.64, and 3.80 ppm (s, 3 OMe); *m/e* 328 (M^+), 314, 315 (M-15), 183, 77, 69 (base).

Found: C, 65.85; H, 4.88%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

The second eluate gave alnustin (**3**) (0.65 g); mp 175—176°C (from *n*-hexane); $FeCl_3$ (dark green); λ_{max}^{EtOH} 207 (4.28), 213 (4.28), 245 (4.00), 271 (4.30), 317 (4.09), $\lambda_{max}^{EtOH+AlCl_3}$ 207 (4.28), 224 (4.15), 253 (3.85), 286 (4.28), 337 (4.08),

392 (4.01), $\lambda_{max}^{EtOH+NaOEt}$ 215 (4.59), 226 (4.60), 289 (4.54), 385 (3.85); ν_{max}^{Nujol} 1660 (CO), 1590, 1300, 1235, 1215, 1175, 1120, 980, 800, 765, and 695 cm^{-1} (monosubst. benzene-ring); δ ($CDCl_3$)=3.89, 3.94, 3.97 (s, 9H, 3 OMe), 6.54 (s, 1H, C_8–H), 7.56 and 8.10 ppm (m, 5H, B-ring protons), 12.85 ppm (s, 1H, C_5–OH), δ (benzene)=3.23, 3.67, and 3.87 ppm (s, 3 OMe); *m/e* 328 (M^+, base), 327, 313 (M-15), 309, 285, 153, 118, 105, 89, 77, 69.

Found: C, 65.90; H, 4.86%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

The third eluate was further subjected to column chromatography on silica-gel using a mixture of chloroform and methanol; this gave pinosylvin monomethyl ether (**25**) (0.25 g) and izalpinin (**5**) (70 mg).

Pinosylvin monomethyl ether (**25**); mp 119—120°C, lit,[21] 118—120°C; λ_{max}^{EtOH} 303 (4.26); ν_{max}^{Nujol} 3338 (OH), 955 (*trans*-CH=CH), 680 cm^{-1}; *m/e* 226 (M^+, base), 225, 211 (M-15), 210, 195 (M–OMe), 194, 165 ($C_{13}H_9^+$: Found 165.0696; Calcd. 165.0704).

Izalpinin (**5**): mp 190—191°C, lit,[21] 192—193°C; δ (CD_3COCD_3)=3.83 (s, 3H, OMe), 6.38 (d, J=2 Hz, 1H), 6.50 (d, J=2 Hz, 1H), 7.62 and 8.17 (m, 5H, B-ring protons), 12.64 ppm (s, 1H, C_5–OH).

The fourth eluate was repeatedly subjected to preparative thin-layer chromatography, thus isolating tectochrysin (**6**), (25 mg), strobopinin (**19**) (12 mg), naringenin (**20**) (22 mg), alpinetin (**21**) (19 mg), and pinosylvin (**24**) (48 mg).

Tectochrysin (**6**): mp 165—166°C, lit,[21] 163—164°C; ν_{max}^{Nujol} 1660 (CO), 795, 759, 681, 632 cm^{-1}; *m/e* 268 (M^+, base), 255, 240, 166, 138, 123, 95, 77, 39.

Strobopinin (**19**): mp 225—226°C, lit,[20] 225—227°C; λ_{max}^{EtOH} 295 (4.33), 338 (3.70); ν_{max}^{Nujol} 1640 (CO), 810, 700 cm^{-1}; *m/e* 270 (M^+), 269, 193, 166 (base), 138, 120, 104, 69, 51, 39.

Naringenin (**20**): mp 251—252°C, lit,[22] 248°C; λ_{max}^{EtOH} 290 (4.33); ν_{max}^{Nujol} 3300—3110 (OH), 1634 (CO), 820 cm^{-1}; *m/e* 272 (M^+), 271, 179, 166, 153 (base), 152, 124, 120, 107, 91, 69, 31.

Pinosylvin (**24**): mp 156—158°C, lit,[21] 153—155°C; λ_{max}^{EtOH} 305 (4.49); ν_{max}^{Nujol} 953 (*trans* CH=CH), 675 cm^{-1}; *m/e* 212 (M^+, base), 211, 197 (M-15), 195, 194, 165 ($C_{13}H_9^+$: Found 165.0709; Calcd. 165.0704), 141, 128, 77, 69, 55, 51, 39.

Methylation with diazomethane yielded pinosylvin dimethyl ether (**26**).

Pinosylvin Dimethyl Ether (26). A sample of a neutral fraction (50 g) was chromatographed on a silica-gel column using a mixture of *n*-hexane and ether (1:1) to give pinosylvin dimethyl ether (**26**) as a yellow oil (0.225 g); λ_{max}^{EtOH} 305 (4.39); $\nu_{max}^{liq.}$ 950 (*trans* CH=CH), 740, 682 cm^{-1}; *m/e* 240 (M^+, base), 239, 225 (M-15), 209 (M–OMe), 194, 165 ($C_{13}H_9^+$: Found 165.0706; Calcd. 165.0704), 152, 77, 55. The demethylation of **26** with pyridine hydrochloride gave pinosylvin (**24**).

Methylation of Alnusin (1). *A) With Diazomethane*: The treatment of a methanol solution of alnusin (0.1 g) with excess diazomethane at 0°C for 3 hr gave 5-hydroxy-3,6,7-trimethoxy flavone (**8**) (74 mg), mp 175—176°C, which was identical with alnustin (**3**) in all respects.

B) With Dimethyl Sulfate: The refluxing of an acetone solution of alnusin (0.4 g) with dimethyl sulfate (2 m*l*) in the presence of dry potassium carbonate (3.0 g) gave 3,5,6,7-tetramethoxyflavone (**9**) (0.3 g); mp 112.0—112.5°C, lit,[7] 110—111°C; λ_{max}^{EtOH} 213 (4.50), 240 (4.21), 260 (4.30), 310 (4.30); ν_{max}^{Nujol} 1637 (CO), 1627, 1232, 973, 813, 790, 778, 701 cm^{-1}; δ ($CDCl_3$)=3.88, 3.92, 3.97, 4.02 (s, 12H, 4 OMe), 6.78 (s, 1H, C_8–H), 7.55 and 8.22 (m, 5H, B-ring protons), δ (benzene)=3.28, 3.75, 3.80, 4.04 (s, 3 OMe); *m/e* 342 (M^+), 327 (M-15, base), 323, 311, 283, 195, 167, 141, 105, 77, 69.

Found: C, 66.11; H, 5.41%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

Acetylation of Alnusin (1). The acetylation of **1** (76 mg) with acetic anhydride in the presence of pyridine gave the triacetate (**7**) (66 mg); mp 142—144°C (from *n*-hexane-ethyl acetate); λ_{max}^{EtOH} 257 (3.89), 300 (3.80); ν_{max}^{Nujol} 1770 (acetate), 1644 (CO), 1182, 699 cm^{-1}; δ ($CDCl_3$)=2.29 (s, 3H, MeCO), 2.38 (s, 3H, MeCO), 2.45 (s, 3H, C_5–MeCO), 3.86 (s, 3H, C_6–OMe), 7.27 (s, 1H, C_8–H), 7.55 and 7.79 ppm (m, 5H, B-ring protons), δ (benzene)=3.69 (s, OMe); *m/e* 426 (M^+), 384, 342, 300 (base,) 285, 282, 271, 257, 105, 77, 69, 43.

Ethylation of Alnusin (1). The heating of the acetone solution of **1** (68 mg) with ethyl iodide (4 g) and dry potassium carbonate (2 g) for 70 hr gave the triethyl ether derivative (**10**) (40 mg); λ_{max}^{EtOH} 262 (3.69), 312 (3.64); δ ($CDCl_3$)=1.28 (t, J=7 Hz, 3H, Me), 1.51 (t, J=7 Hz, 6H, 2 Me), 3.90 (s, 3H, OMe), 4.18 (q, J=7 Hz, 6H, 3 CH_2), 6.71 (s, 1H, C_8–H), 7.48 and 8.08 ppm (m, 5H, B-ring protons), δ (benzene)=1.09 (t, J=7 Hz, 3H, Me), 1.20 (t, J=7 Hz, 3H, Me), 1.56 (t, J=7 Hz, 3H, Me), 3.48 (q, J=7 Hz, 2H, CH_2), 3.48 (q, J=7 Hz, 2H, CH_2), 3.75 (s, OMe), 4.25 (q, J=7 Hz, 2H, CH_2), 4.28 (q, J=7 Hz, 2H, CH_2).

Methylation of Alnetin (2). The methylation of **2** (0.35 g) with dimethyl sulfate in the same manner as above yielded **11** (0.32 g); 112—113°C, lit,[9] 112—113°C; λ_{max}^{EtOH} 207 (4.40), 270 (4.34), 305 (4.08); ν_{max}^{Nujol} 1660 (CO), 763, 680 cm^{-1}; δ ($CDCl_3$)=3.96 (s, 6H, 2 OMe), 4.04 (s, 3H, OMe), 4.10 (s, 3H, OMe), 6.70 (s, 1H, C_3–H), 7.57 and 7.96 ppm (m, 5H, B-ring protons), δ (benzene)=3.65, 3.73, 3.77, 4.01 ppm (s, 4 OMe); *m/e* 342 (M^+), 327 (M-15, base), 284, 197, 182, 83.

Found: C, 66.27; H, 5.30%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

Methylation of Alnustinol (15). The methylation of alnustinol (18 mg) with diazomethane yielded **22** (15 mg); mp 189.0—189.5°C (from benzene); λ_{max}^{EtOH} 216 (4.28), 234 (4.21), 292 (4.31), 340 (3.52), $\lambda_{max}^{EtOH+AlCl_3}$ 227 (4.29), 316 (4.36), 390 (3.22), $\lambda_{max}^{EtOH+NaOEt}$ 244 (4.42), 295 (4.35), 377 (3.87); ν_{max}^{Nujol} 3498 (OH), 1635 (CO), 765 and 698 cm^{-1}; δ ($CDCl_3$)=3.48 (bs, 1H, C_3–OH), 3.83 (s, 3H, C_6–OMe), 6.12 (s, C_8–H), 4.54 (d, J=12 Hz, 1H, C_3–H), 5.10 (d, J=12 Hz, 1H, C_2–H), 7.49 (s, 5H, B-ring protons), 11.03 ppm (s, 1H, C_5–OH); *m/e* 316 (M^+), 287 (M–CHO), 198, 197, (base), 196, 182, 181, 170, 167, 155, 154, 136, 125, 120, 91, 77, 69, 65, 51, 39.

Found: C, 63.95; H, 4.87. Calcd for $C_{17}H_{16}O_6$: C, 63.57; H, 4.67%.

Alkaline Degradation of 3,5,6,7-Tetramethoxyflavone (9). The flavone (**9**) (0.18 g) was refluxed in a mixture of a 50% potassium hydroxide solution (16 m*l*) and ethanol (7 m*l*) in a current of nitrogen for 20 hr. After acidification, the ether extract was washed with a 5% sodium bicarbonate solution. The ethereal layer provided 2-hydroxy-ω-4,5,6-tetramethoxy-acetophenone (**12**) (68 mg); mp 69—71°C; λ_{max}^{EtOH} 211 (4.14). 228 (4.29), 298 (4.33), 308 (4.37); ν_{max}^{Nujol} 3370 (OH), 1625 (CO), 780 cm^{-1}; δ ($CDCl_3$)=3.50 (s, 3H, ω-OMe), 3.73, 3.85, 3.99 (s, 9H, 3 OMe), 4.61 (s, 2H, -COC$\underline{H}_2$–O–), 6.23 (s, 1H, C_3–H), 13.12 (s, 1H, C_2–OH). On the other hand, the sodium bicarbonate washings gave benzoic acid (**14**); mp 121—122°C.

Alkaline Degradation of 5,6,7,8-Tetramethoxyflavone (11). The alkaline degradation of the flavone (**11**) (41 mg) for 20 hr in the same manner as above gave 2-hydroxy-3,4,5,6-tetramethoxy acetophenone (**13**); λ_{max}^{EtOH} 280 (3.74), 345 (3.16);

22) J. Shinoda and S. Kamieda, *Yakugaku Zasshi*, **49**, 575 (1929).

$\nu_{max}^{liq.}$ 3400 (OH), 1620 (CO), 730 cm^{-1}; δ ($CDCl_3$)=2.66 (MeCO), 3.80, 3.85, 3.85, 4.07 ppm (s, 12H, 4 OMe); the 2,4-Dinitrophenylhydrazone: mp 169—171°C, lit,[9] 168—170°C. Benzoic acid was obtained from the sodium bicarbonate washings.

*Dehydrogenation of Alnustinol (**15**).* The heating of alnustinol (40 mg) with palladium charcoal (10 mg) in the presence of cinnamic acid (0.18 g) gave 3,5,7-trihydroxy-6-methoxyflavone, which was identical to alnusin (**1**) in all respects.

The author wishes to express his hearty gratitude to Dr. Takayuki Suga and Professor Emeritus Tamon Matsuura of Hiroshima University for their guidance and encouragement. The author is also indebted to Professor Hyoji Suzuki of Hiroshima University for his suggestions about identifing *Alnus sieboldiana,* to Professor Shô Itô of Tohoku University for the measurement of the mass spectra, and to Dr. M. E. Wall of the Research Triangle Institute for the measurement of the high-resolution mass spectra. Thanks are also due to Professor H. Erdtman of the Royal Institute Technology for kindly supplying tectochrysin, pinocembrin, chrysin, and pinosylvin monomethyl ether and also for his helpful advice, and to Dr. H. H. Lee of the University of Malaya for his kind gift of the 5,6,7,8-tetramethoxyflavone used in this investigation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2766—2770 (1971)

The Total Synthesis of (±)-Taxodione, A Tumor Inhibitor[1]

Takashi MATSUMOTO, Yakudo TACHIBANA, Junji UCHIDA, and Kenji FUKUI

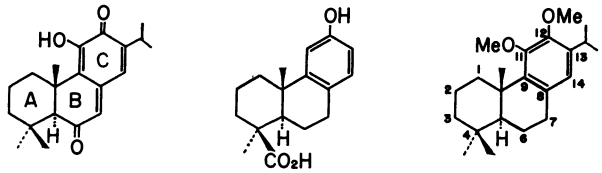
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received March 19, 1971)

A total synthesis of (±)-taxodione (I) has been achieved. The Friedel and Crafts reaction of 1,2-dimethoxy-3-isopropylbenzene (IV) with succinic anhydride gave β-(4-hydroxy-3-isopropyl-5-methoxybenzoyl)propionic acid (V), which was then converted to γ-(4,5-dimethoxy-3-isopropylphenyl)butyric acid (IX). Since the cyclization of IX gave 6,7-dimethoxy-8-isopropyl-1-tetralone (X), the acid (IX) was subjected to bromination, cyclization, and then debromination. Subsequently, 7,8-dimethoxy-6-isopropyl-1-tetralone (XIII) was converted to (±)-7,8-dimethoxy-6-isopropyl-1-methyl-2-tetralone (XV). The condensation of (±)-XV with the methyl vinyl ketone gave a (±)-hexahydro-2-oxo-phenanthrene derivative (XVI), which was then further converted to (±)-11,12-dimethoxyabieta-5,8,11,13-tetraene (XIX). The introduction of a carbonyl group at the 6 position was achieved by the hydroboration of (±)-XIX, followed by the oxidation of the resulting 6-hydroxyl derivative. Finally, (±)-11,12-dimethoxyabieta-8,11,13-trien-6-one (XXI) was converted to (±)-I, whose IR, UV, and NMR spectra were identical in every respect with those of natural taxodione.

Taxodione, a tumor-inhibitory diterpenoid quinone methide, was recently isolated from *Taxodium distichum* Rich (Taxodiaceae) by Kupchan *et al.*[2,3] On the basis of spectral and chemical studies, they deduced the structure of taxodione to be I. Because of its unique structure and, especially, its significant tumor-inhibitory activity against the Walker carcinosarcoma 256 in rats, we planned the total synthesis of I by the route of C→B→A ring construction. During the course of the present work, Mori and Matsui[4] reported on the synthesis of I starting from podocarpic acid (II) *via* 11,12-dimethoxyabieta-8,11,13-triene (III). The appearance of their publication prompts us to report our own results. The present paper will describe the total synthesis of (±)-taxodione.

1,2-Dimethoxy-3-isopropylbenzene (IV),[5] which corresponds to the C ring in I, was chosen as our starting material. The Friedel and Crafts reaction of IV with succinic anhydride in dichloromethane gave a keto-acid (V), which was then methylated with diazomethane to a methyl ester (VI). The V acid gave a positive ferric chloride reaction in ethanol and showed bands at 1703 (CO_2H) and 1659 cm^{-1} (C=O) in its IR spectrum. The NMR spectrum of V in $CDCl_3$ showed signals at δ 7.41 ppm and δ 7.54 ppm (each 1H doublet and J=2 Hz) due to aromatic protons, thus suggesting the presence of two meta-coupling protons. Further, the signal due to the methine proton of the isopropyl group appeared at δ *ca.* 3.3 ppm in $CDCl_3$ and at δ *ca.* 3.7 ppm in pyridine-d_5. This pyridine-induced solvent shift[6] suggested the presence



I II III

1) Although the formulas depicted represent only one enantiomer, they are taken to indicate a racemate.

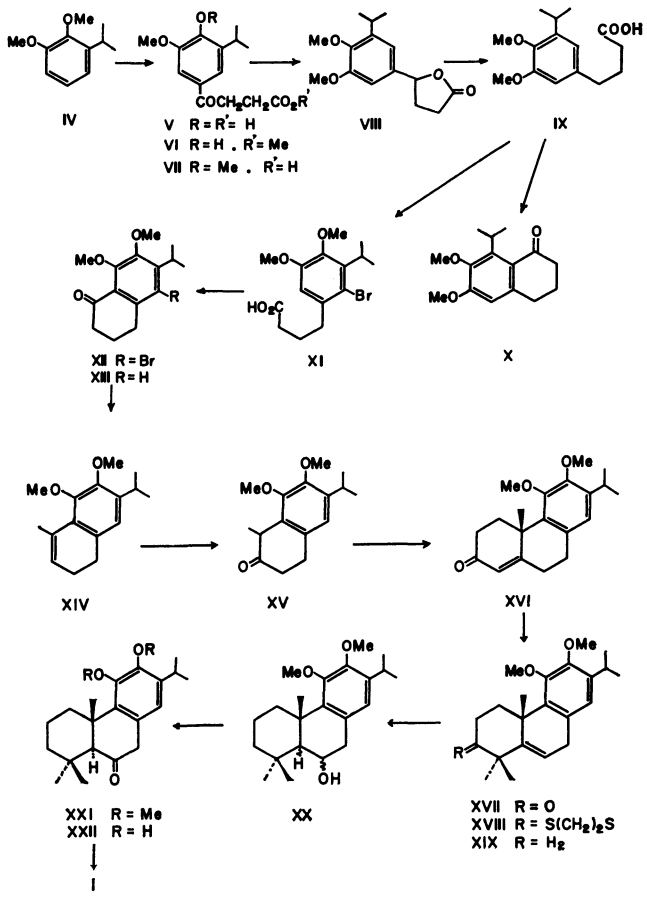
of a hydroxyl group at the position ortho to the isopropyl group. From the above results, the structure of V was identified as β-(4-hydroxy-3-isopropyl-5-methoxy benzoyl)propionic acid. The methylation of V with dimethyl sulfate in an alkaline solution, followed by alkaline hydrolysis, afforded the corresponding methyl ether (VII), which gave a negative ferric chloride reaction. The reduction of the carbonyl group in VII to the corresponding methylene group in an almost quantitative yield was carried out in the following manner. That is, the ketone (VII) in aqueous sodium hydroxide was treated with sodium borohydride at room temperature; the resulting crude product was then heated on a steam bath to give a γ-lactone (VIII). The hydrogenolysis of VIII in methanol in the presence of Pd-C gave γ-(4,5-dimethoxy-3-isopropylphenyl) butyric acid (IX). Subsequently, the treatment of IX in benzene with phosphorous pentachloride, followed by the intramolecular cyclization of the resulting acid chloride with anhydrous stannic chloride, gave a 1-tetralone derivative (X), the NMR spectrum of which showed a signal at δ 4.11 ppm due to the methine proton of the isopropyl group. This chemical-shift value indicates that the methine proton in X is deshielded by a newly-formed carbonyl group, because the spectrum of IX showed a signal at δ 3.36 ppm attributable to the methine proton of the isopropyl group. From this spectral evidence, the structure of X was identified as 6,7-dimethoxy-8-isopropyl-1-tetralone, as had been expected. Since this (X) was not a useful intermediate for the synthesis of (±)-I, the



IX acid was subjected to bromination in carbon tetrachloride; γ-(2-bromo-4,5-dimethoxy-3-isopropylphenyl)butyric acid (XI) was thus obtained. The structure of XI was also assigned on the basis of its NMR spectrum, which showed signals, at δ 3.70 ppm and at δ 6.68 ppm, attributable to the methine proton of the isopropyl group and an aromatic proton respectively. The treatment of XI with phosphorous pentachloride and then with stannic chloride gave a 5-bromo-1-tetralone derivative (XII); this was hydrogenated at room temperature in methanolic potassium hydroxide in the presence of Pd-C to give 7,8-dimethoxy-6-isopropyl-1-tetralone (XIII). The Grignard reaction of XIII with methylmagnesium iodide afforded the corresponding alcohol, which was then dehydrated with dilute sulfuric acid to give 3,4-dihydro-7,8-dimethoxy-6-isopropyl-1-methylnaphthalene (XIV). Subsequently, the naphthalene derivative (XIV) was treated with lead tetraacetate in acetic acid; the resulting crude product was then refluxed with ethanol containing concentrated sulfuric acid to give (±)-7,8-dimethoxy-6-isopropyl-1-methyl-2-tetralone (XV). The construction of the A ring was achieved by the condensation of (±)-XV with methyl vinyl ketone in the presence of sodium ethoxide; after chromatographic purification, (±)-2,3,4,9,10,12-hexahydro-5,6-dimethoxy-7-isopropyl-12-methyl-2-oxophenanthrene (XVI) was thus obtained. The methylation of (±)-XVI with methyl iodide in *t*-butanol in the presence of potassium *t*-butoxide gave (±)-11,12-dimethoxyabieta-5,8,11,13-tetraen-3-one (XVII), which was then further converted to (±)-11,12-dimethoxyabieta-5,8,11,13-tetraene (XIX) *via* a thioketal derivative (XVIII). The IR and NMR spectra of (±)-XIX were in good agreement with those of an optically-active sample[3] derived from natural taxodione. The introduction of a carbonyl group at the 6 position was achieved by the hydroboration of (±)-XIX, followed by the oxidation of the resulting 6-hydroxyl derivative (XX) with the Jones reagent.[7] Thus, (±)-11,12-dimethoxyabieta-8,11,13-trien-6-one (XXI) was obtained. Its IR and NMR spectra were also identical with the data reported for an optically-active XXI.[3,4] Mori and Matsui[4] had reported that the demethylation of XXI[8] with boron tribromide in dichloromethane gave 11,12-dihydroxyabieta-8,11,13-trien-6-one (XXII), which was then further oxidized with silver oxide in chloroform to give taxodione (I). On the other hand, the conversion of XXII[8] to I by aerial oxidation on silica gel had also been reported by Kupchan *et al.*[3] Therefore, our final step in the total synthesis of (±)-I was carried out as follows. By the method of Mori and Matsui,[4] (±)-XXI was demethylated with boron tribromide to give (±)-XXII, which was then immediately chromatographed on silica gel according to the method of Kupchan *et al.*[3] to give (±)-I as a yellow oil. The IR, UV, NMR, and mass spectra of the synthetic (±)-I were identical in every respect with those of natural taxodione.[3]

8) Optically-active substance.

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. Their chemical shifts are presented in terms of δ values; s: singlet; bs: broad singlet; d: doublet; t: triplet; q: quartet; m: multiplet. The column chromatography was performed on Merck silica gel (0.08 mm).

β-(4-Hydroxy-3-isopropyl-5-methoxybenzoyl)propionic Acid (V). Anhydrous aluminum chloride (6.66 g) was stirred, over a period of 15 min, into a mixture of IV (3.60 g), succinic anhydride (2.10 g), and dry dichloromethane (20 m*l*) with cooling at 5—8°C. After the addition was complete, the mixture was stirred at room temperature for 4 hr and was then gently refluxed for 10 min. The mixture was poured into a mixture of concentrated hydrochloric acid (15 m*l*) and ice (*ca.* 100 g) and extracted with ethyl acetate, after which the ethyl acetate solution was extracted with aqueous sodium hydroxide (5%). After the alkaline extract had been acidified with dilute sulfuric acid, the yellow precipitate was collected, washed with water, and then recrystallized from aqueous methanol to give colorless needles, mp 169—171°C, which gave a green ferric chloride reaction in ethanol; yield, 3.2 g (60%). NMR in $CDCl_3$: 1.26 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.80 (2H, t, J=6 Hz, $-C\underline{H}_2CO_2H$), 3.32 (2H, t, J=6 Hz, $-COC\underline{H}_2-$), *ca.* 3.3 (1H, m, overlap, $-C\underline{H}(CH_3)_2$), 3.93 (3H, s, $-OC\underline{H}_3$), 7.41 and 7.54 (each 1H d and J=2 Hz, aromatic protons) ppm. NMR in pyridine-d_5: 1.34 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 3.08 (2H, t, J=6 Hz, $-C\underline{H}_2CO_2H$), 3.56 (2H, t, J=6 Hz, $-COC\underline{H}_2-$), *ca.* 3.7 (1H, m, overlap, $-C\underline{H}(CH_3)_2$), 3.68 (3H, s, $-OC\underline{H}_3$), 7.71 and 7.91 (each 1H d and J=2 Hz, aromatic protons) ppm.

Found: C, 63.11; H, 6.58%. Calcd for $C_{14}H_{18}O_5$: C, 63.14; H, 6.81%.

The starting IV (1.2 g) was recovered from the ethyl acetate solution.

Methyl β-(4-Hydroxy-3-isopropyl-5-methoxybenzoyl)propionate (VI). A solution of V (500 mg) in acetone (40 m*l*) was methylated with an excess ethereal diazomethane solution at room temperature for 3 hr. After a usual work-up, the product was recrystallized from a mixture of ether and petroleum ether (cooled on dry ice) to give VI as colorless prisms, mp 80.5—81.5°C, which gave a blue ferric chloride reaction in ethanol; yield, 410 mg. NMR in $CDCl_3$: 1.25 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.74 (2H, t, J=6 Hz, $-C\underline{H}_2CO_2-$), 3.30 (2H, t, J=6 Hz, $-COC\underline{H}_2-$), *ca.* 3.3 (1H, m, overlap, $-C\underline{H}(CH_3)_2$), 3.69 (3H, s, $-CO_2C\underline{H}_3$), 3.92 (3H, s, $-OC\underline{H}_3$), 6.26 (1H, s, $-O\underline{H}$), 7.39 and 7.55 (each 1H d and J=2 Hz, aromatic protons) ppm. NMR in pyridine-d_5: 1.32 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.87 (2H, t, J=6 Hz, $-C\underline{H}_2CO_2-$), 3.46 (2H, t, J=6 Hz, $-COC\underline{H}_2-$), *ca.* 3.6 (1H, m, overlap, $-C\underline{H}(CH_3)_2$), 3.59 (3H, s, $-CO_2C\underline{H}_3$), 3.68 (3H, s, $-OC\underline{H}_3$), 7.64 and 7.85 (each 1H d and J=2 Hz, aromatic protons) ppm.

Found: C, 64.50; H, 7.33%. Calcd for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19%.

β-(4,5-Dimethoxy-3-isopropylbenzoyl)propionic Acid (VII). Dimethyl sulfate (37.8 g) was stirred, drop by drop at 60—65°C over a period of 1 hr, into a solution of V (26.6 g) in aqueous sodium hydroxide (10%: 100 m*l*). After the stirring had been continued for an additional hour, the mixture was hydrolyzed with aqueous sodium hydroxide (10%: 50 m*l*) at this temperature for 1 hr. The cold solution was then acidified with dilute sulfuric acid, and the precipitate was collected, washed with water, and then recrystallized from aqueous methanol to give VII as colorless needles, mp 131—133°C, which gave a negative ferric chloride reaction in ethanol; yield, 25.0 g (89%). NMR in $CDCl_3$: 1.24 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.80 (2H, t, J=6 Hz, $-C\underline{H}_2CO_2H$), 3.30 (2H, t, J=6 Hz, $-COC\underline{H}_2-$), 3.37 (1H, m, J=7 Hz, $-C\underline{H}(CH_3)_2$), 3.88 and 3.90 (each 3H and s, 2-$OC\underline{H}_3$), 7.42 and 7.53 (each 1H d and J=2 Hz, aromatic protons), 9.15 (1H, bs, $-CO_2\underline{H}$) ppm.

Found: C, 64.00; H, 7.20%. Calcd for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19%.

γ-Hydroxy-γ-(4,5-dimethoxy-3-isopropylphenyl)butyric Acid γ-Lactone (VIII). A mixture of sodium borohydride (380 mg) and VII (4.8 g) in aqueous sodium hydroxide (2%: 40 m*l*) was allowed to stand at room temperature for 24 hr, after which it was acidified with dilute sulfuric acid. The mixture was heated on a steam bath for 20 min and then cooled. The precipitate was collected, washed with water, and then recrystallized from aqueous methanol to give VIII as colorless needles, mp 128—129°C; yield, 4.2 g (93%). IR in nujol: 1765 cm^{-1} (γ-lactone). NMR in $CDCl_3$: 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.8—2.9 (4H, m, $-(C\underline{H}_2)_2-$), 3.38 (1H, m, J=7 Hz, $-C\underline{H}(CH_3)_2$), 3.82 and 3.87 (each 3H and s, 2-$OC\underline{H}_3$), 5.47 (1H, t, J=6 Hz, $-C\underline{H}-O-$), 6.77 (2H, s, aromatic protons) ppm.

Found: C, 68.16; H, 7.62%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

γ-(4,5-Dimethoxy-3-isopropylphenyl)butyric Acid (IX). A solution of VIII (4.2 g) in methanol (150 m*l*) was hydrogenated at room temperature in the presence of Pd-C (10%: 1.4 g). After the absorption of hydrogen had ceased (after *ca.* 40 min), the mixture was filtered and washed with hot methanol; the filtrate was then evaporated. The residue was recrystallized from aqueous methanol to give IX as colorless needles (mp 83.5—84.5°C); yield, 4.1 g (98%). NMR in $CDCl_3$: 1.22 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.8—2.8 (6H, m, $-(C\underline{H}_2)_3-$), 3.36 (1H, m, J=7 Hz, $-C\underline{H}(CH_3)_2$), 3.81 and 3.87 (each 3H and s, 2-$OC\underline{H}_3$), 6.62 and 6.68 (each 1H d and J=2 Hz, aromatic protons), 8.65 (1H, bs, $-CO_2\underline{H}$) ppm.

Found: C, 67.39; H, 8.37%. Calcd for $C_{15}H_{22}O_4$: C, 67.64; H, 8.33%.

6,7-Dimethoxy-8-isopropyl-1-tetralone (X). A mixture of IX (1.33 g), phosphorous pentachloride (1.04 g), and dry benzene (20 m*l*) was stirred at room temperature for 30 min, and then heated at 50°C for 5 min. After the solution had been cooled, a solution of anhydrous stannic chloride (1.5 m*l*) in dry benzene (5.0 m*l*) was added, drop by drop at 5—10°C, over a period of 15 min. The mixture was then further stirred at room temperature for 75 min, heated at 45—50°C for 1 hr, and then poured into dilute hydrochloric acid (5%: 25 m*l*). The organic layer was separated, washed with aqueous sodium carbonate and water successively, and then dried over sodium sulfate. After the removal of the solvent, the residue was recrystallized from aqueous methanol to give X as colorless prisms, mp 87.5—88.5°C; yield, 1.10 g (89%). NMR in $CDCl_3$: 1.34 (6H, d, J=7.5 Hz, $-CH(C\underline{H}_3)_2$), 2.02 (2H, m, J=6 Hz, $-CH_2C\underline{H}_2CH_2-$), 2.63 and 2.88 (each 2H t and J=6 Hz, 2-$C\underline{H}_2-$), 3.84 and 3.91 (each 3H and s, 2-$OC\underline{H}_3$), 4.11 (1H, m, J=7.5 Hz, $-C\underline{H}(CH_3)_2$), 6.65 (1H, s, aromatic proton) ppm.

Found: C, 72.41; H, 8.41%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

γ-(2-Bromo-4,5-dimethoxy-3-isopropylphenyl)butyric Acid (XI). A solution of bromine (10.9 g) in carbon tetrachloride (30 m*l*) was stirred, drop by drop at 3—5°C over a period of 1.5 hr, into a solution of IX (18.0 g) in carbon tetrachloride (120 m*l*).

After the stirring had then been continued for an additional 1.5 hr, the reaction mixture was washed successively with water, aqueous sodium thiosulfate, and water. The subsequent removal of the dried solvent gave a solid which was recrystallized from cyclohexane to give colorless crystals, mp 77.5—78.5°C; yield, 22.5 g (96%). This gave a positive Beilstein halogen test. NMR in $CDCl_3$: 1.34 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.95—2.95 (6H, m, $-(C\underline{H}_2)_3-$), 3.70 (1H, m, J=7 Hz, $-C\underline{H}(CH_3)_2$), 3.83 (6H, s, $2\text{-}OC\underline{H}_3$), 6.68 (1H, s, aromatic proton) ppm.

Found: C, 52.32; H, 6.14%. Calcd for $C_{15}H_{21}O_4Br$: C, 52.17; H, 6.09%.

7,8-Dimethoxy-6-isopropyl-1-tetralone (XIII). A solution of XI (20.7 g) in dry benzene (100 m*l*) was treated with phosphorous pentachloride (12.5 g) and then with anhydrous stannic chloride (25 m*l*) by a method similar to that used for X. The crude product was distilled under a vacuum to give XII as an oil, bp 168—174°C/0.85 mmHg; yield, 17.0 g (87%). NMR in $CDCl_3$: 1.36 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.10 (2H, m, J=6 Hz, $-CH_2C\underline{H}_2CH_2-$), 2.64 and 3.03 (each 2H t and J=6 Hz, $2\text{-}C\underline{H}_2-$), *ca.* 3.8 (1H, m, overlap, J=7 Hz, $-C\underline{H}(CH_3)_2$), 3.87 and 3.93 (each 3H and s, $2\text{-}OC\underline{H}_3$) ppm.

To a solution of the above XII (15 g) in methanol (30 m*l*), methanolic potassium hydroxide (10%: 100 m*l*) and Pd - C (10%: 5.0 g) were added; the mixture was then subjected to hydrogenolysis at room temperature. After the absorption of hydrogen had ceased, the mixture was filtered and the filtrate was evaporated under a vacuum. The residue was extracted with ether, which had been washed with water and then dried over sodium sulfate. After the removal of the solvent, the crude product was distilled under a vacuum to give XIII as an oil, bp 138—143°C/0.8 mmHg, which gave a negative Beilstein halogen test; yield, 10.8 g (95%). NMR in $CDCl_3$: 1.23 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.05 (2H, m, J=6 Hz, $-CH_2C\underline{H}_2CH_2-$), 2.61 and 2.90 (each 2H t and J=6 Hz, $2\text{-}C\underline{H}_2-$), 3.33 (1H, m, J=7 Hz, $-C\underline{H}(CH_3)_2$), 3.88 (6H, s, $2\text{-}OC\underline{H}_3$), 6.87 (1H, s, aromatic proton) ppm.

Found: C, 72.72; H, 8.12%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

3,4-Dihydro-7,8-dimethoxy-6-isopropyl-1-methylnaphthalene (XIV). A solution of XIII (8.20 g) in dry benzene (50 m*l*) was stirred, drop by drop over a period of 30 min, to a Grignard reagent which had been prepared from magnesium (960 mg), methyl iodide (5.70 g), and dry ether (30 m*l*). The mixture was refluxed for 5 hr, cooled, decomposed with dilute hydrochloric acid (10%: 60 m*l*), and then extracted with ether. The extract was washed with water and dried over sodium sulfate. After the removal of the solvent, the residue was dissolved in dry toluene (60 m*l*) containing *p*-toluenesulfonic acid (0.5 g) and the solution was refluxed for 3 hr. Then, the solvent was slowly distilled off over a period of 3 hr and the residue was extracted with ether. The extract was washed with aqueous sodium hydrogen carbonate and water successively, dried over sodium sulfate, and then evaporated. The product was distilled under a vacuum to give an oil (5.4 g), bp 114—136°C/0.9 mmHg (mainly 118—119°C/0.9 mmHg). This was purified by means of column chromatography on silica gel (220 g), using benzene containing 2% ether as the eluent, to give XIV as a colorless oil (4.49 g). NMR in $CDCl_3$: 1.23 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 2.24 (3H, s, $=\overset{|}{C}C\underline{H}_3$), 2.65 (4H, t, J=7 Hz, $-(C\underline{H}_2)_2-$), 3.23 (1H, m, J=7 Hz, $-C\underline{H}(CH_3)_2$), 3.81 and 3.87 (each 3H and s, $2\text{-}OC\underline{H}_3$), 5.90 (1H, bt, J=4 Hz, $=C\underline{H}-$), 6.86 (1H, s, aromatic proton) ppm.

In another experiment, the dehydration of the Grignard reaction product was also carried out by the refluxing of the crude alcohol with dilute sulfuric acid (20 %) for 5.5 hr, similar results were obtained.

Found: C, 78.21; H, 9.11%. Calcd for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00%.

(±)-7,8-Dimethoxy-6-isopropyl-1-methyl-2-tetralone (XV). A solution of XIV (530 mg) in acetic acid (4.0 m*l*) was stirred into a lead tetraacetate solution which had been freshly prepared from red lead oxide (2.06 g) and acetic acid (5.0 m*l*) at 55—60°C. After the stirring had been continued at room temperature for 1.5 hr, a few drops of ethylene glycol were added. The mixture was further stirred for 20 min, diluted with water (40 m*l*), and then extracted with ether which had been washed successively with aqueous sodium hydrogen carbonate and a saturated sodium chloride solution. After the removal of the ether, the residue was refluxed for 3 hr with ethanol (5.0 m*l*) containing concentrated sulfuric acid (0.5 m*l*), diluted with water, and then extracted with ether. The extract was washed successively with aqueous sodium hydrogen carbonate and water, dried over sodium sulfate, and then evaporated. The residue was chromatographed on silica gel (20 g), using benzene containing 2% ether as the eluent, to give XV as an oil (412 mg). IR in $CHCl_3$; 1706 cm^{-1} (C=O). NMR in $CDCl_3$; 1.24 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$, 1.40 (3H, d, J=8 Hz, $-\overset{|}{C}HC\underline{H}_3$), 3.87 and 3.90 (each 3H and s, $2\text{-}OC\underline{H}_3$), 6.88 (1H, s, aromatic proton) ppm.

Found: C, 73.20; H, 8.28. Calcd for $C_{16}H_{22}O_3$: C, 73.25; H, 8.45%.

(±)-2,3,4,9,10,12-Hexahydro-5,6-dimethoxy-7-isopropyl-12-methyl-2-oxophenanthrene (XVI). A solution of XV (3.56 g) in dry ether (20 m*l*) was stirred, at −10°C under a stream of nitrogen, into a sodium ethoxide solution which had been prepared from sodium (400 mg) and absolute ethanol (13 m*l*). After the stirring had been continued at this temperature for 30 min, methyl vinyl keton (1.0 g) was added. The mixture was further stirred at −10°C for 5 hr, at room temperature for 30 min, and then refluxed for 30 min. After cooling, the mixture was poured into dilute hydrochloric acid (10%: 50 m*l*) and extracted with ether. The extract was washed successively with aqueous sodium hydrogen carbonate and water, and then dried over sodium sulfate. After the removal of the ether, the crude product was purified by column chromatography on silica gel (250 g), using benzene containing 5% ether as the eluent, to give XVI as an oil (2.64 g: 61%). IR in $CHCl_3$; 1660 cm^{-1} (C=O). NMR in CCl_4; 1.17 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.63 (3H, s, $-\overset{|}{C}C\underline{H}_3$), 3.69 and 3.82 (each 3H and s, $2\text{-}OC\underline{H}_3$), 5.64 (1H, s, $-COC\underline{H}=$), 6.56 (1H, s, aromatic proton) ppm.

Found: C, 76.70; H, 8.36%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

(±)-11,12-Dimethoxyabieta-5,8,11,13-tetraen-3-one (XVII). A solution of XVI (2.51 g) in absolute *t*-butanol (20 m*l*) was stirred, at room temperature over a period of 10 min under a stream of nitrogen, to a potassium *t*-butoxide solution which had been prepared from potassium (1.19 g) and absolute *t*-butanol (20 m*l*). The mixture was stirred for 30 min, and to this was added methyl iodide (4.30 g). Under a stream of nitrogen, the mixture was stirred for 2 hr, refluxed for 30 min, cooled, poured into dilute hydrochloric acid (5%: 50 m*l*), and then extracted with ether. The ether extract was washed successively with water, aqueous sodium thiosulfate, and water. The solvent, after drying over sodium sulfate, was evaporated; the residue was then recrystallized from methanol to give XVII as colorless crystals (1.75 g), mp 154—154.5°C. The mother liquor of crystallization was evaporated, and the residue was chromatographed on silica gel (80 g), using benzene containing 3% ether as the eluent to give an addition-

al XVII (0.67 g). IR in $CHCl_3$; 1700 cm^{-1} (C=O). NMR in $CDCl_3$; 1.21 (6H, d, J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.31 (6H, s, 2-$\dot{C}C\underline{H}_3$), 1.37 (3H, s, $-\dot{C}C\underline{H}_3$), 3.43 (2H, d, J=4 Hz, $=CH-C\underline{H}_2-$), 3.77 and 3.88 (each 3H and s, 2-$OC\underline{H}_3$), 5.80 (1H, t, J=4 Hz, $=C\underline{H}CH_2-$), 6.74 (1H, s, aromatic proton) ppm.

Found: C, 77.28; H, 9.06%. Calcd for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83%.

(±)-11,12-Dimethoxyabieta-5,8,11,13-tetraene (XIX). A mixture of XVII (1.90 g), ethanedithiol (1.0 m*l*), and freshly-distilled boron trifluoride etherate (3.0 m*l*) was allowed to stand overnight at room temperature. After a usual work-up, the crude product was recrystallized from a mixture of ether and petroleum ether to give a thioketal (XVIII: 1.72 g), mp 156—157.5°C, which showed no carbonyl absorption band in its IR spectrum. NMR in $CDCl_3$; 1.18 and 1.21 (each 3H d and J=7 Hz, $-CH(C\underline{H}_3)_2$, 1.48 (3H, s, $-\dot{C}C\underline{H}_3$), 1.51 (6H, s, 2-$\dot{C}C\underline{H}_3$), 3.73 and 3.85 (each 3H and s, 2-$OC\underline{H}_3$), 5.94 (1H, t, J=4 Hz, $=C\underline{H}CH_2-$), 6.63 (1H, s, aromatic proton) ppm.

Found: C, 69.08; H, 8.27%. Calcd for $C_{24}H_{34}O_2S_2$: C, 68.87; H, 8.19%.

A solution of XVIII (2.15 g) in hot ethanol (200 m*l*) was refluxed for 3 hr with Raney nickel (W-7) prepared from Raney alloy (50 g), allowed to stand overnight at room temperature, and then filtered. The filtrate was evaporated, and, to the residue dilute hydrochloric acid (10%: 10 m*l*) was added. The mixture was extracted with ether. The extract was washed with water, dried over sodium sulfate, and then evaporated. The crude product was purified by column chromatography on silica gel (150 g), using hexane containing 30% benzene as the eluent, to give XIX as an oil (1.27 g), the IR and NMR spectra of which were identical with the data[3] reported for an optically-active sample. NMR in $CDCl_3$; 1.16 and 1.23 (each 3H and s, $-\dot{C}(C\underline{H}_3)_2$), 1.18 and 1.21 (each 3H d and J=7 Hz, $-CH(C\underline{H}_3)_2$), 1.46 (3H, s, $-\dot{C}C\underline{H}_3$), 3.13 (1H, m, overlap), 3.32 (2H, d, J=4 Hz, $=CHC\underline{H}_2-$), 3.75 and 3.84 (each 3H and s, 2-$OC\underline{H}_3$), 5.84 (1H, t, J=4 Hz, $=C\underline{H}CH_2-$), 6.67 (1H, s, aromatic proton) ppm. (±)-11,12-Dimethoxyabieta-8,11,13-trien-6-one (XXI). A solution of XIX (1.470 g) in dry tetrahydrofuran (10 m*l*) was added to a suspension of sodium borohydride (210 mg) in dry tetrahydrofuran (10 m*l*). To the stirred and cooled (0—5°C) suspension, a solution of freshly-distilled boron trifluoride etherate (1.1 m*l*) in dry tetrahydrofuran (3.0 m*l*) was added over a period of 5 min. After the stirring had been continued for 3 hr at 0—10°C, a few drops of water were added to decompose the excess diborane, and then aqueous sodium hydroxide (12%: 1.6 m*l*) and hydrogen peroxide (30%: 1.6 m*l*) were added to the stirred solution. The mixture was stirred for 30 min, poured into a saturated sodium chloride solution, and then extracted with ether. The extract was washed with a saturated sodium chloride solution, dried over sodium sulfate, and then evaporated. The residual oil was chromatographed on silica gel (150 g) to give the crude XX as an oil (590 mg), the IR spectrum of which showed a band at 3600 cm^{-1}(OH).

A solution of the above XX (550 mg) in acetone (10 m*l*) was oxidized with the Jones reagent[7] (2N: 1.3 m*l*) at room temperature for 5 min. The mixture was then poured into water, and extracted with ether, after which the extract was washed with aqueous sodium chloride and then dried over sodium sulfate. After the removal of the ether, the residue was chromatographed on silica gel (50 g), using benzene as the eluent, to give XXI as a solid (126 mg). This was recrystallized from ether containing petroleum ether to give colorless crystals, mp 102—103.5°C. The IR and NMR spectra of XXI were identical with the data reported for an optically-active sample. IR in $CHCl_3$; 1718, 1605, 1560, 1470, 1450, 1405, 1363, 1318, 1065, 1020 $cm.^{-1}$ NMR in $CDCl_3$; 1.02 and 1.27 (each 3H and s, $-\dot{C}(C\underline{H}_3)_2$), 1.18 and 1.21 (each 3H d and J=7 Hz, $-CH-(C\underline{H}_3)_2$), 1.36 (3H, s, $-\dot{C}C\underline{H}_3$), 2.60 (1H, s, $-\dot{C}\underline{H}CO-$), 3.16 (1H, m, $-C\underline{H}(CH_3)_2$), 3.55 (2H, q, $-COC\underline{H}_2-$), 3.77 and 3.84 (each 3H and s, 2-$OC\underline{H}_3$), 6.62 (1H, s, aromatic proton) ppm.

Found: C, 76.89; H, 9.25%. Calcd for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36%.

Literature: IR in $CHCl_3$[3] 1724, 1605, 1565, 1471, 1449, 1406, 1362, 1316, 1068, 1025 cm^{-1}. The authors are grateful to Professor S. Morris Kupchan, University of Virginia, for his gift of natural taxodione.

The Solvent Effect on the Reaction Selectivity in the Chlorination of Propionic Acid

Toshikazu NAGAI, Yukio HORIKAWA, Hon Son RYANG, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received March 25, 1971)

The chlorinations of propionic acid with chlorine were carried out at 70°C in various solvent mixtures with photo-irradiation or with initiation by benzoyl peroxide. Benzene - CCl_4, naphthalene - CCl_4, and anthracene - CCl_4 mixtures, and sulfur dioxide - CCl_4 were used as the solvents. In the benzene - CCl_4 mixtures, the relative reactivity, β/α, of the α and the β positions of propionic acid changed from 1.68 (CCl_4) to 1.11 (benzene), the ratio being inversely proportional to the electron-donor properties of the solvents. In the naphthalene - CCl_4 mixtures, the plot of the relative reactivity, β/α, *versus* the naphthalene content showed a minimun at *ca.* 0.1 mol/*l* of naphthalene; however, the total yield of the chlorinated acids decreased as the content of the naphthalene increased. No chlorinated acids were obtained in the anthracene - CCl_4 system. In the presence of sulfur dioxide, the α-position was more readily substituted than the β-position, the β/α ratio decreasing as the molar ratios of Cl_2/SO_2 were decreased, from 1.3 ($Cl_2/SO_2=0.286/0.036$) to 0.49 (0.286/0.858), by the initiation of benzoyl peroxide. However, dilution with CCl_4 or photo-irradiated chlorination cause no change in the selectivity in spite of the presence of sulfur dioxide. A mechanism to account for such a selectivity has been suggested.

It is well known[1] that the chlorine atom attacks hydrogen atoms more readily in this order: tertiary> secondary>primary hydrogen. However, when a compound bearing an electron-withdrawing substituent, such as propionic acid, is involved, the primary position (β-hydrogen) is more readily substituted than the secondary one (α-hydrogen) because of the lower electron density at the α-position, while the chlorine atom is an electrophilic reagent.

It has been generally assumed that a solvent has little effect upon the course and rate of the free radical reaction. Yet, it has also been accepted that chlorination by a chlorine atom has a remarkable selectivity varying with the solvent used. Chlorine forms a π-complex with the aromatic nucleus by a charge transfer-type interaction.[2] This complexed radical is less reactive and more selective than a free chlorine atom. Thus, the ratio of the relative rates, k_{tert}/k_{prim}, of 2,3-dimethylbutane rises more in benzene or in other donor solvent than in a hydrocarbon.[3]

The present paper is concerned with the study of the reaction and the selectivity of attacking radicals in the chlorination of propionic acid in various solvent mixtures.

Results and Discussion

The chlorination of propionic acid with chlorine was carried out at 70°C in various solvents with photoirradiation or with initiation by benzoyl peroxide (BPO). The solvents used were benzene - carbon tetrachloride mixtures, naphthalene - carbon tetrachloride mixtures, and anthracene - carbon tetrachloride mixtures. The chlorination was also undertaken in the presence of sulfur dioxide and sulfur dioxide - carbon tetrachloride mixtures.

The reactions were performed by passing chlorine gas through the reaction mixtures. As products, α-chloro-, α,α-dichloro-, β-chloro-, and β,β-dichloro- propionic acids and a cyclic anhydride of β-sulfopropionic acid[4] were obtained. A negligible amount of chlorinated aromatic compounds was also formed.

The products were analyzed by the NMR spectral method. In these experiments the authors paid special attention to establishing the relationship between the relative reactivity, β/α, and the concentration of the aromatic compound mixed into the solution or the quantity of sulfur dioxide used.

Table 1 summarizes the results of the chlorination where the effect of benzene in the reaction mixture was examined. The data in this table demonstrate that the relative reactivity, β/α, decreases from 1.68 to 1.11 as the mole fraction of benzene in the solvent (benzene - CCl_4) increases from zero to unity. The values of β/α are not affected by differences in the initiation, the photo-irradiation, or the BPO. The results of the addition of naphthalene to the solvent (CCl_4) are shown in Table 2. The plot of the relative reactivity *vs.* the concentration of naphthalene exhibits a minimum point at *ca.* 0.1 mol/*l* of naphthalene, as is seen in Fig. 2. Moreover, the total yield of the chlorinated products decreases as the concentration of naphthalene is increased.

The addition of anthracene to the solvent (CCl_4) gave no chlorinated propionic acids, even when a very small quantity (0.117 mol/*l*) was present in the reaction mixture. As Table 3 indicates, the decrease in the relative reactivity was more accelerated in the presence of sulfur dioxide. When an equimolar amount of sulfur dioxide or more is mixed with the chlorine, the relative reactivity decreases below unity, indicating the reversal of the reactivities between the α- and β-positions. On the contrary, no change in the selectivity with the sulfur dioxide concentration was observed in the photo-initiated chlorination where the relative reactivity was kept constant, $\beta/\alpha=1.4$; this selectivity is very similar to the relative reactivity in the carbon tetrachloride only.

However, the cyclic anhydride of β-sulfopropionic acid was obtained in both photo- and BPO- initiated processes, and neither the free acid nor the cyclic anhydride of α-sulfopropionic acid was detected in the reaction mixture; these results coincide with the earlier results of photochlorination by Kharasch *et al.*[4] This suggests that the formation of the cyclic anhydride of α-sulfopropionic acid is difficult because of the electronical and sterical effects of the carboxyl group.

Table 3 also lists the results of the reaction of propionic acid with sulfuryl chloride at 70°C. The relative reactivity by BPO initiation, $\beta/\alpha=0.76$, resembles the result of equimolar chlorination with SO_2 and Cl_2 by BPO initiation, 0.87.

These data on the various reactions suggest several interesting things. First, the dependence of the relative reactivities upon the concentrations of aromatic compounds or the quantities of sulfur dioxide suggests that not only the chlorine radical, but also another radical species such as complexed radicals, take part in these reactions. Moreover, the species have more selectivities than the free chlorine atom. Secondly, the con-

Table 3. Chlorination of propionic acid in the presence of SO_2 and by SO_2Cl_2 at 70°C

a) The cyclic anhydride of β-sulfopropionic acid
b) Chlorination by SO_2Cl_2
c) No hydrogen rearrangement between the α- and β- position occurred under the present conditions, which was confirmed using propionic-α,α-d_2 acid-d_1 as the starting material.

tributions of these species to the reactions differ greatly among aromatic compounds.

Thirdly, in the presence of sulfur dioxide, the photo-initiated reaction proceeds quite differently from the BPO-initiated reaction, where there is no dependence of the relative reactivity on the concentration of sulfur dioxide used. Consequently, the chlorination mechanism in the former case should be discriminated.

In the aromatic systems, the radical species different from the free radicals are probably complexed radicals between aromatic compounds and a chlorine radical. The formation of this π-complex had been suggested by Russel.[3] For benzene, it could be written as follows:

(1)

Recently,[2] such a π-complex was detected by means of the UV spectra as arising from a charge-transfer-type interaction. Thus, we presumed that these π-complexed radicals and free chlorine radicals are competitive in the present reaction series. The chain propagation reactions can be formulated thus, where Ar denotes aromatic compounds:

$$Cl_2 + Ini\cdot \longrightarrow IniCl + Cl\cdot \quad (2)$$

$$Cl\cdot + Ar \overset{K_1}{\rightleftarrows} Cl\cdot \rightarrow Ar \quad (3)$$

$$Cl\cdot + 2Ar \overset{K_2}{\rightleftarrows} Ar\rightarrow Cl\cdot\leftarrow Ar \quad (4)$$

$$CH_3CH_2CO_2H + Cl\cdot \xrightarrow{k_{\alpha 0}} CH_3\dot{C}HCO_2H + HCl \quad (5)$$

$$CH_3CH_2CO_2H + Cl\cdot \xrightarrow{k_{\beta 0}} \dot{C}H_2CHCO_2H + HCl \quad (6)$$

$$CH_3CH_2CO_2H + Cl\cdot\leftarrow Ar \xrightarrow{k_{\alpha 1}} CH_3\dot{C}HCO_2H + HCl + Ar \quad (7)$$

$$CH_3CH_2CO_2H + Cl\cdot\leftarrow Ar \xrightarrow{k_{\beta 1}} \dot{C}H_2CH_2CO_2H + HCl + Ar \quad (8)$$

$$CH_3CH_2CO_2H + Ar\rightarrow Cl\cdot\leftarrow Ar \xrightarrow{k_{\alpha 2}} CH_3\dot{C}HCO_2H + HCl + 2Ar \quad (9)$$

$$CH_3CH_2CO_2H + Ar\rightarrow Cl\cdot\leftarrow Ar \xrightarrow{k_{\beta 2}} \dot{C}H_2CH_2CO_2H + HCl + 2Ar \quad (10)$$

We could not explain the results of the naphthalene - CCl_4 system by considering merely the free chlorine radical or the 1:1 complexed radical between the chlorine radical and naphthalene as the reacting species. This is the reason why we wish to propose the presence of another complex, such as a 1:2 complex between the chlorine radical and the aromatic compound, in the reaction mixture.

The step of hydrogen abstraction must be rate-controlling in the chlorine substitution reaction. The formation rates of α-chloropropionic acid and β-chloropropionic acid are given by Eqs. (11) and (12) respectively:

$$\frac{d[CH_3CHClCO_2H]}{dt} = k_{\alpha 0}[Cl\cdot][Pr] + k_{\alpha 1}[Ar\rightarrow Cl\cdot][Pr] + k_{\alpha 2}[Ar\rightarrow Cl\cdot\leftarrow Ar][Pr] = (k_{\alpha 0}+k_{\alpha 1}K_1[Ar] + k_{\alpha 2}K_2[Ar]^2)[Pr][Cl\cdot] \quad (11)$$

$$\frac{d[CH_2ClCH_2CO_2H]}{dt} = k_{\beta 0}[Cl\cdot][Pr] + k_{\beta 1}[Ar\rightarrow Cl\cdot][Pr] + k_{\beta 2}[Ar\rightarrow Cl\cdot\leftarrow Ar][Pr] = (k_{\beta 0}+k_{\beta 1}K_1[Ar] + k_{\beta 2}K_2[Ar]^2)[Pr][Cl\cdot] \quad (12)$$

Hence, the relative formation rate may be represented as Eq. (13):

$$\frac{d[CH_2ClCH_2CO_2H]}{d[CH_3CHClCO_2H]} = \frac{k_{\beta 0}+k_{\beta 1}K_1[Ar]+k_{\beta 2}K_2[Ar]^2}{k_{\alpha 0}+k_{\alpha 1}K_1[Ar]+k_{\alpha 2}K_2[Ar]^2} \quad (13)$$

If the concentration of the aromatic compounds is constant during the reaction time, the relative reactivity can be expressed as the following Eq. (14):

$$\frac{\beta}{\alpha} = \frac{[CH_2ClCH_2CO_2H]}{[CH_3CHClCO_2H]} \times \frac{2}{3} = \frac{k_{\beta 0}+k_{\beta 1}K_1[Ar]+k_{\beta 2}K_2[Ar]^2}{k_{\alpha 0}+k_{\alpha 1}K_1[Ar]+k_{\alpha 2}K_2[Ar]^2} \times \frac{2}{3} \quad (14)$$

Many interesting suggestions about these reaction series were obtained from the differential equation of Eq. (14) with respect to the aromatic concentration (Eq. (15)):

$$\frac{d\left(\frac{\beta}{\alpha}\right)}{d[Ar]} = \frac{(k_{\alpha0}k_{\beta1}K_1 - k_{\alpha1}k_{\beta0}K_1) + 2(k_{\alpha0}k_{\beta2}K_2 - k_{\alpha2}k_{\beta0}K_2)[Ar] + (k_{\alpha1}k_{\beta2}K_1K_2 - k_{\alpha2}k_{\beta1}K_1K_2)[Ar]^2}{(k_{\alpha0} + k_{\alpha1}K_1[Ar] + k_{\alpha2}K_2[Ar^2])^2} \times \frac{2}{3} \quad (15)$$

First, the relation (16) can be derived for the benzene - CCl_4 system, which shows a monotonous decreasing curve in the β/α *vs.* Ar (aromatic) plot, as is indicated in Fig. 1:

$$\frac{k^B_{\beta0}}{k^B_{\alpha0}} > \frac{k^B_{\beta1}}{k^B_{\alpha1}} > \frac{k^B_{\beta2}}{k^B_{\alpha2}} \quad (16)$$

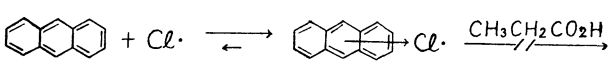
The relation (16) demonstrates that the relative reactivities decrease in this order: the free chlorine radical, the 1:1 complexed radical, and the 1:2 complexed radical. Such a prediction makes it clear that the reactivities of these radical species diminish in this order, so the reactivity of secondary hydrogen in propionic acid increases as compared with the primary hydrogen according to the above order.

The approximate value of each term in the relation (16) can be obtained from the curve of Fig. 1. That is, in benzene - CCl_4 systems the relative reactivities of the free radical, the 1:1 complex radical, and the 1:2 compelx radical are estimated to be 1.68, 1.12, and 1.01 respectively.

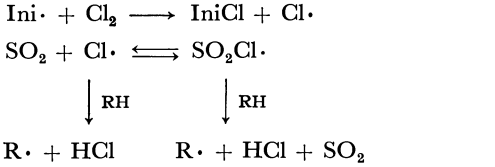
Secondly, in the naphthalene - CCl_4 series a minimum point in the plot is seen as shown in Fig. 2, where the relation (17) may be derived similarly as in the above case:

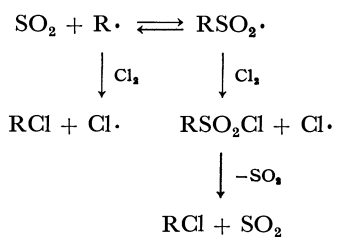
$$\frac{k^N_{\beta0}}{k^N_{\alpha0}} > \frac{k^N_{\beta1}}{k^N_{\alpha1}} \qquad \frac{k^N_{\beta1}}{k^N_{\alpha1}} < \frac{k^N_{\beta2}}{k^N_{\alpha2}} \quad (17)$$

The relation (17) points out the striking tendency that the relative reactivity of the 1:2 complexed radical is larger than that of the 1:1 complexed radical. Thus, it is anticipated that the hydrogen abstraction in the α-position suffers from more steric hindrance, largely because of the bulk of the 1:2 complexed radical. Accordingly, this steric effect will accelerate the increase in the selectivity, indicating a reversal of the reactivity tendency. Thirdly, the two equilibrium constants in the naphthalene - CCl_4 system, K_1 and K_2, are much larger than those in the benzene - CCl_4 system, because the relative reactivityl of the former changes in a much lower concentration of aromatic compounds than that of the latter. Fourthly, the equilibrium constants of the anthracene - CCl_4 systems are so large that the free chlorine radical could scarcely participate in this reaction. Moreover, the recativity of the formed complexed radicals is too low to be able to abstract a hydrogen atom of propionic acid.



In the presence of sulfur dioxide, a new radical such as $SO_2Cl\cdot$ may be formed, as is seen in Scheme 1:





Scheme 1

The chlorine radical has so large an electrophilicity that the reaction is very sensitive to the electron density of the substrate as well as to the solvent used. The relative reactivity (β/α) or the selectivity varies according to the polar effect of the substituent in the substrate and the medium with which the radical may form a complex or a new attacking species.

The present authors have confirmed that propionic acid does not react with chlorine in either *n*-heptane, anisole, or dioxane, where the hydrogens of the solvent molecules have high electron densities. Thus, the relative reactivity (β/α) of propionic acid will diminish upon the decrease in the electrophilicity of the attacking radical, because the electron density at the α-position hydrogen atom is expected to have a lower electron density than that at the β-position in propionic acid.

Ordinarily, a rise in such a selectivity is accompanied by a decrease in the reactivity of the attacking radical.

It has been reported that the sulfochlorine radical is less reactive than the chlorine radical.[5] The increase in the content of the aromatic compound in the reaction mixture results in a proportionate decrease in the total yield of the reaction product. The decrease in the reactivity of the attacking radical will cause an increase in the energy difference due to selectivity (E_s) between primary (β) and secondary (α) hydrogens. On the other hand, the energy difference due to the polar effect (E_p) will decrease as the chlorine radical forms another complex or a new complexed radical, because the nucleophilic character of the latter will increase. The energy difference between the α and the β-positions would be reduced by the compensation of both the effects. If E_s is very large and if E_p is small, as in the sulfochlorine radical, it can be expected that the reversal of the relative reactivity may easily happen.

The energy-level diagram in the reaction course is illustrated in Fig. 3.

In the chlorine - sulfur dioxide system the present authors assumed that a sulfochlorine radical was formed. However, we could not completely rule out the interaction between the carboxyl group of the substrate and the sulfur dioxide molecule. The oxygen atom of sulfur dioxide is bonded with the α-hydrogen atom by a hydrogen bonding, as is indicated in Fig. 4. Thus, the α-hydrogen-carbon bond is weakened and is easily attacked by a chlorine radical to abstract the α-hydrogen atom.

The difference in the results of the photoreactions between the Cl_2 - aromatics - CCl_4 and Cl_2 - sulfur dioxide systems is probably caused by the following factors.

5) G. A. Russell and H. C. Brown, *J. Amer. Chem. Soc.*, **77**, 4031 (1955).

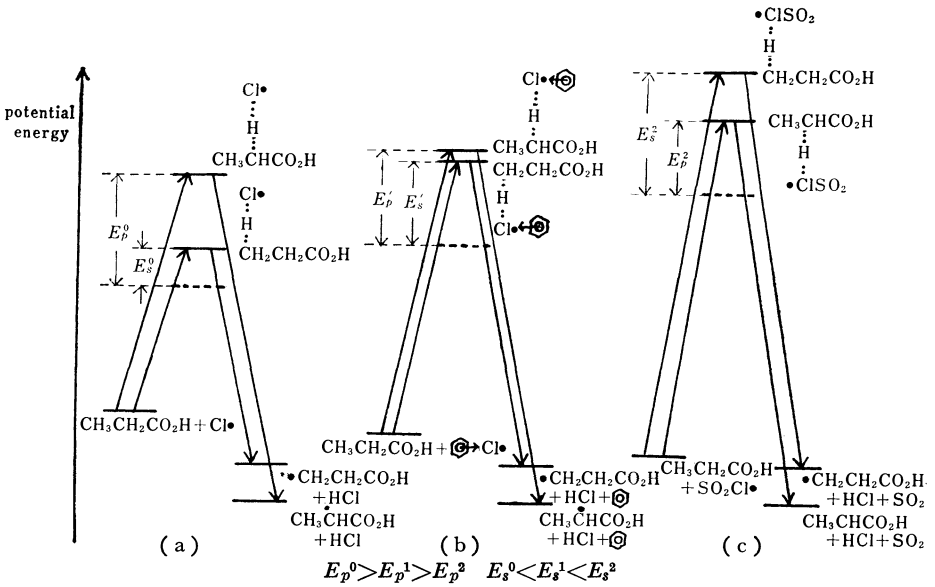


Fig. 3. Schematic energy diagram of chlorination reaction of propionic acid with chlorine, in the absence of solvent (a), in the presence of benzene (b) or sulfur dioxide (c).

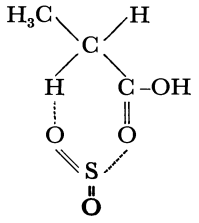

Fig. 4

In the Cl_2-aromatics - CCl_4 system, photo-irradiation has little influenece upon the stabilities of the formed complexed radicals, while photo-irradiation may hinder the formation or may quickly decompose the sulfochlorine radical, as is shown by the following scheme:

$$SO_2 + Cl\cdot \rightleftarrows SO_2Cl\cdot$$

$$SO_2Cl\cdot \xrightarrow{h\nu} SO_2Cl\cdot * \longrightarrow SO_2 + Cl\cdot$$

As has been mentioned above, the relative reactivity in the photoreactions by the $Cl_2 - SO_2$ system was similar to that of the attack by the chlorine radical alone, in spite of the presence of sulfur dioxide.

The selectivity in the reaction of SO_2–Cl_2 diluted with carbon tetrachloride has also indicated no dependence upon the concentration of sulfur dioxide as in the case of the photo-irradiation. The reason for this probably lies in the instability of the $SO_2Cl\cdot$ radical as a result of its dilution by carbon tetrachloride.

The formation of the $SO_2Cl\cdot$ radical as the attacking species in the $Cl_2 - SO_2$ - BPO system may be proved by the results shown in Table 3, where the relative reactivity, β/α, is 0.76, this value being close to the result in the equimolar ($Cl_2 : SO_2 = 1 : 1$) chlorination, $\beta/\alpha = 0.87$.

Experimental

Chlorination of Propionic Acid Initiated by Benzoyl Peroxide in a Benzene - Carbon Tetrachloride Mixed Solvent. Propionic acid (10.59 g, 0.143 mol), a solvent (1.0 mol), and BPO (0.087 g, 0.00036 mol) were placed in a four-necked flask (200 m*l* volume) immersed in a water bath equipped with a thermostat. The solvents used were mixtures of benzene and carbon tetrachloride, mole fractions of benzene varying as 0.0, 0.1, 0.2, 0.3, 0.5, 0.7, 0.8, 0.9, and 1.0. Chlorine gas (0.286 mol), which had been washed and dried by the use of water, concentrated sulfuric acid, calcium oxide and phosphorus pentoxide, was blown into the reaction mixtures at 70°C for three hours. The amount of flowing chlorine gas was set by a flow meter. In these reactions, all the entire reaction apparatus was sheltered from light, and the reaction apparatus was filled with nitrogen gas before the reactions in order to eliminate the effect of oxygen. The solvents were removed by distillation, and the residue was analyzed by means of the NMR spectra. The following compounds were obtained for chlorinated propionic acids.

NMR: $CH_3CHClCO_2H$, τ, 5.70 (quartet) 8.29, (doublet).
$CH_3CCl_2CO_2H$ 7.70 (singlet),
$CH_2ClCH_2CO_2H$ 6.12 (triplet), 7.18 (triplet).
$CHCl_2CH_2CO_2H$ 3.98 (triplet), 6.72 (doublet).

The yields of these compounds were calculated from the areas of their respective peaks. A small white crystal was gained as the by-product. The crystal was recrystallized from ethanol melted at 157—158°C. This product was confirmed as α-benzene hexachloride by a comparison of the IR and NMR spectra, and the retention time in gas-liquid chromatography, with those of an authentic specimen. In addition to this, a very small amount of chlorobenzene was obtained; it was identified by a study of the IR spectrum and by glc.

Chlorination in Naphthalene - Carbon Tetrachloride and Anthracene - Carbon Tetrachloride. The reactions were performed in the same apparatus and using the same procedure as have been described above. The mole fractions of naphthalene in the solvent (CCl_4) used were 0.006, 0.01, 0.014, 0.019, 0.025, 0.05, 0.10, and 0.20, and that of anthracene was 0.0129.

Chlorination with Photo-initiation in Benzene - Carbon Tetrachloride. In a reaction flask we placed propionic acid (10.59 g, 0.143 mol) and solvents (1.0 mol). This reaction flask was then illuminated by a 300-watt unfrosted tungsten light bulb placed near it. The mole fraction of benzene in the mixed solvents were 0.0, 0.5, and 1.0 respectively. Iden-

tification and quantitative analysis were done by the previously-described procedures.

Chlorination Initiated by BPO in the Presence of Sulfur Dioxide. To a four-necked vessel with a volume of 50 m*l* immersed in a water bath and equipped with a thermostat, we added propionic acid (10.59 g, 0.143 mol) and BPO (0.087 g, 0.00036 mol). Dried chlorine gas (0.286 or 0.572 mol) and sulfur dioxide gas were then passed through the reaction mixtures at 70°C for three hours. The total amounts of sulfur dioxide used were 0.036, 0.142, 0.286, 0.572, and 0.858 mol respectively. Soon after the reaction, white crystals were formed. These crystals were separated from benzene - ligroin (1:4) mixtures. The compound was identified as the cyclic anhydride of β-sulfopropionic acid by a comparison of its melting point, NMR, and mass spectra with those of an authentic specimen. Mp, 76—77°C. NMR: centered at 6.97 (multiplet) and 7.38 (multiplet). Mass: exhibited a molecular ion peak at *m/e* 136 with those of fragment ions. The soluble compounds in the solvent were distilled under pressure (10 mm Hg) after the solvents had been removed. The three portions of the distillate at 50—70, 70—80 and 80—90°C were submitted to NMR analyses.

Photochlorination in the Presence of Sulfur Dioxide. Sulfur dioxide (0.858 mol) was passed with chlorine gas (0.143 or 0.286 mol) through a reaction vessel containing propionic acid (0.143 mol). Identification and quantitative analysis were done as has been described in the experimental section concerning initiation with BPO.

Reaction of Propionic Acid with Sulfuryl Chloride. Propionic acid (0.143 mol) was reacted with sulfuryl chloride (0.195 mol) at 70°C with BPO (0.00036 mol).

NMR Spectra. The proton resonance spectra were run on a Nihondenshi spectrometer at 60 MHz.

IR Spectra. The infrared spectra were recorded on an EPI-S2-TYPE Hitachi spectrometer.

Mass Spectra. The mass spectra were run on a Hitachi RMU-6E single-focusing instrument.

Gas-liquid Chromatography. Glc was carried out on a K53-TYPE Hitachi chromatograph, using Silicone SE-30 as the column.

The Hofmann Rearrangement. IV. Kinetic Isotope Effect of *N*-Chlorobenzamide

Tsuneo IMAMOTO, Seung-Geon KIM, Yuho TSUNO, and Yasuhide YUKAWA
The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka

(Received March 25, 1971)

Kinetic isotope effects in the Hofmann rearrangement of phenyl-1-^{14}C and carbonyl-^{14}C labeled *N*-chlorobenzamides were measured in a sodium hydroxide solution at 15°C. The observed isotope effect on the phenyl-1-carbon is

$$k_{12}/k_{14} = 1.0456 \pm 0.0012$$

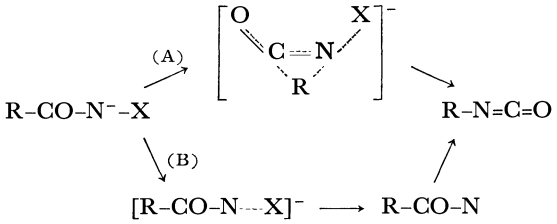
and that on the carbonyl-carbon is

$$k_{12}/k_{14} = 1.0447 \pm 0.0006$$

These results strongly support a concerted mechanism for this rearrangement. Attempts have been made to correlate the isotope effect on phenyl-1-carbon to the *r*-value of the linear aromatic substituent-reactivity relationship in related 1,2-rearrangements.

The most important stage in the course of the Hofmann reaction is the rearrangement step in which the conjugate base of *N*-haloamide is converted into isocyanate accompanying the release of a halide ion. With a view to clarifying the precise reaction mechanism of this step, we have investigated this rearrangement kinetically. Kinetic results of the rearrangements of various substituted *N*-bromo- and *N*-chlorobenzamides in an aqueous sodium hydroxide solution have been reported.[1-3] These results could be interpreted by considering a concerted mechanism (path (A)) rather than an alternative two-step mechanism (path (B)).

We have now studied the kinetic isotope effect of this rearrangement using phenyl-1-^{14}C and carbonyl-^{14}C labeled *N*-chlorobenzamides in order to demonstrate this concerted mechanism.



Results and Discussion

The rate of rearrangement of the non-labeled *N*-chlorobenzamide was measured at 15.00±0.01°C by the iodometric method. The initial concentrations of *N*-chloroamide and sodium hydroxide were 0.05 mol/*l*

2) T. Imamoto, Y. Tsuno, and Y. Yukawa, *ibid.*, **44**, 1639 (1971).
3) T. Imamoto, Y. Tsuno, and Y. Yukawa, *ibid.*, **44**, 1644 (1971).

and 0.5 N, respectively.[4] The first-order kinetic plots formed straight line to at least 85% completion of the reaction. The rate constant obtained from repeated runs was $k_1=7.830\pm0.009\times10^{-5}$ sec^{-1}. This value is larger by *ca.* 1% than the one reported previously.[2] The slight difference in the rate constant refers to the change of the initial concentration of *N*-chloroamide from 0.025 to 0.05 mol/*l*.

Determination of the kinetic isotope effect was carried out under the same reaction conditions by measuring the specific activities of the benzamide derived quantitatively from the remaining reactant *N*-chlorobenzamide. Labeled *N*-chlorobenzamide, prepared from commercial benzoic-^{14}C acid, was dissolved in an aqueous sodium hydroxide solution. A certain amount of the reaction solution was pipetted out at intervals and transferred into hydrochloric acid containing excess potassium iodide. After reduction of the liberated iodine with a sodium thiosulfate solution, the benzamide was extracted and purified by recrystallization. The specific activity of the benzamide thus obtained was determined by an equilibrium voltage method with an ionization chamber and a vibrating reed electrometer connected to a digital integrating voltmeter. These results are listed in Table 2. The kinetic isotope effect was calculated by the least-squares method according to the equation

$$\log A_x = \log A_0 - (1-k_{14}/k_{12}) \log (1-x) \qquad (1)$$

where x is the fraction of reaction calculated from the reaction time and the rate constant ($k_1=7.830\times10^{-5}$ sec^{-1}), and A_x and A_0 are specific activities at $x=x$ and $x=0$ respectively. Figure 1 shows the plots of log A_x *vs.* log$(1-x)$. The calculated kinetic isotope effect on the phenyl-1-carbon is given by

$$k_{12}/k_{14} = 1.0456 \pm 0.0012$$

and that on the carbonyl-carbon by

$$k_{12}/k_{14} = 1.0447 \pm 0.0006$$

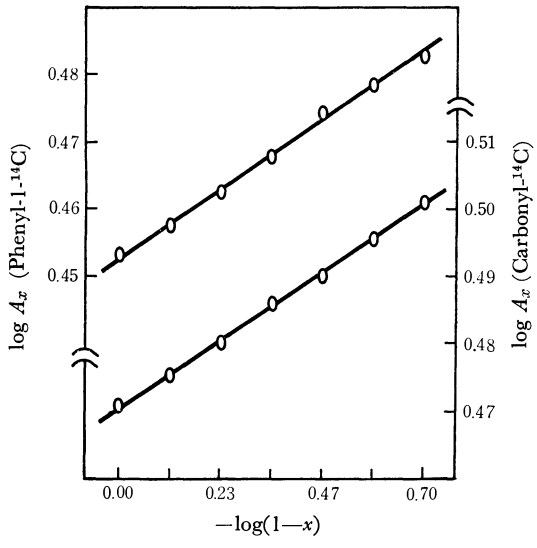

Fig. 1. Plots of log A_x *vs.* −log$(1-x)$

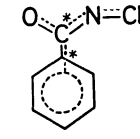
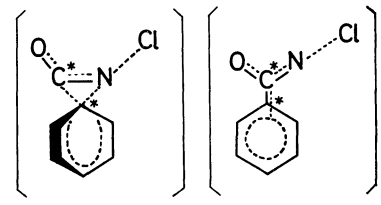
4) From the results of the preliminary experiment on the recovery and the purification of the residual unrearranged benzamide, 0.05 mol/*l* was employed as the most suitable initial concentration of *N*-chloroamide.

Theoretical and experimental studies on the isotope effect lead to the conclusion that the variation of bonding at a labeled position from the initial state to the transition state in the rate-determining step is the most important factor to cause a kinetic isotope effect.[5,6] Thus it is necessary, for elucidation of the precise reaction mechanism of the present Hofmann rearrangement, to examine the variations of the total bondings at respective labeled positions in *N*-chlorobenzamide for the proposed mechanisms.

The initial and transition states for the concerted and two-step mechanisms may be schematically represented as follows.



I. S.



T. S., Concerted T. S., Two-step

In the former mechanism, bondings at the labeled positions change remarkably in proceeding from initial to transition states, and measurable kinetic isotope effects can be expected in this mechanism. On the contrary, if the reaction proceeds through the two-step mechanism, no apparent kinetic isotope effect should be observed, since the transition state resembles the initial state with respect to the bondings at the labeled positions.

Thus the apparent kinetic isotope effects on phenyl-1- and carbonyl-carbons evidently indicate the concerted mechanism for the Hofmann rearrangement.[7]

In addition to the present Hofmann rearrangement, the kinetic isotope effects of Beckmann, Wolff and Schmidt rearrangements have been studied in our laboratory by the use of phenyl-1-^{14}C and carbonyl-^{14}C labeled compounds. The obtained results are summarized in Table 1. An important working hypothesis in the course of these studies is that the apparent observation of the kinetic isotope effect on phenyl-1-carbon indicates the participation of the phenyl group in electron-deficient migration terminus in the transition state. This suggests that the Hofmann and the Beckmann rearrangements proceed through a concerted type transition state. In the cases of other Wolff and Schmidt rearrangements, where kinetic isotope effects

on the phenyl-1-carbon were not observed within experimental error, the migration of the phenyl group might not take place in the rate-determining step.

On the other hand, application of the following LArSR relationship (linear aromatic substituent–reactivity relationship) is useful for elucidating the mechanisms of organic reactions.

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \qquad (2)$$

In particular, empirical facts on the resonance parameter r have enabled us to evaluate quantitatively the degree of conjugation effect on the reactivity.[8]

The calculated r-values of Hofmann, Beckmann and Wolff rearrangements are given in Table 1. Comparatively large positive r-values of the former two rearrangements indicate the additional conjugation effect to the reaction center with the stabilization of the transition state. In contrast, the large negative r-value of the Wolff rearrangement shows that the resonance stabilization of the initial state is the most important factor in the reactivity.

It is of interest to compare these r-values with the kinetic isotope effects on phenyl-1-carbons. The positive r-value indicates an apparent isotope effect and the large negative r-value no effect. This leads to the conclusion that not only the application of the LArSR relationship but also the isotope effect study on phenyl-1-carbon are useful for the elucidation of the precise reaction mechanism of 1,2-rearrangement.

Experimental

Materials. N-*Chlorobenzamide-(Phenyl-1-*^{14}*C)*: A mixture of 10.0 g of phenyl-1-^{14}C labeled benzoic acid (supplied from NENC, USA) and 27 g of purified thionyl chloride was refluxed for 2 hr. The excess thionyl chloride was removed by azeotropic distillation adding twice 10 m*l* of absolute benzene. The benzoyl chloride obtained was added dropwise to 70 m*l* of 28% aqueous ammonia with stirring at 0—5°C. The benzamide precipitated was collected, washed with water and dried, mp 126.5—127.5°C, yield 8.11 g (82%). This crude amide was recrystallized three times from dichloroethane - ligroin (1:1), 6.60 g, mp 127.5—128.5°C. Specific activity 2.830 mCi/mol. The obtained pure amide (6.37 g) was dissolved in 400 m*l* of 3N HCl and chlorine gas was passed for 2 hr. The *N*-chloro derivative thus precipitated was collected, washed with water and dried *in vacuo*, 6.91 g (84%), mp 114—116°C. This was recrystallized twice from dichloroethane - ligroin (1:2), 5.38 g, mp 117.0—118.0°C (reported 117.0—118.0°C[2]). Active chlorine: found 22.85%, calcd. 22.79%. Specific activity 2.830 mCi/mol.

N-*Chlorobenzamide-(Carbonyl-*^{14}*C)*: Carbonyl-^{14}C labeled benzoic acid (supplied from RCC, England) (10.0 g) was converted into *N*-chlorobenzamide (4.95 g) by the same procedure as described in the preceding part. Benzamide: mp 127.5—128.5°C, specific activity 2.961 mCi/mol. *N*-chlorobenzamide: mp 117.0—118.0°C, specific activity 2.960 mCi/mol, active chlorine; found 22.73%, calcd 22.79%.

No mutual contamination of the phenyl-1-^{14}C and the carbonyl-^{14}C labeled *N*-chlorobenzamides was indicated by comparing the specific activities of the derived acetanilides with those of the respective reactants *N*-chlorobenzamides-^{14}C.

Determination of the Rate Constant. The rate constant of the rearrangement of non-labeled *N*-chlorobenzamide was determined at 15.00±0.01°C by the same procedure described previously.[1,2]

Measurement of the Kinetic Isotope Effect. Kinetic Procedure and Preparation of the Sample for Assay. In a measuring flask was placed 400 m*l* of a standardized aqueous sodium hydroxide solution (0.500N), and the flask was immersed in a constant temperature bath (15.00±0.01°C). Labeled *N*-chlorobenzamide (3.112 g) was weighed into a 500 m*l* Erlenmeyer flask and immersed in the same bath. After being kept for several hr, the sodium hydroxide solution was transferred into the Erlenmeyer flask with vigorous swirling. A certain amount of the reaction solution was pipetted out at intervals

8) Y. Yukawa, Y. Tsuno, and M. Sawada, This Bulletin, **39**, 2274 (1966); Y. Yukawa and Y. Tsuno, *Nippon Kagaku Zasshi*, **86**, 783 (1965).

and transferred into 15 m*l* of 6N HCl containing 700 mg of potassium iodide. A sodium thiosulfate solution (0.3N) was added dropwise until the color of the liberated iodine disappeared. The residual unrearranged benzamide was extracted with five 50 m*l* portions of dichloromethane. The solvent was evaporated and the residue was stirred with 50 m*l* of dichloroethane. A small amount of the undissolved salts was excluded by filtration. The filtrate was evaporated to give pale yellow needles, *ca.* 120 mg, mp 125—127°C. This was recrystallized five times from toluene to afford 40—50 mg of sample for assay, colorless plates, mp 127.5—128.5°C.

Measurements of Specific Activity. About 7—8 mg of accurately weighed benzamide-^{14}C was burned by means of a combustion furnace for micro-elemental analysis, and the carbon dioxide generated was introduced into a 200 m*l* ionization chamber. The chamber was set on a Takeda-Riken RS-84 vibrating reed electrometer connected to a digital integrating voltmeter. The ion current was recorded as relative voltage every ten seconds for 1 hr, and the mean value of the voltage was obtained with the standard deviation of $\pm$0.2%. The radioactivity of the sample was calculated by calibration of the obtained voltage with that of the standard chamber. Specific activity measurements were carried out at least twice for each sample. Reproducibility of the specific radioassay was within 0.25% in every case. The results are given in Table 2. The error indicates the standard deviation from the mean value.

Table 2. Specific activities of residual unrearranged benzamide

No.	Time (min)	Fraction of reaction (%)	Specific activity (mCi/mol) Phenyl-1-^{14}C	Carbonyl-^{14}C
1	0	0	2.8404$\pm$0.0024[a)]	2.9567$\pm$0.0016[a)]
2	57.1	23.5	2.8666$\pm$0.0014	2.9877$\pm$0.0024

Synthetic Studies of Amino Acids by the Use of Copper Complex. II.[1] The Condensation Reaction of *N*-Pyruvylideneglycinatocopper(II) Complexes with various Aldehydes

Tetsuya ICHIKAWA, Sadao MAEDA, Toshiro OKAMOTO, Younosuke ARAKI, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 31, 1971)

An investigation of the mechanism of the reaction which involves the base-catalyzed condensation of bis(glycinato)copper(II) with aldehydes was carried out with the purpose of improving it so that it can proceed even with lower molar equivalent ratios of aldehydes to the complex and under milder conditions. On the basis of the results reported in the literature and those of this investigation, the reaction has been carried out as expected and has been newly shown to be applicable to *p*-tolualdehyde and *p*-chlorobenzaldehyde, and, moreover, to such aldehydo sugar derivatives as 2,3-*O*-isopropylidene-D-glyceraldehyde by the use of *N*-pyruvylideneglycinatocopper(II) complexes in the reaction in place of bis(glycinato)copper(II). An attempt at further improvement will also be described in the present communication.

The base-catalyzed condensation reaction of bis(glycinato)copper(II) (**1**) and acetaldehyde (**2**) has been known to be important in the preparation of DL-threonine (**3**),[2] and the mechanism[3] involving the carbanion depicted in Scheme I has generally been accepted on the basis of the masking effect of the copper ion on the amino group[4] or of the electronic polarization effect of the copper ion on the methylene carbon.[3] However, no evidence for the former effect has been reported in connection with these systems.[5]

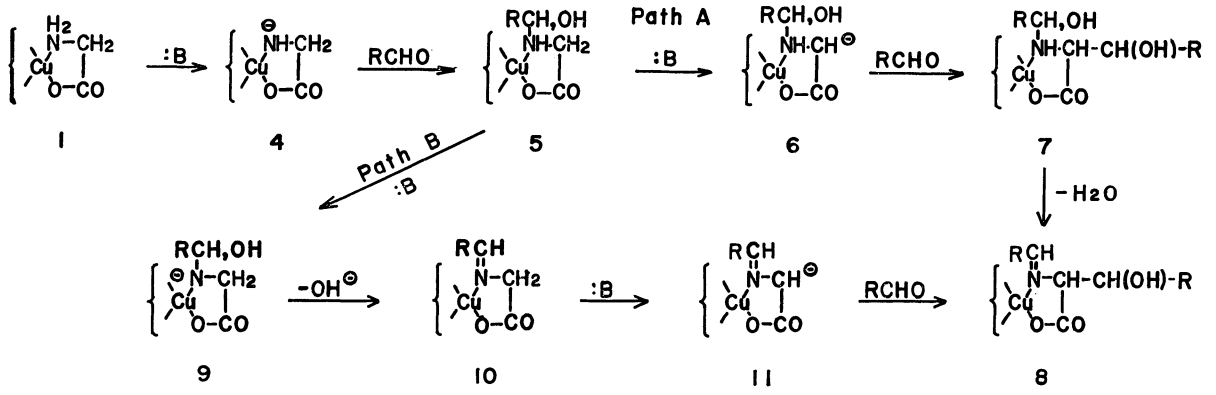

Scheme II

From the synthetic standpoint of view, the reaction is usually carried out under strongly basic conditions in the presence of 2—5 mole equivalents of aldehydes to glycine; it is thus unsuitable for aldehydes which are susceptible to self-condensation or isomerization under basic conditions. The investigation of this series has been undertaken so as to improve the reaction so that it can proceed even under weakly basic conditions and can be used for the aldehydes above mentioned; we have examined the findings on this reaction reported by several groups of investigators.[2-6]

Results and Discussion

Reaction Mechanism. The preferred dissociation of the proton on the nitrogen atom of **1** to that on the methylene carbon atom was explicitly exhibited by the isolation of complexes, *i.e.*, $K[Ni(NHCH_2CO_2)(NH_2CH_2CO_2)]$ and $K_2[Ni(NHCH_2CO_2)_2]$,[7] and by a NMR study of the dissociation of similar complexes of cobalt under slightly alkaline conditions.[8] When mixtures of **1** and **2** (0—2.238 mole equivalents to glycine) were stirred in water at pH 9.5 at room temperature for 5 min, an almost linear relationship was observed between the recovery yield of **1** and the amount of **2** used, as may be in Fig. 1. In this case, it is noticeable that the formation of **3** could not be detected by thin-layer chromatography. This result can be considered to suggest that **2** is not subjected to the attack of the carbanion shown in Scheme I, but to that of the amino group of **1** in the first stage of the reaction. Consequently, the reaction was assumed to proceed *via* a mechanism involving the methylol-type intermediate (**5**), shown in Scheme II. The stability constants of *N*-substituted glycine[9] and ethylenediamine complexes[10] have been known to

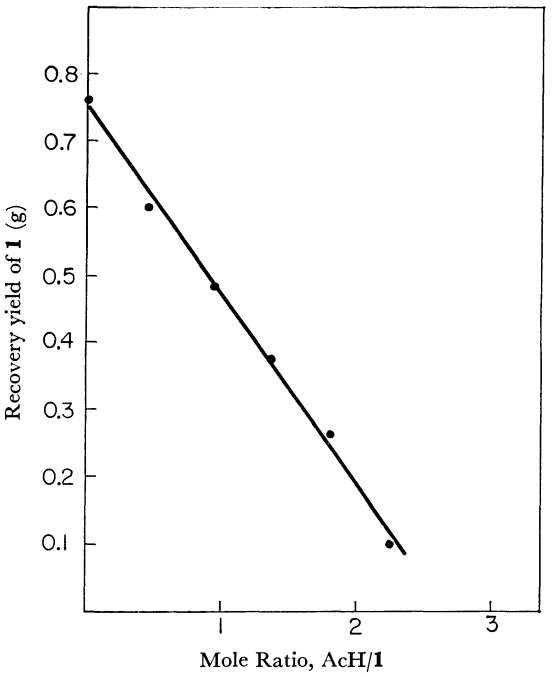

Fig. 1. Plot of recovery yield of bis(glycinato)copper(II)(**1**) *vs.* molar ratio of acetaldehyde (**2**) to glycine in **1** for the reaction of 5 mmol of **1** with **2** which were carried out at pH 9.5 for 5 min at room temperature.

be reduced in proportion to an increment in the bulkiness of *N*-substituent groups. The remarkable difference in reactivity between **2** and propionaldehyde or isobutyraldehyde, which are difficult to condense with **1** in the vicinity of pH 11.0 as far as we examined, may similarly be attributed to the stability or ease of the formation of the intermediate, **5**; *i.e.*, the difference may strongly suggest an important role of **5** in the reaction.

As to the subsequent process of the reaction, two paths, A and B, are conceivable. Path A involves the attack of the **6** carbanion, which is produced from **5** by the dissociation of the proton on the methylene carbon, on aldehydes to give **8** *via* **7**, with a simultaneous dehydration. On the other hand, Path B involves the attack of the Schiff base-type carbanion, **11**, which was produced *via* **9** and **10**, on aldehydes.

If the reaction is assumed to proceed *via* Path A, it can contradictorily be concluded that the dissoci-

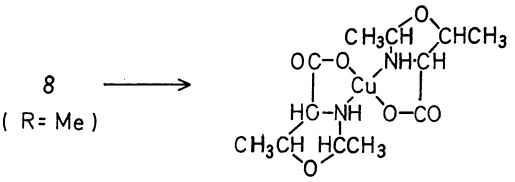
1	5	5	—	—	75	20
2	5	10	—	—	55	42
3	5	10	10	—	47	30
4	5	10	20	—	56	23
5	2.5	—	—	2.5	46	55

a) All the reactions were carried out by dissolving the reagents in water (50 m*l*) at room temperature for 4 hr in the presence of sodium carbonate (1 g).

ation of the proton on the methylene carbon atom takes preference over that of the proton on the nitrogen atom. However, so large an electron-attracting effect of the copper ion on the methylene carbon atom as to produce the **6** carbanion can not be expected from the structure of **5**. The mechanism *via* Path A can thus be discarded on the basis of these considerations. Consequently, the most important step of this reaction is considered to be that of the formation of **10**; hence, a sufficient electron-attracting effect of the copper ion on the methylene carbon atom can be expected from its structure. The structure of bis(2,5-dimethyloxazolidine-4-carboxylato)copper(II) (**12**),[11] which is easily prepared in a good yield by the reaction of **1** with **2** at pH 11, was confirmed by X-ray analysis; this fact suggests that the masking effect of the copper ion on the amino group is not so large as to prevent the reaction with **2**. **12** may be formed from **8** (R=Me) by the ring closure involving the addition reaction of a β-hydroxy group of threonine to the double bond of the *N*-ethylidene group (Scheme III). As can be seen from Table 1, the addition of formaldehyde (**13**) to the reaction system of **1** and **2** brought about a decrease in the yield of **3** as well as one in that of the total amino acids; the formation of DL-serine was not detected even by the use of an amino-acid analyzer.



12

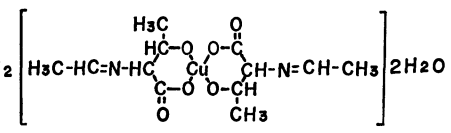
Scheme III

Moreover, the regeneration of **2** from **12** on treatment with **1** under the same conditions was experimentally confirmed. It can be thus stated that the formation of carbanion **11** is prevented by the addition of **13**. It is well known, on the other hand, that **13** can not be condensed with **1** so easily as **2**.[6c)] These facts can be explained on the assumption that the product in the first step of the condensation reaction of **1** with **13** is the *N*-methylol-type complex **5** (R=H) and that it remains as it is on account of the instability of the corresponding Schiff base-type intermediate, **10**, under the such conditions. According to Levy[13] and Tomiyama,[14] the monoformyl compound predominates in the pH range above 8.0 in the case of the formol titration. The above consideration is strongly supported by a recent study in which a Schiff base-type intermediate is also assumed in the racemization reaction of bis(L-alaninato)- and bis(*N*,*N*-dimethyl-L-alaninato)copper(II) under basic conditions.[15]

Attempts at Improvement. From the above point of view, it is natural to consider that the application of a complex such as **10**, whose amino group is protected by a proper carbonyl compound, to this reaction in place of **1** may bring about a considerable improvement. An attempted use of *N*-pyruvylideneglycinatoaquocopper(II) (**14**)[16] in the reaction expectedly brought about an improvement in the yields of amino acids and, moreover, made it feasible to condense various aldehydes with **14**. The reaction conditions

11) a) J. P. Aune and P. Maldonado, *Chem. Commun.*, **1970**, 135: the α-form crystal of **12** was analyzed. b) The corresponding β-form crystal of **12** was also analyzed recently by X-ray crystal structure analysis; it was confirmed to have the structure reported in the previous paper. The detailed results will be published elsewhere.

Although Imado reported the preparation of **12** from bis(DL-threoninato)copper(II) and acetaldehyde in the presence of sodium bicarbonate in water, and that it had the structure of bis(*N*-ethylidene-DL-threoninato)copper(II), as is depicted here, this structure can be considered sceptically because **12** does not react with sodium carbonate but nevertheless should be acidic; moreover,



the same complex is obtained from **1** and **2** under strongly basic conditions (pH 11), while it is well known that usual Schiff bases, which are composed of amino acids and aliphatic aldehydes, are unstable under such alkaline conditions [*cf.* S. Imado, *Yakugaku Zasshi*, **81**, 828, 832, and 837 (1961)].

12) No distinct explanation can be given for the drifting change of the yields of total amino acids; they may be arisen from the formation of a structurally-unestablished polymer [*cf.* G. O. Kalland, *Acta Chem. Scand.*, **19**, 2200 (1965)] or other unexpected factors.

13) M. Levy, *J. Biol. Chem.*, **99**, 767 (1933).

14) T. Tomiyama, *ibid.*, **111**, 51 (1935).

a) All the reactions were carried out by the use of 10 mmol of **14** [except in the case of 2,3-*O*-isopropylidene-D-glyceraldehyde (9 mmol)] at room temperature (23—26°C) except in the case of *p*-nitrobenzaldehyde (30°C).
b) These results were obtained under atmospheric condition.
c) These results were obtained under nitrogen atmospheric condition.
d) The yield was determined by amino acid analysis with Hitachi KLA 3B amino acid analyzer; An extra peak was observed in this case with almost the same strength in the vicinity of the position where the peak of aspartic acid should be observed.
e) To methanol suspension (40 m*l*), 1N methanolic sodium methoxide solution (7 m*l*) was added.

were greatly improved in the following three ways: 1) The reaction is sufficiently induced in the pH range of 9.0—9.5, in contrast with the above pH value, 10.8, which was used in the reaction of **1**. 2) the reaction satisfactorily proceeds in the presence of 1.0—3.0 mol equivalents of aldehydes to **14**, in comparison with the fact that 2—5 mol equivalents have been utilized in the reaction of **1**. 3) It has come to be possible to condense aldehydes which could not be condensed with glycine in **1** with glycine by the use of **14**. The results, along with the reaction conditions, are summarized in Table 2. The reactions of **14** with **2**, propionaldehyde, *n*-butyraldehyde, and *p*-tolualdehyde were carried out under atmospheric conditions. Except for the reaction with **2**, however, the reactions needed a long period to complete, and not very good results were obtained. In the case of formaldehyde, structurally unestablished amino acid, along with DL-serine, was obtained in a low yield. On the basis of the fact that no glycine could be detected by testing the resultant reaction mixtures thin-layer-chromatographically, and the suggestive report of Nyilasi and Vargha[17)] that glycine in **1** can be subjected to oxidative degradation to give glyoxylic acid and ammonia, it was considered possible that the degradation of glycine in **14** can take place similarly; hence, the above reactions were attempted under a nitrogen atmosphere. The yields of the corresponding β-hydroxy amino acids were thus improved greatly, as may be seen by comparing the data in the 6th and the 7th columns of the table. In the case of highly-reactive *p*-nitrobenzaldehyde (**15**), no difference was observed in the yields of β-(*p*-nitrophenyl)-DL-serine with respect to the atmospheres used. In this connection, the reactions with benzaldehyde and *p*-chlorobenzaldehyde were both carried out under a nitrogen atmosphere. It is remarkable, moreover, that 2,3-*O*-isopropylidene-D-glyceraldehyde (**16**) also gave the corresponding 2-amino-2-deoxypentoaldonic acid in a good yield, even under atmospheric conditions, in spite of the short reaction period, although free sugars are generally known to be susceptible to isomerization or polymerization[18a,b)] under weakly basic conditions. These findings promise to make possible the application of the reaction to the field of carbohydrate chemis-

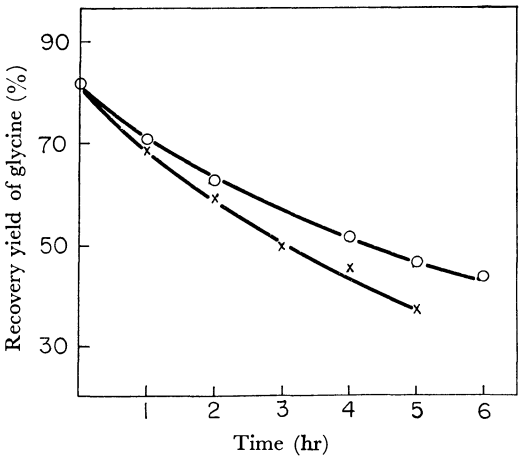

Fig. 2. Plot of recovery yield of glycine *vs.* time for the degradation reaction of *N*-pyruvylideneglycinatoaquocopper(II) (**14**) under nitrogen stream (○) and under atmospheric condition(×).

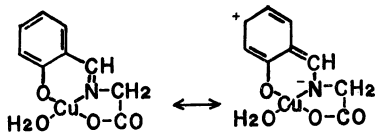
18) a) In the reaction with **1**, the corresponding 2-amino-2-deoxyaldonic acid was obtained in a very small yield in spite of the use of 6 equivalents of **15** to each one of **1**. b) C. D. Gutsche, D. Redmore, R. S. Buriks, K. Nowotony, H. Grassner, and C. W. Armbruster, *J. Amer. Chem. Soc.*, **89**, 1235 (1967). c) T. Ichikawa, T. Okamoto, S. Maeda, Y. Ohdan, Y. Araki, and Y. Ishido, *Tetrahedron Lett.*, **1971**, 79.

try as a procedure of synthesizing 2-amino-2-deoxy-aldonic acids involving a chain lengthening by two carbons on aldehydo-sugars.[18c]

To confirm the degradation of glycine in **14**, it was stirred alone in water at pH 9.4—9.6 under both atmospheric and nitrogen atmospheric conditions for comparison, and the recovery yields of glycine were plotted against the reaction period. The results are shown in Fig. 2. The degradation of glycine in **14** may also be explained by the mechanism which was proposed by Nyilasi and Vargha[17] for the degradation of **1**. The observation of a considerable degradation of glycine under nitrogen atmospheric conditions, on the other hand, may suggest the existence of other degradation paths. In the case of the less reactive aldehydes, accordingly, it may be considered that the lower yields of the β-hydroxy amino acids were brought about by the competitive degradation of glycine, especially under atmospheric conditions. The extent of the degradation in the course of the reactions, however, can not be discussed in parallel with that in the examination since the reactions were carried out in methanol in the presence of sodium methoxide. In addition, the degradation test of **14** in methanol could not be performed on account of its insolubility in methanol in the absence of aldehydes.



17

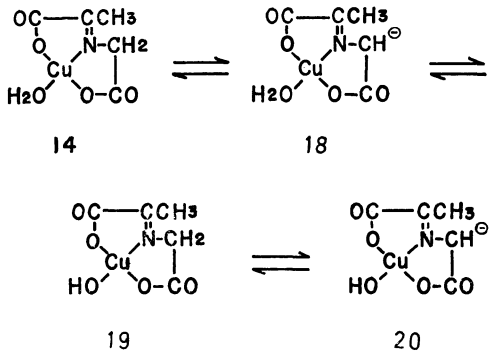
On the other hand, *N*-salicylideneglycinatoaquocopper(II) (**17**),[19] which belongs to the same category as **14**, unexpectedly gave no condensation product, even in the reaction with **15**, under the conditions used for the reaction of **14**, although the reaction of **17** with aldehydes[20] is known to proceed provided that 30 mol equivalents of aldehydes are utilized at pH 8.0. These results may be attributed to the resonance effect on the copper ion arising from the inflow of the electron from the benzene ring, as is depicted; hence, protecting the amino group with salicylaldehyde was concluded not to be so advantageous as has been described by Nakahara.[3]

In spite of an attempt to prepare other copper-glycine complexes whose amino groups were protected with acetylacetone or aldol, the corresponding complexes could not be isolated in a pure form; therefore, attempts to use them to the reaction in place of **1** were abandoned.

An attempt at further improvement was undertaken in view of the behavior of **14** upon treatment with an aqueous sodium hydroxide solution. When the alkali solution was added, drop by drop, an aqueous methanolic suspension of **14** and **15**, the mixture turned from blue to bluish green at about pH 6.0, and a gelatinous mass began to separate from the solution.

19) A. Nakahara, This Bulletin, **32**, 1195 (1959).
20) K. Harada and J. Oh-hashi, *J. Org. Chem.*, **32**, 1103 (1967).

A thin-layer chromatographic test of the solution obtained by treating the supernatant of the reaction mixture with hydrogen sulfide showed that it contains only the complex of the resultant amino acid; a corresponding test of the precipitate, on the other hand, showed that it contains only the complex of glycine. It was thus confirmed that the reaction is already induced at about pH 6.0; however, it failed to proceed, presumably on account of the predominant gel formation. The amount of the gel was increased with the addition of the alkali solution, and the mixture was finally turned into gel at about pH 7.5. Even at this point, it was thin-layer-chromatographically confirmed that the condensation reaction made little progress in comparison with the mixture at about pH 6.0. It was confirmed, in addition, that the reaction was not induced by the addition of **15** to the completely-gelled mixture of **14** in aqueous methanol of about pH 7.5. However, the gel began to dwindle over about pH 8.8 upon the further addition of the alkali solution, and the mixture came to be loose enough at pH 9.0 as the reaction proceed smoothly. On the basis of this phenomenon, an equilibrium composed of the species in Scheme IV was assumed; *i.e.*, the entity of the reactant to aldehyde in the vicinity of pH 6.0 may be **18**, and that in the vicinity of pH 9.0 may be **20**, the latter being produced from **14** *via* the salt of hydroxo *N*-pyruvylideneglycinatocopper(II) (**19**).



14 18

19 20

Scheme IV

Accordingly, **14** was titrated in water with a 2N aqueous sodium hydroxide solution under nitrogen atmospheric conditions in order to secure evidence of its behavior toward alkali, especially in the pH range of 6.0—9.0. The degradation of glycine in **14** may thus offer no problem since the period required for the titration is short and the pH of the titration mixture is under 9.5. The pH value of the mixture were plotted against the molar ratios of sodium hydroxide to **14** to give the curve shown in Fig. 3. However, the inflection point observed was not clear enough for us to explain the postulated equilibrium. This may arise from a rapid equilibrium among the species in Sheme IV and/or other potential ones. An alteration of the molar concentration of **14** from 5 to 10 mmol had practically no effect on the molar ratio of about 0.15 where the gel formation takes place. These facts presumably suggest the existence of an equilibrium for **14**, although a decisive discussion of this phenomenon is impossible. The dissociation of the α-methylene

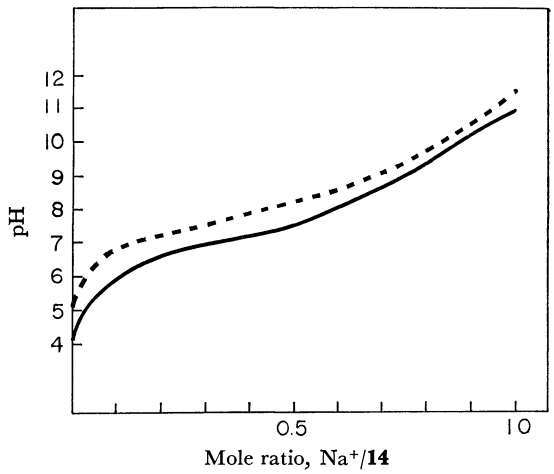


Fig. 3. Titration curves of *N*-pyruvylideneglycinatoaquocopper(II) (**14**) with 2N sodium hydroxide solution in water (50 m*l*) [5 mmol: dotted line; 10 mmol: straight line].

proton of **19** may occur with a certain degree of difficulty compared with that of **14** because of the greater electron density on the copper ion in **18**. However, the active methylene proton of **19** is considered yet to be reactive enough with aldehydes, since an NMR study of sodium chloro *N*-pyruvylideneglycinatopalladium(II) (**21**)[21] established that the α-methylene protons of glycine exclusively dissociate when **21** is dissolved in deuterium oxide. On the basis of these results, it was considered to be favorable for the condensation reaction to replace the aquo ligand in **14** with that which occupies no proton on its coordinating atom; the latter ligand could participate in $p\pi$-$d\pi$ conjugation with copper atom and so minimize the electron density on the copper atom. Pyridine was used as one of the most simple and typical species. *N*-Pyruvylideneglycinatopyridinecopper(II) (**22**) was newly prepared in a good yield by treating equimolar amounts of **14** and pyridine in acetone under vigorous stirring. The equimolar base-catalyzed condensation of **22** with **15** at pH 7.3—7.5 at room temperature was completed within 20 min; it gave β-(*p*-nitrophenyl)-DL-serine in a 67% yield. The reaction conditions in this case are in marked contrast to those used in the reaction of **14**, *i.e.*, at pH 9.5 for 2 hr. Therefore, it is now confirmed that the use of **22** in place of **14** in the condensation reaction with aldehydes brings about so favorable an effect that the reaction proceeds with great ease, even in the vicinity of pH 7.0.

Experimental

All the melting points are uncorrected. Amino acid analyses were carried out by means of a Hitachi KLA-3B Amino Acid Analyzer.

*An Examination of the Recovery of Bis(glycinato)copper (II) (**1**) in Relation to the Mole Equivalents of Acetaldehyde (**2**) Used in the Condensation Reaction.* To a suspension of **1** (1.150 g, 5 mmol) in water (50 m*l*), were added 0—2.238 mol equivalents of **2**; the mixture was then stirred at pH 9.5 for 5 min at room temperature. After the reaction, the undissolved **1** was gathered by filtration, washed with ethanol, and dried by heating *in vacuo*. The melting points (dec) and IR spectra of the recovered **1** were identical with those of the authentic specimen. The results shown below were also presented in Fig. 1.

Run	Acetaldehyde (m*l*)	Acetaldehyde mole equiv. to glycine in **1**	Recovery yield of **1** (g)
1	0	0	0.758
2	0.25	0.448	0.603
3	0.50	0.895	0.485
4	0.75	1.343	0.375
5	1.00	1.790	0.263
6	1.25	2.238	0.100

*An Examination of the Degree of Reactivity between Acetaldehyde (**2**) and Formaldehyde (**13**) with Bis(glycinato)copper(II) (**1**).* A solution of **1** (1.15 g, 5 mmol), **2** (0.5—1.0 mol equivalents), **13** (0—2.0 mol equivalents), and sodium carbonate (1.0 g, 10 mmol) in water (50 m*l*) was stirred at 27°C for 4 hr. After the reaction, concentrated aqueous ammonia (25 m*l*) was added, and the mixture was treated on a column (2.5×9 cm) of Amberlite IR-120B (NH_4 form) and then washed with distilled water (100 m*l*). The effluent and washings were then combined and concentrated to a volume of about 20 m*l* to remove the aldehydes and ammonia. The content of amino acids in the concentrate was determined by amino-acid analysis. The results are summarized in Table 1.

*An Examination of the Regeneration of Acetaldehyde (**2**) from Bis(2,5-dimethyloxazolidine-4-carboxylato)copper(II) (**12**).* A solution of **12** (0.97 g, 2.5 mmol), **1** (0.56 g, 2.5 mmol), and sodium carbonate (1 g, 10 mmol) in water (50 m*l*) was treated in the way described in the previous experiment. The content ratio of the amino acids in the resultant solution was determined by amino-acid analysis; the results are shown in Table 1.

N-*Pyruvylideneglycinatoaquocopper(II) Dihydrate (**14**).* To a suspension of glycine (21.3 g, 284 mmol) in aqueous ethanol (H_2O - EtOH=2:1; 80 m*l*), were added pyruvic acid (25. 0g, 284 mmol). The resultant mixture was stirred at 25°C for 30 min until it become homogeneous. On the addition of freshly-prepared cupric hydroxide, which had been obtained by treating cupric sulfate pentahydrate (71.0 g, 284 mmol) with sodium hydroxide (22.6 g, 568 mmol), a light blue precipitate was formed; the mixture was then allowed to stand overnight with stirring at room temperature. The resultant precipitate was gathered by suctional filtration and dried *in vacuo* over phosphorus pentoxide to give **14** (74.5 g, 75%), mp 195°C(dec).

Found: C, 22.97; H, 4.30; N, 5.32%. Calcd for $C_5H_{11}NO_7Cu$: C, 22.09; H, 4.64; N, 5.39%.

DL-*Serine.* A mixture of **14** (2.60 g, 10 mmol) and formaldehyde (0.9 ml of a 37% aqueous solution, 11 mmol) in aqueous methanol (H_2O - MeOH=3:1; 40 m*l*) was stirred at pH 8.0 for 6 hr at 30°C. After the reaction, the pH of the solution was adjusted to 4 with 3N aqueous acetic acid and the solution was treated with hydrogen sulfide gas. The resultant cupric sulfide was filtered off, and the filtrate was treated on a column (2.5×7 cm) of Amberlite IR-120B (H form) to adsorb the amino acids. After washing with distilled water (5 *l*), the column was eluted with 1N aqueous ammonia (500 m*l*) and the content of amino acids in the eluate was determined by amino-acid analysis. The yield of DL-serine was estimated to be 28%; moreover, an extra peak, one

21) H. Yoneda, Y. Morimoto, Y. Nakao, and A. Nakahara, This Bulletin, **41**, 255 (1968).

observed with almost the same strength, was in the vicinity of the position where the peak of aspartic acid should be observed.

DL-*Threonine.* A mixture of **14** (2.60 g, 10 mmol) and **2** (0.85 m*l*, 15 mmol) in water (50 m*l*) was stirred at pH 9.8 at room temperature for 2 hr. After the reaction, the pH of the resultant mixture was adjusted to 4.5 with 3N aqueous acetic acid; the mixture was then treated with hydrogen sulfide gas and the cupric sulfide was filtered off. The filtrate was concentrated to a volume of about 30 m*l*, and the concentrate was treated on a column (2.5×7 cm) of Amberlite IR-120B (H form), followed by washing with distilled water (5 *l*) and then elution with 1N aqueous ammonia (500 m*l*). The effluent was concentrated almost to dryness, and the residue was treated with ethanol (50 m*l*) to give white crystals of DL-threonine (0.7 g, 61%), mp 216°C (dec).

Found: C, 40.48; H, 7.55; N, 11.51%. Calcd for $C_4H_9NO_3$: C, 40.33; H, 7.62; N, 11.76%.

*β-Hydroxy-*DL-*norvaline.* To a mixture of **14** (2.6 g, 10 mmol) and propionaldehyde (2.1 m*l*, 30 mmol) in methanol (40 m*l*), were added 1N methanolic sodium methoxide (7 m*l*), the mixture was then stirred under a nitrogen atmosphere at 26°C for 4 hr. After the reaction, the resultant mixture was acidified with 3N aqueous acetic acid (5 m*l*), concentrated to a volume of 15 m*l*, and diluted with distilled water (50 m*l*). The solution was washed with diethyl ether (15 m*l*×3 portions) and then with methylene chloride (10 m*l*×2 portions). Then, the aqueous layer was treated with hydrogen sulfide gas, and the resultant cupric sulfide was filtered off. The filtrate was concentrated to a volume of 30 m*l*, and the concentrate was poured onto a column (2.5×7 cm) of Amberlite IR-120B (H form). The column was washed with distilled water (5 *l*) and then eluted with 1N aqueous ammonia (500 m*l*). After the concentration of the effluent *in vacuo* almost to dryness, the residue was treated with ethanol (25 m*l*); the resultant white crystals were gathered by suctional filtration to give *β*-hydroxy-DL-norvaline (1.0 g, 77%), mp 219°C (dec).

Found: C, 44.89; H, 8.14; N, 10.33%. Calcd for $C_5H_{11}NO_3$: C, 45.10; H, 8.33; N, 10.52%.

*β-Hydroxy-*DL-*norleucine, β-Hydroxy-*DL-*leucine, and* DL-*Phenylserine.* These amino acids were obtained by the reaction of *n*-butyraldehyde, isobutyraldehyde, and benzaldehyde respectively with **14** under the conditions described in Table 2 and by the treatment described in the case of propionaldehyde. The melting points and the results of their elemental analyses are shown below:

β-Hydroxy-DL-norleucine, mp 229°C (dec)

Found: C, 48.79; H, 9.20; N, 9.27%. Calcd for $C_6H_{13}NO_3$: C, 48.96; H, 8.90; N, 9.52%.

β-Hydroxy-DL-leucine, mp 225°C (dec)

Found: C, 48.98; H, 9.05; N, 9.61%. Calcd for $C_6H_{13}NO_3$: C, 48.96: H, 8.90; N, 9.52%.

DL-Phenylserine, mp 194.5°C (dec)

Found: C, 60.15; H, 6.47; N, 8.17%. Calcd for $C_9H_{11}NO_3$: C, 59.66; H, 6.47; N, 7.73%.

*β-(*p-*Nitrophenyl)-*DL-*serine.* A suspension of **14** (2.6 g, 10 mmol) and *p*-nitrobenzaldehyde (**15**) (1.5 g, 10 mmol) in aqueous methanol (H_2O - MeOH=1:2; 30 m*l*) was stirred at pH 9.0 for 2 hr at 30°C under a nitrogen stream. After the reaction, water (100 m*l*) was added, the pH of the mixture was adjusted at 5.0 by the addition of 3N aqueous acetic acid, and the resultant suspension was treated with hydrogen sulfide gas and the cupric sulfide was filtered off. The filtrate was treated on a column (2.5×9 cm) of Amberlite IR-120B (H form), washed with distilled water (5 *l*), and then eluted with 1N aqueous ammonia (500 m*l*). The effluent was concentrated almost to dryness and then treated with ethanol (20 m*l*) to give slightly brownish crystals (1.8 g, 80%), mp 181°C (dec). One recrystallization from water gave a pure specimen, mp 182°C (dec).

Found: C, 47.75; H, 4.47; N, 12.30%. Calcd for $C_9H_{10}N_2O_5$: C, 47.79; H, 4.46; N, 12.39%.

*β-(*o-*Nitrophenyl)-*DL-*serine.* *o*-Nitrobenzaldehyde (1.5 g, 10 mmol) and **14** (2.6 g, 10 mmol) were treated in the way described in the previous experiment; the reaction period was 30 min, and the reaction temperature was 20°C. Silghtly brownish crystals (1.5 g, 66%), mp 179°C (dec) were thus obtained.

Found: C, 47.79; H, 4.53; N, 12.52%. Calcd for $C_9H_{10}N_2O_5$: C, 47.79; H, 4.46; N, 12.39%.

*β-(*p-*Chlorophenyl)-*DL-*serine.* To a mixture of **14** (2.6 g, 10 mmol) and *p*-chlorobenzaldehyde (4.2 g, 30 mmol) in methanol (40 m*l*), were added 1N methanolic sodium methoxide (7 m*l*); the mixture was then stirred at 23°C under a nitrogen atmosphere for 10 hr. After the reaction, the mixture was treated with 3N aqueous acetic acid (5 m*l*) and then diluted with distilled water (100 m*l*). The resultant greenish precipitate was filtered off by suction and then washed with benzene (15 m*l*). The filtrate was concentrated *in vacuo* to a volume of 100 m*l*; the concentrate was then washed with diethyl ether (25 m*l*×2 portions) in a separating funnel. The greenish precipitate mentioned above and the aqueous layer were treated together with hydrogen sulfide gas, and the precipitated cupric sulfide was removed by filtration. The filtrate was concentrated to a volume of about 30 m*l*, and the concentrate was treated on a column (2.5×7 cm) of Amberlite IR-120B (H form). Then, the column was washed with distilled water (5 *l*) and eluted with 1N aqueous ammonia (500 m*l*). The effluent was evaporated *in vacuo* almost to dryness, and the residue was triturated with ethanol (10 m*l*). The resultant white crystals were filtered to give *β*-(*p*-chlorophenyl)-DL-serine (0.95 g, 44%), mp 186°C (dec).

Found: C, 50.13; H, 4.65; N, 6.52%. Calcd for $C_9H_{10}NO_3Cl$: C, 50.12; H, 4.67; N, 6.50%.

*β-(*p-*Tolyl)-*DL-*serine.* To a mixture of **14** (2.6 g, 10 mmol) and *p*-tolualdehyde (3.54 m*l*, 30 mmol) in methanol (40 m*l*), were added 1N methanolic sodium methoxide (7 m*l*); the mixture was then stirred at 26°C under a nitrogen atmosphere for 14 hr. After the reaction, the resultant reaction mixture was acidified with 3N aqueous acetic acid (5 m*l*) and diluted with distilled water (100 m*l*). Then, a small amount of the greenish mass washed with diethyl ether (15 m*l*). The filtrate was concentrated *in vacuo* to a volume of 20 m*l*, and the concentrate was washed with diethyl ether (25 m*l*×2 portions) in a seperating funnel. The greenish precipitate and the aqueous layer were treated in the way described in the previous experiment to give *β*-(*p*-tolyl)-DL-serine (0.8 g, 41%), mp 186°C (dec), as white crystals.

Found: C, 61.68; H, 6.98; N, 7.03%. Calcd for $C_{10}H_{13}NO_3$: C, 61.52; H, 6.71; N, 7.18%.

*2-Amino-2-deoxy-4,5-*O*-isopropylidene-*D*-pentoaldonic Acid.* To a solution of 1,2;5,6-di-*O*-isopropylidene-D-mannitol[22] (1.3 g, 5 mmol) in water (50 m*l*), were added sodium metaperiodate (1.1 g, 5 mmol); the solution was then stirred at room temperature for 60 min. The sodium iodate thus precipitated was filtered off, and the filtrate was concentrated *in vacuo* below 40°C almost to a sirup. When the sirup was then treated with ethanol (20 m*l*), the sodium iodate further precipitated was removed by filtration. This

22) D. Horton, J. B Hughes, and J. K. Thompson, *J. Org. Chem.*, **33**, 728 (1968).

operation was repeatedly carried out in order to remove a small amount of the sodium iodate remaining in the sirup. A solution of the sirup thus obtained and an equimolar amount of **14** (2.3 g, 9 mmol) in water (30 m*l*) was adjusted at pH 9.5 by the addition of a 1N aqueous sodium hydroxide solution, and then the mixture was stirred at room temperature for 1 hr. After the reaction, the solution was treated with sodium sulfide ($Na_2S \cdot 9H_2O$: 2.7 g, 11 mmol); the resultant precipitate was filtered off. The filtrate was immediately treated on a column (2.5×9 cm) of Amberlite IR-120B (NH_4 form), after which the column was washed with distilled water (100 m*l*). The combined effluent was concentrated to a volume of 50 m*l* and treated on a column (2.5×5 cm) of Amberlite IR-45 (OH form), after which the column was washed with distilled water (100 m*l*). The effluent was concentrated to a volume of 50 m*l*, and the concentrate was washed with methylene chloride (10 m*l*×3 portions). The aqueous layer was then concentrated to a volume of about 5 m*l*. The white crystals thus precipitated were gathered by filtration and washed with several milliliters of methanol. The filtrate and washings were combined and concentrated almost to a sirup. The white crystals separated on the addition of several milliliters of methanol were similarly gathered by filtration. This procedure was repeated three times more, and then all the crystals were combined and recrystallized from aqueous methanol to give 2-amino-2-deoxy-4,5-*O*-isopropylidene-D-pentoaldonic acid (1.3 g, 70%), mp 198°C (dec).

Found: C, 46.53; H, 7.18; N, 6.96%. Calcd for $C_8H_{15}NO_5$: C, 46.82; H, 7.37; N, 6.83%.

*An Examination of the Degradation of **14** in an Aqueous Alkaline Solution.* Into water (100 m*l*) in a two-necked Erlenmeyer flask (20 m*l*) equipped with a Toa Electronic, Ltd., GC-125 Electrode, were bubbled nitrogen gas more than 1 hr under mechanical stirring; **14** (2600 g, 10 mmol) which had been allowed to stand for 24 hr under a nitrogen atmosphere was then added to the flask. The solution was stirred at 23°C for several hours, its pH value kept at 9.5 by the addition of a 2N aqueous sodium hydroxide solution. After the reaction, the resultant solution was treated in the way described in the reaction of **14** with acetaldehyde. The recoveries of glycine, which were also presented in Fig. 2, were as follows:

Run	Period (hr)	Recovery of glycine (g)	Recovery of glycine (%)
1	0	0.616	82.1
2	1	0.530	70.8
3	2	0.465	62.0
4	4	0.386	51.5
5	5	0.345	46.0
6	6	0.330	43.5

The recoveries of glycine in the examination, obtained under atmospheric conditions in the same way as above, were as follows:

Run	Period (hr)	Recovery of glycine (g)	Recovery of glycine (%)
1	0	0.616	82.1
2	1	0.516	68.8
3	2	0.434	57.9
4	3	0.376	50.1
5	4	0.337	44.9
6	5	0.276	36.8

Titration of N-*Pyruvylideneglycinatoaquocopper(II) (**14**) with an Aqueous Sodium Hydroxide Solution.* *Reagent*: A 2N aqueous sodium hydroxide solution was prepared by the Sörensen procedure to remove the carbon dioxide.

Conditions: A Toa Electronics, Ltd., HM-5A model pH meter with glass and reference electrodes was used to record the hydrogen-ion concentration. The titrations were carried out in a 100 m*l* multi-necked flask with a flat bottom to accommodate gas inlet and outlet tubes, a buret delivery tube, and electrodes. A magnetic stirrer was used for the stirring. In order to obtain a carbon dioxide-free system, nitrogen which had been passed through a 5N aqueous sodium hydroxide solution was bubbled into the system. All the measurements were made at 26°C, and pH values were read 1 min after the addition of one drop of the sodium hydroxide solution.

Titrations: A solution of **14** (1.300 g, 5 mmol and 2.600 g, 10 mmol) in distilled water (50 m*l*) was treated with the 2N aqueous sodium hydroxide solution (f=1.160) under a nitrogen stream; the results are presented in Fig. 3.

N-*Pyruvylideneglycinatopyridinecopper(II) Trihydrate (**21**).* Into a mixture of pyridine (0.8 m*l*, 10 mmol) and acetone (12 m*l*), were stirred **14** (2.6 g, 10 mmol), portion by portion, after which the suspension was stirred at room temperature for 2 hr. Then, blue crystals were precipitated, filtered, and dried to give **21** (3.1 g, 91%), mp 133°C, (a slight coloration began at about 133°C, but the crystals merely turned dark brown without any evolution of gas).

Found: C, 34.98; H, 4.52; N, 7.92%. Calcd for $C_{10}H_{16}N_2O_7Cu$: C, 35.35; H, 4.76; N, 8.24%.

*Preparation of β-(*p*-Nitrophenyl)-*DL*-serine by the Use of **21**.* A solution of **21** (3.4 g, 10 mmol) and *p*-nitrobenzaldehyde (1.5 g, 10 mmol) in aqueous methanol (H_2O - MeOH=1:1; 40 m*l*) was stirred at pH 7.3—7.5 for 20 min at room temperature. The resultant reaction mixture was treated in the way described in the reaction of **14** with the aldehyde; it thus gave slightly brownish crystals. The crystals were recrystallized from water to give β-(*p*-nitrophenyl)-DL-serine (1.5 g, 67%), mp 162°C (dec). The amino acid obtained here was confirmed by paper as well as by thin-layer chromatography to be composed of two amino acids of R_f (paper chromatog) 0.51 and 0.61 (*n*-BuOH: EtCOMe: concd. aq. NH_3: H_2O=5:3:3:1) in a ratio of about 2:3, although it is uncertain which of them corresponds to the *threo* isomer and which to the *allo* isomer.

Found: C, 46.06; H, 4.92; N, 12.37%. Calcd for $C_9H_{10}N_2O_5 \cdot 1/2\ H_2O$ (dried at 65°C over phosphorus pentoxide): C, 45.96; H, 4.72; N, 11.91%.

Studies of Hydroxy Amino Acids. I. Separation of Diastereoisomers of Threonine

Yasuo ARIYOSHI and Naotake SATO

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki, Kanagawa

(Received April 2, 1971)

It was found that DL-allothreonine forms scarcely any soluble compounds with 5-nitronaphthalene-1-sulfonic acid, α-naphthylphosphoric acid, chlorendic acid,[1] and tetrachlorophthalic acid in water. DL-Threonine formed soluble or unstable compounds in water with these acids. The synthetic threonine mixture was successfully separated into DL-threonine and DL-allothreonine.

L-Threonine is used as medicine or a nutrient-enrichment for foodstuffs. However, allothreonine which is always formed as a by-product in the synthesis of threonine has almost no practical use. Most of the synthetic methods for threonine[2] produce more DL-allothreonine than DL-threonine, except for the reaction of copper glycinate with acetaldehyde[3] and the Strecker reaction of 1-ethoxy-1,2-diacetoxypropane.[4] A few methods of separation of diastereoisomers have been reported, in which threonine was changed to its derivative, Cu-acetaldehyde-threonine complex,[5] *N*-benzoyl-DL-threonine ethyl ester,[6] or sodium DL-threoninate.[7] Some aromatic acids have been used as a specific precipitating reagent for amino acids.[8,9] However, none is found in literature for the diastereoisomers of threonine.

In the course of studies on hydroxy amino acids, it was found that DL-allothreonine forms precipitates scarcely soluble in water with 5-nitronaphthalene-1-sulfonic acid, α-naphthylphosphoric acid, chlorendic acid, and tetrachlorophthalic acid. DL-Threonine, on the contrary, formed soluble or unstable compounds in water with these reagents. This finding was successfully applied to the separation of the two diastereoisomers of threonine. When a threonine mixture was brought into contact with these reagents in water, DL-allothreonine selectively precipitated with the reagents, while DL-threonine remained almost quantitatively in the mother liquor (Table 1).

Elementary analyses showed that the precipitate consists of DL-allothreonine and the reagent in 1:1 molar ratio, except for the precipitate with chlorendic acid. The IR spectra of the precipitates showed the absorption band in a region 1720—1750 cm^{-1} due to the free carboxyl group as the salt of DL-allothreonine with the strong acid.

Table 1. Separation of DL-allothreonine and DL-threonine with various precipitating reagents

Reagent	Grams of aThr and Thr in 100 m*l* of aqueous solution	
	Initial solution	Mother liquor
NNS	aThr 10.0 Thr 10.0	aThr 3.8 Thr 9.8
NP	aThr 10.0 Thr 10.0	aThr 2.0 Thr 8.6
CA	aThr 3.5 Thr 7.0	aThr 1.7 Thr 6.9
TCP	aThr 10.0 Thr 10.0	aThr 0.6 Thr 9.8

Abbreviations used are as follows:
aThr, DL-Allothreonine; Thr, DL-Threonine; NNS, 5-Nitronaphthalene-1-sulfonic acid; NP, α-naphthylphosphoric acid; CA, Chlorendic acid; TCP, Tetrachlorophthalic acid.
1.2 equimolar amount of NNS, NP, and TCP, and 2.4 equimolar amount of CA were used to DL-allothreonine in the initial solution.

In the case of chlorendic acid, the precipitate consisted of DL-allothreonine and chlorendic acid in 1:2 molar ratio. Since its IR spectrum only slightly differed from that of the mechanical mixture of DL-allothreonine and chlorendic acid, it was assumed that the precipitate is formed by the hydrogen bonding between DL-allothreonine and chlorendic acid.

DL-Threonine formed soluble salts with α-naphthylphosphoric acid and tetrachlorophthalic acid, but did not form crystalline compounds with 5-nitronaphthalene-1-sulfonic acid and chlorendic acid in water (Table 2). The salts of DL-allothreonine with 5-nitronaphthalene-1-sulfonic acid, α-naphthylphosphoric acid and tetrachlorophthalic acid were recrystallized from aqueous methanol, whereas the salts of DL-allothreonine with chlorendic acid and of DL-threonine with α-naphthylphosphoric acid and tetrachlorophthalic acid decomposed into the two components on recrystallization from various solvent systems.

When the salt of DL-allothreonine with tetrachlorophthalic acid was gradually heated above its melting point of 117°C, the melted material solidified at 148—150°C, and the solid remelted at 203—204°C. The compound with melting point of 203—204°C was assigned to be *N*-tetrachlorophthaloyl-DL-allothreonine from its IR spectrum, with no NH absorption of the

compound with melting point of 117°C in the region of 1500—1600 cm^{-1}. The same phenomenon was observed with the salt of DL-threonine with tetrachlorophthalic acid. The compound with a higher melting point of 204—206°C was also assigned to be tetrachlorophthaloyl-DL-threonine from its IR spectrum.

As seen in Table 1, the most effective precipitating reagent was tetrachlorophthalic acid. Separation tests with this acid were made in more detail using the mixtures of the two diastereoisomers with various ratios and a synthetic threonine mixture obtained by the procedure described by Akabori *et al.*[3] (Table 3).

Table 3. Separation of DL-allothreonine and DL-threonine with tetrachlorophthalic acid

No.	Mixture Thr g	Mixture aThr g	TCP[a] g	Water ml	Recovery[b] Thr g(%)	Recovery[b] aThr g(%)
1	14	7	22	150	13.5(96)	5.8(84)
2	10	10	31	135	10 (100)	9.2(92)
3	15	5	16	170	14.7(98)	3.7(74)
4[c]	10.3	6.3	20	110	10 (97)	5.8(92)

a) Tetrachlorophthalic acid as hemihydrate.
b) Purity of all the amino acids not less than 95%.
c) A synthetic mixture containing 0.4 g of glycine.

The precipitate and the mother liquor were separately treated with hydrochloric acid. After removing the liberated tetrachlorophthalic acid by filtration, DL-allothreonine and DL-threonine were recovered in 74—92% and 96—100% yield, respectively, from the acidic solutions using ion-exchange column. Recrystallization gave chromatographically pure DL-allothreonine and DL-threonine.

Experimental

All melting points are uncorrected. The IR spectra were obtained in Nujol mull with a JASCO IR-S spectrometer.

Determination of DL-*Threonine and* DL-*Allothreonine.* Paper chromatographic analysis was carried out by the descending method on Toyo Roshi No. 51 paper with the solvent system, *n*-butanol-methyl ethyl ketone-28% aqueous ammonia-water (5:3:1:1 v/v),[4] and the chromatogram was stained with cadmium-ninhydrin reagent.[10] Two spots corresponding to allothreonine and threonine were individually cut off, and eluted with methanol, and the absorbances of the eluates were measured at 510 mμ.

Salt of DL-*Allothreonine with 5-Nitronaphthalene-1-sulfonic Acid (I).* A solution of 2.0 g of DL-allothreonine and 5.0 g of 5-nitronaphthalene-1-sulfonic acid in 20 ml of water was prepared and stored in a refrigerator overnight. The crystals formed were collected by filtration; yield, 3.5 g (56%). Recrystallization from aqueous methanol gave pure I as platelets. Anal. and mp (Table 2). IR: 3420, 3160 (sh), 3080, 1750, 1615 (sh), 1603, 1530, 1515 cm^{-1}. On the other hand, DL-threonine gave no crystalline salt in analytically pure state when treated with 5-nitronaphthalene-1-sulfonic acid in the same manner.

Salts of DL-*Allothreonine and* DL-*Threonine with α-Naphthylphosphoric Acid (II and III).* To a solution of 5.4 g of disodium α-naphthylphosphate in 20 ml of 2N hydrochloric acid, 2.0 g of DL-allothreonine or DL-threonine was added with stirring at room temperature. The mixture was stirred for 5 hr and kept in a refrigerator overnight. Crystalline II formed was collected by filtration; yield, 4.5 g (78%). Recrystallization from aqueous methanol gave pure II as platelets. Crystalline III was obtained from the concentrated syrupy solution; yield, 3.3 g (57%). Anal. and mp (Table 2). IR of II: 3300, 3080 (sh), 1720, 1620, 1603, 1585, 1525 cm^{-1}. IR of III: 3580, 3220, 3120, 1740, 1620, 1603 (sh), 1580 (sh), 1505 cm^{-1}.

Crystalline Compound of DL-*Allothreonine with Chlorendic Acid (IV).* To a solution of 2.0 g of DL-allothreonine in 20 ml of water, 7.8 g of chlorendic acid was added with stirring at room temperature. The suspension was stirred for 5 hr, and then allowed to stand in a refrigerator overnight. The crystalline compound formed was collected by filtration; yield, 8.2 g (89%). Anal. and mp (Table 2). IR: 3580, 3420, 3100, 1730 (sh), 1710, 1610, 1580, 1515 cm^{-1}. DL-Threonine gave no such crystalline compound with chlorendic acid.

Salts of DL-*Allothreonine and* DL-*Threonine with Tetrachlorophthalic Acid (V and VI).* A mixture of 2.0 g of DL-allothreonine or DL-threonine and 6.3 g of tetrachlorophthalic acid hemihydrate in 20 ml of water was stirred for 5 hr at room temperature, and stored in a refrigerator overnight. The crystals of V formed were collected by filtration; yield, 6.5 g (84%). Recrystallization from aqueous methanol gave pure V as platelets. The crystals of VI were obtained as

10) J. Heilmann, J. Barrollier, and E. Watzke, *Z. Physiol. Chem.*, **309**, 219 (1957).

needles from a concentrated syrupy solution; yield, 5.6 g (75%). Anal. and mp (Table 2). IR of V: 3500 (sh), 3220, 1750, 1710, 1620, 1600, 1550 (sh), 1520 (sh), 1510 cm^{-1}. IR of VI: 3460, 3200, 1735 (sh), 1705, 1595, 1525 cm^{-1}.

Separation of DL-*Allothreonine and* DL-*Threonine with Various Precipitating Reagents (Table 1).* To an aqueous solution containing DL-allothreonine and DL-threonine was added a precipitating reagent in the amount of 1.2 molar equivalent to DL-allothreonine. In the case of chlorendic acid, 2.4 molar equivalent to DL-allothreonine was used. The mixture was stirred for 5 hr and stored in a refrigerator overnight. The precipitate formed was removed by filtration. An aliquot of the filtrate was analyzed by paper chromatography and the contents of DL-allothreonine and DL-threonine in the filtrate were determined. The results are summarized in Table 1.

Separation of DL-*Allothreonine and* DL-*Threonine using Tetrachlorophthalic Acid (Table 3).* A typical run (No. 4. in Table 3) is as follows: To a solution of a synthetic threonine mixture composed of 10.3 g of DL-threonine, 6.3 g of DL-allothreonine, and 0.4 g of glycine in 110 m*l* of water,[3] was added 20 g of tetrachlorophthalic acid hemihydrate with stirring. The mixture was stirred for 5 hr at room temperature, and then kept in a refrigerator overnight. The precipitate was filtered, washed with a small amount of water, and then suspended in 100 m*l* of N hydrochloric acid. The mixture was boiled for 30 min and allowed to stand at room temperature for 3 hr. After removing tetrachlorophthalic acid liberated by filtration, the solution was passed through a column of Dowex 50 W×8 (H form). The column was washed with water and eluted with 2N ammonia. The eluate was concentrated *in vacuo* until crystallization began and a sufficient amount of methanol was added. The crystals were collected by filtration and washed with a small amount of aqueous methanol, giving 5.8 g (92% recovery) of DL-allothreonine. Recrystallized DL-allothreonine from water-methanol was chromatographically pure. The mother liquor, from which the DL-allothreonine salt was removed, was adjusted to pH 1.35 with hydrochloric acid. After removing tetrachlorophthalic acid liberated, the filtrate was treated in the same manner as described above giving 10.0 g (97% recovery) of DL-threonine. Recrystallized DL-threonine from water-methanol was chromatographically pure.

The authors wish to thank Dr. K. Toi of Ajinomoto Co., Inc. for his advice.

(Received April 12, 1971)

Polarized quartet NMR signals due to methylene protons were observed in the hydrogen-abstraction reactions of phenanthraquinone with *o*-substituted toluenes under the irradiation of light. The relative intensities of these signals could be predicted only by the general treatment of the CKO theory, taking account of the electronic singlet-triplet interactions (S–T_0 and S–T_1) of the radical pair. The scalar electronic-coupling constants, J_e, were evaluated approximately by comparing the theory with the experimental results and were found to be in the order of 7×10^9 sec^{-1}. The rather large value of J_e was discussed in relation to the nature of the reaction system; consequently, the existance of electronic π–π interaction was suggested for the radical-pair intermediate of the reaction.

Fischer and Bargon[2] have proposed a cross-relaxation process between electronic and nuclear-spin systems as the mechanism of the chemically induced dynamic nuclear polarization (CIDNP). However, the observations of combination lines consisting of both absorption and emission lines,[3] and strong nuclear spin polarization[4] over that predicted from the Overhausser effect, can no longer be explained on the basis of the cross-relaxation mechanism alone.

In the present stage, the theory developed by Closs and Trifunac[5] and by Kaptein and Oosterhoff,[6] *i.e.*, the CKO theory, seems to give a more reasonable interpretation of the CIDNP mechanism. This theory is principally based on the formation of a radical-pair intermediate during rapid radical reactions; then reaction products are formed through the radical pair in the electronic-spin singlet state brought about by the mixing of the electronic singlet and triplet states. In the CKO theory as approximated in large magnetic fields, only the mixing between the singlet (S) and triplet state with $m_s=0(T_0)$ is taken into

account; the other two triplet states with $m_s=\pm 1$ (T_1 and T_{-1}) are neglected. Though the aproximate CKO theory has described the major features of CIDNP, it has failed to explain the reactions proceeding in small magnetic fields[7] and, rarely, it could not even predict the nuclear-spin polarization of products resulting from the radical pair, the individual components of which have the same g-value.[8]

The methylene protons of the 1,2-photo-adducts[9] show strongly polarized NMR quartet signals in the photochemical reactions of phenanthraquinone with o-substituted toluenes. The intensities of such quartet signals differed from those predicted from the approximate CKO theory. It was shown, by a more general treatment of the CKO theory, that the S–T_1 interaction as well as the S–T_0 interaction must be taken into account in accounting for the nuclear polarization observed in our experiments.

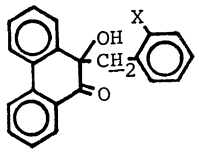
Experimental

The phenanthraquinone was prepared by the oxidation of phenanthrene with potassium dichromate and was purified by recrystallization from an acetic acid solution. Hydrogen-abstraction reactions of phenanthraquinone (0.04M) in a solution of toluene, o-xylene, o-chlorotoluene or o-bromotoluene were photochemically induced at 70°C inside an NMR probe modified for photochemical reactions; the method of modification has been reported in a previous paper.[10] The NMR spectra were observed at 60 MHz by means of a C-60HL-type spectrometer(JEOL. CO., Ltd.) under light.

Theory

The photochemical reaction of phenanthraquinone occurs through its optically-activated triplet state. In the present case, a weakly-coupled radical pair is formed through the hydrogen abstraction of the excited phenanthraquinone from o-substituted toluenes. A finite fraction of the radical pair yields the 1,2-adduct of phenanthraquinone.[11]

Now, let us examine further the particular protons of the adduct, *i.e.*, the methylene protons (underlined) of the 1,2-adduct;



I

a. X=H
b. X=CH_3
c. X=Cl
d. X=Br

As is shown in Figs. 2 to 5, an unusual polarized NMR quartet of signals of the photo-adduct was observed; these signals are not predicted by the CKO theory based on the S–T_0 mixing alone. This finding encouraged us to investigate the more general CKO theory for AB-spin system.

It has been reported that a weakly-interacting radical pair often shows an unusual hyperfine structure of the electron-spin resonance of the triplet state.[12] This is caused by mixing between the electronic-spin singlet and the triplet states of such a radical pair, whose singlet-triplet separation is comparable to the electronic Zeeman energy or less. The effective spin Hamiltonian for such radical-pair tumbling in a fast rate in a solution can be written (if the nuclear Zeeman term is neglected)[6]:

$$\mathcal{H}_0 = \beta H_0(g_1S_1+g_2S_2) - J_e(1/2+2S_1S_2) + \sum_{i,j} A_{ij}I_iS_j + H_d \quad (1)$$

where β is the Bohr magneton, H_0 is the static magnetic field, S and I are the electronic and nuclear-spin operators, J_e is the scalar electronic exchange coupling constant, and A_{ij} is the hyperfine coupling constant between the ith nuclear and the jth electron. The term of dipole-dipole interaction, H_d, is assumed to be negligible because of the establishment of a thermal equilibrium in the electronic-spin system of the triplet precursor.

As the radical pair will have different values of J_e and A_{ij} from one time to another due to the thermal vibration and the collisions, the Hamiltonian, $\mathcal{H}_0$, should be time-dependent. By denoting the total spin-wave function of the radical pair as $\Psi(t)$, the time-dependent Schrödinger equation for the Hamiltonian, $\mathcal{H}_0$, is given by;

$$i\hbar\frac{d\Psi(t)}{dt} = \mathcal{H}_0\Psi(t) \quad (2)$$

The general solution of Eq. (2) produces a linear combination of $U_{ij}{}^0$;

$$\Psi(t) = \sum_{i,j} C_{ij}(t)e^{-iE_{ij}t}U_{ij}^0 \quad (3)$$

where $U_{ij}{}^0$ represents the eigen function describing both ith nuclear and jth electronic states and where E_{ij} is the eigen value of $U_{ij}{}^0$. According to the CKO model, the triplet state of the radical pair does not lie on the reaction coordinate; hence, the rate of population increase to the final product can be assumed to be proportional to the degree of the singlet character of the radical pair (*i.e.*, the probability of the radical pair in the singlet state). Such a probability of the radical pair can be given by the coefficient of the electronic singlet state, $|C_{is}(t)|^2$ for the ith nuclear spin state, where the suffix s refers to the electronic singlet. Thus, by averaging $|C_{is}(t)|^2$ over the lifetime of the radical pair, τ, the rate of the population increase of the ith nuclear spin state follows Eq. (4);

$$k_i = \frac{k_{SE}}{n}\int_0^\infty |C_{is}(t)|^2 e^{-t/\tau}dt \Big/ \int_0^\infty e^{-t/\tau}dt \quad (4)$$

where k_{SE} is the specific rate for the product generated from the radical pair in the pure singlet state and where n is the number of spin states of the nuclear spin system in the problem.

Let us now return to the radical pair in our case;

II

which is simply denoted by $[R_1(H_2)\cdot, \cdot R_2]$. Let us evaluate the rate of the population increase of a given nuclear-spin state for methylene protons of the I adduct. Considering the II radical pair, consisting of two electrons and two hydrogen nuclei, one can rewrite Eq. (1) as;

$$\mathscr{H}_0 = \beta H_0(g_1S_1+g_2S_2) - J_e(1/2+2S_1S_2) + (A_{11}I_1+A_{21}I_2)S_1 \quad (5)$$

The four spin functions of the electronic system are taken as $S=1/\sqrt{2}\,(|\alpha\beta>-|\beta\alpha>)$ for the singlet state, and $T_1=|\alpha\alpha>$, $T_0=1/\sqrt{2}\,(|\alpha\beta>+|\beta\alpha>)$, and $T_{-1}=|\beta\beta>$ for the triplet states. Then, the matrix elements of the Hamiltonian, $\mathscr{H}_0$, for these spin functions become as follows;

$$\begin{pmatrix} J_e & -1/2\sqrt{2}\,(A_{11}I_1^+ + A_{21}I_2^+) & 1/2\beta H_0(g_1-g_2)+1/2(A_{11}I_1+A_{21}I_2) & 1/2\sqrt{2}\,(A_{11}I_1^- + A_{21}I_2^-) \\ * & 1/2\beta H_0(g_1+g_2)-J_e+1/2(A_{11}I_1+A_{21}I_2) & 1/2\sqrt{2}\,(A_{11}I_1^- + A_{21}I_2^-) & 0 \\ * & * & -J_e & 1/2\sqrt{2}\,(A_{11}I_1^- + A_{21}I_2^-) \\ * & 0 & * & -1/2\beta H_0(g_1+g_2)-J_e-1/2(A_{11}I_1+A_{21}I_2) \end{pmatrix} \quad (6)$$

where I^+ and I^- are the nuclear-spin operators, I_x+iI_y and I_x-iI_y respectively, and the element * represents the conjugate of the symmetric elements with respect to the diagonal of the matrix. Matrix (6) shows that the mixing between the electronic singlet and triplet states occurs through off-diagonal elements, *i.e.*, hyperifine coupling constants and g values.

Let us denote the four spin states of the nuclear system as ϕ_i $(i=1\cdots,4)$. A solution of Schrödinger's Eq. (2) for the Hamiltonian (5) can be obtained under suitable initial conditions after solving a secular equation of the matrix with dimensions of 16×16. Such a procedure is very tedious, however, so let us now consider two limiting cases: $2|J_e|\cong|A|$ for case (a) and $|\pm\beta gH_0-J_e|\cong|A|$ for case (b).

Case (a); $2|J_e|\cong|A|$. This is a very important case, one in which the electronic singlet, S, and the T_0 triplet are mixing. As the Zeeman energy is much larger than the hyperfine interaction, the mixing between the singlet, S, and the other two triplets, T_1 and T_{-1}, is negligibly small. Then, we can easily solve the secular equation of matrix (6); we get, as the 16 eigen functions;

$$|T_1\phi_i> \quad (7a)$$
$$|T_{-1}\phi_i> \quad (7b)$$
$$(\cos\theta_i|S>+\sin\theta_i|T_0>)\phi_i \quad (7c)$$
$$(\sin\theta_i|S>-\cos\theta_i|T_0>)\phi_i \quad (7d)$$
$$(i=1,\cdots,4)$$

and, as the 16 eigen values;

$$E_{1i} = 1/2\beta H_0(g_1+g_2) - J_e + 1/2M_i \quad (8a)$$
$$E_{2i} = -1/2\beta H_0(g_1+g_2) - J_e - 1/2M_i \quad (8b)$$
$$E_{3i} = [J_e^2+(1/2\beta H_0\Delta g+1/2M_i)^2]^{1/2} \quad (8c)$$
$$E_{4i} = -[J_e^2+(1/2\beta H_0\Delta g+1/2M_i)^2]^{1/2} \quad (8d)$$
$$(i=1,\cdots,4)$$

where $\tan2\theta_i=J_e/M_i$, $\Delta g=g_1-g_2$, and $M_i=<\phi_i|A_{11}I_1+A_{21}I_2|\phi_i>$. By considering that the radical pair, II, was in the triplet state at the initial time, $t=0$, Eq. (2) can be easily solved by means of Eq. (3) in the zeroth-order approximation as follows;

$$\Psi(t) = \frac{1}{2}\sum_{i=1}^{4}\{e^{-iE_{1i}t}|T_1\phi_i>+e^{-iE_{2i}t}|T_{-1}\phi_i>+\sin\theta_i\cos\theta_i \times(e^{-iE_{3i}t}-e^{-iE_{4i}t})|S\phi_i>+(\sin^2\theta_i e^{-iE_{3i}t} +\cos^2\theta_i e^{-iE_{4i}t})|T_0\phi_i>\} \quad (9)$$

The probability that the radical pair transfers after time t from the electronic triplet state to singlet state is given by;

$$|C_{ij}(t)|^2 = \frac{1}{2}\sin^2\theta_i\cos^2\theta_i\{1-\cos(E_{3i}-E_{4i})t\} \quad (10)$$

Then, by using Eq. (4), we obtain k_i as the rate of population increase for the nuclear-spin state, ϕ_i, of the photo-adduct;

$$k_i = \frac{k_{SE}}{2}\,\frac{(1/2\beta H_0\Delta g+1/2M_i)^2\tau^2}{1+(E_{3i}-E_{4i})^2\tau^2} \quad (11)$$

This is a well-known expression derived by Closs and Trifunac[5] and by Kaptein and Oosterhoff.[6] Since the values of M_i in Eq. (11) differ from one nuclear-spin state to another, the increases in the rates of the adduct are different according to the individual nuclear spin states. Thus, polarization occurs in the nuclear-spin system of the adducts.

Case (b); $|\pm\beta gH_0-J_e|\cong|A|$. This is the case in which the electronic singlet, S, does not mix with the T_0 triplet but with the T_1 or T_{-1} triplet. Let us consider the case of the S–T_1 mixing alone. In this case, the Hamiltonian matrix with dimensions of 16×16 may be expressed as the direct sum of nine submatrices, whose dimensions are eight 1×1 and one 8×8. For the sake of simplicity, let us assume a relationship of hyperfine coupling constants, $A_{11}\cong A_{21}$; this is reasonable because two protons of the radical pair, II, in the problem are attached to the same carbon atom. On denoting the two spin functions of a single nuclear spin by $|+>$ and $|->$, we obtain, as the spin functions for AB-spin system, $s=1/\sqrt{2}\,(|+->-|-+>)$, $t_1=|++>$, $t_0=1/\sqrt{2}\,(|+->+|-+>)$, and $t_{-1}=|-->$. The first function, s, may be reffered to the nuclear-spin singlet, while probably the latter three may be reffered to the nuclear-spin triplets. Thus, we obtain the following four eigen functions concerned with the S–T_1 mixing;

$$\cos\gamma|T_1t_0>-\sin\gamma|St_1> \quad (12a)$$
$$\sin\gamma|T_1t_0>+\cos\gamma|St_1> \quad (12b)$$
$$\cos\delta|St_0>-\sin\delta|T_1t_{-1}> \quad (12c)$$

$$\sin\delta\,|St_0\rangle + \cos\delta\,|T_1t_{-1}\rangle \qquad (12d)$$

where $\tan 2\gamma = A/(\beta gH_0 - 2J_e)$ and $\tan 2\delta = A/(\beta gH_0 - 2J_e - 1/2\ A)$. It is acutually found from Eq. (12) that the mixing of the electronic singlet, S, and triplet, T_1, occurs only through the nuclear-spin triplet (t_1, t_0, and t_{-1}), but is not associated with the nuclear-spin singlet(s).

Assuming that the radical pair is in the electronic triplet state at the initial time, $t=0$, just after being produced, then we can obtain the rate of the population increase for a given nuclear-spin state of the adduct in the same manner as in the case of Eq. (9);

$$k(s) = k(t_{-1}) = 0 \qquad (13a)$$

$$k(t_1) = \frac{k_{SE}}{2}\,\frac{A^2\tau^2}{1 + [(\beta gH_0 - 2J_e)^2 + A^2]\tau^2} \qquad (13b)$$

$$k(t_0) = \frac{k_{SE}}{2}\,\frac{A^2\tau^2}{1 + [(\beta gH_0 - 2J_e - 1/2A)^2 + A^2]\tau^2} \qquad (13c)$$

Eq. (13) leads to an unexpected and interesting conclusion. In the limiting case of the S–T_1 mixing, only the adducts in the states of the nuclear-spin triplets (t_0 and t_1) are exclusively generated from the radical pair in the pure electronic singlet state.

If we consider another limiting case of the S–T_{-1} mixing, it may be deduced that the adducts in the states of the nuclear-spin triplets (t_0 and t_{-1}) are preferentially generated from the radical pair.

Results and Discussion

Signal Observed. The hydrogen-abstraction reactions of phenanthraquinone with toluene, *o*-xylene, *o*-chlorotoluene, and *o*-bromotoluene are photochemically induced to yield their 1,2-adducts. For example, as is shown in Fig. 1, methylene protons of the adduct with *o*-xylene indicate the AB-spin system in the NMR pattern; this system was originally observed by one of the present authors (K.M.). The quartet spectrum of the photo-adduct arises from the fact that the two methylene protons are magnetically different from each other due to the unequality in their conformations.[13]

This was confirmed by the fact that the chemical-shift difference between A and B protons decreased with an increase in the temperature. The absorption line at 226 Hz (down field from TMS) in Fig. 1 is due to a hydroxyl proton of the photo-adduct.

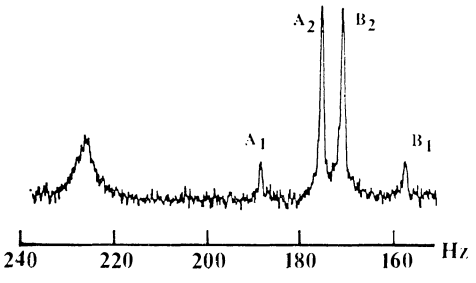

Fig. 1. Normal NMR quartet spectra due to the methylene protons of the 1,2-adduct of phenanthraquinone with *o*-xylene. Chemical shifts are in Hz down-field from TMS.

In Fig. 2 the spectrum (down) was observed for *o*-xylene solution of phenanthraquinone, while the spectrum (up) was recorded in the course of irradiation. The signal at 183 Hz (down-field from TMS) is responsible for a carbon-13 satellite of the methyl group of *o*-xylene, while the small but broad signal at about 180 Hz represents accidental harmonics due to AC power. Strongly-polarized quartet lines are observed during the course of irradiation, where three lines,

Fig. 2. Polarized NMR signals due to methylene protons of the 1,2-adduct of phenanthraquinone with *o*-xylene in photo-induced reaction.

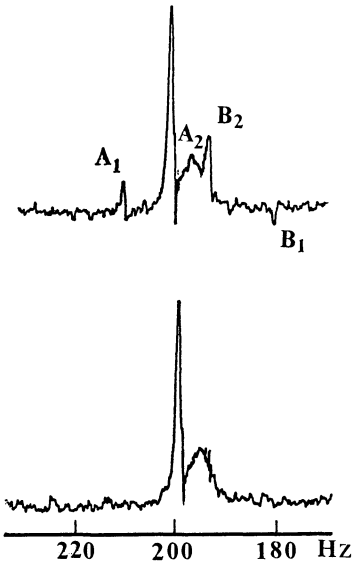

Fig. 4. Polarized NMR signals due to methylene protons of the 1,2-adduct of phenanthraquinone with *o*-bromotoluene in photo-induced reaction.

A_1, A_2, and B_2, at low fields show enhanced absorption, while the remaining line at a higher field (B_1), shows emission.

If the irradiation is shut off, the quartet spectrum promptly decays.

The quartet spectra for adducts of *o*-chlorotoluene and *o*-bromotoluene are illustrated in Figs. 3 and 4. It can be seen from these figures that the A_1 and B_2 lines of the quartet spectra show enhanced absorption, while that the A_2 and B_1 lines show emission. It was observed for the photo-adduct of toluene that the A_2 and B_2 lines are strongly enhanced and that the B_1 line is emission-enhanced. On the other hand, the A_1 line revealed a nearly zero polarization. The parameters of the quartet spectra of these adducts are gived in Table 1.

Table 1. Differences of chemical shifts $\Delta\omega$ spin-spin coupling constants J_n and intensity ratios I_{A_2}/I_{A_1} of quartet spectra of the photo-adducts of phenanthraquinone with hydrogen donors

Hydrogen donor	$\Delta\omega$(Hz)	J_n(Hz)	Intensity ratio, I_{A_2}/I_{A_1}
o-Xylene	12.4	13.1	6.52
o-Chlorotoluene	10.5	12.8	7.81
o-Bromotoluene	11.1	13.5	7.77
Toluene	3.6	8.52	23.0

An Interpretation of Results. As was shown in Eq. (14) of a previous paper[10] the population difference, $[Z_i]-[Z_j]$ between the ith and jth nuclear-spin states of the photo-adduct was thus after light irradiation;

$$[Z_i]-[Z_j] = \frac{k_0 k_a (k_i-k_j) T_1^*}{(k_a+1/\tau_f)\sum_j (k_j+2k_{bd})}(1-e^{-t/T_1^*}) \quad (14)$$

wher k_o and k_a are the specific rate constant for the photo-excited molecule and that for the process of hydrogen abstraction respectively, and where k_i and k_j are the rate constants for the formation of photo-adducts in the ith and jth nuclear spin states respectively. k_{bd} is the rate constant which is associated with the process independent of the nuclear spin. T_1^* is the relaxation time of the nuclear-spin system under the irradiation of light, and τ_f is the lifetime of the excited molecules. On assuming that $k_a \gg 1/\tau_f$, Eq. (14) is reduced to;

$$[Z_i]-[Z_j] = C(k_i-k_j) \quad (15)$$

in the steady-state polarization. Here, C is a constant proper to the reaction system. The relative intensities of the polarized signals of the photo-adduct are proportional to the product of the population difference and to the relative intensities of the normal spectrum (*i.e.*, the transition probability induced by the application of the rf field). Thus, the relative intensities of polarized signals, I_{ij}^*, in steady-state polarization lead to;

$$I_{ij}^* = (k_i-k_j)I_{ij} \quad (16)$$

where I_{ij} is the relative intensity of the spectral line in the thermal equilibrium of the spin system. The (k_i-k_j) factor may be referred to as a relative enhancement factor. One can compare the theoretical results with the experimental results by using Eq. (16).

It must first be investigated whether the polarized quartet signals can or can not be interpreted on the basis of the S–T_0 mixing alone. In the following calculations, it may be reasonable to assume that the hyperfine coupling constant, A_{11}, is nearly eaqual to A_{21} for the reason previously mentioned.

The rates of population increase for the four spin states of the AB-spin system of the photo-adduct can be calculated by means of Eq. (11). The relative intensities of the polarized signals are given by Eq. (17) as follows for the transitions corresponding to the spectral lines, A_1, A_2, B_2, and B_1 in the order of high-resonance frequencies; for lines A_1 and B_2;

$$I^* = \left\{ \frac{1/4(\beta H_0 \Delta g + A)^2\tau^2}{1 + 4[J_e^2 + 1/4(\beta H_0 \Delta g + A)^2]\tau^2} - \frac{1/4(\beta H_0 \Delta g)^2\tau^2}{1 + 4[J_e^2 + 1/4(\beta H_0 \Delta g)^2]\tau^2} \right\} \times I \quad (17a)$$

and for lines A_2 and B_1;

$$I^* = \left\{ \frac{1/4(\beta H_0 \Delta g)^2\tau^2}{1 + 4[J_e^2 + 1/4(\beta H_0 \Delta g)^2]\tau^2} - \frac{1/4(\beta H_0 \Delta g - A)^2\tau^2}{1 + 4[J_e^2 + 1/4(\beta H_0 \Delta g - A)^2]\tau^2} \right\} \times I \quad (17b)$$

It is evident form Eq. (17) that the relative enhancement factor is the same for both the A_1 and B_2 lines and also for both the A_2 and B_1 lines. As was illustrated in Fig. 2, in the polarized quartet signals of the photo-adduct of *o*-xylene, the A_2 line shows a positive polarization, while the B_1 line shows a negative polarization. This fact is substantially inconsistent with the theoretical consideration just mentioned. Thus, we may conclude that the CKO theory approximated to S–T_0 mixing is not satisfactory in discussing the photo-induced reaction examined here.

Now, consider a moderate case; $|A| \ll 2|J_e| < \beta g H_0$. In such a case, the rate of the population increase of the

photo-adduct may be taken as the sum of the contributions from pure S–T_0, S–T_1, and S–T_0–T_1 interactions. Since the contributions from the former two are generally larger than that from the latter, the contribution from the S–T_0–T_1 interaction may be ignored for the sake of simplicity. Therefore, the rates of population increase may be given by Eqs. (11) and (13). Since the A_1,A_2,B_2, and B_1 spectral lines are assumed to correspond to the $t_1 \rightarrow s$, $t_0 \rightarrow t_{-1}$, $t_1 \rightarrow t_{-1}$, and $s \rightarrow t_{-1}$ transitions,[14] the relative intensities of quartet lines are obtained from Eq. (16). On assuming that $2|J_e|$ and $\beta g H_0 \gg |A|$ and $\beta H_0 \Delta g$, they are as follows for individual lines;

$$I^*_{A_1} = \left\{ \frac{1/4A(2\beta H_0 \Delta g + A)\tau^2}{1+4J_e^2\tau^2} + \frac{A^2\tau^2}{1+4(1/2\beta g H_0 - J_e)^2\tau^2} \right\} I_{A_1} \quad (18a)$$

$$I^*_{A_2} = \left\{ \frac{1/4A(2\beta H_0 \Delta g + A)\tau^2}{1+4J_e^2\tau^2} + \frac{A^2\tau^2}{1+4(1/2\beta g H_0 - J_e)^2\tau^2} \right\} I_{A_2} \quad (18b)$$

$$I^*_{B_2} = \frac{1/4A(2\beta H_0 \Delta g + A)\tau^2}{1+4J_e^2\tau^2} \times I_{B_2} \quad (18c)$$

$$I^*_{B_1} = \frac{1/4A(2\beta H_0 \Delta g - A)\tau^2}{1+4J_e^2\tau^2} \times I_{B_1} \quad (18d)$$

The relative intensities of polarized signals in the photo-adduct can be calculated by means of Eq. (18). As for the photo-adducts of *o*-xylene and *o*-chlorotoluene, Fig. 5 (spectra a and b) compares the experimental results with the calculated relative intensities based on the parameters in Table 2; $g=2.0$, $H_0=14000$ gauss, $\tau=10^{-9}$ sec, and A, J_e and Δg were adjusted so as to fit the experimental results. The agreement of the experimental results with the calculations is fairly good. However, the polarized quartet signals of the photo-adduct of toluene could not be interpreted whatever parameter values were used. This discrepancy may be due to the neglect of the S–T_0–T_1 interaction of the radical pair.

The absolute values in Table 2 can not be too significant because of the simplifications adopted in Eq. (18). However, it may be concluded at least that; 1) experimental results are interpreted in terms of the mixing between the electronic singlet (S) and triplet states (T_0 and T_1) of the associated radical pair, and 2) the scalar electronic-exchange coupling constant, J_e, has a positive value intermediate between the Zeeman energy and the hyperfine coupling constant.

TABLE 2. PARAMETERS ADJUSTED TO MAKE FIT WITH THE EXPERIMENTAL RESULTS

Hydrogen donor	$\beta H_0 \Delta g/A$	J_e(Hz)$\times 10^9$
o-Xylene	−0.168	7.31
o-Chlorotoluene	−0.053	6.61

The resulting value of J_e is positive and is larger by about one order than the values reported hetherto.[15] As for our present values, it is not unreasonable to consider that an electronic π–π interaction brought about by the aromatic nature of each component of the radical pair may be responsible. There is strong chemical evidence supporting the above considerations.[16,17]

As was pointed out by Garst and his co-workers,[7] the contribution of S–T_1 interaction to nuclear polarization give a chance to observe the polarization from the reactions of diradicals or corresponding radical pairs. The reaction system reported here seems to be an ideal case where both the S–T_0 and S–T_1 interactions are associated with the nuclear-spin polarization.

14) Strictly speaking, this is the case when the limiting factor, $J_n/\Delta\omega \rightarrow \infty$, but this assumption does not lead to fatal errors in the results of the present study.

Solvent Effect in a Partial Asymmetric Synthesis. III

Kazuyoshi NISHIYAMA and Yuzo INOUYE
Institute for Chemical Research, Kyoto University, Uji, Kyoto

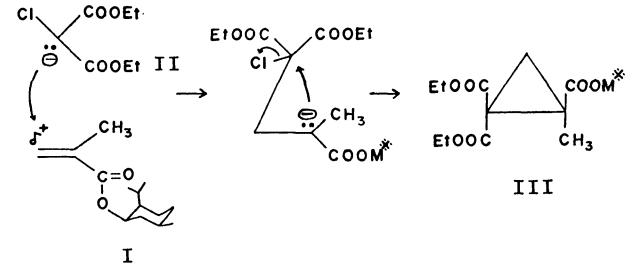
(Received April 22, 1971)

The solvent polarity-dependence of asymmetric stereochemistry was unambiguously corroborated in the Michael type cyclopropane formation in a system designed so as to proceed through the transition state conformations of an equal dipole moment not involving any geometrical isomerism: the NaH-catalyzed condensation of (−)-menthyl methacrylate with ethyl chloromalonate in solvent media of varying polarity resulted in the formation of (−)-1-methylcyclopropane-1,2,2-tricarboxylic acid having the same sign of rotation in all cases. The fit of the stereochemistry to the Kirkwood equation was borne out by the linearity found for the plots of log *R*/*S* against the Kirkwood-Onsager parameter. The *R*-configuration of (−)-1-methylcyclopropane-1,2,2-tricarboxylic acid was established by the correlation to (+)-2,2-diphenyl-1-methylcyclopropanecarboxylic acid of the well-defined (*R*)-configuration.

In previous papers,[1a–d] the solvent polarity-dependence of stereochemistry in the base-catalyzed Michael type cyclopropane formation was unequivocally established and a theory was advanced to rationalize the observed solvent effect. The theory asserts that both the *cis*, *trans*-stereochemistry and simultaneous asymmetric induction are the consequence of a delicate balance between the electrostatic and steric stabilities of the transition state conformations: *i.e.* where the electrostatic factor is dominant over the steric one, the transition state having the greater dipole moment is more stabilized by solvation in polar and strongly solvating media, while the situation is just reversed in non-polar media poor at solvation. This is naturally reflected in the rate of formation and leads to the stereochemical outcome that both *cis*/*trans* and *R*/*S* ratios in the cyclopropane products vary regularly depending upon the solvent polarity, and even a conspicuous reversal of the geometric isomer ratio and the sign of rotation of the cyclopropane products takes place at a given polarity of reaction media. The Kirkwood equation strictly holds for the stereochemistry in this type of reaction.

Gemoetrical isomerism necessarily intervened in all the systems investigated so far[1a–d], which sometime caused an argument[2] against our claim of the solvent effect in asymmetric synthesis. The solvent polarity-dependence of stereochemistry in the system designed so as to afford a single compound capable of existing only in enantiomeric forms would confirm the effect and would also enhance the validity of the theory.

For this purpose, we designed a system involving the NaH-catalyzed Michael type condensation of (−)-menthyl methacrylate (I) with diethyl chloromalonate (II) to give 1-methylcyclopropane-1,2,2-tricarboxylic acid ester (III). In contrast to the earlier systems, product (III) in the present system lacks *cis*, *trans*-isomerism by virtue of structural feature and the reaction gives rise to a single compound as mixture of enantiomers in unequal amounts. This not only simplifies the experimental procedure and makes easier the analysis of stereochemical results of the asymmetric reactions, but also suffices for testing the prediction based on the theory.



Scheme 1

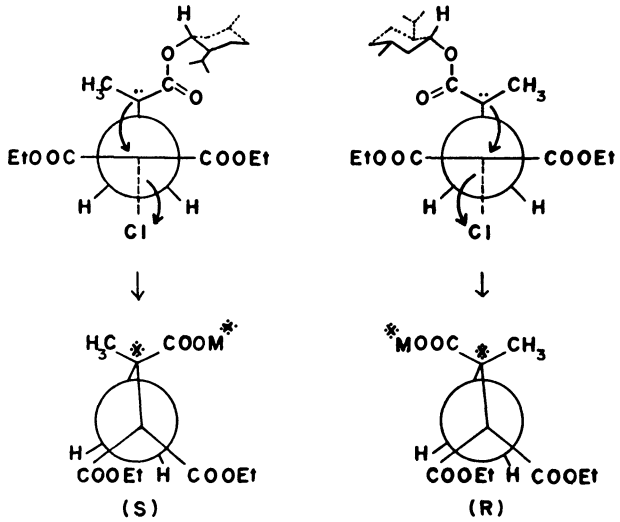


Fig. 1. Transition state conformations leading to *R*- and *S*-1-methylcyclopropane-1,2,2-tricarboxylic acid

Visualized in the Fig. 1 are the transition state conformations (sp^2-model)[1c] which fulfil the stereoelectronic requirements for maximum orbital overlap and charge delocalization and would eventually lead to the enantiomeric *R*- and *S*- products respectively. They have an equal dipole moment (3.2D)[3] and are thus electrostatically equalized to each other. However they differ in steric strain owing to different orientation of the chiral (−)-menthyl moiety.

9:1	19.87	6.5	−4.42	5.68	1.1204
8:2	13.05	6.9	−3.49	4.48	1.0938
7:3	9.45	7.3	−3.03	3.89	1.0809
6:4	7.26	5.6	−2.73	3.50	1.0725
5:5	5.77	6.5	−2.44	3.13	1.0646
4:6	4.69	6.0	−2.06	2.64	1.0542

a) Based on the maximum rotation $[\alpha]_D^{25}$ −77.78°

It is seen that the *R*-transition state conformation is sterically more favored than the *S*-counterpart. It may therefore be safely predicted that inasmuch as the steric factor is the controlling factor, the product acid with the same sign[4] of rotation should result from the reactions. The experimental results are summarized in Table 1.

The yields of the cyclopropane product (III) in the present system were found to be rather poor[5], being accompanied by the formation of ethylenetetracarboxylic acid ester as has been observed in analogous non-dissymmetric reactions,[6] but sufficient for the determination of the sign and magnitude of rotation of the product cyclopropane acid which was isolated pure as trimethylester and fully characterized.

As can be seen from the data, the present asymmetric reaction afforded the cyclopropane acid ester (III-a) of levorotation within experimental errors over the range of polarity investigated (from ε 4.69 through 37.63). The plots of log R/S against the Kirkwood-Onsager parameter showed a satisfactory linearity (Fig. 2).

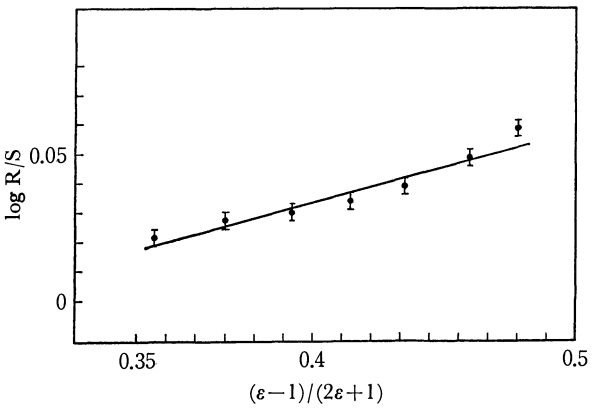

Fig. 2. The plots of logR/S *vs.*Kirkwood-Onsager parameter of reaction medium

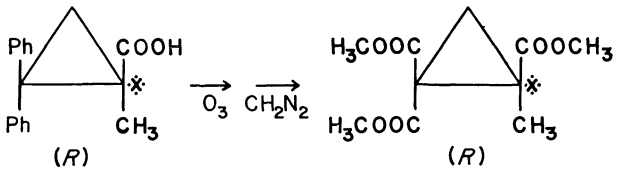
A positive slope of the regression line was found for the plots in the present reactions in contrast to the negative ones in the previous systems. The Kirkwood equation, as applied to the present case (eq. 1) and coupled with the positive slope experimentally found, clearly shows $r_R^* < r_S^*$ (the radius of the transition state carbanion), since the dipole moment μ^* is equal to both transition state carbanions (Fig. 1). This is in good agreement with the qualitative prediction based on the mere visual inspection of the scale model that the *R*-transition state carbanion is sterically more favored, *i.e.* more compact, which would manifest itself in a smaller molecular radius or volume.

$$\ln R/S = C_0 - 1/\kappa T \cdot (\varepsilon-1)/(2\varepsilon+1) \cdot \mu^{*2} \cdot (1/r_S^{*3} - 1/r_R^{*3}) \quad (1)$$

The absolute configuration and the maximum rotation of the product acid ester (III-a), which are indispensable for analysis of the steric course as well as estimation of the extent of optical yields, were obtained by the ozonolysis of (+)-2,2-diphenyl-1-methylcyclopropanecarboxylic acid (IV) of the known *R*-configuration[7] leading to (−)-(III-a). The Brewster calculation of conformational asymmetry predicts $[\phi]$ −45° for (*R*)-(III-a), which shows an agreement with the observed value $[\phi]$ −138.6° in the sign of rotation, but not in the magnitude. Considering the empirical nature of the method and since the solvent interaction is not taken into consideration, the value may not be surprising.



Scheme 2

Experimental

General. Melting and boiling points were uncorrected. Rotations were taken on a Yanagimoto Model ORD-185A recording spectropolarimeter: NMR-spectra were on a Varian A-60.

4) Accumulated knowledge of cyclopropane chirality suggests a levorotation for an *R*-configuration of cyclopropane ring carbon bearing polar groups. This rule of thumb is also in fair agreement with the Brewster conformational asymmetry calculation.

5) This chemical situation may be well understood if one invokes the HSAB principle (R. G. Pearson, *Science*, **151**, 172 (1966) and references cited therein) to the present system: chloromalonate ester carbanion having a moderate base strength comparable to hydroxide anion reacts preferentially with chloromalonate which is harder than (−)-menthyl methacrylate. The self-condensation of chloromalonate thus proceeds *via* the consecutive S_N2 and E2 pathways to give ethylenetetracarboxylate in preponderance.

Asymmetric Synthesis of 1-Methylcyclopropane-1,2,2-tricarboxylic acid ester (III). The synthetic procedure is exemplified by a typical run in a mixture of benzene and DMF (1:9 by volume ratio). The reaction was repeated in exactly the same manner except that the solvent composition was varied.

(−)-Menthyl methacrylate (22.4 g, 0.1 mol, bp 82°C/0.7 mmHg, n_D^{25} 1.4575) and diethyl chloromalonate (19.4 g, 0.1 mol) were allowed to react in the presence of sodium hydride (4.8 g, 0.1 mol; dispersed in oil from Metal Hydride Inc., 52.9% purity) in 150 m*l* of mixed solvent (benzene: DMF=1:9 by volume) at 25°C for 6 hr with stirring. The reaction temperature was maintained constant throughout the reaction by cooling with ice water when necessary. After the reaction period, sufficient water was added. The organic layer was extracted with ether and the combined extract, after removal of ether, was then hydrolyzed by refluxing with 8% potassium hydroxide in methanol (200 m*l*) for 40 hr. The hydrolyzate was concentrated by evaporation under reduced pressure and was dissolved in water and the liberated menthol was removed with ether. The aqueous layer was acidified with equivalent hydrochloric acid and the cyclopropane acid was thoroughly extracted with ether. The acid was esterified by the standard method with diazomethane, and the crude trimethylester was separated pure by means of preparative vpc (Varian Aerograph Autoprep 700) on a 10 mm×6 m column packed with Silicone SE 30 (15%) at 185°C using helium gas as carrier. *Trimethyl 1-methylcyclopropane-1,2,2-tricarboxylate* n_D^{25} 1.4511; Found: C, 51.95; H, 6.29%. Calcd for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13%. NMR (CCl_4): τ 8.22 (d, J_{gem}=5.0 Hz, cyclopropane methylene 2H); τ 8.60 (s, C-1 methyl 3H); τ 6.26 (s, C-1 ester methyl 3H); τ 6.35 (s, C-2 ester methyl 6H). The IR-spectrum was identical with that of the authentic specimen derived from 1-methyl-2,2-diphenylcyclopropanecarboxylic acid *(vide infra)*. Yield 1.5 g (6.5%); $[\alpha]_D^{25}$ −4.42° (*c* 2.05, MeOH); optical yield 5.66% based on the maximum rotation $[\alpha]_D^{25}$ −77.78°.

Ozonolysis of R-*(+)-1-Methyl-2,2-diphenylcyclopropanecarboxylic acid.* (+)-*R*-1-Methyl-2,2-diphenylcyclopropanecarboxylic acid (mp 189°C, $[\alpha]_D^{25}$ +35° (chloroform); 700 mg), obtained by resolution *via* the brucine salt, was dissolved in acetic acid (100 m*l*). Crude ozone was passed through the solution at room temperature. After prolonged ozonolysis, hydrogen peroxide (30%, 20 m*l*) was added and the mixture was allowed to stand still overnight. Some palladium on carbon was added in order to decompose the remaining peroxide prior to evaporation of the mixture. After acetic acid was removed by evaporation at room temperature, diazomethane was added to the residue. The resulting trimethyl ester was separated pure by means of preparative vpc *(vide supra)*. The IR- and NMR-spectra fully substantiated the structure. Found: C, 52.11: H, 6.18%; Calcd for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13%. n_D^{25} 1.4518; $[\alpha]_D^{25}$ −77.78° (*c* 0.78, MeOH); yield 350 mg (54.8%); NMR (CCl_4): cyclopropane methylene protons τ8.22 (d, 2H, J_{gem}=5.0 Hz); C-1 methyl protons, τ 8.60 (s, 3H); ester methyl protons, τ 6.26 (s, 3H) and τ 6.35 (s, 6H).

The dielectric constants of the binary solvent system consisting of DMF and benzene in continuously varied volume ratios were computed by the mixing rule and the data given in a previous paper.[1c].

The authors are indebted to Professor Walborsky at the Florida State University for the generous gift of samples and also to Professor Griffin at Louisiana State University for his kind suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2797—2800 (1971)

A Convenient Method for the Preparation of Primary Amines by the Use of Bisbenzenesulfenimide and Bis-*p*-chlorophenylsulfenimide

Teruaki MUKAIYAMA, Takeo TAGUCHI, and Mineo NISHI

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 28, 1971)

A convenient method for the preparation of primary amines by the use of bisarylsulfenimide has been established. Primary amines were obtained in good yields under mild reaction conditions by treating *N*-substituted bisarylsulfenimides with hydrochloric acid or mercaptan. The *N*-substituted bisarylsulfenimides were prepared in good yields by the reactions of lithium bisarylsulfenimide with alkyl halides or alkyl *p*-toluenesulfonates or by the addition reactions of bisarylsulfenimide to olefinic compounds.

It is well known that the Gabriel synthesis[1] is the most general method for the selective preparation of primary amino compounds. However, there is a disadvantage in the method for the preparation of amino compounds with nitrile, ester, amide or carbonyl groups in the same molecule. These functional groups are hydrolyzed to give carboxylic acid or they react with hydrazine at the same time when phthaloyl group is removed from *N*-substituted phthalimide, an intermediate of the Gabriel synthesis.

In the present study, a new route for the convenient preparation of various primary amines from bisarylsulfenimides, such as bisbenzenesulfenimide or bis-*p*-chlorophenylsulfenimide, and alkyl halides or *p*-toluenesulfonates, or olefinic compounds was investigated with the consideration that the sulfur-nitrogen bond of *N*-substituted bisarylsulfenimide is easily cleaved by hydrochloric acid or mercaptan to afford the corresponding primary amine together with sulfenyl chloride or di-

b) In this case, bis-*p*-chlorophenylsulfenimide was isolated in 8% yield.

sulfide.

It was shown that primary amines are obtained in good yields under mild reaction conditions by treating *N*-substituted bisbenzenesulfenimide with hydrochloric acid or mercaptan.[2] The *N*-substituted bisbenzenesulfenimides are successfully derived from lithium bisbenzenesulfenimide and alkyl halides or alkyl *p*-toluenesulfonates. As an example, benzylamine was obtained in 86% yield by treating *N*-benzyl bisbenzenesulfenimide formed by the reaction of bisbenzenesulfenimide with *n*-butyllithium in tetrahydrofuran at −20°C for 5 min, and the subsequent reaction with benzyl bromide in tetrahydrofuran for 5 hr with 3N hydrochloric acid at room temperature for 3 hr. The yield of the amine was determined from the amount of *N*-benzyl-*N'*-phenylurea obtained by the subsequent reaction with phenyl isocyanate.

$$(ArS)_2NH + n\text{-BuLi} \longrightarrow (ArS)_2NLi$$

$$[II] + RX \longrightarrow (ArS)_2NR \xrightarrow{HCl} RNH_2 + 2ArSCl$$
[III] [IV] [V]

$Ar = C_6H_5$, *p*-ClC_6H_4

Similarly, various primary amines were prepared from alkyl halides or alkyl *p*-toluenesulfonates and lithium bisbenzenesulfenimide or lithium bis-*p*-chlorophenylsulfenimide. (see Tables 1 and 2).

N-Substituted bisbenzenesulfenimides could not be isolated as pure substances because the imides decomposed on distillation or on silica gel column chromatography. On the other hand, some *N*-substituted bis-*p*-chlorophenylsulfenimide was obtained as crystalline; for example, *N*-benzyl bis-*p*-chlorophenylsulfenimide was obtained in 79% yield as a white crystalline, mp 90°C, by treating lithium bis-*p*-chlorophenylsulfenimide formed by the reaction of bis-*p*-chlorophenylsulfenimide with *n*-butyllithium at −50°C in tetrahydrofuran, with benzyl bromide at room temperature in tetrahydrofuran for 5 hr. Treatment of *N*-benzyl bis-*p*-chlorophenylsulfenimide with dry hydrogen chloride in dry ether gave benzylamine and *p*-chlorophenylsulfenyl chloride in quantitative yields.

Bisbenzenesulfenimide was obtained instead of the corresponding condensation product when lithium bisbenzenesulfenimide was allowed to react with β-carbethoxyethyl *p*-toluenesulfonate. Formation of bisbenzenesulfenimide and acrylonitrile in the above reaction may be explained by considering the abstraction of an acidic hydrogen atom on the α-carbon atom of β-carbethoxyethyl *p*-toluenesulfonate by lithium bisbenzenesulfenimide. On the other hand, lithium bis-*p*-chlorophenylsulfenimide, the acidity of which is higher than that of bisbenzenesulfenimide, reacted with the *p*-toluenesulfonate to give *N*-β-carbethoxyethyl bis-*p*-chlorophenylsulfenimide in 57% yield.

$$(ArS)_2NLi + C_2H_5O_2CCH_2CH_2OTs \longrightarrow \begin{cases} (ArS)_2NH + CH_2{=}CHCO_2C_2H_5 \\ (ArS)_2NCH_2CH_2CO_2C_2H_5 \end{cases}$$

It was found that amines with nitrile group in the same molecule, olefinic amines or highly water-soluble amines were also successfully prepared along with disulfide when the corresponding *N*-substituted bisarylsulfenimide are treated with mercaptan. As an example, β-cyanoethylamine was obtained in 64%

a) E: ether b) THF: tetrahydrofuran c) THF: MeOH:AcOH (10:10:1 v/v) d) $ZnCl_2$ was used 5% mol/mol of the imide. e) The yields of amines were determined from *N*-substituted bis-*p*-chlorophenylsulfenimide.

yield as its picrate by the reaction of lithium bisbenzenesulfenimide with β-cyanoethyl *p*-toluenesulfonate in tetrahydrofuran at room temperature for 10 hr and the subsequent treatment with 2 molar equivalents of ethanethiol in ether at room temperature for 1 hr.

Similarly, β-cyanoethylamine was obtained in 88% yield when *N*-β-cyanoethyl bis-*p*-chlorophenylsulfenimide was allowed to react with 2 molar equivalents of benzenethiol in the presence of a catalytic amount of zinc chloride at room temperature in tetrahydrofuran for 3 hr.

On the other hand, *N*-β-cyanoethyl bis-*p*-chlorophenylsulfenimide did not react with benzenethiol even after they were refluxed in tetrahydrofuran for 2 hr.

In a similar way, allylamine, cinnamylamine, β-methoxyethylamine and tetrahydrofurfurylamine were prepared in good yields by the reactions of *N*-substituted bisarylsulfenimides formed from lithium bisarylsulfenimide and alkyl halides or alkyl *p*-toluenesulfonates with mercaptan (see Table 3).

The effects of the solvents on the condensation reactions of lithium bisbenzenesulfenimide with alkyl *p*-toluenesulfonates were studied. It was found that tetrahydrofuran and dimethoxyethane are suitable for this reaction. When diethyl ether or anisole was used as the solvent, diminution in the yield of amine and increase in the yield of unsymmetrical sulfide were observed. This may be due to the rapid decomposition of lithium bisbenzenesulfenimide in comparison with the above mentioned condensation reaction (see Table 4).

The reaction of bisbenzenesulfenimide with *n*-butyllithium in tetrahydrofuran at room temperature for 7 hr, followed by the addition of isoamyl bromide in tetrahydrofuran at room temperature for 5 hr, resulted in the formation of isoamyl phenyl sulfide and diphenyl disulfide in 71% and 67% yields, respectively. This may be explained by considering the decomposition of lithium bisbenzenesulfenimide into lithium thiophenolate and phenylthionitrene. The lithium thiophenolate thus formed reacts with isoamyl bromide to give isoamyl phenyl sulfide and the phenylthionitrene further decomposes to nitrogen and diphenyl disulfide as shown below.

$$(C_6H_5S)_2NH + n\text{-BuLi} \longrightarrow [(C_6H_5S)_2NLi]$$

It was also established that primary amines are successfully prepared from bisarylsulfenimide and olefinic compounds. The addition reaction of bisbenzenesulfenimide to acrylonitrile proceeded smoothly in tetrahydrofuran at room temperature in the presence of a catalytic amount of trimethylbenzylammonium hydroxide (Triton B), and β-aminopropionitrile was obtained in 91% yield by treating the adduct with 2 molar equivalents of ethanethiol in ether at room temperature for 1 hr.

from bisbenzenesulfenimide and the corresponding olefinic compounds (see Table 5).[3]

Experimental

*Synthesis of Bis-*p*-chlorophenylsulfenimide.* Into 1000 m*l* of ether solution saturated with dry ammonia, *p*-chlorophenylsulfenyl chloride (51.0 g, in 150 m*l* of ether) was added dropwise under stirring at a temperature below −5°. The reaction mixture was stirred for 2 hr at −5—0°C. After the resulting precipitate, ammonium chloride, was filtered and washed with 100 m*l* of tetrahydrofuran, the filtrate was evaporated under reduced pressure and a crystalline precipitate was obtained. Recrystallization from benzene gave bis-*p*-chlorophenylsulfenimide, 27.5 g (66%), mp 137—140°C (decomp.).

Found: C, 47.76; H, 3.29; N, 4.76; S, 21.42%. Calcd for $C_{12}H_9NS_2Cl_2$: C, 47.70; H, 3.00; N, 4.64; S, 21.18%.

Preparation of Alkylamines from Lithium Bisarylsulfenimide (IIa and IIb) and Alkyl Halides or Alkyl p-*Toluenesulfonates. General Procedure*: *Method A*: A solution of alkyl halide or alkyl *p*-toluenesulfonate (0.005 mol) in tetrahydrofuran was added into a solution of lithium bisarylsulfenimide formed from bisarylsulfenimide (0.005 mol) and *n*-butyllithium (0.005 mol) in tetrahydrofuran at −20——50°C under stirring. The reaction mixture was stirred at −20—0°C for 2 hr and at room temperature for additional 2—8 hr. After removal of the solvent, the residue was stirred in a mixture of ether (20 m*l*) and 3N hydrochloric acid (10 m*l*) for 10 min—3 hr at room temperature.[4] The aqueous solution extracted from the reaction mixture was concentrated to dryness. The residue was dissolved in an aqueous solution of 20% sodium hydroxide (30 m*l*) and extracted with 50 m*l* of ether four times. The ether extract was dried over anhydrous sodium sulfate.

Method A-1: Into the ether extract phenyl isocyanate (0.60 g, 0.005 mol) was added and stirring was continued for 30 min. After removal of ether, a crystalline precipitate was obtained and washed with petroleum ether. Recrystallization from ethanol gave *N*-alkyl-*N'*-phenylurea.

Method A-2: Into the ether extract picric acid (1.15 g, 0.005 mol) was added and ether was removed by evaporation. The picrate of the corresponding alkyl amine was obtained by recrystallization from ethanol or a mixture of ethanol and benzene. By means of either *Method A-1* or *Method A-2*, *n*-butylamine, *n*-octylamine, *sec*-butylamine, *sec*-octylamine benzylamine and *p*-nitrobenzylamine were prepared. The results are summarized in Tables 1 and 2.

Method B: A solution of alkyl halide or alkyl *p*-toluenesulfonate (0.005 mol) in tetrahydrofuran was added under stirring into a solution of lithium bisarylsulfenimide, formed from bisarylsulfenimide (0.005 mol) and *n*-butyllithium (0.005 mol) in tetrahydrofuran at −20——50°C. The reaction mixture was stirred at −20—0°C for 2 hr and at room temperature for additional 2—8 hr. After removal of the solvent, the residue was poured into 30 m*l* of water and the mixture was extracted with ether.[4] The extract was dried over anhydrous sodium sulfate and into the solution excess mercaptan (0.015 mol) was added under stirring. After stirring at room temperature for 30 min—3 hr, a yellowish precipitate was obtained by the addition of picric acid (1.15 g, 0.005 mol), followed by evaporation of the solvent. Recrystallization from ethanol gave the corresponding alkylamine as its picrate. By means of *Method B*, β-cyanoethylamine, β-methoxyethylamine, tetrahydrofurfurylamine, allylamine and cinnamylamine were obtained as their picrates. The results are summarized in Table 3.

Preparation of β-Cyanoethylamine from Bisbenzenesulfenimide and Acrylonitrile. Into a mixture of bisbenzenesulfenimide (1.17 g, 0.005 mol) and acrylonitrile (0.27 g, 0.005 mol) in tetrahydrofuran, a catalytic amount of trimethylbenzylammonium hydroxide (Triton B) was added under stirring. After stirring at room temperature for 30 min, ethanethiol (0.93 g, 0.015 mol) was added and the mixture was stirred at 0°C for 1 hr. After removal of the solvent, a yellowish precipitate was obtained by the addition of picric acid (1.15 g, 0.005 mol) to the residue. Recrystallization from ethanol gave the picrate of β-cyanoethylamine, 1.32 g, (91%), mp 179°C.

Found: C, 36.13; H, 3.03; N, 23.41%. Calcd for $C_9H_9O_7N_5$: C, 36.62; H, 2.98; N, 23.47%.

Similarly, ethyl β-aminopropionate, β-aminoethyl methyl ketone and β-aminoacrylamide were obtained by the reactions of bisbenzenesulfenimide with ethyl acrylate, methyl vinyl ketone and acrylamide, respectively. The results are listed in Table 5.

3) When bis-*p*-chlorophenylsulfenimide was treated with acrylonitrile in tetrahydrofuran at room temperature for 20 hr in the presence of a catalytic amount of Triton B, *N*-β-cyanoethyl bis-*p*-chlorophenylsulfenimide was obtained only in 18% yield.

4) When alkyl *p*-toluenesulfonate was used in place of alkyl halides, lithium *p*-toluenesulfonate precipitated by the addition of ether was removed by filtration and washed with ether.

Synthesis of *cyclo*-Diglycyl-L-tyrosyl-diglycyl-L-tyrosyl and Hydrolysis by Chymotrypsin

Mitsuhiro KONISHI,[1] Norio YOSHIDA, and Nobuo IZUMIYA[2]

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received May 4, 1971)

A cyclic hexapeptide, *cyclo*-(diglycyl-L-tyrosyl)$_2$, was synthesized by several different routes; the cyclization reactions of a tripeptide active ester, a tripeptide azide, and a hexapeptide azide produced the desired cyclic hexapeptide. The cyclic peptide was hydrolyzed slowly by chymotrypsin to a tripeptide diglycyl-tyrosine, whereas a synthetic linear hexapeptide, diglycyl-L-tyrosyl-diglycyl-L-tyrosine, was hydrolyzed very rapidly to the tripeptide. Since the synthetic *cyclo*-(diglycyl-L-phenylalanyl)$_2$ was insoluble in a buffer, it was not clear whether an incubation mixture of the substrate and enzyme yielded diglycyl-phenylalanine.

For a study of the mode of action of proteolytic enzymes on cyclic peptides, several compounds have been synthesized in this laboratory. In a previous paper, it was shown that *cyclo*-(Gly$_5$-Lys)[3] was completely hydrolyzed to H-Gly$_5$-Lys-OH by trypsin.[4] It was also observed that *cyclo*-(Gly$_2$-Lys)$_2$ was hydrolyzed to H-Gly$_2$-Lys-OH by trypsin though the rate of hydrolysis was extremely slow as compared with that of H-(Gly$_2$-Lys)$_2$-OH.[5] It is known that chymotrypsin hydrolyzes predominantly a peptide bond at the linkage of phenylalanine and tyrosine carbonyl.[6,7] Therefore, it was expected that a cyclic peptide containing Phe or Tyr residue might be hydrolyzed by chymotrypsin.

The present paper describes the syntheses of *cyclo*-(Gly$_2$-Tyr)$_2$ and a linear hexapeptide, H-(Gly$_2$-Tyr)$_2$-OH, and the mode of action of chymotrypsin on these peptides.

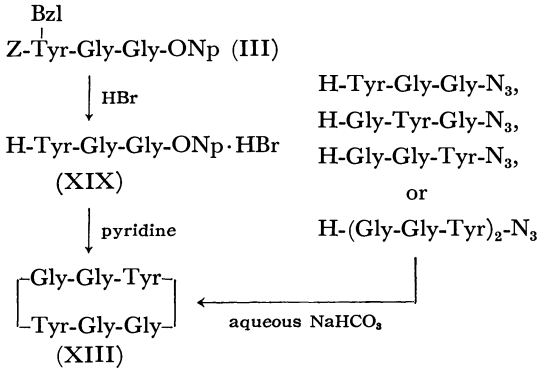

Fig. 1. Synthesis of the cyclic hexapeptide by various reaction sequences.

Five different routes shown in Fig. 1 were undertaken for the synthesis of the cyclic hexapeptide (XIII). In one route, XIII was synthesized *via* a linear tripeptide active ester (XIX), in which Tyr residue occupies the *N*-terminus of a peptide sequence. XIX was treated with a large amount of pyridine, and a pure cyclic hexapeptide was isolated easily though the yield was only 9%. The product was proved to be a dimer by molecular weight determination.

The cyclic peptide was also synthesized *via* linear tripeptide azides, in which Tyr residue occupies three different positions (Fig. 1). Crude cyclic peptide was isolated after the cyclization reaction of the azide in a large amount of water containing sodium bicarbonate. A linear hexapeptide azide was also subjected to the cyclization reaction (Fig. 1). Although the synthetic procedure in azide method to yield a crude cyclic peptide was simpler than that in an active ester method, treatment by a Sephadex LH-20 column with crude cyclic peptide was necessary to isolate a pure cyclic hexapeptide.

TABLE 1. YIELD AND SPECIFIC ROTATION OF CYCLIC HEXAPEPTIDES OBTAINED BY VARIOUS REACTIONS

Starting compound	*cyclo*-(Gly$_2$-Tyr)$_2$[a]	
	Yield, %	$[\alpha]_D^{20}$[b]
Bzl Z-Tyr-Gly$_2$-ONp	9	−63.2°
H-Tyr-Gly$_2$-NHNH$_2$	6	−63.0°
H-Gly-Tyr-Gly-NHNH$_2$	17	−63.5°
H-Gly$_2$-Tyr-NHNH$_2$	15	−62.5°
H-(Gly$_2$-Tyr)$_2$NHNH$_2$	20	−63.1°

a) All samples showed only one spot (R_f 0.80) on the paper chromatogram, and the same mp (decomp.) of 250—255°C. All air-dried samples were assigned to cyclic hexapeptide trihydrate by elemental analyses and molecular weight determinations within experimental errors.
b) *c* 0.2, DMF.

Yields of the cyclic hexapeptide by different routes are summarized in Table 1. It appears that the position of Tyr residue in a tripeptide active ester or azide has an influence on the yield of the cyclic hexapeptide isolated; a lower yield was observed when a bulky Tyr residue occupies *N*-terminus in a tripeptide intermediate.

An incubation mixture of the cyclic hexapeptide (XIII) was analyzed by paper chromatography to check how the susceptibility of XIII toward chymo-

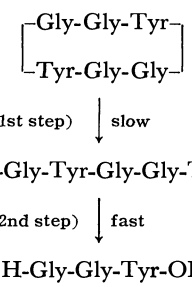

Fig. 2. Hydrolysis of the cyclic hexapeptide by chymotrypsin.

trypsin. It was observed that XIII was completely hydrolyzed to the tripeptide, H-Gly_2-Tyr-OH, after some 6 hr (see Fig. 4). A synthetic linear hexapeptide H-(Gly_2-Tyr)$_2$-OH was also subjected to an enzymatic experiment. The rate of its hydrolysis to the tripeptide was much greater than that of XIII;[8] the linear hexapeptide was completely hydrolyzed after 10 min with the same amount of enzyme used for the cyclic hexapeptide (see Fig. 5). Thus it was deduced that the hydrolysis of the cyclic hexapeptide by the enzyme might proceed in the two steps shown in Fig. 2; the first step, from *cyclo*-(Gly_2-Tyr)$_2$ to H-(Gly_2-Tyr)$_2$-OH, was supposed to be rate-determining.

It was expected that *cyclo*-(Gly_2-Phe)$_2$ (XVIII) would be synthesized more easily than *cyclo*-(Gly_2-Tyr)$_2$ and XVIII would hydrolyzed by chymotrypsin to H-Gly_2-Phe-OH. Since XVIII was insoluble in pH 8.0 buffer, it was not clear whether an incubation mixture of this cyclic hexapeptide and the enzyme yielded the expected tripeptide H-Gly_2-Phe-OH.

Experimental

A spot of material on a paper or plate was detected by spraying ninhydrin, Pauli reagent for Tyr residue or butyl hypochlorite reagent for peptide bond.[9] A spot of an amino group-blocked material on a plate was also detected by spraying 47% by hydrobromic acid and ninhydrin. The R_f refers to paper chromatography on Toyo Roshi No. 52 with a solvent of *n*-butanol-acetic acid-pyridine-water (4:1:1:2, vol). Purity of material was also checked by thin-layer chromatography with the same solvent or chloroform-methanol (5:1, vol).

Z-Tyr(Bzl)-Gly_2-OBzl (I). To a solution of Z-Tyr (Bzl)-ONp[10] (8.4 g) and H-Gly_2-OBzl·TsOH[11] (6.3 g) in chloroform (100 m*l*) was added TEA (2.4 m*l*) at room temperature. The mixture was left to stand overnight, evaporated *in vacuo*, and the oily residue was dissolved in ethyl acetate. It was washed with 2% hydrochloric acid, 4% sodium bicarbonate, and water, successively, dried over sodium sulfate and evaporated. The oil was solidified by the addition of petroleum ether. It was recrystallized from ethyl acetate-ether-petroleum ether; yield, 10.7 g (88%); mp 116—118°C; $[\alpha]_D^{15}$ +4.2° (*c* 1, acetic acid).

Found: C, 68.96; H, 5.77; N, 6.80%. Calcd for $C_{35}H_{35}O_7N_3$: C, 68.95; H, 5.79; N, 6.89%.

Z-Tyr(Bzl)-Gly_2-OH (II). To a solution of I (6.1 g) in a mixture of dioxane-water (2:1; 300 m*l*) was added 2N sodium hydroxide (6 m*l*). After 24 hr, 2N hydrochloric acid (6 m*l*) was added and the solution was evaporated. The residual crystals were collected with the aid of water, and recrystallized from dioxane-ether-petroleum ether; yield, 4.47 g (86%); mp 145—147°C; $[\alpha]_D^{18}$ —21.4° (*c* 1, DMF).

Found: C, 64.42; H, 5.82; N, 7.89. Calcd for $C_{28}H_{29}O_7N_3$: C, 64.73; H, 5.63; N, 8.09%.

Z-Tyr(Bzl)-Gly_2-ONp (III). To a solution of II (1.15 g) in pyridine (7 m*l*) was added di-*p*-nitrophenyl sulfite (3.2 g). After 24 hr, it was evaporated and the residual solid was collected with the aid of a mixture of ether-petroleum ether. The yield was 1.36 g (106%); the *p*-nitrophenyl ester content was estimated to be 93%.[12] The product was used for the preparation of the cyclic peptide (XIII).

Z-Tyr(Bzl)-Gly_2-$NHNH_2$ (IV). A solution of I (1.35 g) and hydrazine hydrate (2.2 m*l*) in DMF (15 m*l*) was allowed to stand for 24 hr, and evaporated *in vacuo*. After the addition of water, the crystals were collected by filtration; yield, 1.35 g (88%); mp 209—212°C; $[\alpha]_D^{21}$ —21.6° (*c* 1, DMF).

Found: C, 62.78; H, 5.92; N, 12.78%. Calcd for $C_{28}H_{31}O_6N_5$: C, 63.02; H, 5.86; N, 13.13%.

H-Tyr-Gly_2-$NHNH_2$·2HCl (V·2HCl). Compound IV (0.89 g, 2 mmol) suspended in 0.43N methanolic hydrogen chloride (7.1 m*l*) was treated with hydrogen in the presence of palladium black. With the progress of reaction the suspended material dissolved into the solution. The filtrate from the catalyst was evaporated; yield of the residual hygroscopic crystal, 0.76 g (approximately 100%); *Rf* 0.50. This was used for the cyclization reaction.

Z-Gly-Tyr-Gly-OBzl (VI). To a chilled solution of Z-Gly-Tyr-$NHNH_2$[13] (2.32 g, 6 mmol) in a mixture of acetic acid (25 m*l*) —N hydrochloric acid (12 m*l*) was added an aqueous solution of sodium nitrite (0.62 g, 9 mmol). After 15 min, water (150 m*l*) was added and the azide was extracted with ethyl acetate. The organic layer was washed with 10% sodium bicarbonate and dried, and the filtrate was added to a mixture of H-Gly-OBzl·TsOH (2.02 g, 6 mmol) and TEA (0.84 m*l*) in chloroform (24 m*l*). After 3 days at O°C, the solution was evaporated, and the oily residue was solidified by trituration with 2% hydrochloric acid and 4% sodium bicarbonate. It was recrystallized from ethyl acetate-ether-petroleum ether; yield, 2.1 g (70%); mp 89—91°C; $[\alpha]_D^{18}$ —5.3° (*c* 1, DMF).

Found: C, 63.69; H, 5.90; N, 8.18%. Calcd for $C_{28}H_{29}O_7N_3\cdot 1/2H_2O$: C, 63.63; H, 5.72; N, 7.95%.

Z-Gly-Tyr-$NHNH_2$ (VII). This was prepared from VI in the same manner as for the preparation of IV; yield, 63%; mp 181—183°C; $[\alpha]_D^{18}$ —10.4° (*c* 1, DMF).

Found: C, 56.64; H, 5.72; N, 15.77%. Calcd for $C_{21}H_{25}O_6N_5$: C, 56.87; H, 5.68; N, 15.79%.

H-Gly-Tyr-Gly-$NHNH_2$·2HCl (VIII·2HCl). A solution of VII (1.05 g) in 0.38N methanolic hydrogen chloride (15 m*l*) was hydrogenated as for the preparation of V·2HCl; yield of hygroscopic crystal, 0.89 g (98%).

H-Gly_2-Tyr-$NHNH_2$·2HCl (IX·2HCl). Z-Gly_2-Tyr-$NHNH_2$[7] (4.56 g) was hydrogenated; yield of hygroscopic crystal, 3.88 g (100%).

Z-(Gly_2-Tyr)$_2$-OEt (X). To azide prepared from Z-Gly_2-Tyr-$NHNH_2$ (1.19 g) was coupled with H-Gly_2-Tyr-OEt·HCl[14] (0.97 g) as described for the preparation of VI.

8) It is of interest to note that H-Gly_2-Tyr-Gly_3-OH or H-Gly_2-Tyr-Gly_4-OH was hydrolyzed by chymotrypsin faster than other homologues, H-Gly_2-Tyr-Gly_n-OH (n=1 and 2).[7]

The product was recrystallized from hot ethanol; yield, 0.82 g (41%); mp 124—126°C; $[\alpha]_D^{22}$ +19.0° (*c* 1, acetic acid).

Found: C, 57.04; H, 5.76; N, 11.06%. Calcd for $C_{36}H_{42}O_{11}N_6$: C, 57.44; H, 5.89; N, 11.17%.

Z-(Gly$_2$-Tyr)$_2$-NHNH$_2$ (XI). Compound X (0.82 g) was treated with hydrazine hydrate (1.12 m*l*) in DMF (10 m*l*) as described for the preparation of IV; yield, 0.64 g (80%); mp 151—153°C; $[\alpha]_D^{15}$ −6.4° (*c* 0.5, DMF).

Found: C, 54.12; H, 5.81; N, 14.79%. Calcd for $C_{34}H_{40}O_{10}N_8 \cdot 2H_2O$: C, 53.96; H, 5.86; N, 14.81%.

H-(Gly$_2$-Tyr)$_2$-NHNH$_2$·2HCl (XII·2HCl). This was prepared from XI (607 mg); yield of hygroscopic crystal, 570 mg (102%)

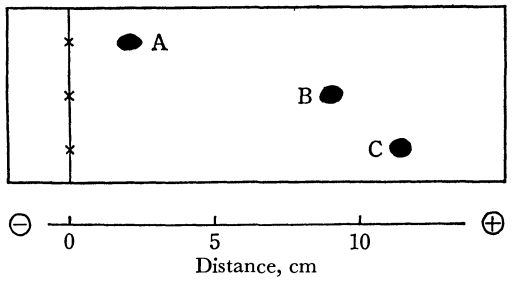

Fig. 3. Paper electrophoresis of *cyclo*-(Gly$_2$-Tyr)$_2$ (A), H-(Gly$_2$-Tyr)$_2$-OH (B) and H-Gly$_2$-Tyr-OH (C). Solvent, 0.01 M citrate buffer (pH 6.7); 600 V/30 cm; 3 hr.

cyclo-*(Gly$_2$-Tyr)$_2$ (XIII)* *(a) From Z-Tyr(Bzl)-Gly$_2$-ONp (III):* III (1.35 g, 2.21 mmol) was dissolved in 25% hydrogen bromide in acetic acid (8 m*l*) at room temperature. After 2 hr, the solution was evaporated and the oily residue (1.1 g), H-Tyr-Gly$_2$-ONp·HBr (XIX), was dissolved in DMF (15 m*l*). It was added to pyridine (600 m*l*) at 55—60°C.[5] After evaporation, the residue was dissolved in a mixture (140 m*l*) of dioxane-methanol-water (7:2:1), and the solution was passed successively through columns of Amberlite IR4B (OH^- form, 1.8×8 cm) and Dowex 50 (H^+ form, 1.8×15 cm). The eluate was evaporated, and the residual crystals were collected by filtration with the aid of ether. It was recrystallized from methanol-ether; yield of an air-dried material, 53 mg (9% from III). Its homogeneity was established by paper electrophoresis (Fig. 3) and paper chromatography (*Rf* 0.80; Fig. 4). The value of specific rotation is shown in Table 1.

Found: C, 51.31; H, 5.90; N, 13.70%; mol wt, 605.[15] Calcd for $C_{26}H_{30}O_8N_6 \cdot 3H_2O$: C, 51.31; H, 5.96; N, 13.81%; mol wt, 609. The air-dried material lost 8.95% of its weight after being dried for 2 hr at 70°C *in vacuo*. Calcd for $3H_2O$: 8.88%.

(b) From Tripeptide Hydrazide (V, VIII or IX): A cyclization reaction of H-Gly-Tyr-Gly-NHNH$_2$ (VIII) is described as an example as follows. To a chilled solution of VIII·2HCl (816 mg, 2.14 mmol) in 0.1 N hydrochloric acid (21.4 m*l*), an aqueous solution of sodium nitrite (162 mg, 2.35 mmol) was added. After 15 min, the solution was poured into cold water (1000 m*l*) containing sodium bicarbonate (2.7 g). After 3 days at 0—4°C, the solution was neutralized with 1 N hydrochloric acid and evaporated. The residue was collected by filtration and washed with water. The product was dissolved in a mixture of dioxane-methanol-water and passed through the columns as described above. Evaporation of the eluate yielded a powder (305 mg) with pale yellow color.[16] A part (100 mg) of the powder dissolved in methanol (1 m*l*) was applied to a column (1.8×35 cm) with Sephadex LH-20, and the development was continued with methanol. Fractions from 39 to 48 m*l* were evaporated, and the crystals were collected with the aid of water; yield of an air-dried product, 40 mg (17%). Data of this product are shown in Table 1.

(c) From Hexapeptide Hydrazide (XII): XII·2HCl (591 mg) was treated in the same manner as described above; yield of an air-dried product, 104 mg (20%). Its properties agreed with those of the products obtained from tripeptide active ester or azides (see Table 1).

Z-(Gly$_2$-Tyr)$_2$-OBzl (XIV). Z-Gly$_2$-Tyr-OBzl[17] (780 mg, 1.5 mmol) was treated with 25% hydrogen bromide in acetic acid (4 m*l*) as described for the preparation of XIX; the H-Gly$_2$-Tyr-OBzl·HBr (XX) (0.7 g) was obtained as an oil. The azide from Z-Gly$_2$-Tyr-NHNH$_2$ (443 mg, 1 mmol) was coupled with XX (0.7 g) as described for the preparation of VI. The product was recrystallized from DMF-ethyl acetate; yield, 509 mg (64%), mp 115—116°C; $[\alpha]_D^{25}$ −5.0°

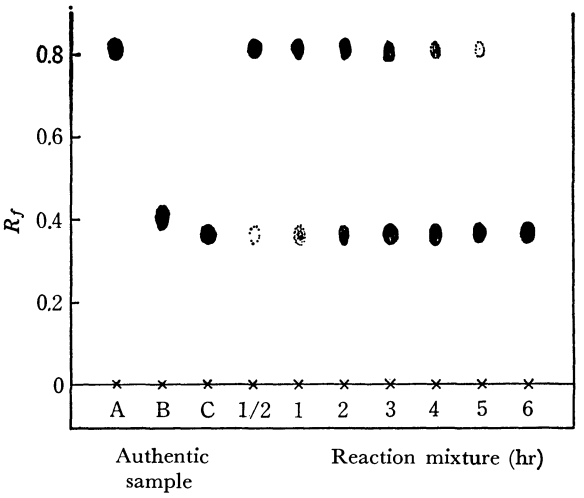

Fig. 4. Paper chromatogram of a reaction mixture (No. 1 of Table 2) of *cyclo*-(Gly$_2$-Tyr)$_2$ and chymotrypsin. A,B, and C, see Fig. 3; solvent, *n*-butanol-acetic acid-pyridine-water (4:1:1:2).

TABLE 2. COMPOSITION OF MIXTURE OF THE ENZYMATIC REACTION

No.	Substrate	Weighed amount (0.04 mmol) of substrate	0.2M Tris buffer, pH 8.0	Weighed amount of chymotrypsin	Total volume
1	*cyclo*-$(Gly_2\text{-}Tyt)_2 \cdot 3H_2O$	24 mg	1.0 ml	10 mg	2.0 ml
2	H-$(Gly_2\text{-}Tyr)_2$-OH$\cdot 4H_2O$	26	1.0	10	2.0

(*c* 1, DMF).

Found: C, 59.75; H, 5.64; N, 10.15%. Calcd for $C_{41}H_{44}O_{11}N_4 \cdot 2/3H_2O$: C, 59.77; H, 5.75; N, 10.20%.

H-(Gly_2-Tyr)$_2$-OH (XV). Compound XIV (240 mg) suspended in a mixture (5 ml) of acetic acid - methanol - water (6:3:1) was hydrogenated, and the filtrate was evaporated. The crystals were collected by filtration with the aid of acetone, and recrystallized from water-ethanol; yield, 135 mg (85%); mp 238—242°C (decomp.); $[\alpha]_D^{20}$ −2.8° (*c* 1, water).

Found: C, 48.04; H, 6.07; N, 12.84%. Calcd for $C_{26}H_{32}O_9N_6 \cdot 4H_2O$: C, 48.44; H, 6.25; N, 13.04%.

Action of Chymotrypsin on cyclo-*(Gly_2-Tyr)$_2$ (XIII) and H-(Gly_2-Tyr)$_2$-OH (XV).* α-Chymotrypsin was salt free, crystalline sample from Worthington Biochemical Corp., U.S.A. H-Gly_2-Tyr-OH was prepared as described in literature.[17] Enzymatic experiments were carried out at pH 8.0 and 30°C. The progress of the reactions was checked by paper chromatography as a function of time. Table 2 shows the composition of the reaction mixture. The control experiments showed that no hydrolysis of XIII and XV occurred in the absence of the enzyme. In the presence of the enzyme, XIII was completely hydrolyzed to linear tripeptide after 6 hr, as can be seen in Fig. 4. On the other hand, the linear hexapeptide (XV) was hydrolyzed to the tripeptide within only 10 min in the same condition (Table 2) as seen in Fig. 5.

Z-Gly_2-Phe-OBzl (XVI). This was prepared from Z-Gly_2-OH (2.66 g) and H-L-Phe-OBz·TsOH (4.27 g) by the mixed anhydride method as described previously[5] yield, 3.2 g (64%); mp 81—82°C; $[\alpha]_D^{23}$ +7.0° (*c* 1, acetic acid).

Found: C, 65.59; H, 5.94; N, 8.13%. Calcd for $C_{28}H_{29}O_6N_3 \cdot 1/2H_2O$: C, 65.61; H, 5.90; N, 8.20%.

Z-Gly_2-Phe-$NHNH_2$ (XVII). This was prepared from XVII as described for the preparation of IV; yield, 68%; mp 134—136°C; $[\alpha]_D^{20}$ +13.0° (*c* 1, acetic acid).

Found: C, 58.55; H, 6.00; N, 16.12%. Calcd for $C_{21}H_{25}O_5N_5 \cdot 1/4H_2O$: C, 58.39; H, 5.95; N, 16.21%.

cyclo-*(Gly_2-Phe)$_2$ (XVIII).* Compound XVII (1.07 g, 2.5 mmol) was hydrogenated as described for the preparation of V·2HCl, and the resulting H-Gly_2-Phe-$NHNH_2$·2HCl (0.90 g, 98%) was obtained as hygroscopic crystals. This product (0.9 g) was subjected to cyclization reaction as described for the preparation of XIV from H-Gly-Tyr-Gly-$NHNH_2$. The crude product dissolved in a mixture of dioxane-methanol-water was passed through the columns of Dowex 1 and Dowex 50. The eluate was evaporated, and the residual nice crystals were collected by filtration with the aid of water; yield of an air-dried material, 164 mg (25%); mp 280—285°C (decomp.); $[\alpha]_D^{20}$ −52.0° (*c* 0.5, DMF); R_f 0.93. The material contained no water of crystallization.

Found: C, 59.66; H, 5.89; N, 15.96%; mol wt, 530. Calcd for $C_{26}H_{30}O_6N_6$: C, 59.76; H, 5.79; N, 16.08%; mol wt, 523. This material (XVIII) did not dissolve in pH 8.0 buffer even at a level of 0.002M. It was therefore, not clear whether an incubation mixture of XVIII and chymotrypsin yielded H-Gly_2-Phe-OH by means of paper chromatography.

The authors wish to express their thanks to Mr. Shunichi Takamura for his valuable assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2804—2807 (1971)

Aminocyclitols. XXVII. Preparation of Deoxyinosamines from *vibo*-Quercitol[1]

Tetsuo SUAMI, Seiichiro OGAWA, Kenji YABE,* and Masaru UCHIDA**
Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received May 8, 1971)

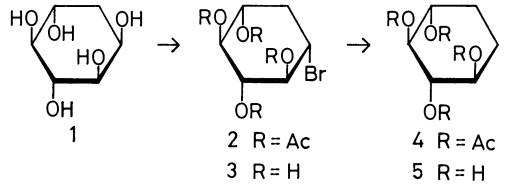
On bromination with acetyl bromide and acetic anhydride at 130°C, *vibo*-quercitol (**1**) gave tetraacetyl 1-bromo-1-deoxy-*scyllo*-quercitol (**2**) in 23% yield. Treatment of **2** with sodium azide in an appropriate solvent afforded three azido compounds, from which, by hydrogenation, corresponding three deoxyinosamines were obtained: 1-deoxy-*scyllo*-2, 5-deoxy-*chiro*-1 and 1-deoxy-*myo*-2-inosamine. The latter two are new compounds and their structures were established by their proton magnetic resonance (PMR) spectra and the reaction sequences.

We previously described the synthesis of two deoxyinosamines from *vibo*-quercitol (**1**).[2] In the present paper, we wish to report an alternative synthetic route to deoxyinosamines using bromodeoxyquercitol.

When **1** was treated with acetyl bromide and acetic anhydride in a sealed tube at 125—130°C for 8 hr, and subsequently acetylated with acetic anhydride and conc. sulfuric acid, hitherto unknown tetraacetyl bromodeoxyquercitol (**2**), mp 148°C, was obtained as a sole crystalline product in 23% yield. Hydrolysis of **2** by refluxing in 3N hydrochloric acid gave bromodeoxy-

*Present address: Toray Industries, Inc., Ohtsu-shi, Shiga.
**Present address: Ube Kosan, Ichihara-shi, Chiba.

1) All the compounds described in this paper are racemic.
2) T. Suami and K. Yabe, This Bulletin, **39**, 1931 (1966).



quercitol (**3**). On catalytic hydrogenolysis in the presence of Raney nickel T-4[3] and Amberlite IR-4B (OH^-), **2** afforded tetraacetyl cyclohexanetetrol (**4**), which was converted into known cyclohexanetetrol (1, 3/2,4) (**5**).[4] Therefore, **2** should be either 1-bromo-1-deoxy-*scyllo*- or 1-bromo-1-deoxy-*vibo*-quercitol. This could be easily differenciated on the basis of its PMR spectrum in deuteriochloroform ($CDCl_3$) (Fig. 1). The

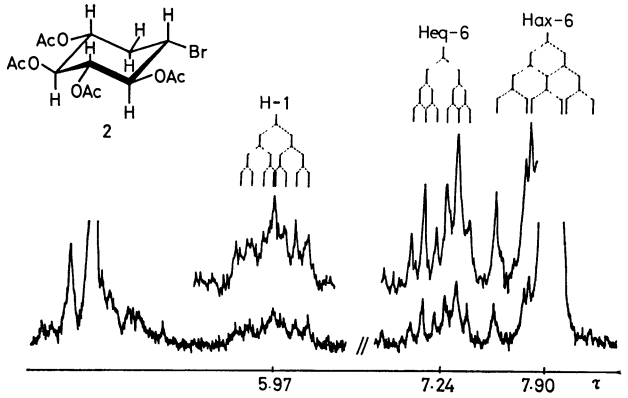


Fig. 1. Partial PMR spectrum of tetraacetyl 1-bromo-1-deoxy-*scyllo*-quercitol (**2**) in $CDCl_3$.

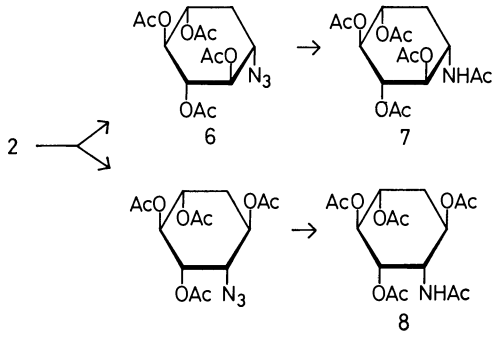
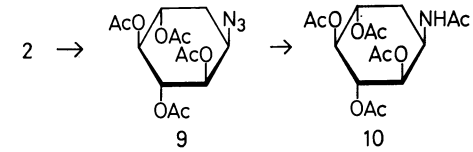
ring proton attached to the carbon atom bearing bromine atom appeared at τ 5.97 as a septet (J=4.5, 9, and 13 Hz), which indicated that the bromine atom should be in equatorial position in the favored conformation and located adjacent to methylene protons. This was further supported by a decoupling experiment. The equatorial methylene proton showed a clearly resolved sextet (J=4.5, 4.5, and 13 Hz) at τ 7.24, which collapsed to a quartet when the septet at τ 5.97 was irradiated at this frequency. While the sextet was irradiated to collapse the septet into a wide triplet. Consequently, **2** was assigned to tetraacetyl 1-bromo-1-deoxy-*scyllo*-quercitol unambigously. The reaction mechanism of the bromination reaction was proposed by assuming an intermediary acetoxonium ion formation between the *cis* hydroxyl groups in *vibo*-quercitol, which was attacked by a bromide ion in a less sterically hindered direction.

When **2** was treated with an excess amount of sodium azide in boiling 90% aqueous 2-methoxyethanol for 40 hr, tetraacetyl 1-azido-1-deoxy-*scyllo*-quercitol (**6**)[2] was obtained in 22% yield. The crude oily product obtained by evaporation of the mother liquor of **6** was hydrogenated in the presence of Raney nickel T-4[3] and subsequently acetylated to afford unknown penta-



acetyl deoxyinosamine (**8**) in 19% yield. While, **2** was treated with methanolic ammonia in a sealed tube at 120°C for 12 hr and subsequent acetylation gave pentaacetyl 1-deoxy-*scyllo*-inosamine-2 (**7**)[2] and **8** in 14 and 10% yield, respectively.

In the PMR spectrum of **8** in dimethylsulfoxide-d_6 (DMSO-d_6), the acetyl methyl protons revealed four signals at τ 8.14 (1), 8.08 (1), 8.02 (2), and 7.93 (1),[5] which were assigned to one axial acetamido, one equatorial acetoxy, two equatrial acetoxy and one axial acetoxy group, respectively.[6] On the other hand, in the spectrum in $CDCl_3$, four signals due to the acetyl methyl protons were appeared at τ 8.01 (1), 7.96 (1), 7.93 (2), and 7.91 (1), which could be assigned to one equatorial acetamido, one equatorial acetoxy, two axial acetoxy and one axial acetoxy group, respectively.[6] The sextet (J=3, 8, and 8 Hz) at τ 5.50 was attributed to the hydrogen atom attached to the carbon atom bearing the acetamido group, because an addition of deuterium oxide collapsed it into a quartet. Therefore, in $CDCl_3$, **8** seems to take a favored conformation having the acetamido group in an equatorial position. Consequently, according to a reaction sequence and its PMR spectra, **8** was assigned to pentaacetyl 5-deoxy-*chiro*-inosamine-1.



Treatment of **2** with sodium azide in boiling 90% aqueous dimethylformamide for 40 hr and subsequent acetylation gave another tetraacetyl azidodeoxyquercitol (**9**) in 60% yield. Hydrogenation of **9**, followed by acetylation, afforded the corresponding pentaacetyl deoxyinosamine (**10**) in 74% yield. The structures of **9** and **10** were established mainly by way of their PMR spectra. The PMR spectrum of **9** in $CDCl_3$ revealed a narrow quartet (J=3 Hz) at τ 5.83, which was assigned to the equatorial hydrogen atom attached to the carbon atom having azido group[7] and, then, the azido group was proved to be adjacent to the methylene protons. The acetyl methyl protons showed two peaks at

5) Values in parenthesis show number of acetoxy methyl groups.

6) F. W. Lichtenthaler and P. Emig, *Carbohyd. Res.*, **7**, 121 (1968).

7) T. Suami, S. Ogawa, and M. Uchida, This Bulletin, **43**, 3577 (1970).

τ 8.01 (3) and 7.93 (1). The latter might be considered to be downshifted from the ordinary chemical shift[6] under the influence of the adjacent azido group.[7] While, the PMR spectrum of **10** in DMSO-d_6 indicated two signals at τ 8.11 (1) and 8.04 (4), which were assigned to one axial acetamido and four equatorial acetoxy groups, respectively. Consequently, **9** should be tetraacetyl 1-azido-1-deoxy-*vibo*-quercitol and the corresponding **10** was assignable to pentaacetyl 1-deoxy-*myo*-inosamine-2.

The reaction mechanism was interpreted by a direct S_N2 attack of azide ion in a dipolar aprotic solvent.[7,8]

Experimental

Melting point were determined on a Mitamura Riken micro hot stage and are uncorrected. PMR spectra were measured on a Varian Associate A-60D (60 MHz) spectrometer at a concentration of *ca.* 10% deuteriochloroform or dimethylsulfoxide-d_6 with tetramethylsilane as in internal standard. All solutions were concentrated by a rotary evaporator at 40—50°C under reduced pressure. Whenever pyridine was employed in a reaction, the residual pyridine was removed by repeated codistillation with dry toluene.

Tetraacetyl 1-Bromo-1-deoxy-scyllo-*quercitol (2).* *vibo*-Quercitol (**1**)[2] (3.0 g) was heated in a sealed tube at 125—130°C for 8 hr with acetyl bromide (2.5 m*l*) and acetic anhydride (7.0 m*l*). The reaction mixture obtained from ten sealed tubes evaporated to dryness and the resulting oily product was treated with acetic anhydride (300 m*l*) and conc. sulfuric acid (15 m*l*) at room temperature overnight. Then the mixture was poured into ice and water (1 *l*) and allowed to stand at room temperature overnight. A thick oily product was extracted with chloroform (300 m*l*) and the extracts were washed with 10% aqueous sodium carbonate and water, successively. The solvent was removed by evaporation and the residue was crystallized from ethanol to yield colorless crystals (22.0 g, 23%) of **2**, mp 147—148°C. Recrystallization from ethanol gave an analytical sample, which showed the same melting point.

Found: C, 42.76; H, 5.08; Br, 20.48%. Calcd for $C_{14}H_{19}O_8Br$: C, 42.54; H, 4.85; Br, 20.22%.

1-Bromo-1-deoxy-scyllo-*quercitol (3).* A mixture of **2** (0.50 g) and ethanol (20 m*l*) containing conc. hydrochloric acid (5 m*l*) was refluxed for 90 min. The reaction mixture was evaporated to give a crystalline residue which was recrystallized from ethanol to afford crystals (0.18 g, 62%) of **3**, mp 178—182°C. An analytical sample was obtained by recrystallization from ethanol, mp 185—187°C.

Found: C, 32.28; H, 5.14; Br, 34.72%. Calcd for $C_6H_{11}O_4Br$: C, 31.73; H, 4.88; Br, 35.19%.

Tetraacetyl Cyclohexanetetrol (1,3/2,4) (4). A solution of **2** (0.39 g) in ethanol (20 m*l*) was hydrogenated in the presence of Raney nickel T-4 (one spatula) and Amberlite IR-4B (OH^-) (6 m*l*) in the hydrogen initial pressure of 3 atm for 20 hr. Filtering off the catalyst and resin, the filtrate was evaporated to give a crystalline residue, which was recrystallized from ethanol to afford colorless plates (0.21 g, 68%) of **4**, mp 138.5—139°C (after melting and resolidifying at 126—128°C). Recrystallization from ethanol gave an analytical sample, mp 125.5—127°C.

Found: C, 53.26; H, 6.40%. Calcd for $C_{14}H_{20}O_8$: C, 53.16; H, 6.37%.

Cyclohexanetetrol (1,3/2,4) (5). A mixture of **4** (0.10 g) and 4N hydrochloric acid (6 m*l*) was heated at 90°C for 5 hr. Then the solution was evaporated to give an oily product, which crystallized upon addition of ethanol to afford colorless prisms (37 mg, 78%) of **5**, mp 184—186°C. Recrystallization from methanol gave a pure sample, whose melting point did not change (lit,[4] mp 187—188°C).

a) Chemical shifts are expressed in τ-values. Values in parenthesis show number of methyl groups. Abbreviations: t (triplet); q (quartet); m (complex multiplet). First-order coupling constants are expressed.

Tetraacetyl 1-Azido-1-deoxy-scyllo-*quercitol (6).* A mixture of **2** (1.8 g), sodium azide (1.5 g), and 90% aqueous 2-methoxyethanol (60 m*l*) was refluxed for 40 hr. The reaction mixture was evaporated to dryness and the residue was treated with acetic anhydride (15 m*l*) and pyridine (15 m*l*) at room temperature overnight. An insoluble material was removed by filtration and the filtrate was evaporated to give an oily product, which crystallized upon addition of ethanol. The crude crystals were recrystallized from ethanol to afford colorless needles (0.35 g, 22%) of **6**, mp 136—138°C. This compound was identified with an authentic sample[2] by a mixed melting point determination and a comparison of infrared spectra.

From the mother liquor of **6**, a small amount of crystals was isolated after long storage in a refrigerator, mp 128—130°C. The infrared spectrum was different from that of **6**, so that this compound might be proposed to be tetraacetyl 4-azide-4-deoxy-*proto*-quercitol.

Found: C, 46.64; H, 5.10; N, 11.39%. Calcd for $C_{14}H_{19}N_3O_8$: C, 47.06; H, 5.36; N, 11.76%.

8) T. Suami, F. W. Lichtenthaler, and S. Ogawa, This Bulletin **38**, 754 (1965).

Pentaacetyl 5-Deoxy-chiro-*inosamine-1 (8).* The mother liquor of **6** was hydrogenated in the presence of Adams' platinum oxide (20 mg) in the initial hydrogen pressure of 3 atm for 12 hr. The hydrogenated product was acetylated with acetic anhydride and pyridine and crystallized from ethanol to give crystals (0.37 g, 22%) of **8**, mp 187—188°C. Recrystallization from ethanol gave an analytically pure sample, which showed the same melting point.

Found: C, 51.56; H, 6.14; N, 3.90%. Calcd for $C_{16}H_{23}NO_9$: C, 51.47; H, 6.21; N, 3.75%.

Ammonolysis of 2 using Methanolic Ammonia. Compound **2** (1.5 g) was heated with methanol (100 m*l*) saturated with ammonia at 0—5°C in an autoclave at 120°C for 12 hr. The reaction mixture was evaporated to dryness and treated with acetic anhydride and pyridine at room temperature overnight. Evaporation of the excess reagent gave a crude mixture, which was fractionally crystallized from ethanol and ether to afford pentaacetyl 1-deoxy-*scyllo*-inosamine-2 (**7**) (0.19 g, 13%), mp 224—226°C, and **8** (0.15 g, 10%), mp 187—188°C.

Tetraacetyl 1-Azido-1-deoxy-vibo-*quercitol (9).* A mixture of **2** (1.5 g), sodium azide (1.0 g) and 90% aqueous dimethylformamide (50 m*l*) was refluxed for 40 hr. The reaction mixture was processed similarly as described in the preparation of **6**. The crude product was crystallized from ethanol to give crystals (0.81 g, 60%) of **9**, mp 142—145°C. Recrystallization from ethanol afforded an analytical sample, mp 143.5—144.5°C.

Found: C, 46.82; H, 5.40; N, 11.79%. Calcd for $C_{14}H_{19}N_3O_8$: C, 47.06; H, 5.36; N, 11.76%.

Pentaacetyl 1-Deoxy-myo-*inosamine-2 (10).* A solution of **9** (0.35 g) in ethanol (50 m*l*) was hydrogenated similarly as described in the preparation of **8**. The crude product was acetylated with acetic anhydride and pyridine and crystallized from ethanol to give colorless crystals (0.27 g, 74%) of **10**, mp 224—225°C. Recrystallization from ethanol afforded an analytical sample, which showed the same melting point.

Found: C, 51.73; H, 6.46; N, 3.77%. Calcd for $C_{16}H_{23}NO_9$: C, 51.47; H, 6.21; N, 3.75%.

The Reactions of Complexes of Thioboronite with Compounds Containing Carbon-Nitrogen Multiple Bond

Teruaki MUKAIYAMA, Shoji YAMAMOTO, and Katsuhiko INOMATA

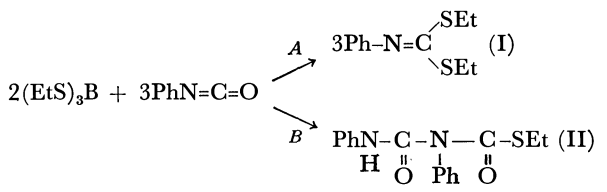
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 10, 1971)

n-Butyl di-*n*-butylthioboronite reacts with isocyanates to give 1 : 2 adducts, and with isothiocyanate or carbodiimide to give a 1 : 1 adduct. It was found that thioboronite forms a 1 : 1 co-ordinated complex with benzyl cyanide, and that the complex reacts with isocyanates to give the corresponding acetamidine derivatives in good yields.

It has been reported by Mikhailov and his co-workers[1] that various thioboronites or thioborates react with carbonyl compounds to give the corresponding mercaptols or mercaptals. The results indicate that the boron-sulphur bond cleavage takes place easily through co-ordinated complexes of carbonyl compounds and boron compounds. The reactions of thioboronites with compounds containing the carbon-nitrogen multiple bond, such as isocyanates, carbodiimide and nitriles, were studied in order to examine the chemical behavior of the boron-sulfur bond.

In the reaction of triethyl orthothioborate with phenyl isocyanate in dry benzene, it was found that *N*-ethylthiocarbonyl-*N*,*N*′-diphenylurea (II) is obtained in a 94% yield (route *B*) instead of the expected mercaptol (I) (route *A*).



n-Butyl di-*n*-butylthioboronite (0.01 M) in carbon tetrachloride was treated with phenyl isocyanate (0.02 M) in the same solvent under nitrogen atmosphere at room temperature. After stirring for 20 min, it was observed that the infrared spectra of the oily substance obtained by evaporating the solvent *in vacuo* showed no bands at 2250 cm^{-1} ($\nu_{N=C=O}$) and 1110 cm^{-1} assignable to *B*–*S* bond, but new bands at about 1700 cm^{-1} ($\nu_{C=O}$) and 1330—1320 cm^{-1} assignable to *B*–*N* bond. It can be assumed that *n*-butyl di-*n*-butylthioboronite and phenyl isocyanate forms an 1 : 2 adduct. This was further confirmed by the fact that *N*-*n*-butylthiocarbonyl-*N*,*N*′-diphenylurea (V) was isolated as white crystal in a 95% yield by hydrolysis of this adduct. The structure was established by elemental analysis and comparison with the authentic compound prepared from phenyl isocyanate and *S*-*n*-butyl thiocarbanilate according to the method of Lakra *et al.*[2]

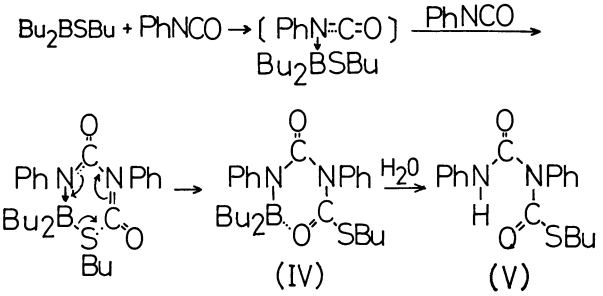
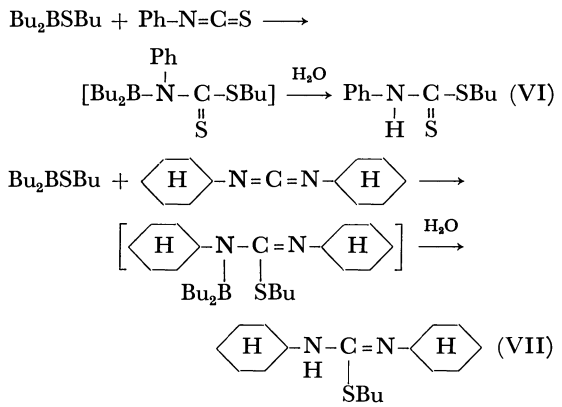
	quant.	65.0—66.0	$C_{18}H_{32}O_2N_2S$	63.50	9.47	8.23	9.40	63.69	9.22	8.53	9.51
C_2H_5	95	(136—140/7 mmHg)	$C_{14}H_{20}O_2N_2S$	51.70	8.68	12.06	13.78	52.04	8.28	12.20	14.64

The reaction is considered to proceed as follows; initially one mole of isocyanate co-ordinates to thioboronite to form a 1:1 complex (III).[3] Then another isocyanate abstracts the mercapto group, activated by the influence of $\overset{\delta-}{B}\leftarrow\overset{\delta+}{N}$ polarization and accompanied by a nucleophilic attack of the nitrogen atom on the carbon atom of initially co-ordinated isocyanate to form (VI).



In a similar way, p-nitrophenyl isocyanate, cyclohexyl isocyanate and ethyl isocyanate gave the corresponding ureas in almost quantitative yields. The results are summarized in Table 1.

The reaction of n-butyl di-n-butylthioboronite with phenyl isothiocyanate and with dicyclohexylcarbodiimide was tried. In both cases, formation of the corresponding 1:1 adducts was confirmed by infrared spectra. The adducts were in turn converted into n-butyl dithiocarbanilate (VI 45%) and S-n-butyl-N,N'-dicyclohexylisothiourea (VII 83%) by hydrolysis, respectively.



Differing from isothiocyanate and carbodiimide, the formation of the 1:2 adduct in the case of isocyanate, might depend on its strong electrophilic character, which abstracts the mercapto group from the 1:1 complex initially formed.

An attempt to synthesize an analogous adduct of n-butyl di-n-butylthioboronite and benzyl cyanide was made according to the report by Mikhailov *et al.*[4] showing that the stable dimerized adduct $(R_2BN{=}CMeSR')_2$ is obtained by the reaction of acetonitrile with thioboronite (R_2BSR'). Unexpectedly, it was found that a 1:1 complex is produced instead of the dimerized adduct when n-butyl di-n-butylthioboronite (0.01 M) was allowed to react with benzyl cyanide (0.01 M) under nitrogen atmosphere at room temperature for 20 min. After removal of the solvent, the band at 2150 cm^{-1} ($\nu_{C\equiv N}$) disappeared and a new strong band appeared at 1810 cm^{-1} in the infrared spectra of the resulting oily substance. With the addition of ethanol amine, the band at 2150 cm^{-1} reappeared and the band at 1810 cm^{-1} disappeared. It is thus clear that thioboronite and benzyl cyanide form a 1:1 co-ordinated complex, and that the band at 1810 cm^{-1} is assignable to the nitrile group shifted greatly to lower frequency by co-ordination. It was found that the 1:1 complex exists in ether and dioxane, but it dissociates into nitrile with the addition of tetrahydrofuran, amines (pyridine, triethylamine) dimethyl sulfide as shown in the following equation.

$$[PhCH_2C\dot{=}N\rightarrow BBu_2SBu] + :L \rightleftharpoons PhCH_2CN + L{:}BBu_2SBu$$

L: THF, pyridine, triethylamine, dimethylsulfide

When the co-ordinated complex obtained by evaporating the solvent *in vacuo* was stirred for a few days, the band at 1810 cm^{-1} in the infrared spectra disappeared and a new band at 1610 cm^{-1} ($\nu_{C=N}$) appeared, the stable adduct (VIII) being obtained as a white crystal in a 40—50% yield. It was also observed that dry air is effective to accelerate the transfer of mercapto group, but the detailed mechanism is not yet clear.

$$[PhCH_2CN\rightarrow BBu_2SBu] \longrightarrow (PhCH_2C(SBu)=N\text{–}BBu_2)_n \quad \text{(VIII)}$$

The results indicate that formation of the co-ordinated complex of thioboronite and benzyl cyanide facilitates the formation of mercapto anion due to the influence of $\overset{\delta-}{B}\leftarrow\overset{\delta+}{N}$ polarization.

Thus, it is expected that an abstraction of the mercapto group from the complex would occur by the use of isocyanates. An equimolar amount of phenyl isocyanate was added to the 1:1 complex in the presence of a catalytic amount of boron trifluoride etherate in the

3) There is another possible pathway for formation of the complex by the oxygen atom of the isocyanate with the boron atom, but this was excluded by the infrared spectra.

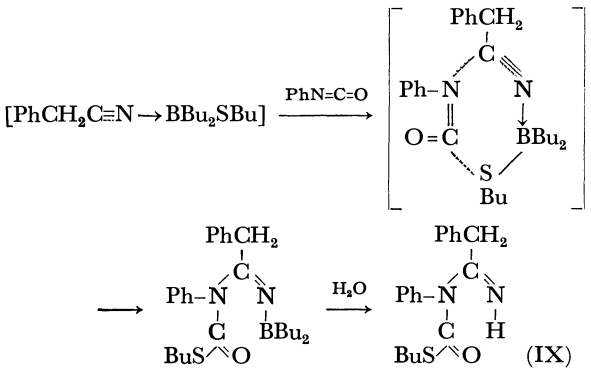
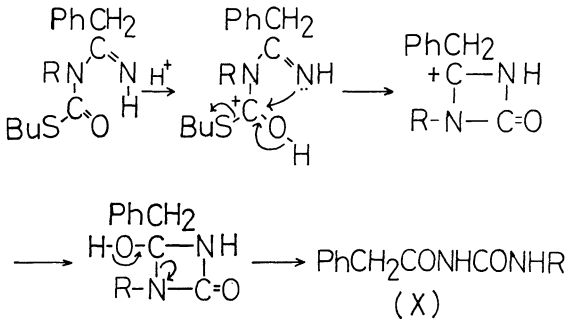
a) Oily substances which undergo decomposition during the course of vacuum distillation. This was confirmed by means of infrared spectra and the hydrolysis to acylurea.

minimum amount of ether at 0°C under dry air[5]. After stirring the mixture for 10 hr, the infrared spectra of the oily substance obtained by evaporating the solvent showed the diappearance of the band at 1810 cm^{-1} and 2150 cm^{-1} ($\nu_{N=C=O}$) and the appearance of a new band at 1605 cm^{-1} ($\nu_{C=N}$). By hydrolysis of the reaction mixture, *N*-*n*-butylthiocarbonyl *N*-phenyl phenylacetamidine (IX) was obtained in a 74% yield as expected. The reaction is considered to proceed as shown below.



The structure was established by elemental analysis, infrared spectra and NMR spectra. In the case of various isocyanates, a similar reaction took place to give the corresponding acetamidine derivatives. The results are shown in Table II.



It was found that acetamidine derivatives thus obtained give the corresponding acylureas (X) quantitatively by acidic hydrolysis as shown in the above scheme.

Experimental

Reaction of n-*Butyl Di*-n-*butylthioboronite and Phenyl Isocyanate.* A solution of phenyl isocyanate (2.38 g, 0.02 mol) in carbon tetrachloride was added dropwise with strirring to a solution of *n*-butyl di-*n*-butylthioboronite (2.20 g, 0.01 mol) in the same solvent at room temperature under nitrogen atmosphere. After stirring for 20 min, the oily substance obtained by evaporating the solvent was hydrolyzed in THF-water for 3 hr at room temperature, and saturated with sodium chloride. The THF layer was then separated and the water layer was extracted with ether three times. The THF layer and the ether layer were combined and dried with sodium sulfate. After removal of the solvent, the residue was chromatographed on silica gel. From the elute of benzene a white crystal was obtained. Recrystallization from 95% ethanol gave *N*-*n*-butylthiocarbonyl-*N*,*N*'-diphenylurea, 3.02 g (95%), mp 90—90.5°C.

In a similar way, the corresponding *N*-*n*-butylthiocarbonylurea derivatives were obtained by the reaction of *n*-butyl di-*n*-butylthioboronite with *p*-nitrophenyl isocyanate, cyclohexyl isocyanate, or ethyl isocyanate, respectively. The results are listed in Table 1.

Reaction of n-*Butyl Di*-n-*butylthioboronite and Phenyl Isothiocyanate.* A mixture of phenyl isothiocyanate (1.35 g, 0.01 mol) and *n*-butyl di-*n*-butylthioboronite (2.23 g, 0.01 mol) in carbon tetrachloride was stirred for 3 days at room temperature under nitrogen atmosphere. The oily substance obtained by evaporating the solvent was hydrolyzed in THF-water for 3 hr at room temperature and saturated with sodium chloride. The THF layer was then separated and the water layer was extracted with ether three times. The THF layer and the ether layer were combined and dried with sodium sulfate. After removal of the solvent the residue was chromatographed on silica gel. From the elute of benzene a white crystal was obtained. Recrystallization from petroleum ether gave *n*-butyl dithiocarbanilate, 1.02 g (45%) mp 55.5—56.0°C.

Found: C, 63.43; H, 7.46; N, 6.69; S, 15.18%. Calcd for $C_{11}H_{15}NS_2$: C, 63.14; H, 7.23; N, 6.69; S, 15.29%.

5) When a large amount of ether is used as solvent, free thioboronite liberated from the complex reacts with isocyanate to give the 1:2 adduct (IV) as shown below.

$PhCH_2CN + Bu_2BSBu \rightleftharpoons PhCH_2CN \rightarrow BBu_2SBu$

$\downarrow$ 2RNCO

1:2 adduct (IV)

Reaction of n-*Butyl Di*-n-*butylthioboronite with Dicyclohexylcarbodiimide.* A mixture of *n*-butyl di-*n*-butylthioboronite (2.14 g, 0.01 mol) and dicyclohexylcarbodiimide (2.06 g, 0.01 mol) in methylene chloride was stirred for 1 hr at room temperature under nitrogen atmosphere. By treating the mixture with water, *S*-*n*-butyl-*N,N'*-dicyclohexyl isothiourea was obtained in an 85% yield as an oily substance which undergoes decomposition during the course of vacuum distillation to give dicyclohexylcarbodiimide.

Reaction of n-*Butyl Di*-n-*butylthioboronite and Benzyl Cyanide.* A solution of benzyl cyanide (0.61 g, 0.005 mol) in methylene chloride was added with stirring to a solution of *n*-butyl di-*n*-butylthioboronite (1.11 g, 0.005 mol) in methylene chloride at room temperature under nitrogen atmosphere. After stirring for 20 min, the 1:1 complex of *n*-butyl di-*n*-butylthioboronite and benzyl cyanide was obtained as a yellow oily substance by evaporating the solvent *in vacuo*. After stirring the complex under dry air for a few days, dimerized adduct was obtained as a white precipitate by adding 95% ethanol.

Recrystallization from acetonitrile at a temperature below 50°C gave a white needle 0.77 g (45%), mp 66.0—66.5°C.

Found: C, 72.25; H, 10.31; N, 4.53; S, 9.85%. Calcd for $C_{20}H_{34}NBS$: C, 72.48; H, 10.36; N, 4.23; S, 9.67%.

Reaction of 1:1 Complex between n-*Butyl Di*-n-*butylthioboronite and Benzyl Cyanide with Phenyl Isocyanate.* The 1:1 complex obtained from *n*-butyl di-*n*-butylthioboronite (1.42 g) and benzyl cyanide (0.78 g) was stirred for 1 hr at room temperature under dry air. A solution of phenyl isocyanate (0.79 g) in 3 m*l* ether was then added all at once to the complex in the presence of a catalytic amount of boron trifluoride etherate at 0°C. After stirring for 10 hr at 0°C, the reaction mixture was dissolved in dry THF. The THF solution was added with vigorous stirring to the mixture of THF and pH 7 buffer (9.10 g, KH_2PO_4+18.90 g Na_2HPO_4/*l*). After stirring 3 hr at 25—30°C, the THF layer was separated and the water layer was extracted with ether three times. Both layers were combined and dried with sodium sulfate. The yellow oily substance obtained by evaporating the solvent *in vacuo* was crystallized in a small amount of petroleum ether at −78°C. The crystal was filtered. The filtrate was concentrated by evaporation and the residue was chromatographed on silica gel. From the elute of benzene a white crystal was obtained. Recrystallization from petroleum ether gave *N*-*n*-butylthiocarbonyl *N*-phenyl phenylacetamidine, 1.57 g (74%) mp 69.5—70.5°C.

The corresponding phenyl acetamidine derivatives were obtained in a similar way. The results are listed in Table 2.

Hydrolysis of N-n-*Butylthiocarbonyl* N-*Phenylacetamidine.* Dilute hydrochloric acid solution was added to a solution of *N*-*n*-butylthiocarbonyl *N*-phenyl phenylacetamidine (0.41 g) in THF at room temperature. After removal of the solvent, the acylurea was obtained as a white crystal (0.32 g). The yield of acylurea was quantitative.

In a similar way, various acylureas were obtained in quantitative yields. The results are listed in Table 3.

Ambident Ion. VI. Kinetical and Thermodynamical Control in the Acylation of β-Dicarbonyl Compounds. Acetylation of Benzoylacetone and Benzoylacetonate Anion

Masakazu SUAMA, Yukimichi NAKAO, and Katsuhiko ICHIKAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto

(Received May 11, 1971)

Kinetically as well as thermodynamically controlled steps have been established in acetylation of ambident ion. Acetylation of sodium benzoylacetonate in pyridine gave initially the kinetically controlled product (I) which isomerized gradually to the thermodynamically controlled (II). *C*-Acetylation product (III) was formed by the reaction of benzoylacetonate ion with *O*-acetylbenzoylacetones at higher temperatures. Comparison of the results in the acetylation of benzoylacetone with those of its sodium salt suggested that enolate anion was the reacting species in both processes of *O*- and *C*-acetylation. Isomerization between I and II was suppressed in α-picoline or 2,6-lutidine solution. Utilizing these results we have prepared three kinds of acetylated products I, II, and III readily in high selectivity.

Alkylation of enolate anions has been extensively studied, but not the acylation of enolates.[1-3]

In this paper we wish to report on the acetylation of benzoylacetone which shows a marked duality in the reaction process, *viz.*, kinetically controlled and thermodynamically controlled processes. Acetylation of the salts of benzoylacetone is expected to give two *O*-acetylated products (I) and (II) and one *C*-acetylated one (III) (Eq. 1). It was found that solvents effected the product distribution remarkably.

$$(PhCOCHCOCH_3)^-Na^+ + AcCl \longrightarrow \underset{\underset{OAc}{|}}{PhCOCH{=}C{-}CH_3} \quad (I)$$

$$+ \underset{\underset{OAc}{|}}{PhC{=}CHCOCH_3} \quad (II) \; + \; \underset{\underset{Ac}{|}}{PhCOCHCOCH_3} \quad (III) \qquad (1)$$

Solvent Effects on the Product Distribution in Acetylation of Sodium Benzoylacetonate. The results of the acetylation of sodium benzoylacetonate with acetyl chloride in several solvents are shown in Table 1.

Total yields including *O*- and *C*-acylated products in ether solvents increased in the order: ethyl ether< dimethoxyethane<diglyme. This suggests that the solvating power to Na^+ plays an important role.[4] The contents of III in the product decreased in the order: ether>dimethoxyethane>diglyme, and those of II increased in the reverse order. This suggests that *O*-acetylation is more favored when the reaction medium is more favorable for the dissociation of the sodium salt to enolate anion. Benzene is distinguished from the others in giving III as the major product. In *N,N*-dimethylformamide, no formation of *C*-acetylated product was detected and the ratio of I/II was 79/21, being much higher than the other cases at 0°C. The ratio, however, changed to 19/81 when acetylation was carried out at 50°C.

Table 1. Solvent effects on the product distribution in the acetylation of sodium benzoylacetonate

Solvent[a]	Reaction temp. °C	Time hr	Yield[b] %	Composition I%	II%	III%
Ether	38	24	31.0	18	45	37
DME	0	24	32.8	21	59	20
DGM	0	24	45.1	22	78	0
Benzene	12	24	26.2	4	6	90
DMF	0	24	32.9	79	21	0
DMF	50	24	26.3	19	81	0

a) DME: 1,2-dimethoxyethane; DGM: diethylene glycol dimethyl ether (diglyme).
b) Based on sodium salt.

Isomerization between the two *O*-acetylated compounds at a higher reaction temperature was confirmed experimentally as shown in Table 2. The same phenomenon was also realized in acetylation in pyridine as mentioned later.

Acetylation of Benzoylacetone and its Sodium Salt in Pyridine at 0°C (O-acetylation). It is well known that the acylation of β-dicarbonyl compounds in pyridine proceeds smoothly and gives *O*-acylation products exclusively, but the reaction mechanism is open to question.[5] By comparing the results in the acetylation of benzoylacetone with those of its sodium salt, the intervention of enolate anion as a reacting species was examined. Changes of the product compositions during the course of the reaction are shown in Figs. 1 and 2.

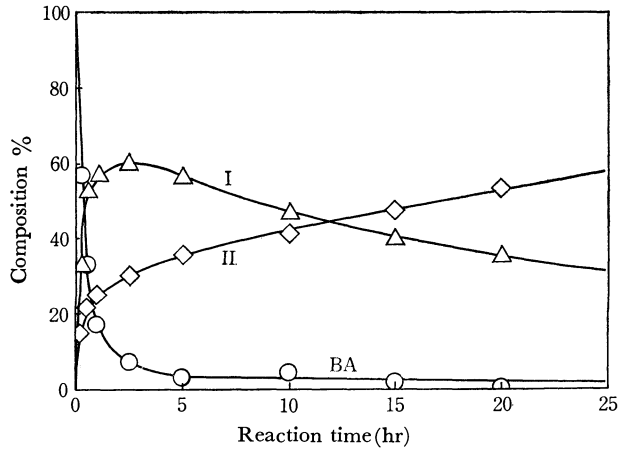

Fig. 1. Acetylation of benzoylacetone (BA) in pyridine at 0°C.

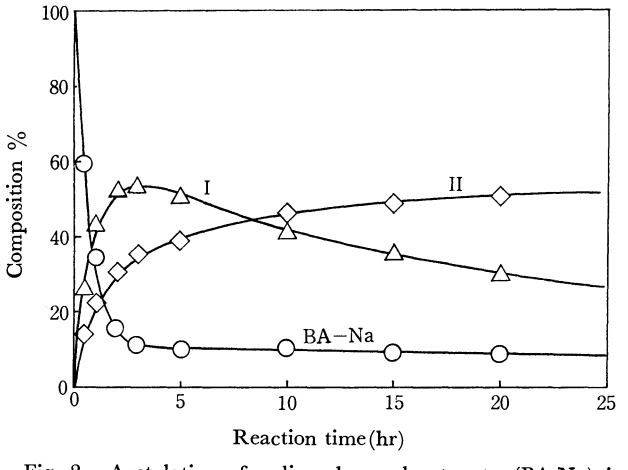

Fig. 2. Acetylation of sodium benzoylacetonate (BA-Na) in pyridine at 0°C.

In each case, acetylation was complete in about 2 hr, and afforded I and II nearly in quantitative yield and only a trace amount of III. Kinetic preference for the formation of I to II can be attributed to the steric hindrance of phenyl group, since no acetylation occurred in the case of dibenzoylmethane under the reaction conditions.

Figures 1 and 2 clearly show that the isomerization of I to II occurred. In the reactions of ambidents, these kinds of isomerization have scarcely been considered so far. However, our data indicate that it is necessary to distinguish the competitive reactions from the isomerization reactions in order to discuss the reactivity of two reaction sites.

Controlled experiments showed that the mutual isomerization between I and II occurred in pyridine and the equilibrium ratio of I to II was about 19/81 at 0°C. The results of the isomerization are shown in Figs. 3 and 4.

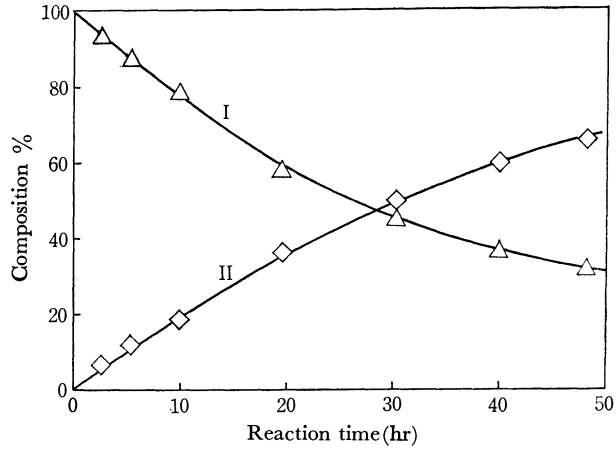

Fig. 3. Isomerization of I to II in pyridine at 0°C.

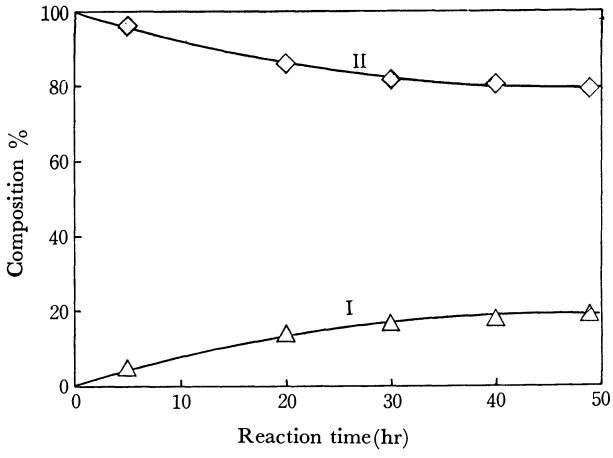

Fig. 4. Isomerization of II to I in pyridine at 0°C.

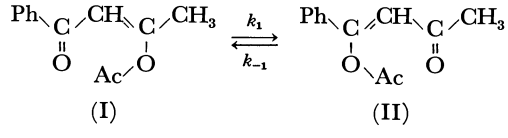

(I) (II)

Isomerization was of first order with respect to both I and II, and the pseudo-first order rate constants were $k_1=0.85\times10^{-5}\,\mathrm{sec}^{-1}$ and $k_{-1}=0.20\times10^{-5}\,\mathrm{sec}^{-1}$, respectively. Considering the absence of any other acylating agents and substrate except solvents in these experiments, the isomerization seems to be an intramolecular rearrangement caused by the assistance of pyridine base.

Under the reaction conditions of Figs. 1 and 2, the rate of isomerization was smaller than that of acetylation, and the effect of the isomerization can be neglected in the early period of the reaction. In the cases of benzoylacetone and its salt, *C*-acetylated product formation was a minor process and the relative ratios of I to II were about 2.0/1.0 in the early stage of the reactions.

The results and similarities in the composition patterns of Figs. 1 and 2 suggest that in the acetylation of benzoylacetone also, enolate anion is the reacting species which is formed by the deprotonation from benzoylacetone by the action of pyridine base. However, the direct acylation process of keto-enol tautomers by acetylpyridinium cation[3] is not yet

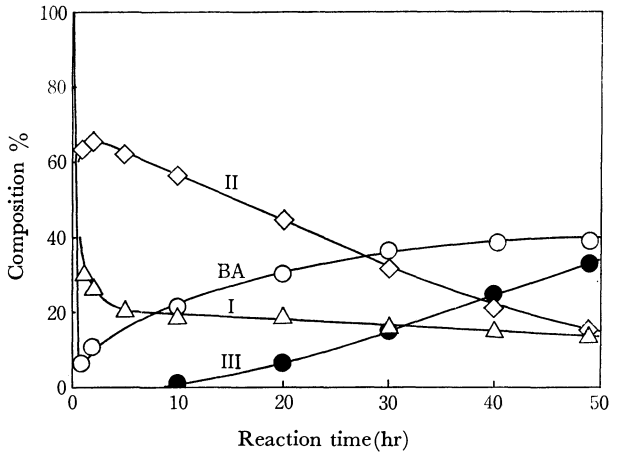

Fig. 5. Acetylation of benzoylacetone in pyridine at 50°C.

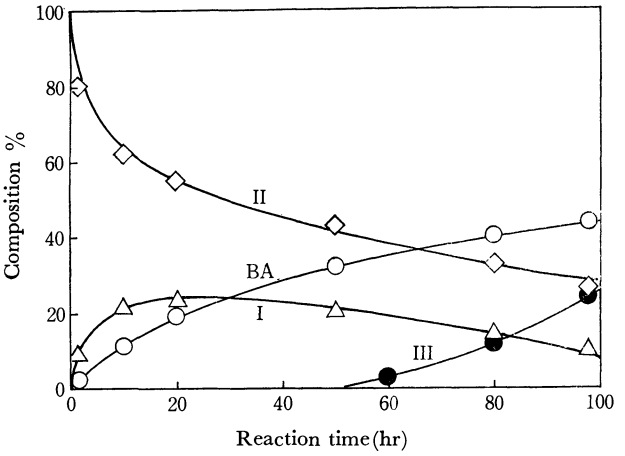

Fig. 6. Isomerization and decompsition of II in pyridine at 50°C.

completely excluded.

Acetylation of Benzoylacetone in Pyridine at 50°C (C-*Acetylated Benzoylacetone Formation).* When acetylation was carried out at 50°C, the composition of the reaction mixtures changed with reaction time as shown in Fig. 5.

During the course of the reaction, III was formed which was a minor product in the acetylation at 0°C as mentioned before. As shown in Fig. 6, when II was kept at 50°C in pyridine, III and benzoylacetone were formed, suggesting that the formation of III and benzoylacetone resulted from the isomerization and decomposition of II. Figures 5 and 6 indicate that the formation of benzoylacetone takes place before the formation of III. When an equimolar mixture of II and benzoylacetone were kept at 50°C in pyridine, formation of III was very slow. However, when sodium salt of benzoylacetone was used instead of benzoylacetone, the formation of III was favored. Consequently, in the process of *C*-acetylation the reacting species is also enolate anion.

Mutual Isomerizations between I and II in Methylpyridines. I and II isomerized mutually in pyridine at 0°C through first order kinetics. The isomerization in methylpyridines was also examined and the results are shown in Tables 3 and 4.

Introduction of methyl group into the 2- and/or

Table 3. Isomerization of I at 0°C in methylpyridines

Solvent	Reaction time hr	Composition			
		BA[a] %	I%	II%	III%
α-Picoline	53	2	89	6	3
γ-Picoline	53	9	25	66	0
2,6-Lutidine	53	1	92	7	0

a) BA: benzoylacetone

Table 4. Isomerization of II at 50°C in methylpyridnes

Solvent	Reaction time hr	Composition			
		BA%	I%	II%	III%
α-Picoline	53	2	13	85	0
γ-Picoline	53	41	10	9	40
2,6-Lutidine	47	0	12	82	0

6-position of pyridine nucleus suppressed the isomerization effectively, but the methyl group in 4-position showed no such inhibition. This indicates that steric bulkiness around the basic nitrogen atom is largely reflected upon the catalytic activity of pyridine base in the isomerization process. However, acetylation of benzoylacetone in α-picoline gave I selectively in high yield (70%) in the reaction at 0°C for 23 hr. Thus, the 2-methyl group which suppresses the isomerization does not effect the first step acetylation rate. The result is very useful for the preparation of I.

Conclusion

The reaction courses of acetylation of benzoylacetone and its sodium salt have been established as follows:

$$(PhCOCHCOCH_3)^-Na^+ + CH_3COCl \xrightarrow{\text{in ethers}} I + II + III$$

$$PhCOCH_2COCH_3 \overset{\text{pyridine}}{\rightleftharpoons} (PhCOCHCOCH_3)^- + \text{N-acetylpyridinium}$$

$$PhCOCH{=}C(OAc)CH_3\ (I) \quad \overset{\text{in pyridine, 0°C}}{\rightleftharpoons} \quad PhC(OAc){=}CHCOCH_3\ (II)$$

$$I \text{ and } II \xrightarrow{\text{pyridine, 50°C}} PhCOCH_2COCH_3 \overset{\text{pyridine, 50°C}}{\rightleftharpoons}$$

$$(PhCOCHCOCH_3)^- \xrightarrow[\text{pyridine, 50°C}]{\text{I or II}} PhCOCHCOCH_3 \quad (III)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad Ac$$

In the acetylation of sodium salt of benzoylacetone in ethers the dissociation into enolate anion favored *O*-acetylation, suggesting that enolate anion is a reacting species in the *O*-acetylation. By comparison of the acylation of benzoylacetone with that of sodium salt, the intervention of enolate anion is also probable in the *O*-acetylation of benzoylacetone itself. The formation of *C*-acetylation product in pyridine at a higher reaction temperature clearly shows that the

enolate anion is acylated by enol ester as pointed out by Muir *et al.*[2]

In the acetylation in pyridine, consecutive mutual isomerizations between I and II proceed even at 0°C. The isomerization is first order reaction with each enol ester I and II and seems to be intramolecular rearrangement reaction. The isomerization can be retarded by the introduction of methyl group into the 2- and/or 6-position of pyridine ring. At a higher temperature further isomerization into III occurred, being an intermolecular migration of acetyl group from the enol ester to enolate anion.

Selection of the reaction condition in the acetylation of benzoylacetone makes it possible to obtain three kinds of acetylated products I, II, and III selectively. Thus, in acetylation in pyridine at 50°C for more than 80 hr, III could be obtained in a selectivity of 83%. Futher, in the acetylation in α-picoline at 0°C, I was formed in 76% selectivity and II was obtained in the selectivity of 77% after a reaction at 0°C for 80 hr. Utilizing these reactions three kinds of acetylated products are readily prepared.

Experimental

Infrared spectra were recorded on a Hitachi EPI-G2. The ultraviolet absorption spectra were determined with a Hitachi EPS-3T spectrophotometer. Nuclear magnetic resonance spectra were recorded on Japan Electronic Optics JNM-3H-60 and JNM-MH-60 using tetramethylsilane as the internal standard in deuteriochloroform. Thin layer chromatography was carried out on silica gel G and developed with benzene or *n*-hexane-ethyl acetate mixtures (90: 10, and 80:20). The spots were detected by standing in an atmosphere of iodine.

Reagents. Benzoylacetone was prepared by the method of Claisen[6] and purified by vacuum distillation and recrystallization from *n*-hexane in 68% yield, bp 104—108°C/2—5mmHg (lit, 132/14 mmHg), mp 56.4—56.6°C (reported 60—61°C). The IR spectrum of the sample was identical with that of Sadtler's data No. 476K and No. 5437. Sodium salt of benzoylacetone was prepared by the reaction of benzoylacetone and sodium metal in dry ether under reflux in the presence of a catalytic amount of ethanol. The white powder precipitated was collected, washed with ether and dried *in vacuo*. Acetyl chloride was purified by distillation of GR grade reagent and stored under nitrogen in a sealed ampule, bp 51.2—51.4°C. Pyridine, α-picoline, γ-picoline, 2,6-lutidine, dimethylformamide, dimethoxyethane, and ethylene glycol dimethyl ether were purified by the procedures described previously.[3]

Analysis of the Composition of the Reaction Mixture. Because of the thermal instability of I, II, and III, glc method was very troublesome. We developed an electronic computer program which determined the concentration of each components by analyzing UV spectra of the reaction mixtures. Aliquots of the reaction mixture were diluted with methanol in order to stop the reaction. UV absorptions were measured and expressed in numerical absorptions in the wave length range 258—334 mμ in every milimicron and the concentration of each component was obtained by the program using computer HARP-5020. The accuracy of the concentration obtained by this method was ±5% in absolute values. It was confirmed that Lambert-Beer's law and the additivity of the absorptions of the components existing in the system holdand the absorptions of the other components except for those cited in Table 5 do not disturb the analysis in this range of concentrations.

Table 5. Ultraviolet absorption of each component

III	280	1.08
	252	1.50

Identification of Acetylated Products. 4-Phenyl-2-acetoxy-2-buten-4-one (I): 16.2 g of benzoylacetone (0.1 mol) was dissolved in 50 g of α-picoline in a flask equipped with a mechanical stirrer, dropping funnel, and a silica gel tube and cooled on an ice-water bath. Acetyl chloride 11.8 g (0.15 mole) was added in portions at a rate which kept the reaction temperature below 4°C. The progress of the reaction was checked by UV spectrum during a period of 10 hr. The reaction mixture was poured into dilute hydrochloric acid. and the neutralized mixture was extracted with ether. After the usual work-up an oily product was obtained which afforded yellow crystals on cooling at −20°C. The crystals were collected and recrystallized from petroleum ether to yield 3.6 g of I, mp 32.5—33.0°C, bp 108—117°C/0.5 mmHg. Found: C, 70.77; H, 5.85%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. IR (KBr) 1750 (s, $\nu_{C=O}$ enol ester), 1680 (s, $\nu_{C=O}$ benzoyl), 1630 (s, $\nu_{C=C}$), 1450, 1380 (m, δCH_3), 1230, 1147 (vs, ν_{C-O} ester), 780, and 710 cm^{-1} (s, phenyl). NMR ($CDCl_3$) τ 7.76 (s, 3H, acetoxy), 7.57 (d, 3H, J=1.1 Hz, $-CH=C(OAc)C\underline{H}_3$), 3.17 (q, 1H, J=1.1 Hz, vinyl proton), and 2.0—2.8 (m, 5H, ArH). UV λ_{max}^{MeOH}=281 mμ (ε=1.55×10^4).

1-Phenyl-1-acetoxy-1-buten-3-one (II): The acetylation of benzoylacetone was carried out in pyridine at 0°C for 24 hr. After a similar working-up as above, the oily product was separated into I and II by means of column chromatography (Wakogel C-200, 30φ×420, elutant: benzene and then ethyl acetate). Recrystallization of crude solid from petroleum ether afforded colorless crystals II mp 38.2—38.5°C, bp 119—123°C/0.5 mmHg. Found: C, 70.73; H, 5.93%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. IR (KBr) 1770 (s, $\nu_{C=O}$ enol ester), 1690 (s, $\nu_{C=O}$ acetyl), 1600 (s, $\nu_{C=C}$), 1450, 1362 (m, δCH_3), 1200, 1160 (vs, ν_{C-O} ester), 765, and 690 cm^{-1} (s, phenyl). NMR ($CDCl_3$) τ 7.75 (s, 3H, acetoxy) 7.65 (s, 3H, acetyl), 3.48 (s, 1H, vinyl proton), 2.0—2.6 (m, 5H, ArH). UV λ_{max}^{MeOH}=262 mμ (ε=1.98×10^4).

ω,ω-Diacetylacetophenone (III): III was prepared by the Schotten-Baumann reaction[7] and purified by vacuum distillation and recrystallization from methanol or petroleum ether in a yield of 42%, mp 28.9—29.4°C (reported 35.0°C), bp 132—135°C/5 mmHg. Found: C, 70.80; H, 5.93%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%. IR (KBr) 1655 (*vs*, $\nu_{C=O}$ intramolecular H-bonded), 1590 (s, $\nu_{C=C}$ enol form), 1450, 1360 (m, δCH_3), 730, and 700 cm^{-1} (s, phenyl). NMR ($CDCl_3$) τ 7.92 (s, 6H, two acetyl), 1.8—2.6

6) L. Claisen, *Ber.*, **38**, 695 (1905).

7) L. Claisen, *Ann.*, **291**, 63 (1896).

(m, 5H, ArH), −7.20 (broad s, 0.8H, enol OH). UV λ_{max}^{MeOH} =253 mμ ($\varepsilon=1.59\times10^4$), and 280 mμ ($1.08\times10^4$).

I and II could be decisively identified by means of NMR—the presence of fine long-range coupling between methyl and vinyl ptotons of $-C\underline{H}=C(OAc)C\underline{H}_3$ in I. Purity of the samples could be readily determined by taking advantage of the signals of vinyl protons.

Acetylation of Sodium Benzoylacetonate. The sodium salt (20 mmol) was dissolved in 50 g of solvent and acetyl chloride (22 mmol) was added under cooling when necessary. A similar treatment of the reaction mixture as mentioned above gave an oily product which was analyzed by glpc (OV-17 5%, 2m, 130°C) with *trans*-stilbene as an internal standard. Besides the glpc analysis, UV technique was also applied directly to the reaction mixture.

Acetylation of Benzoylacetone and Sodium Benzoylacetonate in Pyridine at 0°C. 11.8 g of acetyl chloride (0.15 mol) was added to 35.0 g of pyridine under stirring on an ice-water bath. Pyridine (15.0 g) solution of benzoylacetone 16.2 g (0.10 mol) was added into the suspension of acetylpyridinium chloride in pyridine and aliquots were analyzed by means of UV technique. Acetylation of sodium benzoylacetonate at 0°C was carried out in a similar way.

Acetylation of Benzoylacetone and its Sodium Salt in Pyridine at 50°C. Acetyl chloride (0.15 mol) was added to pyridine (50g) solution of benzoylacetone sodium salt (0.10 mol) at 50°C. Previous addition of acetyl chloride as mentioned above in the experiments at 0°C failed to give rise to reproducibility of the results.

Acetylation of Benzoylacetone in α-Picoline at 0° and 50°C. The procedure is described in the preparation of I. The change of composition was followed by means of UV technique. In the reaction at 0°C, the ratios of I/II were constant (4.8± 0.4) all through the reaction for 8 hr up to 90% conversion. In the reaction at 50°C, acylation was complete in 0.5 hr (cf. at 0°C, 75% conversion after the reaction for 2 hr) but slow isomerization of I to II was observed.

Isomerization between I and II in Pyridine at 0°C. Ca. 1g of pyridine solution of I or II (0.1—2.0 mol/*l*) was kept at 0°C and aliquots were analyzed by means of UV technique at proper time intervals. The changes of composition are shown in Figs. 3 and 4. The plot of $\ln[([I]_0-[I]_e)/([I]-[I]_e)]$ *vs.* reaction time gave a common straight line through the origin over the range of twenty times initial concentration of I or II. From the slope of the straight line (1.05×10^{-5} sec^{-1}) and the equilibrium ratio of I to II (19/81), k_1 (0.85×10^{-5}) and k_{-1}(0.20×10^{-5} sec^{-1}) were obtained.

Isomerization between I and II in Methylpyridines. Ca. 180 mg of methylpyridine solution of I or II (2.0 mol/*l*) was kept at 0 or 50°C and aliquots were analyzed in a similar way. Isomerization was also examined in DMF, dimethoxyethane, diglyme, acetonitrile, and benzene at 50°C but no isomerization was detected. In triethylamine, however, II isomerized to a mixture after the reaction at 50°C for 47 hr, whose composition was benzoylacetone 31, I 18, II 43, and III 8%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2815—2820 (1971)

Studies of Thioiminocarbonates. I. The Formation and Decomposition of *O*-Alkyl *S*-Aryl Thioiminocarbonates in the Reaction of Aryl Thiocyanates with Alcohols in the Presence of the Cyanide Ion[1)]

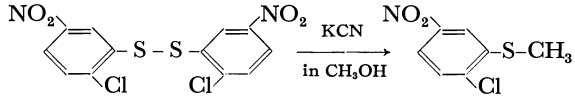
Kazuhiko TANAKA, Jun-ichi HAYAMI, and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

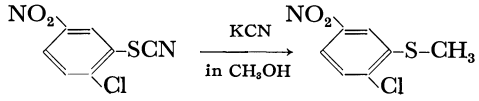
(Received May 17, 1971)

The reactions of aryl thiocyanates (I) with alcohol in the presence of cyanide ion were found to give alkyl aryl sulfides (III). The intermediate was isolated in the case of *p*-tolyl thiocyanate with methanol at 0°C and was determined to be *O*-methyl *S*-*p*-tolyl thioiminocarbonate (IIa) on the basis of NMR and IR spectral studies. The treatment of IIa with the cyanide ion afforded methyl *p*-tolyl sulfide (IIIa) in a high yield. When a mixture of an equimolecular amount of *O*-methyl *S*-*p*-tolyl thioiminocarbonate (IIa) and *O*-ethyl *S*-*p*-chlorophenyl thioiminocarbonate (IId) was treated with sodium cyanide in ethanol, all the anticipated sulfides——methyl *p*-tolyl sulfide (IIIa), *p*-tolyl sulfide (IIIb), methyl *p*-chlorophenyl sulfide (IIIc) and ethyl *p*-chlorophenyl sulfide (IIId)——were isolated. The mechanistic route, which involves the addition of alcohol to aryl thiocyanate, and the dissociation of the resulting *O*-alkyl *S*-aryl thioiminocarbonate (II) into aryl mercaptide ion and aryl cyanate, was proposed.

In the course of the work on the desulfurization of disulfides with the cyanide ion,[2)] an interesting reaction was observed. When bis(2-chloro-5-nitrophenyl) disulfide was treated with potassium cyanide in methanol, methyl 2-chloro-5-nitrophenyl sulfide was isolated (Eq. (1)):



(1)



(2)

1) Presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969.

2) To be published elsewhere.

Methyl 2-chloro-5-nitrophenyl sufide was also obtained in the reaction of 2-chloro-5-nitrophenyl thiocyanate with potassium cyanide under the same reaction conditions (Eq. (2)). The formation of alkyl aryl sulfide was ascribed to the reaction of aryl thiocyanate, which is the intermediate postulated for the desulfurization of diaryl disulfide by the cyanide ion.[2)]

The present study was undertaken in order to clarify the reaction mechanism of the formation of sulfide and to isolate the intermediate formed when aryl thiocyanate is treated with alcohol in the presence of the cyanide ion.

Results and Discussion

Formation of Alkyl Aryl Sulfides in the Reaction of Aryl Thiocyanates with Alcohols in the Presence of the Cyanide Ion. When aryl thiocyanate was treated with alcohol in the presence of an equimolecular amount of sodium (or potassium) cyanide, alkyl aryl sulfide was easily obtained in a fairly good yield. The results are summarized in Table 1. In order to examine the general application of this novel reaction, we attempted to prepare benzyl and *n*-butyl aryl sulfide by the same procedure. However, sodium cyanide and potassium cyanide were only slightly soluble in these alcohols. This was overcome by using dimethyl sulfoxide as the solvent or by using tetraethylammonium cyanide as the cyanide-ion precursor in acetonitrile. Thus, benzyl *p*-tolyl sulfide was obtained in a 68% yield in the reaction of *p*-tolyl thiocyanate with benzyl alcohol in the presence of sodium cyanide in DMSO, and *n*-butyl *p*-tolyl sulfide was obtained in a 59% yield by using tetraethylammonium cyanide in a mixture of

Ross[3)] reported the formation of ethyl phenyl sulfide in the reaction of phenyl thiocyanate and sodium ethoxide in ethanol; he proposed the following pathway:

$$2PhSCN + 2EtONa \longrightarrow PhSNa + EtOCN + PhS\text{-}O\text{-}Et \quad (3)$$

$$PhS\text{-}O\text{-}Et \xrightarrow{O} PhSEt \quad (4)$$

(PhSEt with O)

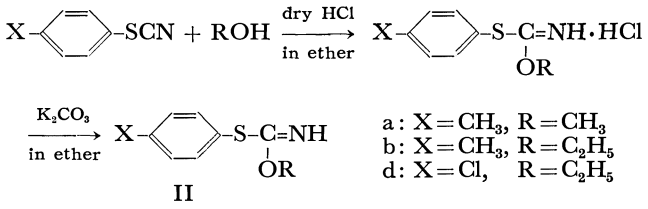
$$PhSEt + 2PhSH \longrightarrow PhSEt + PhSSPh + H_2O \quad (5)$$

(PhSEt with O)

However, he reported that ethyl phenyl sulfide was not obtained in the reaction of ethyl benzenesulfenate and thiophenol in ethanol containing sodium ethoxide. This result shows that sulfenate is not the intermediate. Recently, Mislow *et al.*[4)] reported that methyl *p*-toluenesulfenate does not rearrange to methyl *p*-tolyl sulfoxide. Thus, there remains much doubt about the pathway in Eqs. (3)—(5).

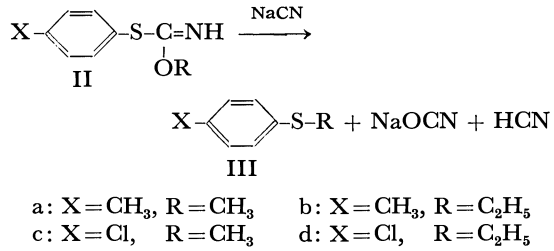
When *p*-tolyl thiocyanate was treated with sodium cyanide in methanol at 0°C, methyl *p*-tolyl sulfide (38%) and a pale yellow oil (2.1 g) were obtained. This oil showed a strong infrared band at 1634 cm^{-1} (C=N) and a weak band at 3360 cm^{-1} (NH), and the NMR peaks at τ 6.40 (OCH_3) and at τ 3.45 (NH), in accordance with the expected formation of *O*-methyl *S*-*p*-tolyl thioiminocarbonate (IIa) as the intermediate.

The *O*-alkyl *S*-aryl thioiminocarbonates (II) were synthesized independently by the following procedure, similar to that reported by Knorr.[5)] The results are reported in Table 5.



Scheme 1

Formation of Alkyl Aryl Sulfides from O-*Alkyl* S-*Aryl Thioiminocarbonates.* *O*-Alkyl *S*-aryl thioiminocarbonates (II) were treated with sodium cyanide in alcohol. In all the cases studied, alkyl aryl sulfide (III) was isolated in a fairly good yield. In DMSO, IIIa was obtained in an 81% yield, since the basicity of the cyanide ion and the nucleophilicity of the mercaptide ion were enhanced in dipolar aprotic solvents.[6)] The results are reported in Table 2.



Scheme 2

The reaction of IIa with sodium cyanide in ethanol afforded IIIa exclusively, while the reaction of IIb in methanol gave a mixture of sulfides, which were shown by glc to be IIIb (64%) and IIIa (7%). These results show that the alkyl moiety of III was derived from that of II, not from the alcohol used as a solvent.

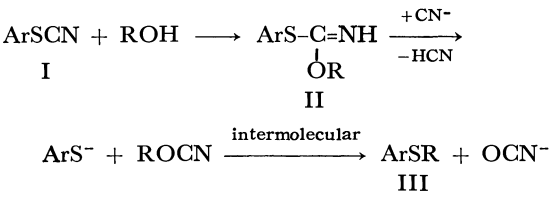
This was also confirmed by the reaction of IIa with sodium cyanide in DMSO, which gave IIIa exclusively and in a high yield (Table 3).

Crossover Experiment with O-Alkyl S-Aryl Thioiminocarbonates. In order to find a clue to the mechanism of the formation of alkyl aryl sulfide (III) from *O*-alkyl *S*-aryl thioiminocarbonate (II), a crossover experiment using a mixture of *O*-methyl *S*-*p*-tolyl thioiminocarbonate (IIa) and *O*-ethyl *S*-*p*-chlorophenyl thioiminocarbonate (IId) was made. The mixture of IIa and IId was treated with sodium cyanide in ethanol, and the resulting mixture of sulfides was analyzed by glc. All four sulfides, *i.e.*, IIIa (23.8 mol%), IIIb (9.7 mol%), IIIc (22.8 mol%), and IIId (43.7 mol%), were found in the reaction mixture. Since IIa underwent no ester exchange with the ethanol used as the solvent, the ethyl moiety in IIIb is probably derived from that of IId.

On the basis of the observations presented earlier, we propose a following mechanism involving the dissociation of II into the aryl mercaptide ion and alkyl cyanate for the formation of sulfide:



Scheme 3

Direct evidence for the existence of aryl mercaptide was obtained by the reaction of IIa with sodium cyanide in the presence of 2,4-dinitro-chlorobenzene, which is known to be a good mercaptide ion scavenger.[7] Thus the reaction of IIa (0.05 mol) with sodium cyanide (0.05 mol) in the presence of 2,4-dinitro-chlorobenzene (0.05 mol) in methanol afforded 2,4-dinitrophenyl *p*-tolyl sulfide in a 24% yield.

Kinetic studies of the formation and the decomposition of II will be reported in forthcoming papers.

Experimental

The melting points are uncorrected; the glc analyses were carried out with a Yanagimoto GCG-5DH chromatograph (Silicone DC-550, 190°) and with a Hitachi-Perkin-Elmer F-6D chromatograph (BDS-15 capillary column, 110°). The IR spectra were recorded on Nippon Bunko IR-S and DS-402G spectraphotometers. The NMR spectra were obtained on a Nihon-Denshi JNM 3H-60 spectrometer.

Reaction of Bis(2-chloro-5-nitrophenyl) Disulfide with Potassium Cyanide in Methanol. A solution of bis(2-chloro-5-nitrophenyl) disulfide (4.7 g, 0.0125 mol) and potassium cyanide (1 g, 0.0154 mol) in 200 m*l* of methanol was stirred for 4 hr under reflux. The precipitates were then removed by filtration, and water was added to the filtrate. The resulting yellow solid was separated by filtration; subsequent recrystallization from methanol gave 2 g of pale yellow needles (87%); mp 98—99°C; NMR ($CDCl_3$): τ 7.45 (SCH_3).

or potassium cyanide (0.05 mol) was stirred. After stirring had been continued for an appropriate period (see Table 1), the sodium (potassium) cyanate was removed by filtration. The filtrate and alcoholic washing were then combined, after which the usual work-up afforded alkyl aryl sulfide.

Preparation of O-*Alkyl* S-*Aryl Thioiminocarbonates. General Procedure*: Into a mixture of aryl thiocyanate (I, 0.134 mol) and absolute alcohol (0.134 mol), a stream of dry hydrogen chloride was introduced at 0°C. After the solution had been solidified, dry ether was added and the pale yellow solid of *O*-alkyl *S*-aryl thioiminocarbonate hydrochloride was pulverized and filtered. The dry hydrochloride was suspended in ether, and an aqueous solution of potassium carbonate was stirred in at 0°C. The ethereal layer was separated and dried with anhydrous sodium sulfate. Distillation *in vacuo* gave II as a transparent liquid. The physical constants and analytical data of II are reported in Table 5, Table 6, and Table 7.

Isolation of the Intermediate in the Reaction of p-*Tolyl Thiocyanate with Sodium Cyanide in Methanol.* Into a mixture of Ia (7.5 g, 0.05 mol) and absolute methanol (170 m*l*), powdered sodium cyanide (2.5 g, 0.05 mol) was stirred. After the stirring had been continued for 1 hr at 0°C, the solution was filtered. The filtrate was concentrated under reduced pressure, and the residue was extracted with ether. The ethereal solution was washed with a saturated aqueous solution of sodium chloride and dried with anhydrous sodium sulfate. Distillation under reduced pressure gave 2.6 g of IIIa (38%) and a pale yellow oil (2.1 g); IR: 3360 cm^{-1} (NH) and 1634 cm^{-1} (C=N).

NMR (TMS): τ 3.20 (aromatic), τ 3.40 (NH), τ 6.40 (OCH_3) and τ 7.83 (CH_3). This oil was identified as IIa.

Formation of Alkyl Aryl Sulfides from O-*Alkyl* S-*Aryl Thioiminocarbonates.* Into a solution of IIa (9.1 g, 0.05 mol) in absolute methanol (200 m*l*), powdered sodium cyanide (2.5 g, 0.05 mol) was added. After stirring had then been continued for 3 hr at 50°C, the precipitated sodium cyanate (1.6 g) was removed by filtration. The filtrate was concentrated under reduced pressure, and the residue was extracted with ether. The distillation of the dried ethereal solution gave IIIa in 55% yield; bp 100—102°C/20 mmHg (lit,[9] bp 104—105°C/20 mmHg). NMR (TMS): τ 3.33 (aromatic), τ 7.80 (S–CH_3) and τ 7.88 (CH_3).

In an analogous way, IIa in ethanol gave 4.6 g of IIIa, while IIb in methanol afforded IIIa and IIIb (90:10) by glc.

Crossover Experiment between O-*Methyl* S-p-*tolyl Thioiminocarbonate (IIa) and* O-*Ethyl* S-p-*Chlorophenyl Thioiminocarbonate (IId).* Sodium cyanide (1.5 g, 0.03 mol) was added to a solution of IIa (2.7 g, 0.015 mol) and IId (3.2 g, 0.015 mol) in absolute ethanol (130 m*l*). After stirring for 3 hr at 50°C, the work-up gave an oil which was found by glc analysis to be a mixture of IIIa (23.8 mol%), IIIb (9.7 mol%), IIIc (22.8 mol%), and IIId (43.7 mol%).

Isolation of 2,4-Dinitrophenyl p-*Tolyl Sulfide.* Into a

mixture of IIa (9.1 g, 0.05 mol) and 2,4-dinitro-chlorobenzene (10.1 g; 0.05 mol) in absolute methanol (200 m*l*), powdered sodium cyanide (2.5 g, 0.05 mol) was stirred. After stirring had been continued for 3 hr at 50°C, the solution was concentrated under reduced pressure; the residue was then recrystallized from ethanol to afford 3.5 g (24%) of 2,4-dinitrophenyl *p*-tolyl sulfide as yellow needles; mp 102—103°C (lit,[5] mp 103°C).

The authors wish to acknowledge the enthusiastic assistance of Mr. Masao Nishikuri in carrying out this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2820—2823 (1971)

Preparation of *p*-Toluenesulfonyl Derivatives of *myo*-Inositol

Tetsuo SUAMI, Seiichiro OGAWA, and Shuichi OKI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received May 18, 1971)

Six *p*-toluenesulfonyl esters of *myo*-inositol, five of which are new, have been prepared by a selective sulfonylation of *myo*-inositol derivatives and the structures of the new compounds were established by means of their proton magnetic resonance (PMR) spectra and the reaction sequences. Preparation of 1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol, an useful intermediary compound for synthesizing *myo*-inosadiamine-1,3, has been improved by the present method.

In the preceding paper,[1] we described the preparations of *p*-toluenesulfonyl esters of *myo*-inositol by selective sulfonylation of 1,2-*O*-cyclohexylidene-*myo*-inositol. In this paper, we wish to report the alternative synthetic route to its positional isomers. Six *p*-toluenesulfonyl esters (1,3-, 1,3,4- 1,3,5-, 1,3,4,5-, 1,3,4,6- and 1,3,4,5,6-) have been prepared by selective sulfonylation of *myo*-inositol derivatives. The structures of the new compounds were confirmed by the PMR spectra of their acetyl derivatives or the reaction sequences. Preparation of 1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol,[2] an important intermediary compound for *myo*-inosadiamine-1,3,[3] has been much improved by the present method.

Treatment of 4,5,6-tri-*O*-acetyl-1,2-*O*-cyclohexylidene-3-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1a**)[1] with boiling 80% aqueous acetic acid resulted removal of cyclohexylidene group to give 4,5,6-tri-*O*-acetyl-1-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2a**) in 68% yield. One of the two hydroxyl groups in **2a** was expected to be selectively esterified by *p*-toluenesulfonyl chloride, since they are in an axial and an equatorial orientation, respectively.[4] When **2a** was treated with 2 molar equivalents of *p*-toluenesulfonyl chloride in dry pyridine at 30°C for 4 days, 4,5,6-tri-*O*-acetyl-1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3a**) was obtained as a sole product in 88% yield. The structure of **3a** was established by converting it into the known tetraacetyl derivative (**4a**)[2] by the usual manner. Therefore, the equatorial hydroxyl group on C-3 was shown to be selectively esterified. While the axial hydroxyl group on C-2 was found to be extremely unreactive due to being highly sterically hindered by the two vicinal *p*-toluenesulfonyloxy groups in *cis* relationship. Even when the reaction of **2a** with an excess amount of *p*-toluenesulfonyl chloride was carried out over 100°C for prolonged periods, a formation of the tri-ester could not be detected by a thin layer chromatography (tlc).

Similarly, 5,6-di-*O*-acetyl-1,4-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2b**) was obtained in 86% yield from 4,5-di-*O*-acetyl-1,2-*O*-cyclohexylidene-3,6-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1b**)[1] by refluxing in aqueous acetic acid. Treatment of **2b** with 3 molar equivalents of *p*-toluenesulfonyl chloride gave 5,6-di-*O*-acetyl-1,3,4-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3b**) selectively in 90% yield. Compound **3b** was also obtained from 4,5-di-*O*-acetyl-1,6-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2c**) which was derived from 5,6-di-*O*-acetyl-1,2-*O*-cyclo-

hexylidene-3,4-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1c**).[1] These results confirmed the proposed structure of **3b** unambiguously. Acetylation of **3b** gave the triacetyl derivative (**4b**) which, in PMR spectrum in deuteriochloroform ($CDCl_3$), revealed a narrow triplet (J= 3 Hz) at τ 4.49. Similar triplet was found in the PMR spectrum of **4a** (τ 4.37), and then it was assigned to the hydrogen atom on C-2 bearing acetoxy group.

Preferential sulfonylation of 4,6-di-*O*-acetyl-1,5-di-*O*-*p*- toluenesulfonyl-*myo*-inositol (**2d**). which was obtained by removal of the cyclohexylidene group of 4,6-di-*O*-acetyl-1,2-*O*-cyclohexylidene-3,5-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1d**),[1] afforded 4,6-di-*O*-acetyl-1,3,5-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3c**) exclusively in 95% yield. On acetylation, **3c** gave the triacetyl derivative (**4c**), which revealed two signals of 1 : 2 relative intensities in an acetoxy methyl region[5] in its PMR spectrum

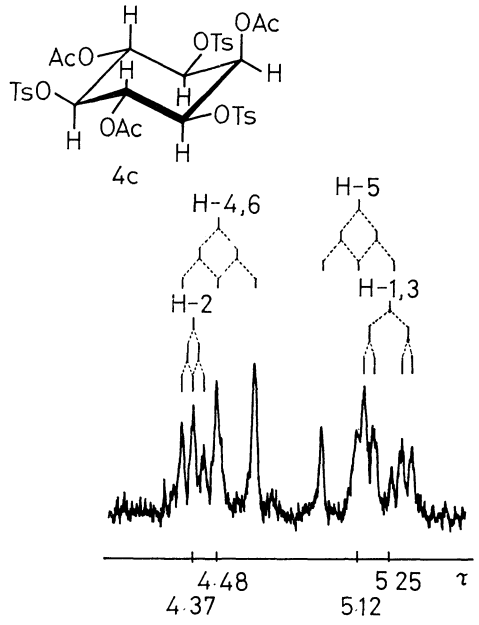

Fig. 1. Partial PMR spectrum of 2,4,6-tri-*O*-acetyl-1,3,5-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**4c**) in $CDCl_3$ at 60 MHz: J_{ae}=3 Hz, J_{aa}=10 Hz.

	8.15 (1)	

a) Measured at 60 MHz in $CDCl_3$. Values in parenthesis show number of methyl groups. Chemical shifts are expressed in τ-values.

in $CDCl_3$. This result supported the proposed structure of **4c**, because it has a symmetrical structure and the signals due to two acetoxy groups on C–4 and C–6 should be overlapped each other (Table. 1). Furthermore, the signals of the ring protons could be resolved by first-order method and assigned unambiguously to each proton, as shown in Fig. 1.

By the same reaction sequences, 5-*O*-acetyl-1,4,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol. (**2e**) and 6-*O*-acetyl-1, 4,5-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2f**) were obtained from 5-*O*-acetyl-1,2-*O*-cyclohexylidene-3,4,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1e**)[1] and 4-*O*-acetyl-1,2-*O*-cyclohexylidene-3,5,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1f**)[1] in 90 and 93% yield, respectively. On sulfonylation with 5 molar equivalents of *p*-toluenesulfonyl chloride, **2e** and **2f** afforded 5-*O*-acetyl-1,3,4,6-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3d**) and 6-*O*-acetyl-1,3-4,5-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3e**) predominantly in 42[6] and 99% yield, respectively. Compound **3d** and **3e** were converted into the diacetyl derivative (**4d**) and (**4e**), respectively, which showed the narrow triplets (J=3 Hz) at τ 4.55 and 4.58, supporting the location of the acetoxy group at C-2.

Sulfonylation of 1,4,5,6-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2g**)[1] produced 1,3,4,5,6-penta-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3f**) as a sole product in 63% yield. Attempt of acetylation of **3f** by the usual manner failed. Introduction of five *p*-toluenesulfonyl group into all the equatorially orientated hydroxyl groups in *myo*-inositol seemed to make the remaining axial hydroxyl group on C-2 extremely unreactive. Therefore, the structure of **3g** was substantially established by an analogy.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. PMR spectra were measured on a Varian Associate A-60D (60 MHz) spectrometer at a concentration of *ca.* 10% deuteriochloroform with tetramethylsilane as an internal standard. Chemical shifts are expressed in τ-values and signals are described as

6) The low yield of **3d** may be due to a partial de-*O*-acetylation of **2d** and/or **3d** during a sulfonylation reaction.

s (singlet), t (triplet), q (quartet), or m (complex multiplet). Values given for coupling constants are first-order. Thin layer chromatography was done with silica gel (Wakogel B-10, Wako pure chemical industries Ltd.) using toluene-methyl ethyl ketone (4:1 or 3:1 volume) as the solvent system. The compounds were detected by exposing the plates to iodine vapor or by heating after spraying 50% sulfuric acid. All solutions were concentrated by a rotary evaporator at 40—50°C under reduced pressure. All the compounds described in this paper are racemic.

4,5,6-Tri-O-*acetyl-1*-O-p-*toluenesulfonyl*-myo-*inositol (2a)*. A mixture of 4,5,6-tri-*O*-acetyl-1,2-*O*-cyclohexylidene-3-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1a**)[1] (1.0 g) and 80% aqueous acetic acid (20 m*l*) was refluxed for 2 hr. The reaction mixture was evaporated to give an oily product which crystallized by trituration with ethanol to afford crystals (0.54 g, 68%) of **2a**, mp 202—204°C. Recrystallization from ethanol gave colorless prisms which showed the same melting point.

Found: C, 50.14; H, 5.26; S, 7.12%. Calcd for $C_{19}H_{24}O_{11}S$: C, 49.55; H, 5.25; S, 6.96%.

4,5,6-Tri-O-*acetyl-1,3-di*-O-p-*toluenesulfonyl*-myo-*inositol (3a)*. To a solution of **2a** (0.46 g) in dry pyridine (5 m*l*) was added *p*-toluenesulfonyl chloride (0.29 g) under ice cooling. The reaction mixture was allowed to stand at 30°C for 4 days, till when the tlc showed the disappearance of **2a**. Poured into ice and water (100 m*l*), the crude crystals (0.64 g) were collected by filtration. A 0.44 g portion of the crude product was recrystallized from ethanol to give colorless needles (0.38 g, 88%) of **3a** monohydrate, mp 207—208.5°C (after melting and resolidifying to plates at 117—125°C).

Found: C, 49.55; H, 5.20; S, 9.62%. Calcd for $C_{26}H_{30}O_{13}S_2 \cdot H_2O$: C, 49.37; H, 5.10; S, 10.14%.

The monohydrate lost water of crystallization when it was dried over phosphorus pentoxide under vacuum at 120°C for 24 hr, mp 207.5—208.5°C.

Found: C, 50.94; H, 4.88; S, 10.46%. Calcd for $C_{26}H_{30}O_{13}S_2$: C, 50.80; H, 4.92; S, 10.43%.

2,4,5,6-Tetra-O-*acetyl-1,3-di*-O-p-*toluenesulfonyl*-myo-*inositol (4a)*. A 0.21 g portion of the crude **3a** monohydrate was treated with a mixture of acetic anhydride (2 m*l*) and pyridine (2 m*l*) at 80°C for 1 hr. Then the mixture was poured into ice and water and the crystals were collected by filtration; yield 0.19 g (90%), mp 220—223°C (lit,[2] mp 220—222°C). This compound was identified with an authentic sample by comparing with IR spectra.

5,6-Di-O-*acetyl-1,4-di*-O-p-*toluenesulfonyl*-myo-*inositol (2b)*. A mixture of 4,5-di-*O*-acetyl-1,2-*O*-cyclohexylidene-3,6-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1b**)[1] (1.27 g) and 80% aqueous acetic acid (25 m*l*) was refluxed for 2 hr. Then the mixture was evaporated and the crystalline residue was triturated with ethanol to afford colorless crystals (0.97 g, 86%) of **2b**, mp 201.5—203.5°C. Recrystallization from ethanol gave an analytical sample, colorless needles, mp 207.5—209°C.

Found: C, 50.52; H, 4.86; S, 11.05%. Calcd for $C_{24}H_{28}O_{12}S_2$: C, 50.33; H, 4.94; S, 11.20%.

5,6-Di-O-*acetyl-1,3,4-tri*-O-p-*toluenesulfonyl*-myo-*inositol (3b)*. To a solution of **2b** (0.19 g) in dry pyridine (2 m*l*) was added *p*-toluenesulfonyl chloride (0.18 g, 2.8 molar equiv.) and the reaction mixture was kept at 30°C for 4 days, followed at 85°C for 1 hr. Then the mixture was poured into ice and water (25 m*l*) and the resulting oily product was extracted with chloroform (25 m*l*), washed with water (3×20 m*l*) and dried over anhydrous sodium sulfate. Evaporation gave a colorless oil, which crystallized on treatment with chloroform and ethanol to give crystals (0.21 g, 90%) of **3b**, mp 201—203°C. Recrystallization from chloroform and ethanol afforded an analytical sample, colorless plates, mp 204.5—206°C.

Found: C, 51.32; H, 4.82; S, 13.14%. Calcd for $C_{31}H_{34}O_{14}S_3$: C, 51.23; H, 4.72; S, 13.23%.

2,5,6-Tri-O-*acetyl-1,3,4-tri*-O-p-*toluenesulfonyl*-myo-*inositol (4b)*. A 100 mg portion of **3b** was treated with acetic anhydride (1 m*l*) and pyridine (1 m*l*) at room temperature overnight. The reaction mixture was poured into ice and water and the resulting crystals were collected by filtration. The crude crystals of **4b** weighed 100 mg (96%), mp 147—150.5°C. An analytical sample was obtained by recrystallization from chloroform and ethanol, mp 166—167.5°C. PMR: τ 4.49 (1, t, H-2, J=2.8 Hz).

Found: C, 51.60; H, 4.65; S, 12.72%. Calcd for $C_{33}H_{36}O_{15}S_3$: C, 51.56; H, 4.72; S, 12.49%.

4,5-Di-O-*acetyl-1,6-di*-O-p-*toluenesulfonyl*-myo-*inositol (2c)*. A mixture of 5,6-di-*O*-acetyl-1,2-*O*-cyclohexylidene-3,4-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1c**)[1] (0.19 g) and 80% aqueous acetic acid (10 m*l*) was refluxed for 2 hr. Then the reaction mixture was evaporated to give a colorless oil which was induced crystallization on addition of aqueous ethanol to afford crystals (0.15 g) of **2c**. Recrystallization from ethanol gave colorless prisms (0.10 g, 58%), mp 184.5—185°C.

Found: C, 50.42; H, 5.17; S, 11.08%. Calcd for $C_{24}H_{28}O_{12}S_2$: C, 50.33; H, 4.94; S, 11.20%.

Selective p-*Toluenesulfonylation of 2c*. To a solution of **2c** (61 mg) in dry pyridine (0.6 m*l*) was added *p*-toluenesulfonyl chloride (0.10 g, 4.9 molar equiv.) and the reaction mixture was kept at 30°C for 70 hr. Then the mixture was processed similarly as described in **3b** to give colorless crystals (63 mg, 81%) of **3b**, mp 206—207°C, which was identified with the compound derived from **2b** by the mixed melting point and comparing with IR spectra.

4,6-Di-O-*acetyl-1,5-di*-O-p-*toluenesulfonyl*-myo-*inositol (2d)*. A mixture of 4,6-di-*O*-acetyl-1,2-*O*-cyclohexylidene-3,5-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1d**)[1] (1.04 g) and 80% aqueous acetic acid (20 m*l*) was refluxed for 2 hr. The mixture was evaporated to give a slightly yellow oil, which crystallized on addition of water to give crude crystals (0.89 g). It was shown to be contaminated with the partly de-*O*-acetylated product by a tlc, then, the crude product was recrystallized two times from ethanol to afford chromatographically pure crystals (0.57 g, 63%) of **2d**, mp 178.5—180.5°C.

Found: C, 49.99; H, 4.95; S, 11.27%. Calcd for $C_{24}H_{28}O_{12}S_2$: C, 50.33; H, 4.94; S, 11.20%.

4,6-Di-O-*acetyl-1,3,5-tri*-O-p-*toluenesulfonyl*-myo-*inositol (3c)*. To a solution of **2d** (155 mg) in dry pyridine (1.5 m*l*) was added *p*-toluenesulfonyl chloride (250 mg, 4.9 molar equiv.) and the mixture was kept at 30°C for 70 hr. Then the reaction mixture was processed similarly as described in **3b** to give crude crystals, which were recrystallized from chloroform and ethanol to afford colorless needles (187 mg, 95%) of **3c**, mp 165—167°C (after sintering at 147°C). Recrystallization from the same solvents gave an analytical sample which showed the same melting point.

Found: C, 51.28; H, 4.72; S, 12.95%. Calcd for $C_{31}H_{34}O_{14}S_3$: C, 51.23; H, 4.72; S, 13.23%.

2,4,6-Tri-O-*acetyl-1,3,5-tri*-O-p-*toluenesulfonyl*-myo-*inositol (4c)*. A 101 mg portion of **3c** was treated with acetic anhydride (1 m*l*) and pyridine (1 m*l*) at room temperature overnight. Then the mixture was poured into ice and water to give crystals (106 mg, 99%) of **4c**, mp 178—185°C. An analytical sample was obtained by recrystallization from ethanol, colorless tiny needles, mp 181.5—183°C (after sintering at 175°C).

Found: C, 51.75; H, 4.73; S, 12.41%. Calcd for $C_{33}H_{36}O_{15}S_3$: C, 51.54; H, 4.72; S, 12.49%.

5-O-Acetyl-1,4,6-tri-O-p-*toluenesulfonyl*-myo-*inositol (2e)*. A mixture of 5-*O*-acetyl-1,2-*O*-cyclohexylidene-3,4,6-tri-*O*-*p*-

toluenesulfonyl-*myo*-inositol (**1e**)[1] (1.0 g) and 80% aqueous acetic acid (50 m*l*) was refluxed for 2 hr. After cooling, the resulting crystals were collected by filtration and washed with ethanol to yield colorless granular crystals (0.79 g, 85%) of **2e**, mp 222.5—224.5°C. Recrystallization from pyridine and ethanol gave an analytical sample, colorless prisms, mp 223—225°C.

Found: C, 51.30; H, 5.19; S, 14.58%. Calcd for $C_{29}H_{32}O_{13}S_3$: C, 50.86; H, 4.72; S, 14.04%.

5-O-*Acetyl-1,3,4,6-tetra*-O-p-*toluenesulfonyl*-myo-*inositol (3d)*. To a solution of **2e** (0.25 g) in dry pyridine (3 m*l*) was added *p*-toluenesulfonyl chloride (0.20 g, 3 molar equiv.) and the mixture was kept at 30°C for 4 days. After heating at 80°C for 1 hr, the reaction mixture was poured into ice and water and the resulting oily product was extracted with chloroform (25 m*l*). The extract was washed with water, dried over anhydrous sodium sulfate and then, evaporated to give a colorless oil which crystallized on addition of ethanol. The crude crystals were shown to be consisted of two major components by a tlc: **3d** and de-*O*-acetylated product, probably 1,3,4,6-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol. Fractional crystallization from ethanol afforded colorless plates (0.13 g, 42%) of **3d**, mp 194.5—199.5°C. An analytical sample was obtained by recrystallization from chloroform and ethanol, mp 200—201°C.

Found: C, 51.67; H, 4.62; S, 15.33%. Calcd for $C_{36}H_{38}O_{15}S_4$: C, 51.53; H, 4.57; S, 15.29%.

2,5-Di-O-*acetyl-1,3,4,6-tetra*-O-p-*toluenesulfonyl*-myo-*inositol (4d)*. Acetylation of **3d** (33 mg) with acetic anhydride (1 m*l*) and pyridine (1 m*l*) at room temperature gave colorless crystals (28 mg, 74%) of **4d**, mp 205—207°C. Recrystallization from chloroform and ethanol afforded an analytical sample, mp 207—209°C. PMR: τ 5.55 (2, q, H-1,3, J=3 and 8 Hz), τ 4.55 (1, t, H-2, J=3 Hz).

Found: C, 51.75; H, 4.75; S, 14.31%. Calcd for $C_{38}H_{40}O_{16}S_4$: C, 51.82; H, 4.58; S, 14.57%.

6-O-*Acetyl-1,4,5-tri*-O-p-*toluenesulfonyl*-myo-*inositol (2f)*. A mixture of 4-*O*-acetyl-1,2-*O*-cyclohexylidene-3,5,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1f**)[1] (1.39 g) and 80% aqueous acetic acid (100 m*l*) was refluxed for 2.5 hr. Then the solution was evaporated to give a crystalline residue. Trituration with ethanol gave crystals (1.16 g, 93%) of **2f**, mp 197—200°C (after melting and resolidifying at 162—168°C). Recrystallization from chloroform and ethanol afforded an analytical sample colorless, needles, mp 202—204°C.

Found: C, 50.90; H, 4.70; S, 13.58%. Calcd for $C_{29}H_{32}O_{13}S_3$: C, 50.86; H, 4.72; S, 14.04%.

6-O-*Acetyl-1,3,4,5-tetra*-O-p-*toluenesulfonyl*-myo-*inositol (3e)*. To a solution of **2f** (0.30 g) in dry pyridine (3 m*l*) was added *p*-toluenesulfonyl chloride (0.27 g, 3.4 molar equiv.) and the mixture was kept at 30°C for 4 days. Then the reaction mixture was processed similarly as described in **3a** to give crude crystals (0.37 g, 99%) of **3e**, mp 197—203°C (after sintering and resolidifying at 170—180°C). Recrystallization from chloroform and ethanol afforded an analytical sample, colorless rods, mp 208—210.5°C.

Found: C, 51.30; H, 4.53; S, 15.55%. Calcd for $C_{36}H_{38}O_{15}S_4$: C, 51.53; H, 4.57; S, 15.29%.

2,6-Di-O-*acetyl-1,3,4,5-tetra*-O-p-*toluenesulfonyl*-myo-*inositol (4e)*. A 0.15 g portion of **3e** was treated with acetic anhydride (1 m*l*) and pyridine (1 m*l*) at room temperature gave crystals (0.15 g, 95%) of **4e**, mp 99—112°C. Recrystallization from ethyl acetate and ethanol gave an analytical sample, colorless needles (0.09 g), mp 180—194°C (after melting and resolidifying at 130—140°C). PMR τ: 4.58 (1, t, H-2, J=3 Hz), τ 4.54 (1, t, H-6, J=9 Hz).

Found: C, 51.92; H, 4.46; S, 15.48%. Calcd for $C_{38}H_{40}O_{16}S_4$: C, 51.82; H, 4.58; S, 14.57%.

1,3,4,5,6-Penta-O-p-*toluenesulfonyl*-myo-*inositol (3f)*. To a solution of 1,4,5,6-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2g**)[1] (0.15 g) in dry pyridine (1.5 m*l*) was added *p*-toluenesulfonyl chloride (0.25 g, *ca.* 7 molar equiv.) and the mixture was kept at 30°C for 2 weeks. Then the reaction mixture was processed similarly as described in **3d** to give colorless crystals (0.12 g, 63%) of **3f**, mp 184—185°C. An analytical sample was obtained by recrystallization from chloroform and ethanol, colorless granular crystals, which showed the same melting point.

Found: C, 51.79; H, 4.53; S, 17.06%. Calcd for $C_{41}H_{42}O_{16}S_5$: C, 51.77; H, 4.46; S, 16.85%.

The authors are grateful to Professor Sumio Umezawa for his kind advice, and to Mr. Saburo Nakada for his elementary analyses. The financial support from the Ministry of Education for this work is gratefully acknowledged.

Selective *p*-Toluenesulfonylation of *myo*-Inositol Derivatives

Tetsuo SUAMI, Seiichiro OGAWA, and Shuichi OKI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received May 27, 1971)

Attempt to know the reactivities, toward sulfonylation, of the hydroxyl groups in *myo*-inositol was carried out using partially sulfonylated derivatives of *myo*-inositol. The present studies indicated that the order of reactivity of the hydroxyl groups is 1-OH and 3-OH>4-OH and 6-OH>5-OH>2-OH. From a preparative standpoint, 1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol was readily obtained in 59% yield from 1-*O*-*p*-toluenesulfonyl-*myo*-inositol by a selective sulfonylation.

In order to know the reactivities toward sulfonylation of the hydroxyl groups in *myo*-inositol, attempts of a selective sulfonylation of *myo*-inositol derivatives were made. Little information is as yet available on the relative reactivities, toward sulfonylation, of the hydroxyl groups of cyclitols.[1] Because of its insolubility in pyridine, direct esterification of *myo*-inositol could not be conducted, and then five partially sulfonylated *myo*-inositol derivatives (1-, 1,3-, 1,4-, 1,4,5- and 1,4,6-)[2,3] were used for the present studies.

First of all, a selective *p*-toluenesulfonylation of 1-*O*-*p*-toluenesulfonyl-*myo*-inositol (**1**)[2] was attempted. Theoretically, twenty four positional isomers of *p*-toluenesulfonyl derivatives of *myo*-inositol can be obtained from **1**. However, if 2-*O*-*p*-toluenesulfonyl derivatives are excluded in view of the unreactivity of the axial hydroxyl group on C-2,[4] thirteen isomers (diesters 4, triesters 5, tetraesters 3 and pentaester 1) would be expected to be obtainable. When **1** was treated with 4 molar equiv. of *p*-toluenesulfonyl chloride (TsCl) in dry pyridine at 30°C and the progress of the reaction was followed by thin layer chromatography (tlc) using silica gel, after 4 days, at least eight components were detected in the reaction mixture. Six of the products formed could be identified by a direct comparison of *Rf* values on tlc with authentic samples. These were found to be the 1,3- (**2**), 1,3,4- (**3**), 1,3,5- (**4**), 1,3,4,5- (**5**), 1,3,4,6- (**6**) and 1,3,4,5,6-isomers (**7**) (Fig. 1).

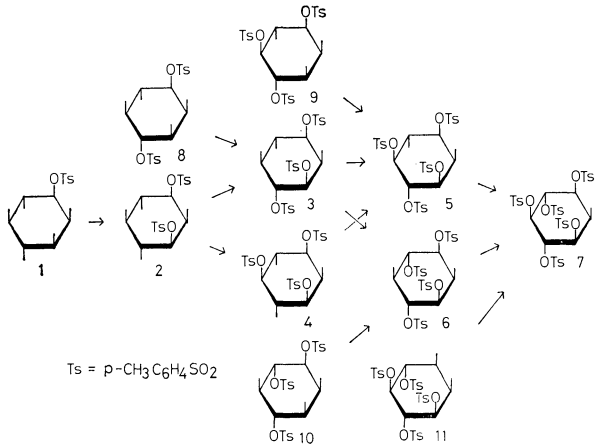

Fig. 1. Course of a selective *p*-toluenesulfonylation of *myo*-inositol[a]

a) All the compounds described in this paper are racemic. In the formulas, the vertical lines represent hydroxyl groups; the hydrogen atoms on the ring carbons are not shown.

Treatment of **1** with 1, 1.2 and 1.5 molar equiv. of TsCl in dry pyridine at 0—30°C for 6—10 days, and subsequent acetylation with acetic anhydride gave 2,4,5,6-tetra-*O*-acetyl-1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2a**) in 50, 59, and 49% yield, respectively, in a pure crystalline state by one recrystallization of the crude product from chloroform and ethanol. Accordingly, the hydroxyl group on C-3 is the most reactive among five hydroxyl groups in **1**. This result was in accordance with the fact that, in the case of 1,2-*O*-cyclohexylidene-*myo*-inositol, the C-3 hydroxyl group which is adjacent to *cis*-arranged cyclohexylidene oxygen atom is the most reactive.[3] The high reactivity at C-3 may be explained by hydrogen bonding between the C-2 and C-3 hydroxyl groups in the transition state of esterification.[1]

When a sulfonylation of **1** was carried out using more than 2 molar equiv. of TsCl, a considerable amount of the tetraesters were formed. On treatment with 3, 4 and 5 molar equiv. of TsCl, **1** gave 1,3,4,6-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol (**6**) in 9, 34, and 28% yield, respectively, which was characterized by converting it into the known diacetate (**6a**).[4]

Then a selective sulfonylation of 1,3- and 1,4-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2** and **8**)[3] was attempted. Monitoring by tlc the progress of the reaction of **2** with 2 and 4 molar equiv. of TsCl, almost the same chromatograms as those observed in the case of **1** under the similar sulfonylation condition were obtained, which indicated that the sulfonylation reaction of **1** proceeded through **2**. On the other hand, from **8**, the 1,3,4,5- and 1,3,4,6-isomers were detected to be formed, then, in view of the high reactivity of C-3 hydroxyl group, the tetraesters should be yielded from the 1,3,4-triester apparently. Therefore, the relative yields of the two tetraesters may accord with the reactivity of C-5 and C-6 hydroxyl groups. According to visual observation of a relative intensity of the 1,3,4,5- and 1,3,4,6-tetraesters on a tlc plate, hydroxyl group on C-6 seemed to be about two times more reactive than that on C-5. This fact might be explained by a steric and electronic effects exerted by an axial hydroxyl group on C-2 in a transition state of esterification.

2) S. J. Angyal, V. Bendor, and J. H. Curtin, *J. Chem. Soc. (C)*, **1966**, 798.
3) T. Suami, S. Ogawa, T. Tanaka, and T. Otake, This Bulletin, **44**, 835 (1971).
4) T. Suami, S. Ogawa, and S. Oki, *ibid.*, **44**, 2820 (1971).

In 4 molar esterification of **2** and **8**, when **8** was completely consumed to be converted into the tetraesters *via* the 1,3,4-triester, the 1,3,4- and 1,3,5-triesters, as well as **2**, were still remaining in the reaction mixture. This indicated that the reactivities of the hydroxyl groups on C-4, 5 or 6 were lower than that on C-3. Furthermore, in the case of **2**, when two triesters almost disappeared on a tlc, the relative intensities of the two spots due to two tetraesters were nearly the same as that observed in **8**. Therefore, in **2**, the hydroxyl group on C-5 was shown to be less reactive than that on C-4 (or 6), even if a theoretical treatment were taken into account. Because the 1,3,4,5-tetraester should be formed from the 1,3,5-triester solely, so that if the latter was yielded from **2** more than half of the 1,3,4-isomer, the yield of the 1,3,4,5-isomer should overwhelmed that of the 1,3,4,6-isomer. This was also understood by an influence of the axial hydroxyl group on C-2.

From the reaction of the 1,4,5- (**9**) and 1,4,6-triesters (**10**) with 4 molar equiv. of TsCl, after 24 hr at 30°C, the 1,3,4,5- and 1,3,4,6-tetraesters were obtained, respectively, in good yield, but even after 10 days, only a trace amount of the 1,3,4,5,6-pentaester was detected in the reaction mixture. On the other hand, from the reaction of the 1,4,5,6-tetraester (**11**) with 4 molar equiv. of TsCl, the 1,3,4,5,6-isomer was obtained comparatively in good yield.[4] Consequently, introduction of *p*-toluenesulfonyloxy group into a vicinal position of hydroxyl group was found to make the remaining free hydroxyl group quite unreactive.[5]

Summarizing the results described above, the reaction sequences of *p*-toluenesulfonylation of *myo*-inositol were shown in Fig. 1. The order of reactivity of six hydroxyl groups in *myo*-inositol could be deduced to be 1-OH and 3-OH>4-OH and 6-OH>5-OH>2-OH. In the case of 1,2-*O*-cyclohexylidene-*myo*-inositol,[3] considering from the relative yield of the isomers, the order of reactivity of its four hydroxyl groups is 3-OH>6-OH>4-OH>5-OH, which seems to be in good accordance with the present result.

Along with the present studies, preferential benzoylation of *myo*-inositol is now underway in our laboratory.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. Infrared (IR) spectra were taken in KBr disks. Tlc was done with silica gel (Wakogel B-10, Wako Pure Chemical Industries Ltd.) using toluene-methyl ethyl ketone (4:1, 3:1, 2:1 or 1:1) or benzene-ethyl acetate (7:2, 3:1 or 1:1) as the solvent system. The compounds were detected by exposing the plates to iodine vapor or heating at 100°C after spraying 30% sulfuric acid. Identification of the compounds was accomplished mainly by mixed tlc and comparison of *Rf* value on a tlc. All solutions were concentrated by a rotary evaporator at 40—50°C under reduced pressure.

p-*Toluenesulfonylation of 1*-O-p-*toluenesulfonyl*-myo-*inositol (1)*. a) 1 molar sulfonylation: To a solution of **1** (0.2 g) in dry pyridine (2 m*l*) was added TsCl (0.12 g) in one portion under ice cooling. The reaction mixture was kept at 30°C for 10 days, and then acetic anhydride (1 m*l*) was added and heated over boiling water bath for 3 hr. The mixture was poured onto ice and water and the resulting precipitates were collected by filtration. The crude product (0.42 g) was recrystallized from chloroform and ethanol to give colorless needles (0.20 g, 50%) of tetra-*O*-acetyl-1,3-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2a**), mp 209—212°C. This compound was identified with an authentic sample[2] by mixed melting point and IR spectra.

b) 1.2 molar sulfonylation: To a solution of **1** (0.20 g) in dry pyridine (2 m*l*) was added TsCl (87 mg) at 0°C and the solution was kept at the same temperature for 24 hr. Then another portion of TsCl (47 mg) was added and the reaction mixture was allowed to stand at 0°C for 2 days. The product was acetylated and processed as described in (a) to afford crystals (0.23 g, 59%) of **2a**, mp 212—213°C.

c) 1.5 molar sulfonylation: Compound **1** (0.21 g) was sulfonylated with TsCl (0.18 g) at 30°C for 10 days and processed as described in (a) to afford crystals (0.20 g, 49%) of **2a**, mp 212—214°C.

d) 2 molar sulfonylation: Compound **1** (0.51 g) was treated with TsCl (0.59 g) in dry pyridine (5 m*l*) at 30°C for 3 days. Then the product was acetylated and processed as described in (a) to give crystals (0.30 g, 30%) of **2a**, mp 213—215°C.

e) 3 molar sulfonylation: Compound **1** (0.50 g) was treated with TsCl (0.88 g) at 30°C for 5 days. The crude product (1.2 g) was fractionated by crystallization from chloroform and ethanol: 0.11 g (the 1,3,4,6-isomer), mp 260—265°C; 0.41 g (the 1,3,4- and 1,3,4,6-isomers); 0.25 g (the 1,3,4-, 1,3,5- and 1,3,4,5-isomers).

f) 4 molar sulfonylation: Compound **1** (0.50 g) was treated with TsCl (1.2 g) in dry pyridine (5 m*l*) at 30°C for 6 days. Then the reaction mixture was poured onto ice and water, and the resulting white precipitates were collected. Recrystallization of the crude product from chloroform and ethanol gave colorless plates (0.40 g, 34%) of 1,3,4,6-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol (**6**), mp 267—269°C. From the mother liquor, the mixture of the tri- and tetraesters (0.17 g) was isolated.

g) 5 molar sulfonylation: Compound **1** (0.50 g) was treated with TsCl (1.5 g) in dry pyridine (5 m*l*) at 0—5°C for 24 hr, and then at 30°C for 24 hr. After heating at 80°C for 5 hr, the reaction mixture was poured onto ice and water to give white powder (1.1 g), which was fractionated by crystallization from chloroform and ethanol to afford colorless plates (0.33 g, 28%) of **6**, mp 265—268°C.

1,3,4-Tri-O-p-*toluenesulfonyl*-myo-*inositol (3)*. A mixture of 5,6-di-*O*-acetyl-1,3,4-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol[4] (0.20 g), conc. hydrochloric acid (2 m*l*) and ethanol (10 m*l*) was refluxed for 3 hr. After cooling, the resulting oily product was collected by decantation and induced to crystallization by addition of chloroform. The crystals were triturated with ethanol and collected by filtration: colorless needles (0.14 g, 80%) of **3**, mp 229—230°C. Recrystallization from ethanol gave an analytical sample, mp 230—230.5°C.

Found: C, 50.02; H, 4.64; S, 15.09%. Calcd for $C_{27}H_{30}O_{12}S_3$: C, 50.45; H, 4.71; S, 14.96%.

1,3,5-Tri-O-p-*toluenesulfonyl*-myo-*inositol (4)*. A mixture of 2,4,6-tri-*O*-acetyl-1,3,5-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol[4] (40 mg), conc. hydrochloric acid (10 m*l*) and ethanol (10 m*l*) was refluxed for 10 hr. After cooling, the resulting crystals were collected by filtration: colorless prisms of **4**, mp 259—263°C. IR spectrum did not show any absorption at ester carbonyl region. Tlc showed a single spot in several solvent systems and the *Rf* value was shown to be identical with that of one of the components observed in the

5) R. W. Jeanloz, A. M. C. Rapin, and S. Hakomori, *J. Org. Chem.*, **26**, 3939 (1961).

sulfonylation mixture of both **1** and **2**.

p-*Toluenesulfonylation of the 1,3- and 1,4-Diesters.* A 30 mg portion of the diester was dissolved in dry pyridine (0.3 m*l*) and TsCl (52 mg, 4 molar equiv.) was added, and the reaction mixture was allowed to stand at 30°C. The course of the reaction was monitored by tlc (solvent system: benzene-ethyl acetate=7:2 and 1:1). The chromatograms (the 1,3-diester) were found to be almost identical with those of the reaction mixture of **1** and 4 molar equiv. of TsCl in pyridine prepared under the same condition. The component, which corresponds to the 1,3,5-triester, was not observed in the sulfonylation mixture of the 1,4-diester. After 5 days, when all the 1,4-diester had been consumed to be converted into the tri- and tetraesters, the 1,3-diester was still remaining unchanged partly in the reaction mixture. The relative intensities of the tetraesters (the 1,3,4,5- and 1,3,4,6-isomers) derived from the 1,4-diester was approximately in the ratio of 1:2.

1,3,4,5-Tetra-O-p-*toluenesulfonyl*-myo-*inositol (5).* a) To a solution of 1,4,5-tri-*O-p*-toluenesulfonyl-*myo*-inositol (**9**)[3] (30 mg) in dry pyridine (0.3 m*l*) was added TsCl (38 mg, 4.3 molar equiv.) and the mixture was kept at 30°C for 21 hr. Then the solution was poured onto ice and water and the precipitates (40 mg) were collected by filtration. The crude crystals were recrystallized from methyl ethyl ketone and ethanol to give colorless needles (22 mg, 58%) of **5**, mp 253—256°C (after sintering at 246°C).

Found: C, 51.46; H, 4.61; S, 15.86%. Calcd for $C_{34}H_{36}O_{14}S_4$: C, 51.24; H, 4.56; S, 16.09%.

b) A mixture of 6-*O*-acetyl-1,3,4,5-tetra-*O-p*-toluenesulfonyl-*myo*-inositol[4] (34 mg), conc. hydrochloric acid (10 m*l*) and ethanol (10 m*l*) was refluxed for 10 hr. After cooling, the resulting crystals were collected and recrystallized from ethanol: colorless prisms of **5**, mp 247—249°C. This compound was identified with the sample obtained from **9** by comparing with IR spectra.

1,3,4,6-Tetra-O-p-*toluenesulfonyl*-myo-*inositol (6).* a) To a solution of 1,4,6-tri-*O-p*-toluenesulfonyl-*myo*-inositol (**10**)[3] (0.21 g) in dry pyridine (2 m*l*) was added TsCl (0.24 g, 3.9 molar equiv.) and the mixture was kept at 30°C for 22 hr, Then the solution was poured onto ice and water and the resulting crystals were recrystallized from 2-methoxyethanol to give colorless needles (0.25 g, 95%) of **6**, mp 269.5—270.5°C.

Found: C, 51.21; H, 4.35; S, 16.13%. Calcd for $C_{34}H_{36}O_{14}S_4$: C, 51.24; H, 4.56; S, 16.09%.

b) To a solution of 1,4-di-*O-p*-toluenesulfonyl-*myo*-inositol (**8**)[3] (0.15 g) in dry pyridine (1.5 m*l*) was added TsCl (0.29 g, 4.9 molar equiv.) and the mixture was kept at 30°C for 7 days. The reaction mixture was poured onto ice and water and the crude crystals were recrystallized two times from chloroform and ethanol to give pure crystals (0.14 g, 56%) of **6**, mp 270—272°C. This compound was identified with the sample obtained from **10** by comparing with IR spectra and mixed tlc.

2,5-Di-O-*acetyl-1,3,4,6-tetra*-O-p-*toluenesulfonyl*-myo-*inositol (6a).* Compound **6** (0.4 g) was acetylated with acetic anhydride (5 m*l*) and pyridine (5 m*l*) at room temperature overnight. The reaction mixture was poured into water and the resulting crystals were recrystallized from chloroform and ethanol to afford colorless crystals (0.39 g, 88%) of **6a**, mp 207—209°C. This compound was identified with the authentic sample by comparing with IR spectra and mixed melting point.[4]

Synthesis and Conformational Studies of [7](2,6)Pyridinophanes

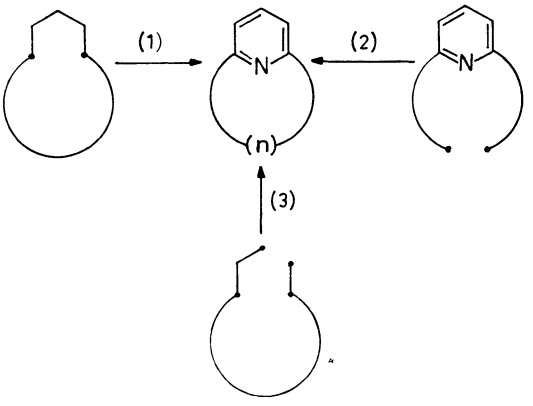
Shinsaku FUJITA and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Kyoto

(Received March 2, 1971)

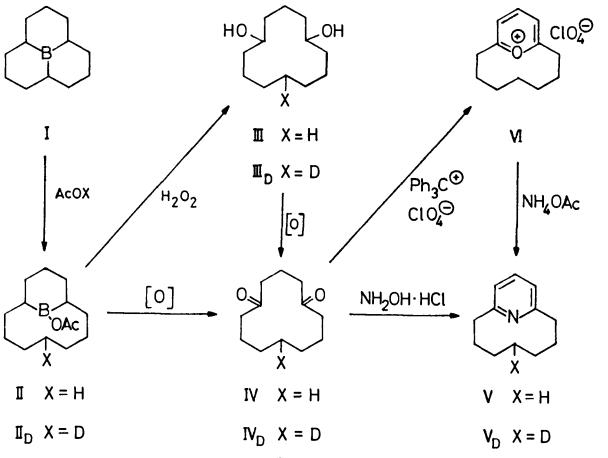
[7](2,6)Pyridinophane (V) and the 4-deuterio derivative (V_D) are prepared from cyclododecane-1,5-diones (IV and IV_D). Lithiation at the α-position of V and the subsequent derivation give 1-methoxycarbonyl- (VIII), 1-hydroxy- (IX), 1-oxo- (X), and 1,1-dimethoxy[7](2,6)pyridinophane (XI). A bathochromic shift in UV spectra is observed and ascribed to the nonplanarity of the pyridine ring. The protons on the C_4 of these heterophanes experience strong shielding due to the magnetic anisotropy of the respective pyridine rings. The shielding of the C_4 protons is more pronounced at low temperatures; this can be explained by assuming an extreme conformation such as XII. The temperature dependence of the NMR spectra is examined, and the energy barriers (ΔG_c^*) for the conformational changes (XII⇄XII′) are estimated to be 9.0 for V and 9.6 kcal/mol for XI. [7](2,6)Pyrylophanium perchlorate (VI) is prepared, in which a similar shielding effect of the pyrylium ring is observed.

The chemistry of uniquely strained meta- and paracyclophanes has been the subject of extensive research.[1] Particularly, their conformational changes have been investigated by means of temperature-variable NMR spectrometry.[2] The heteroaromatic analogs (heterophanes[3]) have recently attracted much attention, since two natural products, muscopyridine[4] and metacycloprodigiosin,[5] were characterized as the derivatives of [10](2,6)pyridinophane and [9](2,4)pyrrolophane respectively. In continuation of our studies of [8]-[6] and [9]heterophanes,[7] the present paper will describe [7](2,6)pyridinophanes with the shortest 2,6-polymethylene bridge ever reported.[8]



Scheme 1

Synthesis of [7](2,6)Pyridinophanes. Scheme 1 shows three possible ways of constructing [*n*](2,6)pyridinophanes: (1) the aromatization of 1,5-bifunctional cyclic compounds,[4,9] (2) the cyclization of 2,6-disubstituted pyridines,[10] and (3) pyridine-ring synthesis accompanying simultaneous bridge formation.[11,12] We have chosen the first approach and have utilized cyclododecane-1,5-dione (IV) as a precursor (see Scheme 2).



Scheme 2

The treatment of 9*b*-boraperhydrophenalene (I) with an equimolar amount of acetic acid and the subsequent Brown oxidation gave IV in a 30% yield.[13] The 1,5-diketone IV was also obtained by the oxidation of the corresponding diol III, which was in turn prepared by the oxidation of a partially-acetolyzed product II with alkaline hydrogen peroxide.

The heating of an alcoholic solution of IV and hydroxylamine hydrochloride gave [7](2,6)pyridinophane (V) in a 44% yield.[14] 4-Deuterated pyridinophane (V_D) was synthesized in a similar method.

12) H. Gerlach and E. Huber, *Helv. Chim. Acta*, **51**, 2027 (1968).

13) The 1,5-diketone IV was previously prepared by fermentation technique. See G. S. Fonken, M. E. Herr, H. Murray, and L. M. Reineke, *J. Amer. Chem. Soc.*, **89**, 672 (1967).

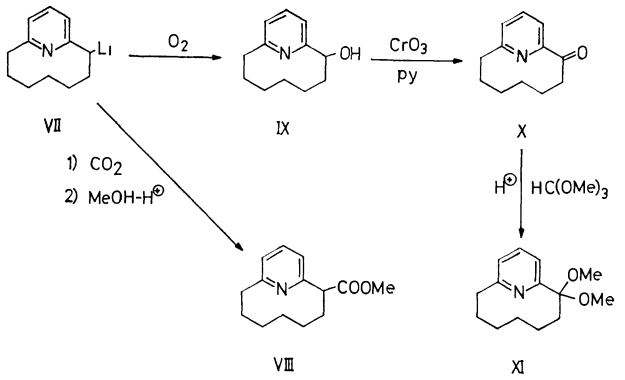
14) Treatment of 9-acetoxycyclododecane-1,5-dione with hydroxylamine hydrochloride gave no pyridinophane derivative. See S. Fujita and H. Nozaki, This Bulletin, **43**, 2995 (1970).

The treatment of I with acetic acid-*d*, oxidation with alkaline hydrogen peroxide, and final oxidation afforded cyclododecane-1,5-dione-9*d* (IV_D), the subsequent cyclization of which gave [7](2,6)-pyridinophane-4*d* (V_D). The C–D stretching absorption of V_D appeared at 2140 cm^{-1}.

The dehydration and hydride abstraction[15] of IV with trityl perchlorate gave [7](2,6)pyrylophanium perchlorate (VI). The treatment of the pyrylium salt VI with ammonium acetate yielded the pyridinophane V, which was identical with the sample prepared directly from IV.

The addition of *n*-butyllithium to a solution of V gave an orange-red solution of 1-lithio[7](2,6)pyridinophane (VII), which then afforded methyl [7](2,6)pyridinophane-1-carboxylate (VIII) upon quenching with carbon dioxide and subsequent esterification. The 1-lithio compound VII reacted with oxygen to form the corresponding alcohol, IX. The Cornforth oxidation of IX gave [7](2,6)-pyridinophan-1-one (X). The treatment of X with methyl orthoformate afforded the corresponding dimethyl acetal (XI).

The heating of V with hydrogen peroxide in acetic acid resulted in the recovery of the starting pyridinophane under conditions sufficient for [10](2,6)pyridinophane to afford the corresponding *N*-oxide in a fair yield.[4] This is due to a steric hindrance introduced by the shorter heptamethylene chain.



Scheme 3

UV and NMR Spectra of [7](2,6)Pyridinophanes and [7](2,6)-Pyrylophanium Perchlorate. The ultraviolet spectra of the [7](2,6)pyridinophanes are summarized in Table 1, together with those of the decamethylene homologs. Bathochromic shifts were observed upon a comparison of the UV bands (^1L_b bands) of [7]pyridinophanes with those of [10]-homologs. This effect can be explained by assuming a nonplanar pyridine ring bridged by the heptamethylene group.[1b]

Table 1. UV spectra of [*n*](2,6)pyridinophanes[a]

α-Substituent	[7](2,6)-Pyridinophane λ_{max}nm (log ε)	[10](2,6)-Pyridinophane[b] λ_{max}nm (log ε)
None	211.5 (3.87)	213 (3.82)
	272 (3.49)	267 (3.62)
-OH	211.5 (3.86)	212 (3.77)
	271 (3.53)	266 (3.54)
=O	236 (3.85)	236 (3.81)
	279 (3.56)	276 (3.66)

a) Ethanol was used as the solvent.
b) Reported in Ref. 4.

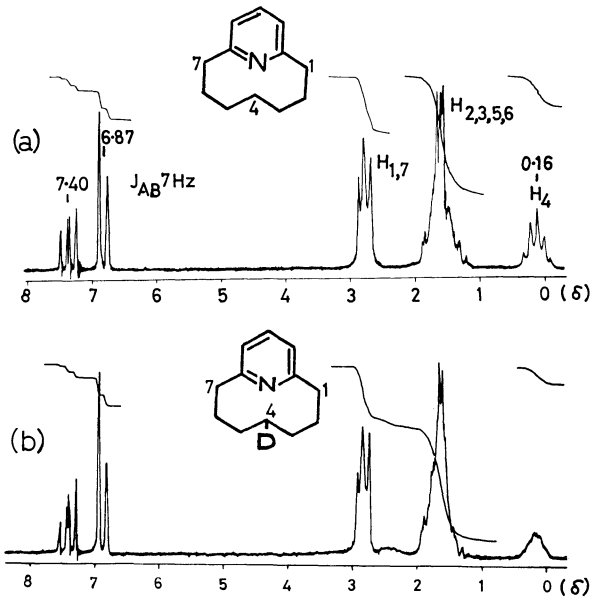


Fig. 1. NMR Spectra of V (a) and V_D (b) (in $CDCl_3$ at 24°C, 60 MHz. TMS as an internal standard).

The NMR spectra of V and V_D are shown in Fig. 1. The aromatic NMR signal of V showed a typical AB_2 pattern, one which resembled the splitting pattern of 2,6-lutidine very closely. The absorptions due to the heptamethylene protons of V were composed of three groups of multiplets (intensity: 4:8:2). In particular, two protons (a quintet at δ 0.16) of the heptamethylene chain were unexpectedly shielded in comparison with usual methylene group linking tetrahedral carbons. The signal at the high field can be ascribed to the C_4 protons, since the 4-monodeuterio-substituted derivative (V_D) showed the corresponding one proton peak which was broadened by a *geminal* H–D coupling. An inspection of the molecular models of V shows that H_a on C_4 is forced close to the π-cloud of the pyridine ring in an extreme conformation, XII. The apparently less crowded conformation, XIII, may be less favored, as the four C–C bonds linking C_2 through C_6 are all in an eclipsed conformation in XIII. The shielding effect in V is ascribed to the magnetic anisotropy of the pyridine ring.[16] Since the peak due to C_1 and C_7 (centered at δ 2.84) and that

15) M. Siemiatycki, *Bull. Soc., Chim. Fr.*, **1961**, 538.

16) The magnetic effect may consist of the diamagnetic ring current of the pyridine ring and/or the anisotropy of the nitrogen atom (Ref. 17). 2,6-Dithia[7]metacyclophane (XVI), in which such magnetic anisotropy of nitrogen atom was absent, was reported to exhibit the signal of C_4 protons at δ 0.45 (in dichloromethane-d_2). See Ref. 18.

Greerts-Evrard, *ibid.*, **20**, 1495 (1964); d) F. Bohlmann, D. Schumann, and C. Arndt, *Tetrahedron Lett.*, **1965**, 2705; e) F. Bohlmann, D. Schumann, and H. Schulz, *ibid.*, **1965**, 173.

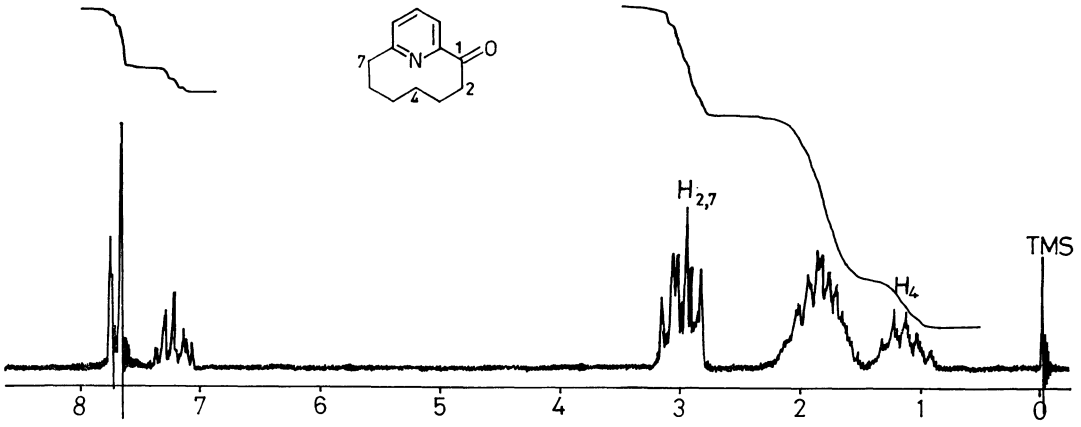

Fig. 2. NMR spectrum of X (in $CDCl_3$ at 24°C, 60 MHz).

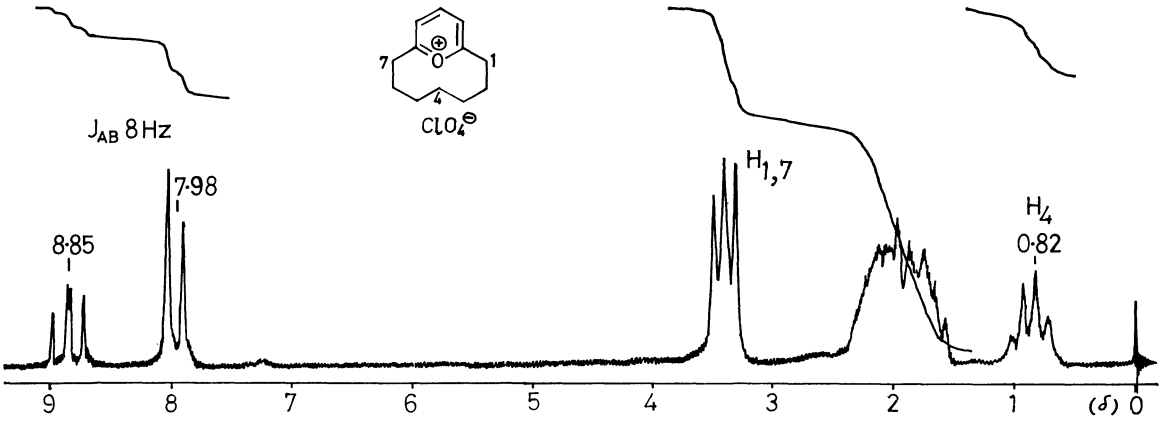

Fig. 3. NMR spectrum of VI (in CF_3COOH at 24°C, 60 MHz).

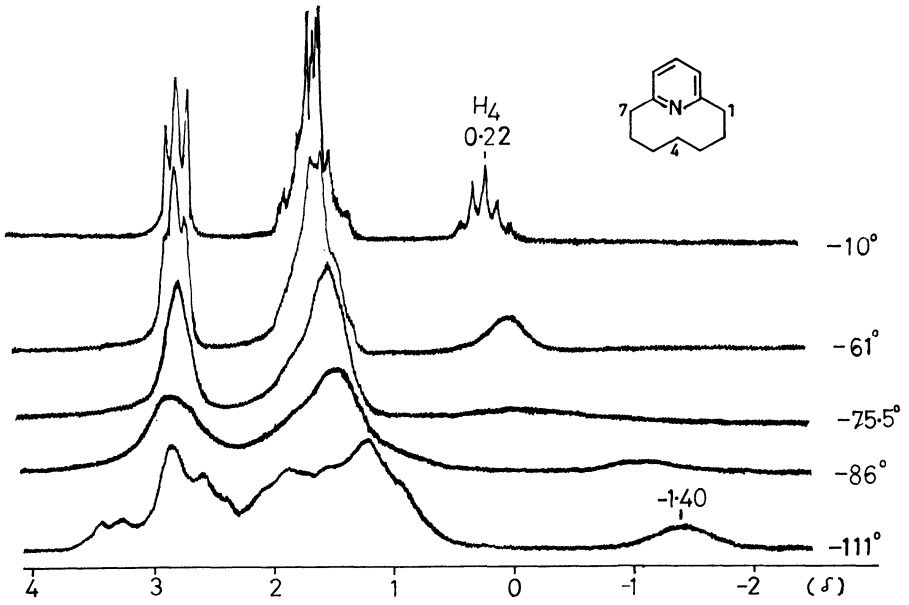

Fig. 4. Dynamic NMR spectra of the heptamethylene chain of V (in $CFCl_3$ at 60 MHz, TMS as an internal standard).

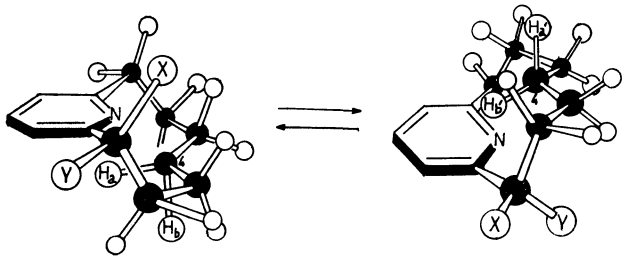
of the C_4 protons can be approximately regarded as a triplet and a quintet respectively, the heptamethylene chain of V possibly flips up and down (XII⇄XII') and its protons show average NMR signals at room temperature (*vide infra*).

The incorporation of a trigonal α-carbon in X resulted in a drastic reduction of the diamagnetic shielding effect as compared with the cases of V, IX, and XI. The conjugation of the pyridine ring of X with the α-carbonyl group should favor a conformer such as XIV, in which C_4 protons are forced out of the center of the pyridine-ring field.

The NMR spectrum of VI (Fig. 3) showed an AB_2-type signal of pyrylium-ring protons. The C_4 methylene of VI was also shielded, appearing at δ 0.82. This is the first example of the diamagnetic shielding effect of a pyrylium ring.



XII XII'

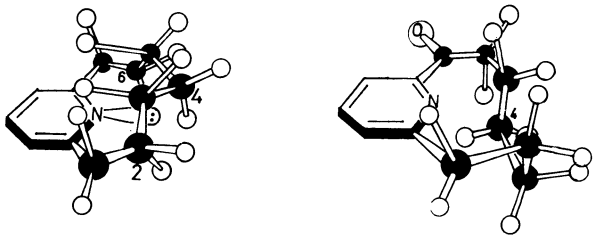
b : X=Y=OMe
c : X=H, Y=COOMe
d : X=H, Y=OH



XIII XIV

Conformational Changes of [7](2,6)Pyridinophanes. The temperature dependence of the NMR spectrum of V is shown in Fig. 4. The signal of the C_4 protons of V broadened at −75.5°C and reappeared at δ −1.40; this is consistent with the extreme conformation, XIIa. The low-field counterpart of the signal is possibly concealed behind the multiplets of the other methylenes.

The C_4 protons of the 1,1-dimethoxy derivative (XI) are also shielded by the magnetic anisotropy of the pyridine ring. Fig. 5 shows the temperature dependence of the NMR spectrum of XI. The signal of the C_4 protons of XI broadened at −62.5°C, and then that of methoxy methyl broadened at −77.0°C. The signals at δ 3.21 and δ 2.98 may be assigned to the *pseudo*-equatorial and *pseudo*-axial methoxy groups of XIIb respectively.

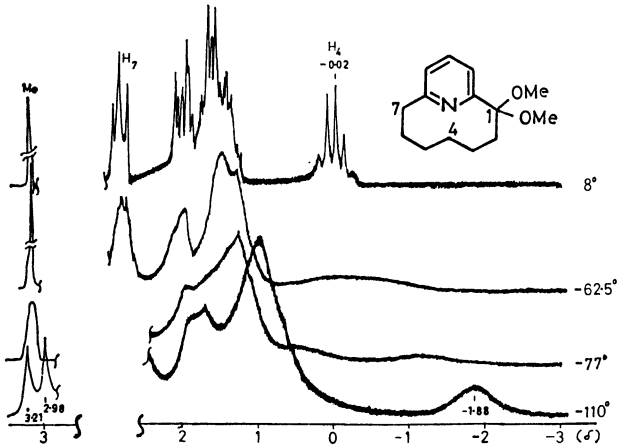


Fig. 5. Dynamic NMR spectra of the heptamethylene chain and methoxy of XI (in $CFCl_3$ at 60 MHz, TMS as an interanl standard).

The estimated energy barriers for the conformational changes (XII⇄XII') of V and XI are shown in Table 2. The ΔG_c^* value reported for 2,6-dithia[7](2,6)pyridinophanes (XV)[10] is smaller than that of our [7](2,6)pyridinophanes. Moreover, even 2,6-dithia[7]metacyclophane (XVI)[18] has a ΔG_c^* value comparable to those of V and XI. The flexibility introduced by S–substitution may be ascribed to the fact that C–S bonds are longer than C–C bonds and C–S–C bending requires much less energy than does C–C–C bending.

Table 2. Energy barriers of the flipping of V and XI[a]

Compd.	Signal	T_c °C	$\Delta\nu$ Hz	k_c[b] sec^{-1}	ΔG_c^*[c] kcal/mol
V	C_4-protons	−75.5	194[d,e]	432	9.0
XI	C_4-protons	−62.5	223[d,f]	495	9.6
	MeO	−77.0	13.8[f]	30.6	10.0

a) The dynamic NMR spectra were determined on a JEOL-C-60-H spectrometer at 60 MHz, using $CFCl_3$ as the solvent and tetramethylsilane (TMS) as the internal standard. See Figs. 4 and 5.
b) $k_c=\pi\Delta\nu/\sqrt{2}$ (Ref. 19)
c) $\Delta G_c^*=2.303RT_c(10.319-\log k_c+\log T_c)$ (Ref. 19)
d) As the signal of the low-field counterpart of the C_4 protons was hidden behind those of other methylenes, $\Delta\nu$ was estimated by the equation, $\Delta\nu=2(\nu_{high}-\nu_{average})$, where ν_{high} was the chemical shift of the high field counterpart at a low temperature and where $\nu_{average}$ was the average chemical shift at room temperature. This approximation may be rough. The discussions in the text may thus be of limited, qualitative meaning. (The authors are grateful to one of the referees for his helpful criticism on this point.)
e) Determined at −111°C.
f) Determined at −110°C.

The two conformers of 1-monosubstituted pyridinophanes (XII and XII') are nonequivalent: the (Y) substituent occupies the *pseudo*-equatorial position in XII and the *pseudo*-axial position in XII'. The NMR spectrum of the 1-hydroxy derivative IX (Fig. 6) showed the multiplet of the two C_4 protons at δ 0.2—δ −0.3. This fact suggests that the conformational change (XIId⇄XIId') is as fast as the NMR time scale at room temperature. On the other hand, even at room temperature, the flipping (XIIc⇄XIIc') of the heptamethylene chain of VIII may be slow enough

to induce the observed coalescence of the C_4 proton signal (Fig. 7). The signal of the two C_4 protons appeared at δ 0.70 at 140°C, corresponding to rapid exchange.

Experimental

All the melting points are uncorrected. The NMR spectra were determined on a JEOL C-60-H spectrometer at 60 MHz with deuteriochloroform, fluorotrichloromethane, and/or hexachlorobutadiene as the solvents. The mass spectra were obtained on a Hitachi RMU-6L spectrometer.

9b-Boraperhydrophenalene (I). A previous method of preparation[20] was modified as follows. A mixture of cyclododeca-1*t*,5*t*,9*c*-triene (42.0 g, 0.26 mol), the trimethylamine-borane complex[21] (19.0 g, 0.26 mol), tetrahydrofuran (THF) (50 m*l*), and cumene (110 m*l*) was added, under a nitrogen atmosphere over a 3-hr period, to cumene maintained at 135—150°C. After concentration *in vacuo*, the oily residue was distilled to give I (33.3 g, 73%); bp 122—128°C/16 mmHg.[20]

Cyclododecane-1,5-dione (IV). *(a) The Brown Oxidation of II*: A solution of I (22.2 g, 0.13 mol) and acetic acid (7.61 g, 0.13 mol) in benzene (150 m*l*) was refluxed at 100—110°C for 3 hr. After the evaporation of the solvent under a nitrogen atmosphere, the oily residue was dissolved in dry ether (120 m*l*) and a chromic acid solution (a mixture of sodium dichromate dihydrate (75.6 g), sulfuric acid (56.6 m*l*), and water 380 m*l*)) was added over a 1-hr period. The reaction mixture was extracted with ether, washed, and dried over sodium sulfate. Concentration and column chromatography on silica gel (ether-benzene 1:9) gave the diketone IV (7.47 g, 30%); mp 66.5—67.5°C (*n*-hexane, lit,[13] mp 64—65°C).

(b) The Jones Oxidation of III: The diol III (20.0 g, quantitative) was obtained from I (17.6 g, 0.10 mol) according to the method in Ref. 20a. A mixture of chromium (VI) oxide (11.2 g), sulfuric acid (9.6 m*l*), and water (30 m*l*) was added at 0°C to a solution of III (20.0 g, 0.10 mol) in acetone (700 m*l*). After filtration, 2-propanol (10 m*l*) and sodium hydrogen carbonate were added to the filtrate. The solid was filtered off, and the filtrate was concentrated and extracted with ether. Concentration and recrystallization then afforded IV (12.3 g, 63%).

[7](2,6)Pyridinophane (V). A mixture of IV (3.19 g, 16 mmol), hydroxylamine hydrochloride (2.84 g, 41 mmol), and absolute ethanol (40 m*l*) was heated at 150—175°C in a 100-m*l* autoclave for 15 hr. The reaction mixture was made strongly basic with concentrated sodium hydroxide, and, the ethanol was removed *in vacuo*. The residue was steam distilled. The distillate was extracted with ether and dried over sodium sulfate. Subsequent concentration and

distillation gave the pyridinophane V (1.26 g, 44%), bp 70—73°C/3 mmHg. IR (neat): 3060 2920, 2840, 1588, 1575, 1458, 1317, 1156, 788, 772, 745, and 723 cm^{-1}. The NMR and UV spectra are found in Fig. 1a and in Table 1 respectively. MS *m/e* (relative abundance): 175 (28), 147 (100), 146 (25), 123 (metastable peak for *m/e* 175→147), 121 (21), and 106 (22).

Found: C, 82.5; H, 9.9; N, 7.7%. Calcd for $C_{12}H_{17}N$: C, 82.2; H, 9.8; N, 8.0%.

[7](2,6)Pyrylophanium Perchlorate (VI). A mixture of IV (1.03 g, 5.3 mmol), trityl perchlorate (1.91 g, 5.6 mmol), and acetic acid (13 m*l*) was heated at 110—120°C for 10 min. After cooling, the reaction mixture was treated with dry ether (50 m*l*); the crystals thus precipitated (VI) (0.94 g, 65%) were collected by filtration. Mp 150°C (dec.). IR (Nujol): 3060, 1627, 1550, 1498, 1088 (broad), 868, and 798 cm^{-1}. The NMR of VI is shown in Fig. 3.

Found: C, 52.6; H, 6.0; Cl, 12.6%. Calcd for $C_{12}H_{17}ClO_5$: C, 52.1; H, 6.2; Cl, 12.8%.

[7](2,6)Pyridinophane (V) from VI. The pyrylium salt (VI) (0.31 g, 1.1 mmol) was added to a solution of ammonium acetate (0.56 g, 7.2 mmol) in acetic acid (10 m*l*). The mixture was then heated at 110°C for 5 min. After cooling, the reaction mixture was diluted with water (30 m*l*), neutralized with sodium carbonate, and extracted with ether. Drying (sodium sulfate) and concentration, followed by column chromatography on silica gel (benzene as an eluent), gave V (0.13 g, 66%); this was identical with the sample described above.

*Cyclododecane-1,5-dione-9*d (IV_D). A solution of I (7.76 g, 44 mmol) and acetic acid-*d* (2.71 g, 44 mmol) in benzene (50 m*l*) was heated at reflux for 2.5 hr and then cooled. To the mixture we then added, successively, methanolic potash (10 g potassium hydroxide in 100 m*l* methanol) and 30% aq. hydrogen peroxide (15 m*l*). After the evaporation of the solvent, the diol, III_D (6.05 g), was collected by filtration. The filtrate was extracted with ether and dried over sodium sulfate. Concentration afforded an additional crop of crystals (3.06 g). The total yield was 9.11 g (quantitative).

The oxidation of III_D (5.26 g, 26 mmol) gave cyclododecane-1,5-dione-9*d* (IV_D) (3.72 g, 72%); mp 58.5—59.0°C (*n*-hexane). IR (Nujol): 2150, 1715, 1216, 1186, 1134, 1120, 1046, 1008, 982, 891, 876, 853, 793, 780, 757, and 702 cm^{-1}. The D content as determined by MS: d_0, 8.3%; d_1, 90.6%; d_2, 1.1%.

*[7](2,6)Pyridinophane-4*d (V_D). A mixture of IV_D (1.45 g, 7.4 mmol), hydroxylamine hydrochloride (1.28 g, 18 mmol), and absolute ethanol (30 m*l*) was heated at 160—170°C in an autoclave. Work-up gave V_D as a colorless oil (0.54 g, 42%), bp 103°C (bath temperature)/7 mmHg. IR (neat): 3060, 2140, 1588, 1576, 1457, 1152, 996, 847, 780, 772, and 745 cm^{-1}. The D content as determined by NMR: 0.87 d_1/molecule. The NMR of V_D is found in Fig. Ib.

Attempted Synthesis of the N-*Oxide of V.* A mixture of V (0.15 g, 0.86 mmol), 30% aq. hydrogen peroxide (0.13 g) and acetic acid (2.0 m*l*) was heated at 80°C during 3 days. An additional 0.2 m*l* of peroxide was added in two portions during this time. The usual work-up resulted in the recovery of the starting pyridinophane.

Methyl [7](2,6)Pyridinophane-1-carboxylate (VIII). To THF (10 m*l*) there was added, at room temperature, a solution (5.0 m*l*) of *n*-butyllithium (0.74 N, 3.7 mmol) in *n*-hexane, and subsequently a solution of V (0.52 g, 3.0 mmol) in THF (10 m*l*). After sitrring under a nitrogen atmosphere for 35 min, the orange-red solution was poured onto dry ice and the solvent was evaporated to give lithium [7](2,6)-pyridinophane-1-carboxylate (0.97 g). A solution of the lithium salt in methanol (35 m*l*) was then saturated with dry hydrogen chloride and allowed to stand at room temperature for 2 days. The evaporation residue was dissolved in chloroform (15 m*l*), neutralized with aq. sodium carbonate, and dried over sodium sulfate. Concentration and dry column chromatography on silica gel (benzene as an eluent) afforded VIII as a colorless liquid (0.36 g, 52%), bp 84°C (bath temperature)/0.03 mmHg. IR (neat): 3060, 2930, 2850, 1738, 1588, 1576, 1457, 1233, 1190, 1150, 1066, 1017, 784, 778, 750, 726, and 710 cm^{-1}. MS *m/e* (relative abundance): 233 (34), 218 (100), 205 (57), 174 (53), 173 (23), 172 (35), 147 (25), 146 (46), 145 (31), 144 (43), 133 (77), 132 (33), and 119 (34). The NMR spectrum of VIII is shown in Fig. 7.

Found: C, 72.2; H, 8.1; N, 6.1%. Calcd for $C_{14}H_{19}NO_2$: C, 72.1; H, 8.2; N, 6.0%.

[7](2,6)Pyridinophan-1-ol (IX). To THF (10 m*l*) we added, successively, a solution (8.0 m*l*) of *n*-butyllithium (0.74 N) in *n*-hexane and a solution of V (0.54 g, 3.1 mmol) in THF (10 m*l*). After stirring under a nitrogen atmosphere for 35 min, the orange-red solution was cooled to −75°C and oxygen was passed through the solution for 1.5 hr. The reaction mixture was then treated with aq. ammonium chloride (5 m*l*), extracted with ether, and dried over potassium carbonate. Concentration and dry-column chromatography on silica gel (benzene and ether as eluents) afforded IX as white crystals (0.38 g, 65%); bp 95°C (bath temperature)/0.1 mmHg; mp 53.5—54.0°C (*n*-hexane). IR (KBr disk): 3250, 3060 (shoulder), 1596, 1576, 1467, 1293, 1264, 1087, 1072, 1050, 1000, 880, 853, 797, 786, 750, 723, and 700 cm^{-1}. MS *m/e* (relative abundance): 191 (100), 174 (22), 172 (23), 163 (51), 144 (36), 134 (76), 121 (41), 93 (27), 77 (26), and 65 (26). The NMR spectrum is found in Fig. 6, and the UV data, in Table 1.

Found: C, 75.4; H, 8.9; N, 7.3%. Calcd for $C_{12}H_{17}NO$: C, 75.4; H, 9.0; N, 7.3%.

[7](2,6)Pyridinophan-1-one (X). To cooled pyridine (10 m*l*) we added a solution of chromium(VI) oxide (1.00 g) in water (1 m*l*) and a solution of IX (0.31 g, 1.6 mmol) in pyridine (10 m*l*). The mixture was then allowed to stand overnight at room temperature, poured into water (200 m*l*), and extracted with ether. The combined extracts were thoroughly washed with water and dried over sodium sulfate. Subsequent concentration and dry-column chromatography on silica gel (benzene as an eluent) yielded the ketone X (0.17 g, 55%); mp 33.5—34.5°C (*n*-hexane). IR (KBr disk): 3060, 1693, 1585, 1455, 1446, 1345, 1310, 1263, 1247, 1216, 1141, 1061, 1029, 1017, 1001, 929, 851, 799, 760, 752, 730 cm^{-1}. MS *m/e* (relative abundance): 189 (47), 161 (13), 133 (100), 132 (26), 91 (19), and 89 (19). The NMR is shown in Fig. 2, and the UV data, in Table 1.

Found: C, 76.1; H, 7.9; N, 7.2%. Calcd for $C_{12}H_{15}NO$: C, 76.2; H, 8.0; N, 7.4%.

1,1-Dimethoxy[7](2,6)pyridinophane (XI). A mixture of X (0.15 g, 0.80 mmol), *p*-toluenesulfonic acid (0.24 g), methyl orthoformate (1.29 g), and methanol (30 m*l*) was heated under reflux for 2 hr and then neutralized after cooling with methanolic sodium hydroxide (1 g of sodium hydroxide in 5 m*l* of methanol). After the evaporation of the solvent, the residue was diluted with water (30 m*l*), extracted with ether, and dried over sodium carbonate. Subsequent concentration and distillation gave XI as a colorless liquid (0.16 g, 86%); 85°C (bath temperature)/0.06 mmHg. IR (neat): 3060, 1590, 1579, 1127, 1099, 1083, 1050, 810, 790, 757, 750, 728 cm^{-1}. MS *m/e* (relative abundance): 235 (1), 220 (38), 204 (15), 203 (19), 188 (100), 160 (32). The

NMR spectrum is shown in Fig. 5.

Found: C, 71.3; H, 9.0; N, 5.9%. Calcd. for $C_{14}H_{21}NO_2$: C, 71.5; H, 9.0; N, 6.0%.

The authors are grateful to Professor K. Sisido for his generous help. Financial support from the Ministry of Education, Japanese Government, and from the Toray Science Foundation is also acknowledged with pleasure.

Stereochemical Studies of Monoterpene Compounds. XII.[1] The Acid-Catalyzed Rearrangements of 2α-Bromo-10β-pinan-3-one

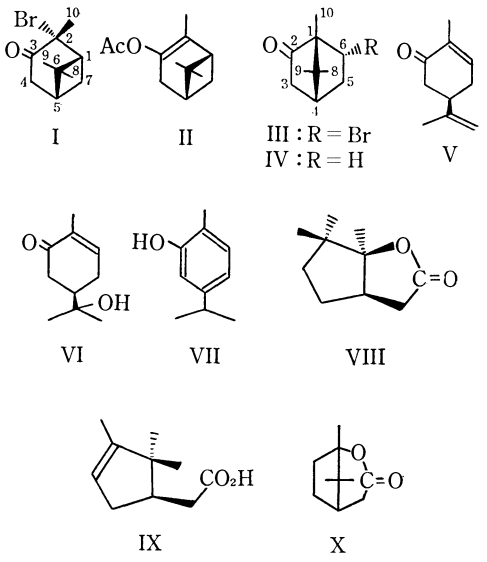
Toshifumi HIRATA and Takayuki SUGA[2]

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received March 13, 1971)

In connection with the bromination of 3-acetoxy-pin-2-ene (II), the acid-catalyzed rearrangement of 2α-bromo-10β-pinan-3-one (I) was investigated under several conditions. The bromoketone (I) was thus found to yield (+)-6-*endo*-bromocamphor (III), (−)-α-carvone (V), (−)-8-hydroxycarvotanacetone (VI), carvacrol (VII), (+)-dihydro-β-campholenolactone (VIII), and (+)-campholenic acid (IX). It also became clear that the bromocamphor (III) and the (V), (VI), and (VII) products are directly formed from the bromoketone (I), whereas the γ-lactone (VIII) is obtained *via* α-campholenic acid (IX) from the bromocamphor (III). The mechanistic implications of the rearrangements are discussed.

Because 2α-bormo-10β-pinan-3-one (I) was necessary in the course of our study of the stereochemistry of the oxygenated pinane system, the bromination of 3-acetoxy-pin-2-ene (II) was carried out by following the method in the literature,[3] but the literature has reported the formation of only the bromoketone (I). In contrast with the results reported in the literature, however, we found the method to result in the formation of not only the bromoketone (I), but also an isomeric bromoketone, 6-*endo*-bromocamphor (III). We now wish to report on the results of the bromination of II and, further, to deal with the acid-catalyzed rearrangement of the bromoketone (I) and the mechanistic implications of the reaction.



Results and Discussion

Under exactly the same conditions as in the literature,[3] the treatment of a carbon tetrachloride solution of (−)-3-acetoxy-pin-2-ene (II) with bromine in the presence of anhydrous sodium carbonate gave an oily reaction mixture, which was composed of (−)-2α-bromo-10β-pinan-3-one (I) (84% yield) and (+)-6-*endo*-bromocamphor (III) (5.0%), accompanied by unchanged enol-acetate (II) (4.0%). The bromocamphor (III) was confirmed by comparing its spectral data with those reported for 6-*endo*-bromocamphor[4] and by converting it into (+)-camphor (IV) on debromination.

In order to clarify the mechanism of the formation of the bromocamphor (III), the bromoketone (I) was subjected to acid treatments under various conditions. In the literature,[3] the treatment of the bromoketone (I) with 10% acetic acid under reflux for 3 hr has been reported to give only an intractable oil. The re-examination of this reaction clarified that the product consisted of (−)-carvone (V), (−)-8-hydroxycarvotanacetone (VI), carvacrol (VII), and (+)-dihydro-β-campholenolactone (VIII), accompanied by a trace of the bromocamphor (III). On the other hand, the bromoketone (I) was converted into the bromocamphor (III) in a 55% yield on treatment with 10% acetic acid at 50°C for 5 hr. The reaction of the bromoketone (I) with dilute hydrobromic acid at 50°C for 5 hr yielded also the bromocamphor (III) in a

2) To whom all inquiries regarding to this paper should be addressed.

3) M. P. Hartshorn and A. F. A. Wallis, *Tetrahedron*, **21**, 273 (1965).

4) M. P. Hartshorn and A. F. A. Wallis, *J. Chem. Soc.*, **1964**, 5254.

34% yield, along with the same kinds of products as above. These results show the ready conversion of the bromoketone (I) into the bromocamphor (III) by the acid-catalyzed reaction. Thus, the formation of the bromocamphor (III) in the bromination of the enol-acetate (II) is clearly due to the acid (probably hydrobromic acid)-catalyzed rearrangement of the bromoketone (I) initially produced.

The heating of the bromocamphor (III) with 10% acetic acid afforded only dihydro-β-campholenolactone (VIII). This shows the bromocamphor (III) to be connected only with the formation of the γ-lactone (VIII), not with that of such products as (V), (VI), and (VII). Moreover, the milder reaction of the bromocamphor (III) with aqueous acetic acid indicated the formation of (+)-α-campholenic acid (IX), along with the γ-lactone (VIII) and 1,2-campholide (X). The acid (IX) is expected as an intermediate in the formation of the lactone (VIII). The formation of the acid (IX) was also proved in the reaction of the bromoketone (I) with aqueous hydrobromic acid.

The formation of the products from the bromoketone (I) is best explained by the following three pathways: (a) the alteration of the bicyclo[3.1.1]skeleton to the monocyclic system, (b) the intramolecular rearrangement to the bicyclo[2.2.1]skeleton, and (c) lactonization involving the Wagner-Meerwein rearrangement. The formation of the (V), (VI), and (VII) products can be explained by the (a) pathway and can be explained as initiated by the detachment of the *t*-bromine atom from the bromoketone (I) with the acid, followed by the opening of the bridge to form the carbonium ion, as is shown in Scheme I. The intramolecular rearrangement in the (b) pathway is supported by the ready conversion of the bromoketone (I) into the bromocamphor (III) even under such conditions as in the absence of bromine. The mutual exchange between the *gem*-dimethyl brigde and the bromine atom in the bromoketone (I), followed by intramolecular rearrangement through a transition state (XI), results in the formation of a more stable compound, the bromocamphor (III), as is shown in Scheme II. The transition state (XI) is not so absurd because of the analogy to the transition state in the diaxial-diequatorial rearrangement proposed by Grob[5] and Barton.[6] Finally, the formation of dihydro-β-campholenolactone (VIII) from the bromocamphor (III) can be explained by the same mechanism as the rearrangement of 2-hydroxypinocamphone with anhydrous oxalic acid, which was reported recently by us.[7] The migration of the bromine atom and the (a) bond affords the acid (IX) as an intermediate product. It suffers protonation on an ethylenic bond, the 1,2-shift of a methyl group of the *gem*-dimethyl group, and then the lactonization of the carboxyl group, thus yielding the γ-lactone (VIII) (Scheme III).

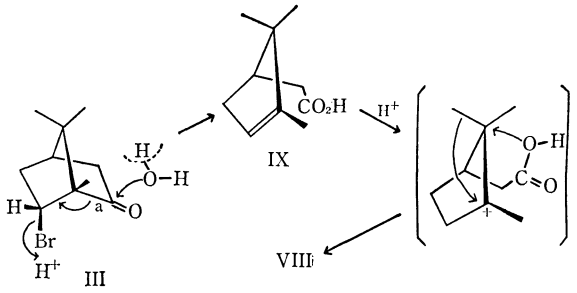

Scheme III

Experimental

The IR spectra were recorded with a Hitachi EPI-S Infrared Spectrophotometer. The NMR spectra were measured with a Hitachi Perkin-Elmer R-20 high-resolution spectrometer, using tetramethylsilane as the internal standard. The mass-spectral analyses were performed by a Hitachi mass-spectrometer, Model RMS-4, ionizing at the order of 80 eV. Vapour-phase chromatographic analyses were made using a Hitachi Perkin-Elmer F6-D gas chromatograph with attached a column packed with 20% PEG-6000 on Celite.

3-Acetoxy-pin-2-ene (II). Following the method in the literature,[3] the treatment of isopinocamphone ($[\alpha]_D^{25}$ −11.1°) with acetic anhydride in the presence of perchloric acid, followed by purification on a silica gel column, afforded II in a 76% yield: $[\alpha]_D^{25}$ −35.0° (*c* 0.29, MeOH), lit[3] $[\alpha]_D^{25}$ +36° (*c* 1.00), derived from (+)-isopinocamphone; $\nu_{max}^{liq.}$ 1760 cm^{-1} (enol-acetate); NMR (CCl_4) δ 0.98 (s, C_9-3H), 1.30 (s, C_8-3H), 1.55 (t, J=1.5 Hz, C_{10}−3H), and 2.09 ppm (s,OAc).

Bromination of 3-Acetoxy-pin-2-ene (II). To a stirred suspension of 1.08 g of II and 1.00 g of anhydrous sodium carbonate in 5 m*l* of carbon tetrachloride, we added 0.94 g of bromine in 4 m*l* of carbon tetrachloride over a 5-min period at 0°C. After stirring for an additional 5 min, the reaction mixture was isolated by ether to give 1.13 g of an

5) C. A. Grob and S. Winstein, *Helv. Chim. Acta*, **35**, 782 (1952).

7) T. Suga, T. Hirata, M. Noda, and T. Matsuura, *Experientia*, **26**, 1192 (1970).

oily product, which was then subjected to column chromatography on silica gel with a mixture of ethyl acetate and *n*-hexane to obtain 0.94 g of I, 0.06 g of III, and 0.05 g of unchanged II. The (I) and (III) products were identified on the basis of the following physical properties and the chemical reaction.

The Bromoketone (I): $[\alpha]_D^{25}$ −101.8° (*c* 1.18, MeOH); $\nu_{max}^{liq.}$ 1722 (C=O), lit[3] 1726 cm^{-1}, and 1376 and 1393 cm^{-1} (*gem*-dimethyl); λ_{max}^{MeOH} 313 nm (ε 135.3), lit[3] 312.5 nm (ε 130). The C-9, C-8, and C-10 methyl proton signals appeared at δ 0.91, 1.41, and 1.93 ppm in a 10% carbon tetrachloride solution, at δ 0.49, 0.93, and 1.88 ppm in a 10% benzene solution, and at δ 0.73, 1.19, and 1.93 ppm in a 10% pyridine solution, respectively, as singlets.

The Bromocamphor (III): mp 132—133°C, lit[4] mp 133—134°C; $[\alpha]_D^{25}$ + 36.6° (*c* 0.63, MeOH), lit[4] $[\alpha]_D^{25}$ + 44° (*c* 1.04); $\nu_{max}^{CCl_4}$ 1751 (C=O), lit[4] 1757 cm^{-1}, and 1381 and 1396 cm^{-1} (*gem*-dimethyl); λ_{max}^{MeOH} 291 nm (ε 40.8); NMR (CCl_4) δ 0.90 (s, C_8- and C_{10}-3H), 0.98 (s, C_9-3H), and 4.11 ppm (d.d, *J*=9.5 and 3.5 Hz, C_6-H); mass spectrum *m/e* (rel. intensity) 232 and 230 (M^+; 4) 217 and 215 (2), 190 and 188 (1), 175 and 173 (13), 151 (66), 135 and 133 (4), 109 (100), 94 (13).

The Debromination of 50 mg of III was carried out in 0.4 m*l* of 70% acetic acid with the addition of 50 mg of zinc powder under reflux over a 1-hr period. Ether extraction of the filtrate freed from the zinc powder afforded 31 mg of (+)-camphor (IV): $[\alpha]_D^{25}$ +30.1° (*c* 0.19, MeOH); $\nu_{C=O}^{KBr}$ 1743 cm^{-1}.

Rearrangement of 2α-Bromo-10β-pinan-3-one (I). *A) With Hydrobromic Acid*: A stirred suspension of 800 mg of the bromoketone (I) in 40 m*l* of 10% hydrobromic acid was heated at 50°C for 5 hr. The reaction product was treated with a 5% sodium carbonate solution, and then it was extracted with ether. The neutral reaction mixture obtained from the ether layer was subjected to column chromatography on silica gel with a mixture of ethyl acetate and *n*-hexane; we thus obtained 153 mg of (+)-6-*endo*-bromocamphor (III), 14 mg of (−)-carvone (V), 158 mg (−)-8-hydroxycarvotanacetone (VI), 24 mg of carvacrol (VII), and 90 mg of (+)-dihydro-β-campholenolactone (VIII). The aqueous layer, after it had been acidified with dilute hydrochloric acid, was extracted with ether to yield 25 mg (+)-α-campholenic acid (IX). Each component was confirmed by comparing its spectra and physical properties with those of an authentic sample[8] and/or by preparing their crystalline derivatives, as is shown below.

(+)-Bromocamphor (III): mp 132—133°C; $[\alpha]_D^{25}$ +37.0° (*c* 0.63, MeOH); ν_{max}^{KBr} 1752 cm^{-1} (C=O).

(−)-Carvone (V): $[\alpha]_D^{25}$ −45.0° (*c* 0.15, MeOH); $\nu_{max}^{liq.}$ 1677 (α,β-unsaturated C=O) and 3063 cm^{-1} (*endo*- methylene); λ_{max}^{MeOH} 236 nm (ε 6900); the 2,4-dinitrophenylhydrazone, mp 187—188°C.

(−)-8-Hydroxycarvotanacetone (VI): $[\alpha]_D^{25}$ −40.5° (*c* 0.15, MeOH); $\nu_{max}^{liq.}$ 1660 (α,β-unsaturated C=O) and 3400 cm^{-1} (OH); λ_{max}^{MeOH} 235 nm (ε 9100); NMR (CCl_4) δ 1.18 (s, C_9- and C_{10}-3H), 1.72 (b.s, C_7-3H), and 6.66 ppm (b.s, C_6-H); the semicarbazone, mp 178—179°C.

Carvacrol (VII): $\nu_{max}^{liq.}$ 1619 and 1584 (aromatic C=C), 1370 and 1385 (isopropyl), and 3400 cm^{-1} (OH); λ_{max}^{MeOH} 277 nm (ε 2150).

(+)-Dihydro-β-campholenolactone (VIII): mp 30°C; $[\alpha]_D^{25}$ +22.8° (*c* 0.15, EtOH); ν_{max}^{KBr} 1775 cm^{-1} (C=O); NMR (CCl_4) δ 0.90, 1.08, and 1.26 ppm (s, 3H, respectively).

(+)-α-Campholenic Acid (IX): $[\alpha]_D^{25}$ +5.3° (*c* 0.10, MeOH); $\nu_{max}^{liq.}$ 1710 (COOH), 1370 and 1392 cm^{-1} (*gem*-dimethyl); NMR (CCl_4) δ 0.78 (s, 3H), 0.99 (s, 3H), 1.58 (b.s, 3H), and 5.17 ppm (b.s, 1H).

B) Under Other Conditions: The reactions were carried out under various conditions, as is shown below. The bracketed figures in the heading show the experimental number in Table 1. (1) A solution of the bromoketone (I) (100 mg) in carbon tetrachloride (5 m*l*) was maintained at 50°C for 5 hr. (2) The bromoketone (300 mg) was stirred into a suspension of bromine (300 mg) and anhydrous sodium carbonate (300 mg) in carbon tetrachloride (15 m*l*) at 50°C over a 5-hr period. (3) The bromoketone (100 mg) was heated in 10% acetic acid-carbon tetrachloride (5 m*l*) at 50°C for 5 hr. (4) A suspension of the bromoketone (100 mg) in 10% aqueous acetic acid (5 m*l*) was stirred at 50°C for 5 hr. (5) The bromoketone (100 mg) was refluxed in 10% aqueous acetic acid (5 m*l*) for 3 hr. (6) A suspension of the bromoketone (100 mg) in 5% hydrobromic acid (5 m*l*) was stirred at 50°C for 5 hr. (7) The bromoketone (100 mg) was maintained in a mixture of 5% hydrobromic acid (5 m*l*) and methanol (10 m*l*) at 50°C for 5 hr. (8) The bromoketone (100 mg) was heated in the stirred suspension of 10% hydrobromic acid (2.5 m*l*) and 10% aqueous acetic acid (2.5 m*l*) at 50°C for 5 hr.

After the reaction, the whole reaction mixture were extracted with ether. The ether solution was washed with a sodium bicarbonate solution, and then water, after which it was dried over anhydrous sodium sulfate. The removal of the solvent from the solution gave a reaction mixture, which was subjected to preparative thin-layer chromatography on silica gel with a mixture of ethyl acetate and *n*-hexane (3:7 by volume) in order to separate the components. Each component was confirmed by comparing its spectra and physical properties with those of an authentic sample. The results of these reactions are summarized in Table 1.

Table 1. Rearrangements of bromoketone (I) under various conditions

Expt. No.	Yield of products (%)					
	III	V	VI	VII	VIII	I (unchanged)
1	trace[a]	—	—	—	—	95
2	2.3	—	—	—	—	94
3	7.6	—	—	—	—	87
4	55	12	21	trace[a]	trace[a]	—
5	trace[a]	3.0	17	41	13	—
6	30	8.0	11	trace[a]	trace[a]	13
7	22	9.5	6.1	trace[a]	5.6	22
8	30	5.1	32	1.0	3.2	—

a) These were only detected by gas chromatographic and thin-layer chromatographic analyses.

Rearrangements of (+)-6-endo-Bromocamphor (III). *A) Under Reflux for 3 hr*: The bromocamphor (III) (50 mg), dissolved in 10% acetic acid (2.5 m*l*) was stirred under reflux for 3 hr. The reaction mixture was extracted by ether to obtain a reaction product (36 mg). Gas-chromatographic analysis showed the product to consist of 93% of the γ-lactone (VIII) and 1.6% of the unchanged bromocamphor (III). The product was subjected to preparative thin-layer chromatography with silica gel with 30% ethyl acetate - *n*-hexane in order to isolate the lactone (VIII) (32 mg): mp 30—31°C; $[\alpha]_D^{25}$ +29.8° (*c* 0.24, EtOH); ν_{max}^{KBr} 1775 cm^{-1} (γ-lactone).

B) Under Milder Conditions: A suspension of III in

8) T. Hirata, T. Suga, and T. Matsuura, This Bulletin, **43**, 2588 (1970).

10% acetic acid was stirred at 105°C for 2 hr in the same manner as above. The ether solution of the reaction mixture was then treated with a 5% sodium carbonate solution in order to isolate (+)-α-campholenic acid (IX) (16%): $[\alpha]_D^{25}$ 5.0° (*c* 0.15, MeOH); $\nu_{max}^{liq.}$ 1710 cm^{-1} (COOH). The neutral reaction mixture freed from the acid was composed of (+)-γ-lactone (VIII) (55%), 1,2-campholide (X) (1.5%), and the unchanged bromocamphor (III) (4.5%). The δ-lactone (X) was only detected by gas-chromatographic and thin-layer chromatographic analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2836—2839(1971)

Studies of *N*-Sulfinyl Compounds. VI.[1] The Preparation of *N*-Sulfinylbenzamide and Its Reaction with Styrene Oxide

Otohiko TSUGE and Shuntaro MATAKA

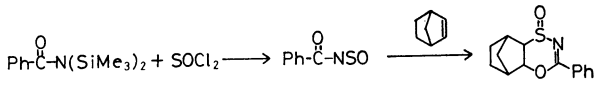
Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received March 18, 1971)

The reaction of benzamide with thionyl chloride in the presence of pyridine gave *N*-sulfinylbenzamide and *N,N'*-dibenzoylsulfurdiimide. It has been found that *N*-sulfinylbenzamide reacted with styrene oxide in the presence of tetraethylammonium bromide to give 4-oxo-5-benzoyl-2,6-diphenyl-1,4,3,5-oxathiadiazepine as the main product, accompanied by lesser quantities of two *N*-benzoyl-phenylaminoethanols, 2,5-diphenyloxazoline, benzonitrile, and benzamide. The pathways for the formation of the products are suggested.

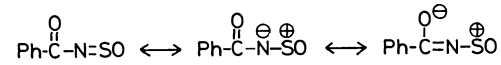
In previous papers in which the reactions of *N*-sulfinylanilines (Ar-NSO)[2] and of *N*-sulfinyl-*p*-toluenesulfonamide (Tos-NSO)[3] with styrene oxide in the presence of tetraethylammonium bromide (Et_4NBr) were investigated, the corresponding two tetraarylpiperazines were formed in the reactions of *N*-sulfinylanilines, while the reaction of *N*-sulfinyl-*p*-toluenesulfonamide gave the 1-oxo-1,2,5-thiadiazolidine compound, accompanied by two aminoalcohols.

Recently, it has been reported by Scherer and Schmitt[4] that *N*-sulfinylbenzamide (I) which had been prepared from the reaction of *N,N*-bis-trimethylsilylbenzamide with thionyl chloride, reacted with norbornene to give the (2+4) cycloadduct, 4-oxo-2-phenyl-4a,5,6,7,8,8a-hexahydro-5,8-methano-1,4,3-benzoxathiazine.



I

On the basis of the above fact, it may be inferred that I is not only more reactive than *N*-sulfinylanilines, but also behaves as the 1,4-dipole in the following resonance structures.



Accordingly, the reaction of I with styrene oxide can be expected to give products of a different type from those in the reactions of *N*-sulfinylanilines and of *N*-sulfinyl-*p*-toluenesulfonamide.

In the present paper we wish to report on the preparation of I by the reaction of benzamide with thionyl chloride, and on the formation of the 1,4,3,5-oxathiadiazepine compound as the main product in the reaction of I with styrene oxide.

Results and Discussion

The Reaction of Benzamide with Thionyl Chloride. It has been found by Olah[5] that benzamide reacted with thionyl chloride to give *N*-sulfinylbenzamide (I), but he failed to isolate I in a pure form.

After the reaction of benzamide with thionyl chloride was conducted in a mixed solvent of benzene and pyridine at temperatures below 10°C, the reaction mixture was rapidly filtered to remove the pyridine hydrochloride; then the filtrate was distilled under reduced pressure to give I, bp 76°C/0.16 mmHg (lit,[4] bp 70°C/0.1 mmHg), as an yellow oil in a 62% yield and dark brown crystals (II), together with a small amount of benzonitrile. It is very important that distillation is carried out at temperatures below 100°C, because an appreciable decomposition of I takes place above 100°C.

As I proved rather unstable and was decomposed by moisture in the air, the elemental analysis of I was not carried out. However, the IR spectrum of I was in agreement with that reported by Scherer and Schmitt.[4] Furthermore, I was easily hydrolyzed to give benzamide, and was violently decomposed at 130°C to yield benzonitrile.

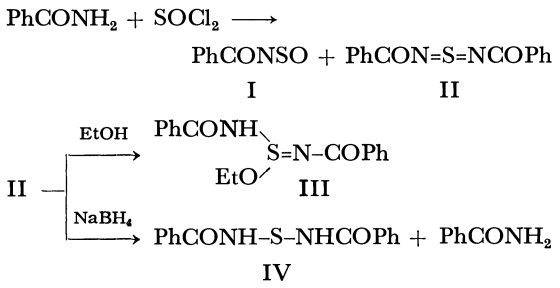
5) The authors wish to express their appreciation to Professor G.A. Olah of Case-Western Reserve University for his personal communication.

On the other hand, the compound II which was obtained as a residue on distillation, was also unstable and was easily hydrolyzed to give benzamide. Although II could not be isolated in a pure form, its



structure was assumed to be *N,N'*-dibenzoylsulfurdiimide (II) on the basis of the following chemical transformations.

The treatment of II with excess amounts of ethanol gave *S*-benzamido-*S*-ethoxy-*N*-benzoylsulfilimine (III), mp 135—140°C (decomp.), which was then gradually decomposed on standing at room temperature to give benzamide in a low yield. The structure of III was confirmed by a study of its IR spectrum as well as by the elemental analysis. Furthermore, II was reduced with sodium borohydride, affording *N,N'*-thiodibenzamide (IV) and benzamide under the elimination of hydrogen sulfide.

It is known[6] that *N*-sulfinyl compounds react with a base to give the corresponding sulfurdiimides under the elimination of sulfur dioxide. Although Scherer and Schmitt[4] reported that attempts to prepare II by the reaction of I with a trace amount of a base were unsuccessful, it may be considered that II was obtained *via* the reaction with pyridine of I formed from benzamide and thionyl chloride.

The Reaction of N-*Sulfinylbenzamide with Styrene Oxide.* When a solution of *N*-sulfinylbenzamide (I) and styrene oxide (V) in benzene was refluxed with Et_4NBr for 1 hr, a colorless crystalline compound VII, mp 171—172°C (decomp.), was obtained as the main product, accompanied by lesser quantities of crystals, VI, mp 126—7°C, a pale green liquid, VIII, benzonitrile and benzamide.

Although VI was proved, by the elemental analysis as well as by a comparison of its IR and NMR spectra with those of authentic samples of *N*-benzoyl-*β*-phenyl-*β*-aminoethanol (VIa), mp 151°C (lit,[7] mp 154—154.5°C), and *N*-benzoyl-α-phenyl-*β*-aminoethanol (VIb), mp 147—148°C (lit,[8] mp 148.6—149.1°C), to be a mixture of nearly equal amounts of VIa and VIb, attempts to isolate VIa and VIb in pure forms were unsuccessful.

The results of the elemental analysis and the molecular weight (M^+ *m/e* 390) of VII were consistent with those of the compound derived from a 2:1 adduct of I and V under the elimination of sulfur dioxide. The IR spectrum of VII showed characteristic bands ascribed to the C=O and/or C=N bonds at 1660 and 1630 cm^{-1}, while the NMR spectrum in deuteriochloroform ($CDCl_3$) exhibited double doublets at δ 4.75 (H_A, 1H), 5.64 (H_B, 1H) and 6.25 ppm (H_X, 1H), with coupling constants of $J_{AB}=8$, $J_{BX}=2$, and $J_{AX}=7$ Hz, besides a signal of aromatic protons (15H).

On the basis of the above observations and inspections of reaction courses, the following compounds (VII-1—VII-7) can be said to be possible for the structure of VII (Chart 1); the compounds VII-1—VII-3 correspond to the apparent cycloadducts of I to 1-benzoyl-2-phenylaziridine,[9] while compounds VII-4—VII-7 correspond to the cycloadducts of I to the sulfurdiimide II.

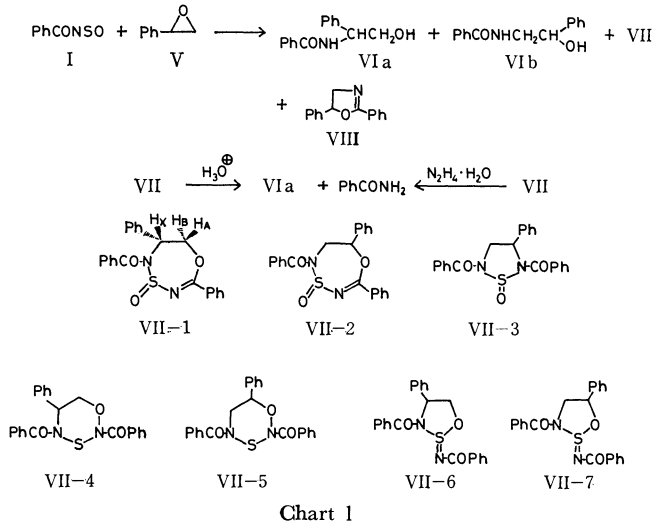


Chart 1

The hydrolysis of VII with hydrochloric acid in methanol gave the aminoethanol VIa and benzamide in 38 and 97% yields respectively. Also, VII reacted with hydrazine hydrate under the elimination of hydrogen sulfide, affording VIa and benzamide in good yields. The production of VIa from VII eliminated the possibility of VII-2, VII-5 and VII-7 for the structure of VII.

On the other hand, the mass spectrum of VII showed peaks at *m/e* 390 (M^+), 389 (M^+–H), 342 (M^+–SO), 238 (342^+–$PhCH=CH_2$), 223 (M^+–PhCONSO and/or 342^+–PhCON, base peak), 193 (223^+–CH_2O), and 105 ($PhCO^+$). The appearance of the peak at *m/e* 342 in the spectrum excluded the compounds VII-4 and VII-6 as the possible structure of VII.

Previously,[3] we reported that 1-oxo-2,5-di(*p*-toluenesulfonyl)-3-phenyl-1,2,5-thiadiazolidine, which had been obtained from the reaction of *N*-sulfinyl-*p*-toluenesulfonamide with V, was hydrolyzed with hydrochloric acid in methanol, thus affording *N,N'*-di(*p*-toluenesulfonyl)-1-phenylethylene-1,2-diamine in a good yield.

If VII is the 1,2,5-thiadiazolidine VII-3, the corresponding ethylenediamine compound should be given

8) A. J. Castro, D. K. Brain, H. D. Fischer, and R. K. Fuller, *J. Org. Chem.*, **19**, 1444 (1954).

9) 1-Benzoyl-2-phenylaziridine corresponds to the compound derived from the 1:1 adduct of I and V under the elimination of sulfur dioxide.

by the hydrolysis of VII.

Consequently, it may be deduced that the most reasonable structure for VII is 4-oxo-5-benzoyl-2,6-diphenyl-1,4,3,5-oxathiadiazepine (VII-1).

On the other hand, VIII was proved to be 2,5-diphenyloxazoline by the spectral studies as well as by the identification of its picrate with the authentic sample prepared by the method of Wolfheim.[10]

The formation of 4-oxo-1,4,3,5-oxathiadiazepine VII is of interest in connection with the contribution of the 1,4-dipole of I.

Several pathways for the formation of VII and oxazoline VIII are possible.[11] On the basis of the previously reported results,[3,4,12-14] and of the formation of aminoalcohols VIa and VIb, however, we considered that compounds VII and VIII were derived from the 2-oxo-1,2,3-oxathiazolidine intermediates A and B which were formed by the (2+3)cycloaddition of I to 1,3-dipoles arising from the cleavage of the bond *a* or *b* in V, as shown in Chart 2.

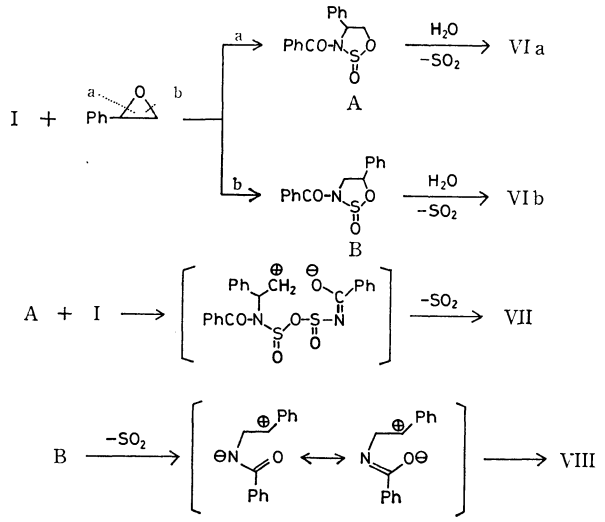

Chart 2

As has previously been reported,[3] reactive *N*-sulfinyl-*p*-toluenesulfonamide reacted with V under similar conditions, giving 1-oxo-1,2,5-thiadiazolidine whose structure corresponded to the compound derived from a 2:1 adduct of the *N*-sulfinyl compound and V under the elimination of sulfur dioxide.

Because I as well as *N*-sulfinyl-*p*-toluenesulfonamide is more reactive than *N*-sulfinylanilines, I will be able to further attack 2-oxo-1,2,3-oxathiazolidine intermediates; the attack of I on A will be preferable to that on B having 5-phenyl group.

As is shown in Chart 2, the reaction of I with A leads to the formation of VII under the elimination of sulfur dioxide. On the other hand, the elimination of sulfur dioxide from the intermediate B and subsequent ring closure results in the formation of VIII. The by-products, benzonitrile and benzamide, may be secondarily formed from I and VII.

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were determined at 60 MHz with a Hitachi-20 NMR spectrometer, using TMS as the internal reference, while the mass spectra were obtained on a Hitachi RMS-4 mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

Reaction of Benzamide with Thionyl Chloride. To a stirred solution of 48.2 g of benzamide and 64.0 g of pyridine in 400 m*l* of benzene, a solution of 47.6 g of thionyl chloride in 200 m*l* of benzene was added, drop by drop, at a temperature below 10°C over a period of 12 hr. After the reaction mixture was allowed to stand overnight at room temperature, the precipitated pyridine hydrochloride was rapidly removed by filtration. The filtrate was evaporated *in vacuo* to remove the solvents and benzonitrile, and then a residue was distilled under reduced pressure to give 41.3 g (62%) of *N*-sulfinylbenzamide (I), bp 76°C/0.16 mmHg (lit,[4] bp 70°C/0.1 mmHg), as an yellow oil, and to leave 10 g of crude *N,N'*-dibenzoylsulfurdiimide (II) as dark brown crystals.

The IR spectrum (neat) of I was in agreement with that reported by Scherer and Schmitt.[4] The main absorption bands are as follows: 3060, 1700, 1675, 1600, 1585, 1490, 1450, 1380, 1320, 1240, 1180, 1140, 1100, 1075, 1030, 1005, 950, 850, 810, 740, 710, 685, 655, 620, and 520 cm^{-1}.

The treatment of crude II, whose IR spectrum was similar to that of I, with an excess of ethanol gave colorless crystals. The crystals were rapidly collected by filtration and washed with ethanol to give *S*-benzamido-*S*-ethoxy-*N*-benzoylsulfilimine (III), mp 135—140°C (decomp.), which gradually decomposed on standing in air to give benzamide.

Found: C, 60.79; H, 4.76; N, 8.87%. Calcd for $C_{16}H_{16}O_3N_2S$: C, 60.75; H, 5.10; N, 8.86%. IR (KBr): 3040 (ν_{NH}), 1683 cm^{-1} (ν_{CO}).

Reduction of N,N'-Dibenzoylsulfurdiimide (II) with Sodium Borohydride. A suspension of 1.74 g of crude II in 20 m*l* of diethyl ether was stirred with 0.25 g of sodium borohydride at room temperature for 24 hr. The reaction mixture was poured into an ice-water mixture and was then extracted with chloroform. The chloroform-extract was washed with water, dried over sodium sulfate, and then evaporated *in vacuo* to give 0.82 g of crystals. Recrystallization from acetonitrile gave 0.28 g (16%) of *N,N'*-thiodibenzamide (IV), mp 191°C (decomp.) (lit,[15] mp 188°C), as colorless needles.

Found: C, 61.58; H, 4.29; N, 10.21%. Calcd. for $C_{14}H_{12}O_2N_2S$: C, 61.76; H, 4.44; N, 10.29%. IR (KBr): 3220 (ν_{NH}), 1655 cm^{-1} (ν_{CO}).

The mother liquor was concentrated *in vacuo* to leave a residue, which was then recrystallized from carbon tetrachloride to give 0.41 g (26%) of benzamide.

Reaction of N-Sulfinylbenzamide (I) with Styrene Oxide (V). After a solution of 1.01 g (0.006 mol) of I and 0.73 g (0.006 mol) of V in 10 m*l* of benzene had been refluxed with 0.06 g (0.0003 mol) of Et_4NBr for 1 hr, the reaction mixture was concentrated *in vacuo* to leave a residue. The residue was

10) F. Wolfheim, *Ber.*, **47**, 1440 (1914).

11) The sulfurdiimide II did not react with V in the presence of Et_4NBr. On the other hand, it has been found that the reaction of I with 1-*p*-toluenesulfonylaziridine did not give a compound of VII type, but 1-oxo-2-benzoyl-5-*p*-toluenesulfonyl-1,2,5-thiadiazolidine and 1,2,3,6-thiatriazine compounds: the results will be reported in detail elsewhere.

12) O. Tsuge, S. Mataka, M. Tashiro, and F. Mashiba, This Bulletin, **40**, 2709 (1967).

15) K. G. Naik, *J. Chem. Soc.*, **119**, 1168 (1921).

triturated with 5 m*l* of methanol to give colorless crystals, which on recrystallization from methanol, gave 0.47 g (41%) of 4-oxo-5-benzoyl-2,6-diphenyl-1,4,3,5-oxathiadiazepine (VII), mp 171—172°C (decomp.), as colorless prisms.

Found: C, 67.70; H, 4.39; N, 7.11%. Calcd. for $C_{22}H_{18}O_3N_2S$: C, 67.68; H, 4.65; N, 7.18%. IR (KBr): 1660 (ν_{CO}), 1630 cm^{-1} ($\nu_{C=N}$).

The filtrate was concentrated *in vacuo* to give a residue, which was then chromatographed on alumina using benzene and then methanol as eluents. A trace amount of benzonitrile and 0.23 g (17%) of 2,5-diphenyloxazoline (VIII) were obtained from the benzene-eluent. The methanol-eluent was evaporated *in vacuo* to leave a viscous substance, which was then extracted with hot carbon tetrachloride. The colorless solid obtained from the carbon tetrachloride-extract was treated with 10 m*l* of aqueous hydrochloric acid to dissolve the benzamide (0.1 g). The recrystallization of insoluble crystals from carbon tetrachloride gave 0.05 g (3.5%) of colorless crystals, mp 126—127°C, which were found to be a mixture of nearly equal amounts of *N*-benzoyl-*β*-phenyl-*β*-aminoethanol (VIa) and *N*-benzoyl-α-phenyl-*β*-aminoethanol (VIb) by NMR spectroscopy.

A similar reaction of V with two molar quantities of I gave VI, VII and VIII in yields of 12, 32, and 3% respectively, accompanied by trace amounts of benzonitrile and benzamide.

The IR spectrum of VI mp 126—127°, revealed all the distinctive bands of authentic samples of VIa and VIb, the results of elemental analysis agreed with the calculated values of VI.

Found: C, 74.99; H, 6.26; N, 5.36%. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81%.

On the other hand, VIII (M^+ *m/e* 223), a pale green oil whose IR spectrum showed the characteristic band ascribed to $\nu_{C=N}$ at 1650 cm^{-1}, was derived to its picrate, mp 141—142°C. The picrate was identical with the picrate, mp 141—142°C (lit,[10] mp 141—142°C) of 2,5-diphenyloxazoline prepared by the method of Wolfheim.[10]

N-Benzoyl-α-phenyl-β-aminoethanol (VIb). To a suspension of 17 g of a mixture of α-phenyl- and *β*-phenyl-*β*-aminoethanol, bp 119—126°C/6 mmHg (lit.[16] bp 135—144°C/4—6 mmHg), which had been prepared from styrene oxide and ammonia according to the method of Castro *et al.*[8], in 50 m*l* of diethyl ether and 100 m*l* of 10% aqueous sodium hydroxide, 25 m*l* of benzoyl chloride was added, drop by drop, at 0°C. The precipitated solid was collected by filtration, washed with water, and dried. Several recrystallizations from benzene gave 6.3 g of VIb, mp 147—148°C (lit,[8] mp 148.6—149.1°C), as colorless plates.

Found: C, 74.21; H, 6.17; N, 5.73%. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81%. IR(KBr): 3440 (ν_{OH}), 3320 (ν_{NH}), 1623 cm^{-1} (ν_{CO}). NMR (DMSO-d_6): δ 3.35—3.6 (multiplet, 2H, $-CH_2-$), 4.7—5.0 (multiplet, 1H, >CH), 5.55 (doublet, 1H,–OH, exchanged with D_2O), 7.2—8.0 (multiplet, 10H, aromatic protons), 8.55 ppm (triplet, 1H, –NH–, exchanged with D_2O).

Reaction of VII with Hydrazine Hydrate. When 2 m*l* of hydrazine hydrate was added to a solution of 0.5 g of VII in 20 m*l* of ethanol at room temperature, hydrogen sulfide evolved immediately. After the reaction mixture had been stirred at room temperature for 1 hr, it was concentrated *in vacuo* to leave crystals. The crystals were washed with benzene and then recrystallized from carbon tetrachloride, thus affording 0.22 g (68%) of *N*-benzoyl-*β*-phenyl-*β*-aminoethanol (VIa), mp 151°C (lit,[7] mp 154—154.5°C), as colorless needles.

Found: C, 74.34; H, 6.06; N, 5.69%. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81%. IR (KBr): 3440 (ν_{OH}), 1630 cm^{-1} (ν_{CO}). NMR (DMSO-d_6): δ 3.71 (double doublet, 2H, $-CH_2-$), 4.8—5.4 (multiplet, 2H, >CH, and –OH), 7.2—8.2 (multiplet, 10H, aromatic protons), 8.75 ppm (doublet, 1H, –NH–).

The benzene washings were evaporated *in vacuo*, leaving 0.17 g (100%) of benzamide.

The hydrolysis of 0.3 g of VII with hydrochloric acid in methanol gave 70 mg (38%) of VIa and 90 mg (97%) of benzamide.

NOTES

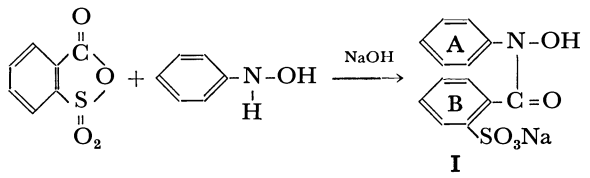
BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2840 (1971)

Preparation of Sodium *o*-(*N*-Hydroxy-*N*-phenylcarbamoyl)benzenesulfonate and Reactions with Metal Ions

S. P. BHARGAVA and N. C. SOGANI
Chemistry Department, University of Rajasthan, Jaipur, India

(Received January 12, 1971)

N-Benzoyl-*N*-phenylhydroxylamine (BPHA) has been recommended as a gravimetric reagent for 16 metal ions including copper, iron, aluminum, and titanium,[1] cobalt and nickel,[2] and uranium.[3] The interest in BPHA and its analogues can be judged from the number of papers and reviews.[4] Bass and Yoe[5] surveyed 33 hydroxamic acids and 3 *N*-substituted hydroxamic acids as reagents for metal ions and concluded that BPHA is the most popular compound for this purpose. We thought it worthwhile to study its sulfonic acid derivative, which should prove a useful spectrophotometric reagent for a number of metal ions. Thus, sodium *o*-(*N*-hydroxy-*N*-phenylcarbamoyl)benzenesulfonate (I) was prepared as water-soluble chelating reagent. The preparation could be easily accomplished by allowing *o*-sulfobenzoic anhydride to react phenylhydroxylamine.



I

With a view to preventing the possibility of steric hindrance in the formation of metal chelates by a sulfonic acid group ortho to the coordinating carbonyl group, attempts were made to introduce it in ring A or meta or para to carbonyl group in ring B, but with no success.

o-Sulfobenzoic anhydride is a weak acylating agent and gives only *N*-acyl derivative. In the preparation of BPHA, however, benzoylation of phenylhydroxylamine yields both *N*-and *o*-substituted products, which must be separated by using ammonium hydroxide solution.

There is no difference in the colours of metal complexes of BPHA and its sulfonic acid derivative, indicating that the sulfonic acid group has not altered the chelating properties.

Conventional procedures were adopted for studying the reactions of the reagent towards various metal ions. Results are recorded in Table 1.

The reagent did not give any colour reactions with Mn(II), Ni(II), Hg(II), Pb(II), Al(III), Sn(IV), Sn(II), Bi(III), Cd(II), Sb(III), Rh(III), Ir(III), Pt(IV), Tl(III), La(III), Ce(IV), Th(IV), Zr(IV), alkali and alkaline earth metals.

TABLE 1. REACTIONS OF THE REAGENT WITH METAL IONS

Metal ion	pH	Colour of complex
Fe(III)	below 1.5	Purple
	1.5—3.8	Wine-red
	3.8—9.5	Orange
Fe(II)	6—7	Brown
V(V)	1—3	Orange-red

Ru(III)	3—4	Light violet
W(VI)	2—3	Yellow
Cr(III)	3—4	Dirty yellow
Pd(II)	2—4	Light yellow-orange

The application of I as a spectrophotometric reagent for iron(III), vanadium(V), molybdenum(VI), uranium(VI), *etc.* is in progress.

Experimental

Preparation. *O*-Sulphobenzoic anhydride was prepared by the reaction of ammonium *o*-sulphobenzoate and thionyl chloride.[6]

Dry phenylhydroxylamine (22 g,0.2 mol) was dissolved in 200 m*l* of dry benzene and *o*-sulphobenzoic anhydride 37 g,0.2 mol) in 150 m*l* of dry dioxane was run slowly under continuous mechanical stirring. After the addition was complete, stirring was continued for 15 min. A viscous mass appeared. With a vacuum pump the major bulk of the solvent was removed under reduced pressure. The viscous mass was dissolved in 10% ethanolic sodium hydroxide solution and the pH was maintained between 7.0 and 8.5. Sodium salt was precipitated by addition of ether. The crude material was crystallised by dissolving it in a minimum quantity of water and adding excess of ethanol. The compound came out as white cane-sugar like crystals. Yield: 50%. Dec. point: 118—120°C; $\lambda_{max}^{H_2O}$: 250—255 nm ($\varepsilon = 5.51 \times 10^4$).

Found: C, 49.49: H, 3.10; N, 4.21; S, 10.02%. Calcd for $C_{13}H_{10}NO_5SNa$: C, 49.52; H, 3.17; N, 4.44; S, 10.15%.

The compound is highly soluble in water but insoluble in organic solvents. In solid state it is stable indefinitely, but in solution it starts decomposing in about 24 hr.

The authors express their gratitude to Prof. R. C. Mehrotra for providing facilities in the department.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2841—2842 (1971)

On the Reaction of Limonene with Chloranil[1,2]

Shin-ichi FUJITA,* Yasuo KIMURA, Rikisaku SUEMITSU, and Yasuji FUJITA**

Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

***Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda-shi, Osaka*

(Received June 20, 1970)

In 1942, one of the present authors[3] examined the reaction of *d*-limonene with chloranil and proved the formation of dipentene and *p*-cymene, together with a large amount of polymerized substances. A further study of this reaction will be reported here.

Experimental

Materials. The *d*-limonene (**1**) was found to be 98.2% pure by gas-liquid chromatography (GLC), it had the following properties; bp 177°C/765 mmHg, d_4^{30} 0.8393, n_D^{30} 1.4678, $[\alpha]_D^{15}$+99.75°. The chloranil (**2**) was a commercial product of an extra pure grade; mp 288°C.

Reaction I. A mixture of 5.0 g (0.037 mol) of **1** and 1.1 g (0.005 mol) of **2** was heated at 170°C for 1 hr. The reaction mixture turned brown, and the generation of a small amount of hydrogen chloride was observed. The reaction product was then distilled with steam, and the distilled oil was extracted with ether and subsequently dried over anhydrous sodium sulfate. When the solvent was removed, 4.1 g of oil were obtained.

Reactions II_1, II_2, and II_3. Mixtures of 5.0 g of **1** and 2.2 g (0.009 mol) of **2** were heated at 130°C for 1 hr and 6 hr, and another at 170°C for 1 hr. After the same treatment, 4.4 g, 3.8 g, and 2.7 g respectively of oils were obtained.

Reactions III_1 and III_2. Mixtures of 5.0 g of **1** and 4.5 g (0.018 mol) of **2** were heated at 150°C and 170°C for 1 hr; 2.3 g and 1.4 g of oils respectively were thus obtained.

Reaction IV. A mixture of 5.0 g of **1** and 9.0 g (0.037 mol) of **2** was heated at 170°C for 2 hr, 1.6 g of oil were thus obtained.

Examination of the Reaction Products. The GLC was carried out by using Yanagimoto GC-3D Model equipment equipped with a thermal conductivity detector; the contents of the components were calculated from the peak areas of the gas-chromatograms. The components were isolated by preparative GLC with PEG 6000 column, and were identified by a comparison of their IR spectra with those of authentic samples.

d-*Limonene (1) and Dipentene (6).* Component **1** was isolated from the reaction product of I, and was identified as limonene. However, the specific rotation of this limonene was $[\alpha]_D^{20}$+27.56°, indicating that it contained about 70% of dipentene; this compound also afforded tetrabromide, mp 124°C.

8-p-*Menthene (3)*, *1*-p-*Menthene (4)*, *α-Terpinene (5)*, *γ-Terpinene (7)*, p-*Cymene (8)*, *Terpinolene (9)*, *1-Methyl-4-iso-propenylbenzene (10).* Each component was isolated from the reaction products of II_3—IV and was identified by a comparison of the IR spectrum[4] and retention time of GLC with those of authentic sample.

Reactions V, VI, VII, and VIII. Mixture of 5.0 g (0.037 mol) of *p*-cymene (**8**) (98.7% purity by GLC; bp 176°C/760 mmHg, d_4^{30} 0.8546, n_D^{30} 1.4867), and 1.1 g (0.005 mol), 2.2 g (0.009 mol), 4.5 g (0.019 mol), and 9.0 g (0.037 mol) of chloranil (**2**) were each heated at 170°C for 1 hr. By this treatment, 4.0 g, 3.6 g, 3.3 g, and 1.9 g of oils respectively were obtained. The reaction products consisted of **10** and large amounts of unreacted **8**. These results are shown in Fig. 1 and in Tables 1 and 2.

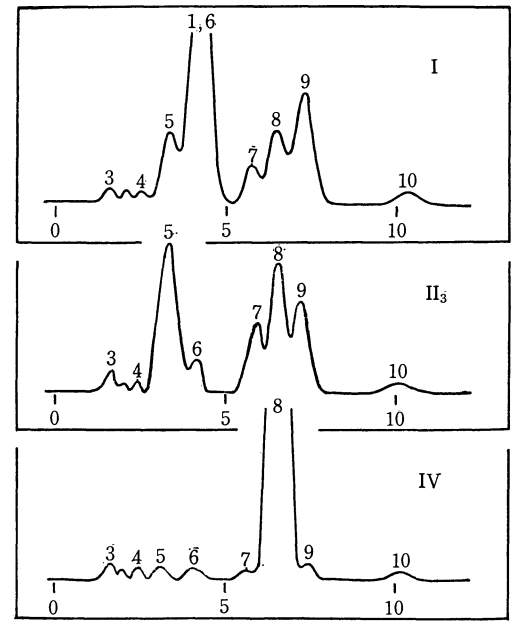

Fig. 1. Gas chromatograms of the volatile products of the reactions I, II_3 and IV.
Condition: PEG 6000 (30%), 2m×5mmϕ, 165°C, 40 ml/min H_2.

Nonvolatile Products. The nonvolatile residues of the steam distillation of the products of the reactions IV and VIII were each extracted with ether; after the separation of the chloranol (mp 233°C) formed, 1.6 g and 1.5 g portions of viscous oils were obtained respectively. These components were examined by GLC. In the case of the reaction VIII, the main component amounted to 76% of the oil. The IR spectrum of this compound showed bands at 1515(s), 1495(m), 1455(s), 1385(m), 1375(m), 1365(m), 1190(m), 1020(m), 815(s),

Condition: PEG 6000 (30%), 1m×5mmϕ, 175°C, 200 ml/min H_2.

Results and Discussion

When *d*-limonene (**1**) is heated at 150—170°C with chloranil (**2**), there occur several reactions, such as racemization, isomerization, dehydrogenation, disproportionation, and dimerization. Moreover, the formation of 8-*p*-menthene (**3**), 1-*p*-menthene (**4**), α-terpinene (**5**), dipentene (**6**), γ-terpinene (**7**), *p*-cymene (**8**), terpinolene (**9**), 1-methyl-4-isopropenylbenzene (**10**), and 1,3,3,6-tetramethyl-1-*p*-tolylindan (**11**) has been confirmed. These reactions may be concluded to be as is shown in Fig. 3.

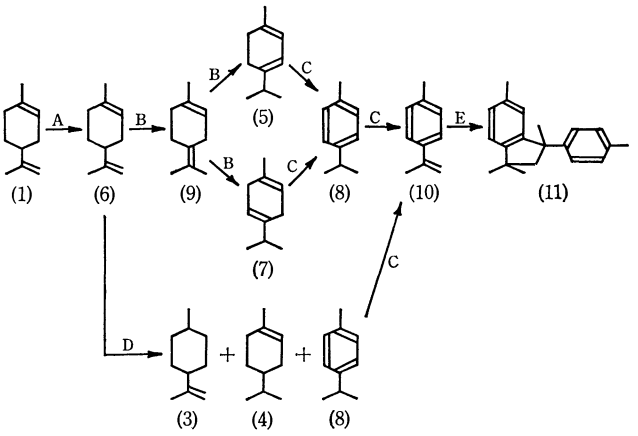

Fig. 3. The schematic mode of formation of the reaction products of *d*-limonene (1) with chloranil (2).
A: Racemization, B: Isomerization, C: Dehydrogenation, D: Disproportionation, E: Dimerization

The monoterpene compounds obtained in these reactions frequently occur in natural essential oils and can be considered in some cases to be formed by similar complex reactions of quinonoid compounds *in vivo*.

In a previous paper,[6] the present authors examined the reaction of citral with chloranil in a benzene solution under refluxing and proved the formation of **6**, **8**, and **10**.

The NMR Chemical Shifts of Aromatic Ring Protons. I. The Chemical Shifts of the Ring Protons of Mono-substituted Benzenes

Yasuhide YUKAWA, Yuho TSUNO, and Nobujiro SHIMIZU

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita, Osaka

(Received September 25, 1970)

The ring protons of *mono*-substituted benzenes generally give complicated NMR spectra as a result of complex spin-spin coupling with their neighbors. This creates difficulties in determining the chemical shift of the respective ring protons and, subsequently, in examining effects. While recent computer analysis of ordinary spectra has provided a set of parameters,[1] the most practical method easily applicable in a laboratory of organic chemistry to solve this problem seems to be the deuterium-decoupling technique. Spiesecke and Schneider[2] and Schmid[2] determined the chemical shifts of ring protons of *mono*-substituted benzenes in a cyclohexane solution by means of deuterium substitution at specific positions. As a more convenient method, Garnett[3] suggested the application of massive deuteration.

Although the chemical shifts of the ring protons of benzene derivatives have been studied over a wide variety of substituents,[4,5] a comprehensive set of SCS data for *mono*-substituted benzenes under the same conditions is only available in carbon tetrachloride[1] and cyclohexane solutions.[2] Therefore, we determined the chemical shifts of *mono*-substituted benzenes in various solvents.

Our method of chemical-shift determination is essentially an application of Garnett's deuterium decoupling (massive deuteration). A statistical mixture of isomeric *mono*-substituted benzene-d_4, obtained by introducing a substituent to monoprotio deuteriobenzene, gives a highly simplified absorption pattern which consists of three singlets for the *o*-, *m*-, and *p*-proton. Thus, the chemical shifts of the respective protons were directly obtained from the spectra.

Mono-protio pentadeuteriobenzene was prepared from hexadeuteriobenzene by the bromination and subsequent reduction of the Grignard reagent with light water. This starting material was converted by direct substitutions and subsequent reactions to a series of *mono*-substituted monoprotio deuteriobenzenes.

The measurements were carried out with a Hitachi R-20 spectrometer operating at 60 MHz. The chemical shifts were determined relative to TMS as an internal standard at three concentrations below 5.0 mol% and were extrapolated to infinite dilution values. The shift values were determined rather precisely; the uncertainty involved in the infinite dilution values may be estimated as far less than ± 0.5 Hz, except when the signals are coalesced. Since the relative intensity of the signals corresponds to the relative amounts of the existing protio-isomers, 2: 2: 1 for *o*-, *m*-, and *p*-isomers, the signals for *p*-protons could be assigned from their intensities without difficulty. The assignment of the *m*- and *o*-protons for most of the derivatives was confirmed by comparison with existing data.[1,2]

The SCS for the compounds for which no literature data were available were further confirmed by a study of the spectra of specifically-deuterated materials. The chemical shifts determined in carbon tetrachloride were in good accordance with those given by theoretical analysis; the discrepancy did not exceed ± 0.5 Hz. This indicates the reliability of the present sets of data, obtained by the conventional method, as indicating the actual shifts of *mono*-substituted benzenes.

According to the results, the substituent chemical shifts (SCS values) appears to vary to a considerable extent depending on the solvents. Table 1 lists the SCS values in dimethylacetamide (DMA) as a representative polar solvent and in cyclohexane as a non-polar solvent. The *meta*- and *para*-SCS values are magnified in DMA as compared with those in C_6H_{12}, but the *ortho*-SCS values remain approximately the same in both solutions. The SCS in C_6H_{12} is found to be proportional to that in CCl_4. On the contrary, no such linear correlation can be obtained between the SCS's in DMA and in C_6H_{12} or CCl_4. In a DMSO solution, practically the same SCS values as in DMA were reproduced within the order of experimental uncertainty. These findings suggest that the SCS should be treated independently in each solvent.

A number of studies of the correlation of the chemical shifts of substituted benzene dreivatives with the substituent parameters have been successfully made,[4-6] although actual correlations have always suffered from the significant deviations of the anisotropic substituents. However, the direct application of Hammett σ-constants does not necessarily result in satisfactory correlations.

This failure should be attributed to the changes in the relative importance of the π-electronic delocalization (resonance) effect relative to the non-delocalization polar effect, changes depending on the structure of the systems and also on the nature of the detection variables (*i.e.*, the proton NMR chemical shifts compared to the pK_a of benzoic acids).

We have previously demonstrated[4,5] that the substituent effect on the chemical shift of side-chain protons can be described generally by Eq. (1):

$$\Delta\delta = \rho(\sigma^0 + r^+\Delta\bar{\sigma}_R^+ + r^-\Delta\bar{\sigma}_R^-) \qquad (1)$$

ρ is the reaction constant, and σ^0 is the standard substituent constant. $\Delta\sigma_R^+$ and $\Delta\sigma_R^-$ are the resonance substituent constants measuring the capacity of −R and +R groups respectively for electron donation and attraction through π-electronic delocalization. Either r^+ and r^- is the resonance reaction constant describing the extent of additional π-electronic interaction with conjugatively electron-donating(−R) or electron-attracting (+R) substituents.

Our linear Aromatic Substituent-Reactivity (**LArSR**) relationship (1) can be applied to the SCS's of the ring protons of *mono*-substituted benzenes. By the least-squares treatment, the following correlations were derived for the respective ring protons in DMA solution:

$$\Delta\delta_p = -39.6(\sigma_p^0 + 0.87\Delta\bar{\sigma}_R^+) + 0.24$$
$$(n=13,\ \mathrm{SD}=2.81,\ \mathrm{R}=0.995)$$
$$\Delta\delta_m = -34.5(\sigma_m^0 + 0.42\Delta\bar{\sigma}_R^+) - 0.61$$
$$(n=9,\ \mathrm{SD}=2.03,\ \mathrm{R}=0.993)$$

Equation (1) was also employed successfully for the SCS's in C_6H_{12} solution; $\sigma_p = -25.4$, $r_R^+ = 0.98$ and $\sigma_m = -18.9$, $r_m^+ = 0.48$. Halogens in the *meta*-correlation and dimethylamino group were not included in these calculations. The results are shown in Fig. 1 and 2 for

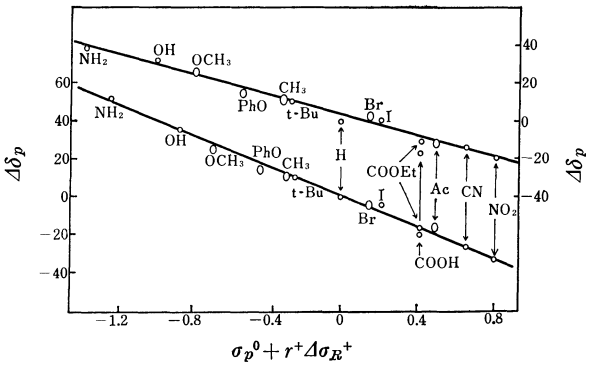

Fig. 1. Application of **LArSR** Eq. (1) to *para*-SCS values; Upper line, SCS in C_6H_{12}, and lower in DMA solutions.

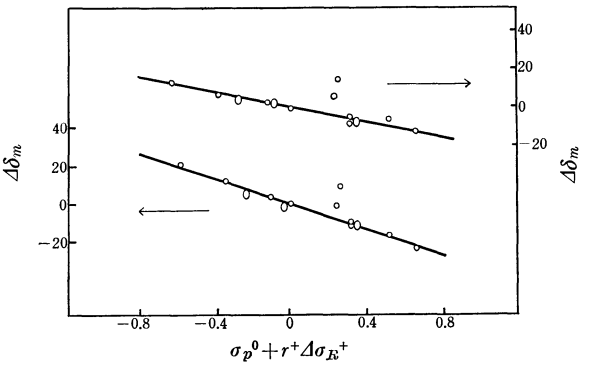

Fig. 2. Application of **LArSR** Eq. (1) to *meta*-SCS values; Upper in C_6H_{12} and lower in DMA solutions.

m- and *p*-protons respectively. Yamamoto *et al.*[1] pointed out that the SCS values in CCl_4 were linearly correlated with σ^+ This means that the shifts in CCl_4 correlate with an r_p^+ value near unity.

From these results, it is evident that our **LArSR** Eq. (1) can be employed as a useful approximation to describe the physical properties mainly brought about

by the electronic distributions of the ground-state molecules.

In para correlations, the resonance contribution of the —R substituents is remarkably exalted to give high r^+ values near unity, while the contribution of the $r^-\Delta\bar{\sigma}_R^-$ term is not significant; in effect, $r^-=0$. This suggests that the benzene ring works more effectively as a π-electron acceptor than as a π-electron donor in the π-delocalization in the ground-state *mono*-substituted benzenes. The change in r from one solvent to another may result in the non-linearity between the *para*-SCS values in different solvents. The significant solvent-variations of σ as well as of r values suggest that the simple sum treatment[1] should be applied only to data obtained in the same solvent or at least in a closely related group of solvents.

It should be noticed that the *meta*-correlation also requires exalted r^+-values, contraty to the negligible additional resonance term ($r_m^+=0$) in the ordinary *meta*-reactivity correlations. This might be caused by certain secondary contributions from the *ortho* and *para* π-charges.[8] Whatever the origin of the exalted resonance contribution,[8] the fact that the r_m value is just a half as much as the corresponding r_p value may be important, as the 1/2 ratio is a characteristic of the resonance contribution in the insulated σ^0-reactivity.

The substantial deviation of certain substituents might be attributed mainly to the specific magnetic effect. It is interesting to note that the effect of anisotropic substituents appears somewhat solvent-dependent (see Table 1). Dimethylamino group was not successfully correlated with the ordinary $\Delta\sigma_R^+$ value. In usual solvents, dimethylamino group was less electron-releasing than amino group, but it was more electron-releasing in carbon tetrachloride. No plausible explanation of this fact is available.

The chemical shift of the *ortho* proton can not be described simply by Eq. (1) alone. This is quite reasonable because the proximity of the *o*-proton to substituents may give rise to predominant non-electronic effects, such as anisotropic, local-field, and steric interactions. However, practically a linear correlation, $\Delta\delta_o=-55.3(\sigma^0{}_p+0.59\Delta\bar{\sigma}_R^+)$, can be obtained in DMA from selected well-behaving substituents. Similar results were obtained in other solvents. This means that the electronic effect predominantly controls the chemical shifts of the *o*-proton despite significant contributions of non-electronic factors.

The same method of determination and a similar type of SCS analysis have been used successfully in the study of particular solvent effects or of the complex formation of substituted benzenes and naphthalenes; the results will be reported in the near future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2845—2847 (1971)

Electrical Conductivity in Crystalline Hexamethylbenzene

Kazuhiko KUREMATSU, Nagao KANEKO, and Shoichi MATSUMOTO

Toshiba Research and Development Center, Tokyo Shibaura Electric Co., Ltd., Komukai, Kawasaki

(Received December 1, 1970)

The influence on the electrical property of organic crystals of their phase transition has been found for phthalocyanine,[1,2] chlorpromazine,[3] phenanthrene,[4,5] and so on. It has, however, been reported by Kronick and Labes that no change was discernible in the electrical property accompanying the phase transition of hexamethylbenzene crystals at 110°C.[6] Recently, Chojnacki has found an increase in the electrical conductivity of hexamethylbenzene at the transition point, while he has reported no change in the activation energy for conduction at that point.[7]

The crystal structure of hexamethylbenzene below 110°C is a triclinic modification, belonging to the space group of C_1'—$P_{\bar{1}}$. A unit cell whose dimensions are a=8.92Å, b=8.86Å, and c=5.30Å (α=44°27′, β=116°43′, γ=119°34′) at 20°C contains one molecule.[8] Through the phase transition, the molecules within the plane of the molecular rings shift slightly, so that the triclinic symmetry becomes orthorhombic. Here, the unit cell whose dimensions are a=9.06Å, b=15.70Å, and c=7.52Å (at 155°C) belongs to the space group of $D_{2h}^{23}F_{mmm}$ and contains four molecules.[9]

This paper will report on studies of the temperature dependence characteristic of the electrical conductivity

of crystalline hexamethylbenzene. The results of the increase in the activation energy through the transition will be discussed in connection with both crystallographic forms.

Experimental

Material. Hexamethylbenzene of an extra pure grade obtained from Tokyo Kasei Kogyo Co., Ltd., was purified by recrystallization from a chloroform solution and then by the zone-melting technique.[10]

Electrical Measurements. The powdered specimen was packed in a rigid Teflon cylinder and compressed between the metal (stainless steel) plungers which were used as electrodes. Their effective area was 1 cm^2. The specimen compressed under a pressure of 120 kg/cm^2 was 1—2 mm thick. The electrical measurements were then carried out by means of a vibrating-reed electrometer (Takeda-TR15) in a vacuum of 10^{-3}—10^{-4} mmHg, while applying a voltage of 100V to the cell.[4,5] The sample heating rate was 0.2—0.4°C per minute.

Dilatometric Measurements. A dilatometric investigation was made by using a modified differential dilatometer of the type originated by Chevenard.[11] Our dilatometer was designed to magnify 2000 times the differential expansion between the specimen and an equal length of fused silica used as the standard.

In this study, the heating rate was about 0.9°C/min, except in the vicinity of the anomalous point, where the temperature was raised as slowly as possible.

Samples were prepared by casting molten rods of zone-refined hexamethylbenzene 11.7 mm in length.

Results and Discussion

In the electrical investigation over the temperature range of 85—130°C, a distinct anomaly was found in the temperature dependence of the electrical resistivity of crystalline hexamethylbenzene. A typical example of the temperature dependence of the electrical resistivity in the heating process by the DC method is shown in Fig. 1. The relation between the logarithm of the resistivity and the reciprocal absolute temperature shows an anomaly at 110±3°C, while the relations both below and above that point are linear. The reproducibility of this amonalous phenomenon was good within the range of experimental error.

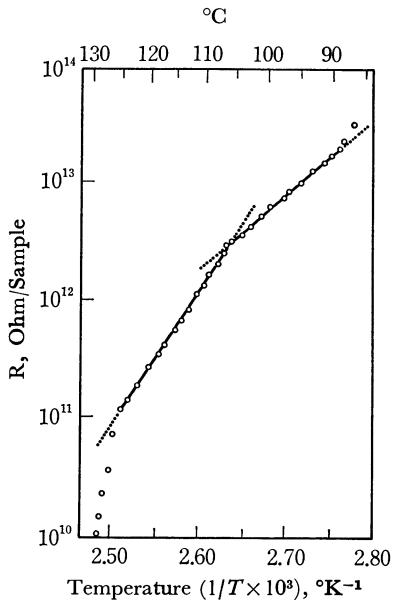

Fig. 1. The temperature dependence of the electrical resistivity of crystalline hexamethylbenzene for heating.

Assuming the resistivity, R, to obey the usual semiconductor relation:

$$R = R_0 \exp(\Delta\varepsilon/2kT) \quad (1)$$

the values of the activation energy for conduction, $\Delta\varepsilon$, obtained from the above relation, were found to be, respectively, 2.5 eV and 4.5 eV below and above the anomalous point.

In the electrical study by Kronick and Labes, using a hexamethylbenzene specimen cast between glass plates, no anomaly was reported. The activation energy was 1.78 eV. According to the report by Chojnacki, the increase in the electrical conductivity of a pellet specimen made from powdered hexamethylbenzene crystal under a pressure of 1000 atm. doubled, the activation energy for conduction did not change, and the activation energy was 2.0 eV.

There seems to have been no anomaly in the results reported by Kronick and Labes caused by their measurement technique. On the other hand, Chojnacki discussed his experimental results, in which no change was found in the activation energy at the phase transition, on the basis of these being no dependence of the $\Delta\varepsilon$ on the crystallographic direction. However, his discussion may be confused because one cannot regard the effect on the electrical conductivity influenced by the crystal-phase transition as being equal with the anisotropy of conductivity.

The intrinsic band-gap energy can be fundamentally induced from the crystal ionization potential, I_c, and the crystal electron affinity, A_c, corresponding to the energy gap between the top of the valence band and the bottom of the conduction band, $\Delta\varepsilon_0$.[5] If the values of I_g and A_g are available, the intrinsic band-gap energy, $\Delta\varepsilon_0$, may be calculated from the following equation:

$$\Delta\varepsilon_0 = I_c - A_c \quad (2)$$

Thus, Eq. (3) is derived from Eq. (2):

$$\Delta\varepsilon_0 = I_g - A_g - P_+ - P_- \quad (3)$$

where I_g and A_g are the gaseous ionization potential and the electron affinity respectively, and where P_+ and P_- are the stabilization energies attributed to polarization by positive and negative centers in the crystal respectively.

If the activation energy for conduction, $\Delta\varepsilon$, is equal to the band-gap energy, $\Delta\varepsilon_0$, the activation energy will vary more or less with the change in the crystallographic form, since the stabilization energy of polarization, P, depends on the crystal structure. However, $\Delta\varepsilon$ probably does not depend on the crystallographic direction, because P would have little anisotropy.

In the dilatometric study, a distinct discontinuity

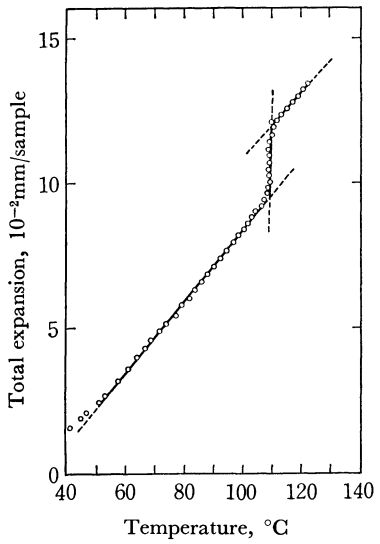

Fig. 2. The linear expansion-temperature relation of hexamethylbenzene crystal for heating.

was found in the linear expansion-temperature relation of the hexamethylbenzene crystal at 110.3°C. Figure 2 gives, as a typical example, a graphical representation of the total linear expansion of Sample No. 2 (listed in Table 1) plotted against the temperature, where the curve consists of three distinct lines. These phenomena were quite reversible with the temperature. These features of the expansion-temperature relation show that the thermal expansion coefficient of the specimen is almost constant below or above 110.3°C, but that it undergoes an abrupt change of linear expansion at the transition point. Each expansion coefficient can be evaluated from the slope of each line. The results are summarized in Table 1, where β_I is the mean coefficient of the linear thermal expansion between the temperatures of 40°C and Ttr. (the transition point) and where β_{II} is the coefficient between Ttr. and 130°C.

Table 1. The mean coefficient of linear thermal expansion of hexamethylbenzene crystal measured with a dilatometer

Trial	Ttr., °C	β_I ($\times 10^{-4}$)	β_{II} ($\times 10^{-4}$)
Sample No. 1	111.2	1.01	0.794
Sample No. 2	110.0	1.06	0.814
Sample No. 3	109.8	1.08	0.811
Average	110.3	1.05	0.806

The molar volumes calculated from the data of the crystal structure,[8,9] using the results obtained from our experiments of the thermal expansion, are 156.11 cm^3/mol in the triclinic system at 110°C and 159.43 cm^3/mol in the orthorhombic system at 110°C. Thus, the increase in the molar volume by the phase transition at 110°C is 2.13% of the molar volume at 110°C in the triclinic system.

Through the transition from a triclinic system to an orthorhombic system at 110°C, the increase in the molar volume would induce a decrease in the stabilization energy of polarization, P. Therefore, it seems reasonable, from Eq. (3), that an increase in the activation energy at the transition point was found in these experiments.

The Crystal Structure of *N*-Methylphenothiazine

Nobuko I. WAKAYAMA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received December 8, 1970)

Phenothiazine derivatives are used widely in medical practice. Their actions change entirely with the side chains attached to the phenothiazine nucleus. *N*-substituted phenothiazine can take two different forms, quasi-equatorial and quasi-axial (Fig. 1). According to the calculation based on the molecular orbital theory by Malrieu and Pullman,[1] the electronic states of the two forms are different. The energy state and ionization potential of the quasi-equatorial form are lower than those of the quasi-axial one, the former being more reactive towards electrophilic reagents since the nitrogen lone pair electrons participate in the conjugated electronic system. The N–H bond of phenothiazine (PT) has been found to have a quasi-equatorial orientation by X-ray structure analysis.[2] PT has a

Fig. 1. Configuration of *N*-substituted phenothiazine derivatives.
(a) quasi-equatorial form (b) quasi-axial form

1) J. P. Malrieu and B. Pullman, *Theor. Chim. Acta*, **2**, 293 (1964).

2) J. D. Bell, J. F. Blount, O. V. Briscoe, and H. C. Freeman, *Chem. Commun.*, **1968**, 1656; C. J. Fritchie, Jr., and B. L. Trus, *ibid.*, **1968**, 833; C. J. Fritchie, Jr., *J. Chem. Soc., A*, **1969**, 1328.

0.24—0.34 eV lower ionization potential[3] and is more reactive[4] towards electrophilic reagents than *N*-substituted derivatives which are supposed to take a quasi-axial form because of the steric hindrance of a large substituent.

We report the configuration of *N*-Methylphenothiazine (NMPT) which is regarded as a model substance of *N*-substituted phenothiazine. NMPT has a 0.15 eV higher ionization potential in the acetonitrile solution[5] and is less reactive towards electrophilic reagents than PT. NMPT cation was reported to take a quasi-axial form from the spin densities obtained from ESR measurement.[1] A single crystal, colorless and a prismatic needle in shape, was prepared by evaporation at room temperature from its benzene solution.

Crystallographic data are as follows:

$C_{13}H_{11}NS$

Orthorhombic: $a=14.9$, $b=11.4$, $c=6.79$Å

Density observed: 1.17_2 g·cm^{-3}

Density calculated: 1.18_2 g·cm^{-3}

Four formula units per unit cell

Space group: $Cmc2_1$

A set of intensity data was collected up to 5th layer around the *c*-axis, and up to 8th layer around the *b*-axis with a Weissenberg camera using Cu$K\alpha$ radiation. In total, 383 independent reflections were observed from 755 possible reflections, the rest being too weak to be observed. The intensities were estimated visually and corrected for Lorenz and polarization factors. The scale factor of each layer was determined by the least square method. From the space group $Cmc2_1$, the nitrogen, sulfur atoms and the carbon atom of the methyl group should be on the mirror plane perpendicular to the *b*-axis. The structure was solved by the Patterson and Fourier methods, and refined by diagonal, isotropic least squares. The final *R* factor was 0.135. The final atomic parameters are given in Table 1. The arrangement of the molecules in the crystal is shown in Figure 2. The bond lengths are C–N 1.43Å (0.026) and C–S 1.82Å (0.017). Bond angles are C–S–C 97° (0.77) and C–N–C 120° (2.5). The figure in parenthesis shows the value of standard deviation. The mean bond length of C–C is 1.41Å (0.033) and the mean bond angle of C–C–C is 120° (2.0). The plane equation of a benzene ring is $0.766x+0.294y+0.572z+4.72=0$. The N and S atoms deviate significantly from the planes of the benzene rings (N; 0.07, S; 0.18Å). The dihedral angle of the two benzene rings is 151° which is as large as that of PT. The configuration of the bonds about the nitrogen atom is a flattened tetrahedron, as is also the case with PT. Thus NMPT is determined to take a quasi-equatorial form in the crystal. This is not strange if we consider the fact that the steric effect of the methyl group is small and the molecule with this form is flattened and can be packed well. However, the present result contradicts the presumption based on the similarity of the chemical property to the other *N*-substituted derivatives. It is interesting to study whether the conversion from a quasi-axial form to a quasi-equatorial one happens in crystallization or not. Measurement of the ionization potential of the crystal of PT and NMPT is in progress to explain the difference in electronic state and structure between PT and *N*-substituted derivatives. All calculations were performed with the use of UNICS programs.

A Polarographic Study of the Rates of the Dissociation Reactions of Nickel(II)-Ethylenediaminemonoacetate and -*N*-(2-Hydroxyethyl)ethylenediamine Complexes

Mutsuo KODAMA and Noboru OYAMA*

Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki

**Chemistry Department, Faculty of Engineering, Ibaraki University, Narisawa, Hitachi, Ibaraki*

(Received December 22, 1970)

In a previous paper,[1] we studied the dissociation reactions of nickel(II)- and cobalt(II)-acetylacetonate complexes and of nickel(II)-glutamate, -aspartate, and -iminodiacetate complexes by investigating systematically the nature of the kinetic currents due to their dissociation at the electrode surface; we also determined their rate constants. The nickel(II) ions in ethylenediaminemonoacetate (EDMA) and *N*-(2-hydroxyethyl)ethylenediamine (EtEN) solutions also gave the kinetic waves due to the dissociation of the nickel(II)-EDMA and -EtEN complexes at the electrode surface preceding the electron-transfer step. In this investigation, we also studied thoroughly the nature of the kinetic waves of nickel(II)-EDMA and -EtEN complexes and determined the dissociation mechanism and their dissociation rate constants. The detailed structure of reaction intermediate was also determined.

Experimental

Reagents. The EDMA was prepared by the method of Fujii, Kyuno, and Tsuchiya.[2] The way of preparing the standard nickel(II) nitrate solution was also described in a previous paper.[3] The EtEN was purified by distillation under reduced pressure. The other chemicals used were of analytical reagent grade and were used without further purification.

Apparatus and Experimental Procedures. All the apparatus and the experimental procedures employed in this study were the same as those described in the previous paper.[1] In the present study, no buffer reagent was used, because all the sample solutions always contained an appreciable amount of uncomplexed EDMA or EtEN.

Results and Discussion

As in the cases of nickel(II) ions in acetylacetonate, glutamate, aspartate, and iminodiacetate solutions,[1] the nickel(II) ions in EDMA and EtEN solutions also exhibited the reduction waves corresponding to the reduction of the nickel(II) ion, which are kinetic-controlled in nature (the first waves). The second waves can be ascribed to the direct reduction of the nickel(II) complexes of EDMA and EtEN. In both EDMA and EtEN systems, the total wave-height was almost constant under the present experimental conditions. The log-plot examination for the first waves of nickel(II)-EDMA and -EtEN complexes gave straight lines with reciprocal slopes of about 60 and 72 mV respectively, corresponding to the two-electron irreversible reduction. Provided that the other experimental conditions are kept constant, the plot of the reciprocal of the limiting current for the first wave, i_l^{-1}, against the $(1+K_2'[X]_f)[X]_f^{1/2}$ or $(1+K_2'[X]_f)/(\alpha_H)_x^{1/2}$ value invariably gave the linear relation. However, the plot of i_l^{-1} against $(1+K_2'[X]_f)/(\alpha_H)_x^{1/2}[H^+]^{1/2}$ did not give a straight line in either system. Typical examples are shown in Fig. 1. Here, K_2' denotes the conditional

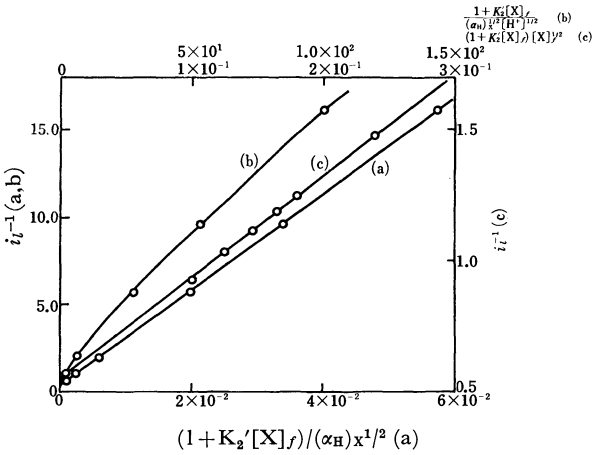

Fig. 1. The plot of $1/i_l$ against $(1+K_2'[X]_f)/(\alpha_H)x^{1/2}$, $(1+K_2'[X]_f)/(\alpha_H)x^{1/2}\cdot[H^+]^{1/2}$, or $(1+K_2'[X]_f)[X]_f^{1/2}$
The concentration of nickel(II) ion=1.0 mM 25.0°C

second formation constant of the nickel(II)-EDMA or -EtEN complex; $[X]_f$, the concentration of uncomplexed EDMA or EtEN, and $(\alpha_H)_x$, the (α_H) value of EDMA or EtEN, defined as $1+[H^+]/K_n+[H^+]^2/K_nK_{n-1}+\cdots$. Furthermore, in both EDMA and EtEN systems, the plots of the half-wave potential against-log $[X]_f$ or log $(\alpha_H)_x$ gave straight lines, the slopes of which were 30 and 37 mV respectively. As was discussed previously,[1] these facts indicate that the electrode reaction for the first waves observed in nickel(II)-EDMA and -EtEN complexes can be expressed as:

$$NiX_2^{2-2m} \rightleftharpoons NiX^{2-m} + X^{m-} \quad \text{rapid}$$

$$NiX^{2-m} \overset{k_d}{\rightleftharpoons} Ni^{2+} + X^{m-} \quad \text{slow}$$

$$Ni^{2+} + 2e^- + Hg \rightleftharpoons Ni(Hg)$$

where X^{m-} means the completely-deprotonated EDMA

Nickel(II)-ethylenediaminemono-acetate complex	10.40[8]

anion or EtEN. From the slopes of the linear relation between the i_l^{-1} value and the $(1+K_2'[X]_f)[X]_f^{1/2}$ or $(1+K_2'[X]_f)/(\alpha_H)_x^{1/2}$ value obtained by using Eq. (10_a) in Ref. 1, the dissociation rate constants, k_d's, were determined (Table 1).

The k_d value for the nickel(II)-EtEN complex is nearly equal to the rate constant for the breakage of a nickel(II)-nitrogen bond, which forms part of a five-membered chelate ring in which both ends of the chelate are amino nitrogen atoms.[4] This fact evidently implies that, in the dissociation of a 1:1 nickel-(II)-EtEN complex, the bond breakage of the first nitrogen is the rate-determining step, and that the hydroxyethyl group in the EtEN has little effect on the rate of dissociation of the nickel(II)-EtEN complex.

In the dissociation of the nickel(II)-EDMA complex, it is very hard to believe that all three nickel(II)-EDMA bond breakages are involved in the rate-determining step. Therefore, the dissociation may proceed through one of the three reaction intermediates shown in Fig. 2. The reaction intermediate where the leaving EDMA anion is bonded to the nickel(II) ion through an acetate group can be eliminated, because the nickel-oxygen bond rupture is much faster than the nickel-nitrogen bond rupture.[5] As was discussed in the previous paper,[1] by relating the observed rate constant to the rate constant calculated on the basis of the proposed reaction intermediate, we determined the correct reaction intermediate. The rate constants calculated on the basis of the reaction intermediates in Fig. 2 by using the following relation are given in Table 2. Here, K_{MX} is the formation constant of the nickel(II)-EDMA complex with a 1:1 ratio; k_{rds},[4,6,7] the rate constant for

$$k_d = \frac{K_{int}}{K_{MX}} k_{rds}$$

the rate-determining step, and $K_{int.}$, the stability constant of the reaction intermediate prior to the rate-determining step. In the calculation, the electrostatic contribution to the stability of the reaction intermediate was also taken into consideration. The rate constant calculated on the basis of the reaction intermediate I agreed best with the observed one. We have already mentioned that the substitution reaction of the nickel-(II)-EDMA complex with cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (CyDTA) proceeds through the reaction intermediate in which the displaced EDMA anion is bonded to the nickel(II) ion through an ethylenediamine five-membered chelate ring.[8] Therefore, the finding that the dissociation of the nickel(II)-EDMA complex proceeds through the reaction intermediate with an ethylenediamine five-membered chelate ring suggests that, in the nucleophilic substitution reaction involving the nickel(II)-EDMA complex, the attacking group just assists the dissociation of the EDMA anion from the nickel(II) ion, without effecting any change in the detailed dissociation mechanism of the nickel(II)-EDMA complex.

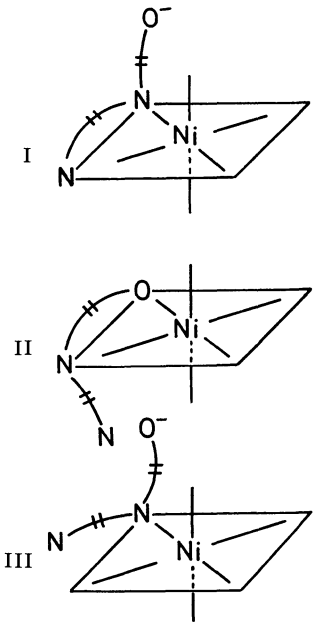

Fig. 2. Reaction intermediates for the dissociation of nickel (II)-EDMA complex

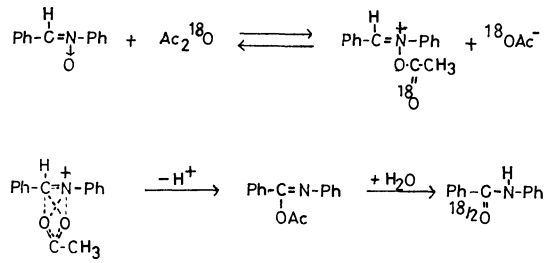
Tertiary Amine *N*-Oxide XXXIII. Reaction of α,*N*-Diphenylnitrone with Acylating Reagents

Seizo TAMAGAKI and Shigeru OAE

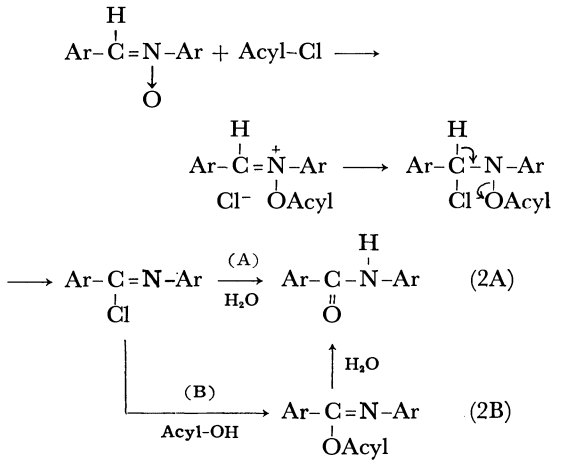
Faculty, of Engineering Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received February 1, 1971)

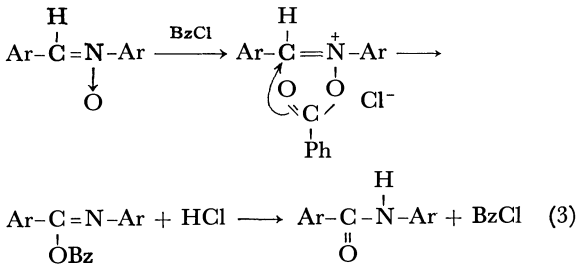
In the preceding paper of this series,[1] it was proposed on the ground of oxygen-^{18}O tracer experiments and kinetic studies that the mechanism of the reaction of aldonitrone with acetic anhydride cannot be represented by the intramolecular cyclic rearrangement alone as suggested by Umesawa,[2] but by the intramolecular rearrangement in which both the cyclic and sliding migrations of the acetoxy group take place concomitantly:



Krohenke[3] suggested that the rearrangement reaction of aldonitrone to amide proceeded *via* addition-elimination. According to his mechanism the reaction of aldonitrones with benzoyl chloride, benzenesulfonyl chloride, and phosphoryl chloride could be written as follows.



It was observed[2] that even less than one mol equivalent of acyl halide is sufficient to complete the reaction, and that in the reaction system there is not enough water to hydrolyze either the iminochloride or the acyloxyimine. Umesawa ruled out the two possibilities (2A and 2B) and postulated the following intramolecular cyclic rearrangement mechanism taking benzoyl chloride as an example.



There are still controversies concerning the mechanistic interpretation of these rearrangement reactions.

In order to disclose the mechanistic picture of these reactions, we carried out ^{18}O-tracer experiments for the reactions of α,*N*-diphenylnitrone with benzoyl chloride, benzenesulfonyl chloride, and phosphoryl chloride enriched with excess ^{18}O.

Mechanism (3) would require the benzanilide to be completely scrambled with ^{18}O-distribution of all the oxygens incubated into the system when uniformly ^{18}O-labeled acyl halide is used, because, when the mechanism is operative the benzoyl chloride or other halides would be used repeatedly. Results of ^{18}O-analysis are given in Table 1. We see that the use of a greater amount of benzoyl chloride results in increasing incorporation of oxygen-^{18}O in benzanilide. The results are in line with the fact that benzoyl chloride in the system is used repeatedly, where the oxygen-^{18}O content in benzoyl chloride is diluted gradually with natural oxygen originated from the unlabeled nitrone.

Since benzoyl chloride can be recovered without decomposition, this reaction take place satisfactorily with only a catalytic amount of benzoyl chloride and affords benzanilide even when water is not present in the reaction mixture. Thus, the reaction likely proceeds through the initial formation of adduct and subsequent intramolecular cyclic or sliding transition state, as in the case for the reaction with acetic anhydride,[1] to give the **C**-benzoyloxyimine which is then attacked by chloride ion, rather than the cyclic rearrangement suggested by Umesawa.

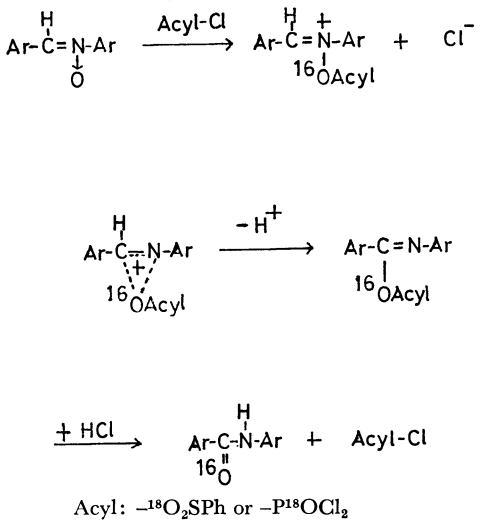
a) Chlorides were repeatedly used during the reaction.
b) Based on intramolecular cyclic mechanism
c) Based on intramolecular sliding mechanism
d) Based on scrambling mechanism

The other acyl chlorides, such as benzenesulfonyl and phosphoryl chlorides were treated in a similar way with α,N-diphenylnitrone. Data of ^{18}O-analysis show that the ^{18}O-results are not incompatible with all the previous mechanisms. The benzanilide obtained was found to contain no excess oxygen-18. Thus, the most reasonable mechanism for these reactions appears to involve the formation of the initial acyl adduct and the subsequent intramolecular sliding shift with no scrambling of the oxygens in the acyloxy group.



Acyl: $-{}^{18}O_2SPh$ or $-P^{18}OCl_2$

Experimental

Reaction with Benzoyl Chloride. To 3.0 g of α,N-diphenylnitrone without solvent or in chloroform, 2.14 g of benzoyl chloride was added portionwise under ice-cooling. The reaction mixture was then heated on a boiling water bath for 15 min. The mixture was cooled to room temperature and then solidified. The solids obtained were recrystallyzed from benzene or benzene-hexane.

This was identified as benzanilide by mixed melting point with the authentic sample, mp 163—164°C (lit, 163°C).

The yield was quantitative.

Reaction with Benzenesulfonyl Chloride. To a solution of 2.56 g α,N-diphenylnitrone in 7 cc of $CHCl_3$, 2.27 g of benzenesulfonyl chloride was added carefully.

The whole mixture was refluxed on a boiling water bath for 15 min. After it was cooled and an aqueous sodium hydrogen carbonate solution was added, the aqueous layer was extracted with chloroform. The solvent was evaporated to dryness. The residue was chromatographed on alumina eluted with benzene.

First elution product of pale yellow crystals, mp 155°C was recrystallized from benzene-hexane. Yield: 0.51 g(20%)

Reaction with Phosphoryl Chloride. To a solution of 3.20 g of α,N-diphenylnitrone in chloroform, 2.50 g of phosphoryl chloride was added. The column chromatographic treatment gave benzanilide, yield 6.5%.

The Beckmann Rearrangement of *p*-Nitrobenzophenone Oxime with Thionyl Chloride

Tsuyoshi OGATA, Sakuya TANAKA, Hiroshi YOSHIDA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received February 24, 1971)

As is well known, many works on the Beckmann rearrangement have been reported.[1] Generally, it has been shown that the rearrangement is brought about by acids including Lewis acids, and that the mechanism proceeds in the migration of the *trans*-substituent for the hydroxyl group into the nitrogen atom (*trans*-migration).

Recently, Yukawa has reported the migratory aptitude in the Beckmann rearrangement varies according to the kind of catalysts.[2] However, the details have not yet been published. The authors are interested in this point and have done the present work seeking a clue to elucidate the effect of a migrating catalyst on the Beckmann rearrangement.

p-Nitrobenzophenone oxime I was chosen as the starting material, because it can be purified and separated into *syn*- and *anti*-isomers readily. The Beckmann rearrangements of this oxime with phosphorus pentachloride[3] and phosphoryl chloride[4] have been reported in the migration of the *trans*-substituent for the hydroxyl group. For the present paper, the authors chose thionyl chloride as the migrating catalyst, and the reactions were carried out in both benzene and chloroform.

Results and Discussion

p-Nitrobenzophenone oxime I was separated into *syn*- and *anti*-isomers (Ia and Ib) by the method of Sutton.[3] To the solution of Ia or Ib we then slowly stirred three equivalent moles of thionyl chloride. The given amides II were hydrolysed with an aqueous sodium hydroxide solution, and then aromatic acids were separated. These aromatic acids, IIIa and IIIb, were silylated with trimethylchlorosilane and hexamethyldisilazane to form volatile derivatives. That procedure is shown in Scheme 1. These silyl esters, IVa and IVb were determined quantitatively by gas-liquid chromatography, using methyl *p*-nitrobenzoate as the internal standard substance.[5]

The results are shown in Table 1. On the basis of these results, the following conclusions are deduced.

1) On using thionyl chloride as a migrating catalyst, only phenyl group which is situated in the *trans* position for the hydroxyl group in Ia migrated (*trans* migration), while in Ib either a *trans* or a *cis* migration took place simultaneously. It appears that Ib isomerized into Ia, along with a small amount of hydrogen chloride which

Table 1. Migratory aptitude of *p*-nitrobenzophenone oxime

Oxime	Migrating catalyst	Solvent	Reaction temperature °C	Ratio of TMS ester of acid IVa:IVb	Migratory aptitude
Ia	$SOCl_2$	Benzene	10	only IVa[a)]	*trans*
			26	only IVa[a)]	*trans*
		Chloroform	10	only IVa[a)]	*trans*
			26	only IVa[a)]	*trans*
	PCl_5	Benzene	29	only IVa[a)]	*trans*
Ib	$SOCl_2$	Benzene	10	82:18	*cis* : *trans*
			26	80:20	*cis* : *trans*
			20	81:19	*cis* : *trans*
		Chloroform	−8	50:50	*cis* : *trans*
			26	69:31	*cis* : *trans*
			58	45:55	*cis* : *trans*
	PCl_5	Benzene	29	only IVb	*trans*

a) The given amide was identical with authentic sample which was prepared from aniline and *p*-nitrobenzoic acid.

was produced in the reaction system; then Ia was rearranged into IIa with thionyl chloride.[6] At any rate, it is necessary to measure both the isomerizing and migrating rates of Ib in order to clarify the mechanism in detail.

2) The *cis* migrating ratio in benzene predominates over that in chloroform. It appears that the migration proceeds faster than the isomerization in chloroform, because generally the migrating rate in the Beckmann rearrangement increases in a polar solvent.[7]

3) Within the limits of these experiments, the migrating aptitudes are independent of the reaction temperature.

4) Regardless of whether the oxime is of the *syn*- or *anti*-form, only the *trans* migration took place with phosphorus pentachloride.

It is clear from the above conclusions that the migratory aptitude varies greatly with the migrating catalyst and that it is affected by the stability of "*anti*-oxime" for a catalyst.

Experimental

p-*Nitrobenzophenone.* *p*-Nitrobenzophenone was prepared by the method of Schroether.[8] Mp 138°C (recrystallized from acetic acid); yield, 80%.

syn- *and* anti-p-*Nitrobenzophenone oxime Ia, Ib.* *p*-Nitrobenzophenone oxime I was prepared by the method of Brady.[3] Mp 108—116°C. *syn*- and *anti*-Oximes were separated by the method of Sutton.[3] Ia: mp 158°C; yield, 25%; NMR spectrum, 11.69 ppm in DMSO (*syn*-=N-OH). Ib: mp 136°C; yield, 25%; NMR spectrum, 11.88 ppm in DMSO (*anti*-=N-OH). The IR spectrum of Ia was identical with that of Ib.

Purification of Thionyl Chloride. Commercial-grade thionyl chloride was further purified by the method of Fieser.[9] Bp 76°C; colorless.

The Beckmann Rearrangement of p-*Nitrobenzophenone Oxime.* Into 1.2 g (0.005 mol) of oxime in anhydrous benzene (5 m*l*) we stirred thionyl chloride (1.1 m*l*, 0.015 mol) in benzene (2.5 m*l*). The reaction was carried out for 30 min at the temperatures shown in Table 1. After the solution has then been left standing for a night, the excess amount of thionyl chloride was decomposed with water, and the benzene was removed. The precipitate was filtered and used for the following procedure. In each case, the product was obtained quantitatively.

Hydrolysis of the Given Amide. To a given amide (0.6 g) we added a 2N sodium hydroxide aqueous solution (13 m*l*), after which the mixture was refluxed in an oil bath at 140°C for 6 hr. The solution was then cooled to room temperature and neutralized with hydrochloric acid. The precipitate was filtered and dried in a desiccator. The aromatic acid was obtained quantitatively.

Silylation and Quantitative Determination of Aromatic Acids. III. The aromatic acids were convertedi nto their volatile trimethylsilyl derivatives and were determined quantitatively by a modification of the method of Horii.[5] To crude III (0.04 g) in dry pyridine (0.6 m*l*), we added trimethylchlorosilane (0.2 m*l*) and then hexamethyldisilazane (0.2 m*l*). The formation of their trimethylsilyl derivatives occurred very rapidly at room temperature; after the pyridine hydrochloride has been removed by means of centrifuge, within a few minutes the entire reaction mixture was injected directly into the chromatograph.

Instrument: Yanagimoto GCG-550T.
Conditions: Column, 2 m×3 mmϕ
Column packing, 40% Silicone DC-Hv grease on 60-80 mesh Celite 545.
Column temperature, 170°C (Determination for IVa) 150°C (Determination for IVb)
H_2 flow rate, 40 m*l* per min.

6) The oxime Ib was isomerized into Ia with hydrogen chloride at room temperature, but Ib did not rearrange into amide under the same conditions.

Self-Diffusion Coefficients of Carbon Tetrachloride and Cyclohexane in the Carbon Tetrachloride-Cyclohexane System

Akio NISHI, Yoshinobu KAMEI, and Yasumichi OISHI
Department of Nuclear Engineering, Faculty of Engineering, Kyushu University, Fukuoka

(Received February 25, 1971)

The carbon tetrachloride-cyclohexane system shows relatively small compositional dependence of density,[1] viscosity, and interdiffusion coefficient[2,3] compared with other organic binary systems. Equilibrium vapour pressures[1,4] determined indicate a high thermodynamical ideality of this binary system.[2] This suggests that the self-diffusion coefficients of both components also show small and simple compositional dependence. This was confirmed by determining the self-diffusion coefficients of both components for the whole composition range of the system by a capillary-cell technique.

Experimental

An apparatus with a cell of 8 cm diameter, a capillary of 0.8 mm I.D. and 40 mm length, and a stirrer similar to Wang's[5] was used. All determinations were made at 25± 0.02°C. The carbon tetrachloride and cyclohexane used were of spectrum analysis reagent grade. A sample solution having a certain composition in the cell was adjusted to a radioactivity of about 0.06 μCi/cc with the ^{14}C-labelled CCl_4 or C_6H_{12}. The capillary filled with an unlabelled solution of the same chemical composition was dipped in the cell solution to a depth of 5 mm. The velocity of the stirrer was 30 rpm. The diffusion time of 20—25 hr was so scheduled as to result in the diffusion of an amount corresponding to about one third of the final uptake. After the diffusion run the radioactivities of the solutions in the capillary and the cell were determined in toluene solutions of 2,5-diphenyloxazole and *p*-bis-[2-(5-phenyloxazolyl)]-benzene with a liquid scintillation counter. In scintillation counting, difference in the concentration of sample in scintillator solution generally causes a different degree of quenching effect on counting. A correction was made in calculating the concentration of tracer so as to give different sample solutions an equal counting efficiency. Equation (1) gives the ratio of amounts diffusing at time t and infinite time under the above boundary conditions.[6]

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{2\alpha(1+\alpha)}{1+\alpha+\alpha^2 q_n^2} \cdot \exp(-Dq_n^2 t/l^2) \qquad (1)$$

$$\tan q_n = -\alpha q_n \qquad (2)$$

where M_t and M_∞ are the amounts diffusing at time t and infinite time, α the ratio of volumes of solutions in the capillary and in the cell, l the length of the capillary, and D the diffusion coefficient which is to be determined. q_n in Eq. (1), not being zero, is the solution of Eq. (2).

Results and Discussion

Figure 1 shows both the self-diffusion coefficients of carbon tetrachloride, $D(CCl_4)$ and cyclohexane, $D(C_6H_{12})$ determined at 25°C, and the reported viscosity, η[2] as a function of mole fraction of CCl_4,

$N(CCl_4)$. All are the averaged values of more than four determinations. Both self-diffusion coefficients show similar, relatively small compositional dependence as predicted. The compositional dependence is in reverse trend to that for the viscosity as seen in Fig. 1. Figure 2 shows the ratio of $D(CCl_4)$ and $D(C_6H_{12})$ and the products of viscosity and respective self-diffusion coefficients as a function of composition. The compositional dependence of the ratio $D(CCl_4)/D(C_6H_{12})$ is small compared with many other organic binary systerms. The ratio is close to that of molar volumes for pure cyclohexane and pure carbon tetrachloride: $V(C_6H_{12})/V(CCl_4)=1.12$, which means that Bearman's relation[7] holds. Compositional dependence of $\eta \cdot D(CCl_4)$ and $\eta \cdot D(C_6H_{12})$ is also small compared with water-acetone[8] and many other organic binary systems. The results together with the small compositional dependence of density, viscosity, and equilibrium vapour pressure[1,4] indicate the thermodynamical ideality of the system. In consequence, molecular association will be negligible and the diffusing species for both components will be essentially single molecules in the carbon tetrachloride-cyclohexane system at 25°C.

The Paal-Knorr Condensation of Acetonylacetone with 5-Aminopyrazoles

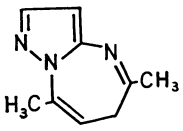
Isaburo HORI* and Minoru IGARASHI*,**

*The Institute of Physical and Chemical Research, Wako, Saitama

**Department of Chemistry, Faculty of Science, Ibaraki University, Mito, Ibaraki

(Received March 8, 1971)

There are very few reports on the Paal-Knorr condensation using heterocyclic amine. The reaction was undertaken with the expectation of formation of pyrazolo-1,3-diazepine ring, but it gave rise to only normal condensation.



This paper deals with the condensation of acetonylacetone with several 5-aminopyrazoles (**1**, **2a,b** and **3**) in the presence of acetic acid to form a new series of 1-(pyrazol-5-yl)-2,5-dimethylpyrroles (**4**, **5a,b** and **6**). 1,4-Disubstituted 5-aminopyrazole such as **2c** and **2d** could not be condensed under these conditions, due perhaps to steric requirements.

The structure of **4** obtained from 1,2-unsubstituted 5-aminopyrazole (**1**) was confirmed by means of NMR spectral data and chemical evidence. All NMR spectra of **4**, **5**, and **6** show two sharp singlets in the ranges δ 1.92—2.05(6H) and 5.61—5.90(2H) corresponding to the α-methyl protons and β-protons of pyrrole nucleus, respectively. Methylation of **4a—d** with methyl iodide gave the corresponding 1-(1-methylpyrazol-5-yl)-2,5-dimethylpyrroles (**5**). Support for the structures **5c** and **5d** was provided by NMR spectra, in which the *N*-methyl protons are located at high magnetic field than that of the corresponding 1-(2-methylpyrazol-5-yl)-2,5-dimethylpyrroles (**6**) similar to other cases. Furthermore, with two moles of methyl iodide, **4a** reacted to give methiodide (**7**), which could be also derived from either **5a** or **6a** by similar methylation.

Condensation of Acetonylacetone with 5-Aminopyrazoles. To a solution of acetonylacetone (0.02 mol) and 5-aminopyrazole (0.02 mol) dissolved in benzene (50 m*l*), acetic acid (0.5 m*l*) was added, and the mixture was refluxed with a water-separator until the formation of water ceased. After the reaction mixture had been evaporated on a rotary evaporator at 50°C, the residue was purified by washing or recrystallization from an appropriate solvent or by distillation under reduced pressure to give 1-(pyrazol-5-yl)-2,5-dimethylpyrroles (**4**, **5a**, **b** and **6**).

Both **2c** and **2d** did not react and were quantitatively recovered. The results along with the NMR data are summarized in Table 1.

Methylation of 4a–d with Methyl Iodide. A mixture of **4** (5.0 mmol) and methyl iodide (5.0 mmol) in methanol (5 m*l*) was heated in a sealed tube at 100°C for 5 hr. After cooling the reaction mixture was evaporated on a rotary evaporator at 40°C. The dark-reddish residue was distillated under reduced pressure to give mono-methylated products as colorless oil.

The products thus obtained from **4a** and **4b** were identical with the corresponding **5** prepared by the above condensation (yields 40.0 and 32.5%, respectively). The products obtained from **4c** and **4d** were inferred to be the corresponding **5** from NMR spectral study (yields 36.6 and 38.0% respectively). The physical properties, analyses and NMR data are shown in Table 1.

Formation of Methiodide (7). *a)* From **4a**: A mixture of **4a** (0.40 g, 2.5 mmol) and methyl iodide (0.71 g, 5.0 mmol) in methanol (3 ml) was heated in a sealed tube at 100°C for 12 hr. After cooling the reaction mixture was evaporated on a rotary evaporator at 40°C. The dark-reddish residue was triturated with ether-methanol to yield brown crystals. Gel filtration (Sephadex LH-20) with methanol gave the methiodide (**7**) (0.55 g, 70.0%) as nearly colorless needles; mp 159—161°C (dec). NMR (CD_3COCD_3): δ 2.08(s, 6H), 4.03(s, 3H), 4.56(s, 3H), 5.96(s, 2H), 7.04(d, J=3 Hz, 1H),

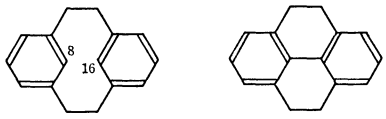
Photolytic Cyclodehydrogenation Reactions of [2.2]Metacyclophane by Means of Aryl Ketones and Alkoxyl and Thiyl Radicals[1]

Takeo SATO, Kozaburo NISHIYAMA, Shigeru SHIMADA, and Kazuo HATA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received March 12, 1971)

The irradiation of [2.2]metacyclophane (I) in benzene or cyclohexane solutions containing iodine through a quartz vessel led to a transannular dehydrogenation reaction to give 4,5,9,10-tetrahydropyrene (II) as the major product.[2,3] As a result of subsequent dehydrogenation processes occurring at a slower rate, the reaction mixture contained 4,5-dihydropyrene (III) and pyrene (IV).[3] Several alkyl derivatives of I were similarly converted into the corresponding 4,5,9,10-tetrahydropyrenes.[4]



I II

The quantum yield of the initial dehydrogenation step for I was found to be 0.006.[3] The reaction mechanism was suggested to involve the photoexcitation of charge-transfer complex between I and iodine followed by dehydroiodination.[3] The formation and dissociation constants of the charge-transfer complexes involving I were studied spectroscopically.[5,6]

Oxygen is less effective as oxidant. The irradiation of an aerated solution of I in benzene using a high-pressure lamp produced only trace amounts of II and III after 45 hr.[7]

From mechanistic view, we wished to know whether photocyclodehydrogenation was possible with oxidants other than iodine or oxygen.[8] In this paper we will describe the attempts using aryl ketones, di-*t*-butyl peroxide (DTBP), and dibenzyl disulfide.

A benzene solution of I in the presence of a three-fold excess of benzophenone was irradiated under a nitrogen current using a 100-W low-pressure lamp for 25 hr. A 41% yield of II together with further dehydrogenation products were produced (Table 1). Formation of pinacol during the reaction was noticed.

Similar results were obtained by irradiation with a 1-kW high-pressure lamp using a quartz vessel though the conversion was less complete. 4,4'-Dimethoxybenzophenone was also found to bring about the dehydrogenation reaction, while acetophenone, desoxybenzoin and fluorenone were less effective.[9]

The results are surprising since the abstraction of aryl hydrogens instead of benzylic ones is just the reverse of what is to be expected. The photoreduction of benzophenone is known to occur only with good hydrogen donors but never with aromatic hydrogens.[10] In the present case, the loss of aryl hydrogens at $C_{8,16}$ occurred more rapidly than the following aromatization steps leading to III and IV.

No cyclodehydrogenation with benzophenone took place when the reaction was carried out in a Pyrex vessel, where the excitation of only the carbonyl compound was possible since shorter wavelength regions required for I (λ_{max} 266 nm) were cut by a filter.

Cyclodehydrogenation with benzophenone was effectively quenched by naphthalene (E_T=61 kcal/mol) or by triphenylene (E_T=67 kcal/mol)(Table 1).[7]

These results suggest that direct photoexcitation of both the substrate and the aryl ketone is necessary for transannular reaction and no energy transfer from the aryl ketone to I occurs. If a triplet state of I is to be

5) S. Hayashi and T. Sato, *Nippon Kagaku Zasshi*, **91**, 950 (1970).

6) S. Hayashi and T. Sato, unpublished results.

7) The cyclodehydrogenation reaction of I was noticed with aerated and degassed solutions [Y. Takayama, K. Sorimachi, H. Shizuka, and T. Morita, Abstracts of Papers, the 23rd Annual Meeting of the Chemical Society of Japan, April, 1970 (Tokyo)]. The reaction rate appears to be lower compared with the case in which iodine is used.

8) *p*-Benzoquinone was found to be effective for the conversion of I to II.[6]

9) As a control experiment a benzene solution of I was irradiated for 45 hr under nitrogen. Only trace amounts (less than 1%) of II and III were detected.

a) Dilute benzene solutions of I (4×10^{-3} M) containing appropriate aryl ketones were irradiated with a 1-kW high-pressure lamp. The reaction mixture was analyzed by gas chromatography using 1 m XE-60 silicone gum rubber on Chromosorb W column. The yields are shown in product ratios.

b) A 100-W low-pressure lamp was used as the light source.

involved, E_T must be higher than that of benzophenone, namely, 69 kcal/mol. We propose that the reaction proceed through an excited singlet state since the iodine-induced reaction is not quenched by oxygen. Recently, Takayama, Sorimachi, Shizuka, and Morita[7] suggested a singlet-state mechanism for the photoreaction of I on basis of quenching experiments and emission spectra measurements.

The results with benzophenone led us to examine the photoreactions of I toward alkoxy and thiyl radicals. Whereas no reaction occurred when I was reacted with *t*-butoxy radicals generated by the thermal decomposition of DTBP at 140°C, the irradiation of a benzene solution of I containing DTBP under nitrogen produced II (7.4%), III (2.3%), and IV (trace). *t*-Butoxy radicals are believed not to abstract hydrogens on an aromatic ring.

The photolysis of a benzene solution containing I and dibenzyl disulfide also gave II (10.8%), III (6.1%), and IV (trace).

The inertness of the methylene groups in I toward radical attack can be ascribed to steric restrictions, rigidity of the molecule and bond angle deformation, which restrict usual charge stabilization associated with a benzylic radical. Tendency of I to undergo transannular reactions is explained by large angle and bond-distance changes. An enhanced reactivity of the aryl hydrogens upon photoexcitation appears to be explainable only by postulating an intermediate that possesses a transannular bonding between C_8 and C_{16} positions.

Experimental

Photolysis of I with Aryl Ketones. The results are summarized in Table 1. For quenching experiments three-molar equivalent of an additive was employed. A typical example is shown below.

A solution of 25.4 mg (0.12 mmol) of I and 68.7 mg (0.38 mmol) of benzophenone in 30 m*l* of benzene was irradiated under nitrogen using a 100-W low-pressure lamp for 25 hr. By gas chromatographical analysis using 1 m XE-60 on Chromosorb W column II (41%), III (13%), and IV (4%) were identified by comparing retention times with those of authentic materials.

Photolysis of I with DTBP. Irradiation of a benzene solution (30 m*l*) of 30.0 mg (0.14 mmol) of I and 57.3 mg (0.39 mmol) of DTBP contained in a quartz vessel using a 1-kW high-pressure lamp for 45 hr under nitrogen produced II (7.4%), III (2.3%), and IV (trace) as analyzed by gas chromatography.

Photolysis I with Dibenzyl Disulfide. Irradiation of a benzene solution (30 m*l*) of 26.0 mg (0.13 mmol) of I and 93.3 mg (0.38 mmol) of dibenzyl disulfide as above gave II (10.8%), III (6.1%), and IV (trace). The rest of the material was recoverable as I.

The Gas-Phase Radiolysis of Cyclopropane

Jun-ichi TANAKA, Yoshihiko HATANO, and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received March 19, 1971)

Cyclopropane is used as a good positive-ion scavenger in the radiolysis of hydrocarbons[1] and it can undergo an H_2 transfer reaction with a hydrocarbon positive ion.[2] On the radiolysis of cyclopropane itself, however, only a few reports have been published.[3-6] In the present study, the effects of additives, such as SF_6 and C_2H_4, on the formation of hydrogen and various hydrocarbon products in the gas-phase radiolysis of cyclopropane have been examined. The results are rather similar to those in the radiolysis of olefins, although cyclopropane apparently belongs to paraffinic hydrocarbons in chemistry. The olefinic properties of cyclopropane have also been pointed out elsewhere.[7] The effects of some paraffinic hydrocarbons added to cyclopropane have also been examined: a large increase of propane formation has been observed and ascribed to ion-molecule reaction involving H^- and H_2^- transfer processes.

Experimental

All the materials in the experiment were supplied by the Takachiho-Shoji Co. The gas-chromatographic analysis of cyclopropane using a dimethyl sulfolane column showed a purity of 99.96%. The cyclopropane contains 0.024% of propane and 0.016% of propylene. It was used after usual degassing and distillation in a vacuum line. The sulfur hexafluoride and some paraffins used as additives were of a high purity and were used without further purification. The cell for irradiation was a glass ampule with a volume of 50m*l*. The total gas pressure was 760 mmHg. The samples were irradiated by Co^{60} γ-rays at room temperature. The dose rate was 5.0×10^{19} eV/g·hr, and the total dose was 6.0×10^{20} eV/g. The quantitative analysis of hydrogen and methane was carried out by means of a Toepler pump equipped with a gas burette. Hydrocarbon products were analysed by gas chromatography using a dimethyl sulfolane column and by mass spectrometry.

Results and Discussion

Table 1 shows the *G*-values of products in the gas-phase radiolysis of cyclopropane. The relative yields of C_2 and C_3 hydrocarbon products are different from those reported by Ausloos *et al.*[6] This difference may be due to the large difference in the sample pressure in the experiments. The *G*-value of hydrogen is almost equal to that of Yang.[4] It is known in general that the *G*-values of hydrogen from paraffinic hydrocarbons in the gas-phase radiolysis are about 5—8,[8-12] while they are about 1 from olefins.[13] As is evident from Table 1, the yield of hydrogen from cyclopropane is very near to those from olefins. In the gas-phase radiolysis of paraffins, a rapid decrease in $G(H_2)$ is observed upon the addition of a small amount of an electron scavenger.[10] In this experiment, however, $G(H_2)$ from cyclopropane is scarcely suppressed at all by the addition of SF_6 as an electron scavenger, even at high concentrations, ~1 mol%. This hydrogen yield is also unaffected by the addition of C_2H_4 (~1 mol%). The experimental results described above are rather similar to those of olefins. Thus, the primary process of the hydrogen formation in the gas-phase

Table 1. *G*-Values[a] of products from the gas-phase radiolysis of cyclopropane

radiolysis of cyclopropane may be interpreted, similarly to the case of olefins,[14] in terms of the following two processes: the molecular detachment of the hydrogen molecule and the hydrogen-atom abstraction of hot hydrogen atoms formed by the direct excitation which may involve superexcitation.

Table 2. Effect of addition of hydrocarbons on the yields of propane and propylene in the gas-phase radiolysis of cyclopropane

n-C_6H_{14}			c-C_6H_{12}		
mol%	$G(C_3H_8)$	$G(C_3H_6)$	mol%	$G(C_3H_8)$	$G(C_3H_6)$
0	0.52	0.27	0	0.52	0.27
0.4	1.1	0.50	0.7	0.94	0.42
1.0	0.92	0.49	2.1	1.1	0.46
1.5	1.0	0.50	3.0	1.1	0.46
2.1	1.1	0.50			

The addition of small amounts of some paraffinic hydrocarbons, C_2H_6, n-C_4H_{10}, n-C_5H_{12}, n-C_6H_{14}, and c-C_6H_{12}, caused a definite increase in the propane formation; *e.g.*, in the case of n-C_6H_{14} or c-C_6H_{12}, as is shown in Table 2, the yield of propane increases by as much as that from pure cyclopropane. This increase may be interpreted neither in terms of the direct radiolysis of the additive hydrocarbons nor in terms of simple charge-transfer processes from cyclopropane to the additives. Since, as is also shown in Table 2, the increase in propylene formation due to the addition of c-C_6H_{12} is not very large, the large increase of propane can not be interpreted only by the simple free-radical mechanism, the disproportionation of propyl radicals.

The isotopic distribution of the propane produced in the radiolysis of the following two mixtures was examined; c-C_3H_6- 3 mol% c-C_6D_{12} and c-C_3H_6- 3 mol% c-C_6D_{12}- 5 mol% O_2. In each case, the formation of $C_3H_6D_2$ and C_3H_7D was observed and the quantity of C_3H_7D was more than that of $C_3H_6D_2$. The ratio of these two quantities, about 2.0, is not affected by the presence of O_2. The above results have led us to conclude that the increase in the propane formation may be interpreted in terms of the following ion-molecule reactions:

$$c\text{-}C_3H_6^+ + RH_2 \longrightarrow C_3H_8 + R^+ \quad (1)$$

$$c\text{-}C_3H_6^+ + c\text{-}C_3H_6 \longrightarrow C_3H_7^+ + C_3H_5 \quad (2)$$

$$C_3H_7^+ + RH_2 \longrightarrow C_3H_8 + RH^+ \quad (3)$$

where RH_2 is an additive hydrocarbon. Judging from the results of the isotopic experiments, the H^--transfer reaction (3) is more important for the increase of the propane formation than the H_2^--transfer reaction (1). The occurrence of reaction (2), *i.e.*, the presence of $C_3H_7^+$, was observed in the mass-spectrometric experiment on cyclopropane.[15] The H_2^--transfer to the $C_3H_6^+$ ion produced by the photoionization of propylene[16,17] or by the gas-phase radiolysis of c-C_5H_{10}[18] has already been investigated. In the case of the cyclopropane parent ion, c-$C_3H_6^+$, however, the H_2^--transfer reaction in radiolysis has not been reported in detail, although this process was suggested by Ausloos *et al.*[19] in connection with the gas-phase radiolysis of c-C_6H_{12} with c-C_3D_6 as an additive. The H_2^--transfer reaction of c-$C_3H_6^+$ in a mass spectrometer was reported by Futrell *et al.*[15]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2861—2863 (1971)

Alkylation of 2,6-Lutidine

Ichiro KAWASAKI, Isao KUSUMOTO,* and Takeo KANEKO**

Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 20, 1971)

For a study of the intramolecular oxidative coupling of phenolic compounds, we tried to prepare 2,6-bis(*p*-hydroxyphenyl)alkyl- and alkenylpyridine.

Attempts to condense 2,6-lutidine with cinnamaldehyde and hydrocinnamaldehyde by heating or with acetic anhydride were unsuccessful.

Some reactions of 6-methyl-2-picolyllithium have been reported, but discrepancies are found in literature regarding the possibility of generating and using a dilithium derivative of 2,6-lutidine.[1)]

The reaction of lutidyllithium with cinnamaldehyde afforded no simple reaction products. 1-(6-Methyl-2-pyridyl)-4-phenyl-2-butanol (Ia) was formed by the action of hydrocinnamaldehyde along with 3,3-di(6-methyl-2-pyridylmethyl)-1-phenylpropane (II), which was formed from two moles of lutidine with one mole of aldehyde. Further treatment of lithium derivative of tetrahydropyranyl ether Ib with aldehyde gave no

* Present address: Central Research Laboratories, Ajinomoto Co. Inc., Suzuki-cho, Kawasaki.

1) K. Schofield, "Hetero-Aromatic Nitrogen Compounds," Butterworth & Co. Ltd., London (1967), p. 381.

reaction products, only the starting material Ib and Ia being recovered.

The product obtained from 2,6-lutidine and benzyl chloride with two equivalents of phenyllithium has been reported as 2-dibenzylmethyl-6-methylpyridine.[2)]

The same results were obtained by the action of lutidyllithium on cinnamyl chloride. The product ($C_{25}H_{25}N$) was assigned to 2-dicinnamylmethyl-6-methylpyridine by NMR spectra (2.50 ppm, 3H singlet of α-methyl proton of pyridine).

On the other hand, symmetrical dialkylation occurred by using γ-phenylpropyl bromide. The product IVa ($C_{25}H_{29}N$) showed no absorption at 2.50 ppm in NMR spectra. This prompted us to try the reaction with γ-(*p*-methoxyphenyl)-propyl bromide. The structure of IVb is supported by NMR and MS which has a parent ion peak at *m/e* 403. Fragmentation peaks at *m/e* 255, 121, and 107 are assigned to ions $[CH_3O\text{-}C_6H_4\text{-}(CH_2)_4\text{-}C_5H_4N\text{-}CH_2]^+$, $[CH_3O\text{-}C_6H_4\text{-}CH_2]^+$ and $[CH_3\text{-}C_5H_4N\text{-}CH_2]^+$ respectively. Phenolic compound IVc was produced by boiling IVb with 48% hydrobromic acid.

Experimental

Reaction of 2,6-lutidine with hydrocinnamaldehyde.

1) To a solution of phenyllithium (0.2 mol) in ether (200 m*l*) was added dropwise 2,6-lutidine (21.4g, 0.2 mol) at room temperature and stirred for 3 hr. A solution of hydrocinnamaldehyde (26.8g, 0.2 mole) in ether (30 m*l*) was then added and the reaction mixture was stirred overnight at room temperature. The cooled reaction mixture was decomposed by addition of ice-water. The aqueous layer was extracted with ether and the ethereal extracts were washed with water, and dried. The residual oil obtained by evaporation of the solvent was distilled to give 37g (78%) of Ia, bp 137—142°C/0.001 mmHg. NMR: δ (CCl_4) 1.75 (m, 2), 2.52 (s, 3), 2.60-3.00 (broad, 4), 3.92 (quintet, 1, *J*=*ca.* 6 Hz), 4.97 (broad s, 1), 6.8—7.6 ppm (8). IR: 3400, 1600, 1585 cm^{-1}.

Found: C, 79.74; H, 7.96; N, 5.84%. Calcd for $C_{16}H_{19}ON$: C, 79.63; H, 7.94; N, 5.80%.

Tetrahydropyranyl ether of Ia, bp 170—175°C/0.001 mmHg.

Found: C, 77.47; H, 8.39; N, 4.23%. Calcd for $C_{21}H_{27}O_2N$: C, 77.50; H, 8.36; N, 4.30%.

2) The reaction was effected by 0.05 mol of 2,6-lutidine and 0.18 mol of hydrocinnamaldehyde and the product was extracted with ether. The organic layer was extracted with 6N hydrochloric acid and the acidic extract was made basic with sodium carbonate and then reextracted with ether. The ethereal extracts were washed with sodium hydrogen sulfite solution and water, and dried. The solvent was removed and the residual oil was distilled at 180—190°C/0.001 mmHg, 2.2 g. The oil showed two spots (R_f 0.60, 0.69: ethyl acetate) on TLC (silica gel G). One (R_f 0.69) was identical with that of Ia. Chromatography over 40 g of silica gel and elution with benzene-ether (99: 1) afforded 700 mg of II: R_f 0.60, bp 220—250°C/0.001 mmHg. NMR: δ(CCl_4) 1.37—1.77 (broad, 3), 2.45 (s, 6), 2.48—2.90 (broad, 6), 6.65—7.42 ppm (11).

Found: C, 82.84; H, 8.01; N, 8.15%. Calcd for $C_{23}H_{26}N_2$: C, 83.59; H, 7.93; N, 8.48%.

Picrate: mp 174°C (from ethanol).

Found: C, 53.45; H, 4.13; N, 14.23%. Calcd for $C_{35}H_{32}O_{14}N_8$: C, 53.30; H, 4.09; N, 14.21%.

2-Dicinnamylmethyl-6-methylpyridine (III). To a stirred solution of lutidyllithium (0.06 mol) in ether was added dropwise cinnamyl chloride (21.2 g, 0.16 mol) at −15°C during a period of 2.5 hr. After standing overnight at 0°C, the reaction mixture was refluxed for 1 hr. The product obtained in the usual way was distilled to give 9.8 g (48%) of III, bp 215—217°C/0.001 mmHg. NMR: δ (CCl_4), 2.50 (s, 3), *ca.* 6.2 (2), 6.7—7.4 ppm (15).

Found: C, 88.33; H, 7.35; N, 4.12%. Calcd for $C_{25}H_{25}N$: C, 88.45; H, 7.42; N, 4.13%.

2,6-Bis-(δ-phenylbutyl)pyridine (IVa). To a stirred solution of lutidyllithium (0.05 mol) in ether (100 m*l*) was added a solution of γ-phenylpropyl bromide (20 g, 0.1 mol) in ether (50 m*l*) at 0°C. After stirring for 2 hr at room temperature and for 30 min under reflux, the reaction was quenched by addition of water. The separated ethereal layer was washed with water and dried. The residue obtained by evaporation of the solvent was distilled to give two kinds of oily products. The first fraction amounted to 5.1 g (45%) of 6-methyl-2-(δ-phenylbutyl)pyridine, bp 107°C/0.1 mmHg. NMR: δ (CCl_4) 1.7 (m, 4), 2.5 (s, 3), 2.65 (m, 4), 6.67—7.6 (8).

Found: C, 84.95; H, 8.56; N, 6.03%. Calcd for $C_{16}H_{19}N$: C, 85.28; H, 8.50; N, 6.22%.

The second fraction was 8.3 g (48%) of IVa, bp 183°C/0.1 mmHg. NMR: δ (CCl_4) 1.7 (m, 8), 2.65 (m, 8), 6.67—7.6 ppm (13).

Found: C, 87.14; H, 8.48; N, 4.10%. Calcd for $C_{25}H_{29}N$: C, 87.41; H, 8.51; N, 4.08%.

2,6-Bis[δ-(p-methoxyphenyl)butyl]pyridine (IVb). To a stirred solution of lutidyllithium (0.1 mol) in ether (170 m*l*) was added a solution of γ-(*p*-methoxyphenyl)propyl bromide[3)] (45.8 g, 0.2 mol) in ether (100 m*l*) at 0°C. After further stirring for 3 hr at 0°C, 2 hr at room temperature and 1 hr under reflux, the reaction was quenched by addtion of water and the products obtained in the usual way were fractionally distilled. The main fraction was 17.3 g (43%) of IVb, bp 230—235°C/0.001 mmHg. NMR: δ (CCl_4), 1.3—2.0 (broad, 8), 2.3—2.9 (broad, 8), 3.65 (s, 6), 6.5—7.5 ppm (11). IR: 1610, 1585, 1580 cm^{-1}. MS: *m/e* 403(3), 268 (5), 255(21), 121(100), 120(75), 107(48), 91(9), 79(5), 78(9), 77(12%).

Found: C, 80.14; H, 8.26; N, 3.47%. Calcd for $C_{27}H_{33}O_2N$: C, 80.36; H, 8.24; N, 3.47%.

The low boiling fraction (bp 132—135°C/0.001 mmHg) was 6.1 g of 2-[δ-(*p*-methoxyphenyl)butyl]-6-methylpyridine.

Found: C, 79.83; H, 8.22; N, 5.53%. Calcd for $C_{17}H_{21}ON$: C, 79.96; H, 8.29; N, 5.49%.

Further treatment of the lithium derivative of this compound with equimolecular amount of bromide yielded IVb, 60%.

*2,6-Bis[δ-(*p*-hydroxyphenyl)butyl]pyridine (IVc).* IVa (26 g) was dissolved in 48% hydrobromic acid (1 *l*) and heated for 8 hr under reflux. The residue obtained by evaporation of the solution *in vacuo* was crystallized from alcoholic water to give 16 g(54 %) of IVc-hydrobromide, mp 181—182°C.

Found: C, 65.74; H, 6.54; N, 3.02; Br, 17.30%. Calcd for $C_{25}H_{30}O_2NBr$: C, 65.79; H, 6.65; N, 3.07; Br, 17.51%.

The solution of IVc-hydrobromide in methanol was treated with sodium carbonate solution and evaporated to dryness *in vacuo*. The residue was extracted with hot ethyl acetate. The crystal obtained by evaporation of the solvent was recrystallized from ethanol, mp 124—126°C. NMR: δ (pyridine-d_5), 1.5—2.0 (broad, 8), 2.56 (t, 4, J=*ca.* 7 Hz), 2.82 (t, 4, J=*ca.* 6 Hz), 7.02 (s, 8), 6.8—7.9 (t, 3), 8.6 ppm (broad s, 2). IR: 3320—2300 cm^{-1}.

Found: C, 79.89; H, 7.77; N, 3.68%. Calcd for $C_{25}H_{29}O_2N$: C, 79.96; H, 7.79; N, 3.73%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2863—2864 (1971)

Preparation and Properties of Metal Complexes in Non-aqueous Solutions. III. Preparation of Tetrammine-monoethylenediamine- and -monopropylenediamine-cobalt(III) Complexes in Dimethyl Sulfoxide

Hayami YONEDA, Masayuki MUTO, and Kyoko TAMAKI
Department of Chemistry, Wakayama University, Masagocho, Wakayama

(Received March 24, 1971)

Tetramminemonoethylenediaminecobalt(III) complex is prepared by an indirect route[1]:

$$NH_4[Co(SO_3)_2(NH_3)_4] \xrightarrow{en} NH_4[Co(SO_3)_2(NH_3)_2en] \xrightarrow{HCl} [CoCl_2(NH_3)_2en]Cl \xrightarrow{KNCS} [Co(NCS)_2(NH_3)_2en]^+ \xrightarrow{H_2O_2} [Co(NH_3)_4en]^{3+}$$

Such a roundabout method of preparation is necessary because of the lability of cobalt(III)ammine complexes in an alkaline solution. Even the basicity of ethylenediamine is enough to expel the coordinated ammonia from the coordination sphere. Previously Yoneda[2] suggetsed that cobalt(III)ammines are decomposed *via* the proton dissociation of the coordinated ammonia. That is, ammonia is linked to the cobalt(III) ion fairly firmly as long as it keeps its three hydrogen atoms and remains as NH_3, but it becomes labile when it loses a proton to form NH_2. If this interpretation is valid, we can expect that the monoethylenediamine complex can be prepared directly from the diacidotetrammine complex by using some non-aqueous solvent which prevents the proton dissociation of the coordinated ammonia. Thus, we tried to use dimethyl sulfoxide (DMSO) in the preparation of $[Co(NH_3)_4en]^{3+}$ and $[Co(NH_3)_4pn]^{3+}$ and obtained the expected results. The present paper will describe the details of the preparation and the PMR spectra of these two complexes.

Experimental

Preparation of the Complexes. Five grams (1/63 mol) of $[Co(NO_3)_2(NH_3)_4]NO_3$ were dissolved in 30 m*l* of DMSO, and to this solution there was added 0.95 g (slightly less than 1/63 mol) of ethylenediamine in 10 m*l* of DMSO. The solution was then kept at 60°C for three hours. Then, 130 m*l* of ethanol was added to precipitate the desired complex. Yield, 3.3 g. Orange crystals were obtained by recrystallization from a hot aqueous solution acidified with acetic acid. Found: C, 6.33; H, 5.47; N, 33.47%. Calcd for $[Co(NH_3)_4en](NO_3)_3$: C, 6.44; H, 5.41; N, 33.78%.

The monopropylenediamine complex was prepared in a similar way. Found: C, 9.09; H, 5.65; N, 32.68%. Calcd for $[Co(NH_3)_4pn](NO_3)_3$: C. 9.30; H, 5.74; N, 32.56%.

PMR Measurements. The spectra reported here were recorded on a Varian A60 Analytical NMR spectrometer. The spectra were run in trifluoroacetic acid (TFA), and the chemical shifts were measured relative to tetramethylsilane as an internal reference.

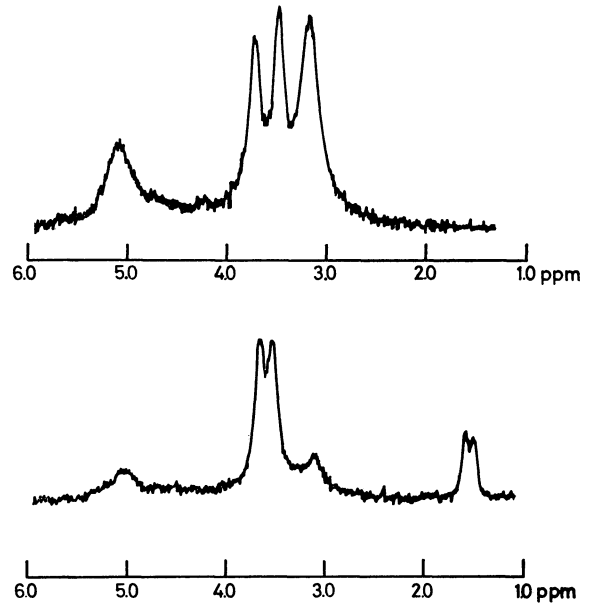

Fig. 1. The PMR spectra of $[Co(NH_3)_4en](NO_3)_3$ (above) and $[Co(NH_3)_4pn](NO_3)_3$ (below) in TFA.

2) H. Yoneda, *ibid.*, **31**, 74 (1958).

TABLE 1. ASSIGNMENTS OF PMR SIGNALS OF $[Co(NH_3)_4en](NO_3)_3$ AND $[Co(NH_3)_4pn](NO_3)_3$ IN TFA MEASURED AT 60MHz (PPM UNIT)

	CH_2CH_2	NH_3		NH_3			
$[Co(NH_3)_4en]^{3+}$	3.18	3.50	3.57	5.10			
	CH_3		CH_2	CH	NH_3		NH_2
$[Co(NH_3)_4pn]^{3+}$	1.50	1.58	3.08	*ca.* 3.33	3.53	3.67	5.0

Interpretation of the PMR Spectra

The PMR spectra of $[Co(NH_3)_4en](NO_3)_3$ and $[Co(NH_3)_4pn](NO_3)_3$ are shown in Fig. 1. The intensity ratios of the PMR signals in these spectra snd the comparison of these spectra with those of $[Co\ en_3]^{3+}$ and $[Co\ pn_3]^{3+}$ complexes lead to unambiguous assignments of these signals, as is shown in Table 1. Both spectra have the NH_3 signal in two separate peaks of equal intensity, which confirms that the complexes prepared are in fact $[Co(NH_3)_4en]^{3+}$ and $[Co(NH_3)_4pn]^{3+}$.

Convenient Synthesis of Chloroiodomethane from Dichloromethane and Sodium Iodide in DMF

Sotaro MIYANO and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai

(Received March 24, 1971)

Organozinc reagent obtained from chloroiodomethane and zinc-copper couple is useful for the synthesis of α-olefins from aldehydes.[1] Chloroiodomethane is usually synthesized from dichloromethane and sodium iodide by refluxing in acetone for several days.[2] The reaction period can be shortened to several hours by the use of an autoclave.[1] However, the procedure is not suitable for a large scale synthesis. It is well known that dipolar-aprotic solvents accelerate S_N2 type reaction remarkably.[3] Suitable solvents and reaction conditions for the synthesis of chloroiodomethane were investigated.

Results and Discussion

Table 1 shows the effect of solvent on the reaction of dichloromethane and sodium iodide. Chloroiodomethane was obtained in only poor yield with acetone, while DMSO, DMF, and HMPA gave much better results. From its availability and the yield of chloroiodomethane, DMF seems to be the most suitable solvent. When the reaction was carried out in DMF for 10 hr, the yield of chloroiodomethane amounted to 83% based on the used sodium iodide, accompanying the formation of 10% of diiodomethane. In the synthetic procedure, pure chloroiodomethane was isolated by distillation in 63% yield, providing a convenient method for the synthesis. In a similar way, bromoiodomethane was also obtained from dibromomethane and sodium iodide.

Table 2 shows that water retards the reaction, presumably because of the solvation of iodide ion. Preliminary experiments have shown that commercially available dichloromethane, DMF, and sodium iodide can be used without significant decrease in the yield of chloroiodomethane.

Table 3 shows the effects of the cation on the yield of chloroiodomethane. The degree of the solvation of cation by DMF seems to decrease in the order Li>Na

TABLE 1. EFFECT OF THE SOLVENT ON THE REACTION OF CH_2Cl_2 AND NaI[a]

Solvent	(ml)	Reaction temp. (°C)	Product Yield[b] CH_2ClI (%)	Product Yield[b] CH_2I_2 (%)
Actone	30	51	2.6	0

Table 2. Effect of water on the reaction of CH_2Cl_2 and NaI[a]

Added water (ml)	Reaction temp. (°C)	Product yield[b] CH_2ClI (%)	Product yield[b] CH_2I_2 (%)
0	55—66	48.0	3.8
0.3	55—64	46.6	3.1
0.6	54—63	38.4	1.9
1.0	54—61	38.9	1.8

a) NaI 0.100 mol, CH_2Cl_2 0.47 mol, DMF 30 ml. Reactions were carried out under gentle reflux for 5 hr.
b) Based on NaI.

>K.[4] This seems to account for the fact that sodium iodide gives a better yield of chloroiodomethane than potassium iodide. On the other hand, the lower yield of chloroiodomethane in case of lithium iodide can be ascribed to an occurrence of the reverse reaction. This is supported by the fact that the reaction of chloroiodomethane with lithium chloride is so fast that only 27% of initial chloroiodomethane is detected after 5 hr.

Table 3. Effect of the cation on the reaction of CH_2Cl_2 and NaI[a]

Alkali Metal Halide	CH_2Cl_2 (mol)	Reaction temp. (°C)	Product yield[b] CH_2ClI (%)	Product yield[b] CH_2I_2 (%)
NaI	0.47	55—66	48.0	3.8
KI	0.47	60—65	32.4	1.5
LiI[c]	0.47	53—58	24.6	1.8
LiCl	0.37 CH_2ClI 0.100	62—59	27.0[d]	1.4[d]

a) Alkali metal halide, 0.100 mol, DMF 30 ml. Reactions were carried out under gentle reflux for 5 hr.
b) Based on alkali metal halide.
c) Contained 0.12 g of water.
d) Based on CH_2ClI initially used.

Experimental

Materials. All solvents were purified by the usual methods before use. Alkali metal halides except for lithium iodide were dried at 150°C for 10 hr under reduced pressure (2mm Hg). Commercial lithium iodide trihydrate was dehydrated at temperatures up to 150°C for 20 hr under reduced pressure. The Vorhard titration showed that the resulting cake contained 91.8% of lithium iodide, the rest appearing to be water. Commercial dihalomethanes were dried with calcium chloride and fractionated before use.

Typical Experimental Procedure. As a typical reaction procedure, the reaction of dichloromethane and sodium iodide in DMF is described. The reaction was carried out in a 100 ml round-bottomed flask equipped with a magnetic stirrer, reflux condenser topped with drying tube, thermometer and dropping funnel. Sodium iodide (15.0g, 0.100 mol) and dichloromethane (40g, 0.47 mol) were placed in the flask and stirred at room temperature. DMF (30ml) was added in about 3 min, whereupon the temperature of the reaction mixture rose from 20°C to 50°C. The reaction mixture became almost homogeneous, but precipitation of sodium chloride was soon observed. After the addition of DMF, the flask was heated to maintain gentle reflux for 5 hr under stirring. At the end of the reaction period, 30 ml of water was added to the chilled reaction mixture. The organic layer was separated, and the aqueous layer was extracted several times with portions of dichloromethane. The combined organic layer was analysed by glc for the determination of resulting chloroiodomethane and diiodomethane using bromobenzene as an internal standard.

Synthesis of Chloroiodomethane. The reaction was carried out according to the same procedure as avobe, except that the reaction scale was 8 times larger, and was continued for 10 hr, during which period, the reflux temperature rose from 51°C to 71°C. The reaction mixture was allowed to stand overnight at room temperature. The content was then steam distilled. The organic layer was separated from the distillate, and washed with several portions of water. The aqueous layer was extracted with CH_2Cl_2, and the extract was washed with water. The combined organic layer was dried with calcium chloride. Distillation through a 20 cm Vigreux column yielded 93.5 g (63% based on NaI) of pure chloroiodomethane boiling at 108—109°C (lit,[2] bp, 108°C). The residue contained chloroiodomethane, DMF, and diiodomethane.

Dibromomethane (82.0 g, 0.472 mol) and sodium iodide (15.0 g, 0.100 mol) was allowed to react in DMF (30 ml) for 5 hr.

A similar work up gave 7.5 g of bromoiodomethane boiling at 138—139°C (lit,[5] bp 137.8—141.2°C), which was contaminated with 3% of diiodomethane (34% yield based on NaI).

Identity of each product was confirmed by comparison of the chemical shift of NMR with that of authentic sample: CH_2ClI, τ, 5.00; CH_2BrI, τ, 5.41 (TMS, 5 mol% solution in CCl_4).

Stereochemical Studies in Friedel-Crafts Reactions. IV. The Reactions of *cis*-1,2-Disubstituted 4-Cyclohexenes with Benzene

Kaichiro SUGITA and Shuzi TAMURA

Department of Chemistry, Ritsumeikan University, Kita-ku, Kyoto

(Received March 26, 1971)

In a previous paper,[1] we reported that the aluminum chloride-catalyzed reactions of benzene with *trans*-1,2-disubstituted 4-cyclohexenes, such as *trans*-2-benzoyl-4-cyclohexene-1-carboxylic acid and its methyl ester and methyl *trans*-2-chloroformyl-4-cyclohexene-1-carboxylate, give stereoselectively *r*-1, *c*-2, *t*-5-trisubstituted cyclohexane in all cases. The present paper will describe two reactions, those of benzene with methyl *cis*-2-chloroformyl-4-cyclohexene-1-carboxylate (**1**) and with *cis*-2-benzoyl-4-cyclohexene-1-carboxylic acid (**3**) in the presence of aluminum chloride.

The reaction of methyl *cis*-2-chloroformyl-4-cyclohexene-1-carboxylate (**1**) with benzene gave methyl *c*-2-benzoyl-*t*-5-phenylcyclohexane-*r*-1-carboxylate (**2**)[1,2] in a 54% yield. In the reaction of *cis*-2-benzoyl-4-cyclohexene-1-carboxylic acid (**3**) with benzene, a carboxylic acid (**4A**) was obtained in an 11% yield. The acid **4A** was converted to *c*-2-benzoyl-*t*-5-phenylcyclohexane-*r*-1-carboxylic acid (**4B**)[1,2] by treatment with sodium ethoxide in ethanol, followed by acidification. This epimerization indicates that the two acids, **4A** and **4B** are stereoisomeric with each other. When **4A** was treated with bromine in acetic acid, the bromine color disappeared, while in the case of **4B** the bromine color did not change under similar conditions.[2] Since the ease of bromination depends on the rates of enolization,[3] the difference in the behavior of **4A** and **4B** should be attributed to the presence of the axial benzoyl group in **4A**. These results support the **4A** structure.

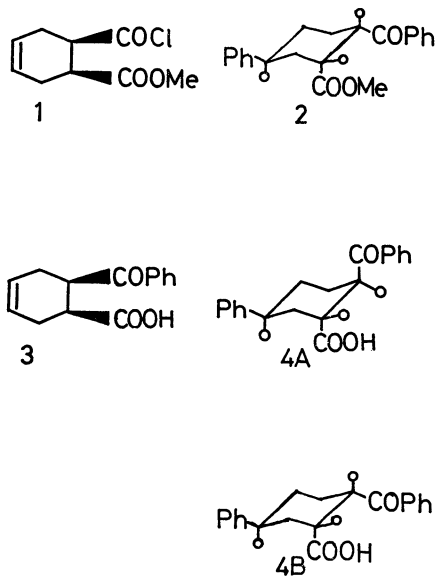

Fig. 1.

Experimental[4]

Material. The *cis*-methoxycarbonyl-4-cyclohexene-1-carboxylic acid was prepared by the procedure reported by Nazarov and Kucherov.[5] The *cis*-2-benzoyl-4-cyclohexene-1-carboxylic acid (**3**) was prepared by the procedure reported by Fieser and Nevello.[6]

Methyl cis-*Chloroformyl-4-cyclohexene-1-carboxylate (1).* A mixture of *cis*-2-methoxycarbonyl-4-cyclohexene-1-carboxylic acid (18 g) and thionyl chloride (18 g) was treated in a manner similar to that described previously. Methyl *cis*-2-chloroformyl-4-cyclohexene-1-carboxylate (**1**) was thus obtained quantitatively. The crude product was used without distillation. IR: (neat) 1795 (acid chloride), 1740 (ester), and 1655 cm^{-1} (olefin). NMR: δ ($CDCl_3$) 2.65—2.25 (m, 4H, $2CH_2$), 3.40—2.85 (m, 2H, 2CH), 3.72 (s, 3H, CH_3), and 5.70 ppm (m, 2H, CH=CH).

Reaction of Methyl cis-*2-Chloroformyl-4-cyclohexene-1-carboxylate (1) with Benzene.* Into a suspension of aluminum chloride (29 g) in dry benzene (90 m*l*) the ester chloride (**1**) (20 g) was vigorously stirred, drop by drop, below 10°C. The stirring was continued for one hour without further cooling and then for five additional hours reflux. Then the reaction mixture was poured onto ice-water. The resulting benzene solution was separated, washed with water, and dried over anhydrous magnesium sulfate. The benzene solution was finally evaporated to dryness. The distillation of the reaction residue gave **2** (17 g, 54%); bp 210—212°C/4 mmHg. The IR and NMR spectra of the ester **2** are identical with those of authentic methyl *c*-2-benzoyl-*t*-5-phenylcyclohexane-*r*-1-carboxylate. (Found: C, 78.59; H, 7.02%).

Reaction of cis-*2-Benzoyl-4-cyclohexene-1-carboxylic Acid (3) with Benzene.* Into a solution of the acid **3** (20 g) in dry benzene (90 m*l*) we stirred aluminum chloride (23 g) over a five-minute period below 10°C; the stirring was then continued for one hour without further cooling and for two hours under reflux. Then the reaction mixture was poured onto ice-water. The resulting benzene solution was separated, washed with water, and dried over anhydrous magnesium sulfate. The benzene solution was finally evaporated to dryness. A crystalline solid was thus obtained (25 g, 82%); mp 105—145°C. Recrystallization from 45% alcohol gave **4A** as colorless

2) K. Sugita and S. Tamura, This Bulletin, in press.
3) H. E. Zimmerman, *J. Org. Chem.*, **20**, 549 (1955).

4) All the melting points and boiling points are uncorrected. The IR spectra were taken on a Hitachi EPI-S spectrometer. The NMR spectra were obtained on a Japan Electron Optics C-60-H spectrometer.

5) I. N. Nazarov and V. F. Kucherov, *Ordel. Khim. Nauk*, **1954**, 329; *cf. Chem. Abstr.*, **49**, 5328 (1955). It is reported that methyl *cis*-2-chloroformyl-4-cyclohexene-1-carboxylate (**1**) was isomerized to a mixture of **1** and methyl *trans*-2-chloroformyl-4-cyclohexene-1-carboxylate under the conditions used for distillation (118—119°C/7 mmHg).

6) L. F. Fieser and F. C. Nevello, *J. Amer. Chem. Soc.*, **64**, 802 (1942).

prisms (3.4 g, 11%); mp 156—157°C. The IR spectra of **4A** is different from that of *c*-2-benzoyl-*t*-5-phenyl-cyclohexane-*r*-1-carboxylic acid (**4B**).[1] The melting point of **4A** was depressed by mixing it with **4B**. IR: (KBr) 2800—2500 (-OH), 1700 (carboxyl), 1680 (ketone) and 1600 cm^{-1} (aromatic). Found: C, 77.83; H, 6.44%. Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%.

*Conversion of **4A** to **4B**.* To a sodium ethoxide solution prepared from absolute ethanol (50 m*l*) and sodium (100 mg), we added **4A** (500 mg). The solution was refluxed for five hours and then cooled. After the subsequent addition of water (100 m*l*) to the reaction mixture, the resulting mixture was acidified and filtered. The precipitates thus collected were washed with water and dried; 450 mg of a white product was thus yielded; 95%; mp 179—181°C. The IR spectrum of the product was identical with those of **4B**. The melting point of the product, without any purification, was not depressed by mixing it with **4B**.

A MO-theoretical Account for the Molecular Structure of the Grignard Reagent

Katsutoshi OHKUBO and Fumio WATANABE

Department of Synthetic Chemistry, Kumamoto University, Kurokami-machi, Kumamoto

(Received April 8, 1971)

Concerning the molecular structure of the Grignard reagent,[1] two representative chemical formulae (RMgX and $R_2Mg \cdot MgX_2$) have been proposed by Ashby[2] and Dessy.[3] However, the structure has not yet been strictly established. In view of the association of the reagent in such a solvent as ether, the structure of the reagent can also be characterized by the following equilibrium:

$$\underset{\text{I}}{(RMgX)_2} \rightleftarrows \underset{\text{II}}{2RMgX} \rightleftarrows$$

$$\underset{\text{III}}{R_2Mg + MgX_2} \rightleftarrows \underset{\text{IV}}{R_2Mg \cdot MgX_2}$$

We intend to clarify which is the most plausible structure among the reagents expressed by the above chemical formulae. The extended Hückel method[4] was applied to the discussion of this feature. For the discussion from the energetic point of view, R and X were taken to be C_2H_5 and Cl respectively.

First, let us discuss the change in the total energy (E_{EH}) of the symmetrical dimer, $(RMgCl)_2$, with the variation in the angle of Cl–Mg–Cl (named by θ) at the fixed distance of Mg–Cl (2.39 Å), together with the variation in the distance of Mg–Cl at the fixed angle ($\theta=90°$). As Fig. 1 indicates, the most energetically stable structure of the symmetrical dimer can be found in the configuration of $\theta=130°$ (Mg–Cl=2.39 Å).

Second, it is of interest to discuss this problem with respect to the structure of the anti-symmetrical dimer, $R_2Mg \cdot MgX_2$. The Mg–Cl distance of 1.80 Å gives the most stable structure of the anti-symmetrical dimer, as may be seen from Fig. 2.

Third, the extended Hückel-MO calculations were also performed on RMgX ($R=C_2H_5$ and X=Br),

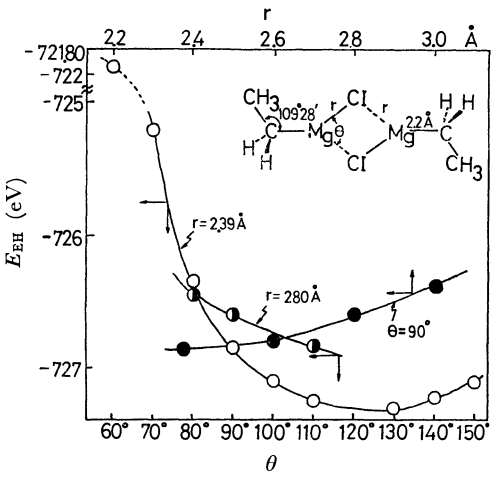

Fig. 1. Changes in the total energy (E_{EH}) of the symmetrical dimer, $(C_2H_5MgCl)_2$. (The bond length of Mg-C was cited from Ref. 8).

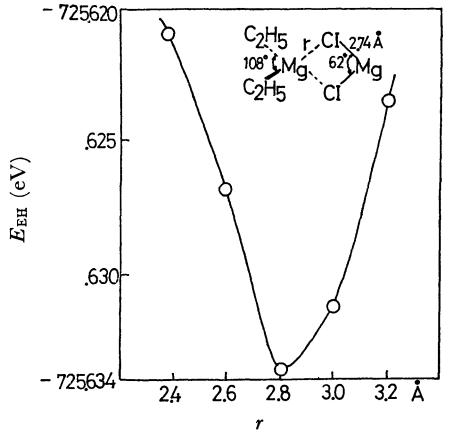

Fig. 2. Change in the total energy (E_{EH}) of the anti-symmetrical dimer, $(C_2H_5)_2Mg \cdot MgCl_2$. (The bond lengths and angles were cited from Ref. 9).

which is considered to take two distinct configurations, *i.e.*, an angular-type RMgX[5] and a linear-type RMgX. These configurations are presented below, together with

1) V. Grignard, *Ann. Chim. Phys.*, **24**, 433 (1901); Grignard has suggested the structure of the reagent by the chemical formula of RMgX.

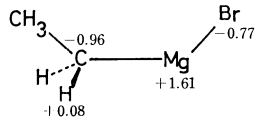
2) E. C. Ashby, *Quart. Rev.* (London), **21**, 259 (1967), and the references cited therein.

3) R. E. Dessy, *J. Org. Chem.*, **25**, 2260 (1960).

4) R. Hoffmann, *J. Chem. Phys.*, **39**, 1397 (1963); *ibid.*, **40**, 2474 (1964). The Coulomb intergrals of Mg are −8.95 eV (for 3*s*) and −4.52 eV (for 3*p*).

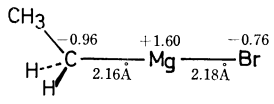
their atomic charges and total energies (E_{EH}).

Angular-type RMgX



$E_{EH}=-359.55$ eV

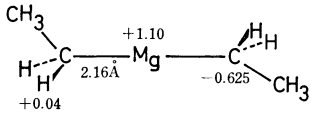
Linear-type RMgX



$E_{EH}=-359.67$ eV

In view of the orientation effect of the solvent surrounding RMgX, the former structure of RMgX seems more possible than the latter one, although the value of E_{EH} in the latter structure is lower than that in the former. Accordingly, the angular-type RMgX ($R=C_2H_5$, X=Cl, and $E_{EH}=-365.11$eV) was adopted for the structure of II.

Finally, we studied the system involving R_2Mg and MgX_2. Their atomic charges and total energies are shown below:



$E_{EH}=-470.05$ eV

$E_{EH}=-258.04$ eV

On the basis of the above discussions, the order of the energetic stability of the Grignard reagents expressed by I, II, III, and IV is as follows: II(−730.22eV)> III(−728.09eV)>I(−727.09eV)>IV(−725.63eV). In other words, the monomer-type structure of II is the most stable and the Schlenk's equilibrium reaction[6] between II and III can be accepted on the basis of some evidence.[7] However, the equilibrium mentioned before can be expected at a low concentration of the Grignard reagent (at least, below 0.3 mol/l). In the case of a high concentration, the reagent is apt to take a dimeric structure in a solvent, in particular in ether. Table 1 indicates the stabilization energy of RMgX as solvated by several solvents. Considering that RMgX exists as a monomer in tetrahydrofuran or triethylamine while, in ether, RMgX is present as a dimer at a high concentration, the number of the molecules interacting with the reagent may be different between the solvents according to the values of E_{EH} listed in Table 1.

Table 1. The stabilization energy (ΔE_{EH}) in the system of RMgX and solvents

RMgX[a] solvated	Mg–O or Mg–N (Å)	∠CMgO or ∠CMgN	ΔE_{EH} (eV)	ΔE_{calcd}[c] (eV)
RMgX monoetherate[b]	2.04	110°	1.13	1.19
RMgX monotetrahydrofuranate	2.04	110°	1.06	—
RMgX monotrimethylaminate	2.1	110°	1.18	0.87

a) R=C_2H_5 and X=Br.
b) Methyl derivative was used for the simplicity of computations.
c) This stands for the stabilization energy estimated from a rough approximation: $\Delta E_{calcd}=e^2(1-1/\varepsilon)/2a$, where a is taken to be 5.0 Å and ε is the dielectric constant of the solvent. The assumed value of 5 Å was estimated from the ionic radii of Mg and Br and van der Waals radius of CH_3CH_2 group.

On the Enantiotropic Transitions in the Phenanthrene Picrate

Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 12, 1971)

Phenanthrene has long been known to form an equimolecular addition compound with picric acid.[1] The presence of an enantiotropic transition at 106°C in this compound was noted by Kofler in 1944.[2] We newly observed the presence of another transition in the phenanthrene picrate. Contrary to the one reported by Kofler, the change from the high-temperature form to the low-temperature one is very slow in the new transition located at 77°C. As ordinary phenanthrene is often contaminated with an appreciable amount of anthracene, the effect of the impurity on the transitions was also examined. As will be described later, a reason why Kofler missed one of the transitions can be proposed on the basis of this examination.

Phenanthrene, Eastman white label, was boiled with maleic anhydride in xylene to remove any anthracene.[3] The picrate crystallized from benzene was mixed with anthracene picrate separately prepared, in various ratios (0.97—10.0 mol%) and then fused together. After annealing at room temperature for three days or longer, the specimens were examined by means of a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C, at a heating rate of 3°C/min. The heats of transition were estimated by comparing the peak areas with that for the transition in hexamethyl-

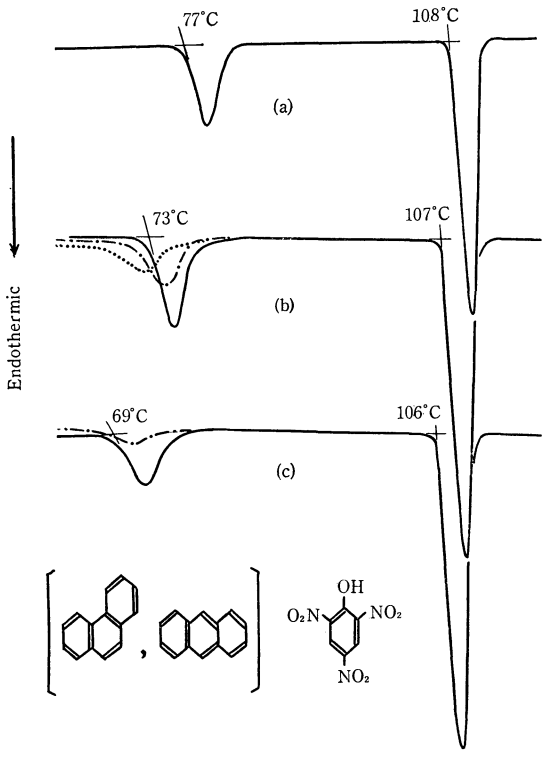

Fig. 1. The DSC thermograms of phenanthrene picrate annealed over one month (—), for one day (····), and for three days (-·-·-): (a) 18.8 mg of the pure specimen, (b) 22.3 mg of the specimen containing 0.97 mol% of anthracene picrate and (c) 22.8 mg of the specimen containing 3.12 mol% of anthracene picrate.

benzene, which is known to take place at 110.6°C with ΔH=0.422 kcal/mol.[4]

The transitions in pure phenanthrene picrate are located at 77°C with ΔH=1.1 kcal/mol and at 108°C with ΔH=3.1 kcal/mol. The first transition cannot be observed in the second run if it is recorded immediately after the first heating. A similarly slow transition has been known to occur in anthracene picrate at about 85°C.[2] As is shown in Fig. 1, both the first and second transition points move to lower temperature upon the addition of anthracene picrate. Although the heat of transition due to the second phase-change stays almost constant up to a 5 mol% addition of anthracene picrate, that due to the first phase-change decreases slightly to 0.8—0.9 kcal/mol in the range of 2—3 mol%. Furthermore, the higher the contamination with anthracene, the slower the rate of the recovery of the low-temperature form. After annealing for three days, which is long enough for pure phenanthrene picrate, the specimens containing 0.97—3.12 mol% anthracene picrate produce a peak area due to the first phase-change much smaller than that obtained after a prolonged annealing. In addition, it must be noted that the peak observed after a partial recovery appears at temperatures lower than that observed after the complete recovery. Above a 5 mol% addition of anthracene picrate, the first phase-change is no longer detectable even after over-one-month storage at room temperature. Thus, not only the magnitude of the heat of the newly-found transition, but also the rate of the recovery of the low-temperature form are very sensitive to contamination with anthracene. From these observations it would appear that the visual examination of this transition employed by Kofler is difficult if the phenanthrene contains anthracene in the order of one mol percent. On the other hand, the second phase-change in phenanthrene picrate remains even in the presence of 10 mol% anthracene picrate. Therefore, it seems likely that the discrepancy between the present observation and Kofler's can be ascribed to the difference in purity of the phenanthrene used.

Electronic Structures of Dialkyl Peroxides

Katsutoshi OHKUBO and Masahide OKADA

Department of Synthetic Chemistry, Kumamoto University, Kurokami-machi, Kumamoto

(Received April 12, 1971)

Dialkyl peroxides (ROOR) have often been postulated as intermediates in hydrocarbon oxidations. The chemical properties of the said peroxides are closely akin to those of alkyl hydroperoxides (ROOH) in terms of the bond-dissociation energies[1] of their O–O linkages and their reactivities to nucleophiles[2] or electrophiles.[3] The bond character of the O–O linkage in ROOR, however, has not yet been established strictly. The present study intends to illuminate the electronic structures of ROOR in connection with those of ROOH by the use of the extended Hückel method.[4]

Calculation Method

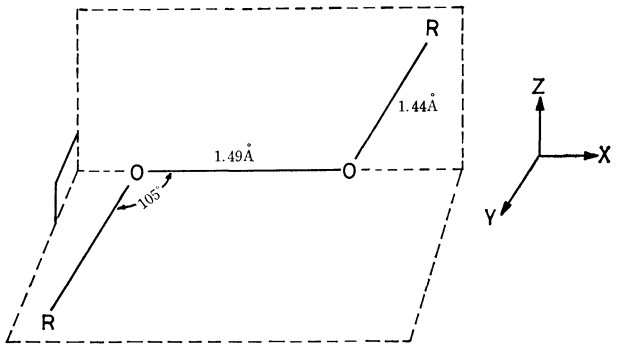
The geometries of ROOR used for the calculations were set up similarly to those of ROOH,[5] as is indicated below:

1) A. D. Kirk and J. H. Knox, *Trans. Faraday Soc.*, **56**, 1296 (1960).

2) For instance, L. S. Silbert, and D. Swern, *J. Amer. Chem. Soc.*, **81**, 2365 (1959); J. K. Kochi, *ibid.*, **85**, 1958 (1963).

3) F. Haber and P. Weiss, *Proc. Roy. Soc.*, London, **A147**, 233 (1939); N. Uri, *Chem. Rev.*, **50**, 375 (1952).

4) R. Hoffmann, *J. Chem. Phys.*, **39**, 1397 (1963); **40**, 2474, 2480, 2745 (1964).



R=H, CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, and t-C_4H_9

The orbital exponents and Coulomb intergrals ($H_{\mu\mu}$) were supplied by Clementi[6] and Jaffé[7] respectively. Especially, as the $H_{\mu\mu}$ values of the oxygen atom, the following values were taken:
$H_{\mu\mu}$(eV)=−36.07 (O 2s) and −15.85(O 2p).
The resonance integrals ($H_{\mu\nu}$) were evaluated by the Wolfsberg-Helmholtz approximation[8]: $H_{\mu\nu}=0.875(H_{\mu\mu}+H_{\nu\nu})S_{\mu\nu}$, where $S_{\mu\nu}$ is the overlap intergral between AO's.

Results and Discussion

First, let us discuss the bond character of the O–O linkage in ROOR. As Table 1 indicates, the bond population of the O–O (M_{oo}) is relatively small, falling in the range, 0.353—0.369. This range of M_{oo} is the same as or slightly smaller than that of ROOH.[5] From this result, it can be deduced that the energy required for the homolytic scission of the O–O linkage (E_{dec}) in ROOR is much the same as that in ROOH; In fact, the observed values are 37.9± 0.4 kcal/mol for the former and 41.1 kcal/mol for the latter, on the average. A parallelism between M_{oo} and E_{dec} could be observed with some exceptions. This close resemblance in the bond character of the O–O linkage between ROOR and ROOH can also be observed in the orbital energy (see Table 1). The lowest unoccupied molecular orbitals (LU MO) of both peroxides are localized in O–O, as is illustrated by the following examples:[9]

$$\varphi^{LU}(RO_\alpha O_\beta R) = 0.823X_\alpha + 0.823X_\beta + 0.207S_\alpha - 0.207S_\beta - 0.132Y_\alpha + 0.016Y_\beta - 0.016Z_\alpha + 0.132Z_\beta + \cdots$$

and

$$\varphi^{LU}(RO_\alpha O_\beta H) = 0.833X_\alpha + 0.813X_\beta + 0.217S_\alpha - 0.201S_\beta - 0.139Y_\alpha + 0.017Y_\beta - 0.009Z_\alpha + 0.145Z_\beta + \cdots$$

where R denotes CH_3. These wave functions show that the LU MO's are mainly the 2p AO's of oxygen atoms.

Table 1. Bond character of the O–O linkage and orbital energies in dialkyl peroxides (ROOR)

ROOR (R)	M_{oo}	N_{oo} ($p\sigma$)	Orbital energy (eV) HO	Orbital energy (eV) LU	E_{dec}[a] (kcal/mol)

e) Cited from J. Murawski, J. S. Roberts, and M. Szwarc, *J. Chem. Phys.*, **19**, 698 (1951).
Values in parentheses stand for those in ROOH.

Next, let us examine the reactivity of ROOR to nucleophiles or electrophiles. The LU MO and the HO MO play an important role in weakening the O–O linkage by means of interaction with nucleophiles and electrophiles respectively. The LU MO is strongly localized in the O–O linkage, as has been mentioned before, and has an antibonding character with respect to the O–O bond, whereas the HO MO is occupied predominantly by the nonbonding oxygen orbitals. Consequently, nucleophiles attack ROOR in the direction of the O–O axis, while electrophiles approach the nonbonding oxygen orbital expansion from the opposite side of R.

As the reactivity indices we employed the value of

the partial AO bond population of the antibonding $p\sigma$-orbital of the O–O in the LU MO, $\frac{1}{4}N_{P\sigma}^{LU}$, and that of the partial AO population of the nonbonding oxygen orbital in the HO MO, $\frac{1}{2}N_{nbo}^{HO}$, both of which are given in Fig. 1. A presumption can be made that the reactivity of ROOR to nucleophiles or electrophiles lessens with the bonding of the larger alkyl groups to the O–O.

Finally, it is of interest to compare the reactivity indices to nucleophiles in ROOR with those in ROOH. Three alkyl hydroperoxides selected for the sake of comparison, CH_3OOH, n-C_3H_7OOH, and t-C_4H_9OOH, have the following values of $-N_{P\sigma}^{LU}$: -0.1547, -0.1539, and -0.1528 respectively. On the basis of the facts derived above, we may conclude that ROOH is more reactive than ROOR to the nucleophilic attack.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2871—2873 (1971)

Direct Iodination of Trimethylbenzoic Acids and Tetramethylbenzoic Acids with Iodine-Periodic Acid[1]

Hitomi SUZUKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

No report seems to be found in literature on the preparation and properties of iodotrimethyl- and iodotetramethylbenzoic acids. In view of the high propensity for iodine atom to undergo displacement, an attempt to introduce carboxylic group into the nucleus of reactive iodopolymethylbenzenes seems to be practically meaningless. The commonly used indirect method wihch involves the replacement of amino group by iodine atom is unsuitable in the present case, since most of the required polymethylaminobenzoic acids are unknown and not readily available. In previous papers,[2,3] *iodine used with periodic acid* has been proposed as a convenient iodinating agent for polyalkylbenzenes because of the simple procedure, excellent yield, and high purity of products. Although the reagent has not been used extensively for the iodination of polyalkyl compounds other than hydrocarbons, satisfactory results recently obtained with less activated compounds, such as halopolyalkylbenzenes and halobiphenyls,[4] seem to promise a successful use of this reagent for one-step synthesis of iodopolymethylbenzoic acids from the corresponding polymethylbenzoic acids. Thus, some trimethylbenzoic acids and tetramethylbenzoic acids were treated with the above reagent in aqueous acetic acid containing a small amount of sulfuric acid as catalyst.

Trimethylbenzoic acids were readily iodinated with iodine-periodic acid to give the monoiodo derivatives in a high yield of 85% or higher. General character of the reaction suggests an ionic scheme, with the ease of iodination in the decreasing order 2,4,6>2,4,5> 2,3,4~2,3,6> 3,4,5-trimethylbenzoic acid. 2,4,5-Trimethylbenzoic acid gave almost exclusively 3-iodo-2,4,5-trimethylbenzoic acid. 5-Iodo-2,3,4-trimethylbenzoic acid was obtained from 2,3,4-trimethylbenzoic acid. The meta position to the carboxylic group was in every case preferred to ortho position. The position occupied by iodine atom in these systems was established by spectral comparison with the chloro or bromo analogs. Replacement of chlorine or bromine atom by iodine atom led to only a slight change in the general patterns of infrared and PMR spectra of these compounds.

With the use of excess reagent, 2,4,6-trimethylbenzoic acid (mesitoic acid) was readily converted into 3,5-diiodo-2,4,6-trimethylbenzoic acid, but diiodination of other isomeric acids was quite slow and usually accompanied by an appreciable extent of iododecarboxylation, giving diiodotrimethylbenzenes as an alkaline-insoluble part. 2,4,5-Trimethylbenzoic acid was especially hard to be diiodinated.

Iodination of tetramethylbenzoic acids proceeded with much ease. Of three isomeric acids, 2,3,4,6-tetramethylbenzoic acid was the most reactive, followed by 2,3,5,6-tetramethylbenzoic acid and 2,3,4,5-tetramethylbenzoic acid. The reaction was also subjected to iododecarboxylation to some extent, although iodotetramethylbenzoic acid was stable towards further action of the reagent (Fig. 1).

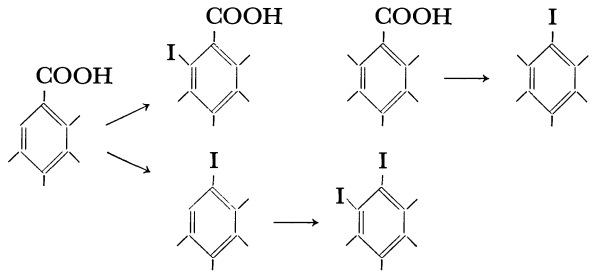

Fig. 1

In order to find a substitutional process on the alkyl side-chain, pentamethylbenzoic acid was treated with the above iodinating agent. The fully methylated benzoic acid readily underwent iodination to give a white crystalline solid, which, however, contained no acidic function and proved to be identical with iodopentamethylbenzene by direct comparison with the authentic specimen (Fig. 1). Spectral inspection of

the crude reaction product had no indication of the side-chain substitution.

All the iodotrimethylbenzoic acids, diiodotrimethylbenzoic acids and iodotetramethylbenzoic acids are well crystallized solids with high melting points. They dissolve very slightly in light petroleum, benzene, carbon tetrachloride, and cold aqueous ethanol, and are moderately or readily soluble in hot ethanol, dioxane and tetrahydrofuran. Some physical properties of these iodopolymethylbenzoic acids are summarized in Table 1.

Experimental

2,4,6-Trimethylbenzoic acid (mesitoic acid), 2,4,5-trimethylbenzoic acid, and three isomeric tetramethylbenzoic acids were prepared by the Friedel-Crafts carboxylation of the corresponding hydrocarbons with oxalyl chloride.[5,6] A similar treatment of 1,2,3-trimethylbenzene gave a mixture of 2,3,4-trimethylbenzoic acid and 3,4,5-trimethylbenzoic acid. Fractional crystallization of the product mixture from aqueous ethanol gave the former acid as a more soluble and the latter acid as a less soluble part. 3,4,5-Trimethylbenzoic acid was also prepared by the oxidation of 3,4,5-trimethylacetophenone with sodium hypochlorite.[7] 2,3,6-Trimethylbenzoic acid was obtained by carbonation of the Grignard reagent from 3-bromo-1,2,4-trimethylbenzene.[8] Pentamethylbenzoic acid was prepared from hexamethylbenzene through side-chain nitrooxylation followed by potassium permanganate-pyridine oxidation.[9]

Infrared spectra were measured on Nujol mulls with a Jasco 402G spectrophotometer and only prominent peaks are recorded. PMR spectra were determined in dioxane solutions with a JEOLCO 3H-60 spectrometer against internal TMS.

Procedure for the Iodination of Polymethylbenzoic Acids. The general procedure is illustrated below by the reaction of mesitoic acid.

3-Iodo-2,4,6-trimethylbenzoic Acid (Iodomesitoic Acid). A mixture of mesitoic acid (4.1 g), iodine (2.55 g), periodic acid dihydrate (1.14 g), and 80% acetic acid (40 ml) containing catalytic amounts of sulfuric acid was heated with stirring at 70—75°C for about 15—20 min until the color of iodine disappeared. After cooling, water was added and the crystalline deposit was collected. The crude product was dissolved into aqueous sodium hydroxide and any trace of

insoluble by-product was removed over decolorizing charcoal. The clear filtrate was made acidic with concentrated hydrochloric acid and the precipitate was collected, thoroughly washed with water, and crystallized from aqueous ethanol to give *iodomesitoic acid* as colorless fine needles, mp 196—197°C. Yield, 6.2 g (86%).

When mesitoic acid was treated with twice the amount of the reagent under the same conditions, white crystals soon deposited from the mixture. They were collected and crystallized from aqueous ethanol to yield *diiodomesitoic acid* in 78% yield. Colorless large leaflets, mp 242—243°C.

Iododecarboxylation of Pentamethylbenzoic Acid. Pentamethylbenzoic acid (3.2 g) was suspended in 80% aqueous acetic acid (40 m*l*) containing a small amount of sulfuric acid as catalyst, and treated with iodine (1.7 g) and periodic acid dihydrate (0.75 g) in a similar manner as above. After several hours, iodine was mostly consumed and white crystalline powder deposited from the solution. It was filtered and crystallized from dilute ethanol to give colorless prisms (3.8 g), mp 139—141°C. It was identified as iodopentamethylbenzene (mp 141—142°C)[10] by direct comparison with the authentic specimen. IR: 901, 996, 1010, 1060, and 1197 cm^{-1}. PMR (CCl_4): 7.95 (Me), 7.86 (2 Me), and 7.63τ (2 Me).

The Oxidation of Phenols by Potassium Disulfonate Nitroxyl

Kazuhiro MARUYAMA and Tetsuo OTSUKI

Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Sakyo-ku, Kyoto

(Received April 30, 1971)

The oxidation of phenols is one of the most stimulating subjects in the chemical and biochemical fields. When potassium disulfonate nitroxyl (Fremy's salt; $\cdot ON(SO_3K)_2$)[1] is used as an oxidizing agent, phenols are oxidized to produce benzoquinones in high yields. Teuber and his co-workers[2] have investigated the reaction through product analysis, but no details on the reaction mechanism have been published. The reaction is characteristic in that benzoquinones (*i.e.*, *o*-benzoquinones and *p*-benzoquinones) are produced exclusively, accompanied by no coupling products, and the yields are relatively high. Moreover, whereas *p*-benzoquinones are selectively produced when the para position of phenols is not occupied by any substituents, *o*-benzoquinones are the sole products in high yields when the para position is substituted.

Because of our interest in this high selective oxidation of phenols by Fremy's salt, we attempted to elucidate the reaction mechanism.

Results and Discussion

We will now investigate the relative reactivity of phenols to Fremy's salt. The substrates examined here are phenols with no substituents at the position para to their hydroxyl group, such as phenol, 2-methylphenol, 3-methylphenol, 2,5-dimethylphenol, 2,6-dimethylphenol, 2-*t*-butylphenol, 2,6-di-*t*-butylphenol, 2-chlorophenol, and 2-nitrophenol.

The course of the reaction and the subsequent spectrophotometric determination of *p*-benzoquinones produced are depicted in Fig. 1. The amount of *p*-benzoquinones produced 10 min after the beginning of the reaction is determined as a measure of the relative rates of the oxidation of phenols (Table 1).

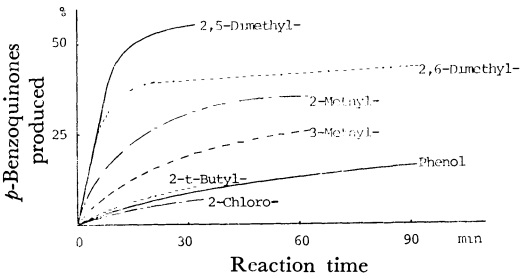

Fig. 1. Relative oxidation rates of phenols.

TABLE 1. RELATIVE REACTIVITIES OF PHENOLS AND THEIR NMR CHEMICAL SHIFT OF HYDROXYL PROTONS

Phenols	*p*-Benzoquinones	Yields after 10 min (%)	Chemical shift of OH[a] (ppm)
Phenol	*p*-Benzoquinone	4	4.31
2-Methyl-	2-Methyl-	19	4.33
3-Methyl-	2-Methyl-	9	4.21
2,5-Dimethyl-	2,5-Dimethyl-	44	4.22
2,6-Dimethyl-	2,6-Dimethyl-	35	4.30
2-*t*-Butyl-	2-*t*-Butyl-	5	4.47
2,6-Di-*t*-butyl-	no reaction		4.96
2-Chloro-	2-Chloro-	3	5.38
2-Nitro-	no reaction		10.57

a) The values are measured in infinite dilution with CCl_4.

From these results, it can be deduced that the rate of this reaction is enhanced by electron-donating substituents and that it is depressed with strong electron-withdrawing substituents, such as the nitro group. 2-Nitrophenol, for instance, is not oxidized and is recovered quantitatively after being treated with Fremy's salt for 30 min. When the reaction rates of monomethylphenols are compared with those of di-

2) a) H. J. Teuber and G. A. Jellinek, *Chem. Ber.*, **85**, 95 (1952). b) H. J. Teuber and W. Rau, *ibid.*, **86**, 1036 (1953).

methylphenols, dimethylphenols such as 2,5-dimethylphenol and 2,6-dimethylphenol are found to be more reactive than monomethylphenols. According to Teuber and Rau,[2b] 2-chlorophenol could not be oxidized to 2-chloro-*p*-benzoquinone by Fremy's salt. However, in this work, 2-chlorophenol is found to be oxidized to the corresponding *p*-benzoquinone, although the reaction rate is considerably slow, because of the electron-withdrawing nature of the chlorine atom.

Although the reaction rate of 2-*t*-butylphenol is nearly the same as that of non-substituted phenol, 2,6-di-*t*-butylphenol is not oxidized under the same conditions. That is; the reaction rate of phenols with the *t*-butyl group at the *o*-position is rather slower than would be expected only from the above-mentioned electronic effects. The observed effect of the *t*-butyl group may be explained as the steric hindrance to the attack of the reagent on the hydroxyl group in phenols.

The molar ratio of phenols to Fremy's salt varies from 0.4 to 4.0. Within this range, the reaction rate is changed linearly with the molar ratio. The reaction between phenols and Fremy's salt can thus be described as follows:

$$\text{Rate} = k[\text{Phenols}][\text{Fremy's salt}]$$

$k = 2.01 \times 10^{-2}$ *l*/mol·sec for 2,6-dimethylphenol at 0°C

On the other hand, the decay of Fremy's salt in the reaction system was followed by using ESR spectroscopy, as is shown in Fig. 2. The peak height of the ESR absorption signal is proportional to the concentration of Fremy's salt, because the ESR absorption signal of Fremy's salt has the same half-height width at every stage of the reaction. Thus, in view of the decay rate of the peak height of the ESR absorption signal, Fremy's salt in the reaction system decreases in first order to time. This result is also in good agreement with the rate equation presented above.

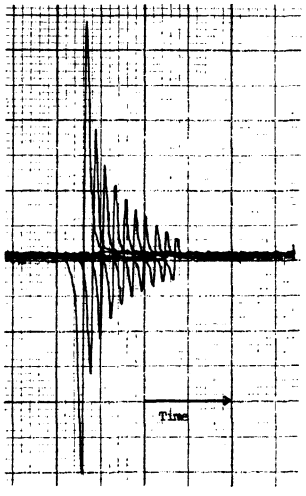

Fig. 2. Decay of Fremy's salt in its reaction with 2,6-dimethylphenol. Time interval; 170 sec

These results indicate that the electrophilic attack of Fremy's salt on phenols is the rate-determining process in this reaction. As a matter of fact, the steric factor of the substituents to the hydroxyl group of phenols should be considered at the same time. Moreover, whether or not the reaction proceeds is well correlated with the NMR chemical shift of the hydroxyl proton and, consequently, with the acidity of phenols. The NMR chemical shifts of the hydroxyl protons are shown in Table 1. Considering from the NMR data, the fact that 2-nitrophenol is not oxidized may be explained by its high acidity.

In the reaction described above, no coupling products were isolated, and the ESR spectra of free phenoxy radicals could not be observed. Thus, no free phenoxy radicals with a fairly long lifetime may exist under those reaction conditions; that is, the phenoxy radicals produced decay too rapidly to establish their existence by ESR spectroscopy. These results also indicate that the rate-determining process may be the stage of the first attack of Fremy's salt on phenols.

The decay of Fremy's salt, as followed by ESR measurements, is considerably fast if the phenols have no substituent on the *o*- and/or *p*-position to their hydroxyl group, such as 2,6-dimethylphenol. In the case of 2,4,6-trimethylphenol, however, the decay of Fremy's salt is rather slow. Although the ESR spectra of free phenoxy radicals could not be observed at any stage of the reaction, the ESR spectra corresponding to Fremy's salt are broadened and the coupling constant due to nitrogen, a_N, becomes slightly smaller than that of free Fremy's salt (Fig. 3). The above-mentioned

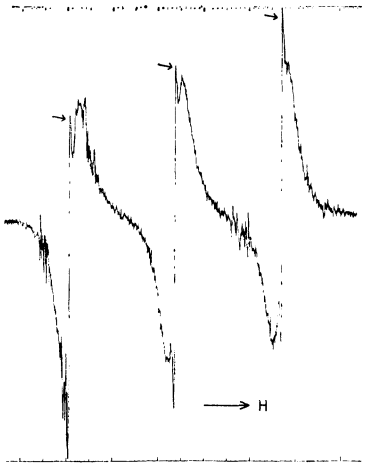

Fig. 3. ESR spectra observed in the reaction of 2,4,6-trimethylphenol with Fremy's salt. Three lines indicated by arrows are due to free Fremy's salt as an external standard.

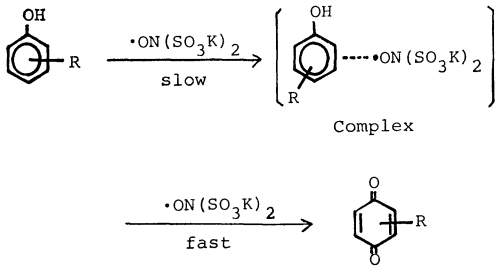
deformation may be ascribed to a complex formation between Fremy's salt and 2,4,6-trimethylphenol. Considering a_N, some part of the free spin of Fremy's salt may be delocalized onto 2,4,6-trimethylphenol, thus making a labile molecular complex. In the case of phenols with free *o*- and/or *p*-positions, therefore, the formation of such a complex would make the subsequent attack of Fremy's salt easier than the first attack on phenols; this would be the origin of the high selectivity of this reaction.

Considering the above results, the course of the reaction may be described as follows:

Table 2. Physical properties of *p*-benzoquinones

p-Benzoquinones	Mp (°C)	$\lambda^{a)}$ (nm)	ε ($CHCl_3$)	Chemical shift (CCl_4)	
				Substituents (ppm)	Benzene ring (ppm)
p-Benzoquinone	111	437	20.4	—	6.70
2-Methyl-	66	436	28.2	2.05	6.50—6.70
2,5-Dimethyl-	123—124	430	27.0	2.03	6.50—6.60
2,6-Dimethyl-	71	430	42.5	2.04	6.48
2-*t*-Butyl-	53	440	24.0	1.28	6.50—6.65
2-Chloro-	55	415	24.0	—	6.75—6.95

a) The wavelength used for determination for *p*-benzoquinones.



Experimental

2.5×10^{-3} mol of Fremy's salt[1] was dissolved into 50.0 m*l* of water buffered with sodium acetate (pH 8.2), after which the solution was cooled to about 2°C. To the solution, 1.0×10^{-3} mol of phenols dissolved in 2.0 m*l* of ether was then added all at once (0—3°C). After the reaction had stopped, the products were separated by using TLC and were determined spectroscopically. The physical properties of *p*-benzoquinones thus produced are shown in Table 2. An ME-3X-type ESR spectrometer with 100 kHz modulation was used in this experiment.

Mechanism of the Oxygen Exchange Reaction of Diaryl Sulfoxides in Hydrochloric Acid[1]

Hiroshi YOSHIDA,* Tatsuo NUMATA, and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received May 4, 1971)

Mislow *et al.*[2] showed that sulfoxides undergo stereomutation together with oxygen exchange in hydrochloric acid-dioxane media. While the rate of oxygen exchange of *p*-tolyl phenyl sulfoxide was equal to that of racemization, the rate of racemization was found to be affected markedly by the steric requirement of the group attached to the central sulfur atom. The rate-determining step of the reaction was assumed to be the interconversion of the enantiomorphic chlorosulfonium chloride to the other.

Landini *et al.*[3] studied the acid-catalyzed stereomutation of sulfoxides with chloride ion and found that the rate of racemization of *p*-tolyl methyl sulfoxide was accelerated by the increase of chloride ion concentration in aqueous perchloric acid media, while the logarithms of the rates of racemization were nicely correlated with the Hammett acidity function (*Ho*). They suggested that the rate-determining step of the reaction is the formation of chlorosulfonium salt.

The two investigations seem to deal with the same reaction system. However, there is a disagreement as to the rate-determining step of the reaction. In order to correlate the two investigations and to find the rate-determining step of the oxygen exchange and racemizations of sulfoxide with hydrochloric acid, and also to confirm the importance of the steric effect of this reaction, we have carried out a kinetic study on the oxygen exchange and racemization reactions of both ^{18}O-labeled and optically active *p*-tolyl phenyl sulfoxide, and also a more sterically hindered *p*-tolyl mesityl sulfoxide in 3.93N HCl in 80% dioxane-water mixture. We also reinvestigated the correlation of the rates of racemization of both sulfoxides with the Hammett acidity function (*Ho*). The rates of racemization of both sulfoxides were determined in hydrochloric acid with various concentrations of hydrogen chloride in 80% dioxane-water solution, and the logarithms of k_{rac}/[HCl] were plotted against the Hammett acidity function (*Ho*). Strainght lines with a slope 0.80 and 0.81 were obtained for *p*-tolyl phenyl and *p*-tolyl mesityl sulfoxides, respectively, as shown in Table 1.

a) Sulfoxide; 0.1 mol/*l*; *p*-Tol=*p*-$CH_3C_6H_4$
b) E_a=15.4 kcal/mol $\Delta S^{\ddagger}$=−23.3 *e.u.*
c) E_a=15.8 kcal/mol, $\Delta S^{\ddagger}$=−30.9 *e.u.*

This means that the protonated species are involved in the transition state of the reaction, indicating that the reaction is of the A-1 type mechanism according to Zucker-Hammett's hypothesis.[4]

The rates of oxygen exchange of both sulfoxides in 3.93N hydrochloric acid were determined. The results are listed in Table 2 together with rates of racemization.

Table 2. Kinetic data of oxygen exchange and racemization reactions of *p*-Tol-S(O)Ar[a] at 25°C

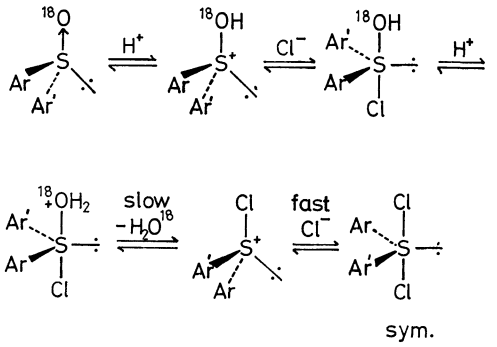
Ar	$10^6k_{ex}(sec^{-1})$	$10^6k_{rac}(sec^{-1})$	k_{ex}/k_{rac}
Phenyl	326	276	1.18
Mesityl	1.55	1.25	1.24

a) Sulfoxide; 0.1 mol/*l*

The results reveal that the rate of oxygen exchange is nearly the same as that of racemization in both cases. This means that the two reactions share a common rate-determining step which is presumed to be the A-1 type S-O bond cleavage in view of the Hammett acidity correlation.

The rate of oxygen exchange of *p*-tolyl mesityl sulfoxide was about 210 times smaller than thet of *p*-tolyl phenyl sulfoxide. The marked rate retardation by the *ortho* substituents is for the most part due to the difference in the activation entropies of racemization reactions of both sulfoxides (Table 1). This is steric hindrance at either one of the two conceivable steps or both steps of the reactions; namely, the nucleophilic attack of chloride ion at the sulfur atom of the hydroxysulfonium salt to form the chlorosulfonium intermediate and the prior second protonation to form the diprotonated species. The steric hindrance for the double protonation was suggested to be responsible for the substantial retardation of the rates of racemization of *p*-tolyl mesityl sulfoxide in concentrated sulfuric acids.[5]

The fact that the rate of HCl-catalyzed racemization is markedly greater than that of H_2SO_4 catalyzed reaction suggests that the attack of chloride ion facilitates the S-O bond cleavage in the rate-determining step. We have found that the acid-catalyzed oxygen exchange and racemization reactions in concentrated sulfuric acids is markedly accelerated by the addition of chloride ion.[6] A plausible scheme of the oxygen exchange reaction of sulfoxide in hydrochloric acid can be illustrated as follows.



The reaction seems to proceed through the nucleophilic attack of chloride ion at the sulfur atom of protonated sulfoxide, followed by the rate-determining S-O bond cleavage to afford an unstable chlorosulfonium intermediate.

The subsequent step of either the formation of sulfonium dichloride or the hydrolysis of chlorosulfonium salt should be very fast.

Experimental

Optically Active Sulfoxides and ^{18}O*-Labeled* p-*Tolyl Phenyl Sulfoxide* were synthesized in the usual procedure as described.[5a]

^{18}O*-Labeled* p-*Tolyl Mesityl Sulfoxide* was prepared from the ^{18}O-labeled methyl *p*-toluenesulfinate with the Grignard reagent of mesityl bromide in tetrahydrofuran. 55% yield mp 75—77°C.

The Values of Ho were determined with *p*-nitro, *o*-chloroaniline as an indicator in UV spectrometry by the method of Jorgenson and Harter.[7]

Kinetic Procedures of Oxygen Exchange and Racemization Reaction. The procedures were similar as those described previously.[8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2877 (1971)

Basicities of Formamide, Acetamide, and Their Alkyl Derivatives in Aqueous Solution

Goro WADA and Takako TAKENAKA

Department of Chemistry, Nara Women's University, Nara

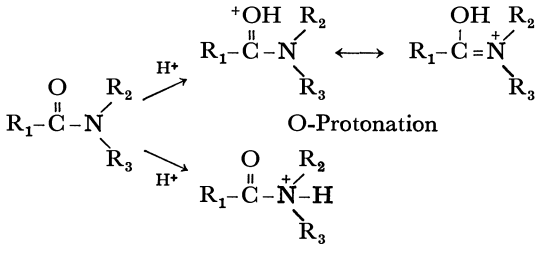
(Received May 10, 1971)

The basicity constants pK_a of formamide, acetamide and their alkyl derivatives, generally represented by $R_1CONR_2R_3$ where R_1, R_2, and R_3 stand for H, CH_3, C_2H_5, CH_2Cl, or $CHCl_2$ respectively, were measured in aqueous solution spectrophotometrically,[1] using *o*-nitroaniline as indicator. Measurements were carried out at 25°C for wavelengths of 380, 410, and 440 nm, and ionic strength of μ=0.55M. The acid dissociation constant of *o*-nitroaniline, $K_{In}=[H^+][In]/[HIn^+]$, was taken to be 1.27M.[1]

The results of the determination of pK_a related to various amides are listed in Table 1, together with the values of their donor numbers $DN(SbCl_5)$[2] and dielectric constants D. The thermodynamical constants pK_a^0 can be approximately estimated by the following equation.

$$pK_a^0 = pK_a - 0.5\sqrt{\mu}$$

According to recent NMR studies,[3] the protonation of most amides was found to occur predominantly at O-atom and not at N-atom, as revealed by the fact that the double bond character between C and N atoms and the barrier to rotation around the C–N bond increase with the protonation of amides.[4] The nature of amides is thus acidic and far less basic than ammonia and alkylamines.



Alkylamines usually exhibit pK_a values 9—11, in remarkable contrast to -0.1 ± 0.2 as the mean value of pK_a^0 of the nine amides in Table 1. The values of pK_a^0 of some amides given in Table 1 were separately measured by potentiometric titration with perchloric acid in acetic scid with chloranil electrode and coincide well with our results within the mean discrepancy ±0.4[5]

Although the pK_a does not seriously vary with the substitution of H by alkyl radicals in both formamide and acetamide, there is a slight tendency for pK_a to grow higher as R_2 or R_3 changes in the direction H→ CH_3→C_2H_5. The effect of chlorine atom in R_1 in acetamide upon pK_a is distinct, making the compound less basic. No close relationship of pK_a with the donor numbers and the dielectric constants is noticed, as far as our data are concerned.

TABLE 1. BASICITY CONSTANTS, DONOR NUMBERS AND DIELECTRIC CONSTANTS OF VARIOUS AMIDES

Compound	R_1	R_2	R_3	pK_a	pK_a°	DN ($SbCl_5$)	D
Formamide	H	H	H	0.12	−0.25		109

Effect of the Number of Sulfur Atoms on the Chemical Shifts of Mercapto Protons in Aralkyl Hydropolysulfides

Shunichi KAWAMURA, Toyokazu HORII, and Jitsuo TSURUGI
Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

(Received May 25, 1971)

Chemical shift of group X in organic polysulfides $X(S)_nY$ has been observed to be sensitive to the character of far distant group Y and the number of sulfur atoms.[1-5] This phenomenon is useful for the analyses of polysulfide mixtures.[2-4] However, little information is available on protons directly attached to sulfur except for that on sulfanes[6] [$H(S)_nH$]. We wish to report on the PMR study on aralkyl hydropolysulfides [$R(S)_nH$, n=1—3].

TABLE 1.[a] CHEMICAL SHIFTS OF $R(S)_nH$ (n=1—3)

No.	R	Thiols, RSH	Hydrodisulfides, RSSH	Hydrotrisulfides, RSSSH
1	$C_6H_5CH_2$	1.51[b]	2.74[d]	3.38
2	$(C_6H_5)_2CH$	2.05[b]	2.72[d]	3.17
3	$(C_6H_5)_3C$	2.90[c]	2.48	2.63

a) Values are in δ ppm, 7 w/w% in CCl_4. All SH peaks of course disappear by addition of D_2O. In benzyl and benzhydryl hydrodisulfides, each singlet peak accompanies beats, from which long range coupling constants with methylene or methine proton, J=0.4 and 0.6 Hz, are estimated. In hydrotrisulfides, peaks are singlet.
b) J. Tsurugi, T. Horii, T. Nakabayashi, and S. Kawamura, *J. Org. Chem.*, **33**, 4133 (1968).
c) J. Tsurugi, Y. Abe, T. Nakabayashi, S. Kawamura, T. Kitao, and M. Niwa, *ibid.*, **35**, 3263 (1970).
d) S. Kawamura, Y. Abe, and J. Tsurugi, *ibid.*, **34**, 3633 (1969).

Table 1 shows the PMR data obtained for dilute carbon tetrachloride solutions; chemical shifts of sulfhydryl groups of thiols, hydrodisulfides and hydrotrisulfides, in which R groups are the series of benzyl, benzhydryl and triphenylmethyl. Fig. 1 presents a graphical explanation of the results. In thiols, the chemical shift of benzhydryl compound is in a lower field than that of benzyl, triphenylmethyl being in the lowest, whereas a reverse relation is noted in hydrotrisulfides. As to the triphenylmethyl derivatives, their chemical shifts are not lowered with the increase of the number of sulfur atoms.

We see that at least two factors are required for explanation of the relation of the chemical shifts. One which clearly originates from the length of sulfur chain is anisotropy or inductive effect by sulfur atoms, and the other anisotropy and/or inductive effect of R group. In the PMR study of alkyl polysulfides or analogous compounds, Van Wazer and Grant[1] reported on C_y and C_z values (These are defined as follows; for the molecule $X(S)_nY$, C_y is the shift contribution of the terminal group Y separated from the group X, containing the magnetic nucleus, by n sulfur atoms, and C_z is the shift contribution of each sulfur atom.), which is calculated based on the theory for so-called "neighbor anisotropy effect." For our data, a similar calculation is possible.[7] In Table 2 are cited C_y values for each aralkyl group and C_z. The relation of the chemical shifts to calculated curves is also shown in Fig. 1.

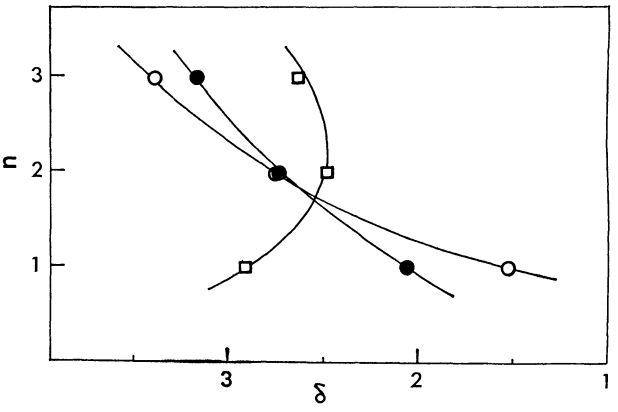

Fig. 1. Relationship between the chemical shifts and the number of sulfur atoms(n).
○ $C_6H_5CH_2(S)_nH$ ● $(C_6H_5)_2CH(S)_nH$ □ $(C_6H_5)_3C(S)_nH$
—— Calculated curve

7) C_y and C_z values were obtained by computer-programmed calculation. The computation was performed by the least mean square method, using the following linear equation,

$$\Delta\delta = C_y(1)\cdot U_1(n) + C_y(2)\cdot U_2(n) + C_y(3)\cdot U_3(n) + C_z\cdot V(n) \quad (1)$$

where $\Delta\delta=\delta_2-\delta_n$, and $C_y(1)$, $C_y(2)$, $C_y(3)$ and C_z correspond to coefficients which designate the magnitudes of neighbor anisotropy effects of benzyl, benzhydryl, and triphenylmethyl groups, and of sulfur atom, respectively. Variables $U_i(n)$ and $V(n)$ which are the functions of the number of sulfur atoms n are derived from the Van Wazer's equation;[1]

$$U_i(n) = 1/R_{n+1}^3 - 1/R_3^3$$

$$V(n) = \sum_{j=1}^{n} 1/R_j^3 - \sum_{j=1}^{3} 1/R_j^3$$

where R denotes the distance between the center of contributing group or atom and the nucleus in question, which is obtained by the random-flight calculation. In Eq. (1), $U_i(n)$ is taken as zero, except when the chemical shifts of a series of compounds are referred to. As an example, when the value of $\Delta\delta$ of α-toluenethiol, 2.74 −1.51=1.23, is replaced in Eq. (1), one would obtain $1.23=C_y(1)\cdot U_1(1)+0.0+0.0+C_z\cdot V(1)$.

Table 2. Anisotropic parameters for R(S)H (n=1—3)

No.	R	C_y	C_z
1	$C_6H_5CH_2$	−8.0	−9.7
2	$(C_6H_5)_2CH$	−12	−9.7
3	$(C_6H_5)_3C$	−21	−9.7

The large negative C_z value in Table 2 means that divalent sulfur atoms markedly deshield the directly attached neighboring protons. The fact that the value of C_y is also negative and increases in its absolute value with the number of benzene nucleus in the aralkyl group may imply that the sulfhydryl proton is mainly present near the plane of benzene nucleus. The reverse winding of the curve for triphenylmethyl series in Fig. 1 or the large negative C_y value of triphenylmethyl group compared with that of benzyl or benzhydryl, seems to suggest a sterically significant relation. In benzyl or benzhydryl derivatives, sulfhydryl protons have the chance to project over the surface of benzene nuclei. On the other hand, an extremely restricted rotation of benzene nuclei in triphenylmethyl groups diminishes the possibility, or the bulky groups prevent the real random-flight motion, and chemical shifts might be much lowered.

Van Wazer's equation gives an excellent fit for the relative position of the chemical shifts, but does not determine their absolute values. Therefore, some other effects such as the inductive effect should be taken into consideration to elucidate the fact that the chemical shift of diphenylmethanethiol is lower than that of α-toluenethiol, *etc.*

Experimental

PMR spectra were taken on a JNM 3H-60 spectrometer with tetramethylsilane as an internal standard (7 w/w% in CCl_4). Values of C_y and C_z in Table 2 were obtained by computer-programmed least squares calculation using Eq. (1) in Ref. 7 and data in Table 1. Benzyl,[8] benzhydryl,[8] and triphenylmethyl[9] hydrodisulfides, and benzyl[10] and triphenylmethyl[9] hydrotrisulfides were prepared by known procedures. Benzhydryl hydrotrisulfide (86% purity) was obtained as a carbon tetrachloride solution by the following procedure. To a solution of acetyl benzhydryl trisulfide (1 g) in *n*-propyl alcohol (20 m*l*) was added 1N *n*-propyl alcoholic hydrogen chloride (5 m*l*). The solution was kept at 29°C for 1 hr. Volatiles were evaporated under reduced pressure, and carbon tetrachloride was added to the residual oil. Acetyl benzhydryl trisulfide was prepared by the same method as that given in literature.[9] 77% of crude material, mp 53—57°C was obtained. This was purified by repeated recrystallization from ether to obtain white crystals, mp 57—58.5°C.

Found: C, 58.49; H, 4.82; S, 31.64%. Calcd for $C_{15}H_{14}OS_3$: C, 58.79; H, 4.60; S, 31.38%.

The authors wish to thank Dr. T. Nakabayashi for the synthesis of acetyl benzhydryl trisulfide and Mr. R. Ito for his assistance in computer calculation.

SHORT COMMUNICATIONS

Admittance Behavior of Electrode Reaction of Water at a Dropping Mercury Electrode

Kiyoshi MATSUDA, Katsuo TAKAHASHI, and Reita TAMAMUSHI
The Institute of Physical and Chemical Research, Wako-shi, Saitama
(Received June 4, 1971)

The DC and AC polarographic behavior of dropping mercury electrode (DME)/dilute aqueous electrolyte solution systems was studied in the potential region from zero to ± 5V. In AC polarography, conductance and susceptance components of the cell admittance were measured by a phase-sensitive AC polarograph constructed in our laboratory.[1]

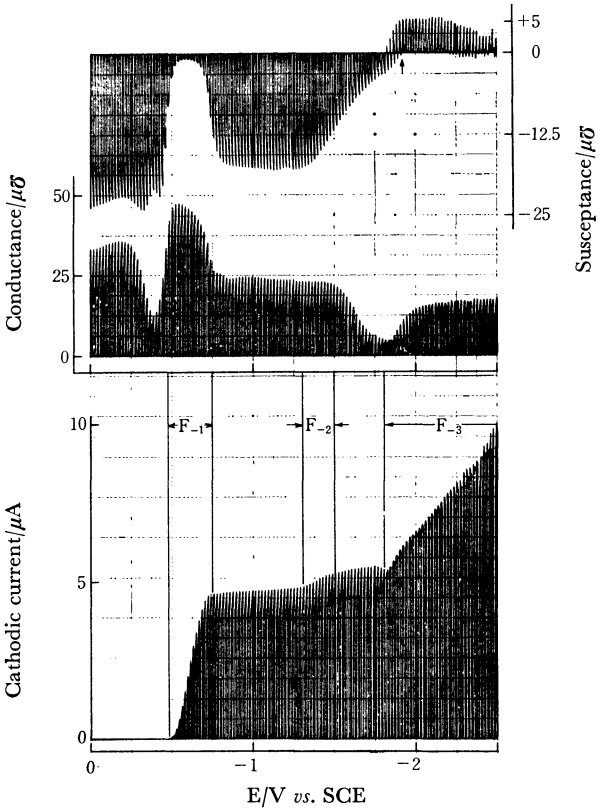

Fig. 1. DC polarogram, conductance-potential and susceptance-potential curves of a DME/0.5 mM $Cd(NO_3)_2$ system in negative potential region at 25°C, the conductance and susceptance being measured at 31 Hz.

Figure 1 shows typical DC and AC polarograms of a DME/0.5 mM $Cd(NO_3)_2$ system (pH=4—5) in the negative potential region. The reduction waves of cadmium and hydrogen ions were observed on the DC polarogram in potential regions F_{-1} and F_{-2}, respectively. The cathodic current increased almost linearly with potential in the more negative potential region F_{-3}. This increase in cathodic current is attributed to the reduction of water.[2]

In the potential region F_{-3}, a remarkable change in the direction of the susceptance vector was observed as indicated by an arrow in Fig. 1, when the admittance was measured at relatively low frequencies. This type of anomaly in the susceptance component was also observed in solutions of various cations such as H^+, Na^+, K^+, Ag^+, Hg_2^{2+}, Tl^+, Ca^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cd^{2+}, and Pb^{2+}. Exceptions were solutions containing Mg^{2+}, NH_4^+, $(CH_3)_4N^+$ and $HgCl_2$; in case of Mg^{2+} the DC reduction wave of Mg^{2+} and that of water overlapped, and in NH_4^+-, $(CH_3)_4N^+$- and $HgCl_2$-systems the DC and AC polarograms were strongly disturbed in the potential region F_{-3}, which prevented us from making further analysis of susceptance components.

The analysis of the frequency dispersion suggested the contribution of some inductive components to the electrical equivalent circuit of the cell system in the potential region F_{-3}. The admittance behavior of this nature has been reported by Epelboin and his coworkers[3] in the electrochemical dissolution of iron and nickel electrodes. In case of cathodic processes, the possibility of the contribution of inductive components to the faradaic admittance has been suggested theoretically for hydrogen evolution.[4] It seems, however, that this paper provides the first experimental evidence for the contribution of an inductive susceptance to the equivalent circuit of the cathodic reduction of water at a DME.

In solutions containing hydroxide and thiocyanate ions, inductive susceptances were also detected in the positive potential region where anodic currents are observed. Details of the experimental results and the theoretical consideration will be reported elsewhere.

Infrared Spectra of Crystalline Chloroform at High Pressure

Mitsuko KOYAMA and Haruka YAMADA
Department of Chemistry, Kwansei Gakuin University, Nishinomiya
(Received March 31, 1971)

Infrared absorption spectra of polycrystalline chloroform were measured at 100°K and the results were discussed in comparison with the X-ray diffraction data.[1] In order to justify the previous analysis and to determine the assignment of components of internal mode splittings in the crystal field, measurements of spectra of single crystals or oriented crystals are most desirable.

In the present work, single crystals of chloroform have been produced in a diamond high-pressure cell at room temperature. Sample crystals were grown from liquid chloroform sealed between a molybdenum gasket and diamond anvils in a high-pressure cell (High Press. Optics, Co.). Pressure was increased up to about 30 kbar on the sample until solidification to a polycrystal occurred (the pressure in the cell was roughly estimated by counting the rotations of the screw as shown in its catalogue). The pressure was then decreased gradually until the crystal melted, and the pressure was again increased rapidly until single crystals were grown. By repeating the procedure, the single crystals as shown in Fig. 1 were obtained. Although the crystals grown in the cell consisted not of one block but of several blocks, the polarization effect on the spectra was observed, indicating some orientation of the single crystals.

Infrared spectra were recorded on a modified Jasco DS-301 prism (triple-pass) spectrometer, whose beam was first focussed on the sample using a mirror of long focal length. An AgBr grid wire polarizer was employed. No polarization effect from the diamond cell was detected at 1 atm and also at high pressures.

Spectra of samples 1 and 2 are shown in Figs. 2 and 3, respectively. Sample 1 shows two peaks at 3053 and 3008 cm^{-1} in the ν_1 region and three peaks at 1226, 1207 and 1198 cm^{-1} in the ν_4 region, while sample 2 has two peaks at 3048 and 3008 cm^{-1} in the ν_1 region as well as two peaks at 1225 and 1210 cm^{-1} in the ν_4 region without the lowest frequency peak. In these figures the dotted lines represent the spectra in ploarized light. The polarizer was used in such a way that the most significant spectral changes from the unpolarized spectra might be observed. For polycrystals the spectra obtained at high pressures are very similar to those reported for the polycrystalline film at 100°K, though the crystal field splittings for the ν_4 vibration are somewhat larger for the crystals at high pressures than for that at 100°K. The peak at 3050 cm^{-1} was not reported for the polycrystalline film, but we have observed it by making a thicker film at 100°K.

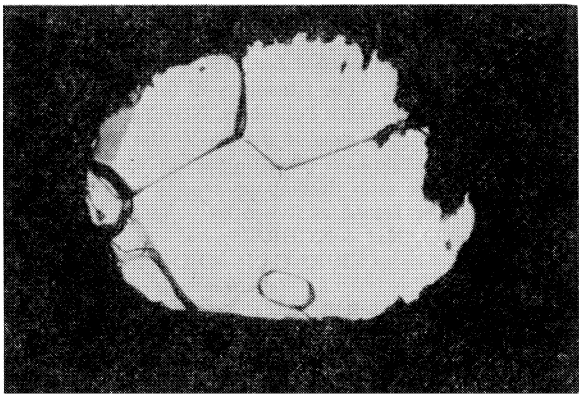

Fig. 1. $CHCl_3$ single crystals grown in diamond cell at *ca.* 30 kbar (sample 2).

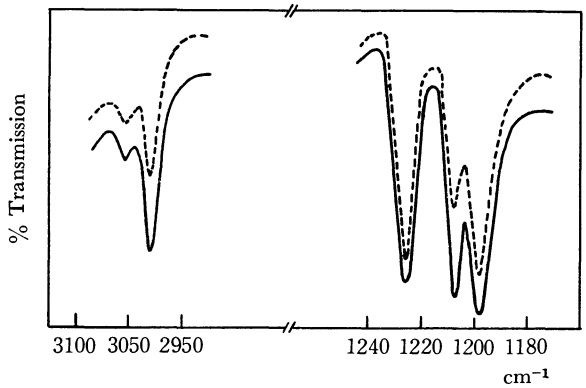

Fig. 2. ν_1 and ν_4 bands of $CHCl_3$ for sample 1.
—— unpolarized, ------ polarized

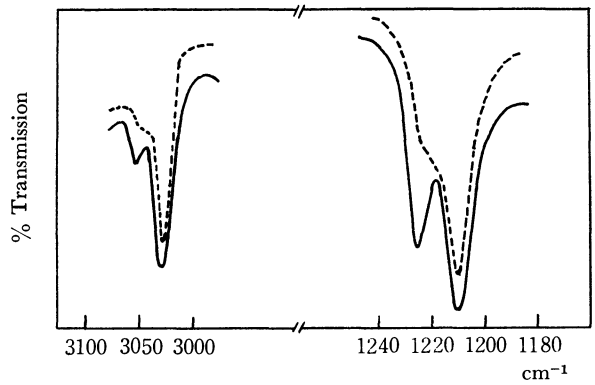

Fig. 3. ν_1 and ν_4 bands of $CHCl_3$ for sample 2.
—— unpolarized, ------ polarized

As can be seen from Figs. 2 and 3, the central peak at 1207 cm^{-1} in the ν_4 band and the peak at 3008 cm^{-1} in the ν_1 band are ascribed to one crystal axis component while the peaks at 1225 cm^{-1} and at 3050 cm^{-1} are assigned to another crystal axis component. Since the chloroform crystal belongs to D_{2h}^{16} and the CH bonds lie on the ac plane, making an angle of 14° with the *a* axis, the peak at 3008 cm^{-1} is assigned to the *a* axis component. The three peaks in the ν_4 band can then be assigned to the *c*, *a*, and *b* axis components, respectively, from high to low frequencies, supporting the previous analysis.

Synthesis of 4-Substituted Isoxazole-3,5-dicarboxylic Acids from 2-Substituted-1,3-dinitroglutarates and the Reaction Mechanism therefrom[1,2]

Shonosuke ZEN and Masao KOYAMA

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo

(Received May 29, 1971)

A solution of 1 mol of 2-substituted-1,3-dinitroglutarates[3] (**1**) in absolute ethanol was added to about 10 mol of a primary amine, such as *n*-butylamine or *n*-propylamine. The reaction mixture was refluxed for several hours, and upon concentration crude 4-substituted bis-carbamoylisoxazoles (**5**) were obtained as oils, which were crystallized after washing, digesting or extracting with suitable solvents. Compounds **5**, listed in Table 1 were identified by comparison with authentic samples[4] (except 5-E and 5-F). They were hydrolysed with aqueous sodium hydroxide to give free acids[5] (**6**).

1 was decomposed in the presence of the amines. After liberation of nitrous acid, it gave isoxazoline-*N*-oxide (**3**) which might be produced *via* an olefin intermediate (**2**), followed by the intramolecular addition as suggested by Nielsen and Archibalt.[6]

Since compound (**3**) is also classified as "*Cyclic Nitronic Esters*,[7,8] the following mechanism seems to be reasonable. (a) Compound **3** is decomposed into an oximino-ketone (**4**), and (**4a**), the enol-form of **4** yields a dehydrated product, an isoxazole (**5**) as observed by Worrall.[9] (b) Two ester groups of (**4a**) form diamide of the corresponding primary amine in the final step.

The mechanism was confirmed by the following results. (i). An isoxazoline-*N*-oxide (**3a**, $R^1=C_6H_5$, $R^3=CO_2CH_3$ of **3**), mp 94.5—96°C; IR (KBr), 1730 (ester CO), 1610 (phenyl), 1340 cm^{-1} (*N*-oxide); NMR ($CDCl_3$), 2.61 (s. 5H phenyl), 5.02 (d, 1H ring), 5.12 (d, 1H ring), 6.06 (s. 3H methyl), 6.24 τ (s. 3H methyl), could be obtained from a solution of a diethylamine salt of 2-phenyl-1,3-dinitroglutarate in methanol at room temperature. (ii). When an excess of *n*-butylamine was added to an ethanol solution of **3a**, it was converted into isoxazole (**5**, $R^1=C_6H_5$, $R^2=C_4H_9$) in a 97% yield. As emphasized in previous papers,[4,5] compound **1** should be regarded as a key compound for the reaction of α,β-unsaturated α-nitroesters with *n*-butylamine to give **5**.

The postulated mechanism is shown in Chart 1.

All new compounds reported above (**3a**, 5-B($R^2=n$-C_3H_7), 5-E, and 5-F) gave satisfactory results in C, H, and N analyses.

8) Generally, nitronic ester is given as *O*-alkylated product by the reaction of metallic salts of nitroparaffins with alkyl halides. This acyclic nitronic ester decomposes readily to form an oxime and an aldehyde or ketone as shown by

$$R^1R^2\cdot C{=}NO_2^-Na^+ + XCHR^3R^4 \longrightarrow R^1R^2\cdot C{=}N(\rightarrow O)OCHR^3R^4 \longrightarrow$$

(*acyclic nitronic ester*)

$$R^1R^2\cdot C{=}N{-}OH + R^3R^4\cdot C{=}O$$

9) Dibenzoyl phenyl monoxime is readily converted into triphenylisoxazole (D. E. Worrall, *J. Amer. Chem. Soc.*, **57**, 2299 (1935)).

The Crystal and Molecular Structure of *trans*-Bis(dinitrogen)bis[1,2-bis(diphenylphosphino)ethane]molybdenum(0)

Tokiko UCHIDA, Yasuzo UCHIDA,* Masanobu HIDAI,* and Teruyuki KODAMA*

Department of Industrial Chemistry, Faculty of Science and Technology, The Science University of Tokyo, Noda, Chiba

**Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo*

(Received June 16, 1971)

Since the discovery of the dinitrogen-coordinated complex of a transition metal,[1] attention has been drawn to dinitrogen complexes of transition metals in relation to nitrogen fixation in biological systems. Molybdenum-dinitrogen complexes are especially interesting because of the key role of molybdenum in both chemical and biological nitrogen fixation. In previous papers[2] we reported briefly the preparation of molybdenum-dinitrogen complexes of the types $Mo(N_2)(PPh_3)_2 \cdot C_6H_5CH_3$ and *trans*-$Mo(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2$ obtained by the reduction of molybdenum(III) acetylacetonate with trialkylaluminum in the presence of triphenylphosphine or 1,2-bis(diphenylphosphino)-ethane under a nitrogen atmosphere. In this communication we wish to report the crystal and molecular structure of the latter molybdenum-dinitrogen complex, *trans*-bis(dinitrogen)bis[1,2-bis(diphenylphosphino)-ethane]molybdenum(0), determined by three-dimensional X-ray analysis.

Orange crystals suitable for X-ray analysis were obtained by recrystallization of the complex from toluene/*n*-hexane. The specimen was sealed off in a thin-walled Pyrex capillary in a nitrogen atmosphere. Crystals are triclinic, space group $P\bar{1}$ with one molecule in a unit cell of dimensions, $a=10.64$, $b=12.63$, $c=10.51$Å, $\alpha=92.47$, $\beta=118.91$, and $\gamma=71.20°$. Intensity measurements were carried out on the four-circle diffractometer using monochromatized Mo$K\alpha$ radiation. A total of 3253 reflections were recorded in the range of $2\theta \leq 55°$. Lorentz and polarization corrections were made, absorption correction being neglected. The positions of molybdenum atom and two phosphorus atoms were determined from three-dimensional Patterson map. All other light atoms except hydrogen atoms then revealed their positions on three-dimensional electron density map calculated on the basis of molybdenum and phosphorus contributions. Structure was refined by block-diagonal least-squares with isotropic temperature factors, to an R factor of 0.148.

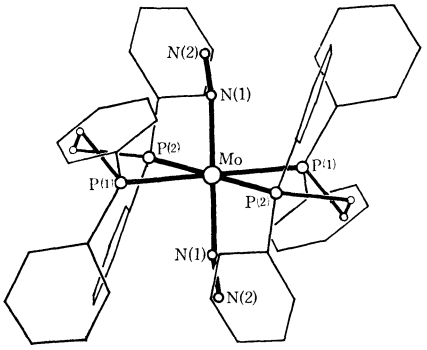

TABLE 1. BOND LENGTHS AND ANGLES

Bond length			Bond angle	
Mo–P(1)	2.50 Å	(0.004)	P(1)–Mo–P(2)	80.9°(0.1)
Mo–P(2)	2.45	(0.005)	N(1)–Mo–P(1)	87.3 (0.4)
Mo–N(1)	2.01	(0.012)	N(1)–Mo–P(2)	84.3 (0.5)
N(1)–N(2)	1.10	(0.02)	N(2)–N(1)–Mo	171.8 (1.1)

Values in parentheses indicate standard deviation.

Molybdenum atom occupies the center of symmetry, and four phosphorus atoms and *trans* two nitrogen molecules form a distorted octahedron. The end view along the b axis is shown above. The bond lengths and angles at this stage are summarized in Table 1. There is no significant elongation of the N–N bond upon coordination, as in the case of ruthenium- and cobalt-dinitrogen complexes.[3] The Mo–N bond length of 2.01 Å is not significantly shorter than a metal-nitrogen (M–N) single bond distance (1.95—2.15 Å). It is of great interest that the Mo–N–N entity is slightly bent in contrast to the M–N–N entities of ruthenium- and cobalt-dinitrogen complexes which are almost linear.[3]

Calculations were carried out at the Computer Center, the University of Tokyo, with programs of UNICS.

The Photosensitized Decomposition of Methane Adsorbed on Porous Vycor Glasses Coated with Metal Oxides at 77°K

Yuzaburo FUJITA, Keiichiro HATANO, Michiyasu YANAGITA, Takashi KATSU, Mitsuo SATO, and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 18, 1971)

As has been reported previously, it has been found that various types of methyl radicals have been trapped at 77°K on the surface of porous Vycor glass (PVG).[1,2]

We were interested in the influence of the metal oxides coated on the surface of PVG on the photodecomposition mechanisms of methane, and so we studied the photolysis of methane at 77°K on various PVG surfaces (abbreviated PVG(V_2O_5) and so on) by the technique of ESR spectroscopy.[1] We have found an interesting new effect of these metal oxides; that is, the photosensitivity of these metal oxides for the formation of methyl radicals at 77°K was quite different from one metal oxide to the other.

Though some of these metal oxides are catalytically active for the oxidation of organics,[3] their photosensitivities have not yet been revealed.

In this communication we will report briefly some results on the photosensitivities of various oxides coated on the PVG for the formation of the methyl radical at 77°K.

Oxide-coated PVG samples were prepared as follows: after the leaching of a PVG rod (Corning #7930, 4 mmϕ, 1 cm in length, 38 m^2/sample) with concentrated nitric acid, an appropriate metal salt, for example, ammonium meta-vanadate (NH_4VO_3) for vanadium oxide, was absorbed from an aqueous solution in an amount sufficient for a coverage of θ=0.01—0.001%; the PVG thus treated was ignited at 500—600°C in air to convert the salt into an oxide.

A tenth of the monolayer amount of methane was then introduced at room temperature, followed by repeated oxidation and degassing at 500—600°C in a quartz sample tube. Irradiation of the sample tube was carried out at 77°K directly in a Dewar vessel inserted in the cavity of an ESR apparatus with a filtered light of an ultra-high-pressure mercury lamp (USH-500D, Ushio Electric Co., Ltd.).

Some representative results on the wavelength characteristics of the oxide-coated PVGs for the methyl radical formation at 77°K are shown in Fig. 1.

On these oxide-coated PVGs, the CH_3(II) or CD_3-(II), the so-called abnormal methyl radical (g=2.002, $A^H_{CH_3}$=19.3 G, $A^D_{CD_3}$=3.0 G),[1] was observed preferentially by the photolysis at 77°K; this methyl radical showed the characteristic linewidth alternation with a sharper line in the lower magnetic field.

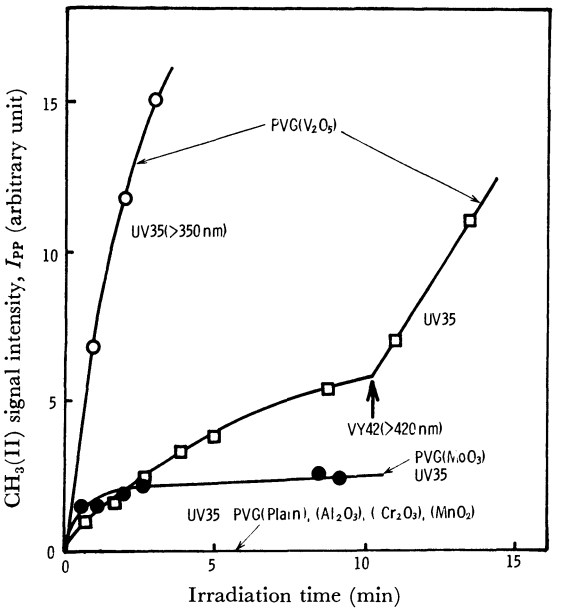

Fig. 1. Photosensitized formation of CH_3(II) radical on metal oxide coated PVGs.

The second hf line from the lower field (m_I=−½) with the largest peak-to-peak intensity, I_{pp}, was used as a monitor for the CH_3(II) radical concentration; its change with the irradiation time is plotted in Fig. 1.

The largest photosensitization was observed on the PVG(V_2O_5), and even a visible light larger than 420 nm showed a relatively large photosensitizing effect on the radical formation. Although the PVG(MoO_3) also showed the photosensitizing activity, its activity was less than that of the PVG(V_2O_5). On the PVG(plain) and PVG(Al_2O_3), no photosensitization was observed, and the CH_3(II) radical was observed only with the full light of a low-pressure mercury lamp. Here, it is very interesting that, on the PVG(MnO_2) and PVG-(Cr_2O_3), a "photodesensitization" was clearly observed, and that, in these cases, none of the methyl radical could be observed even with the full light of a low-pressure mercury lamp.

It may be worthy of note here that the oxides showing the "photodesensitization" are well known active oxidation catalysts, while, on the other hand, V_2O_5 and MoO_3 are considered to be weak oxidizing catalysts for the complete oxidation of methane.[4] Therefore, one can deduce that there is a reverse correlation between the radical trapping efficiencies and the oxidizing abilities of the oxide-coated PVGs.

When a trace of oxygen was present in the PVG-(V_2O_5)-CH_4 system, a large signal of a peroxyradical (g_1=2.002, g_2=2.01, g_3=2.03) was observed in place of the CH_3(II).

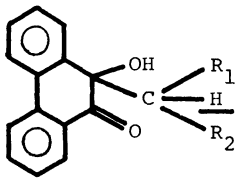
Reaction of Photo-excited Phenanthraquinone with Dibenzyl Ether. Formation of an Adduct and its Decomposition studied by CIDNP Method.

Kazuhiro MARUYAMA and Tetsuo OTSUKI

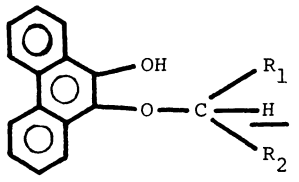
Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Kyoto

(Received June 18, 1971)

Whereas photo-excited phenanthraquinone reacts with alkyl aromatics showing enhanced PMR absorption signals for 1,2-adducts,[1] it reacts with dibenzyl ether showing an enhanced PMR emission signal for 1,4-adduct (Fig. 1-A). Dibenzyl glycol, phenyl benzyl ether, and hydroquinone dibenzyl ether undergo the same type of reaction showing all the enhanced PMR emission signals. Protons giving the enhanced signals are indicated in (1) and (2) (underlined). All these



1,2-adduct
(1)



1,4-adduct
(2)

reactions are rationalized if we consider the hydrogen abstraction by photo-excited phenanthraquinone in n-π^* triplet state followed by recombination of the resulting radicals in a solvent cage, because none of the reactions are affected even if we use a UV-cut filter.[2] By comparing their PMR and/or IR spectra one can easily differentiate the 1,2-adduct and 1,4-adduct.[3]

1,4-Adduct which is transparent in visible region shows a slightly enhanced absorption signal (2 to 10 times) when it is irradiated with UV light and decomposes photochemically at an elevated temperature to give phenanthraquinhydrone, benzaldehyde, *sym*-diphenylethane, toluene and unidentified products.[4] During the course of photochemical decomposition we can observe the enhanced PMR absorption signal of the resulting benzaldehyde (due to formyl proton) (Fig. 1-B). When light was cut off, the enhanced signal decayed promptly. Thus, it is confirmed that the neutral molecule, *i.e.* benzaldehyde, produced by fragmentation of radical can take the nuclear spin polarized state. The photochemical decomposition is effective only with UV light. No such enhanced signal of benzaldehyde could be observed when we applied a UV-cut filter.[5]

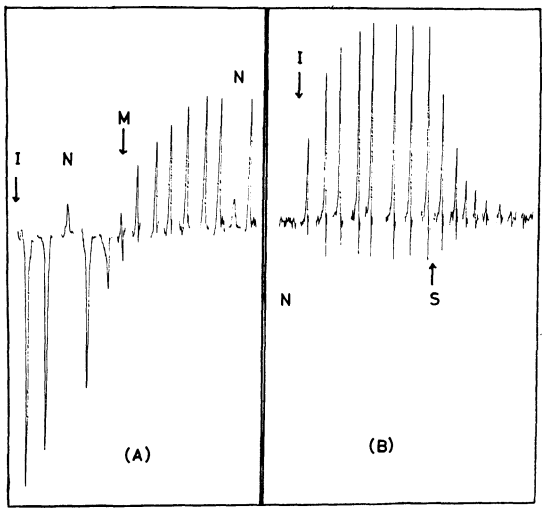


Fig. 1. (A) Enhanced PMR signals of 1,4-adduct (τ: 4.12) observed in the photochemical reaction of phenanthraquinone with dibenzyl ether (70°C). I: Irradiation initiated. N: The normal signal of the accumulated adduct under no irradiation. I→M: Enhanced emission signals. M: Enhanced emission and absorption signals balance, and nearly all of the phenanthraquinone in the reaction system is consumed.
(B) Enhanced PMR signals of benzaldehyde (τ: 0.35) observed in the photochemical decomposition of the 1,4-adduct (90°C). N: No irradiation. I: Irradiation initiated. I→S: enhanced absorption signals of benzaldehyde. S: Irradiation stopped.

2) A 500 W high pressure Hg lamp as a light source and a Toshiba V-Y 42 filter were used. A 60 MHz C-60HL NMR spectrometer manufactured by JEOL was used.

3) 1,2-Adducts show the following characteristic spectra;
IR, ν_{OH}: sharp ~3500 cm^{-1}, $\nu_{C=O}$: 1690 cm^{-1}
PMR, τ_{OH}: ~6.0 region, $\tau_{methine\ or\ methylene}$: ~7.0 region
1,4-Adducts show the following characteristic spectra;
IR, ν_{OH}: broad ~3300 cm^{-1}, $\nu_{C=O}$: none
PMR, τ_{OH}: in phenolic OH region, $\tau_{methine\ or\ methylene}$: 4.0—5.0 region

4) These decomposition products were identified by PMR, TLC, GLC, and chemical analyses.

5) 1,4-Adduct can decompose also thermally very slowly without any light. However, no PMR enhanced signal could be observed during the course of the reaction.

ESR Spectrum of Triplet Species in Würster's Red Perchlorate

Michiya Itoh

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received June 23, 1971)

Numerous investigations have been carried out on the electronic and magnetic properties of Würster's salts in both solution and solid. Thomas *et al.*[1] reported a triplet species in a single crystal of Würster's blue perchlorate (WBP) below the temperature of the phase transition (186°K), and suggested the dimerization of the cation through small molecular displacement in the crystal below transition point. Sakata and Nagakura[2] showed that the intensity of the charge transfer band between the cation in the solid WBP increased remarkably below transition temperature. Oohashi *et al.*[3] reported the extremely strong charge transfer band in solid Würster's red perchlorate (WRP), compared with those of WBP and of Würster's red bromide (WRB). No crystal sturcture of WRP was reported, while the cation in the solid WRB was reported by Tanaka and Mizuno[4] to be stacked at equal distances from each other.

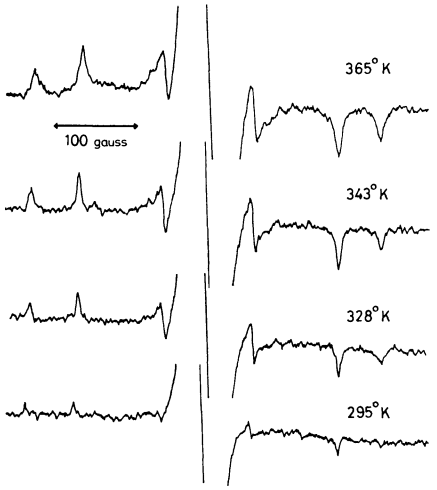

Fig. 1. The ESR spectra of the solid Würster's red perchlorate with random orientation at various temperatures.

We observed the ESR spectrum of triplet species in the powdered WRP[5] for the first time at various temperatures ranging from 290°K to 370°K. The results suggest the dimer structure of the cation in the solid WRP. Figure 1 shows a strong signal at $g=\sim 2.002$, and weak signals characteristic to the triplet species with random orientation at various temperatures. The ESR signals due to the triplet species showed reversible increment with increasing temperature up to the melting point of the crystal, while the central signal increased irreversibly with temperature. This might be due to the paramagnetic impurity decomposed in the crystal with increasing temperature. From three pairs of lines in ESR spectrum the zero-field splitting parameters were obtained to be $D=0.0189\ \mathrm{cm^{-1}}$ and $E=0.0098\ \mathrm{cm^{-1}}$ with $2D=406$ gauss.[6] The D value is consistent with a spin-spin dipolar interaction for an average distance of 5.1 Å.[7]

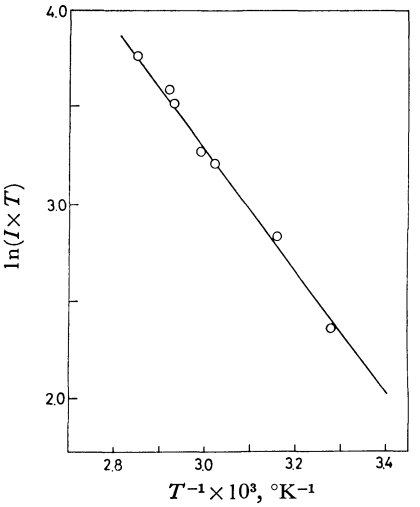

Fig. 2. Temperature dependence of the ESR spectrum due to the triplet species. Intensity of the signal obtained actually from the Y component[6] is in arbitary unit.

Figure 2 shows a linear relationship of $\ln(IT)$ against $1/T$, where I is the intensity of the ESR signal due to the triplet at various temperatures. From a slope of the straight line in Fig. 2, a singlet-triplet separation J was obtained to be $2100\pm 200\ \mathrm{cm^{-1}}$, where $I\propto \exp(-J/kT)$ was assumed because of $J\gg kT$. The value of J so obtained was compared with that in WBP (235—$246\ \mathrm{cm^{-1}}$).[1,2] The present results suggest that the WRP crystal consists of the dimer structure of the cation *at room temperature*. The large singlet-triplet separation is consistent with the extremely strong charge transfer band in WRP, and with the first observation of the ESR spectrum due to the triplet in the ion radical salts *at room temperature*.

Glassy Liquid Crystal of the Nematic Phase of *N*-(*o*-Hydroxy-*p*-methoxybenzylidene)-*p*-butylaniline

Michio Sorai and Syûzô Seki

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 25, 1971)

In general, glass transition takes place through a delicate balance between the relaxation time of molecular motion and the time scale of observation. The ordinary glassy state can be established by quenching many supercooled liquids below their glass transition points without crystallization, and by other suitable procedures.[1-3] Adachi *et al.*[4] reported the possible existence of glassy state even in crystalline materials as the non-equilibrium state of many plastic crystals. We also reported the new finding of glassy state in the metastable liquid crystal of cholesteryl hydrogen phthalate (CHP) and proposed to designate this state as "**glassy liquid crystal.**"[5]

N-(*p*-Methoxybenzylidene)-*p*-butylaniline (MBBA)[6] is a rare example of nematic liquid crystal at room temperature and has widespread applications to display devices, but the material is relatively unstable against cleavage or reaction of the anil linkage. In contrast, OHMBBA, an *o*-hydroxy analog of MBBA which was recently synthesized,[7] has an intramolecular hydrogen bonding stabilizing the anil linkage. The melting point T_m of OHMBBA is 44°C and the enantiotropic transition T_{tr} from the nematic mesophase to the isotropic liquid is 64.5°C.

OHMBBA of special grade obtained from Tokyo Ohka Kogyo Co., Ltd. was dried in a vacuum by a freeze-and-thaw technique for 24 hr. Differential thermal analysis (DTA) was carried out. Typical results are illustrated in Fig. 1. Run 1 shows a heating curve of crystalline OHMBBA with a rate of 2.5K/min. Run 2 gives a cooling curve of the isotropic liquid with a rate of −12K/min. The transition from the isotropic

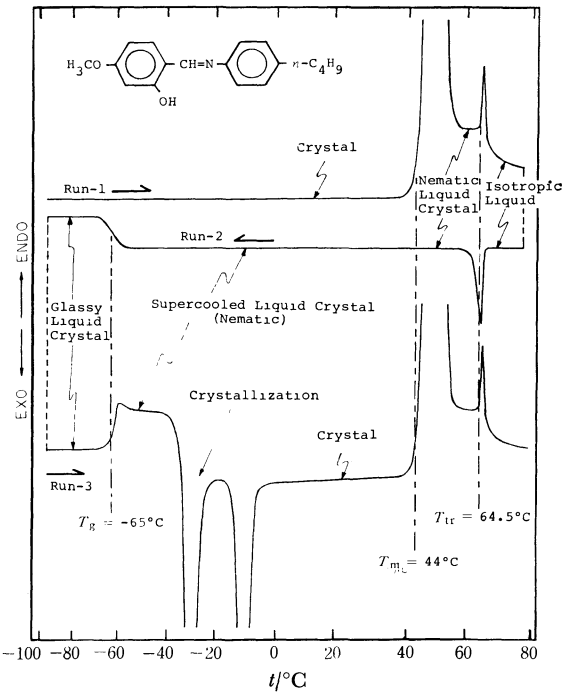

Fig. 1. DTA curves for *N*-(*o*-hydroxy-*p*-methoxybenzylidene)-*p*-butylaniline.

liquid to the nematic phase was observed even in a rapid cooling as fast as −80K/min. When the cooling rate was greater than −10K/min, the nematic mesophase was easily quenched to give a glassy state. Run 3 shows a heating curve of the glassy liquid crystal with a rate of 2.5K/min. A clear glass transition phenomenon was observed at −65°C. On further heating, the supercooled nematic liquid crystal was transformed into a stable crystal through a crystallization process around −30°C. The values of T_m and T_{tr} agree well with the previous data.[7]

Thus we found a glass transition phenomenon for a *stable* liquid crystal, but in the case of CHP it was observed only for a *metastable* one. In this respect, OHMBBA may be more appropriate material than CHP for studying the glass transition phenomenon in liquid crystals.

A Mass Spectrometric Study of the Reaction of Hydrogen Atom with Butadiene

Seiichiro KODA and Tsutomu HIKITA

Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 25, 1971)

The reaction of hydrogen atom with simple olefins has been extensively investigated,[1-4] but few studies have been published on the reaction kinetics of hydrogen atom with conjugated dienes. In this communication, we describe the evidence for the existence of butenyl radical in the reaction of hydrogen atom with 1,3-butadiene, and suggest the reaction mechanism in a low pressure reaction with a relatively high concentration of hydrogen atom, in comparison with the reaction of butenes with hydrogen atom now under investigation.

Hydrogen atoms produced by a 2450 MHz microwave discharge in the mixture of about 20% hydrogen in agron, are introduced into a Pyrex reaction tube with a flow velocity of about 4 m/sec at 0.38 Torr (total pressure: Ar, 0.31 Torr: H_2, 0.07 Torr). Butadiene is added *via* a movable inner tube to control the reaction time in the range of 2—30 msec. The reaction is studied at room temperature. The reaction products are fed into a time-of-flight-type mass spectrometer through a pin hole positioned at the end of the reaction tube.

The analysis of the mass spectra shows that butenes (1-, *trans*-2-, and *cis*-2-butene), propylene, ethane, and methane are the main reaction products, and that *n*-butane, propane, and ethylene are minor ones. For example, the reaction at the initial concentration of butadiene of 4.6×10^{-8} mol/*l* and of hydrogen atom[1] of 2.0×10^{-7} mol/*l* at the total pressure of 0.38 Torr is explained at the reaction time of 8.1 msec as $C_4H_6 \rightarrow 0.70C_4H_8 + 0.19C_3H_6 + 0.04C_2H_6 + 0.04CH_4 +$ other minor products. Some pentenes and several species which have an eight-carbon-structure are also detected.

In this analysis, the peak intensities of $m/e=55$ in the spectrum are in excess compared with those calculated from the standard mass spectral patterns of the above products. In order to decide what product contributes to the $m/e=55$ peak, the ionization efficiency curve was observed as shown in Fig. 1. The appearance potential is 7.7 eV lower than the ionization potential of argon atom,[5] *i.e.*, 15.8—7.7=8.1 eV. This value agrees fairly well with that of 2-butenyl(α-methylallyl) radical[6] 7.7 eV our data, 8.1 eV is considered to be slightly higher than the true value, because our method gives slightly higher potentials than true ones, for example, that of butadiene is measured to be 9.3 eV (9.0—9.2 eV[5]). It was slso reported that 2-butenyl radical was detected by means of electron spin resonance in the reaction of butadiene with hydrogen at 77°K.[7]

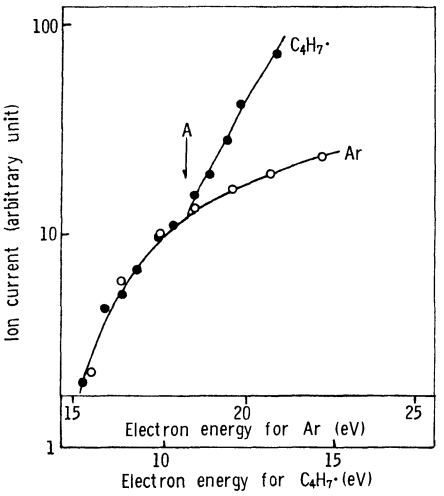

Fig. 1. Ionization efficiency curve of butenyl radical in the reaction mixture
reaction conditions
$[\text{butadiene}]_{\text{initial}}=1.0\times10^{-7}$ mol/*l*
$[\text{hydrogen}]_{\text{initial}}=1.3\times10^{-7}$ mol/*l*
reaction time, 2.7 msec; total pressure, 0.38 Torr at room temperature.
Point A shows the beginning of the contribution of fragment ions from other species in the reaction mixture.

From the above results and consideration on the reactions of butenes, propylene and ethylene[1] with hydrogen atom, the following successive reactions are concluded to be dominant in the present condition. The ratios of decomposition reactions *vs.* stabilization reactions from the hot species (hot butenyl radial and hot butenes) are considered to be small, from the distribution of the reaction products.

$$C_4H_6 + H \longrightarrow C_4H_7\cdot{}^* \longrightarrow C_4H_7\cdot$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad \downarrow \longrightarrow \text{decomposition (minor)}$$
$$C_4H_7\cdot + H \longrightarrow C_4H_8{}^* \longrightarrow C_4H_8$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad \downarrow \longrightarrow \text{decomposition (minor)}$$
$$C_4H_8 + H \longrightarrow C_3H_6,\ C_2H_6,\ CH_4, \text{ and others}$$

(* means hot species)

The apparent second-order reaction rate constant of butadiene with hydrogen atom was determined to be $(1.1—1.7)\times10^9$ *l*/mol·sec at the above total pressure, by measuring the decreasing rate of butadiene.

Reaction Kinetics of the Redox Decomposition of Hydroxymercurated Propylene in Aqueous Solution Followed by Time-Sequential NMR Spectroscopy

Masashi MATSUO and Yasukazu SAITO

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received December 15, 1970)

The redox decomposition process of hydroxymercurated propylene in aqueous solution yielding acetone has been followed by time-sequential NMR spectroscopy *in situ*. No reaction intermediates and reaction products other than acetone were observed. Stoichiometric relationship holds between the reactant and the product during the reaction, which was verified by NMR spectra. The reaction rate was confirmed to be of first order with respect to mercurial. Although the rate was accelerated at higher acidity in solution, a similar rate enhancement took place by addition of neutral salts. At a certain ionic strength, no close linear correlation between the apparent rate constants and proton concentration was observed. In contrast, excellent linear dependence was obtained by the thermodynamic activities of the added electrolytes including acid. Since the apparent rate constant was independent of the concentration of free mercuric ion, a monomolecular mechanism is proposed. Taking into account the rate dependence upon added electrolytes, the redox decomposition of the hydroxymercurated olefins to give carbonyl compounds seems to proceed only when an aquo ligand is removed from the carbon-bonded mercuric ion.

Olefin oxidation by metal ions in aqueous solution has long been investigated from the industrial, synthetic, and mechanistic viewpoints, with a good deal of knowledge compiled for Pd(II)[1] and Tl(III)[2] as well as for Hg(II).[3-5] Similarities and contrasts were pointed out by Henry between Pd(II) and Tl(III) in olefin oxidation.[6] Although common reaction products, *i.e.*, saturated carbonyl compounds, are obtainable,[5] little attention has been paid to Hg(II) oxidation. In order to elucidate the catalytic oxidation of olefins with metal ions, comparison from the mechanistic viewpoint seems to be indispensable between Pd(II), Tl(III), and Hg(II) oxidation. The reaction schemes of the σ-complex formation *via* π-complex intermediates are commonly postulated for these metal ions toward olefins. In the case of Hg(II), σ-complex is considered to be formed *via* mercurinium ion, a π-complex intermediate.[7] The redox decomposition of the σ-complexes is known to proceed fast for both Pd(II) and Tl(III) oxidation, but slowly for Hg(II) oxidation, which is ascribed to the stability of β-hydroxyalkylmercury(II) complexes. Thus information concerning the redox decomposition step of σ-complexes can only be afforded by studying Hg(II) oxidation.

The first order kinetics with respect to free mercuric ion was confirmed for the formation of unsaturated carbonyl compounds.[3] However, proton dependence on the rates of redox decomposition has never been investigated in spite of the following facts. (1) The rate of hydroxymercuration of olefins[8] is independent of proton concentration. (2) The rate of deoxymercuration yielding original olefins[7] is dependent on proton concentration, since proton is incorporated in the pre-equilibrium step of deoxymercuration. In the present work, kinetics on both proton and free mercuric ion as well as neutral salt effects were studied in order to elucidate the reaction mechanism of the redox decomposition of hydroxymercurated olefins yielding saturated carbonyl compounds. The time-sequential NMR spectroscopy was adopted to monitor the reaction, since it affords the possibility for detecting reaction intermediates, if any.

Experimental

Materials. All the reagents were of G.R. grade, prepared by Kojima Kagaku Co., Ltd. (Tokyo), and were used without further purification. Absence of impurities was confirmed by gas chromatography using a β,β′-dioxypropionitrile column for each gaseous olefin prepared by Takachiho Kagaku Kogyo Co., Ltd. (Tokyo). Mercuric solutions were prepared by dissolving mercuric nitrate into concentrated nitric acid, which was diluted with ion-exchanged water up to a given concentration. The concentration of mercuric ion was determined by titration with potassium thiocyanate.

Procedure. Propylene was introduced from the cylinder for 2 min at room temperature into 10 m*l* of the aqueous solution consisting of 6.5 g (20 mmol) of mercuric nitrate and 0.69 g (11 mmol) of nitric acid with or without additional electrolytes. The concentration dependence of the free mercuric ion was studied for the series of solutions consisting of a certain amount of hydroxymercurated propylene and of various amounts of free mercuric ion. The concentration of hydroxymercurated propylene, which is stable at room temperature, was determined from the NMR peak intensity by comparing it with that of the external tetramethylsilane reference.

The time-sequential NMR spectra were obtained at a given temperature with a JEOL C-60 NMR spectrometer constructed by Japan Electron Optics Laboratory Co. Ltd. The reaction temperature was regulated by blowing cooled nitrogen gas and determined by the relative chemical shifts of 1,3-propanediol. The reaction was thus followed by NMR spectroscopy *in situ*.

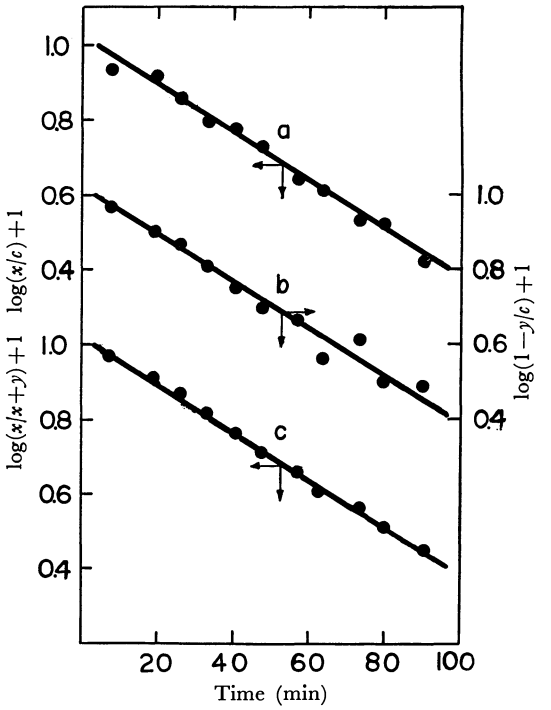

Fig. 1. Reaction kinetics represented by the following three equations.
a. $\ln[x/c]=-kt$
b. $\ln[1-(y/c)]=-k't$
c. $\ln[x/(x+y)]=-k''t$
where x and c are the concentrations of hydroxymercurated propylene at time t and $t=0$, respectively, and y is that of acetone at time t.

The first order rate equation for the redox decomposition with respect to hydroxymercurated olefin was ascertained previously[5] by comparing three kinds of parallel straight lines, obtained from the peak decrease of the reactant mercurial *versus* the external reference, from the peak increase of the product ketone *versus* the reference, and from mercurial *versus* ketone without intermediary of tetramethylsilane. A typical example of the analysis is shown in Fig. 1.

Calculation of thermodynamic activities of electrolytes. With regard to the estimation of thermodynamic activities, the square root of ionic strength is not a good measure of concentrations higher than *ca.* 0.1 molality in aqueous solution. However, it was verified at elevated temperatures that the logarithms of the activity coefficient of hydrogen chloride in aqueous solution mixed with sodium chloride or of hydrogen bromide mixed with potassium bromide varied linearly with concentration up to about 3 molality.[9]

It is assumed, therefore, that a linear relationship holds between the logarithm of the activity coefficient of a certain electrolyte in aqueous solution and the concentration of the added electrolyte in the present solutions as well. Since the activity coefficients of electrolytes such as nitric acid, lithium nitrate, sodium nitrate, potassium nitrate, and sodium perchlorate in aqueous solution as a single component are all available up to highly concentrated regions,[10] the values of the activity coefficients of each electrolyte in the mixed aqueous solution can thus be calculated on the basis of the above-mentioned assumption.

Results

Dependence of Reaction Rates on Acid and Salt Concentration. Although the rate of the redox decomposition of hydroxymercurated propylene yielding acetone[5] was determined to be first order with respect to the concentration of hydroxymercurated propylene, no kinetic investigation concerning the concentration of either proton or free mercuric ion has been carried out. At a certain ionic strength, *i.e.*, $\mu=9.49$, regulated by adding either lithium nitrate, sodium nitrate, or potassium nitrate, the concentration of nitric acid increased and monotonous enhancement of rate constants was obtained at 45.6°C as shown in Fig. 2.

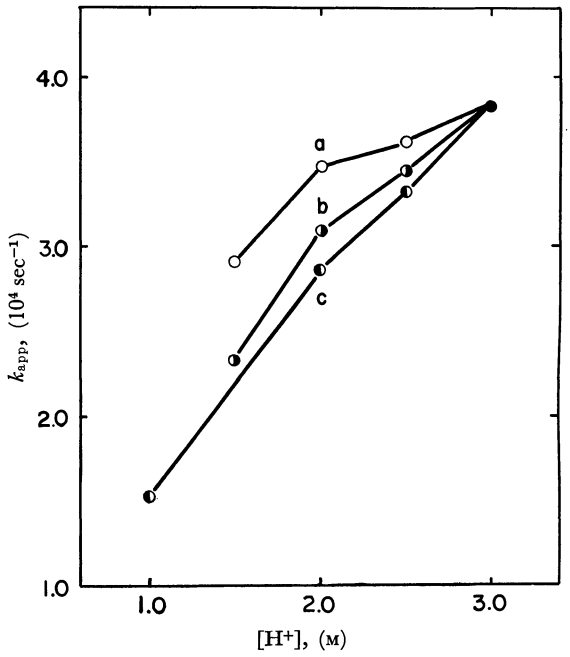

Fig. 2. Apparent rate constants of hydroxymercurated propylene yielding acetone as a function of proton concentration at constant ionic strength regulated by nitrates.
a. $LiNO_3$, b. $NaNO_3$, c. KNO_3

When the concentrations of nitric acid and the neutral salts cited above increased with no control in ionic strength, a similar monotonous enhancement was observed (Fig. 3).

Dependence of the Reaction Rates on Acid and Salt Activity. Excellent linear relationship between the rate constants and the estimated thermodynamic activities of added electrolytes were found for nitric acid, lithium nitrate, sodium nitrate, potassium nitrate, and sodium perchlorate (Fig. 4).

A better linearity is found in Fig. 4 than in Fig. 3. The apparent rate constants are, therefore, not correlated to the concentrations but to the activities of added electrolytes. All the results are summarized in Table 1.

The rate equation to yield acetone from hydroxymercurated propylene, given previously as

$$v = k_{app}\,[\text{mercurial}], \qquad (1)$$

should be expressed as

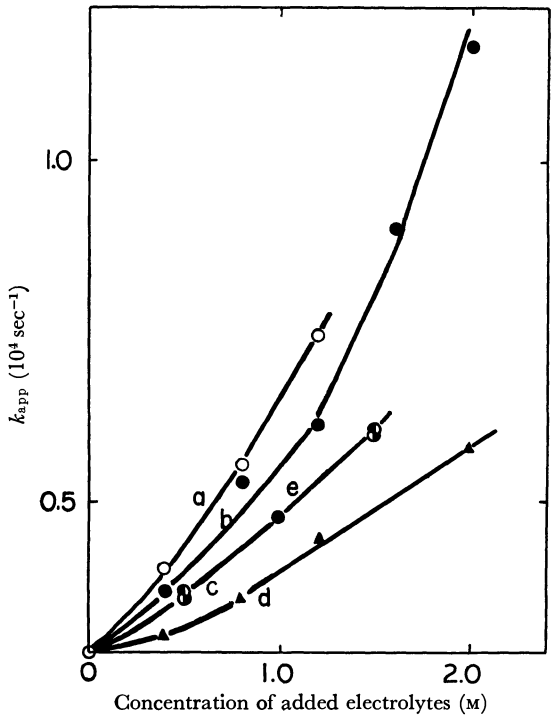

Fig. 3. Plots of apparent rate constants of hydroxymercurated propylene yielding acetone as a function of the concentrations of added electrolytes.

Table 1. Apparent rate constants of the redox decomposition of hydroxymercurated propylene in correlation to the concentration and the activity of added electrolytes

Added acid Concentration	activity (M)	Added salts Concentration	activity (M)	k_{app} (sec^{-1})
HNO_3		$LiNO_3$		
1.60	1.67	0.04	0.48	9.8×10^{-3}
	1.78	0.80	1.00	13.4
	2.17	1.60	2.38	20.3
	2.58	2.00	3.32	26.0
HNO_3		$NaNO_3$		
1.60	1.69	0.50	0.29	10.3
	1.87	1.00	0.51	12.3
	2.13	1.50	0.91	15.2
HNO_3		KNO_3		
1.60	1.67	0.40	0.27	8.3
	1.87	0.80	0.39	9.2
	1.98	1.20	0.49	10.7
	2.58	2.00	0.69	14.2
HNO_3		$NaClO_4$		
1.60	1.69	0.50	0.30	10.8
	1.87	1.00	0.61	12.0
	2.13	1.50	0.93	15.4
HNO_3				
1.20	1.08			5.2
1.60	1.52			7.3
2.00	2.16			9.3
2.40	2.96			12.1
2.80	3.65			16.3

$$v = (k_0 a_0 + k_i a_i)\ [\text{mercurial}], \qquad (2)$$

where k_0 and a_0 are the rate constant and the thermodynamic activity of HNO_3, and k_i and a_i are the corresponding quantities of added neutral salts. The rate constant k_0 for HNO_3 was obtained as 4.5 g/sec·mol and k_i for $LiNO_3$, $NaNO_3$, KNO_3, and $NaClO_4$ as 4.0, 4.8, 5.2, and 4.8 g/sec·mol, respectively. The effect of nitric acid on rate enhancement was thus eventually equal to that of neutral salts.

Dependence of Reaction Rates on Free Mercuric Ion Concentration. The apparent rate constants given in Eq. (1) were independent of the concentrations of free mercuric ion as shown in Fig. 5. The first order kinetics with respect to free mercuric ion was established for acrolein formation from hydroxymercurated propylene.[3] The reaction kinetics of acetone formation from the same reactant is in contrast to that of acrolein formation. Although both are redox decomposition products of hydroxymercurated propylene, it is to be noted that the change of oxidation state of the former is four, while that for the latter is two.

Time-sequential NMR Spectra for Monitoring the Reaction. No reaction intermediates or products other than acetone were recognized and no chemical shifts of the mercurial signals during the reaction process were observed in the time-sequential NMR spectra. Stoichiometric relationships between the reactant mercurial and the product acetone were confirmed from peak heights.

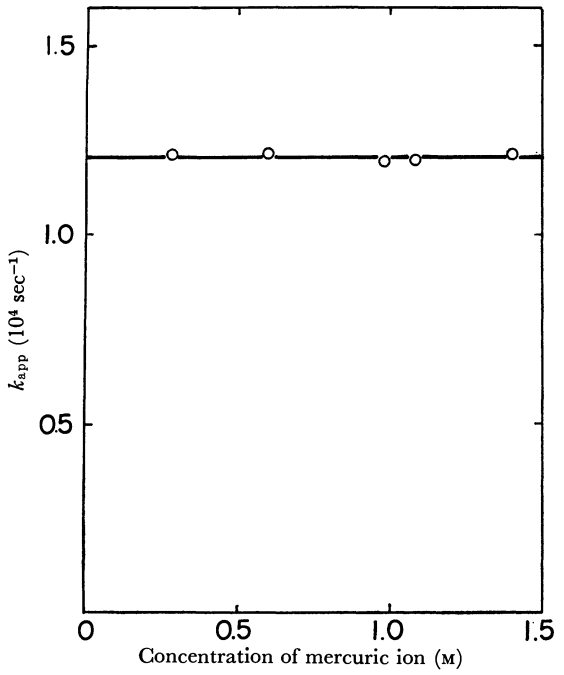

Fig. 5. Apparent rate constants of hydroxymercurated propylene yielding acetone as a function of the concentration of free mercury(II) ions.

Discussion

Influence of the Activities of Added Electrolytes on Reaction Rates. It should be noted that the concentration level of the electrolytes adopted in the present work is far higher than the values ordinarily used for the reactions in aqueous solutions[11] due to the need of NMR observation. This is why considerations were made not only on concentrations but also on activities, and the activity coefficients of electrolytes were calculated by the above-mentioned method.

As far as a reaction of first order with respect to a reactant A (including a pre-equilibrium step $A+B \rightleftharpoons C \rightarrow X+Y$) is concerned, the rate equation is given by

$$v = k_{app}[A] = k_0[C], \quad (3)$$

where k_{app} and k_0 are apparent and true rate constants, respectively. Since the equilibrium constant K is given as the ratio of activities,

$$K = \frac{a_C}{a_A a_B} = \frac{[C]}{[A][B]} \frac{\gamma_C}{\gamma_A \gamma_B} \quad (4)$$

the following rate equation is derived.

$$v = k_0 K \frac{\gamma_A \gamma_B}{\gamma_C}[A][B] = k a_B[A] \quad (5)$$

where $k=k_0 K \gamma_A/\gamma_C$ is used for brevity. By comparing Eqs. (3) and (5), a linear relationship between k_{app} and a_B would be anticipated for the runs of different high concentration levels of B, as far as the participation of the substance B to the reaction is expected at the pre-equilibrium step.

With regard to the redox decomposition reaction of hydroxymercurated propylene followed by NMR spectroscopy *in situ*, it has been ascertained in Fig. 3 and Fig. 4 that a linear correlation with the reaction rates is not obtained for the concentrations but for the activities of the added electrolytes. This would suggest the participation of these added electrolytes to the reaction at a pre-equilibrium step, since the electrolytes can reduce water activities of the solutions, with an aquo ligand replaced from the mercurial to the electrolyte. In other words, the step of an aquo ligand removal from the carbon-bonded mercuric ion would be assumed prior to its redox decomposition as follows.

$$CH_3CH(OH)CH_2Hg^+(OH_2) + MX \rightleftharpoons CH_3CH(OH)CH_2Hg^+ + MX(OH_2) \quad (6)$$

$$CH_3CH(OH)CH_2Hg^+ \longrightarrow CH_3COCH_3 + Hg(0) + H^+ \quad (7)$$

Although water activities in the solutions can be calculated by use of the Gibbs-Duhem equation, no additional data processing was made, as undesirable decrease in reliability might take place in high concentration region.

It is known that the rate of ethylene oxidation by Tl(III) in aqueous solution is of first order in the concentration of both Tl(III) and ethylene.[2] The rate is considerably accelerated by increasing salt concentration, the effect being related also to changes in the activity of water. It was presumed that more complexing between the metal ions and olefins would occur at lower water activity,[12] since the lower the activity of water in the solution, the more vacant the ligand sites for the metal ions.

A similar acceleration with the increase of the ionic strength of the solution is also recognized in aromatic mercuration.[13]

No Rate Dependence on Free Mercuric Ion. First order kinetics with respect to the concentrations of both the mercurial and the free mercuric ion were reported for acrolein formation from hydroxymercurated propylene in similar acidic aqueous media.[3] As for acrolein formation, the four equivalent oxidation is necessary in total, whereas acetone is made by two equivalent oxidation. It seems, therefore, reasonable that zero order dependence on the free mercuric ion was found in the present reaction. Moreover, lack of incorporation of free mercuric ion in either pre-equilibrium steps or the rate-determining process for this two-equivalent oxidation reaction would suggest a monomolecular mechanism in which two-electron transfer takes place. It does not necessarily mean that metallic mercury is found in the reaction products, because the following disproportionation reaction is fast and the equilibrium is much favored to Hg^{2+} side.[14]

$$Hg(0) + Hg^{2+} \rightleftharpoons Hg_2^{2+} \quad (8)$$

Reaction Process Followed by Time-sequential NMR Spectroscopy. Generally speaking, chemical species prevailing in spectroscopy are not necessarily prevailing kinetically for reaction processes. As for spectroscopic approach to reaction analysis, monitoring the reaction process *in situ* is important for this reason. The time-sequential NMR spectroscopy is advantageous not only in qualitative discrimination or quantitative identification but also in molecular characterization of chemical species concerned, especially for reaction intermediates, if they exist above the detection level of high resolution NMR spectroscopy.

In the present reaction the concentration of the reaction intermediate of the successive type, $R \rightarrow I \rightarrow P$, was concluded to be sufficiently low, since no signals other than the reactant's and product's were found in each of the time-sequential spectra. Moreover, coincidence was recognized between the rate constants obtained from the reactant decrease and the product increase independently for the total period of the reaction. The contribution of reaction intermediates of the pre-equilibrium type, $R \rightleftharpoons I \rightarrow P$, would also be sufficiently small, since no change in chemical shifts during the reaction was observed.

The authors are grateful to Professor Y. Yoneda for his encouragement and helpful discussion. Financial support from the Kawakami Memorial Fund is acknowledged.

Reaction of Methanol with Accelerated Rare Gas Ions

Takashi KOTOYORI,* Makoto TAKAHASI, and Akira ICHINOSE**

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo

(Received December 31, 1970)

Reaction of methanol with accelerated rare gas ions was studied. The yields of the reaction products, H_2, CO, CH_4, HCHO, and ethylene glycol, were determined, varying the initial kinetic energy of ion (2—6 kV), ionic species, (Ar, Xe, and Kr), and pressure of methanol ($(2—14)\times 10^{-3}$ Torr). No appreciable effect on the product yields was observed by adding carbon tetrachloride as electron scavenger or propylene as radical scavenger. The product yields are found to be linear against ln E_i, (E_i is initial kinetic energy of ions). Although the detailed reaction mechanism is left for future investigation, the reaction seems to be interpreted in terms of billiard model, momentum of ion being transferred directly to a local part of the target molecule at the contact time.

Studies on the chemical reaction of neutral compounds with accelerated ions have been rather few except in the field of mass spectrometric studies and radiation chemistry. It is well known that the ion-molecule reaction takes an important part in the processes of radiation chemistry and plasma chemistry in electrical discharge, but the studies on the reaction initiated directly by accelerated ions are few, apart from the radiation chemical studies with α-particles. In these recent years, a remarkable progress has been achieved in elucidating the characteristics of ion-molecule reaction using single or tandem-type mass spectrometer technique. Study of ion-molecule reaction with mass spectrometer has a pronounced advantage, in observing directly the behavior of the secondary ions produced by impact of primary ions. However, we consider it is also important and interesting to get the information on the final reaction products obtained by ion impact. For this purpose, a small chemical accelerator was constructed which is furnished with an ion source of relatively strong beam intensity and enables us to obtain enough amount of reaction products to be analysed by the conventional analytical methods. With this apparatus we studied the reaction of methanol with accelerated rare gas ions and obtained some preliminary results on the reaction mechanism.

Experimental

Apparatus and Procedures. Figure 1 shows a schematic drawing of the apparatus. Details of the construction and performance of this apparatus is describred elsewhere.[1] Impact ions are generated by electrical discharge of 70 MHz radio waves. Discharge tube is made of Pyrex glass, and is similar to that used in some neutron generator. Gas pressure in discharge tube is adjusted to obtain maximum ion intensity, and the optimum rate of gas feeding is about 10 m*l* STP per hour. The ions are accelerated by DC voltage from 2 to 6 kV. The efficiency of ion extraction is found to be very sensitive to the shape and size of quartz tube for ion exit. The ion extraction efficiency from discharge tube increases with increase of DC voltage, and maximum intensity of ion obtained is about 70 μA. F is an ion focussing lens to which DC voltage is applied, and the optimum ratio of ion focussing voltage to source voltage in the present apparatus is about 1.16. The reaction tube is made of Pyrex glass of 30 cm of length and 3 cm in diameter. A cold trap C is provided to collect condensable vapours and methanol

and reaction products (formaldehyde and ethylene glycol) can be collected almost quantitatively in the trap. Incondensable gases such as argon, hydrogen, methane, and carbon monoxide are collected in an evacuated bulb of 2 *l* through oil diffusion pump, closing the valve V during the irradiation time. It was checked beforehand that oil diffusion pump does not give any decomposition products, although mercury diffusion pump may be more preferable. Ion current is measured by a Faraday cup attached at the end of the reaction tube, and auxiliary electrodes are furnished to remove charge accumulated on the glass wall. At present, the reaction tube of 5 cm in diameter instead of that of 3 cm in diameter is used, and in this case, it is found that these auxiliary electrodes are unnecessary. Target vapour is supplied from the end of the reaction tube, and the rate of feeding is regulated by a needle valve, monitoring the pressure with Pirani gauge. The gauge was calibrated for methanol in the range of 0.001 to 10 Torr. The working pressure of methanol in the experiment is $(2—14)\times10^{-3}$ Torr. Methanol is purified by refluxing with magnesium metal and distilled in the vacuum line. The irradiation time is 5 min for collecting condensable products, and 2 min for collecting incondensable gases. Incondensable gases collected in an evacuated bulb are compressed by a Toepler pump and analysed by gas chromatography with Molecular Sieve 5 A column. The amount of formaldehyde was determined by spectrophotometric method after being treated with chromotropic acid.[2] The amount of ethylene glycol was determined separately after being oxidized with periodic acid to formaldehyde.[3] To collect these reaction products quantitatively, it is necessary to heat the reaction tube with electrical heater of nichrome wire wound on outside of the reaction tube. Water may also be produced, but its analysis was not attempted in the present experiment.

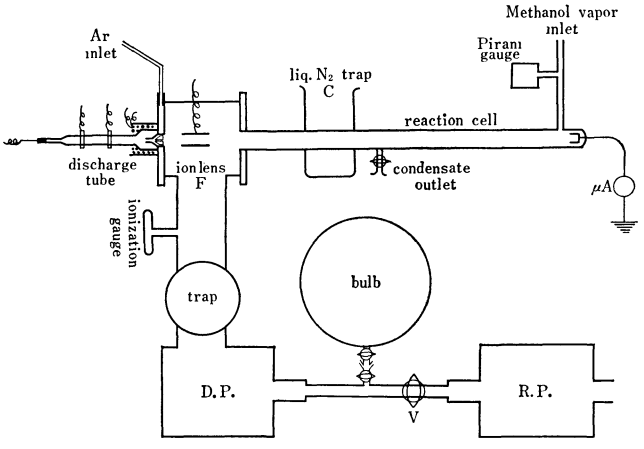

Fig. 1. Diagram of ion impact apparatus.

Results

Spread of Energy of Incident Ar Ion and Abundance of Double Charged Ion. It is generally known that the spread of energy of ion beam generated by electrical discharge is fairly large, and in order to determine the magnitude of the energy spread under the present experimental condition, the ion source is installed to a mass spectrometer which is 60° sector type with analysing tube of 20 cm radius. The maximum beam intensity of Ar at the ion accelerating voltage of 5kV is about 6μA, but the intensity fluctuates slowly. Since it can be easily recovered by adjusting the magnetic field, this fluctuation must be due to that of the energy, which seems to be caused by the periodic slow instability of plasma in the discharge tube. Due to this fluctuation of beam intensity, it is difficult to determine the exact shape of the beam against magnetic field, but the approximate energy spread of Ar at 5 kV is estimated to be about 150 V. The relative abundance Ar^{2+} to Ar^{+} is also estimated to be about 1 to 40 by scanning the magnetic field. In the actual impact experiments, the ion source is directly attached to the reaction tube as shown in Fig. 1, to obtain enough intensity of the ion beam, without eliminating double charged ions, assuming that their contribution is negligible.

Proportionality of Product Yields with Ion Intensity and Product Distribution Pattern. In order to confirm the reliability of our apparatus and the reproducibility of the product yields, the proportionality of the yields of the reaction products per unit irradiation time with the intensity of impact ion was investigated in the range from 20 to 40 μA in the impact experiment of methanol with Ar ion. The proportionality of the yields is satisfactory.

As will be described later, the product distribution in the methanol impact experiment depends to some extent on the pressure of methanol and the energy of impact ions, but an example of the product distribution under a specified condition is presented in Table 1, including the photochemical and radiation chemical results obtained by the other authors for comparison.[4,5]

Table 1. Product distribution patterns in the reaction of methanol with 5 kV Ar^{+} at[6] 8.5×10^{-3} Torr of methanol and other data for comparison

	Unit	H_2	CO	CH_4	$(CH_2OH)_2$	HCHO
5kV Ar^{+}	molecule per Ar^{+}	41.0	10.7	2.7	3.2	1.0
Co γ-ray[4]	*G* value	10.4	0.84	0.26	3.1	5.6
1849 Å photon[5]	mole per cc sec, 10^{-13}	86	2	1.5	60	16

Hitherto, in interpreting the product distribution patterns of the radiolysis of organic compounds, calculations have been made by several authors[7,8] on the basis of the relative abundance of ions observed in mass spectra. In the case of methanol radiolysis,

TABLE 2. PRODUCT DISTRIBUTION PATTERNS CALCULATED ON THE BASIS OF VARIOUS ASSUMPTIONS OF THE PRIMARY ION PRODUCT DISTRIBUTIONS AND SUCCESSIVE ION-MOLECULE REACTION SCHEMES

Assumption adopted		Final products ratio[a]					
Distribution of primary ions	Secondary ion-molecule reaction scheme	H_2	$(CH_2OH)_2$	HCHO	CO	CH_4	H_2O
Proposed values by Lindholm	Proposed scheme by Lindholm	10	8.3	5.7	0.51	4.0	4.0
Observed values by Lindholm(10VAr$^+$)	Lindholm	10	9.1	11.2	2.8	9.6	9.6
Same as above	Baxendale	10	3.4	5.3	1.2	1.0	—
Observed values in electron impact	Baxendale	10	3.4	5.1	0.9	0.3	—
Present experimental values		10	0.78	0.25	2.6	0.66	—

a) normalized to hydrogen

calculations by Lindholm *et al.*[9] and Baxendale *et al.* show fairly good agreement with the experimental results. We attempted the similar calculation to our ion impact case, assuming that the primary ion distribution in the present case is same as that of ion impact spectrum of 10 V Ar$^+$ reported by Lindholm.[9] This assumption may be acceptable because it is known that the ion impact spectra do not vary so much with the kinetic energy of ion in the case of charge transfer. Since Lindholm and Baxendale assumed slightly different reaction schemes for the successive secondary processes, we made calculations on the both reaction schemes. As shown in Table 2, the calculated results do not agree with our experimental result. The distiguished feature in our observed result is very low yields of formaldehyde and ethylene glycol, and the calculation cannot give high yield of carbon monoxide, unless a fundamentally different mechanism is introduced.

Variations of Yields of the Reaction Products with Different Incident Ionic Species. Several authors[9-11] proposed that the secondary ion spectra of organic compounds obtained by ion impact may be explained assuming that the most part of energy required to produce secondary ions from the original target molecule comes from the charge neutralization energy of the incident ions due to the charge transfer process. Lindholm observed the ion impact mass spectra of methanol due to charge transfer with various positive ions of low kinetic energy (4—900 V). He concluded that for most ions the mass spectra of methanol are almost independent of the kinetic energy of the incident ions, and that the energy transferred to methanol equals the electron recombination energy of the incident ions. If this could be applied to the present impact case, we would expect the variation of yields of the reaction products with ionic species of various electron recombination energies. To investigate the effect of recombination energy of impact ions, Ar (I_p=15.75, 15.95 eV), Kr (I_p=14.0, 14.67 eV), and Xe (I_p=12.15, 13.44 eV) are used as source gas. Since the ionization potential of methanol is 10.88 eV, the gain of energy due to the charge transfer is at most 4.87 eV for Ar$^+$, 3.12 eV for Kr$^+$, and 1.27 eV for Xe$^+$ for each ground state of ions. As Fig. 2 shows, the yields of the reaction products per ion at a fixed translational energy are almost the same within the experimental errors irrespective of the species of ion used.

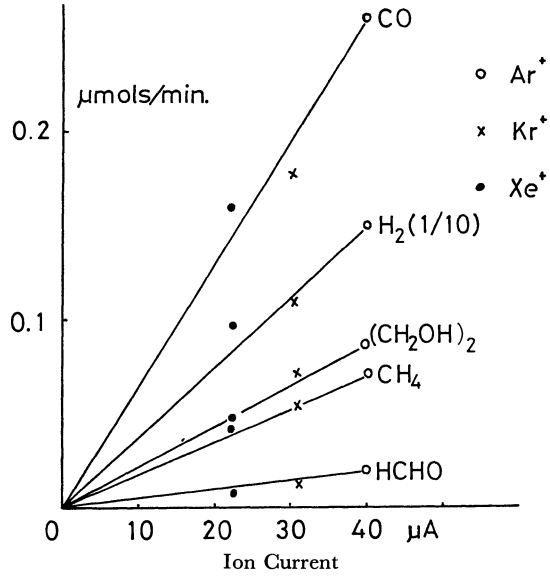

Fig. 2. The yields of the reaction products per ion with Ar$^+$, Xe$^+$, and Kr$^+$.

This figure shows that the product yields of five components, if normalized to ion intensity, do not show any appreciable difference. (In Fig. 2, the beam intensities are not normalized, since the extraction efficiencies of ions from ion source depend on the ionic species). Therefore, the present result cannot be interpreted in terms of charge transfer process. It can be understood if we consider that our experimental conditions (high energy of incident ion, long reaction path, and higher pressure of methanol in the reaction chamber than in the ionization chamber of mass spectrometer) result in the multiple collisions of incident ion. Table 1 shows that a single ion reacts with more than one molecule of methanol, although we have not definite evidence that all of these products are produced by the reaction with initial ions. At any rate, we may conclude that the charge transfer process does not contribute predominantly, although it may be involved in the initial step to some extent.

The Effect of Initial Kinetic Energy of Impact Ion and of Pressure of Methanol. The variation of product

yields with the initial kinetic energy of ion (2 to 6 kV) was investigated. The plot of product yields with logarithm of the initial energy E_i shows a fairly good linear relationship, as Fig. 3 shows. Another interesting point to be noted is that the extrapolations of slopes for carbon monoxide, ethylene glycol, and methane intercept the abscissa nearly at the same position. Interpretation of these results will be given in discussion part.

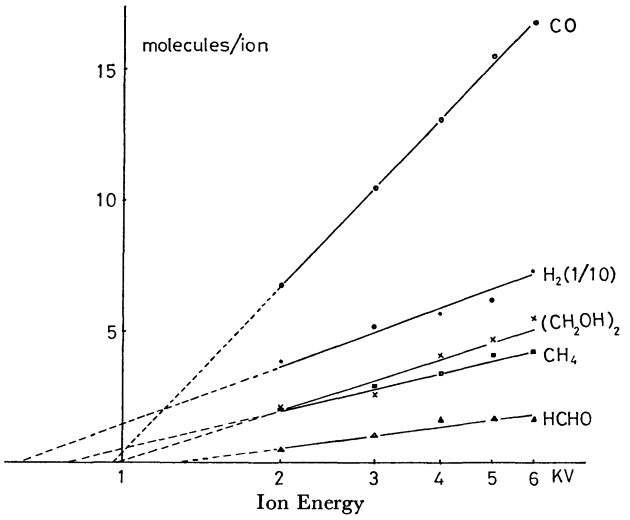

Fig. 3. The plots of the yields of the reaction products against logarithm of the initial energy, ln E_i.

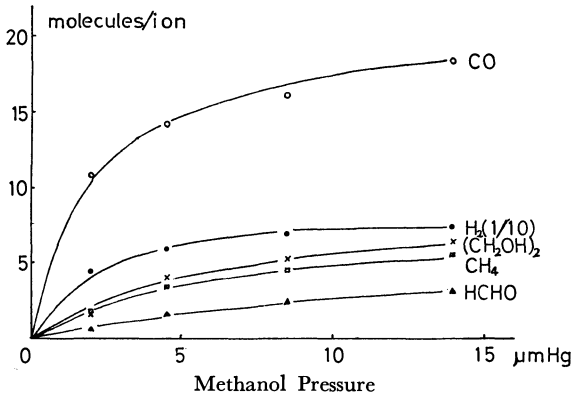

Fig. 4. The variation of the reaction product yields with the increase of the pressure of methanol.

The variation of the reaction product yields with the increase of the pressure of methanol was also investigated in the range $(2—14)\times10^{-3}$ Torr. (Fig. 4). When the pressure of methanol is increased, the yields of all the reaction products increase, approaching to constant values. Five components of the reaction products do not show the same behavior, particularly the yields of hydrogen and carbon monoxide increasing more rapidly with methanol pressure than those of the other reaction products. If the simple bimolecular collision of methanol with ion is assumed, we would expect for the product yields to be proportional to flux of incident ions, length of the reaction tube and pressure of methanol. It is already shown that the product yields are proportional to the ion intensity. The fact that the product yields increase first and approach to limiting values with the increase of methanol pressure indicates some more complicated mechanism is involved in the present reaction. We have not yet definite interpretation for the pressure effect, but some ideas will be given later.

Effect of the Addition of Carbon Tetrachloride and Propylene. It is well known that in the radiolysis of organic compounds with γ-ray the energetic secondary electrons produced by Compton scattering take an important role. However, in the present case, the average energy of the electrons produced by ionizing penetration of heavy charged particles is supposed to be very near to the thermal energy, since the kinetic energy of incident ion is at most 6 kV. Therefore, the direct excitation of methanol by energetic electrons is unlikely, but the production of excited methanol by charge neutralization of methanol ion might be possible, resulting the decomposition of excited methanol.

$$CH_3OH^+ + e \longrightarrow CH_3OH^*$$
$$CH_3OH^* \longrightarrow \text{Products}$$

Meaburn and Mellows[12] found the reduction of the yield of hydrogen in the radiolysis of methanol vapour with the addition of 0.01% of carbon tetrachloride ($G(H_2)=4.1$), and assumed that carbon tetrachloride interrupts the following process, scavenging slow electrons.

$$CH_3OH^+ + CH_3OH \longrightarrow CH_3OH_2^+ + CH_3O\cdot$$
$$CH_3OH_2^+ + e \longrightarrow CH_3OH + H$$

To know whether these processes play any role in the present case, we examined the effect of the addition of carbon tetrachloride. As Fig. 5 shows, no appreciable effect in the product yields was observed except in formaldehyde, and it is concluded that these processes seem not to contribute appreciably in the production of hydrogen. The increase of the yield of formaldehyde with the addition of carbon tetrachloride was noticed. Any conclusive interpretation for this

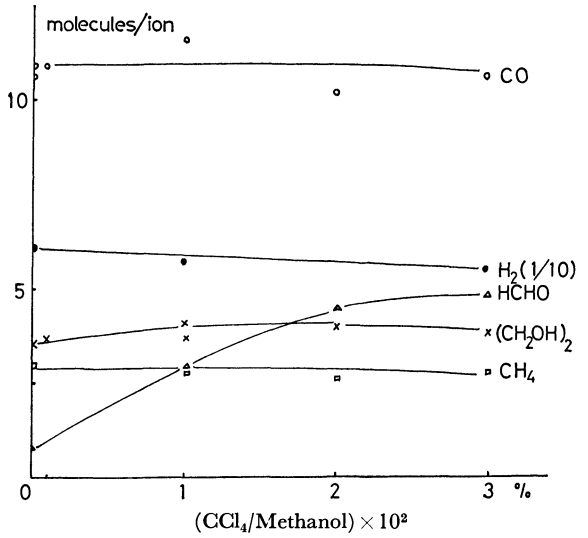

Fig. 5. The effect of the addition of carbon tetrachloride on the yields of the reaction products.

12) M. Meaburn and P. W. Mellows, *Trans. Faraday Soc.*, **61**, 1701 (1965).

finding is not available at present, but if chlorine atom is assumed to be produced by impact of carbon tetrachloride, it may induce the abstraction of hydrogen from methanol, resulting $\cdot CH_2OH$ or $CH_3O\cdot$ which may be finally converted into formaldehyde.

In view of the existence of ethylene glycol among the reaction products, the formation of free radicals (hydrogen atom and methylol radical $\cdot CH_2OH$) is supposed to be quite probable, and propylene was added as radical scavenger to find the extent of the contribution of free radicals to the whole reaction. Contrary to out expectation, no remarkable decrease of yields of the reaction products was observed, as Fig. 6 shows. It seems to be difficult to assume that the whole hydrogens were produced by molecular mechanism, so that an alternative possible explanation may be that produced hydrogen atoms are hot. Hatano and Shida[13] found that hot hydrogen atoms produced in irradiation of liquid olefins with Co 60 γ-rays do not add to olefins and rather abstract hydrogen. No reduction of ethylene glycol with addition of propylene may be understood, if we consider the fact that methylol radical is stabilized by conjugation of odd electron with oxygen and cannot add to propylene at room temperature.

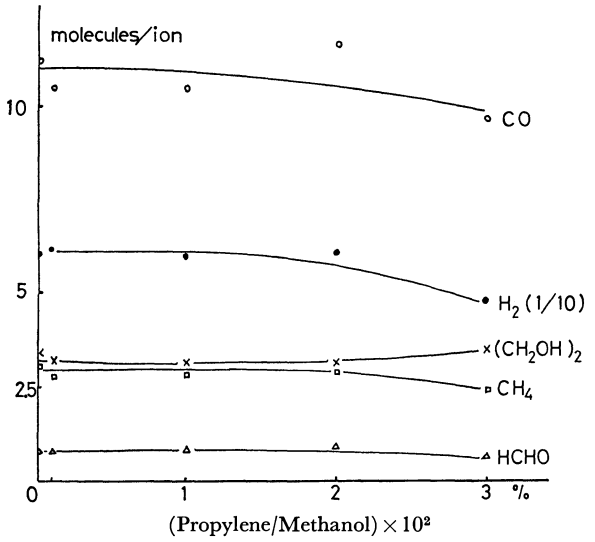

Fig. 6. The effect of the addition of propylene on the yields of the reaction products.

Luminescence by Ion Impact. Faint purple luminescence was observed in the reaction tube, when methanol vapour was introduced. Spectra in the visible region were taken by a spectrograph, with exposure time of 30 min. The spectra consisted of line spectra of hydrogen Balmer series and some unidentified bands (band heads at 4311.8 Å, 3978 Å, and 3955 Å). More detailed investigations for the interpretation of these spectra are left for future study.

Discussions

Summarizing the above experimental results, the contributions of the possible processes are considered and evaluated.

(1) Charge Transfer Process.

$$X^+ + CH_3OH \longrightarrow X + CH_3OH^{*+}$$

$$CH_3OH^{*+} \longrightarrow \text{Products}$$

As described in experimental results, no variation of the yields of the reaction products with different ionic species was observed. As excess energy left on methanol ion, CH_3OH^{*+}, must depend on the amount of recombination energy of incident ion X^+, different product distribution patterns would be expected, depending on the ionic species used. Present results are incompatible with this expectation, and the charge transfer process appears not to play an important role under the present conditions.

(2) Complex Formation Process as Considered in Ion-molecule Reaction. Now it is generally admitted that the complex formation mechanism in ion-molecule reaction takes place only in the very low translational energy range,[14,15] and the energy range of the present experiment is well above this energy range. Therefore, the contribution of this type of reaction may not be necessary to be considered.

(3) Excitation Process by Secondary Electrons. At present, we have no direct experimental evidence whether the excitation of methanol by secondary electrons produced by ionizing penetration of heavy charged particles is involved or not. The data of cross sections for the ionization of methanol by rare gas ions in the energy range of several kV are not available, but the cross sections reported in the case of accelerated ion with various atomic particles are in 10^{-16} cm^2 range,[16,17] indicating that the probability of ionization by charged heavy particles in several kV range is generally large. However, it is less likely that the electrons produced have enough energy to excite methanol, since the relative velocity of ion is fairly low compared with the velocity of orbital electron.

(4) Dissociative Excitation of Methanol Ions by Charge Neutralization. If methanol ion is produced by ionization, excited methanol may be formed through charge neutralization, resulting in its decomposition. However, our experimental result on the effect of addition of carbon tetrachloride seems not to favour this process.

(5) Direct Dissociation Process by Momentum Transfer.

$$X^+ + M \longrightarrow X^+ + R_1 + R_2,$$

or

$$X^+ + M \longrightarrow X^+ + M^* \longrightarrow X^+ + R_1 + R_2.$$

The collision dynamics by classical or semiclassical treatment has been recently developed for interpreting the product yields, the isotope effect and the moderator

effect in hot atom chemistry.[18-20] The main characteristic of this type of reaction is transfer of momentum of hot atom to molecule in the collision process. The same type of collision is also observed in molecular beam experiment of alkali atom with halogen[21] and ion-molecule reaction in relatively high energy impact.[22] In these experiments, only the reactions to give stable association products such as HT in the reaction, $T+H_2$, MX in the reaction, M (alkali metal) $+X_2$, and ArH^+ in the reaction, Ar^++H_2 have been considered. However, if the energy of incident particles is high, more drastic reactions to give fragmental products must be considered. We presume that this type of reaction takes an important role in the present ion impact experiment, considering that the processes (1)—(4) mentioned above are rather less likely. To interprete the relation of the product yields with the initial kinetic energy of ions, a similar formula as derived for the relative yields of hot atom products is considered.

Miller and Dodson[23] gave the following formula for the yield of hot product,

$$N_{\mathrm{hot}j} = N_s\int f_j p_j(E)n(E)\mathrm{d}E, \qquad (1)$$

where N_{hot} is the number of hot product, N_s is the total number of hot atoms available for the reaction, f_j, the relative probabilty of collision, $p_i(E)$, the probability of hot combination reaction in such collision at energy E, and $n(E)$ is the average number of collision per unit energy at E (collision density). Estrup and Wolfgang[24] derived the following equation for the number of collisions between energies E and $E+\mathrm{d}E$ of a hot atom not undergoing hot combination reaction, assuming elastic and reactive collisions are taking place competitively,

$$n(E)\mathrm{d}E = -\frac{\mathrm{d}E}{\alpha E}\left\{1-\sum_j\int_{E_1}^{E} f_j p_j(E)n(E)\mathrm{d}E\right\}, \qquad (2)$$

where $\alpha=\sum f_i\alpha_i$, and for hard sphere collision,

$$\alpha_j = 1+\frac{\beta_j\ln\beta_j}{1-\beta_j} \quad \text{and} \quad \beta_j=\left[\frac{(M_j-m)}{(M_j+m)}\right]^2,$$

where m is the mass of hot atom and M_j, that of the particle struck. The quantity in the bracket of Eq. (2) is the probabiliy that the hot atom has escaped reaction in the energy interval E_2 to E. Here, the reactions to form stable products by hot atom combination (such as CH_3T in the reaction, $T+CH_4$) are only considered.

In the present ion impact system, the incident ions are not lost, since they do not form any stable products by collision, and therefore we may simply assume that the number of ion impact products N_j is proportional to the collision number of methanol with incident ions in the energy range between E_i (initial energy of ion) and E_f (final energy). In this case, the formula similar to the equation (1) can be used, redifining N_s as the total number of incident ions.

$$N_j = N_s\int_{E_f}^{E_i} p_j n(E)\mathrm{d}E \qquad (3)$$

Since the form of scattering function for reactive and nonreactive collision is not known, the exact form of $n(E)$ cannot be derived. However, if we simply assume that the collision density function approaches rapidly to the following well known asymptotic solution[23]

$$n(E) = 1/\alpha E, \qquad (4)$$

the equation (3) can be simplified,

$$N_j = N_s\int_{E_f}^{E_i} p_j\left(\frac{1}{\alpha E}\right)\mathrm{d}E = N_s\frac{p_j}{\alpha}\ln(E_i/E_f), \qquad (5)$$

assuming p_j and α are both independent of energy, although this is obviously an approximation.[25] From the experimental point of view, since Fig. 3 shows that the yields per ion, (N_j/N_s) are proportional to logarithm of initial ion energy E_i, p_j/α can be determined as slope and $\ln E_f$ as intercepts with abscissa. Here, E_f can be interpreted as the lowest limits of energy to give appreciable reaction products.

In Table 3, the values calculated by least squares method are given. Here, it is interesting to compare

Table 3. Average logarithmic energy loss α and minimum energy to give reaction rpoduct calculated by the least squares method from the experimental results shown in Fig 3.

	α/p_j	$\ln E_f$	E_f, volt

25) In a strict sense, the asymptotic equation (4) cannot be applied to the region near E_i. However, Placzek (*Phys. Rev.* **67**, 423 (1964)) and Hsiung, Verosub, and Gordus (*J. Chem. Phys.*, **41**, 1595 (1964) have shown that $n(E)$ approaches rapidly to $1/\alpha E$, if β is much less than 1.

p_j/α with values α calculated for isotropic elastic scattering for several collision pairs.

The values of p_j are not known, but they must be less than unity, so the values of α in the experiment must be below 0.035, indicating that the average energy fraction lost in reactive collision is rather small corresponding to a small value of β. This seems to suggest that momentum is transferred to a part of light mass in a molecule (possibly to hydrogen atom), not to the whole molecule at the collision instant. After collision, the struck atom may depart from molecule, carrying kinetic energy, or dissipate energy to the whole molecule as in unimolecular decomposition. The latter process is taken into consideration, in view of the pressure effect on the product yields described below.

Pressure Effect on the Product Yields. Apparently, the pressure effect shown in Fig. 4 might be explained in terms of exponential law like Lambert-Beer type as

$$N_j = N_s \exp(-n_{CH_3OH}\sigma_j l) \quad (6)$$

However, under the present experimental conditions, "so-called single collision condition" is not the case, and our experimental result of pressure dependency itself does not fit to Lambert-Beer type law. Although plot of logarithm of product yields against pressure of methanol is linear, the extrapolation of plot does not pass through origin at pressure zero, but rather intercepts the ordinate at much larger values. Instead, if the reciprocals of the product yields per ion are plotted against the reciprocal of pressure, again linear relationships are obtained. This type of linear relationship is known in the unimolecular decomposition mechanism, fluorescence and photochemical quenching, indicating the involvement of deactivation process of excited species by collision. Since the detailed reaction mechanism is not yet established, the following reaction scheme might be oversimplified one, but it may be helpful for understanding the feature of the reaction.

$$X^+ + CH_3OH \xrightarrow{\sigma_j l} X^+ + CH_3OH^* \quad 1$$

$$CH_3OH^* + CH_3OH \xrightarrow{k_{2j}} 2CH_3OH \quad 2$$

$$CH_3OH^* \xrightarrow{k_{3j}} \text{Product } j \quad 3$$

The rate of formation of primary products to give j-th final product per ion, R_j may be as follows,

$$R_j = n_{CH_3OH}\sigma_j l\left(\frac{k_{3j}}{k_{3j}+n_{CH_3OH}k_{2j}}\right), \quad (7)$$

or

$$1/R_j = \frac{1}{\sigma_j l}(k_{2j}/k_{3j} + 1/n_{CH_3OH}),$$

assuming steady state condition. n_{CH_3OH} is the number of methanol per ml, l, the length of reaction tube (30 cm), σ_j, macroscopic cross section for the process 1, and k_{2j} and k_{3j} are the rate constants for the processes 2 and 3, respectively.[26] The values σ_j[27] and k_{2j}/k_{3j} determined from the experimental values are given in Table 5. We consider a very large cross section for hydrogen production is an apparent one, since more than one hydrogen molecule must be produced per single collision. Relating to our observation, it is interesting that Tachikawa and Kahara[28] recently reported the similar pressure dependence of the reaction of recoil Br produced from ^{80m}Br with CH_4 and CD_4. They concluded the lifetime of the excited species is in the range of 10^{-8} to 10^{-9} sec. In the present case, much longer life-time (10^{-3} sec) must be assigned on the basis of our experimental values of k_{2j}/k_{3j}.

Table 5. Slopes and intercepts calculated from the plots of $1/R_j$ against $1/p$, cross sections σ_j, and k_{2j}/k_{3j}

Product	Slope (molecule ion)$^{-1}$/(10^{-3} Torr)$^{-1}$	Intercept (molecule/ion)$^{-1}$	σ_j (10^{-14} cm^2)	k_{2j}/k_{3j} (10^{-14}cc/molecule)
H_2	0.023	0.012	4.2	1.5
CO	0.086	0.051	1.1	1.7
$(CH_2OH)_2$	0.601	0.12	0.16	0.55
CH_4	0.743	0.13	0.09	0.34
HCHO	1.955	0.19	0.05	0.27

We are now undertaking the experiment in the presence of moderator, and more definite scheme for ion impact process will be obtained in near future.

26) In order to introduce the pressure effect into the equation (5), Eq. (7) must be combined with Eq. (5), but this is left for future investigation. We point out here only that it is necessary to modify the meaning of p_j to some extent.

27) As Table 5 shows, σ for each reaction product is not constant. This seems to be peculiar, but the appropriate interpretation is not available at present.

Near Ultraviolet Absorption Spectrum of Pyridine-d_5 Vapor

Yoshinori HASEGAWA

College of General Education, Tohoku University, Kawauchi, Sendai

(Received March 2, 1971)

The near ultraviolet absorption spectrum of pyridine-d_5 vapor due to n–π^* transition was measured and analyzed. The origin is at 34951 cm^{-1} and higher than that of pyridine-h_5 by 182 cm^{-1}. The ground-state frequencies 582 and 1019 cm^{-1} and their counterparts of 511 and 953 cm^{-1} in the upper state dominate the progressions in the spectrum. Besides the above frequencies, several active frequencies were obtained.

The near ultraviolet absorption spectrum of pyridine-h_5 vapor has been observed by Henri and Angenot[1] and by Sponer and Stücklen.[2] Assuming that the electronic transition is polarized in the molecular plane perpendicular to a twofold axis passing through the nitrogen atom, Sponer and Stücklen have assigned many bands in the region to the progressions with several totally and nontotally symmetric frequencies. In the spectrum of Sponer and Stücklen, the origin and the progressional members with the totally symmetric frequencs 542 cm^{-1} have been observed to belong to the parallel bands of an oblate symmetric top. The electronic transition has, therefore, been assigned to the A_1–B_1 transition with the electronic transition moment perpendicular to the molecular plane.[3] Although Sponer and Stücklen have reported on several fundamental frequencies in the ground and upper states, ambiguity remains on the character of the vibrations.

The infrared and Raman spectra of pyridine and deuteropyridines and their vibrational analyses have been extensively studied by many workers.[3–7] Their works provide us with much information on the n–π^* absorption spectrum of pyridine.

The purpose of the present study is to analyze the n–π^* absorption spectrum of pyridine-d_5 vapor in relation to that of pyridine-h_5 vapor.

Experimental

The spectrum was photographed in the second order of a Shimadzu GE-100 Ebert type grating spectrograph with a 500 W xenon arc lamp as light source. The reciprocal dispersion was 4.1 Å/mm. A Toshiba UV-D2 filter was used to eliminate all radiation in the other orders. Fuji spectroscopic plates were used. The wavelengh calibration was made by an iron arc. The absorption cells with quartz windows had light path lengths 20 and 60 cm. The 20 cm cell had a side arm in which the sample was kept during exposures at temperatures varying from −16°C to room temperature. The 60 cm cell into which the sample was introduced was helically wound with nichrome wire over an asbestos sheet and covered with an asbestos sheet. The cell temperature could be regulated between room temperature and 50°C.

The 99% pure pyridine-d_5 was a Merk product. The sample was twice distilled in a vacuum and then introduced into the absorption cell in a vacuum. The spectrum of pyridine-d_5 showed no spectrum of pyridine-h_5.

Results and Discussion

The n–π^* absorption bands of pyridine-d_5 vapor observed at −16°C appear in the wavelength region 2860—2620 Å. The bands have narrow line-like shapes in the longer wavelength region, but become diffuse in the shorter wavelengths and finally are submerged in a strong continuum. The strongest band at 34951 cm^{-1} in the longest wavelength region is taken as the origin, which is shifted by 182 cm^{-1} toward the blue compared

a) The values taken from Corrsin *et al.*[4]
b) The values by Sponer and Stücklen.[2]
c) Cunliffe-Jones has assigned the frequencies 700 and 746 cm^{-1} to the modes 4 and 11, respectively.[6]
d) Wilmshurst and Bernstein have assigned the frequencies 567 and 823 cm^{-1} to the modes 4 and 5, respectively.[5]

with that of pyridine-h_5.[2] With the rise of temperatures, many line-like bands appear in the longer wavelength side of the origin.

Table 1 represents our measurements with visually estimated intensities and assignments of the bands. Table 2 shows the active frequencies of the pyridine-d_5 spectrum together with those of the pyridine-h_5 spectrum.[2]

The interval 582 and 1019 cm^{-1} are most prominent in the longer wavelength region of the origin. These are identical with the frequencies 582 and 1006 cm^{-1} assigned to the totally symmetric in-plane ring bending modes 6a and 12, respectively, in the vibrational spectra.[4,5] The frequency 582 cm^{-1} corresponds to the prominent frequency 601 cm^{-1} in the pyridine-h_5 spectrum and has a counterpart of 511 cm^{-1} (542 cm^{-1} in pyridine-h_5) in the upper state. The frequency 1019 cm^{-1} has a counterpart of 953 cm^{-1} in the upper state. The frequencies 1031 and 995 cm^{-1} in the ground and upper states, respectively, in the pyridine-h_5 spectrum correspond to the frequencies.

The separation 680 cm^{-1} of the strong hot band at 34271 cm^{-1} from the origin might coincide with a frequency of 690 cm^{-1} in the vibrational spectra. This frequency is assigned to the out-of-plane hydrogen bending mode 10a with species a_2. It may be expected that the bands caused by a nontotally symmetric vibration of species a_2 show a perpendicular type.[8] The shape of the band is, however, line-like and can not be distinguished from those of the parallel bands. The frequency 680 cm^{-1} corresponds to 891 cm^{-1} in the pyridine-h_5 spectrum and has a counterpart of

8) A. C. Albrecht, *J. Chem. Phys.*, **33**, 156 (1960).

558 cm^{-1} (probably 672 cm^{-1} in pyridine-h_5) in the upper state.

Separations 371, 520, 622, 765, and 828 cm^{-1} of weak bands to the red from the origin coincide with the respective frequencies in the vibrational spectra as shown in Table 2 and assigned as in Table 1.

Separations 891, 958, 1325, and 1335 cm^{-1} of very weak bands to the red from the origin are identical with the respective frequencies in the vibrational spectra and assigned as in Table 1.

Separation 316 cm^{-1} of the strong hot band at 34635 cm^{-1} from the origin might coincide with the frequency 329 cm^{-1} in the vibrational spectra. The analogous band separated from the origin in the pyridine-h_5 spectrum by 378 cm^{-1} is, however, extremely weak. Thus ambiguity of the band remains.

The most characteristic feature of the pyridine-d_5 spectrum is the prominence of frequency 953 cm^{-1} in the upper state. Vibration 953 cm^{-1} makes overtone bands with three members and dominates progressions in combination with other vibrations. In the pyridine-h_5 spectrum, the 542 cm^{-1} progression starting from the origin appears up to the fourth member, but the analogue of 511 cm^{-1} in pyrinine-d_5 has only two progressional members.

The other fundamental frequencies in the upper state are 558 and 1078 cm^{-1}. The frequency 558 cm^{-1} seems to make no overtone and is a counterpart of the ground-state frequency 680 cm^{-1}. The frequency 1078 cm^{-1} probably corresponds to the ground-state frequency 1325 cm^{-1}.

On both sides of the origin, satellites appear with separations −164, −56, −40, −20, 34, 62, and 120 cm^{-1}. The satellite band separated from the origin by 120 cm^{-1} corresponds to the band separated from the origin by 139 cm^{-1} in the pyridine-h_5 spectrum, which disappears from the spectrum in solid solution at low temperature.[9] This satellite might be due to a v–v transition of a low frequency vibration. The other satellites might be due to v–v transitions of some vibrations.

The author is particularly indebted to Prof. H. Azumi for use of the spectrograph.

Kinetic Studies of the Solvent Extraction of Metal Complexes. I. The Extraction of the Beryllium(II)-TTA Chelate from Aqueous Perchlorate Media into Carbon Tetrachloride and Methyl Isobutyl Ketone

Tatsuya SEKINE, Yasuaki KOIKE, and Yū KOMATSU

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 8, 1971)

The rate of extraction of beryllium ions from aqueous 4.0M or 0.1M sodium perchlorate-chloride or -nitrate ionic media into carbon tetrachloride or MIBK (methyl isobutyl keton) as a chelate complex with TTA (thenoyltrifluoroacetone) has been determined at 25°C. The rate of extraction in the carbon tetrachloride system is first-order with respect both to the beryllium ion and the dissociated TTA anion in the aqueous phase. The rate constant for this reaction is about 2×10^{4}M^{2}min^{-1}. The rates in these systems are not influenced by the replacement of perchlorate ions by nitrate or chloride ions in the ionic media when the ionic concentration is kept constant. On the other hand, it was found that three extraction reactions take place in the MIBK systems. The rate of these extractions is in all cases first-order with respect both to the beryllium ion and the dissociated TTA anion, but is zeroth-, first, or second-order with respect to the perchlorate ions in the aqueous phase. Because of this, the extraction is much faster when the perchlorate concentration is larger; for example, when the concentration of the TTA anion is kept constant, the extraction from a 4.0M sodium perchlorate solution is about 200 times faster than that from the 4.0M sodium chloride solution. From these experimental results, the following conclusions were reached. In the carbon tetrachloride system, the beryllium ion first forms the TTA chelate in the aqueous phase, and then the complex is extracted into the organic phase. The rate-determining step is the 1:1 complex formation in the aqueous phase. In the MIBK system, on the other hand, the formation of the TTA complex in the aqueous phase, followed by its extraction into the organic phase (zeroth-order reaction with respect to the perchlorate ion), also occurs, but at the same time, the beryllium ion in the aqueous phase is first extracted into the organic phase as ion-pairs, such as $BeCl(ClO_4)$ or $BeNO_3(ClO_4)$ and $Be(ClO_4)_2$ (first- and second-order reactions with respect to the perchlorate ions respectively), and the ion-pairs then react with the TTA anions in the organic phase. The enhancement of the rate of extraction by the perchlorate ions in the MIBK system seems to be explained by the overall effect of these extraction mechanisms.

The solvent extraction of the beryllium(II)-TTA (thenoyltrifluoroacetone) chelate complex has been known as a slow reaction. It was reported that the rate of this extraction is dependent on the hydrogen-ion concentration and that a prolonged agitation is necessary until the distribution equilibrium is estab-

lished, especially when the pH is not high;[1] an agitation for one week was carried out in order to obtain the distribution equilibrium of the beryllium(II)-TTA chelate between *o*-xylene and aqueous solutions,[2] for instance. A slow beryllium(II) extraction with TTA has been also observed in our laboratory; it took one week or more to obtain the distribution equilibrium when beryllium(II) in perchlorate media was extracted with 0.01M to 0.1M TTA in chloroform or in carbon tetrachloride by the mechanical agitation of the two phases in glass tubes placed on a rotating framework at 20 rpm.[3] At the same time, it was also observed that the extraction is much faster when MIBK (methylisobutyl ketone) is used as the organic solvent; the extraction equilibrium was achieved within 12 hr by the same mechanical agitation.[3,4]

In this paper, the present authors have carried out a kinetic study of the beryllium(II) extraction with TTA in order to ascertain further details on this remarkable difference in the rate of extraction when these two organic solvents are used. The aqueous phase employed was 4.0M or 0.1M constant ionic media containing sodium perchlorate and sodium chloride or sodium nitrate. From these experimental data, the rate of extraction was given as a function of the concentration of the components and the important role of the perchlorate ions in the extraction mechanism has been established. The results were further discussed by comparing them with these of a distribution equilibrium study carried out under the same conditions.[4]

Experimental

Reagents. A radioactive tracer, beryllium-7, has always been used in order to determine the distribution ratio. It was obtained as a hydrochloric acid solution and was diluted with 0.01M perchloric acid in order to prepare the stock tracer solution. A reagent-grade beryllium hydroxide was dissolved in perchloric acid, and the concentration was determined by gravimetry after beryllium(II) 2-methyloxinate had been precipitated. The stock carrier solution was prepared by the dilution of this solution. It contained 5×10^{-3}M beryllium and 0.01M perchloric acid. The TTA was obtained from the Dōjindō Co. The MIBK was obtained from the Tokyo Kasei Co.; it was washed with 0.1M perchloric acid, water, and a 0.1M aqueous sodium hydroxide solution successively, and then several times with water. The sodium perchlorate was prepared from sodium carbonate and perchloric acid. It was recrystallized three times from water. All of the other reagents were of a reagent grade and were used without further purification.

Procedures. All of the procedures were carried out in a thermostatted room at 25±0.3°C. Stoppered glass tubes (volume, 20 m*l*) were always used in order to equilibrate the two phases. The organic solution of TTA prepared was stored overnight before the experiments. The aqueous phase initially contained 1.0×10^{-4}M labeled beryllium, sodium perchlorate, and, in some cases, sodium chloride or sodium nitrate and a 0.01M sulfanilate buffer. The total ionic concentration was 4.0M or 0.1M. A 5.0-m*l* portion of the organic solution and a 5.0-m*l* portion of the aqueous solution were placed in the glass tube, and the two phases were agitated vigorously by means of a mechanical shaker. In order to ascertain the effect of the material diffusion on the rate of extraction, a series of experiments were carried out as follows: a 5.0-m*l* portion of the aqueous solution and a 5.0-m*l* portion of the organic solution were taken, each from a certain batch, and placed in a glass tube. The tube was placed on the mechanical shaker and was shaken for 5 min at a certain shaking speed. The distribution ratio of beryllium(II) was then determined in a manner which will be described later. Several experiments were carried out by changing the shaking speed, and the distribution ratio thus obtained was plotted against the speed. It was found that the distribution ratio was dependent on the speed when it was low. However, beyond a certain speed (which was dependent on the nature and the volume of the two phases), the distribution ratio (which was much lower than the value at equilibrium) became no longer dependent on the speed. Such a "plateau region" of the shaking speed was determined before each series of experiments, and the shaking of that series of experiments was always carried out under those conditions.

In order to determine the rate of extraction, a series of experiments were carried out at different shaking intervals, but otherwise under the same experimental conditions. When the agitation was stopped, the two phases in the tube were immediately centrifuged and a certain portion was pipetted from each phase and transferred into small test tubes. The γ-radioactivity of each phase was counted by means of well-type (NaI) scintillation counter. Another portion was also taken from the aqueous phase and transferred into a glass vessel. The hydrogen-ion concentration (the stoichiometric unit) was determined by potentiometry by using standard perchloric acid, in which the ionic concentration was 0.1M or 4.0M.

The beryllium content in the two phases was determined from the initial beryllium concentration and the γ-radioactivity of the two phases as:

$$[\mathrm{Be(II)}]_{org} = [\mathrm{Be(II)}]_{initial} \times (\gamma\text{-count-rate})_{org}/(\gamma\text{-count-rate})_{initial}$$

$$[\mathrm{Be(II)}] = [\mathrm{Be(II)}]_{initial} \times (\gamma\text{-count-rate})_{aq}/(\gamma\text{-count-rate})_{initial}$$

Statistical

The rate of extraction could be influenced by many factors. As has been described, the agitation of the two phases in this study was always done in the plateau region, where the rate was independent of the speed of the two-phase agitation. Thus, the diffusion or the transport of materials could be eliminated from consideration; the rate is dependent only on the concentrations of the materials in the system.

On the basis of these facts, the extraction rate may be generally described as follows:

$$-\frac{d[Be^{2+}]}{dt} = k^*[Be^{2+}]^a[HA]_{org}^b[H^+]^c[ClO_4^-]^d \qquad (1)$$

Here, the term of water is omitted because it is not possible to change the water activity without influencing the other factors.

2) H. J. Debruin and R. B. Temple, *Aust. J. Chem.*, **15**, 153 (1962).
3) T. Sekine and M. Sakairi, This Bulletin, **40**, 261 (1967).
4) T. Sekine, Y. Komatsu, and M. Sakairi, *ibid.*, **44**, 1480 (1971).

The dissociation and the distribution constants of the chelating acid are described as:

$$K_a = \frac{[H^+][A^-]}{[HA]} \quad (2)$$

$$K_D = \frac{[HA]_{org}}{[HA]} \quad (3)$$

$$\frac{K_D}{K_a} = \frac{[HA]_{org}}{[H^+][A^-]} \quad (4)$$

When b is equal to c^{-1}, Eq. (1) can also be described as:

$$-\frac{d[Be^{2+}]}{dt} = k[Be^{2+}]^a[A^-]^e[ClO_4^-]^d \quad (5)$$

where $k=k^*K_DK_a^{-1}$.

As the perchlorate and the extractant (HA) are in a large excess in relation to beryllium, and as the aqueous phase is buffered, the rate can be described as follows:

$$-\frac{d[Be^{2+}]}{dt} = q[Be^{2+}]^a \quad (6)$$

Here q is the multiplication of the rate constant, k^*, and the other concentrations which are kept at certain values. When the reaction order with respect to beryllium is unity, as it is in the present study, the following simplified statistical treatments are possible.

Equation (6) can be rewritten as:

$$-\frac{d[Be^{2+}]}{dt} = q[Be^{2+}] \quad (7)$$

$$-\log[Be^{2+}] = qt + c_0 \quad (8)$$

Equation (8) shows that the above assumption should stand if the $\log[Be^{2+}]$ *vs.* t plot is a straight line with a slope of $-q$.

The reaction order with respect to the other species can be determined from the rate measurements when two of the concentrations out of these three are kept at certain values. For example, when the concentrations of the extractant and perchlorate ions are kept at B and D, then the quantity q_{H^+} can be defined as follows:

$$\log q_{H^+} = \log k^*B^bD^d + c\log[H^+] \quad (9a)$$

As can be seen from Eq. (9a), the $\log q_{H^+}$ *vs.* $-\log[H^+]$ plot should be a straight line with a slope of $-c$ under such conditions; thus, the reaction order with respect to the hydrogen ion, c, can be determined.

By similar procedures, the rest of the values of the b and d reaction orders can be determined from the slope of the plot given by the following equations:

$$\log q_{HA} = \log k^*C^cD^d + b\log[HA]_{org} \quad (9b)$$

$$\log q_{ClO^-} = \log k^*B^bC^c + d\log[ClO_4^-] \quad (9c)$$

However, as will be seen below, the reaction order with respect to the perchlorate ions, d, was not a constant in some systems, but changed as the perchlorate concentration was changed; this was, therefore, further treated.

The reaction order with respect to the perchlorate can, then, be generally described as:

$$-\frac{d[Be^{2+}]}{dt} = k^*[Be^{2+}][HA]_{org}^b[H^+]^c(1+k_1[ClO_4^-] + \cdots + k_n[ClO_4^-]^n) \quad (10)$$

or

$$= k[Be^{2+}][A^-]^e(1+k_1[ClO_4^-] + \cdots + k_n[ClO_4^-]^n) \quad (11)$$

In such cases, the following equation should be used instead of Eq. (9c):

$$\log q_{ClO_4^-} = \log k^*B^bC^c + \log(1+k_1[ClO_4^-] + \cdots + k_n[ClO_4^-]^n) \quad (12)$$

Thus, the $\log q_{ClO_4^-}$ *vs.* $\log[ClO_4^-]$ plot is not a straight line but a curve with two asymptotes:

$$[ClO_4^-] \to 0 \quad \log q_{ClO_4^-} = \log k^*B^bC^c$$

$$[ClO_4^-] \to \infty \quad \log q_{ClO_4^-} = n\log[ClO_4^-]$$

As the limiting slope was found to be $+2$ in the present study, the k_1 and k_2 constants were determined by a curve-fitting of the $\log q_{ClO_4^-}$ *vs.* $\log[ClO_4^-]$ with the following family of standard curves, as has been described in other papers:[5,6]

$$Y = \log(1+pv+v^2) \qquad X = \log v \quad (13)$$

The above treatments are probably valid only when the effect of the reverse reaction or the back extraction is negligible.

Results

In the present study, beryllium was always added to the aqueous phase, and the data used for the analysis were obtained only from the early stage of the extraction; therefore, the statistical treatments given above can be adopted without any corrections for the back extraction.

6) T. Sekine, M. Sakairi, and Y. Hasegawa, *ibid.*, **39**, 2141 (1966).

In all of the experiments, the TTA concentration in the initial organic phase was 0.1M and the perchlorate concentration was 0.1M or 4.0M, except when the dependence of the rate on these concentrations was determined. The hydrogen-ion concentration was, in general, 1.0×10^{-3}M. However, when the rate was too small or too large for accurate measurement, the experiments were carried out at a somewhat higher or lower hydrogen-ion concentration and the q_{HA} and $q_{ClO_4^-}$ values in Eqs. (9b) and (9c) were normalized to those at $-\log[H^+]$ 3 by assuming that they are inversely proportional to the hydrogen-ion concentration.

Extraction of Beryllium Perchlorate. Beryllium(II) in sodium perchlorate solutions is extracted even into MIBK in the absence of any chelating ligand, as has been pointed out (Ref. 4 Fig. 1). This extraction proceeds very rapidly, and the distribution equilibrium is reached within 30 sec under the present experimental conditions. The distribution ratio of beryllium(II) between MIBK and 4.0M sodium perchlorate is $10^{-1.16}$.

Reaction Order with Respect to Be^{2+}. In most experiments, the $-\log[Be^{2+}]$ *vs.* *t* plot under certain conditions was a straight line. Figure 1 gives an example of this. As can be seen from Eq. (8), this shows that the reaction order with respect to the beryllium ion is unity. However, when the two-phase agitation was carried out for a very long time, a deviation of the plot from a straight line was observed. The deviation is probably caused by the back extraction.

(A) Extraction into Carbon Tetrachloride. Reaction Order with Respect to the Hydrogen Ions: The rate of extraction was determined when the TTA concentration in carbon tetrachloride was 0.1M, the aqueous sodium perchlorate concentration was 0.1M or 4.0M and the hydrogen-ion concentration was between $10^{-2.5}$ and $10^{-3.5}$M. The value of *q* in Eq. (8) at a certain hydrogen-ion concentration was determined from the slope of the $-\log[Be^{2+}]$ *vs.* *t* plot; the series of log *q* values thus obtained at different hydrogen-ion concentrations, log q_{H^+}, are plotted against $-\log[H^+]$ in Fig. 2a. In the 4.0M ionic media, the plot is a straight line with a slope of +1, although the results are somewhat erroneous; it would be possible to conclude that the rate of extraction is inversely proportional to the hydrogen-ion concentration in this system. In the 0.1M ionic media, the plot is also almost a straight line with a slope of +1 in the higher $-\log[H^+]$ region. However, it deviates from the line as $-\log[H^+]$ decreases. The present authors cannot yet explain this deviation in the lower $-\log[H^+]$ region, but still it could be concluded that the reaction order with respect to the

4.0M $NaClO_4$ (open circles).
0.1M $NaClO_4$ (closed circles).

hydrogen-ion concentration is -1 when the hydrogen-ion concentration is around 1×10^{-3}M or less.

Reaction Order with Respect to TTA: The rate of extraction was determined when the hydrogen-ion concentration was $10^{-2.9}$M in the 0.1M ionic media and $10^{-3.1}$M in the 4.0M ionic media. The results are given in Fig. 3a. In the 4.0M ionic media, the plot is a straight line with a slope of $+1$, it was concluded that the extraction is proportional to the TTA concentration. In the 0.1M media, the plot is also almost a straight line with a slope of $+1$ in the higher TTA concentration region. However, it deviates from the line as the concentration decreases. The authors also cannot explain this deviation now, but they believe that it could be concluded that the reaction order with respect to TTA is $+1$ when the TTA concentration is about 5×10^{-2}M or more.

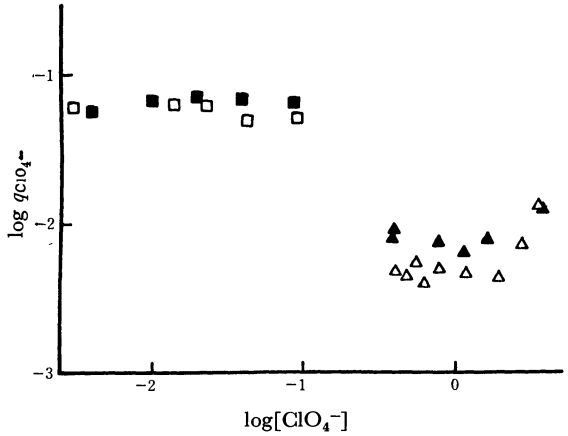

Fig. 4. Dependence of the rate of Be(II) extraction as TTA chelate on the aqueous perchlorate concentration when it is replaced by sodium nitrate (closed symbols) or by sodium chloride (open symbols). The notation $q_{ClO_4^-}$ on the ordinate is given in Eq. (9c).
Org. phase. CCl_4 containing 0.1M TTA.
Aq. phase. 4.0M Na(Cl, ClO_4) (open triangles)
4.0M Na(NO_3, ClO_4) (closed triangles)
0.1M Na(Cl, ClO_4) (open squares)
0.1M Na(NO_3, ClO_4) (closed squares)

Reaction Order with Respect to Perchlorate Ions. The rate of extraction was determined when the TTA concentration was 0.1M and the perchlorate ion concentration was changed. The hydrogen-ion concentration in these experiments was $10^{-3.5}$M in the 4.0M or 0.1M Na(NO_3, ClO_4) media, $10^{-3.6}$M in the 4.0M Na(Cl, ClO_4) media, and $10^{-2.8}$M in the 0.1M Na(Cl, ClO_4) media. Figure 4 gives the results (*cf.* Eq. (9c)). From Fig. 4, it can be seen that the rate of extraction is almost constant in the 0.1M media, that it decreases somewhat in the 4.0M media when the perchlorate ions are replaced by chloride or nitrate ions, but that it becomes almost constant when the concentration of these ions is above 2.0M. Thus, it can be concluded that the rate of extraction is practically independent of the composition of the salt in the aqueous phase.

From these findings, it was concluded that the rate of beryllium extraction into carbon tetrachloride with TTA is expressed by the following equation (*cf.* Eq. (1)):

$$-\frac{d[Be^{2+}]}{dt}=k^*[Be^{2+}][HA]_{org}[H^+]^{-1}[ClO_4^-]^0 \quad (14)$$

As may be seen from Eqs. (2) to (5), Eq. (14) can also be rewritten as:

$$-\frac{d[Be^{2+}]}{dt}=k[Be^{2+}][A^-] \quad (15)$$

The rate constants calculated from these results are given in Table 1.

Table 1. A summary of the rate constants for the extraction of beryllium(II)-TTA chelate complexes at 25°C

(A) Extraction into carbon tetrachloride

$$-\frac{d[Be^{2+}]}{dt}=k[Be^{2+}][A^-][ClO_4^-]^0$$

	0.1M $NaClO_4$	4.0M $NaClO_4$
log k	4.5	4.3

(B) Extraction into MIBK

$$-\frac{d[Be^{2+}]}{dt}=k[Be^{2+}][A^-](1+k_1[ClO_4^-]+k_2[ClO_4^-]^2)$$

	0.1M ionic media		4.0M ionic media	
	Na (NO_3, ClO_4)	Na (Cl, ClO_4)	Na (NO_3, ClO_4)	Na (Cl, ClO_4)
log k	4.8	4.7	4.9	4.4
log kk_1	6.5	6.3	5.8	5.7
log kk_2	5.9	5.7	4.9	5.2

The dissociation and distribution constants at 25°C used for the calculation of $[A^-]$ from $[HA]_{org}$ and $[H^+]$ are as follows. (taken from unpublished data by T. Sekine *et al.*)

		0.1M $NaClO_4$	4.0M $NaClO_4$
$\log\frac{[H^+][A^-]}{[HA]}$		−6.46	−6.57
$\log\frac{[HA]_{org}}{[HA]}$	CCl_4	1.30	1.93
	MIBK	2.25	2.62

(B) Extraction into MIBK. The distribution ratio of beryllium(II) between MIBK and 0.1M sodium perchlorate media is estimated to be $10^{-4.5}$ from the extrapolation of the data in Fig. 1, Ref. 4. Thus, the perchlorate extraction is negligible in the 0.1M ionic media. However, in the 4.0M ionic media, the distribution ratio into MIBK is already $10^{-1.16}$ in the absence of TTA. As has been described, the rate of extraction of the perchlorate ion-pairs is very large; thus, the beryllium(II) extraction with TTA from 4.0M perchlorate media is proceeded by the much faster perchlorate extraction.

On the basis of these findings, the rate of beryllium(II) extraction with TTA in MIBK was calculated after a correction for this beryllium(II) perchlorate extraction made as follows. In a preliminary experment, an aqueous phase initially containing the same amounts of beryllium, hydrogen, and perchlorate ions as in the systems to be studied had been equilibrated with an MIBK phase containing no TTA, and the beryllium concentrations in the two phases were measured. The extraction into MIBK containing TTA was

assumed to be started from these phases; that is, the aqueous beryllium(II) concentration measured above was used as the initial aqueous beryllium(II) concentration, and the organic beryllium(II) concentration preliminarily determined (which should correspond to the organic beryllium perchlorate fraction) was substracted from the organic concentration obtained in the presence of TTA.

Reaction Order with Respect to Hydrogen Ions: The rate of extraction was determined when the hydrogen-ion concentration was between $10^{-2.0}$ and $10^{-3.5}$M. The results are given in Fig. 2b. Both in the 0.1M and in the 4.0M media, the plot is a straight line with a slope of +1, as can be seen from Fig. 2b. Thus, it was concluded that the extraction is inversely proportional to the hydrogen-ion concentration in the aqueous phase.

Reaction Order with Respect to TTA: The rate of extraction was determined when the hydrogen-ion concentration was $10^{-2.5}$M in the 0.1M ionic media and $10^{-2.4}$M in the 4.0M media. In both these ionic media, the log q_{HA} *vs.* log$[HA]_{org}$ plot is a straight line with a slope of +1, as is shown in Fig. 3b. Thus, it was concluded that the extraction rate is proportional to the TTA concentration in the organic phase.

Reaction Order with Respect to Perchlorate Ions: The rate of extraction was determined when the TTA concentration was 0.1M and the hydrogen-ion concentrations were $10^{-3.0}$M (0.1M $Na(NO_3, ClO_4)$), $10^{-3.4}$M (0.1M $Na(Cl, ClO_4)$), $10^{-2.7}$M (4.0M $Na(NO_3, ClO_4)$), and $10^{-3.3}$M (4.0M $Na(Cl, ClO_4)$). In all of the experiments, the log $q_{ClO_4^-}$ *vs.* log$[ClO_4^-]$ plot was not a straight line. The slope always increased as the perchlorate concentration increased. Figures 5 and 6 show the results.

The data in these figures were analyzed by the curve-fitting, and it was concluded that the limiting slope for each plot was always +2; the plot can be represented by the following equation (*cf.* Eq. (12)):

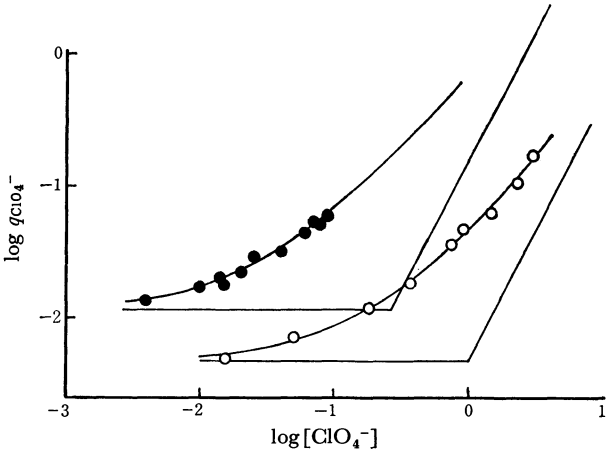

Fig. 5. Dependence of the rate of Be(II) extraction as TTA chelate on the perchlorate concentration in the sodium perchlorate-nitrate systems.
Org. phase. MIBK containing 0.1M TTA.
Aq. phase. 4.0M $Na(ClO_4, NO_3)$ (open circles).
0.1M $Na(ClO_4, NO_3)$ (closed circles).
The solid curve for the open circles gives
$Y=4.9\times10^{-3}(1.0X^2+8.0X+1)$
and for the closed circles gives
$Y=1.2\times10^{-2}(15X^2+48X+1)$.

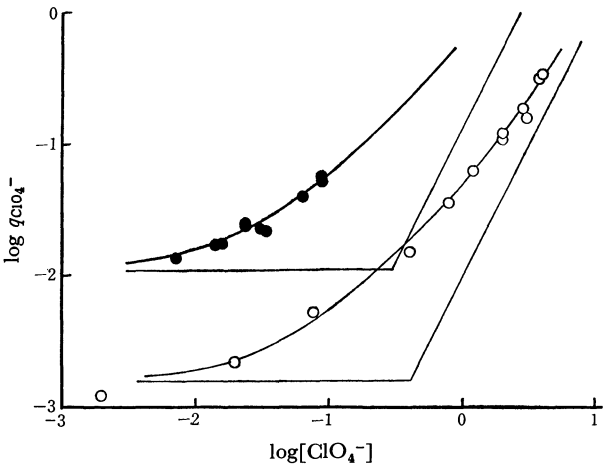

Fig. 6. Dependence of the rate of Be(II) extraction as TTA chelate on the perchlorate concentration in the sodium perchlorate-chloride systems.
Org. phase. MIBK containing 0.1M TTA.
Aq. phase. 4.0M $Na(ClO_4, Cl)$ (open circles).
0.1M $Na(ClO_4, Cl)$ (closed circles).
The solid curve for the open circles gives
$Y=1.6\times10^{-3}(5.9X^2+19X+1)$
and for the closed circles gives
$Y=1.1\times10^{-2}(11X^2+44X+1)$.

$$\log q_{ClO_4^-} = \log k[A^-] + \log(1+k_1[ClO_4^-] + k_2[ClO_4^-]^2) \quad (16)$$

The constants, k^*, k_1, and k_2, in Eq. (10) (and, at the same time, k_1 and k_2 in Eq. (16)) were determined from the parameters of the best-fit standard curve, and the values of k in Eq. (16) were calculated from these values of k^* and the dissociation and distribution constants of TTA in Eqs. (2) and (3) by using Eqs. (4) and (5). The constants are listed in Table 1.

(C) *Effect of the Rate of TTA Distribution.* As has been pointed out, the rate of the distribution of TTA in the organic phase into aqueous solutions is rather slow. For example, the distribution equilibrium is established after 18 hr of two-phase agitation when carbon tetrachloride containing 0.1M TTA is placed in contact with 0.1M sodium perchlorate at pH 2[7] (by a rotating framework at 20 rpm on which stoppered glass tubes containing the two phases were placed. The two-phase agitation in the present study is much more vigorous than this). In order to see the effect of this slow distribution of TTA into the aqueous phase on the rate of beryllium extraction, carbon tetrachloride containing TTA was agitated with aqueous solutions containing no beryllium, but otherwise the same as in the experiments shown in Fig. 1. After the two phases had been agitated vigorously for 5 min, the tracer and carrier were added to the aqueous phase, the agitation was started again, and the extraction was determined as a function of the interval of the agitation after this addition of beryllium to the aqueous phase. However, it was found that the results were practically identical with those in Fig. 1: that is, no difference was observed in the rate of beryllium(II) extraction when the TTA

7) T. Sekine and Y. Hasegawa, "Solvent Extraction Research," ed. by A. S. Kertes and Y. Marcus, Wiley-Interscience, New York (1969), p. 289.

has been distributed between the two phases beforehand and when the TTA was initially added to the organic phase and the beryllium(II) was initially added to the aqueous phase: thus, the distribution of the TTA started at the same time as the metal extraction.

Discussion

Freiser and his co-workers have presented a series of papers on the kinetics of the solvent extraction of divalent metal ions with dithizone and its derivatives.[8-11] They have established that the rate-determining step of the solvent extraction in these system is the formation of the first metal chelate in the aqueous phase (with the exception of zinc extraction with di-α-naphthyldithiocarbazone)[9] if the two phases are vigorously shaken; thus, the effect of the diffusion of materials is eliminated.

In these papers, it was suggested that the rate of metal dithionate formation increases in an approximately linear fashion with the rate of dissociation of water from various metal ions, and that a loss of coordinated water is involved in the rate-determing step.[8-9] However, it was also suggested that, as a relatively minor variation in large ligand anions changes the rate constant for the complex formation considerably in some cases, the initial complex involves a metal-ligand bonding of some sort; in other words, the first complex which is formed rapidly can not be a simple ion-pair.[10]

There have been also some studies of the rate of solvent extraction.[12] It was pointed out that the rates of extraction of chelating systems containing TTA, *N*-benzyl-*N*-phenyl-hydroxylamine, or pyridylazonaphthol seem to be controlled by the chelate formation.[13]

Enhancements of the rate of extraction by the addition of other ligands to the aqueous phase have been pointed out. Finston and his co-workers[14-16] have reported that the rate of extraction of iron(III) and zirconium with TTA in benzene enhanced by the addition of ammonium thiocyanate to the aqueous perchlorate media and that the enhancement is larger when MIBK is added to the organic phase. They suggested in these papers that the enhancements of the extraction caused by the thiocyanate is due to a change in the mechanism of the extraction; the thiocyanate formed in the aqueous phase is first extracted into the organic phase, and then the thiocyanate ions are replaced by TTA in the organic phase. The enhancement of the rate caused by the addition of the thiocyanate is probably due to the fact that above two processes are faster than the TTA chelate formation in the aqueous phase, which is the rate-determining step when the thiocyanate is absent in the system. They also suggested that the synergic enhancement of metal chelate extraction can, at least in some cases, be explained in terms of this kind of kinetic effect.

The addition of acetate ions was found to enhance the rate of zinc dithizonate extraction; $ZnOAc^+$ reacts 25 times as fast as Zn^{2+}, whereas the formation of $NiOAc^+$ does not accelerate the nickel dithizonate extraction.[12] It was also reported that the extraction of chromium(III) with TTA is accelerated by the addition of fluoride ions;[17] this was explained in terms of the intermediate fluoride complexes, which destroy the hydrate shell of Cr^{3+} but do not prevent the formation of extractable chromium(III)-TTA complexes.

The extraction and complex formation equilibria in the systems studied in the present paper have already been reported in another paper.[4] It was observed that nitrate and chloride form relatively weak complexes with beryllium(II); the stability constants are log $\beta_1=-0.63$ for the $BeNO_3^+$ and log $\beta_1=-0.35$ and log $\beta_2=-0.70$ for the $BeCl^+$ and $BeCl_2$ species. At the same time, it was found that beryllium(II) in the aqueous phase containing 4.0M sodium perchlorate is extracted into MIBK containing TTA in three forms, $Be(ClO_4)_2$, $BeAClO_4$, and BeA_2. The extraction of beryllium(II) into MIBK containing no TTA is very small; the distribution ratio is almost proportional to the square of the aqueous sodium perchlorate concentration, which is lower than 4.0M (*cf.* Fig. 1 in Ref. 4).

As has been described, the two phases in this study were agitated so vigorously that the diffusion of materials had no effect on the rate of extraction; the rate-determining step in the system is probably a chemical reaction in one of the phases. This rate-determining reaction could be concluded from the results to be shown below.

The data in Figs. 2 and 3 indicate that the rate of extraction in the carbon tetrachloride systems can be described by $-d[Be^{2+}]/dt=k[Be^{2+}][A^-]$ except for the following data. It can be seen from Figs. 2a and 3a that the plot of the extraction from 0.1M ionic media into carbon tetrachloride deviates from the straight line with a slope of +1 in the lower $-\log[H^+]$ or $[HA]_{org}$ region. From the distribution and dissociation constants of TTA given in Table 1, it can be concluded that the rate of extraction is practically proportional to $[A^-]$ when it is higher than $10^{-6.0}$M, but that the apparent reaction order with respect to the TTA anions becomes larger than +1 for some unknown reasons when $[A^-]$ is lower than this.

The complex formation with nitrate or chloride ions seems to have no remarkable influence on the rate of extraction, for, as can be seen from Fig. 4, the rate in the carbon tetrachloride systems somewhat decreases when 4.0M sodium perchlorate is replaced by chloride
