The Steric Course of the Formation of 1-Phenylethylphenols from 1-Phenylethyl Ethers of Various Phenols in the Acidic Phenol Solvents. In order to confirm the rate and the steric course of the acidic rearrangement of 1-phenylethyl group under the phenolysis condition, the rearrangement of optically active 1-phenylethyl ethers of phenol, *p*-cresol, *p*-chlorophenol, and 2,6-xylenol were carried out in the presence of hydrogen chloride in the respective phenolic solvents. The respective 1-phenylethyl ethers rearranged rapidly to the corresponding 1-phenylethylphenols (92—97% yield) in the respective phenol–benzene (1: 1 by wt.) solvents at the same temperature as the phenolyses were conducted. A summary of the stereochemical results is given in Table 4.

It is shown for each rearrangement that the 1-phenylethyl group rearranges to the *ortho* position with partial retention of the configuration whereas the *para* rearrangement proceeds with predominant inversion of configuration.

Besides the acidic intramolecular rearrangement of 1-phenylethyl phenyl ether, the rearrangement products, *i.e.*, *ortho*- and *para*-alkylated phenols may partly stem from the S_N1 phenolysis of reproduced 1-phenylethyl chloride due to the hydrogen chloride cleavage[5] of the 1-phenylethyl phenyl ether. This is a sort of intermolecular course for the rearrangement of 1-phenylethyl phenyl ethers in the acidic phenol solvent, and illustrated in the following scheme, using ^{18}O-labelled phenyl ether.

$$R^{18}OPh + HCl \longrightarrow RCl + Ph^{18}OH$$

$$RCl + PhOH \longrightarrow ROPh + o\text{-}RC_6H_4OH + p\text{-}RC_6H_4OH$$

In fact, it is known that this ether is cleaved by hydrogen chloride to give partially retained 1-phenylethyl chloride in toluene,[5c] 3-pentanone,[5c] isobutyl alcohol,[5b] benzene,[5b] acetone,[5b] and phenol–dioxane.[5d]

Furthermore, it is also conceivable as another course for the intermolecular rearrangement in the phenolic solvent that the protonated 1-phenylethyl phenyl ether might be phenolyzed, and give intermolecularly the alkylated phenols, as is shown in the following scheme.

$$R^{18}OPh + H^+ (Cl^-) \longrightarrow R^{18}\overset{\overset{H}{|}}{O}\text{-}Ph$$

$$R^{18}\overset{\overset{H}{|}}{O}\text{-}Ph + PhOH \longrightarrow ROPh + o\text{-}RC_6H_4OH + p\text{-}RC_6H_4OH + Ph^{18}OH$$

In order to estimate the amounts of these intermolecular courses in the acidic rearrangement of 1-phenylethyl phenyl ether, ^{18}O-labelled 1-phenylethyl phenyl ether was subjected to the acidic rearrangement in the presence of *p*-toluenesulfonic acid in the phenol–benzene (1: 1 by wt) solvent at 25 °C. As illustrated in Table 5, it is evident that only 44.9% of *o*-1-phenylethylphenol and 25.7% of *p*-1-phenylethylphenol were intramolecularly produced from the labelled phenyl ether, but the rest of the alkylphenols was produced by the phenolysis of the oxonium ion of the phenyl ether or, less probably, by the phenolysis of 1-phenyl-

ethyl *p*-toluenesulfonate, produced by the acidic cleavage of the phenyl ether with *p*-toluenesulfonic acid.

In conclusion, in view of these findings mentioned above, the formation of the *ortho*-alkylates with *retained* configuration in the phenolysis without an added base is attributed not to the direct retentive alkylation of the phenols, but to the rapid rearrangement of the 1-phenylethyl ethers with net *retention* of configuration, caused by the hydrogen chloride liberated in the S_N1 phenolysis of 1-phenylethyl chloride in the respective phenolic solvents.

Experimental[6)]

Materials. *S*-(−)-1-Phenylethyl chloride was prepared by the reaction of *S*-(−)-1-phenylethanol with thionyl chloride in a manner previously described.[1)] Sodium *p*-substituted phenoxide was prepared by refluxing the toluene solution of *p*-substituted phenol with sodium metal. All the other reagents employed were of an analytical reagent grade and were fractionated just prior to use.

Synthesis of 1-Phenylethyl Phenyl Ether-^{18}O. According to the method of Stevens and Bentel,[7)] phenol-^{18}O (4.46 g; containing some ether) was prepared by a diazotization of aniline (2.8 g, 0.030 mol) with sodium nitrite (2.1 g, 0.030 mol) in $H_2{}^{18}O$ (^{18}O 3 atom% excess; 15 ml). 1-Phenylethyl phenyl ether-^{18}O (0.66 g; ^{18}O 0.863 atom% excess) was synthesized by refluxing an acetone solution (60 ml) of phenol-^{18}O (4.46 g; containing some ether), 1-phenylethyl chloride (3.3 g, 0.020 mol), and potassium carbonate (4.1 g, 0.030 mol) after the method described by Hart and Eleuterio.[9)] The ^{18}O content was determined by the method of Rittenberg and Ponticorvo.[8)]

Rate Measurement. The previous procedure[1)] was followed. Aliquots (1 ml) were removed at intervals from a reaction mixture (15 ml) placed in a constant-temperature bath. The increase of acid concentrations was followed by titration with standard sodium acetate in acetic acid, using crystal violet as an indicator. In each case, a first-order linear relationship was obtained to *ca.* 20% conversion. Infinity titers were calculated from the weight of the chloride used. These results are summarized in Table 1.

Product Isolation (General Procedure). The vessel, containing a reaction mixture, was placed in a constant-temperature bath; at the desired time the reaction was quenched by cooling and dilution with ether. The mixture was successively washed with 10% aq. NaOH and 10% aq. NaCl, dried with $MgSO_4$, and concentrated. The concentrate was subjected to preparative thin-layer chromatography on silica gel. The detailed procedures are described in representative cases which follow.

1-Phenylethyl Chloride Phenolysis in p-*Cresol in the Presence of Sodium* p-*Cresoxide.* A mixture of 1-phenylethyl chloride (1.500 ml, 0.01136 mol; $\alpha_D^{27.2}$ −34.50±0.05° (neat, 1 dm)) and *p*-cresol (220 ml) containing sodium *p*-cresoxide (0.0541 M: determined by titration) was kept at 100.0±0.1 °C for 5 hr. After the working-up mentioned above, 1-phenylethyl *p*-cresyl ether (0.9601 g, 39.8% yield; bp 160—165 °C/4 mmHg; $\alpha_D^{32.0}$ −0.201±0.013° (neat, 1 dm)) and *o*-(1-phenylethyl)-*p*-cresol (0.3350 g, 13.9% yield; bp 170—175 °C/4 mmHg; $[\alpha]_D^{34.0}$ +1.12±0.074° (*c* 2.016, benzene)) were obtained.

1-Phenylethyl Chloride Phenolysis in p-*Cresol in the Absence of an Added Base.* A mixture of 1-phenylethyl chloride (0.6410 g, 0.00456 mol; $\alpha_D^{27.2}$ −34.5° (neat, 1 dm)) and *p*-cresol (90 ml) was maintained at 100 °C for 5 hr and worked up as mentioned above: *o*-(1-phenylethyl)-*p*-cresol (0.8442 g, 87.3% yield; bp 170—175 °C/4 mmHg; $[\alpha]_D^{32.6}$ +0.118±0.010° (*c* 9.31, benzene)) and 1-phenylethyl *p*-cresyl ether (24.2 mg, 2.50% yield; bp 155—160 °C/4 mmHg; $[\alpha]_D^{34.0}$ +0.431±0.330° (*c* 0.232, benzene)) were obtained.

The Acidic Rearrangement of 1-Phenylethyl p-*Cresyl Ether in* p-*Cresol–Benzene (1:1 by wt).* A mixture of 1-phenylethyl *p*-cresyl ether (1.0651 g, 0.00502 mol; $\alpha_D^{32.0}$ +1.890± 0.030° (neat, 1 dm)) and *p*-cresol–benzene (1:1 by wt.; 100 ml) containing anhydrous hydrogen chloride (0.0505 M) was kept at 100 °C for 5 hr. After the working-up mentioned above, *o*-(1-phenylethyl)-*p*-cresol (0.9971 g, 93.5% yield; bp 170—177 °C/4 mmHg; $[\alpha]_D^{29.8}$ +0.182±0.051° (*c* 18.5, benzene)) was obtained.

The Acidic Rearrangement of 1-Phenylethyl Phenyl Ether-^{18}O in Phenol–Benzene (1:1 by wt). A mixture of 1-phenylethyl phenyl ether-^{18}O (0.2911 g; 0.00147 mol; ^{18}O 0.863 atom% excess) and phenol–benzene (1:1 by wt.; 14.5 ml) containing anhydrous *p*-toluenesulfonic acid (0.00396 M) was kept at 25 °C for 10 min (49% conversion by glc) and worked up in a manner mentioned above. *o*-(1-Phenylethyl)phenol (0.9115 g, 31.3% yield; ^{18}O 0.387 atom% excess) and *p*-(1-phenylethyl)phenol (0.0515 g, 17.7% yield; ^{18}O 0.222 atom% excess) were obtained.

We wish to thank Prof. Kameo Asada, Department of Nuclear Engineering, Kyoto University, for his kind technical guidance in the measurement of mass spectrograph and Prof. Jyun Oishi, Dept. N. E., Kyoto Univ., for his good offices with Prof. Asada.

A Convenient Method for the Preparation of Ketones by the Reaction of Grignard Reagents with Carboxylic Acid Derivatives

Masashi ARAKI, Shigeru SAKATA, Hisashi TAKEI, and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 20, 1974)

It was found that ketones were prepared in excellent yields by the reaction of Grignard reagents with *S*-(2-pyridyl) thioates and their analogues or with 2-pyridyl esters. The mechanism of this reaction was also discussed. This useful method for the preparation of ketones was successfully applied to the syntheses of *cis*-jasmone and dihydrojasmone.

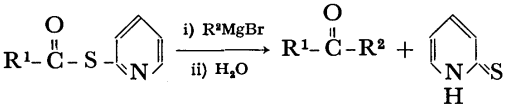
Many works have been reported on the synthesis of ketones from carboxylic acid derivatives and organometallic compounds.[1] The reaction of Grignard reagents with acid chlorides, nitriles, acid amides, or acid anhydrides is frequently employed for this purpose; however, tertiary alcohols, undesirable by-products, are invariably accompanied with the formation of ketones except in the case of nitriles.

Staab and Jost[2] reported that the treatment of Grignard reagents with *N*-acylimidazoles affords ketones in fairly good yields. Recently, a convenient method for the synthesis of ketones from Grignard reagents and 8-acyloxyquinolines was reported by Sakan and Mori.[3] The reaction was suggested to proceed through an important intermediate of 8-acyloxyquinoline metal complex.

As part of our study on the carbon-carbon bond forming reaction by the use of 2-pyridyl sulfides,[4] it was found that various *S*-(2-pyridyl) thioates react very rapidly with Grignard reagents to give ketones in excellent yields by simple procedures. The preliminary report of this work was published elsewhere.[5]

This paper describes a scope and a limitation of this useful method for the preparation of ketones by the reaction of Grignard reagents with *S*-(2-pyridyl) thioates and their analogues or with 2-pyridyl esters, and the application of this method to the syntheses of *cis*-jasmone and dihydrojasmone.

S-(2-Pyridyl) thioates of various carboxylic acids were prepared according to the following two methods; (A) the reaction of 2-pyridinethiol with carboxylic acid halides in the presence of tertiary amine such as triethylamine, or (B) the reaction of carboxylic acids with triphenylphosphine and 2,2′-dipyridyl disulfide.[6] In general, the reaction of *S*-(2-pyridyl) thioates with Grignard reagents was carried out in dry tetrahydrofuran (THF) at 0 °C under argon atmosphere by the inverse addition. Usual work-up afforded various ketones in excellent yields as shown in Table 1.



The effects of the solvents on this reaction clearly indicate that THF is the most suitable solvent (see Table 2). In THF, the reaction proceeded in homogeneous solution throughout the addition of Grignard reagents. While, in the cases of other solvents, white precipitates immediately appeared when Grignard reagents were added to the solution of *S*-(2-pyridyl) thioates.

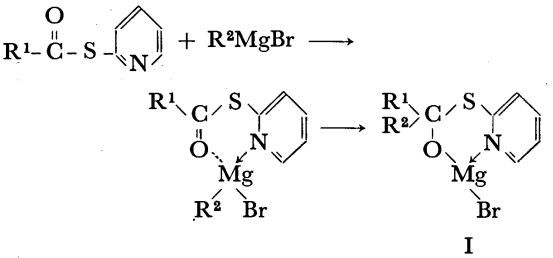
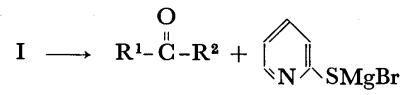
a) Isolated yields by preparative tlc (silica gel). b) The mixture of benzophenone and triphenylmethanol was isolated and their ratio was determined by glpc.

In the early stage of this study, it was assumed that the preferential formation of ketones would be accomplished by the formation of a stable six-membered intermediate **I** which would react very sluggishly with



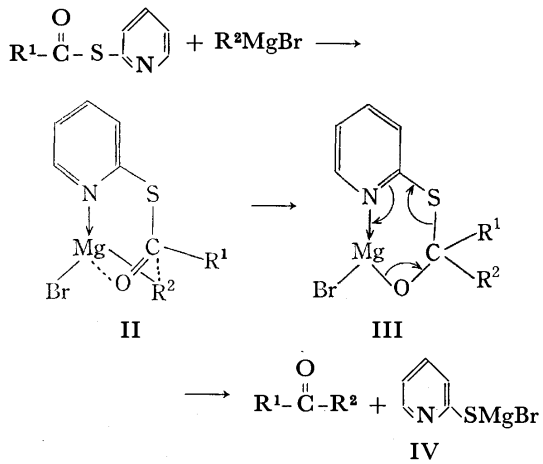
I

Grignard reagents as compared with *S*-(2-pyridyl) thioates. But, the IR spectra of the reaction mixture of *S*(2-pyridyl) isobutanethioate and cyclohexylmagnesium bromide in argon atmosphere showed the absorption at 1710 cm^{-1} which was assigned to the stretching vibration of the carbonyl group of the ketone. This result may indicates that the intermediate I is not kept stable under the reaction condition, but decomposes rapidly into ketones and magnesium thiolate. Thus, it can be concluded that the preferential formation of ketones by the present reaction depends only on the high reactivity of Grignard reagents toward *S*-(2-pyridyl) thioates as compared with ketones. This was confirmed by the following results; 1) benzophenone was obtained quantitatively by the reaction of *S*-(2-



pyridyl) benzothioate with phenylmagnesium bromide in the presence of an equimolar amount of benzophenone without accompanying triphenylmethanol, and 2) the treatment of the *S*-(2-pyridyl) thioate of 6-oxoheptanoic acid or 5-carboethoxyvaleric acid with phenylmagnesium bromide without protection of the carbonyl group afforded the corresponding diketone or ketoester in high yields.

High reactivity of *S*-(2-pyridyl) thioates toward Grignard reagents would be attributed to the following three reasons; (1) Grignard reagents are activated by the formation of complex II with *S*-(2-pyridyl) thioates, (2) the addition reaction of Grignard reagents to the carbonyl group of *S*-(2-pyridyl) thioates proceeds through the favorable six-membered intermediate, (3) after the addition of Grignard reagents to the carbonyl group, magnesium thiolate IV is eliminated smoothly through electrocyclic mechanism as sketched in III.



II III IV

The above-mentioned mechanism indicates that 2-pyridyl esters  or the thioates having

such a skelton as R–C–S–C–N– would similarly react with Grignard reagents to result in the exclusive formation of ketones. Expectedly, ketones were obtained in high yields by the addition of Grignard reagents to a

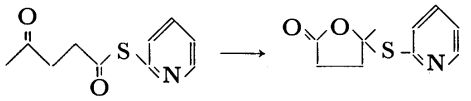
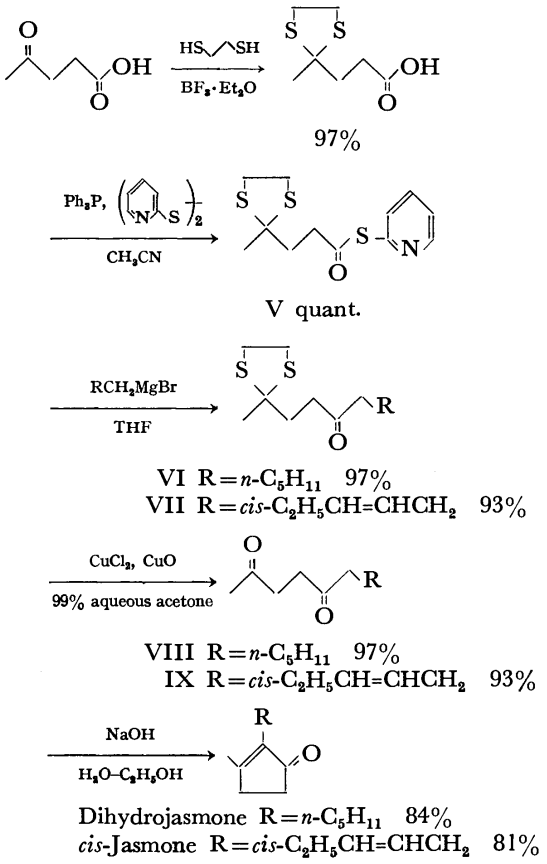
a) 1-Butyl-1-phenylpentanol was isolated in *ca.* 29% besides the ketone. b) Reaction at −78°C.

The present ketone synthesis by using *S*-(2-pyridyl) thioates was successfully applied to the preparation of *cis*-jasmone and dihydrojasmone through 1,4-diketones starting from levulinic acid as in Scheme 1.

In the above scheme, the protection of the carbonyl group by ethanedithiol seems to be unnecessary from the results shown in Table 1. But, *S*-(2-pyridyl) 6-oxopentanethioate (X), prepared by the reaction of levulinic acid with triphenylphosphine and 2,2′-dipyridyl disulfide, is not stable at room temperature and is readily converted to γ-pyridylthio-γ-valerolactone (XI).



X XI



Scheme 1. Syntheses of *cis*-jasmone and dihydrojasmone

Therefore, the carbonyl group was led to ethylene dithioacetal in order to isolate the pure thioate V. The thioate V was isolated by silica gel column chromatography in 97% yield based on levulinic acid. The ketone VI was obtained in 97% yield by the reaction of V with *n*-hexylmagnesium bromide, and the hydrolysis of VI by our method[7] afforded 1,4-diketone (VIII) in 98% yield. Dihydrojasmone was obtained from VIII according to the method of Hunsdieker[8] in 84% yield. Analogously, olefinic 1,4-diketone IX was isolated in 82% yield by the reaction of V with 3-*cis*-hexenyl magnesium bromide, followed by the deprotection of the carbonyl group.[7] IX was converted to *cis*-jasmone in 81% yield by the ordinary procedure.[8]

In conclusion, it is noted that all the common ketones were easily prepared in high yields without accompanying tertiary alcohols by treating *S*-(2-pyridyl) thioates and 2-pyridyl esters with Grignard reagents. Further, this procedure was proved to be applicable to the syntheses of 1,6-diketone as 1-phenyl-1,6-dioxoheptane without the protection of carbonyl group or 1,4-diketones as 2,5-dioxo-*cis*-8-undecene and 1,5-dioxoundecane, precursors of *cis*-jasmone and dihydrojasmone.

Experimental

All the melting points and boiling points are uncorrected.

General Method for the Preparation of S-(2-Pyridyl) Thioates. *S*-(2-Pyridyl) thioates were prepared by the following two methods. (A) To a solution of 2-pyridinethiol[9] (2.22 g, 20 mmol) and triethylamine (2.02 g, 20 mmol) in dry THF (30 ml) was added 20 mmol of an acid halide at 0 °C with stirring. The reaction mixture was stirred for 4 hr at room temperature. After removal of triethylamine hydrochloride by filtration, the solvent was removed under reduced pressure and the residue was dissolved in ether. The ether layer was washed with saturated sodium chloride solution and dried over sodium sulfate. Removal of the solvent gave a crude *S*-(2-pyridyl) thioate quantitatively. The crude thioate was purified by distillation or recrystallization. (B) To a mixture of 2,2'-dipyridyl disulfide (2.20 g, 10 mmol), triphenylphosphine (2.62 g, 10 mmol), and a carboxylic acid (10 mmol) was added dry acetonitrile (30 ml) at once with stirring. The reaction mixture was stirred for 10 min and then the solvent was removed under reduced pressure. The residue was chromatographed over silica gel to give a *S*-(2-pyridyl) thioate.

S-(2-Pyridyl) thioates obtained by the method A or B were listed in Table 5.

Table 5. *S*-(2-Pyridyl)thioates $\left(R-\overset{O}{\overset{\|}{C}}-S-\text{(2-pyridyl)}\right)$

R	Method	Yield (%)	Mp °C (Bp °C/mmHg)
Ph	A	80	50.0—51.0[a]
CH_3	A	60	(98—99/4)
n-C_5H_{11}	A	84	(111—112/1)
$PhCH_2CH_2$	A	82	56.0—58.0[b]
$(CH_2)_4$	A	57	44.5—45.0[c]
$CH_3CO(CH_2)_4$	A	80[d]	oil
$C_2H_5OCO(CH_2)_4$	B	78[d]	oil

Recrystallized from a) benzene–hexane, b) cyclohexane, c) ether. d) Purified by silica gel column chromatography.

Other Thioates. *S*-[2-(*N*-Methylimidazolyl)] benzothioate and *S*-(2-benzothiazolyl) benzothioate were prepared similarly according to the method A mentioned above using 2-(*N*-methylimidazole)thiol of 2-benzothiazolethiol instead of 2-pyridinethiol (74% mp 104.5—105.0 °C (benzene–hexane), 75% mp 125.0—126.0 °C (cyclohexane)).

2-Pyridyl Esters. To a mixture of 2-hydroxypyridine (0.951 g, 10 mmol) and triethylamine (1.012 g, 10 mmol) in 50 ml of dry ether was added benzoyl chloride (1.406 g, 10 mmol) at 0 °C with stirring. After stirring for 4 hr at room temperature, precipitated triethylamine hydrochloride was removed by filtration. The filtrate was washed with saturated sodium chloride solution and dried over sodium sulfate. Removal of the ether gave a solid, which was recrystallized from cyclohexane–hexane to afford 2-pyridyl benzoate (1.05 g, 53% mp 41.0—42.0 °C).

In a similar manner, 2-pyridyl β-phenylpropionate was prepared using β-phenylpropionyl chloride instead of benzoyl chloride in benzene as a solvent. It is necessary that the benzene solution containing 2-pyridyl β-phenylpropionate is dried quickly over sodium sulfate, since this ester is readily hydrolyzed. (68% bp 128—130 °C/1.3×10^{-1} mmHg).

General Procedure for the Reaction of Thioates with Grignard Reagents under Argon. In a 50 ml two-necked flask equipped with dropping funnel and gas inlet tube were placed 20 ml of dry THF and 2 mmol of a thioate. The flask was cooled in ice-water bath and a THF solution of Grignard reagent (approximately 1 equivalent) was added from the dropping

funnel until the thioates were consumed (checked by tlc). The reaction mixture was quenched with 10% ammonium chloride and the resulting solution was extracted with ether. The organic layer was washed with 1 M sodium hydroxide to remove the thiol formed, with saturated sodium chloride and dried over sodium sulfate. After removal of the solvent the residue, almost pure ketone, was further purified by silica gel chromatography or distillation.

General Procedure for the Reaction of 2-Pyridyl Esters with Grignard Reagents under Argon. In 10 ml of THF a 2-pyridyl ester (1 mmol) was allowed to react with a Grignard reagent according to the above procedure. After quenching with 10% ammonium chloride, the resulting mixture was extracted with ether. The organic layer was washed with saturated sodium chloride and dried over sodium sulfate. After removal of the solvent the residue, whose IR spectra showed no absorption assigned to the stretching vibration of alcoholic O–H bond, was chromatographed over silica gel to give pure ketone.

Levulinic Acid Ethylene Dithioacetal. To a mixture of levulinic acid (0.231 g) and ethanedithiol (0.234 g) was added boron trifluoride etherate (0.2 ml) with stirring. An exothermic reaction occurred and after 2.5 hr, the resulting white solid was dissolved in ether. The ether layer was washed with water and dried over sodium sulfate. After removal of the ether, the obtained acid was purified by silica gel thin layer chromatography (0.370 g 97% mp 53.0—55.0 °C). In the case of larger scale experiment, recrystallization may be recommended instead of the chromatography.

The Configuration at C-21 of Hydroxyhopanone

Kazuo SEKIGUCHI, Hiroaki KANEMOTO, Yoji HIRAO, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received March 29, 1974)

Hydroxyhopanone (**1**) was converted *via* two alternative routes (**1**→**9**→**11a**→**12**→**14**→**15**→**16** and **1**→**10**→**17**→**18**→**19**→**20**) to A-neohop-21-ene (**16**) and A-neohop-3-ene (**20**), respectively. These unsaturated hydrocarbons (**16** and **20**) were found to be identical; this provided evidence to confirm the 21β-H configuration for **1**.

Hydroxyhopanone is a pentacyclic triterpene isolated from dammar resin.[1] The structure had been determined as **1**[2] with a 21β-H configuration based on an isomerization of the norketone (**2**) to its isomeric norketone (**3**).[2a]

Later, this configuration at C-21 of **1** was questioned in connection with studies which led to a revision of the 21β-H (**4a** and **5a**) to the 21α-H structures (**4b** and **5b**) for zeorin and hopane, respectively.[3] However, this revision has recently been withdrawn by the same authors[4] on re-investigation of some derivatives of leucotylin (**6**). The 21β-H configuration was thus confirmed for hopane (**5a**) in accordance with the earlier observation[2a] as well as with the results obtained for adipedatol (**7**)[5] and adiantol B bromoacetate (**8**).[6]

We wish to present another chemical evidence to confirm the 21β-H configuration for hydroxyhopanone (**1**).

Dehydration of **1** with phosphorus oxychloride in pyridine gave hop-21-en-3-one (hopenone-a) (**9**)[7] and hop-22(29)-en-3-one (hopenone-b) (**10**)[7] in a ratio of about 2: 1. The isopropylideneketone (**9**) was reduced with sodium borohydride to give hop-21-en-3β-ol (**11a**) and hop-21-en-3α-ol (**11b**) in a ratio of 4: 1. The former alcohol (**11a**) was converted to its mesylate (**12**). Solvolysis of **12** in a mixture of dioxane and water (1: 1) in the presence of calcium carbonate afforded A-neohopa-3,21-diene (**13**) (yield: 53%), A-neohop-21-en-4-ol (**14**) (y: 24%), and A-neohopa-4(23),21-diene (**15**) (y: 5%). Dehydration of **14** with phosphorus oxychloride in pyridine yielded **13** and **15** in a ratio of about 2: 1. The latter (**15**) in ethanol was hydrogenated over platinum catalyst to give A-neohop-21-ene (**16**).

On the other hand, hydrogenation of the isopropenylketone (**10**) in ethanol[4] over platinum catalyst yielded hopan-3-one (**17**) which was reduced with sodium borohydride to give hopan-3β-ol (**18**) as a main product. The alcohol (**18**) was converted to its mesylate (**19**) and then submitted to solvolysis to give A-neohop-3-ene (**20**) (y: 34%) and A-neohopan-4-ol (**21**) (y: 18%).

Two unsaturated hydrocarbons (**16** and **20**) thus obtained were found to be identical.

It has already been reported that dehydration of hydroxyhopane (**22**) with phosphorus oxychloride in

pyridine gave hop-21-ene (hopene-a) (**23**) and hop-22(29)-ene (hopene-b) (**24**),[7] and that reaction of methylmagnesium iodide with the norketone (**2**), obtained by oxidation of **24**, reproduced **22**.[2a] This showed that the configurations of the side chain at C-21 of **24** and **22** are the same. A parallel argument could lead to the same configuration at C-21 for the isopropenylketone (**10**) and hydroxyhopanone (**1**).

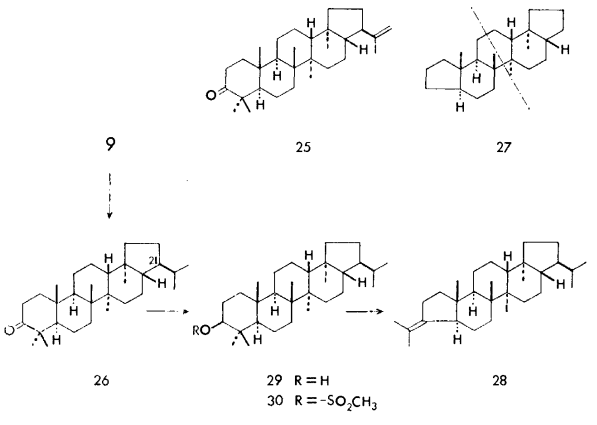
When treated with *p*-toluenesulfonic acid in chloroform, **10** isomerized completely to the isopropylideneketone (**9**). During hydrogenation of **10** in neutral conditions (ethanol, platinum catalyst) to give hopan-3-one (**17**), an isomerization of **10** *via* **9** to form an isomeric isopropenylketone (**25**) and successive hydrogenation leading to isohopan-3-one (**26**) are less probable. The isopropylideneketone (**9**) was found unchanged on hydrogenation in neutral conditions. The Wolff-Kishner reduction of **17** furnished hopane (**5a**)[8] whose configuration at C-21 has been shown to be the same as that of **1**.[8] Thus, no isomrization at C-21 has taken place during the hydrogenation of **10** to give **17**.

Based on a parallel argument, it could be concluded that the configurations at C-3 of **15** and **16** must be the same.

A β(equatorial) nature for the hydroxyl group at C-3 of **11a** and **18** was shown by the formation of A-neo derivatives from the tosylates (**13**, **14**, and **15** from **12**; **20** and **21** from **19**) in accordance with the stereochemistry required by the mechanism of ring contraction.[9] Thus, the side chains at C-3 of **14**, **15**, and **21** should be in a β-configuration.

These findings showed the structure with 3β-isopropyl side chain (**16**) for A-neohop-21-ene. The identity of **16** with **20** as shown above led to a 21α-configuration for the isopropyl group of A-neohop-3-ene (**20**) due to the C_2 symmetry of hexanor-A-neohopane (**27**). As stereochemistry at C-21 of **20** has been shown to be retained as that of **1**, the configuration at C-21 of hydroxyhopanone (**1**) should be 21β-H.

For a further confirmation of the result, A-neoisohop-3-ene (**28**) was prepared by the following transformation. Hydrogenation of **9** in acidic conditions (acetic acid, platinum catalyst)[4,10] gave isohopan-3-one (**26**) which was reduced with sodium borohydride to yield 3β-hydroxyisohopane (**29**) as a main product. The alcohol (**29**) was converted to the mesylate (**30**). Solvolysis of **30** gave **28** which was found to be not identical with **16** (=**20**).



Thus, 21β-H configuration of hydroxyhopanone (**1**) was confirmed.

Experimental

IR spectra were measured using a Hitachi EPI-G2 spectrometer in Nujol mull, unless otherwise stated. NMR spectra were taken on a JEOL JNM-C-60 or a Hitachi R-24 spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard. Mass spectra were measured using a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV. Measurements of optical rotation were carried out using a JASCO polarimeter DIP-SL in chloroform solution. Gas chromatographic (glc) analyses were performed on a Shimadzu gas chromatograph model GC-4A. For column chromatography Wakogel C 200 (Wako Pure Chemical Industries) and Activated Alumina (Mesh 200—300, Showa Chemical Co.) were used. Thin layer chromatography (tlc) was carried out on Kieselgel PF_{254} (E. Merck, Darmstadt) in 0.25 mm thickness. All melting points were determined on a hot block and reported uncorrected.

Hydroxyhopanone (1): Hydroxyhopanone (**1**) was isolated from dammar resin by the procedure described by Dunstan *et al.*[7] Mp 249—250 °C; $[\alpha]_D^{19}$ +58° (*c* 0.76); IR 3450 (OH) and 1710 cm^{-1} (C=O); NMR δ 0.79, 0.95, 0.98, 1.09 (each 3H, s, *t*-CH_3), 1.03 (6H, s, 2×*t*-CH_3), and 1.23 (6H, s, -C(OH)($C\underline{H}_3$)$_2$); mass *m/e* 442 (M^+), 424, 205, and 189 (base peak); Found: C, 81.51; H, 11.62%. Calcd for $C_{30}H_{50}O_2$: C, 81.39; H, 11.38%; glc retention time 9.7 min (column: OV-1 (2%), 260 °C).

Dehydration of Hydroxyhopanone (1): To a solution of hydroxyhopanone (**1**; 0.6 g) in pyridine (55 ml), phosphorus oxychloride (6 ml) was added with stirring at 0 °C. The reaction mixture was allowed to stand overnight at room temperature, poured into ice-water, and extracted with ether. The ethereal extract was washed with diluted hydrochloric acid, sodium hydrogen carbonate solution and then water, and dried over sodium sulfate. After evaporation, the mixture was chromatographed on silica gel (50 g, impregnated with 25% silver nitrate; each fraction 200 ml). The fractions 34—41, eluted with petroleum ether–benzene (4: 1) were combined, and crystallized from acetone to afford hop-21-en-3-one (**9**; 0.35 g) as needles. Mp 209—210.5 °C; $[\alpha]_D^{19}$ +54° (*c* 1.10); IR 1700 cm^{-1} (C=O); NMR δ 0.61, 0.94, 0.98, 1.07 (each 3H, s, *t*-CH_3), 1.02 (6H, s, 2×*t*-CH_3), 1.58, and 1.73 (each 3H, s, C=C(CH_3)$_2$); mass *m/e* 424 (M^+), 205, and 189 (base peak); Found: C, 84.87; H, 11.34%. Calcd for $C_{30}H_{48}O$: C, 84.84; H, 11.39%; glc retention time 13.8 min (column: OV-1 (2%), 250 °C).

The fractions 43—51, eluted with petroleum ether–benzene (2: 1), gave 0.15 g of hop-22(29)-en-3-one (**10**) as needles after crystallization from acetone. Mp 219—220 °C; $[\alpha]_D^{19}$ +89° (*c* 0.57); IR 1700 (C=O), 1640, and 885 cm^{-1} (C=CH_2); NMR δ 0.75, 1.08 (each 3H, s, *t*-CH_3), 0.95, 1.03 (each 6H, s, 2×*t*-CH_3), 1.75 (3H, s, C=C-CH_3), and 4.78 (2H, br.s, C=CH_2); mass *m/e* 424 (M^+), 205, and 189; Found: C, 84.73; H, 11.58%. Calcd for $C_{30}H_{48}O$: C, 84.84; H, 11.39%; glc retention time 15.1 min (column: OV-1 (2%), 260 °C).

Isomerization of Hop-22(29)-en-3-one (10) to Hop-21-en-3-one (9): Hop-22(29)-en-3-one (**10**; 27 mg) in chloroform was treated with *p*-toluenesulfonic acid overnight at room temperature. After usual work-up, the solvent was removed to afford crude crystals (one spot on tlc), which was recrystallized from acetone. The isomerized product (20 mg) was

identical with hop-21-en-3-one (**9**) in respects of IR, NMR, mass spectra, and glc.

On the same treatment of hop-21-en-3-one (**9**; 22 mg), only the starting material (**9**; 19 mg) was recovered. No formation of the other product was observed.

Reduction of Hop-21-en-3-one (9): To a solution of hop-21-en-3-one (**9**; 2.92 g) in ethanol (1.4 l), sodium borohydride (1.6 g) was added and allowed to stand overnight at room temperature. After the reaction mixture was concentrated, acetone was added and left overnight at room temperature to destroy the excess sodium borohydride. Evaporation of the solvents gave crude products (2.54 g), which were subjected to silica gel column chromatographic separation: fractions 1—12, benzene (each fraction 200 ml); and fractions 13—20, benzene–ether (5: 1, each fraction 100 ml).

Fractions 8—11, on evaporation of the solvent, gave crude crystals, which were recrystallized from ethanol to give hop-21-en-3α-ol (**11b**; 0.56 g). Mp 161—162.5 °C; $[\alpha]_D^{13}$ +3° (*c* 0.31); IR 3470 cm^{-1} (OH); NMR δ 0.60, 0.96 (each 3H, s, *t*-CH_3), 0.85, 1.00 (each 6H, s, 2×*t*-CH_3), 1.57, 1.73 (each 3H, br.s, C=C(CH_3)$_2$), and 3.39 (1H, t, J=3 Hz, –CH_2–C<u>H</u>–OH).

Fractions 17 and 18 were combined, evaporated and crystallized from ethanol. Hop-21-en-3β-ol (**11a**; 1.91 g) was obtained. Mp 200—201.5 °C; $[\alpha]_D^{14}$ +40° (*c* 0.49); IR 3270 cm^{-1} (OH); NMR δ 0.60, 0.77, 0.83 (each 3H, s, *t*-CH_3), 0.97 (9H, s, 3×*t*-CH_3), 1.57, 1.72 (each 3H, br.s, C=C(CH_3)$_2$) and 3.20 (1H, dd, J=10 and 6 Hz, –CH_2–C<u>H</u>–OH); mass *m/e* 426 (M^+), 207, and 189 (base peak); Found: C, 84.60; H, 11.51%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%.

Mesylation of Hop-21-en-3β-ol (11a): Hop-21-en-3β-ol (**11a**; 1.32 g) was dissolved in dry pyridine (45 ml) and kept at 0 °C. To the solution, methanesulfonyl chloride (1 ml) in pyridine (5 ml) was added dropwise with agitation. The mixture was further stirred for 30 min and then left overnight at room temperature. The reaction mixture, after addition of ice-water in order to destroy the excess reagent, was extracted with ether and worked up as usual giving rise to 1.20 g of crude crystals. On recrystallization from acetone, hop-21-en-3β-yl mesylate (**12**; 0.70 g) was obtained as colorless needles. Mp 145—145.5 °C; $[\alpha]_D^{22}$ +26° (*c* 0.10); IR 1350 and 1180 cm^{-1}; NMR δ 0.59, 1.02 (each 3H, s, *t*-CH_3), 0.86, 0.97 (each 6H, s, 2×*t*-CH_3), 1.57, 1.73 (each 3H, s, C=C-(CH_3)$_2$), and 2.97 (3H, s, CH_3–SO_2–).

Solvolysis of Hop-21-en-3β-yl Mesylate (12): A mixture of hop-21-en-3β-yl mesylate (**12**; 0.44 g) and calcium carbonate (0.4 g) in dioxane–water (100 ml, 1: 1) was heated under reflux for several hours. Most of the solvents were removed under reduced pressure, acetic acid was added to dissolve calcium carbonate and the reaction product was extracted with chloroform. The extract was washed with sodium hydrogen carbonate solution, water and then saturated sodium chloride solution, and the solvents were removed. The crude crystal in benzene was passed through a column of alumina (15 g) and eluted with the following solvents: fractions 1—3, benzene (each fraction 30 ml); fractions 4—6, benzene–ether (1: 1, each fraction 20 ml); and fractions 7 and 8, ether (each fraction 30 ml).

On evaporation of the solvent, fraction 1 gave white crystals (0.31 g, mp 168—188 °C; IR 892 cm^{-1}) which were shown to be a mixture of olefins by NMR measurement. Signals due to olefinic protons were observed at δ 4.78 and 5.74, and each was a broad singlet with intensity less than one proton. The mixture was further chromatographed on silica gel impregnated with 10% silver nitrate and eluted with petroleum ether–benzene (9: 1, each fraction 40 ml). Evaporation of fraction 3 followed by recrystallization from dichloromethane–methanol gave A-neohopa-3,21-diene (**13**; 190 mg) as colorless plates. Mp 190—191 °C; $[\alpha]_D^{14}$ +45° (*c* 0.77); NMR δ 0.60, 0.98 (each 6H, s, 2×*t*-CH_3), 1.59, and 1.73 (each 6H, s, C=C(CH_3)$_2$); mass *m/e* 408 (M^+) and 189 (base peak); Found: C, 87.98; H, 11.76%. Calcd for $C_{30}H_{48}$: C, 88.16; H, 11.84%. Fractions 9—12 were combined and crystallized from chloroform–ethanol to afford A-neohopa-4(23),21-diene (**15**; 19 mg) as colorless needles. Mp 185—186 °C; IR 1640 and 894 cm^{-1} (C=CH_2); NMR δ 0.57, 0.72 (each 3H, s, *t*-CH_3), 0.95 (6H, s, 2×*t*-CH_3), 1.59 (3H, br.s, C=C–CH_3), 1.75 (6H, br.s, 2×C=C–CH_3), and 4.77 (2H, br.s, C=CH_2); mass *m/e* 408 (M^+) and 189 (base peak); Found: C, 88.04; H, 11.58%. Calcd for $C_{30}H_{48}$: C, 88.16; H, 11.84%.

Fraction 8 of the first chromatography afforded A-neohop-21-en-4-ol (**14**; 91 mg) as colorless needles by crystallization from chloroform–ethanol. Mp 193—194 °C; $[\alpha]_D^{20}$ +46° (*c* 0.17); IR 3400 cm^{-1} (OH); NMR δ 0.59, 0.78 (each 3H, s, *t*-CH_3), 0.98 (6H, s, 2×*t*-CH_3), 1.19, 1.22 (each 3H, s, –C(OH)(C<u>H</u>$_3$)$_2$), 1.59, and 1.73 (each 3H, s, C=C(CH_3)$_2$); mass *m/e* 426 (M^+), 408, and 189 (base peak).

Dehydration of A-Neohop-21-en-4-ol (14): To a solution of A-neohop-21-en-4-ol (**14**; 36 mg) in dry pyridine (10 ml), phosphorus oxychloride (1 ml) was added dropwise with stirring at 0 °C. The reaction mixture was allowed to stand overnight at room temperature, poured into ice-water and extracted with chloroform. The extract was washed with diluted hydrochloric acid, sodium hydrogen carbonate solution, water and then with saturated sodium chloride solution. After drying over sodium sulfate, evaporation of the solvent gave a residue (24 mg), which was chromatographed on silica gel impregnated with 10% silver nitrate and eluted with the following solvents (each fraction 20 ml): fractions 1—3, petroleum ether; fractions 4—7, petroleum ether–benzene (10: 1); fractions 8—10, petroleum ether–benzene (5: 1).

From fraction 4, on evaporation of the solvent, 15 mg of colorless crystal was obtained by crystallization from chloroform–ethanol. The mp and spectral data were identical with those of A-neohop-3,21-diene (**13**), obtained by solvolysis of hop-21-en-3β-yl mesylate (**12**).

Fractions 5—8, after crystallization from chloroform–ethanol, gave 7 mg of colorless needles, which was identical with A-neohopa-4(23),21-diene (**15**) in respects of IR, NMR, and tlc.

Hydrogenation of A-Neohopa-4(23),21-diene (15): A-neohopa-4(23),21-diene (**15**; 17 mg) in ethanol (30 ml) was catalytically hydrogenated in the presence of platinum oxide (about 5 mg) with stirring at 40 °C overnight. The solvent was removed under reduced pressure to afford crude crystals, which were recrystallized from chloroform–ethanol. A-neohop-21-ene (**16**) was obtained and weighed 8 mg. Mp 191.5—192.5 °C; $[\alpha]_D^{16}$ +49° (*c* 0.30); IR (KBr disk) 1380, 1360, 1165, and 1145 cm^{-1}; NMR δ 0.59, 0.72 (each 3H, s, *t*-CH_3), 0.97 (6H, s, 2×*t*-CH_3), 1.57, and 1.73 (each 3H, s, C=C(CH_3)$_2$), (signals due to protons of two secondary methyls could not be assignable); tlc R_f 0.4 (10% $AgNO_3$–SiO_2, petroleum ether); mass *m/e* 410 (M^+), 191 (base peak), and 189; Found: C, 87.39; H, 12.54%. Calcd for $C_{30}H_{50}$: C, 87.73; H, 12.27%; glc retention time 19.1 min (column: SE-30 (0.7%), 220°) and 20.2 min (column: OV-17 (2%), 250 °C).

Hydrogenation of Hop-22(29)-en-3-one (10): Hop-22(29)-en-3-one (**10**; 0.21 g) in ethanol (200 ml) was hydrogenated in the presence of platinum oxide (0.07 g) for 12 hr to the same procedure as above. Filtration of the catalyst followed by evaporation of the solvent gave a residue (0.21 g), which was recrystallized from acetone to afford hopan-3-one (**17**) as needles. Mp 230—232 °C; $[\alpha]_D^{19}$ +78° (*c* 0.75); IR 1700

0.97 (6H, s, 2×*t*-CH_3), 1.59, and 1.73 (each 3H, br.s, C=C-(each 3H, s, *t*-CH_3); mass *m/e* 426 (M^+), 205, and 191 (base peak); Found: C, 84.29; H, 11.91%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81; glc retention time 14.6 min (column: OV-1 (2%), 260°) and 63.5 min (column: OV-17 (2%), 250 °C).

Hydrogenation of Hop-21-en-3-one (9): Hop-21-en-3-one (**9**; 62 mg) in ethanol (100 ml) was hydrogenated in the presence of platinum oxide (19 mg) overnight. Treatment as usual gave a substance (61 mg; one spot on tlc) which was found to be identical with the starting material (**9**). No formation of the other product was observed.

Reduction of Hopan-3-one (17): Hopan-3-one (**17**; 0.85 g) was dissolved in ethanol (650 ml), sodium borohydride (0.67 g) was added and left overnight at room temperature. After a small quantity of acetone was added, the solvents were removed. The residue, dissolved in chloroform, washed with water and evaporated, gave crude crystals (0.85 ; two spots on tlc), which were chromatographed on silica gel (100 g). The fractions 20—29 (one spot on tlc), eluted with benzene, were collected and recrystallized from ethanol to afford hopan-3β-ol (**18**; 0.46 g) as a main product. Mp 238—239 °C; IR 3300 cm^{-1} (OH); NMR δ 0.74, 0.78, 0.85, 0.99 (each 3H, s, *t*-CH_3), and 0.96 (6H, s, 2×*t*-CH_3); mass *m/e* 428 (M^+), 207, and 191 (base peak).

Mesylation of Hopan-3β-ol (18): To a solution of hopan-3β-ol (**18**; 0.4 g) in pyridine (20 ml), methanesulfonyl chloride (1 ml) in pyridine (9 ml) was added dropwise with agitation at 0 °C. The reaction mixture was allowed to stand overnight at room temperature and poured into ice-water. Extraction with ether and usual work-up gave a residue (0.39 g), which was recrystallized from ether to afford hopan-3β-yl mesylate (**19**; 0.12 g). Mp 119—120 °C; $[\alpha]_D^{21}$ +35° (*c* 0.49); IR 1170 cm^{-1} (SO_2); NMR δ 0.73, 1.02 (each 3H, s, *t*-CH_3), 0.87, 0.96 (each 6H, s, 2×*t*-CH_3), and 3.00 (3H, s, CH_3–SO_2–).

Solvolysis of Hopan-3β-yl Mesylate (19): A mixture of hopan-3β-yl mesylate (**19**; 0.32 g) and calcium carbonate (0.5 g) in dioxane (150 ml) and water (150 ml) was heated under reflux for 5 hr. The solvents were removed under reduced pressure and the residue was dissolved in ether. The ethereal solution was treated as usual manner and the residue was dissolved in petroleum ether–benzene, which was chromatographed on silica gel (10 g) and the following solvents (each fraction 40 ml) were eluted: fractions 1 and 2, petroleum ether–benzene (2: 1); fraction 3, petroleum ether–benzene (1: 1); and fraction 4, ether.

On evaporation of the solvents, fraction 1 gave a mixture (0.20 g) of olefins. IR 1640 and 894 cm^{-1}; NMR δ 1.58, 1.73 (each 3H, s, C=C(CH_3)$_2$), 4.8, and 5.4 (each less than 1H, olefinic proton); mass *m/e* 410 (M^+). The mixture gave four spots (R_f 0.9, 0.8, 0.5, and 0.2) on tlc (10% $AgNO_3$–SiO_2, petroleum ether). The olefin mixture was subjected to column chromatographic separation using silica gel impregnated with 10% silver nitrate, and eluted with petroleum ether (each fraction 30 ml). Fractions 8—15, after recrystallization from ethanol, gave A-neohop-3-ene (**20**; 88 mg) as colorless needles. Mp 193.5—193.7 °C; $[\alpha]_D^{16}$ +52° (*c* 0.28); IR (KBr disk) 1380, 1360, 1165, and 1145 cm^{-1}; NMR δ 0.60, 0.72 (each 3H, s, *t*-CH_3), 0.97 (6H, s, 2×*t*-CH_3), 1.58, and 1.73 (each 3H, s, C=C(CH_3)$_2$), (signals due to protons of two secondary methyls could not be assignable); tlc R_f 0.4 (10% $AgNO_3$–SiO_2, petroleum ether); mass *m/e* 410 (M^+), 191 (base peak), and 189; Found: C, 87.74; H, 12.42%. Calcd for $C_{30}H_{50}O$: C, 87.73; H, 12.27%; glc retention time 19.1 and 10.4 min (column: SE-30 (0.7%), 220 and 250 °C respectively) and 20.2 min (column: OV-17 (2%), 250 °C). This compound was shown to be identical (mp, mixed mp, IR, NMR, mass spectra, tlc, and glc) with **16**.

Fraction 4, eluted with ether, afforded A-neohopan-4-ol (**21**; 0.05 g). Mp 198.5—199 °C; $[\alpha]_D^{19}$ +64° (*c* 0.75); IR 3470 cm^{-1} (OH); NMR δ 0.70, 0.77 (each 3H, s, *t*-CH_3), 0.96 (6H, s, 2×*t*-CH_3), 1.18, and 1.21 (each 3H, s, –C(OH)-($C\underline{H}_3$)$_2$); mass *m/e* 428 (M^+), 410, 191, and 189 (base peak); Found: C, 84.03; H, 12.42%. Calcd for $C_{30}H_{52}O$: C, 84.04; H, 12.23%.

Reduction of Hopan-3-one (17): A mixture of hopan-3-one (**17**; 70 mg), potassium hydroxide (0.2 g), diethylene glycol (5 ml) and hydrazine hydrate (80%, 0.1 ml) was heated under reflux for 1 hr. After removal of water and hydrazine by distillation, the reaction mixture was further heated under reflux for 1 hr. Completion of the reaction was confirmed by tlc examination and then water was added to the reaction mixture. Extraction with ether, usual treatment and recrystallization from *n*-hexane–ethanol gave hopane (**5a**; 19 mg) as colorless needles. Mp 209.5—211 °C; $[\alpha]_D^{20}$ +50° (*c* 0.14); NMR δ 0.70, 0.79, 0.81, 0.84 (each 3H, s, *t*-CH_3) and 0.95 (6H, s, 2×*t*-CH_3), (signals due to protons of two secondary methyls could hardly be assignable); mass *m/e* 412 (M^+). These data coincide with those published for hopane (**5a**)[8] rather than for isohopane (**5b**) (moretane).[8]

Hydrogenation of Hop-21-en-3-one (9) in Acidic Condition: A solution of hop-21-en-3-one (**9**; 113 mg) in ethyl acetate (15 ml) and acetic acid (0.5 ml) was catalytically hydrogenated in the presence of platinum oxide at room temperature. After removal of the catalyst by filtration, evaporation under reduced pressure gave crude crystals, which were crystallized from chloroform–ethanol to give crude isohopan-3-one (**26**; 96 mg). IR 1700 cm^{-1} (C=O); NMR: signals due to vinyl methyls were not observed.

Reduction of Isohopan-3-one (26): Crude isohopan-3-one (**26**; 96 mg) without further purification, was dissolved in ethanol (50 ml) and treated with sodium borohydride and allowed to stand overnight. Addition of acetone followed by evaporation of the solvents under reduced pressure afforded a residue, which showed two spots on tlc. This was dissolved in benzene, passed through a column of silica gel (10 g) and eluted with the following solvents (each fraction 50 ml): fraction 1, benzene; fractions 2 and 3, benzene–ether (50: 1); and fractions 4—8, benzene–ether (10: 1).

A main component, isohopan-3β-ol (29), eluted in fractions 5 and 6, was obtained as crude crystals (78 mg), which gave one spot on tlc. IR 3350 cm^{-1} (OH).

Mesylation of Isohopan-3β-ol (29): Crude isohopan-3β-ol (**29**; 78 mg) obtained above, was dissolved in pyridine (6 ml) and kept at 0 °C. Methanesulfonyl chloride (about 0.5 ml) in pyridine was added and usual treatment gave crude isohopan-3β-yl mesylate (**30**; 90 mg) as pale yellow crystals, in which no starting material (**29**) was detected by tlc.

Solvolysis of Isohopan-3β-yl Mesylate (30): Calcium carbonate (0.1 g) and crude isohopan-3β-yl mesylate (**30**; 90 mg) without further purification, were suspended in dioxane (10 ml) and water (10 ml), and the mixture was heated under reflux for 13 hr. After the same treatment as in the case of solvolysis of hop-21-en-3β-yl mesylate (**12**), the residue was chromatographed on silica gel (5 g). Elution with benzene (30 ml) and evaporation of the solvent gave a mixture (52 mg) of olefins, which was subjected to column chromatographic separation on silica gel (3 g) impregnated with 10% silver nitrate using petroleum ether as eluent (each fraction 30 ml). Fractions 2—6, on crystallization from acetone, gave A-neoisohop-3-ene (**28**; 30 mg) as colorless needles. Mp 156—158 °C; IR (KBr disk) 1440, 1380, 1365, 1170, and 1140 cm^{-1}; NMR δ 0.62, 0.68 (each 3H, s, *t*-CH_3),

cm^{-1} (C=O); NMR δ 0.73, 0.94, 0.96, 1.00, 1.03, and 1.10 $(CH_3)_2$), (signals due to protons of two secondary methyls could not be assignable); mass *m/e* 410 (M^+); glc retention time 7.8 min (column: OV-1 (2%), 250 °C).

Studies on Benzoquinolines(f) and (h). Part II

Rameshwar P. TYAGI and Bhuwan C. JOSHI
Chemical Laboratories, University of Rajasthan, Jaipur 302004, India
(Received January 14, 1972)

3-Hydrazino-1-methyl, 1-hydrazino-3-methylbenzo(f) quinoline (IA, IIA) and 2-hydrazino-4-methyl, 4-hydrazino-2-methylbenzo(h) quinoline (IIIA, IVA) were reported[1] to give triazines and diazepines with nitrous and formic acids. It would be interesting to study the reactions of IA—IVA with acetylacetone and ethyl acetoacetate respectively.

Reactions of alcoholic solution of IA with acetylacetone yielded IB, $C_{19}H_{19}ON_3$. A characteristic absorption band at 1730 cm^{-1} in IR spectrum indicated the presence of a carbonyl group. NMR spectrum indicated the presence of six aromatic protons at δ 7.6—8.0 ppm, one aromatic proton as singlet at δ 7.10 ppm, nine protons as three singlets for methyl groups at δ 2.50, 2.25, and 2.10 ppm and the presence of two protons of a methylene group as singlet at δ 3.25 ppm. Therefore, IB had the structure as assigned, thereby indicating the formation of an intermediate hydrazone. IB on further refluxing in glycerol in the presence of fused sodium acetate, gave a mixture of products from which a compound, IC ($C_{19}H_{17}N_3$) was isolated. In IC, absence of an absorption band at 1730 cm^{-1} and the presence of an absorption band at 1602 cm^{-1} indicated the existence of a 1,2-diazepine system in it.[2] NMR spectrum indicated the presence of six aromatic protons at δ 7.60—8.00 ppm and nine protons of three methyl groups as singlets at δ 2.95,

a) No sharp melting point obtained.

2.80, and 2.40 ppm respectively. A signal at δ 9.20 ppm due to the –NH proton and a singlet at δ 6.10 ppm due to =CH- proton also indicated the presence of a 1,2-diazepine system.[2] The absence of a proton at position 2 of the benzoquinoline ring, the presence of an –NH proton and an absorption band at 1602 cm^{-1} would explain the fusion of a 1,2-diazepine ring with benzoquinoline system. Based on these observations, IC proved to be 10,12,13-trimethyl-8*H*-benzo(f)-[1,2]diazepino[3,4-*b*]quinoline.

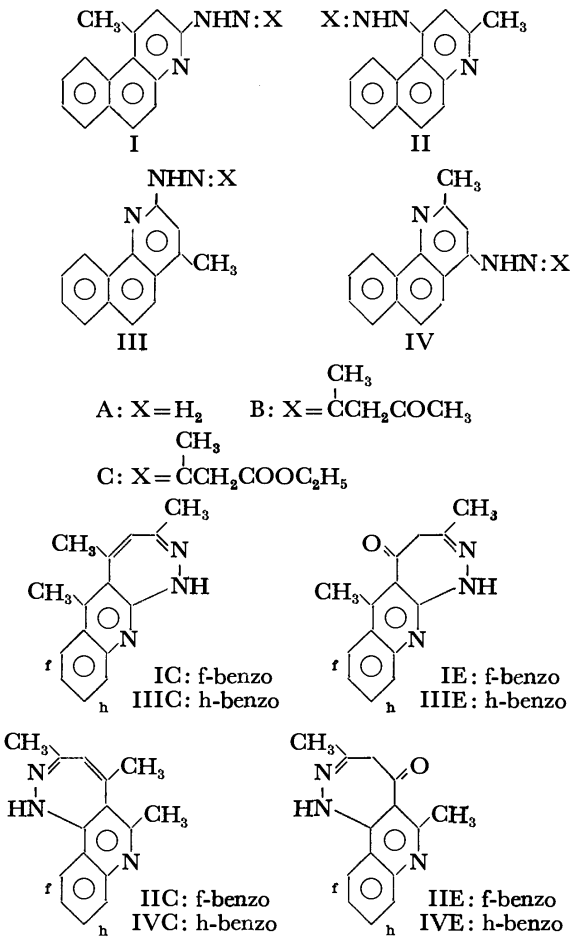

Fig. 1.

IA with ethyl acetoacetate yielded an intermediate hydrazone, ID ($C_{20}H_{21}O_2N_3$), the IR spectrum of which with an absorption band at 1735 cm^{-1} indicated the presence of an ester group. On further refluxing in glycerol in the presence of fused sodium acetate, IE ($C_{18}H_{15}ON_3$) was obtained. IR spectrum gave absorption bands at 1702 and 1602 cm^{-1} showing the presence of diazepinone moiety in it. NMR spectrum indicated the presence of six aromatic protons at δ 7.6—8.00 ppm, six protons as two singlets of methyl groups at δ 2.60 and 2.50 ppm, two protons of methylene group as singlet at δ 3.10 ppm, an –NH proton at δ 8.80 ppm and there was no proton at position 2 of the benzoquinoline ring. Thus, IE was assigned the structure to be 10,13-dimethyl-12-oxo-8*H*-11,12-dihydrobenzo(f)[1,2]diazepine[3,4-*b*]quinoline.

Similar observations were made when IIA—IVA were reacted with acetyl acetone and ethyl acetoacetate respectively (Fig. 1). The characteristic absorption bands and chemical shifts obtained in the NMR spectra of various products are compiled in Table 1. From these observations it can be concluded that cyclization of intermediates, hydrazones, occurred at position 2 in benzo(f) or at position 3 in benzo(h) quinolines to yield benzo(f) or benzo(h) quinolino-1,2-diazepine compounds.

Experimental

All the reported melting points are uncorrected. Microanalyses, IR and NMR spectra were from Central Drug Research Institute, Lucknow. IR spectra were recorded on Perkin-Elmer infrared in nujol and NMR spectra on a Varian A-60D model (using $CDCl_3$ or TFA as solvent and TMS as internal reference standard).

Acetylacetone-1-methyl-benzo(f)quinolyl-3-hydrazone(IB). To a well stirred solution of 3-hydrazino-1-methyl-benzo(f)-quinoline (IA) (8.92 g, 0.04 M) in absolute alcohol, acetylacetone (4.49 g, 0.045 M) was added dropwise and the reaction mixture was refluxed for 1 hr. It was cooled, poured

into ice-cold water and kept overnight at 0°C. The solid was washed well with water and dried. After repeated crystallization from ethanol IB, 9.8 g (80%) was obtained having no sharp melting point.

Similarly, IIB from IIA, IIIB from IIIA, and IVB from IVA were prepared. These hydrazones have no sharp melting points.

*10,12,13-Trimethyl-8*H-*benzo(f)* [*1,2*] *diazepino* [*3,4-*b] *quinoline (IC).* IB (7.6 g, 0.025 M) was refluxed in glycerol in the presence of fused sodium acetate for 4—5 hr with occasional shaking. It was poured into ice-cold water, kept overnight at 0 °C. The solid was washed well with water and repeatedly crystallized from ethanol to give pure IC, 3.58 g (50%), mp 114—115 °C.

Similarly, IIB yielded IIC, 8,9,11-trimethyl-13*H*-benzo(f)-[1,2]diazepino[3,4-*c*]quinoline. IIIB yielded IIIC, 10,12,13-trimethyl-8*H*-benzo(h)[1,2]diazepino[3,4-*b*]quinoline.

IVB yielded IVC, 8,9,11-trimethyl-13*H*-benzo(h)[1,2]-diazepino[3,4-*c*]quinoline.

Ethyl Acetoacetate-1-methyl-benzo(f) quinolinyl-3-hydrazone (ID). To a well stirred solution of IA (8.92 g, 0.04 M) in absolute alcohol, freshly distilled ethyl acetoacetate (5.72 g, 0.045 M) was added dropwise and the reaction mixture was refluxed for 1 hr. It was cooled and poured into ice-cold water. The solid obtained was washed well with water and repeatedly crystallized from ethanol to give pure ID, 9.38 g (70%).

Similarly, IID from IIA, IIID from IIIA and IVD from IVA were prepared.

*10,13-Dimethyl-12-oxo-8*H-*11,12-dihydro-benzo(f)* [*1,2*] *diazepino-* [*3,4-*b] *quinoline (IE).* ID (8 g) was refluxed in glycerol in the presence of fused sodium acetate for 6—7 hr, with occasional shaking. The reaction mixture was cooled, poured into ice-cold water and kept overnight at 0 °C. The crude product was crystallized from ethanol, when a pure compound, IE (3.45 g), was obtained.

Similarly, IID yielded IIE, 8,11-dimethyl-9-oxo-13*H*-9,10-dihydro-benzo(f)[1,2]diazepino[3,4-*c*]quinoline.

IIID yielded IIIE, 10,13-dimethyl-12-oxo-8*H*-11,12-dihydro-benzo(h)[1,2]diazepino[3,4-*b*]quinoline.

IVD yielded IVE, 8,11-dimethyl-9-oxo-13*H*-9,10-dihydro-benzo(h)[1,2]dizepino[3,4-*c*]quinoline.

Authors are thankful to the Head, Chemistry Department of this University for providing necessary facilities and University Grants Commission for financial assistance.

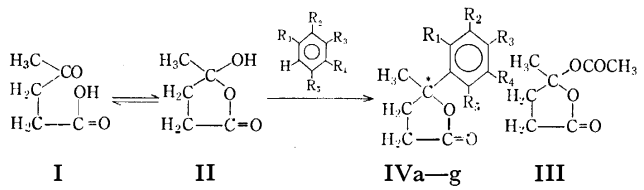
(Received February 12, 1973)

A new series of compounds, succin-as-eins(SAE)—methyl phenol SAE, methyl resorcinol SAE, methyl catechol SAE, methyl quinol SAE, methyl phloroglucinol SAE, methyl pyrogallol SAE and methyl orcinol SAE have been prepared by condensing 2-acetyl propionic acid with appropriate phenols. The structure of methyl resorcinol SAE, based on chemical reactions and spectral data is discussed. The λ_{max} values for few of the dyes are comparable with their analogous succineins and phthaleins.

2-Acetyl propionic acid (I) has been shown to be a mixture of ring (II) and chain (I) tautomers by various workers.[2-4] The lactol (II), which yields well crystalline acetyl derivative (III),[5] on condensation with phenols gave a new series of compounds, succin-as-eins (IV). The condensation process proceeds through the equilibrium process of lactol (II) of acid (I) and with excess of phenol whole of the acid reacts as lactol.

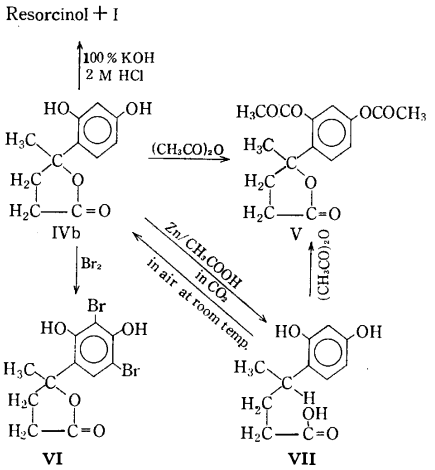
Seven succin-as-eins (SAE)—methyl phenol SAE (IVa), methyl resorcinol SAE (IVb), methyl catechol SAE (IVc), methyl quinol SAE (IVd), methyl phloroglucinol SAE (IVe), methyl pyrogallol SAE (IVf) and methyl orcinol SAE (IVg) have been prepared by condensing acid (I) with respective phenols.



I II IVa—g III

(IVa) $R_1=R_2=R_4=R_5=H$; $R_3=OH$
(IVb) $R_2=R_4=R_5=H$; $R_1=R_3=OH$
(IVc) $R_3=R_4=R_5=H$; $R_1=R_2=OH$
(IVd) $R_2=R_3=R_5=H$; $R_1=R_4=OH$
(IVe) $R_2=R_4=H$; $R_1=R_3=R_5=OH$
(IVf) $R_4=R_5=H$; $R_1=R_2=R_3=OH$
(IVg) $R_2=R_4=H$; $R_5=CH_3$; $R_1=R_3=OH$
(V) $R_2=R_4=R_5=H$; $R_1=R_3=OCOCH_3$
(VI) $R_5=H$; $R_2=R_4=Br$; $R_1=R_3=OH$

The column chromatography, supplemented with thin-layer chromatography, was used for the purification of condensed products. Their IR (KBr) spectra show a strong band at 1760 cm^{-1} due to γ-lactone. The KOH treatment of IVb followed by acid hydrolysis yielded resorcinol and the acid (I). The dye (IVb; 1760 cm^{-1}) when refluxed with Zn-dust and acetic acid gave methyl resorcinol succin-as-in[6] (VII; IR (KBr) bands at 3600—3000 cm^{-1}, -OH in -COOH; 1700 cm^{-1}, >CO in -COOH). The acid (VII) on acetylation gave diacetyl compound (V). The diacetyl (V; IR (KBr) bands at 1760, 1200, and 1125 cm^{-1} due to γ-lactone and phenolic acetate) and dibromo (VI; 1760 cm^{-1}, γ-lactone) derivatives of IVb are also indicative of resorcinol molecule in it.



The absorption maxima (λ_{max}) of SAE (IV) given in Table 1 have been found comparable with their analogous succineins and phthaleins.

Experimental

All melting points are uncorrected. The λ_{max} (UV and visible) have been recorded on model DU-2 Beckmann Spectrophotometer and IR determined using a Perkin-Elmer Infracord.

The phenols have been taken in a little excess of molecular proportion than the acid (I). Conc H_2SO_4 (4—6 drops) was used as a condensing agent throughout.

Methyl Resorcinol SAE (IVb). An intimate mixture of acid (I) (5 g) and resorcinol (5 g) was heated at 120 °C for 2 hr. Conc H_2SO_4 (4—6 drops) was added cautiously and the heating was continued for additional 6 hr at 160 °C. The brittle product was extracted with 3% NaOH and precipitated with dil HCl. The precipitate was chromatographed over silica gel with chloroform–acetone mixture (80:20). The third fraction (200 ml) on crystallization gave a red crystalline dye (6.4 g), mp 300 °C, which dissolved with yellow-red colour in ethanol while in alkali (pH, 8) gave a bright pink-violet colour with light green fluorescence.

The preparation of the rest of compounds given in Table 1 was done in identical manner as described in IVb above taking acid (I) and appropriate phenols (yield, 60—65%).

* Owing to unsymmetric central carbon atom (C*) present in IV they may be named as succin-as-eins; -as representing unsymmetry and -ein the class of compound (Succin-ein[1]).

a) The alkaline solution decomposed during the measurement of λ_{max} value.

Acetylation of IVb. The dye (IVb) (0.5 g), acetic anhydride (10 ml) and fused sodium acetate (1 g) were refluxed at 130—140 °C for 3 hr to give pale yellow crystalline diacetyl compound (V) (0.5 g), mp 190 °C (from 80% ethanol); $\lambda_{max}^{EtOH}(\varepsilon)$ 330 (3358).

Found: C, 61.82; H, 5.28; CH_3CO, 29.28%. Calcd for $C_{15}H_{16}O_6$: C, 61.64; H, 5.48; CH_3CO, 29.45%.

Bromination of IVb. The dye (0.5 g) was dissolved in ethanol (10 ml) and to this solution Br_2 (1 ml) was slowly added with stirring. It was refluxed for 45 min, on a water bath to give red crystalline dibromo compound (from 90% ethanol) (VI; 0.6 g), mp 300 °C; λ_{max}^{EtOH} (at neutral and at pH, 8.5) (ε) 530 (1390).

Found: Br, 43.96%. Calcd for $C_{11}H_{14}O_4Br_2$: Br, 43.7%.

Potassium-hydroxide Treatment of IVb. The dye (IVb) (2 g) and aqueous KOH (100%, 25 ml) were refluxed for 1 hr. The solution was diluted with 500 ml water and acidified with dil HCl, filtered and washed well with water. The solid residue was boiled with acidic water (50 ml, 1 ml 2 M HCl) to give the acid (I), mp 37 °C (lit,[4] mp 33—35 °C); bp 137—139 °C/10 mmHg (lit,[4] bp 137—139 °C/10 mmHg); amide, mp 106 °C (lit,[5] mp 107 °C); acetyl, mp 77 °C (lit,[5] mp 78 °C).

The light brown filtrate from solid residue was extracted with ether to give resorcinol (0.9 g), mixed mp 110 °C and identical IR with its authentic sample.

Zn-dust Reduction of IVb. The dye (IVb) (2 g) was refluxed in glacial acetic acid (100 ml) with Zn-dust (5 g) for 15 min, to yield a colourless crystalline acid (VII; 1.7 g), mp 245 °C, which does not give fluorescence in alkaline solution.

Found: C, 63.02; H, 6.48%. Calcd for $C_{11}H_{14}O_4$: C, 62.85; H, 6.66%.

The acid (VII) when left overnight changed to red compound IVb, with superimposible IR and the same λ_{max} values. The acetylation of the mixture of acid (VII) and red compound was carried out as in V above to give diacetyl (V), mixed mp and identical IR, λ_{max} values and elemental analysis.

The authors are grateful to Dr. J. D. Tewari for his useful suggestions. A grant and fellowship (to R. G.) from CSIR, New Delhi is acknowledged.

High-precision Flow Meter for Gas Chromatography

Yoshio HORI* and Riki KOBAYASHI

Department of Chemical Engineering, Rice University, Houston, Texas 77001, U.S.A.

(Received September 28, 1973)

Synopsis. A gas-chromatographic apparatus with an empty tubing in place of a packed column can be used as a flow meter. The detector signal, processed by a differentiator-timer system, gives a precision of 0.06% in the measurement of the flow rate.

Gas chromatography in physico-chemical application requires precise measurements of the retention volume. Sources of error in the measurements of retention time have been analyzed, and various improvements have been made.[1-2] On the other hand, a soap film flow meter has been conventionally used for the measurement of the carrier-gas flow rate. Because of the visual observation of the soap film motion, the experimental uncertainty in the retention volume is at least 0.2—0.5%. No flow-measuring device can give much more precise measurements.

During the gas-chromatographic studies of physical adsorption and gas-liquid equilibrium at elevated pressures, a new flow meter was developed in this laboratory to give more precise measurements.

Apparatus

High-pressure Gas-chromatographic Apparatus. The main features of the equipment are similar to those described previously.[3] Two high-pressure regulators made by the Matheson and Grove Valve & Regulator Co. were connected in series; they held such a constant pressure of the carrier gas that no change was detected in the Heise Gauge during any experimental run. The pressure was measured by means of Heise Gauges with certified accuracy of 0.1% of the full scale. Their ranges were 200, 1000, and 2000 psi. The pressure was kept constant at all experimental conditions (up to 120 atm) between the inlet and the expansion valve; the pressure drop across the packed column is negligible, as has been verified previously.[3] The pressure of the carrier gas is reduced to 1 atm at the expansion valve.

Flow-measuring Device. In a common gas chromatographic apparatus, a packed column can be replaced with an empty tubing of a known volume. Then one can obtain a definite retention time in accordance with the flow rate. This is the principle of the present flow meter.

A six-way linear gas-sampling valve manufactured by Varian Aerograph was used as the perturbation gas-injection valve. The volume of the sample loop of the valve was 0.18 ml. Two sets of copper tubing 1/4 inch in diameter were used as the empty tubing; one was 2 m long, and the other, 8.6 m long. Either of the two empty tubings was used according to the flow conditions. The pressures at both the inlet and the outlet of the empty tubings were measured by means of manometers filled with water. A Gow-Mac thermal conductivity cell (Model 10-460, Flo-thru type) was used. The flow-meter system was immersed in a thermostat, filled with silicone oil and maintained at 35.0± 0.03 °C.

The flow-meter system was connected to the outlet of the high-pressure gas-chromatographic apparatus. The flow-meter system is regulated at the constant temperature (35 °C), and the pressure in the empty tubing is measured (atmospheric pressure), so that the flow meter can work under any experimental conditions of the high-pressure equipment.

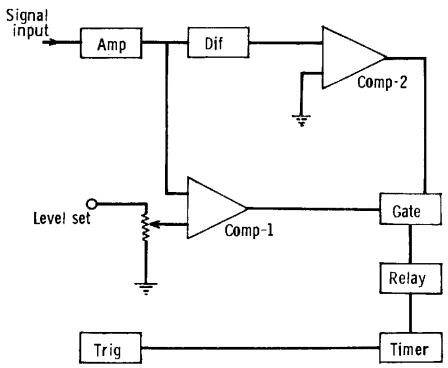

Fig. 1. Block diagram of the differentiator-timer system.

After the carrier-gas (methane) flow reaches a steady state, a dose of perturbation gas (argon) is injected by means of the sample injection valve, which triggers a microswitch at the same time. Then the timer starts. The perturbation gas, passing through the empty tubing, reaches the detector. The signal from the detector is differentiated by the differentiator and is compared with zero level by means of the comparator-2 (Fig. 1). When the elution peak reaches its maximum, the differentiated signal becomes zero, the relay system being driven to turn off the timer. The timer stops only when the input signal exceeds the preset threshold level (comparator-1) and the differentiated signal reaches zero. The timer, a Model S-6 Precision Timer manufactured by the Standard Electric Company, gives readings as precise as 1/1000 minute.

The present flow meter was calibrated against a soap-film flow meter, the volume of which had previously been calibrated. The retention time, t (min), is related to the carrier gas flow rate, f (cm³/min) (at 35.0 °C, atmospheric pressure), and the effective volume between the injection valve and the detector cell, v (cm³):

$$f \cdot t = v + f \cdot \Delta t \qquad (1)$$

where Δt (min) is a constant. Δt corresponds to the delay in the detector system and the variation in the flow pattern according to the flow rate. The linear relationship (1) was found to hold for flow rates less than 180 cm³/min, using an

* Present address: Research Department, Kikumoto Works, Sumitomo Chemical Co., Ltd., Niihama, Ehime 792.

appropriate one of the empty tubings (2 m and 8.6 m long). The *accuracy* of the present flow meter depends upon that of the soap-film flow meter. However, the *precision* is much improved, as is exemplified below.

Results of Measurements

A lot of flow measurements were made for each experimental run by means of the present flow meter. Some of them are tabulated in Table 1. The retention times in the third line were obtained during the time shown in the fourth line. The constancy of the measurements is excellent.

Table 1. Reproducibilty of the measurements of flow rate

Chromatographic pressure in the high pressure part[a] (atm)	3.0	10.5	15.5
Average flow rate at 35.0 °C, latm (cm^3/min)	12.539	36.754	62.385

	3.3114	1.1331	0.6692
	3.3117	1.1331	0.6701
	3.3113	1.1332	0.6701
		1.1331	0.6698
		1.1330	0.6698
		1.1322	0.6701
Duration in which the measurements were made (min)	39	25	34

a) The flow meter is connected to the outlet of the high pressure gas chromatographic apparatus. The pressures before the expansion valve in high pressure apparatus are shown here.

According to the series perturbation technique,[3-6] the adsorption of methane on Porasil was precisely measured by means of a high-pressure gas chromatograph equipped with the present flow meter. The carrier gas was methane, and the retention volume of the methane was measured by the use of radioactive methane. The detailed experimental results will be reported elsewhere.[7] The retention volume of helium perturbation is a first-order approximation of the gas-phase volume of the column packed with Porasil. Figure 2 gives the helium perturbation obtained by means of the apparatus equipped with the present flow meter in comparison with those obtained with a soap-film flow meter. If the density of the adsorbed methane is constant at a fixed temperature, the gas-phase volume decreases linearly with the methane adsorption.[3] The present flow meter improved the measurement very much. As may be seen in Table 1, the scattering is approximately 0.06%, at least 4 times better than in careful measurements by means of a soap-film flow meter.

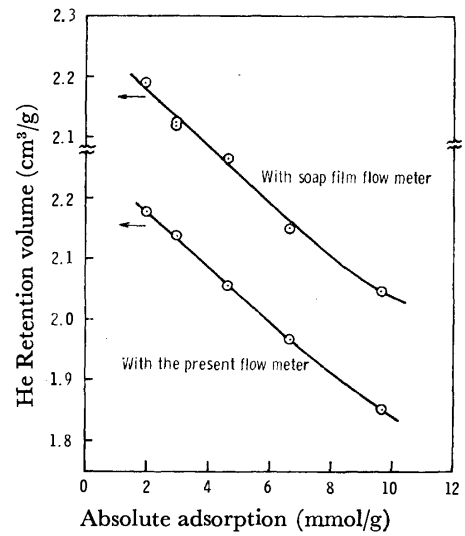

Fig. 2. Measurement of He retention volume by high pressure gas chromatographic apparatus equipped with and without differentiator.

Financial support was supplied by the U. S. National Science Foundation.

Tritium Fractionation in the Crystallization of Aluminum Alums from Their Aqueous Solutions

Haruhiko TANAKA,* Hiroko ANDO, and Hisao NEGITA

*Shinonome Branch School, Faculty of Education, Hiroshima University, Shinonome, Hiroshima 734
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received November 12, 1973)

Synopsis. The tritium fractionation in the crystallization of $NH_4Al(SO_4)_2 \cdot 12H_2O$ from a solution was found to be larger than those in $NaAl(SO_4)_2 \cdot 12H_2O$ and $KAl(SO_4)_2 \cdot 12H_2O$. This fact was discussed in terms of the proton exchange between NH_4^+ and H_2O.

In previous studies,[1] the fractionation of tritiated water (HTO) has been investigated in the crystallization of a number of hydrated crystals. It was found that HTO is generally diluted with crystallization water to a small percentage. It seems to be of some importance to examine the behavior of NH_4^+ in the tritium fractionation in $NH_4Al(SO_4)_2 \cdot 12H_2O$, with reference to the results in $NaAl(SO_4)_2 \cdot 12H_2O$ and $KAl(SO_4)_2 \cdot 12H_2O$.

Experimental

The aluminum alums of commercial origin were purified by recrystallization. The large single crystal of the salt was grown from a slightly supersaturated aqueous solution containing a trace of HTO at around 20 °C.

The water from the single crystals of sodium- and ammonium alums was recovered by heating them at *ca.* 300 °C in a stream of nitrogen gas and at *ca.* 50 °C *in vacuo* respectively. The water from the mother solution was recovered through distillation and subsequent dehydration. The tritium radioactivity was compared between the dehydrated water and the mother liquid as has been described in a previous paper.[1] Simultaneous TGA and DTA were carried out for the dehydration of the three kinds of alums with a thermal analyzer, M8002 TG-DTA, of the Rigaku Denki Co. Ltd., at the rate of 5 °C/min in an atmosphere of nitrogen.

Results and Discussion

The separation factor, S, of HTO for the crystallization of a hydrated salt from an aqueous solution can be given as $S=N_s/N_l$, where N_s and N_l are the net count rates for a 0.1 g portion of water recovered from the solid and liquid phases respectively.[1] Table 1 gives the separation factors, S, for the aluminum alums. We see that there is only a small percentage of dilution of HTO in the water of crystallization of sodium- and potassium aluminum alums,[2] as is the case with many inorganic hydrated crystals.[1]

TABLE 1. THE SEPARATION FACTOR, S, OF HTO FOR ALUMS

Crystal	Net count rate (cpm) of HTO[a]		$S(N_s/N_l)$
	N_s	N_l	
$NaAl(SO_4)_2 \cdot 12H_2O$	19419	20076	0.967 ± 0.006
$KAl(SO_4)_2 \cdot 12H_2O$	26426	27097	0.975 ± 0.004[b]
$NH_4Al(SO_4)_2 \cdot 12H_2O$	13121	14061	0.933 ± 0.006

a) Averaged from 5—6 independent experiments for 0.1 g of water with 35% efficiency.
b) From Ref. 2.

The fractionation in $NaAl(SO_4)_2 \cdot 12H_2O$ can be explained by a mechanism similar to that in $KAl(SO_4)_2 \cdot 12H_2O$. On the contrary, a remarkable dilution of HTO is found in $NH_4Al(SO_4)_2 \cdot 12H_2O$. It seems that hydrogen atoms in the NH_4^+ ion are responsible for the considerable dilution, because the dilution due to the crystallization water in sodium- and potassium aluminum alums is found to be small.

It can be assumed here that the dilution in the crystallization water of $NH_4Al(SO_4)_2 \cdot 12H_2O$ is equal to that in $KAl(SO_4)_2 \cdot 12H_2O$, This is supported by the facts that (1) the crystal-growth mechanism of these alums is identical,[3] (2) the K^+ and NH_4^+ ions have similar ionic radii and viscosity-B coefficients,[4] and (3) these alums give very similar DT–TGA curves for the dehydration, as is shown in Fig. 1.

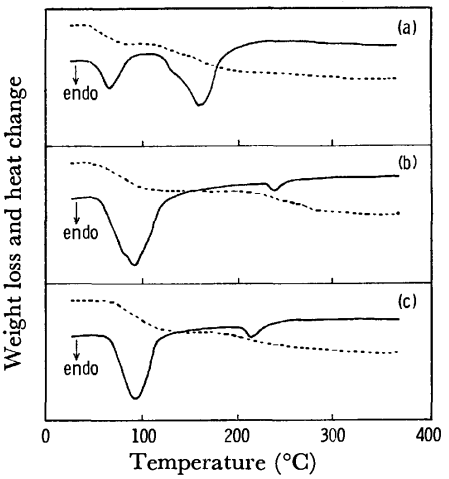

Fig. 1. DTA (——) and TGA (-----) diagrams for dehydration of alums.
(a): $NaAl(SO_4)_2 \cdot 12H_2O$, (b) :$KAl(SO_4)_2 \cdot 12H_2O$,
(c): $NH_4Al(SO_4)_2 \cdot 12H_2O$.

It is well-known that the proton-exchange reaction occurs readily in the aqueous solution of NH_4^+:[7]

$$HTO + NH_4^+ \rightleftharpoons H_2O + NH_3T^+ \quad (1)$$

In Eq. (1), tritium may be diluted in NH_4^+ according to the theory of isotope effect in an equilibrium reaction, because the proton in NH_4^+ is labile in comparison with that in H_2O.[8] It follows that tritium is diluted in the NH_4^+ of the crystal of $NH_4Al(SO_4)_2 \cdot 12H_2O$ grown from the aqueous solution.

Accordingly, a considerable dilution of tritium in the dehydrated water may become possible since a proton-exchange reaction is expected to occur between NH_4^+ in the amorphous $NH_4Al(SO_4)_2$ and dehydrated water during the vacuum dehydration, as has been suggested for the dehydration of $(COOH)_2 \cdot 2H_2O$ by Okazaki and Takemura.[9,10]

In conclusion, the too small S value for $NH_4Al(SO_4)_2 \cdot 12H_2O$ compared with those for the other alums can be explained qualitatively in terms of the proton-exchange reaction between NH_4^+ and H_2O in both the aqueous solution and the vacuum dehydration.

The authors wish to express their thanks to Dr. Osamu Yamamoto for his help in analysing the activity of tritium.

Extrinsic Photoconductivity of *N*-Ethylcarbazole Single Crystals

Keishi KATO, Masaaki YOKOYAMA, and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received February 20, 1974)

Synopsis. An extrinsic photocurrent was observed in pure *N*-ethylcarbazole single crystal, contrary to the current view that it does not exist in *N*-isopropylcarbazole.[8] It was reduced to a great extent in anthracene-containing crystal due to the decrease in carrier quantum yield caused by the energy transfer from *N*-ethylcarbazole (host) to anthracene (guest) molecules.

Studies have been made on the photoconductivity of poly-*N*-vinylcarbazole (PVCz),[1-7] as regards application to electrophotography. For a better understanding of the photoconductive properties of this polymer, it is desirable to investigate the differences in photoconductive property of the polymer and the corresponding molecular crystals. *N*-Ethylcarbazole (EtCz) and *N*-isopropylcarbazole (IPCz) were chosen as suitable model compounds, each corresponding to the monomeric unit of PVCz.

The photoconductivity of IPCz was studied by Sharp who reported that the compound exhibits no extrinsic photoconduction in the lowest π-π^* absorption region in contrast to the presence of both extrinsic and intrinsic photoconduction in PVCz. In view of current aspects of the photoconductivity of anthracene, the absence of extrinsic photoconduction in IPCz seems unusual. It seems necessary to reinvestigate the photoconductive properties of molecular crystals of the model compounds.

The present paper gives the results concerning the photoconductivity of EtCz single crystal. EtCz exhibits extrinsic photoconduction in the lowest π-π^* absorption region which could be largely reduced by the presence of a small amount of anthracene.

Experimental

Commercial EtCz contains anthracene as an impurity which is very difficult to remove by the usual methods of purification.[9] EtCz of high purity could be obtained only when synthesized EtCz was used as a starting material.

In our present work we used two kinds of EtCz crystal, one obtained from commercial EtCz purified first by repeated recrystallization and finally by vacuum distillation followed by zone melting, and containing about 2×10^{-3} mol/mol anthracene, the other a zone-refined EtCz crystal prepared from synthetic carbazole, the purity of the crystal being confirmed by the fact that the fluorescence lifetimes remained constant (about 20 ns) over the whole spectral region. Single crystals were obtained in a Bridgman furnace. Pillar crystals (about 2 mm×2 mm×5 mm) cut from the ingot along the a-axis (crystallographical) were used for the DC steady-state measurements, the surfaces of both ends being painted with silver-paste (Du Pont). A 500 W-xenon light source was used together with a prism-monochromator. Monochromatic light was cast onto the crystal perpendicular to the applied electric field. The photocurrent was measured with a vibrating-reed electrometer (Takeda Riken TR-81).

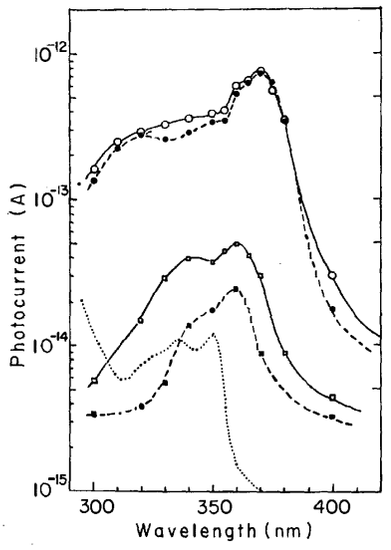

Fig. 1. The spectral dependence of the photocurrent for both pure and anthracene-containing EtCz crystals, applied field strength being 5000 V/cm.
(—○—); pure EtCz crystal in high vacuum, (--●--); pure EtCz crystal in air, (—□—); anthracene-containing EtCz crystal in high vaccum, (--■--); anthracene-containing EtCz crystal in air. The dashed line indicates the absorption spectrum of EtCz solid (KBr disk).

Results and Discussion

Figure 1 shows the spectral dependence of the photocurrent for both pure and anthracene-containing crystals of EtCz. The photocurrent was proportional to the light intensity irrespective of the exciting wavelength.

The pure EtCz crystal shows a relatively large photocurrent, nearly equal to that of PVCz. The photocurrent rises at the onset of the lowest singlet absorption, its peak being located at about 370 nm. This antibatic behaviour of the action spectrum of the photocurrent is similar to that of PVCz reported by Bauser and Klöpffer[1] and Okamoto *et al.*,[3] carriers are generated by extrinsic processes involving the interaction of singlet excitons with impurity or defects in the bulk of the crystal.

In anthracene-containing crystals, a considerable reduction of the photocurrent is observed over the whole spectral range by factor of about 10. This results is similar to the case of tetracene-doped and acridine-doped anthracene crystals.[10] The reduction of the photocurrent might be due to either the decrease of the quantum efficiency of the charge-carrier formation process or the decrease of the effective mobility of the carriers. The latter effect can be neglected for the following reasons. (1) Carrier mobility is independent of the wavelength of the incident light. In spite of

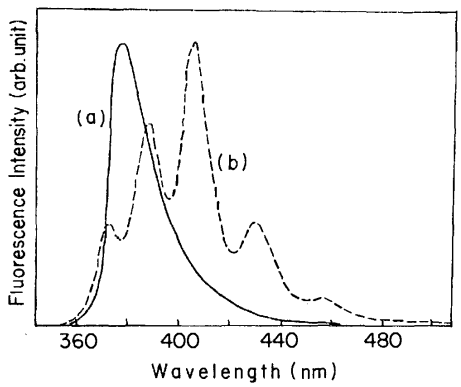

Fig. 2. The fluorescence spectra of pure and anthracene-containing crystals of EtCz at room temperature. (a); pure EtCz single crystal, (b); anthracene-containing crystal of EtCz (2×10^{-3} mol/mol).

this, the spectral dependence of the photocurrent changes in anthracene-containing crystals, the photocurrent peak showing a blue shift to 360 nm. (2) In anthracene-containing crystals, the fluorescence of EtCz is remarkably quenched and the intensive fluorescence of anthracene is observed as shown in Fig. 2. This is due to an efficient energy transfer from the lowest excited singlet state of EtCz (3.5 eV) to that of anthracene (3.3 eV). Thus it can be concluded that the reduction of the photocurrent in anthracene-containing crystals is mainly due to the decrease in the carrier-generation efficiency due to the energy transfer. The shift of the photocurrent peak to about 360 nm can be interpreted as follows. Since anthracene molecules are distributed uniformly in the crystal, anthracene molecules available as the dissipating center of the singlet-excitation energy decrease if the light is absorbed near the surface of the crystal, thus causing a blue-shift of the action spectrum of photoconductivity.

Preliminary experiments on the transient photoconductivity of EtCz single crystal with a pulsed light of the π-π^* absorption region showed that the hole photocurrent was remarkably larger than the electron photocurrent. Hence, the photocurrent measured with pillar crystals is mainly due to the hole photocurrent in the lowest π-π^* absorption region.

Thus the photoconductivity of EtCz crystal can be described as follows: The photocarrier (mainly holes) are generated by an extrinsic process involving the interaction of singlet excitons with impurity or defects in the bulk of the crystal. The small contribution of photocarrier generation on the surface of the crystal is explained by the experimental result in which the photocurrent was not affected, or only a little, by the atmosphere. If the crystal contains anthracene molecules, they act as traps of the singlet-excitation energy in EtCz crystal causing a decrease in carrier generation efficiency. Complete quenching of the photoconductivity may thus occur in the lowest π-π^* absorption region, if the crystal contains a considerable amount of impurity which quenches the excited energy of the host EtCz molecules. The result obtained by Sharp[8] showing no photoconduction in the lowest π-π^* absorption region, a sharp contrast to the present results of

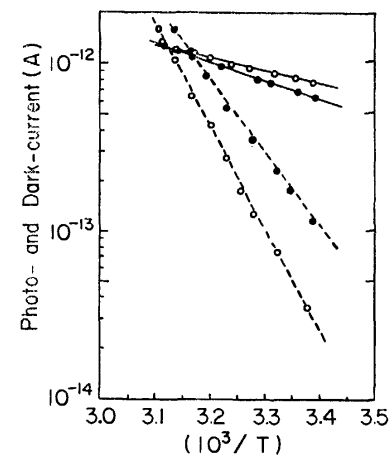

Fig. 3. The temperature dependence of the photo- and dark-currents of pure EtCz single crystal. (—○—); photocurrent in high vacuum, (—●—); photocurrent in air, (--○--); dark-current in high vacuum, (--●--); dark-current in air.

Table 1. The activation energies of EtCz crystal and PVCz film (eV)

Current	EtCz crystal		PVCz film[2]	
	photo-	dark-	photo-	dark-
In vacuum	0.06	0.5	0.1—0.3	1.0—1.3
In air	0.08	0.45	0.5—0.6	0.7—0.8

EtCz crystal, might be attributed to the presence of some impurity such as anthracene in the crystal.

Figure 3 shows the temperature dependence of the photo- and dark-currents in pure EtCz crystal. The relation $i \propto \exp(-E_a/kT)$ holds for dark- and photocurrents. The activation energies (E_a) are given in Table 1, compared with those of PVCz. The activation energies of both dark- and photo-current in EtCz crystal are smaller than those of PVCz. Since it is expected that carrier-generation process requires a very small activation energy, these differences in activation energy seem to reflect the differences of the behaviours in carrier transport between molecular crystals and polymers.

(Received March 4, 1974)

Synopsis. The ENDOR spectra of 1,3,5-triphenylverdazyl radical and its methyl derivatives were observed in toluene, and the effects of methyl substitution on the proton hyperfine coupling constants were investigated.

Verdazyls, a series of very stable neutral radicals containing four nitrogen nuclei, were previously studied by Kuhn, Neugebauer, and Trischmann.[1,2] Recent studies of the magnetic susceptibility of 1,3,5-triphenylverdazyl and its methoxy or methyl derivatives have clarified some interesting magnetic properties in these radicals,[3-5] as is explained by the one-dimensional Heisenberg model or the linear Ising model. The X-ray diffraction analyses[6,7] of the above verdazyls revealed the variety of molecular packing. The magnetic property is very sensitive to both the packing of the radical molecules in the crystal and the distribution of the unpaired electron on the radical. ESR is a frequently used method for determining the distribution of the unpaired electron on radical molecules. However, the ESR spectra of verdazyl radicals usually show only nine line splittings (a^N=6G[1]) due to the four nitrogen atoms in verdazyls.

Electron nuclear double resonance (ENDOR) spectroscopy is a valuable method for the determination of proton isotropic hyperfine couplings of organic radicals in solution, since the effective resolution is much higher than for ESR.[8] However, due to the quadrupole moment of the nitrogen atom, the observation of ENDOR spectra of the radicals which include nitrogen atoms is generally difficult compared to those of other radicals. Particularly, in the case of verdazyl radicals, four nitrogens are contained in the heterocyclic ring. Thus, we carefully selected adequate temperature, solvent, radical concentration, ESR and NMR powers, and ESR and NMR modulations.[9]

In the present paper, proton hyperfine splitting constants measured from the solution ENDOR spectra of the 1,3,5-triphenylverdazyl radical and its methyl derivatives in toluene are reported, in order to present fundamental data which are essential for a more detailed understanding of the magnetic properties of these radicals.

I	H	H	H
II	H	CH_3	H
III	CH_3	H	H
IV	CH_3	CH_3	H
V	H	H	CH_3

Experimental

Verdazyls (I—V) (see Fig. 1) were prepared by the method of Kuhn and Trischmann,[1] followed by recrystallization from an acetone–ethanol mixture. They were identified by their elementary analyses and melting points, and the values obtained were in good agreement with those presented in the literature.[1] The radical concentrations were determined by their magnetic susceptibilities in the temperature range from 77 to 300 K. The respective spin concentrations were 100% as $S=1/2$, within the limit of the experimental error.

The paramagnetic susceptibility measurements were carried out with a Shimadzu type MB-2 magnetic torsion balance, equipped with a low temperature cryostat. The ENDOR spectra were recorded by a JEOL type ES-EDX-1 spectrometer, operated with 80 Hz magnetic field modulation. About 150 watts of the continuous radio wave frequency modulated at 6.5 kHz were running inside of the cavity for NMR excitation.[10]

Results and Discussion

The ESR spectra of 1,3,5-triphenylverdazyl (I) and its methyl derivatives (II), (III), (IV), and (V) show only nine line splittings due to four nitrogens in the heterocyclic ring. We were unable to resolve splittings from the protons. The nitrogen hyperfine splittings, a^N, observed in 2-methyltetrahydrofuran (2-MeTHF)

at room temperature are listed in the first column of Table 1.

Figure 2 shows three typical ENDOR spectra of the verdazyls in toluene at temperature −70∼−80 °C. Toluene, chloroform, 2-MeTHF and *n*-heptane were used as solvents, and it was found that toluene is the most suitable solvent for the verdazyls.

The ENDOR spectrum of 1,3,5-triphenylverdazyl radical (I) (see Fig. 2(a)) clearly exhibits three different proton hyperfine splittings (1.22_2, 1.11_2, and 0.42_5 G). The orbitals containing the unpaired electron of the 1,3,5-triphenylverdazyl have, at least in the Hückel approximation, a node in 3-phenyl ring, giving a zero spin density on the phenyl ring. In the McLachlan approximation, the orbitals are spin polarized so as to yield nonvanishing spin densities in the 3-phenyl ring of the radical.[11] However, these spin densities are not large enough to account for the above proton hyperfine splittings. In fact, aryl-substituted verdazyls with selectively introduced D-, Cl-, Br-, F- and ethoxycarbonyl groups give well resolved ESR spectra[12] at room temperature, and the observed proton hyperfine splittings are explained as splittings ($a_o^H = a_p^H = 1.06$—1.09 G, $a_m^H = 0.41$—0.49 G) in equivalent 1,5-phenyl rings. On the other hand, recent NMR study[13] of 1,3,5-triphenylverdazyl in $CDCl_3$ shows paramagnetic shift lines due to all protons contained in the verdazyl radical. The hyperfine splittings are assigned for 1,5-phenyl ring protons ($a_6^H = 1.195$, $a_o^H = 1.12$ and $a_m^H = 0.425$ G), for 3-phenyl ring protons ($a_p^H = 0.31$, $a_o^H = 0.425$, and $a_m^H = 0.16$ G), and for C-6-methylene protons in the verdazyl ring ($a_6^H = 0.027$ G[14]). A comparison of the hyperfine splittings obtained in the present ENDOR study with those of ESR and NMR studies indicates that the hyperfine splittings (1.22_2 and 1.11_2 G) arise from the *para* and *ortho* protons respectively in the 1,5-phenyl rings, and 0.42_5 G from both *meta* protons in the 1,5-phenyl rings and *ortho* protons in the 3-phenyl ring. The verdazyl (III) also shows three pairs of similar hyperfine splittings.

As shown in Fig. 2(b), in addition to the above three splittings of verdazyl (I), a pair of signals with weak intensity and smaller splitting (0.30_0 G) is clearly observed for verdazyl (II), in which the *para* proton in the 3-phenyl ring is substituted by methyl group. This signal is attributed to the methyl protons. Verdazyl (IV) also shows four pairs of similar hyperfine splittings. These values are listed in Table 1. Hyperfine splittings of *ortho* and *para* ring protons remain constant within experimental error, indicating that methyl substitution does not affect the distribution of the unpaired electron. The small increase in hyperfine splitting of the *para* proton observed for verdazyls (III) and (IV) is explained as a larger Q-value for the methyl proton than for the ring α-proton.

In addition to the hyperfine splittings of 1.26_5, 1.15_4, and 0.42_2 G due to 1,3,5-phenyl ring protons, an abnormally large hyperfine splitting (0.97_6 G) was observed for verdazyl (V), in which one of C-6-methylene protons is substituted by a methyl group. C-6-Methylene protons have small hyperfine splittings of about 0.03 G,[13,14] and thus this large hyperfine splitting should be attributed to the substituted methyl γ-protons. We usually cannot expect such a large splitting for a γ-proton. However, the Stuart model shows that the methyl protons locate just above the 1- and 5-nitrogen atoms having large spin densities and should couple more strongly, because of hindered rotation of C-6-methylene group. In fact, X-ray studies have revealed such a configuration, with the shortest distance of 2.72 Å between the 1-nitrogen and the methyl protons.[15] A small change in hyperfine splittings of *ortho* and *para* proton was also observed for verdazyl (V). This arises from the variation of the distortion angle of the 1,5-phenyl rings connected to the centeral verdazyl ring by substituted methyl group.

In conclusion, as was expected, the effect of the methyl substitution on the spin distribution is fairly small. Therefore, these radicals are useful for the study of how molecular packing affects the magnetic properties of the organic radical crystalline.

The Back-extraction Behavior of Chelate Compounds. I. The Extraction and the Back-extraction of the Metal Oxinates

Takaharu HONJO, Kiyoshi AMENO, Masanobu HORIUCHI, and Toshiyasu KIBA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa 920
(Received November 15, 1973)

Synopsis. The behavior of trace amounts of silver, bismuth, cadmium, cerium, cobalt, europium, iron, mercury, indium, manganese, lead, scandium, and zinc in back-extraction have been examined in order to ascertain the basic conditions for the mutual separation of metals as their oxinates by back-extraction.

In recent years a number of investigations concerning the liquid-liquid extraction of metal oxinates have been reported and reviewed, but only a few back-extraction techniques have been treated and applied to the separation of metals.[1,2] In this investigation, the behavior of trace amounts of silver(I), bismuth(III), cadmium(II), cerium(III), cobalt(II), europium(III), iron(III), mercury(II), indium(III), manganese(II), scandium(III), and zinc(II) in back-extraction have been examined in order to ascertain the basic conditions for the mutual separation of metals as their oxinates by back-extraction. The results have then been applied to the separation of cobalt from mixtures of iron radioisotopes by means of back-extraction.

Experimental

Extraction. Extraction was carried out for a buffered solution containing a radioactive tracer; the solution was made to have 0.1 M acetic acid (in the acidic region) or 0.1 M boric acid (in the basic region), and its pH was adjusted to an appropriate value. A solution of 0.01—0.1 M oxine in chloroform (5 ml) was shaken by means of a mechanical shaker with an equal volume of an aqueous solution containing each metal for 30 min at room temperature (20—25 °C). After centrifugation, a 3 ml portion of each phase was pipetted out into a test tube, and the radioactivity was counted with the NaI(Tl) scintillation counter. The pH of the aqueous phase was measured again after extraction by means of the pH meter.

Back-extraction. A 5 ml aliquot of an organic phase which had been prepared by the standard extraction procedure was shaken with a 5 ml portion of an aqueous solution adjusted to a desired pH for 30 min at room temperature. The distribution was determined as in the case of the extraction.

Theoretical

The percentage of extraction, % E, and the percentage of back-extraction, % E_{back}, can be calculated by means of the following equations:

$$\%E = D/(1+D)\cdot 100 \quad (1)$$

$$\%E_{back} = D^*/(1+D^*)\cdot 100 \quad (2)$$

where D and D^* are the net distribution ratios of a metal in the extraction and in the back-extraction respectively.

Results and Discussion

The extraction of trace amounts of 13 metals was carried out with 0.01—0.1 M oxine in chloroform for each, while the back-extraction of the metal oxinates was done with various acidic and basic aqueous solutions.

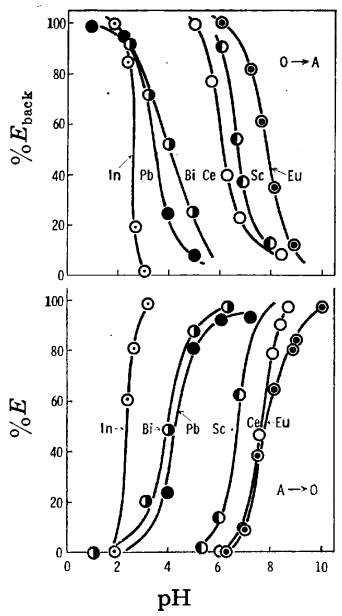

Fig. 1. The effect of pH or HCl(M) on the extraction and the back-extraction of trace amounts of Ag(I), Cd(II), Co(II), Fe(III), Hg(II), Mn(II), and Zn(II)-0.01—0.1 M oxine-chloroform system.

The results are shown in Figs. 1—2 as a function of the pH or HCl(M) of the aqueous phase. The symbols in the two figures, A→O and O→A, denote the extraction and the back-extraction of chemical species respectively.

The data on the $pH_{1/2}$ values of metal oxinates obtained in the present extraction system are summarized in Table 1. The difference in $pH_{1/2}$ gaves larger in the order of Fe(III), Sc(III), Zn(II)<Cd(II), Eu(III)<Bi(III)<In(III)<Hg(II)<Ce(III)<Ag(I)<Pb(II)<Mn(II)<Co(II). The disagreement of the $pH_{1/2}$ values appearing in the liquid-liquid extraction of the chelates indicates that the extraction equilibrium is not strictly reached under the present conditions. The fact that the extraction and the back-extraction curves of cobalt oxinate are quite different, *i.e.*, the nonequilibrium nature of the process, may be useful for the back-extraction separation of metals.

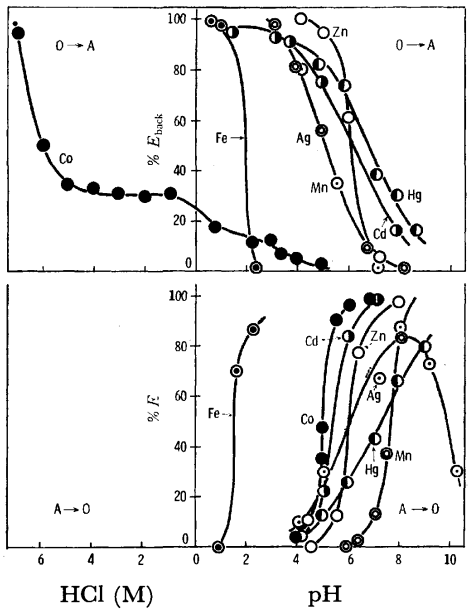

Fig. 2. The effect of pH on the extraction and the back-extraction of trace amounts of Bi(III), Ce(III), Eu-(III), In(III), Pb(II), and Sc(III)-0.01—0.1 M oxine–chloroform system.

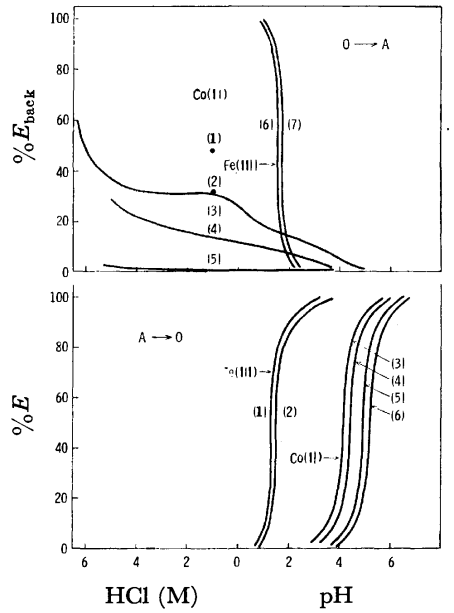

Fig. 3. The extraction and the back-extraction of Co(II) and Fe(III) with 0.01 M oxine in chloroform under various conditions.

Extraction: Co(II) (M)							
(1)	(2)	(2)	(3)	(4)	(5)	(5)	(6)
None	None	10^{-3}	Trace	Trace	Trace	10^{-3}	Trace
Fe(III) (M)							
(1)	(2)	(2)	(3)	(4)	(5)	(5)	(6)
10^{-3}	Trace	Trace	10^{-3}	10^{-4}	10^{-5}	None	None

Back-extraction:	(1)	(2)	(3)	(4)	(5)
Extraction pH	6.0	6.0	6.0	8.0	6.0
Shaking time (min)	30	5	30	30	90
Co(II) (M)	10^{-1}	Trace	Trace	Trace	Trace
Fe(III) (M)	None	None	None	None	None

	(5)	(6)	(6)	(8)
Extraction pH	6.0	3.5	3.5	3.5
Shaking time (min)	90	30	30	30
Co(II) (M)	Trace	None	10^{-3}	None
Fe(III) (M)	10^{-3}	Trace	Trace	10^{-3}

As can been seen in Fig. 3, the back-extractability of cobalt decreases as the shaking time becomes longer, and the pH values increase.

This abnormal behavior of cobalt oxinates seems to be caused by the transformation of $Co(Ox)_2$ into a certain inert complex such as $Co(Ox)_3$.[3]

The range of the extraction of cobalt shifts to a lower pH as the concentration of the coexisting iron increases; that is, the mutual separation of cobalt and iron with oxine in chloroform seems to be unattainable in the regular extraction. When a sample solution the pH of which had been adjusted to 6.0 was shaken with a 0.01 M oxine-chloroform solution for 90 min, the extraction of cobalt and iron proceeded quantitatively. Iron, however, could be stripped out of the organic phase by shaking it with an aqueous solution of a 1 M HCl solution for 30 min, while all cobalt remained in the organic phase. Thus, the data on metal oxinates in the extraction and the back-extraction may give valuable hints for finding the best conditions for the mutual separation of other metals as their oxinates by back-extraction, as has already been reported by the present authors for the Co(II)–Ni(II)–STTA–cyclohexane system.[4]

Table 1. $pH_{1/2}$ determined by the extraction and the back-extraction of metals with 0.01—0.1 M oxine in chloroform

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(7), 1801—1802 (1974)

The Standard Free Energy of the Formation of $LaFeO_3$ at 1204°C

Noboru KIMIZUKA and Takashi KATSURA*

National Institute for Researches in Inorganic Materials, Sakuramura, Niiharigun, Ibaragi 300-31

**Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received November 20, 1973)

Synopsis. The standard free energy of the formation of $LaFeO_3$ was detemined to be -68700 ± 200 cal·mol^{-1} at 1204 °C by the following reaction: 1/2 $La_2O_3(s)+Fe(s)+3/4\ O_2(g)=LaFeO_3(s)$, based on precise phase equilibria in the Fe–Fe_2O_3–La_2O_3 system.

Moruzzi and Shafer[1] have investigated phase equilibria in the La_2O_3–iron oxide system at high temperatures up to 1900 °C in air. They found two compounds in this system; one is the orthorhombic perovskite-type $LaFeO_3$, while the other is a compound, $LaFe_{12}O_{19}$, with a magnetoplumbite structure. The latter is stable at temperatures between 1380 and 1421 °C. Cassedanne and Forestier[2] have also studied the Fe_2O_3–La_2O_3 system at temperatures from 900 to 1300 °C in air, and determined the cell constants of $LaFeO_3$.

One objective of the present study is to determine the standard free energy of the formation of $LaFeO_3$ on the basis of precise phase equilibria in the Fe–Fe_2O_3–La_2O_3 system at 1204 °C by changing the oxygen partial pressure from one to $10^{-15.75}$ atm under one atmospheric total pressure.

Experimental

Since the experimental methods and apparatus used in this study are the same as those described elsewhere,[3,4] a brief description will suffice for the general procedure.

A vertical quench furnace was used for every equilibrium run under a controlled oxygen partial pressure at 1204 °C. The atmospheres of the desired oxygen partial pressures were obtained by using CO_2–H_2 mixtures. Every value of P_{O_2} was measured by means of a solid electrolyte cell composed of $(ZrO_2)_{0.85}(CaO)_{0.15}$.[5] The calculated values of P_{O_2} based on the thermochemical data[6] and the measured ones showed a very good consistence within ±0.01 in terms of $\log P_{O_2}$. The funance temperature was measured by means of a Pt-87%Pt13%Rh thermocouple calibrated against the gold point; it was kept constant within ±1 °C.

A guaranteed reagent, Fe_2O_3, metallic iron powder (99.98%), and optical-grade La_2O_3 were used as the starting materials. The mixture of Fe_2O_3/La_2O_3 or Fe/La_2O_3 was primarily calcined at 1300 °C, then it was ground finely in an agate mortar and heated again at 1300 °C for 20 hr in air. The sintered material thus obtained was put into an alumina crucible, and the weight change was followed thermogravimetrically with an automatic balance at every controlled P_{O_2} value at 1204 °C. The equilibrated specimens were quenched rapidly, as has been described before,[3,4] and the phases present were identified by an X-ray powder method.

Results and Discussion

The phase equilibria obtained in the present study are illustrated in Fig. 1. No solubility of the lanthanum

L: La_2O_3, P: $LaFeO_3$, Fe: γ-iron, W: wüstite, M: magnetite, H: hematite.
$-\log P_{O_2}(1)=13.57$, $-\log P_{O_2}(2)=11.92$, $-\log P_{O_2}(3)=9.12$
where $P_{O_2}(1)$, $P_{O_2}(2)$, and $P_{O_2}(3)$ mean the equilibrium oxygen partial pressures over the three phases L+P+Fe, P+Fe+W, and P+W+M, respectively.

ion in the hematite, wüstite, and metallic iron phases was observed within present limits of experimental error. The La_2O_3 phase was stable in reducing atmospheres below $10^{-15.75}$ atm P_{O_2} without any deviation from the stoichiometry.

A perovskite-type compound, $LaFeO_3$, was stable in the range of oxygen partial pressures from one to $10^{-13.57}$ atm P_{O_2}, at which point $LaFeO_3$ was decomposed to form metallic iron and La_2O_3. The equilibrium state may be written as follows at an oxygen partial pressure of $10^{-13.57}$ atm:

$$1/2La_2O_3(s) + Fe(s) + 3/4O_2(g) = LaFeO_3(s) \qquad (1)$$

The existence of ferric iron in the $LaFeO_3$ structure under such an extremely low oxygen partial pressure may be attributed to the stable lattice energy of the perovskite-type structure, and also to the fact that the association of the oxygen ion with the La^{3+} ion in the structure has a profound influence upon the bonding between Fe^{3+} and oxygen ions.

The lattice constants of $LaFeO_3$ equilibrated with Fe_2O_3 and with La_2O_3 are almost identical within the limits of experimental errors (see Table 1). On the basis of these X-ray data, together with the thermogravimetric results, it may be safely said that the $LaFeO_3$ phase exists only as a stoichiometric compound under the present experimental conditions.

Since the La_2O_3, metallic iron, and $LaFeO_3$ phases

Table 1. Lattice constants of $LaFeO_3$
(Space group: D_{2h}^{16}–Pbnm, distorted Perovskite structure)

are all stoichiometric at 1204 °C, the standard free energy of the formation of $LaFeO_3$ from La_2O_3, Fe, and oxygen may be directly calculated on the bais of Eq. (1) as follows:

$$\Delta G^\circ(1) = -3/4RT \ln P_{O_2}(1)$$
$$= -68700 \pm 200 \text{ cal} \cdot \text{mol}^{-1}$$

where R means the gas constant and T is the absolute temperature. The experimental error was estimated on the basis of the fluctuations of both temperature and oxygen partial pressure during the present study. In addition, as is shown in Fig. 1, the equilibrium oxygen partial pressures, $P_{O_2}(2)$ for metallic iron and wüstite, and $P_{O_2}(3)$ for wüstite and magnetite, were identical with those obtained by Darken and Gurry.[7,8]

The authors are grateful to Dr. Mitsuoki Nakahira and Mr. Jiichiro Yoshimoto, National Institute for Researches in Inorganic Materials, for their many useful discussions, and to Mr. Kenzo Kitayama, Tokyo Institute of Technology, who assisted in the present study.

The Synthesis of Methylthio- and Bis(methylthio)phenazine Derivatives

Masao TADA

The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Hirosemachi, Sendai 980

(Received October 6, 1973)

Synopsis. A number of methylthio- and bis(methylthio)phenazine derivatives have been prepared by the reactions of various halogenophenazines and their *N*-oxides with sodium methyl sulfide.

Phenazine derivatives have received much attention because of their potential biological activities.[1] In previous paper,[2-4] the syntheses of piperidino-, morpholino-, and carboxymethylthiophenazines were reported. This note will describe the preparation of methylthiophenazines. Kidani *et al.*[5] reported that 1- and 2-methylthiophenazine were prepared from 1- and 2-phenazine isothiouronium chloride respectively. Recently 1-methylthiophenazine 5-oxide was derived from *N*-acyl-2'-methylthio-2-nitrodiphenylamine by a photochemical reaction.[6] In the present work, methylthio- and bis(methylthio)phenazines were prepared by nucleophilic displacement on the corresponding halogenophenazine derivatives.

The reactions of monohalogenophenazines, their *N*-oxides, and *N,N'*-dioxides with an equimolecular quantity of sodium methyl sulfide gave the corresponding methylthiophenazine derivatives in good yields. The reactions of dihalogenophenazines, their *N*-oxides, and *N,N'*-dioxides with a two-molar quantity of the sulfide gave the corresponding bis (methylthio)phenazine derivatives. In these reactions, the *N*-oxides, and *N,N'*-dioxides underwent a partial elimination of the oxide group to form the desired methylthiophenazines and their *N*-oxides respectively. In the presence of an excess of the reagent, the replacement reaction of the halogenophenazine *N*-oxide or *N,N'*-dioxide is accompanied by the removal of the oxide group to give the methylthio compound, as was found during substitution with sodium mercaptoacetate.[4,7] The results of the deoxygenation reactions observed during the nucleophilic displacement of halogen atoms of the monohalogenophenazine *N*-oxides are summarized in Table 1. By these replacement reactions, all the isomers of methylthio- and bis(methylthio)-phenazine could be prepared from the corresponding halogenophenazine derivatives.

The results of the series of reactions show that the halogen atoms of the mono- and dihalogenophenazines are easily displaced with the methyl sulfide, in

contrast to the cases of the alcoholysis[8] and the hydrolysis,[8,9] as can be expected in view of the high nucleophilicity of the sulfide.[10] These substitutions are especially useful for the identification of the halogenophenazine derivatives.

The methylthiophenazine *N*-oxides and *N,N'*-dioxides were deoxygenated more effectively by treatment with zinc powder in acetic acid to give the methylthiophenazines, from which the sulfones were then prepared by oxidation with a limited amount of hydrogen peroxide in acetic acid. The oxidation of these compounds with an excess of hydrogen peroxide afforded the methylsulfonylphenazine *N*-oxide or *N,N'*-dioxide, which was subsequently converted into the methylsulfonylphenazine by reduction with zinc powder in acetic acid.

The syntheses and properties of the methylthio- and bis(methylthio)phenazine derivatives thus obtained are listed in Table 2.

Experimental

All the melting points are uncorrected.

Starting Materials. The following compounds were prepared by the methods given in the literature: phenazine (1-chloro-,[8] 1-chloro-6-methoxy-,[11] 2-bromo-,[12] 2-chloro-,[8] 2-chloro-7-methoxy-,[13] 2-chloro-9-methoxy-,[11] 2-chloro-9-methyl-,[14] 1,2-dichloro-,[15] 1,3-dichloro-,[15] 1,4-dichloro-,[15] 1,6-dichloro-,[16] 1,8-dichloro-,[17] 1,9-dichloro-,[17] 2,3-dichloro-,[15] 2,7-dibromo-,[18] 2,7-dichloro-,[9] and 2,8-dichloro-[15]), phenazine 5-oxide (1-chloro-,[8] 2-bromo-,[12] 2-chloro-,[8] 2-chloro-7-methoxy,[8] 3-bromo-,[12] 3-chloro-,[8] 1,2-dichloro-,[15] 1,3-dichloro-,[15] 1,7-dichloro-,[17] 1,8-dichloro-,[17] 1,9-dichloro-,[17] 2,3-dichloro-,[17] 2,7-dibromo-,[18] 2,7-dichloro-,[8] and 2,8-dichloro-[15]), and phenazine 5,10-dioxide (2-bromo-,[19] 2-chloro-,[9] 2-chloro-7-methoxy-,[19] 2,3-dichloro-,[17] 2,7-dichloro-,[8,9] and 2,8-dichloro-[17]).

Syntheses of Methylthio- and Bis(methylthio)phenazine Derivatives. These compounds were prepared by the six general methods (A, B, C, D, E, and F). The mthods, the reaction times, the yields, and the melting points, for each compound are summarized in Table 2. All the products had satisfactory elemental analyses (C, H, and N).

Method A. To a hot solution of the halogenophenazine derivative (10 mmol) in ethanol (80—500 ml), a 20% aqueous solution of sodium methyl sulfide (50 mmol) was added. After refluxing, the hot mixture was diluted with water. The crystals thereby separated were chromatographed over alumina, using benzene as the solvent, and then recrystallized from an appropriate solvent.

Method B. This method is the same as Method A except that the theoretical quantity of the sulfide is used.

Method C. This method is the same as those above except that a ten molar quantity of the sulfide is used.

Method D. A solution of methylthiophenazine (5 mmol) in a 30% aqueous solution (2 ml) of hydrogen peroxide and acetic acid (50 ml) was warmed at 55 °C and then poured into water. To the aqueous solution, sodium bicarbonate (15 g) was added. The crystals thus separated were recrystallized from an appropriate solvent.

Method E. To a solution of methylthio- or methylsulfonylphenazine (5 mmol) in acetic acid (100—200 ml) and acetic anhydride (10 ml), a 30% aqueous solution (20 ml) of hydrogen peroxide was added. The mixture was warmed at 55 °C and then poured into water (1—1.5 l). The crystals thus separated were recrystallized from an appropriate solvent.

Method F. Into a solution of the pheanzine *N*-oxide (2 mmol) in acetic acid (20—50 ml), zinc powder (1—1.5 g) was stirred in small portions. The mixture was then heated on a water bath and filtered while hot. After the ordinary treatment, the recrystallization of the product from an appropriate solvent afforded the phenazine.

The author wishes to express his gratitude to Miss Mieko Sasaki for her assistance in these experiments.

The Reaction of Dicarboximides with Benzonitrile in Liquid Ammonia

Choji KASHIMA, Makoto YAMAMOTO,* Susumu KOBAYASHI, and Noboru SUGIYAMA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received November 10, 1973)

Synopsis. Acyclic dicarboximides were treated with benzonitrile in the presence of sodium amide to give 4-hydroxypyrimidines. However, the reaction of succinimide with benzonitrile gave 5-hydroxy-2-phenyl-2-pyrroline-3-carboxamide. Also, glutarimide gave a similar product.

In a previous paper[1] we reported that β-diketone condensed with benzonitrile (**1**) to give 4(1*H*)-pyridone directly. In this reaction it was assumed that an intermediately-formed imino-β-diketone was dehydrocyclized to 4(1*H*)-pyridone. A similar reaction has been shown in the reaction of **1** with ethyl acetoacetate.[2]

Diacetimide (**2**), *N*-acetylbenzamide (**3**), ethyl *N*-acetylcarbamate (**4**), succinimide (**5**) and glutarimide (**6**) all have the same $-CH_2CONHCO-$group. Since this group is expected to behave in liquid ammonia much like the $-CH_2COCH_2CO-$group, these compounds were subjected to a reaction with **1** in the presence of alkali amide in liquid ammonia.

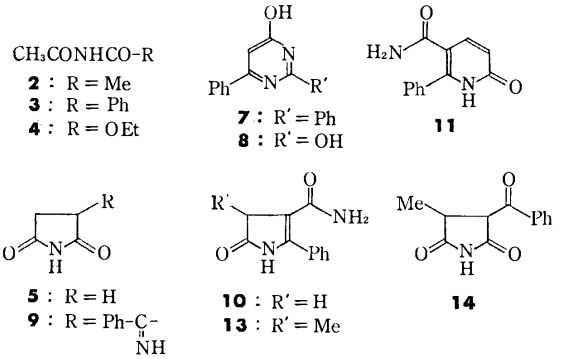

Fig. 1.

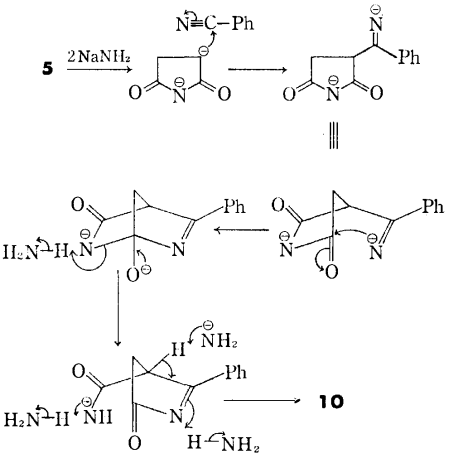
Compound **2** did not react with **1** in the presence of sodium amide in liquid ammonia. However, **3** reacted with an equimolar **1** in the presence of three molar equivalents of sodium amide to give 4-hydroxy-2,6-diphenylpyrimidine (**7**). The structure of **7** was verified by comparing the spectral data of **7** with those described in the literature.[3] Compound **7** was also identified with the product which was obtained by the reaction of ethyl benzoylacetate with benzamidine hydrochloride. Ethyl *N*-acetylcarbamate (**4**) also reacted with **1** in the presence of three molar equivalents of potassium amide in liquid ammonia to give 10.8% of 2,4-dihydroxy-6-phenylpyrimidine (**8**). The structure of **8** was identified by mean of a comparison with an authentic sample[4] and was also supported by the infrared spectrum.

Compound **5** was allowed to react with equimolar **1** in the presence of three molar equivalents of sodium amide in liquid ammonia. However, instead of the expected product, *i.e.*, 3-benzimidoylsuccinimide (**9**),[5] colorless needles were obtained in a 58.2% yield. The infrared spectrum of this compound showed three amide bands, at 3450, 3320, and 3300 cm^{-1}, and two carbonyl bands, at 1730 and 1675 cm^{-1}. The NMR spectrum was assignable for the signals at δ 3.33 and 7.40 ppm for the methylene and aromatic protons; moreover, the amino protons were observed at δ 8.13 and 11.98 ppm, but they disappeared with the use of deuterium oxide. From these spectral data and the elemental analysis, the structure of this compound was proved to be 5-oxo-2-phenyl-2-pyrroline-3-carboxamide (**10**). When glutarimide (**6**) and **1** were treated under conditions similar to those described above, 3,4-dihydroxy-6-phenyl-2(1*H*)-pyridone-5-carboxamide (**11**) was obtained in a 35% yield. The structure of **11** was proved by the spectral data and the elemental analysis. Although this type of synthesis is known in the literature,[6] our synthetic method is still simpler and more useful.

In order to investigate the change in the reactivity of succinimide with a substituent at the 2-position, the reaction of 2-methylsuccinimide (**12**) with **1** was carried out. However, instead of the expected pyrrolinecarboxamide (**13**), 3-benzoyl-2-methylsuccinimide (**14**) was obtained in a 22% yield.



Scheme 1.

The formation mechanism of **10** from **5** and **1** was speculated as follows: Imide **5** reacted with **1** to give **9**, followed by recyclization to **10**, as is illustrated in Scheme 1. On the reaction of **12** and **1**, we supposed that the benzimidoyl intermediate was also formed first and was then hydrolyzed to **14**, because of some steric

* Present Address: Department of Chemistry, Saga University, Saga-shi 840.

hindrance and inductive effect of the methyl group at the cyclization stage.

Experimental

4-Hydroxy-2,6-diphenylpyrimidine (7). *Method A*: To a solution of 0.15 mol of sodium amide in about 300 ml of liquid ammonia in a three-necked flask, we added 0.05 mol (8.15 g) of **3**. After 1 hr's stirring, 0.05 mol (5.2 g) of **1** in 30 ml of anhydrous ether was added. The mixture was then stirred for an additional 3 hr at −33 °C and then neutralized with 8.1 g of solid ammonium chloride. The liquid ammonia was driven off rapidly, and 100 ml of dilute hydrochloric acid was added. The white precipitates thus obtained were collected, washed with ether, and recrystallized from hot pyridine to give 2.80 g (22.6%) of **7** as colorless needles; mp 284—286 °C (lit, 289—290 °C[5]).

Method B: Compound **7** was also prepared by the following method. To a solution of 0.2 mol of sodium amide in 300 ml of liquid ammonia, we added 0.05 mol (8.0 g) of benzamidine hydrochloride dihydrate.[7] After 1 hr's stirring, 0.05 mol (9.6 g) of ethyl benzoylacetate in 30 ml of anhydrous ether was added, drop by drop. The mixture was then stirred for an additional 3.5 hr at −33 °C and subsequently treated as above.

2,4-Dihydroxy-6-phenylpyrimidine (8). According to Method A, **8** was synthesized from 0.15 mol of potassium amide, 0.05 mol (6.6 g) of **4** and 0.05 mol (5.2 g) of **1**. Yield, 1.02 g (10.8%); yellowish white prisms (from hot water); mp 269—271 °C (lit, 270 °C[6]).

Reaction of **2** *with* **1**. According to Method A, 0.05 mol of **2**, 0.05 mol of **1**, and 0.15 mol of sodium amide were treated in liquid ammonia. No pyrimidine compound could be detected.

5-Oxo-2-phenyl-2-pyrroline-3-carboxamide (10). According to Method A, 0.15 mol of sodium amide, 0.05 mol (4.95 g) of **5**,[8] and 0.05 mol of **1** were treated in liquid ammonia. After neutralization with 8.1 g of solid ammonium chloride, the liquid ammonia was completely evaporated. Then 400 ml of ethanol was added to the residue, and the insoluble substance was dissolved in 100 ml of pyridine. The ethanol solution was then concentrated to about 50 ml under reduced pressure to yield 2.98 g of a white precipitate after standing overnight. The pyridine solution was evaporated to dryness under reduced pressure to give 2.90 g of a white substance. The combined precipitate (5.88 g, 58%) was again recrystallized from ethanol to give pure **10** as colorless needles; mp 197—197.5 °C. Found: C, 65.36; H, 5.16; N, 13.76%. Calcd for $C_{11}H_{10}N_2O_2$: C, 65.33; H, 4.98; N, 13.86%. UV: λ_{max}^{EtOH} 230 (ε 5100) and 314 nm (14700).

3,4-Dihydro-6-phenyl-2(1H)-pyridone-5-carboxamide (11). According to Method A, **11** was prepared from 0.15 mol of sodium amide, 0.05 mol of **1**, and 0.05 mol (5.65 g) of **6**.[9] After the evaporation of the liquid ammonia, we added 300 ml of hot pyridine to the residue; after filtration, the filtrate was concentrated to dryness, and to this residue we added a benzene–ethanol mixture. The resulting insoluble substance (2.75 g) was filtered, and the filtrate was concentrated. The residue was chromatographed on a silica gel (Merck 7734, 0.05—0.2 mm) column using a benzene–ethyl acetate (1: 1 v/v) mixture. The fraction which showed an R_f value of 0.56 on silica gel (Wakogel B-5) thin layer chromatography (tlc) with the benzene–ethyl acetate (1: 1 v/v) mixture was collected and concentrated to give a white solid (1.03 g), which was proved to be the same compound as the above insoluble substance by the results of tlc and by the spectral data. The combined product (3.78 g, 35.0%) was recrystallized from hot pyridine to give pure **11** as colorless crystals; mp 231—232 °C. Found: C, 66.42; H, 5.66; N, 13.19%. Calcd for $C_{12}H_{12}N_2O_2$: C, 66.65; H, 5.59; N, 12.96%. IR (KBr): 3410, 3220, 3130, 1700, 1650, 1635, 1615, and 695 cm^{-1}. UV: λ_{max}^{EtOH} 225 (ε 10600) and 281 nm (8030). NMR: $\delta^{pyridine-d_5}$ 2.80 (m, 4H), 7.05 (broad s, 2H), 7.40 (m, 5H), and 10.90 ppm (broad s, 1H).

3-Benzoyl-2-methylsuccinimide (14). According to Method A, **14** was obtained from 0.15 mol of sodium amide, 0.05 mol of **1**, and 0.05 mol of **12**. After the evaporation of the liquid ammonia, to the residue we added 200 ml of dilute hydrochloric acid and the resulting white precipitate (**14**) was collected. The filtrate was extracted with two 200 ml portions of ether. The ether extracts were combined and washed with water and dried over anhydrous sodium sulfate. After evaporating the solvent, we added an *n*-hexane–benzene (1: 1 v/v) mixture to the viscous product. The resulting precipitate was recrystallized from benzene to give 2.40 g (22.1%) of **14** as colorless leaflets; mp 147—149 °C. Found: C, 66.26; H, 5.08; N, 6.56%. Calcd for $C_{12}H_{11}NO_3$: C, 66.35; H, 5.10; N, 6.45%. IR (KBr): 3075, 3200, 1780, 1710, 1670, and 700 cm^{-1}. UV: λ_{max}^{EtOH} 250 (ε 13100) and 287 nm (2420). NMR: $\delta^{acetone-d_6}$ 1.77 (d, 3H), 3.22—3.68 (oct, 1H), 4.87 (d, 1H), 7.31—7.81 (m, 3H), 8.04—8.22 (m, 2H) and 10.15 ppm (broad s, 1H, disappeared by D_2O).

A Platinum Complex Bound to Iodinated Polystyrene by a Platinum-Carbon σ-Bond

Noboru KAWATA, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received December 28, 1973)

Synopsis. A platinum complex bound to iodinated polystyrene was prepared by the reaction of $Pt(P\phi_3)_4$ with iodinated polystyrene. The reaction of the synthesis was confirmed by means of direct oxidative addition of aryl iodide to $Pt(P\phi_3)_4$.

Recently much attention has been paid to the immobilizing of a soluble organotransition metal complex catalyst by fixing it on a polymer, not only from a practical point of view, but also for examining the effect of polymer ligand on the catalytic activity and selectivity. Polystyrene containing phosphorus, nitrogen or cyclopentadiene has been widely used to immobilize transition metal complexes such as $RhCl(CO)(P\phi_3)_2$ ($\phi=C_6H_5$)[1-3] and $TiCp_2Cl_2$ ($Cp=C_5H_5$)[4] through the coordination bond of metal-phosphine, metal-nitrogen or metal-cyclopentadiene.

In the preceding paper,[5] it was reported that treatment of a halogenated polystyrene with tetrakis(triphenylphosphine) nickel (0) or palladium(0) gave an insoluble nickel(II) or palladium(II) complex combined to polystyrene by metal-carbon σ-bond as follows:

$$\}\text{-}C_6H_4X + M(P\phi_3)_4 \longrightarrow \}\text{-}C_6H_4\text{-}\underset{\displaystyle P\phi_3}{\overset{\displaystyle P\phi_3}{M}}\text{-}X + 2P\phi_3$$

(M=Ni or Pd, X=Br or I)

This method of immobilizing metal complexes was extended to the reaction of tetrakis(triphenylphosphine)-platinum(0) (denoted by [I]) with iodinated polystyrene. An insoluble polystyrene containing platinum complex was obtained. The present paper reports on the oxidative addition of iodinated polystyrene to complex [I].

Platinum Complex Supported on Iodinated Polystyrene. To a benzene solution (150 ml) of iodinated polystyrene (3.0 g, average P.D. 1100, 96.4% iodination on *para*-position) prepared according to the method given in the literature[6] was added another benzene solution (100 ml) of [I] (5 g) under nitrogen atmosphere. The mixture was warmed up to 70—80 °C and kept for 5—6 hr with stirring, during which a precipitate was obtained. The precipitate was washed three times with benzene and twice with *n*-hexane, and then dried under vacuum. Pale yellow powder (3.6 g), insoluble in common solvents and stable in the air at ambient temperature, was obtained. The amount of platinum supported on iodinated polystyrene could be estimated to be about 4 atoms per ten phenyl rings by assuming that platinum was bound to the polymer as $\}\text{-}C_6H_4\text{-}Pt(P\phi_3)_2I$. ^{31}P-FT-NMR[7] of the platinum-polystyrene complex suspended in methylene dichloride showed a fairly sharp absorption (26.7 ppm, $J_{Pt-P}=3066$ Hz) in a low field in reference to free triphenylphosphine. This indicates that the platinum-polystyrene complex has *trans*-square planar structure, since only one absorption and one large coupling constant of J_{Pt-P} were observed. It is to be noted that the local magnetic field around the platinum atom is well averaged out in the solvent, since NMR absorptions of solid materials are usually too broad to be detected due to local magnetic fields.

In order to clarify the synthesis reaction and to characterize the platinum-polystyrene complex, a direct oxidative addition of aryl iodide to complex [I] was attempted. The known method of preparing *trans*-bis(triphenylphosphine)σ-phenyl(halo) platinum(II) complexes is to utilize the thermal desulfurylation of $C_6H_5SO_2Pt(P\phi_3)_2X$,[8] which can be prepared from the oxidative addition of $C_6H_5SO_2X$ to complex [I]. The direct oxidative addition of phenyl halide to [I] has not been reported. This seems to be a difficult reaction, although $Pt(PEt_3)_4$ ($Et=C_2H_5$), which is regarded to have a more nucleophilic nature, is subjected to the oxidative addition of phenyl halide.[9] It was found, however, that σ-aryl platinum(II) complexes are readily synthesized only by warming the mixture of [I] and aryl iodide in benzene.

Oxidative Addition of Aryl Iodide to Complex [I]. A commercial iodobenzene (36 mmol) was added to a

benzene solution of [I] (4.5 g, 3.6 mmol) under nitrogen atmosphere. The solution was kept at 50—60 °C for 2—3 hr with stirring, during which a white crystal was deposited. The solution was decanted. The crystal was dissolved in hot benzene (200 ml), recrystallized by adding *n*-hexane, well washed with *n*-hexane, and then dried under vacuum. The same method was applied to *p*-tolyl, *p*-nitrophenyl, and *p*-bromophenyl iodide. There was practically no difference in the reactivity of these aryl iodides. No complex was obtained by the treatment with aryl bromide even at a higher temperature (80 °C), most of [I] being decomposed to metallic platinum. The results are summarized in Table 1. ^{31}P-FT-NMR of the complexes also shows that they all have the same *trans*-square planar structure as the platinum-polymer complex.

The authors wish to thank Mr. Y. Nakamura for his help in the NMR measurement.

Dissociation Constants of 2-Aminotropones

Kimiaki IMAFUKU, Yasuyoshi TAKATA,* and Hisashi MATSUMURA
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860
(Received January 10, 1974)

Synopsis. The dissociation constants of 2-aminotropones were measured in 50% aqueous methanol at 20 °C and shown to be correlated by the Hammett equation with $\rho=3.40$. The difference between 4- and 6-substituents is discussed.

The dissociation constants of tropolone derivatives with a seven-membered ring structure have been reported[1] to be linearly correlated with Hammett's substituent constants. Furthermore, we have ourselves discussed[2] the Hammett relationships in the tropolone derivatives on the basis of a simple HMO method.

On the other hand, no systematic study of the dissociation of 2-aminotropones has been reported, although a few dissociation constants are known.[3]

This communication will deal with the measurements of the dissociation constants of 2-aminotropone derivatives (Fig. 1) and with their analysis by means of the Hammett relationships.

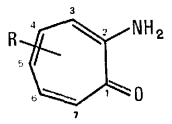

Fig. 1. 2-Aminotropones.

Results and Discussion

Dissociation Constants. The dissociation constants of 4-, 5-, and 6-substituted 2-aminotropones were determined spectrophotometrically in 50% aqueous methanol at 20 °C. The results expressed in terms of pK_a values are listed in Table 1, together with the Hammett substituent constants.[4]

TABLE 1. DISSOCIATION CONSTANTS OF 2-AMINOTROPONES

No.[a]	R	σ	pK_a
1	5-CH_3	−0.170	2.63
2	4-CH_3	−0.069	2.52
3	6-CH_3	−0.059[b]	2.36
4	6-CH=CH-Ph	−0.041[b]	2.30
5	H	0	2.16
6	4-CH=CH-Ph	0.025[c]	2.11
7	5-Cl	0.227	1.34

a) Numbering of substituents refers to that given in Fig. 2. b) Results in this work. c) Value in Ref. 8.

The 2-aminotropones show pK_a values between 2.63 (5-methyl) and 1.34 (5-chloro) and are less basic than the aniline derivatives. The pK_a values for the corresponding aniline derivatives are from 5.10 (*p*-methyl) to 3.98 (*p*-chloro).[5] This difference may be attributed to the electron-withdrawing effect of the carbonyl group adjacent to the amino group in the tropone ring.

The pK_a values for 2-amino-5-nitrotropone could not be measured, since the nitro group is a strong electron-attracting group ($\sigma_p=0.778$) and so reduced the basicity to $pK_a<1$.

Substituent Effects. When the pK_a values of 2-aminotropones are plotted against the substituent constants, the plot gives the straight line shown in Fig. 2. Here, the substituent constants, the σ_m and σ_p values, are respectively applied to the 4- and 5-positions in the tropone nucleus in the same manner as those of the tropolones.[1,2] The following equation was obtained by the least-squares method:

$$pK_a = 2.16-3.40\sigma \quad (r=0.982) \qquad (1)$$

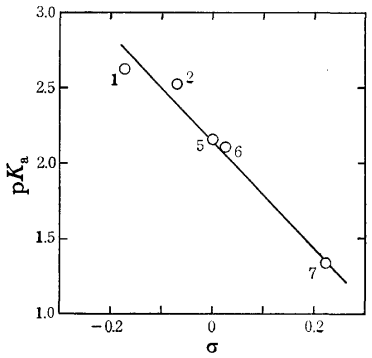

Fig. 2. The Hammett plot of pK_a.

It is of some interest to compare the ρ value obtained in the present work with those of tropolones, phenols, and anilines. The ρ value (3.40) for 2-aminotropones is comparable to that ($\rho=3.44$ in 30% ethanol at 25 °C) for anilines.[6] It has also been shown that the ρ value for tropolones ($\rho=2.68$ in water at 25 °C)[1] is comparable to that of phenols ($\rho=2.55$ in 48.9% ethanol at 20—22 °C).[7] The ratios of amino-substituted compounds to hydroxy-substituted compounds are 1.27 for troponoids and 1.35 for benzenoids. These ratios are almost equal.

4- and 6-Substituents. 4-Substituted tropolones show only one pK_a value, though they can exist in two non-equivalent tautomeric forms—as 4- and 6-substituted 2-hydroxytropones. On the other hand, 4- and 6-substituted 2-aminotropones were both obtained as pure materials, and the σ values for the 6-substituents could be estimated by using 6-substituted isomers.

The substituent constants for the 6-methyl and 6-styryl groups were estimated to be −0.059 and −0.041 respectively by using Eq. (1). The substituents in the 4- and 6-positions cannot conjugate with the

* Present address: Dainichi-seika Color & Chemicals Mfg. Co., Ltd., Iwata-shi, Shizuoka 438.

amino group; their effect is mainly due to the inductive effect.

As regards the methyl groups, the σ_6 value (−0.059) is larger than the $\sigma_4(\equiv\sigma_m)$ value (−0.069).[4] The electron-donating effect of the 6-methyl group decreases in comparison with that of the 4-methyl group. This may be attributed to the difference in distance between the methyl group and the amino group.

The 4-styryl group (σ_m=0.025)[8] decreased the basicity of 2-aminotropone by its inductive electron-attracting effect, while 6-styryl group enhanced the basicity to pK_a=2.30. The pK_a value gave σ_6=−0.041 for the 6-styryl group in the same manner as for the 6-methyl group. The resonance of the 6-styryl group with a carbonyl adjacent to the amino group enriches the electron density of the oxygen atom. Consequently, the hydrogen bonding of hydrogen in the amino group with the carbonyl oxygen atom is enhanced and the dissociation of the ammonium ion becomes difficult. This is consistent with the difference in $\nu_{C=O}$ values of the two series of 4- and 6-styryl-2-aminotropones.[9]

Experimental

Materials. The 2-aminotropones used for the measurements of the dissociation constants were prepared by the methods described in the references.

Their melting pointed are as follows: 2-Aminotropone, mp 107—108 °C (ref.[10,11] 106—107 °C); 4-methyl-2-aminotropone, mp 124.5—125.5 °C (ref.[12,13] 122—123 °C); 5-methyl-2-aminotropone, mp 109—111.5 °C (ref.[12] 105—107 °C); 6-methyl-2-aminotropone, mp 113.5—114.5 °C (ref.[12,14] 111—112 °C); 5-chloro-2-aminotropone, mp 160.5—161.5 °C (ref.[15] 157 °C); 4-styryl-2-aminotropone, mp 194—195 °C (ref.[16] 194.5—195 °C); 6-styryl-2-aminotropone, mp 137—138 °C (ref.[16,17] 137—138 °C).

Measurements of the Dissociation Constants. The dissociation constants of 2-aminotropones were measured spectrophotometrically in 50% aqueous methanol at 20 °C by the method of Albert and Serjeant.[18]

The absorption spectra were taken on a Hitachi EPS-3T spectrophotometer, while the pH values were measured by means of a Hitachi-Horiba pH meter.

The authors wish to thank Professor Tetsuo Nozoe and Sankyo Co. Ltd. for supply of tropolone.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(7), 1811—1812 (1974)

Base Catalyzed Oxygenation of 3,5-Di-*t*-butylpyrocatechol and Its Related Compounds

Akira NISHINAGA, Toshio ITAHARA, and Teruo MATSUURA

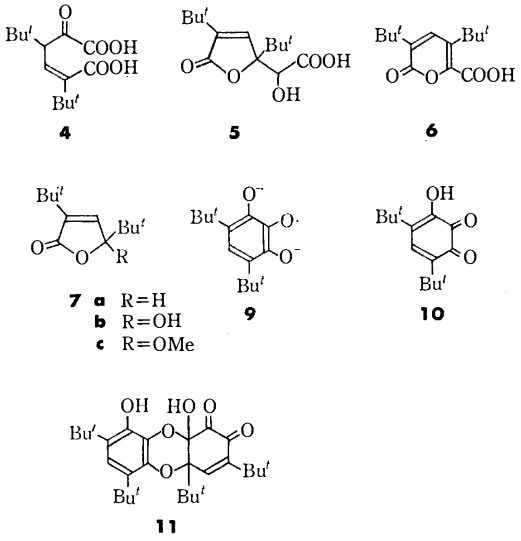
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received Junuary 14, 1974)

Synopsis. The oxygenation of 3,5-di-*t*-butylcatechol (**1**) and its related compounds 3,5-di-*t*-butyl-*o*-benzoquinone (**2**), 4,6-di-*t*-butylpyrogallol (**3**), 2,4-di-*t*-butyl-5-oxo-2-hexenedioic acid (**4**), 2,4-di-*t*-butyl-4-(carboxyhydroxymethyl)-2-buten-4-olide (**5**), and 3,5-di-*t*-butyl-6-carboxy-2-pyrone (**6**) in DMF–Bu^{t}OK gave 2,4-di-*t*-butyl-4-hydroxy-2-buten-4-olide (**7b**). A possible mechanism and the relation between **4**, **5**, and **6**, the products in aqueous alkaline autoxidation of **1** and **3**, are discussed.

As a part of studies on model catalytic oxygenation for enzyme reactions, the base catalyzed oxygenation of 3,5-di-*t*-butylcatechol (**1**) and its related compounds has been investigated. The autoxidation of **1** in aqueous and methanolic NaOH solutions is known to give 2,4-di-*t*-butyl-5-oxo-2-hexenedioic acid (**4**) and 2,4-di-*t*-butyl-4-(carboxyhydroxymethyl)-2-buten-4-olide (**5**), respectively.[1,2] Compound **5** has also been obtained in the oxidation of 3,5-di-*t*-butyl-*o*-benzoqunone (**2**) with H_2O_2[2]. Campbell *et al.*[3] isolated **4** and 3,5-di-*t*-butyl-6-carboxy-2-pyrone (**6**) in the alkaline autoxidation of 4,6-di-*t*-butylpyrogallol (**3**). However, there has been no attempt to elucidate the relationship among these products sporadically obtained under different conditions.

We have found that the oxygenation of **1** in a DMF–Bu^{t}OK system newly gives 2,4-di-*t*-butyl-4-hydroxy-2-buten-4-olide (**7b**), and have made an attempt to correlate the products. When **1** was dissolved in DMF containing Bu^{t}OK under air, the solution assumed an intense blue color due to the formation of 3,5-di-*t*-butyl-*o*-benzosemiquinone (**8**) which was detected by ESR. The solution gradually turned brown with decay of the ESR signal. From the reaction mixture **7b**, the same product as that obtained in the photooxygenation of **3** in DMF–Bu^{t}OK showed the ESR spectrum of 4,6-di-*t*-butylpyrogallol anion radical (**9**), which rapidly disappeared by O_2 bubbling. The fact that **7b** was obtained in the oxygenation of **4**, **5**, and **6** in high yield suggests that they are correlated with each other to give an intermediary species in the oxygenation of **1**. Thus, the mechanistic pathway of the following scheme is suggested.



In aqueous alkaline oxygenation of **1** or **3**, one of **4**, **5**, or **6** is isolated depending on the conditions, while compounds **4**, **5**, and **6** are deprotonated to anion 2,4-di-*t*-butyl-5-oxo-2-hexen-4-idodioate (**13**) which would undergo further oxygenation to give **7b** in the DMF–Bu^{t}OK system. Hence, the poor yield of **7b** from **1** and **3** should be due to that of **13**.

As **5** is also obtained in high yield by the oxidation of 4,6-di-*t*-butylresorcinol[4] was isolated. The structure of **7b** was confirmed by the fact that its acid catalyzed methanolysis gave 2,4-di-*t*-butyl-4-methoxy-2-buten-4-olide (**7c**), and also by examination of its spectral data (Table 1) and elemental analyses. Compound **7b** was also obtained in the oxygenation of **1** in MeOH containing MeONa (yield, 41%), and in that of **2**, **3**, **4**, **5**, and **6** in DMF–Bu^{t}OK. The results are summarized in Table 2. The air saturated solu-

of **2** with H_2O_2[2], it is quite reasonable to assume the transient formation of 3,5-di-*t*-butyl-6-oxido-*o*-benzoquinone (**12**) just before **13** in the scheme, although 3,5-di-*t*-butyl-6-hydroxy-*o*-benzoquinone (**10**), protonated compound of **12**, has not been synthesized so far. The oxidation of **3** with *p*-benzoquinone,[5] Ag_2O,[6] and KIO_3[7] all gave a dimer, whose structure is believed to be **11**,[7] but not **10**. The dimer, upon dissolving in DMF–Bu^{t}OK, also gave **9**, and then **7b** by bubbling of O_2. It is obscure whether the formation of **13** is caused by the oxidation of quinones **2** and **12** with H_2O_2 formed during the course of reaction or by the coupling of semiquinones **8** and **9** with O_2 or O_2^- in the oxygenation.

Experimental

Oxygenation of 1 in DMF–Bu^{t}OK. A solution of **1** (0.54 g), prepared according to the method of Schulze and Flaig,[1] in DMF (15 ml) containing Bu^{t}OK (1 g) was bubbled with O_2 at room temperature for 19 hr. The resulting light brown reaction mixture was extracted with ether. The extract was washed with water, dried (Na_2SO_4), and evaporated. The silica gel tlc separation of the residue developed with a mixture of benzene–ether (3: 1 v/v) gave **7b**; colorless prisms; recrystallized from isooctane; mp 101.5—102 °C; yield, 0.18 g.

Found: C, 67.59; H, 9.45%. Calcd for $C_{12}H_{20}O_4$: C, 67.89; H, 9.50%.

Acid Catalyzed Methanolysis of 7b. A solution of **7b** (0.072 g) in MeOH (10 ml) containing a small amount of concd. H_2SO_4 was allowed to stand at room temperature for one week. The mixture was diluted with water and extracted with ether. The extract was washed (water), dried (Na_2SO_4), evaporated, and chromatographed on a silica gel column. The elution with a benzene–ether (5: 1 v/v) mixture gave **7c**; mp 60.5—61.5 °C; recrystallized from light petroleum; yield, 0.046 g (59%).

Found: C, 68.73; H, 9.75%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%.

Oxygenation of 2, 3, 4, 5, 6, and 11 in DMF–Bu^{t}OK. Compounds **3**, **4**, **5**, **6**, and **11** were prepared according to the method of Schulze and Flaig,[1] Grinstead,[2] Campbell,[4] and Critchlow *et al.*,[7] respectively. The compounds were oxygenated and worked up as described above to give **7b**. The results are summarised in Table 2.

Decomposition of 1,4-Dimethoxybenzene Radical Cations in CH_3NO_2–$AlCl_3$ System[1)]

Akira NISHINAGA, Hidetoshi HAYASHI, and Teruo MATSUURA

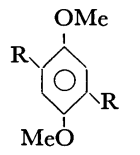
Department of Synthetic Chemistry, Faculty of Engneering, Kyoto University, Kyoto 606

(Received February 4, 1974)

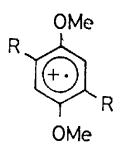
Synopsis. The decomposition of 1,4-dimethoxybenzene cation (**2a**) and 1,4-dimethoxy-2,5-dimethylbenzene cation (**2b**) gave 2,2′,5,5′-tetramethoxydiphenyl and 2,5-dimethyl-*p*-benzoquinone indicating that the reaction pathway depends on substituent at nucleus of the radical cations **2**.

In a previous work,[1)] we reported that 1,4-dialkoxybenzenes are rapidly oxidized in various nitro compounds in the presence of $AlCl_3$ quantitatively to form fairly stable corresponding radical cations.[1,2)] In the CH_3NO_2–$AlCl_3$ system, however, they slowly decompose on being left to stand at room temperature. The initial step of oxidation of alkoxybenzenes has been considered to be radical cation formation,[3-5)] but the reaction of actual alkoxybenzene radical cations is little known. The chemical reactions of several stable radical cations, such as those from perylene,[6)] thianthrene,[7)] and aromatic amines[8)] have been reported. The present paper reports on the decomposition of 1,4-dimethoxybenzene radical cations in the CH_3NO_2–$AlCl_3$ system predominantly giving a dimerized product or quinoid compound depending on the substituent at nucleus of the radical cations.

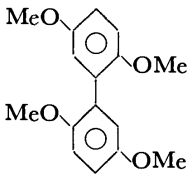
When solutions of radical cations **2** quantitatively generated by dissolving **1** in CH_3NO_2–$AlCl_3$ sytsem were allowed to stand at room temperature, the radical cations slowly deteriorated with fading of the initial deep green color of **2**. **1a** (34%) and dimer **3** (39%) were isolated from decomposition products of **2a** and **1b** (45%), **4** (14%), and small amounts of **5** from those



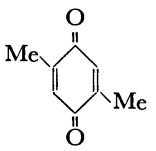
1a : R=H
b : R=Me



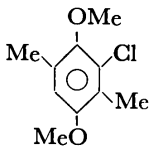
2a : R=H
b : R=Me



3



4

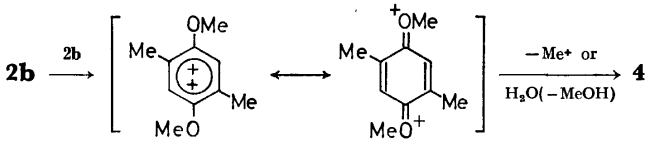


5

of **2b**. The products except for the starting materials (**1**) were not obtained from the solution of **1** in CH_3CN–$AlCl_3$, CH_2Cl_2–$AlCl_3$, or CH_3NO_2 alone where no **2** is formed, indicating that the products resulted from **2**.

The formation of **3** from **2a** provides a direct evidence for the proposed radical cation mechanism for the oxidation of methoxybenzenes to give such dimerized products (Scholl reactions).[5,9)]

In the case of **2b**, neither the dimer of type **3** nor one dimerized at the methyl carbon such as that formed in the reaction of 9,10-dimethylanthracene radical cation in which the highest spin density is at the methyl carbon[10)] was obtained, suggesting that the reaction path way is largely affected by the substitution of radical cations. It seems likely that coupling at the 3 and 6 positions in **2b** is hampered by the steric effects of the flanking groups, and coupling at the methyl group is put away by disproportionation to give the corresponding dication **7** which can be brought by the stabilizing effects of lone pairs in the 1,4-dimethoxy groups, and gives **4** either by leaving methyl cation or by reaction with water in working-up of the reaction mixture. Compound **5** is considered to form by chlo-



7

rination of **1b** reformed in a secondary reaction since the amount of **5** increases by longer standing of the reaction mixture with decrease in the yield of **1b**.

Experimental

Formation and Decomposition of **2**. To a solution of **1** (5 mmol) in CH_3NO_2 (50 ml) was added anhydrous $AlCl_3$ (1.33 g) under anhydrous atmosphere. The solution immediately assumed a green color due to the quantitative formation of **2** as determined by ESR. After the solution had been left to stand at room temperature for 1 hr, the mixture was poured into excess amount of ice-water and extracted with ether. The ether extract was washed (water), dried (Na_2SO_4), evaporated and chromatographed.

The separation of the products from **2a** by tlc (silica gel) developing with C_6H_6 gave **1a** (0.23 g) and **3**,[11)] mp 113—114 °C (0.265 g).

The products from **2b** were chromatographed on a silica gel (50 g) column. Elution with benzene gave **2a** (0.37 g), **5**, colorless plates, mp 135—137 °C (small amounts), and **4**, mp 121—122 °C (0.01 g) identified with authentic samples.

(Received March 1, 1974)

Synopsis. The C-13 NMR spectra of four α- and two β-ribonucleosides have been measured and all carbon signals have been assigned.

Although a naturally occuring α-ribonucleoside is found only as a part of vitamine B_{12},[1] there is a great possibility to find α-ribonucleosides which are highly biologically active like vitamine B_{12}. Carbon-13 NMR spectroscopy is a useful tool for the investigation of biologically important substances because of large chemical shift differences and susceptibilities to conformational and configurational changes.[2] The present authors have shown its application to oligosaccharides and glucans.[3,4] At the present time, its application to α-ribonucleosides has been intended.

Carbon-13 NMR studies of β-ribonucleosides and nucleotides have been published by Dorman and Roberts[5] and Jones *et al.*[6] Recently, Mantsch and Smith have indicated the reverse assignment of C-13 signals due to C-2′ and C-3′.[7] Our assignment of C-13 signals in the spectra of α-ribonucleosides was based on a comparison with those studies. As shown in the Table, the signals due to carbons of the sugar moiety appear between δ 90 and 60 ppm and those of the base moiety do between δ 160 and 130 ppm except the methyl signals. The C-2′ and C-3′ signal assignments for the β-anomers by Dorman[5] and Jones[6] are reversed to those given in the Table. The present assignment is based on the sterical reason as follows. The anomeric change from α to β should afford a more marked effect on the C-2′ chemical shift than on the C-3′ chemical shift, and the C-2′ and C-3′ signals of the α-anomers appear at the same field strength. Therefore, the signal which shows a downfield shift should be assigned to C-2′ of the β-anomers. As a result, the signal at δ 74 ppm is attributed to C-2′, and the assignment by Mantsch and Smith seems more reasonable. The C-3′ and C-5′ signals of both anomers appear at the same field strength. The C-4′ signals of the α-anomers appear at a little lower field than those of the β-anomers except that of theophylline.

Carbons in the base moieties of the purine-α- and -β-ribosides show almost the same chemical shifts, but those of the pyrimidine-α- and -β-ribosides show little different chemical-shifts as seen from the Table. Jones *et al.* showed that the chemical shifts for a base moiety change according to the *syn* and the *anti* conformation of the C–N riboside bond.[8] Hence, the distribution of the rotamer of the purine ribosides on the riboside bond is the same in the both α- and β-anomers.[9] In the case of the pyrimidine ribosides, that is different between α- and β-anomers. Since *N*-acetylproline shows the higher Cα chemical shift in the *trans*-rotamer than in the *cis*-rotamer,[10] the signal at δ 27.6 ppm in the spectra of (IIα and β) can be assigned to N_1–Me and that at δ 29 ppm to N_3–Me. In the case of (IIβ), the C-3′, C-4′, and N_3–Me signals are shifted to higher fields than those of (IIa). This fact can be explained by the reason that N_3–Me of the *syn* rotamer comes over on C-3′ and C-4′ and interacts sterically with those atoms.

Experimental

Materials. The all α-ribosides[11] and theophylline[12] and thymine β-ribosides[13] were synthesized as reported before. Adenine and uracil β-ribosides were purchased from Seikagaku Kogyo.

Measurement of C-13 NMR Spectra. The spectra were measured with a JEOL PFT-100 spectrometer and an EC-6 computer at 25.15 MHz. Deuterium internal-lock on a solvent was used. Pulse width and repetition time were

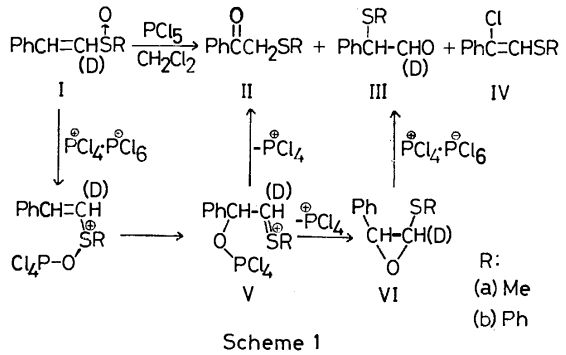
A Novel Rearrangement of Styryl Sulfoxide Induced by Phosphorus Pentachloride[1]

Norioki MIYAMOTO, Daisuke FUKUOKA, Kiitiro UTIMOTO, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yosida, Sakyo-ku, Kyoto 606

(Received March 13, 1974)

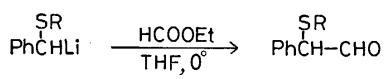
Synopsis. The reaction of both isomers of methyl styryl sulfoxide (Ia) with the title chloride affords methyl phenacyl sulfide (IIa) and phenyl(α-methylthio)acetaldehyde (IIIa) besides β-chlorostyryl methyl sulfide (IVa). Phenyl styryl sulfoxide reacts similarly.

The reaction of sulfoxides with Lewis acids is well known to involve the Pummerer rearrangement.[2] We now wish to describe a novel rearrangement of methyl styryl sulfoxide (I) induced by phosphorus pentachloride in methylene chloride at room temperature. The isolated products were the β-keto sulfide II and the aldehyde III besides β-chlorostyryl sulfide (IV) (Scheme 1). A series of experiments gave results, which are given in the order of the starting sulfoxide and the



Scheme 1

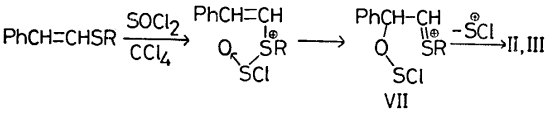
products (% yield[3]): *cis* Ia,[4] IIa[5] (25), IIIa[6] (23), IVa[7] (42); *trans* Ia,[7] IIa[5] (30), IIIa[6] (10), IVa[7] (27); *cis* Ib,[4] IIb[5] (20), IIIb[8] (18), IVb (53). The aldehyde III was identified on the basis of the comparison of the spectra with those of the authentic specimen, which were independently synthesized by a novel procedure involving the reaction of the sulfur-stabilized anion with ethyl formate as follows:



III

The formation of each product II, III, or IV is rationalized as shown in Scheme 1. The chlorination should proceed in the similar manner as suggested by Russell *et al.* in the reaction of the sulfoxide Ia with thionyl chloride.[7] The formation of II and III is explained by assuming V to be the common intermediate. The evidence supporting the proposed route to III is secured by the reaction of *trans* α-deuteriostyryl methyl sulfoxide[7] (Iad). Treatment of Iad with phosphorus pentachloride yielded the aldehyde IIIad having the deuterium at the formyl carbon. The structure of IIIad was determined on the basis of the NMR analysis. Since it is obvious from the above observations that the methylthio group shifts to the benzylic carbon, the formation of IIIa should involve the known, acid-catalyzed rearrangement[9] of the α,β-epoxy sulfide VI derived from the intermediary V. The formation of the β-keto sulfide III is explained by assuming V as the intermediate.

An additional proof for the proposed reaction scheme 1 is furnished by the observation that the methyl styryl sulfide[10] or phenyl styryl sulfide[10] reacts with thionyl chloride in carbon tetrachloride under reflux to yield the β-keto sulfide II (*a*, 42%[11]; *b*, 29) and III (*a*, 53; *b*, 38) besides the recovered vinylic sulfide. The formation of II and III can be rationalized in terms of the well-known [2,3]sigmatropic rearrangement[12] involving VII as the intermediate, whose structure is similar to that of V proposed in the reaction of the sulfoxide I with phosphorus pentachloride.



Experimental

The NMR spectra were obtained on a JEOL C-60H spectrometer in CCl_4. The chemical shifts are given in ppm from the TMS internal standard, and the abbreviations are used with their common meanings.

Reaction of Styryl Sulfoxide with Phosphorus Pentachloride. To the methylene chloride (20 ml) solution of the vinylic sulfoxide (I, 3.0 mmol) was added portionwise with stirring phosphorus pentachloride (630 mg, 3.0 mmol) at 0 °C. After the stirring at room temperature for 1 hr, the reaction mixture was poured into cold water in order to hydrolyze the remaining phosphorus pentachloride. Extraction with methylene chloride, drying (Na_2SO_4), and column chromatography (silica gel) gave the products II, III, and IV. IVa: bp 120—123 °C/3 mm, NMR δ 6.55 ppm (s, 1H, vinylic). Found: C, 68.3; H, 4.6%. Calcd for $C_{14}H_{11}ClS$: C, 68.1; H, 4.5%.

Independent Synthesis of the Aldehyde (III). The aldehyde III was prepared by the following new procedure in far better yield than the published ones.[6,8]

To the THF (10 ml) solution of benzyl methyl sulfide[13] (2.0 g, 15 mmol), was added *n*-butyl lithium (18 mmol) at 0 °C under nitrogen. The dark green solution was stirred for 30 min. Then the anion thus obtained was added with stirring to the THF (2.0 ml) solution of ethyl formate (30 mmol) at 0 °C. After the stirring at room temperature for 1 hr, the reaction mixture was poured into dilute hydrochloric acid. Extraction with ether, drying (Na_2SO_4), and distillation afforded the aldehyde (IIIa,[6] 2.1 g, 86%).

The aldehyde IIIb[8] was similarly prepared from benzyl phenyl sulfide[13] (84%).

Reaction of Styryl Sulfide with Thionyl Chloride. The

styryl sulfide (3.3 mmol) was allowed to react with thionyl chloride (1.0 g, 8.4 mmol) in carbon tetrachloride (20 ml) under reflux in a nitrogen atmosphere for 12 hr. Work-up with water, concentration *in vacuo*, and column chromatography (silica gel) gave II and III in addition to the recovered vinylic sulfide.

Syntheses of α-Hydroxyamino Acids from α-Keto Acids

Afzal AHMAD

Department of Chemistry, University of Islamabad, P.O. Box No. 1090, Islamabad, Pakistan

(Received May 7, 1973)

Synopsis. A new general method for the synthesis of α-hydroxyamino acids has been developed. Lithium cyanohydridoborate reduces α-keto acid oximes to the corresponding α-hydroxyamino acids and not to the corresponding α-amino acids.

During the course of investigations into the chemical and biological oxidation of α-amino acids it was considered essential to study the chemistry of analogous α-hydroxyamino acids. α-Hydroxyamino acids had been prepared earlier by several methods,[1-6] most of which gave contaminated products showing considerable discrepancies in their physical and chemical properties. One approach which appeared attractive entailed the synthesis of α-oximino acids from α-keto acids as the first step with a subsequent controlled reduction to obtain α-hydroxyamino acids as final products. All attempts, using methods to generate a stoichiometric amount of active hydrogen to convert α-oximino acid into the corresponding α-hydroxyamino acid resulted in complete failure. In every case a mixture of the corresponding α-amino acid and unchanged α-oximino acid was recovered.

Borch and Durst[7] have demonstrated a reaction of an aldehyde or ketone with ammonia in the presence of lithium cyanohydridoborate ($LiBH_3CN$) under neutral conditions in absolute methanol to give good yields of the corresponding amines. On application of this reaction, it was observed that when excess lithium cyanohydridoborate was stirred with α-oximino acids in aqueous medium at pH 5 for 48 hr at room temperature, α-hydroxyamino acids were also obtained in good yields. It was also found that in this reaction α-oximino acid could be replaced by the corresponding α-keto acid and hydroxylamine in equimolar quantities.

$$\begin{array}{l} R\text{-}\underset{\underset{O}{\|}}{C}\text{-}COOH + NH_2OH \text{ or } R\text{-}\underset{\underset{NOH}{\|}}{C}\text{-}COOH \\ \xrightarrow{LiBH_3CN} R\text{-}\underset{\underset{NHOH}{|}}{CH}\text{-}COOH \end{array}$$

α-Hydroxyamino acids prepared by this method are listed in Table 1. They are colorless crystalline compounds, having dipolar ion structure, and can be titrated with both acids and alkalies. pK_1 (2.05—2.45) and pK_2 (5.20—5.95) were measured in aqueous solutions and their isoelectric points calculated (pH 3.6—4.1). When they were titrated with sodium hydroxide in the presence of formaldehyde (Sørensen formal titration) a considerable decrease in the apparent values of pK_2 was observed. The dissociation constant pK_2 should therefore be associated with the hydroxyamino group ($R\text{-}NH_2^+OH \rightleftharpoons R\text{-}NHOH + H^+$), and constant pK_1 should thus be associated with the dissociation of carboxylic group ($R\text{-}COOH \rightleftharpoons R\text{-}COO^- + H^+$). An additional evidence in favor of the dipolar structure came from IR absorption studies. Like α-amino acids α-hydroxyamino acids show two characteristic bands for $-COO^-$ group, a prominent one occurring in the region 1580—1620 cm^{-1} and a weak one near 1410 cm^{-1}. Absorption band due to NH_2^+ deformation also appears near or coincident with the ionized carboxyl (1600 cm^{-1}) resulting in the broadening of the peak in this region. A complex series of medium scale continuous absorptions in the range 2400—2800 cm^{-1} were also observed in all cases.[8] Persistant absorption bands near 1300 cm^{-1} (NH_2 deformation) and 800 cm^{-1} (NH_2 rock) were displayed by all α-hydroxyamino acids.

Experimental

α-Keto Acids. Most of the α-keto acids were commercial products. Phenylglyoxylic acid[9] and phenylpyruvic acid[10] were prepared by known methods.

α-Oximino Acids. These were prepared by well-established methods, either from suitably substituted α-keto or malonic ester or malonic acids, by nitrosation with freshly prepared butyl nitrite,[11] or from α-keto acids and hydroxylamine.

α-Hydroxyamino Acids. A General Procedure: Either

a) Reaction time 48 hr in each case. b) Reported Mps.[9] c) Reported Mps.[5]

α-oximino acid (0.001 mol) or a mixture of the corresponding α-keto acid (0.001 mol) and $NH_2OH \cdot HCl$ (0.001 mol) is taken in water (10 ml). Enough alkali (NaOH) is added to raise the pH of the solution to approximately pH 5. A large excess of lithium cyanohydridoborate ($LiBH_3CN$) (0.002—0.003 mol) is added and the solution is stirred at room temperature for 48 hr. The reaction is interrupted by decomposing the unreacted $LiBH_3CN$ by adding concd HCl dropwise. The pH of the reaction mixture is adjusted to 1. The solution is filtered and the clear filtrate is evaporated to dryness under vacuum at room temperature. The residue so obtained is taken in water (10 ml) and evaporated again as before to remove free acid. The brown residue is then taken up in water (5 ml) and passed through a column (1 × 10 cm) of cation exchange resin (Bio-rad., Ag 50 W-x8, H^+ form). After thorough washing of the column with distilled water, α-hydroxyamino acid is taken off the column with aqueous ammonia (2%). The eluate is evaporated to dryness under vacuum at room temperature to give almost pure α-hydroxyamino acid. Further purification is achieved by crystallization from aqueous ethanol. Occasionally it was found necessary to purify α-hydroxyamino acids by passing through a column of anion exchange resin (Bio-Rad., Ag 1-x8, OH^- form) also. α-Hydroxyamino acids prepared by this method are recorded in Table 1. The IR spectrum of α-hydroxyaminopropionic acid is given (cm^{-1}) as a specimen: 655(s), 790(s), 895(s), 960(w), 1000(s), 1060(m), 1090(s), 1140(s), 1260(s), 1305(s), 1370—1620 (strong and broad), 2350(sh.) and 2400—2800 (a continuous medium absorption).

Film Rupture of Polyvinyl Alcohol in the Presence of Surfactants

Waichi NAGASHIRO, Makoto TANAKA, Tadao OKABE, and Mitsuru OIKAWA
Central Research Laboratory, Hitachi Ltd. Kokubunji, Tokyo 185

(Received Junuary 26, 1974)

Synopsis. It was observed that polymer film coated over a mask hole broke down on drying. The phenomenon is related to the surface chemical properties of the coating solution.

Film rupture phenomenon of polyvinyl alcohol was studied in the presence of various surfactants. Polymer film coated over a mask hole breaks down little by little on drying. The rupture starts from the center of the hole. The coating solution consists of polyvinyl alcohol, graphite and surfactants. After the drying of the solution, hardened polymer consisting of graphite remains on the inner side of the hole, making the diameter of the hole reduced. The rupture is related to the surface chemical properties of the coating solution.

Experimental

Surface tension and foam stability were measured as regards surface chemical properties of the coating solution. Surface tension was determined with a Du Noüy tension meter. Various methods have been given[1-4] for the measurement of foam stability. The present work was carried out by measuring the relative foam height from the instant the foam formation ceased. Foam formation was carried out by stirring the coating solution uniformly. The relative foam stability was estimated by the foam height 90 min after foam formation was completed.

Results and Discussion

A schematic view of the reduction mechanism of the size of a mask hole is given in Fig. 1. The suspension of polyvinyl alcohol, graphite, and surfactants is coated over the mask hole (Fig. 1—1,2). Graphite particles at the center of the mask hole move toward the edge of the hole (Fig. 1—3), while the coating solution is dried at room temperature. We observed two types of drying processes resulting from the difference in additive surfactants; in one case the coated polymer film remained unbroken on being dried (Fig. 1—4,5), in the other the coated polymer film at the center of the hole gradually broke down on being dried (Fig. 1—4′,5′).

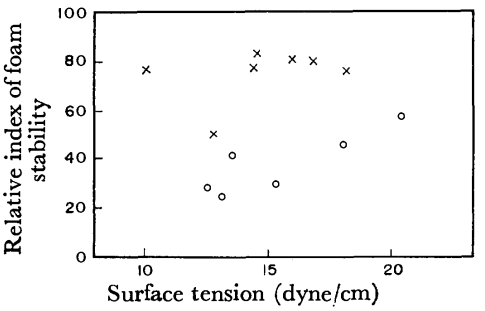

Fig. 2. Relation between foam stability and surface tension. (○; rupture, ×; no rupture)

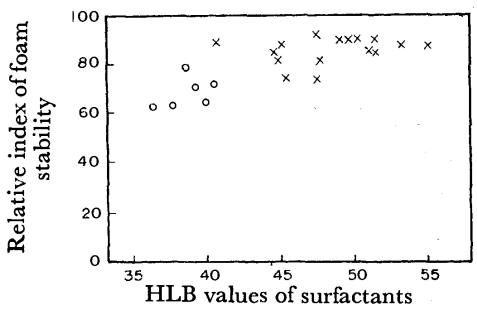

Fig. 3. Relation between foam stability and HLB value of additive surfactants. (○; rupture, × ; no rupture)

It is considered that this film rupture is related to the foam stability of the solution. The relation between film rupture and the surface chemical properties of the coating solution was studied. The results of the measurements of surface tension and foam stability of coating solutions containing various surfactants are summarized in Table 1, the film rupture being given in the order of foam stability.

The foam stability is plotted against the surface tension in Fig. 2. It is evident that film rupture occurs in a lower surface tension and lower foam stability region of a coating solution. A coating solution with a lower foam stability or a lower surface tension does not always rupture. The relation between foam stability and HLB value of surfactants is given in Fig. 3. The relation is not reliable. Film rupture does not seem to be related directly to any of the surface chemical properties of the coating solution. It occurs in the region of lower foam stability and lower surface tension.

Reductions of Cobalt(III) Complexes by Ferrous Chelates. II. The Reductions of Cobalt(III) Complex with Polymeric Ligands by Means of Some Ferrous Chelates

Yoshimi KURIMURA, Ikuko SEKINE, Eishun TSUCHIDA,* and Yukio KARINO*

Department of Chemistry, Ibaraki University, Mito, Ibaraki 310

**Department of Polymer Chemistry, Waseda University, Shinjuku-ku, Tokyo 160*

(Recieved May 28, 1973)

The effects of polymeric ligands on the electron-transfer reaction of the cobalt(III) complex have been studied for the reductions of the complex ions of *cis*-$Co(en)_2ACl^{2+}$ (A=poly-4-vinylpyridine, PVP, or pyridine, py) by the aquo ferrous ion and some Fe(II)-nitrilopolycarboxylate chelates. The specific rate of the Fe^{2+} reduction of the $Co(en)_2PVPCl^{2+}$ is smaller than that of the $Co(en)_2PyCl^{2+}$. The specific rate of the Fe(II)-chelate reduction increases considerable when the pyridine ligand in the $Co(en)_2$-$PyCl^{2+}$ is replaced by PVP. The effects of the chelating agents, the degree of coordination, the ionic strength, and the concentration of the reductant on the reduction rate of the $Co(en)_2ACl^{2+}$ by the Fe(II)-nitrilopolycarboxylate were also examined. The resulting reactivity patterns of the polymer complex ions could mainly explained by the effect of the higher electrostatic field caused by the positively-charged polymer structure.

Kinetic studies have been made of the $FeEDTA^{2-}$ reduction of $Co(NH_3)_5Y^{2+}$ (Y=halogen ions, NCS^-, NO_3^-, and N_3^-) and of $Fe^{II}Z^{m-}$ (Z=EDTA, CyDTA, EDTAOH, and EDTA)[1] reductions of $Co(NH_3)_5Cl^{2+}$: the results were reported in a previous paper.[2] The pattern of reactivities for the $FeEDTA^{2-}$ reductions of the $Co(NH_3)_5Y^{2+}$, in which the Y ligand is varied, indicates the inner-sphere natuer of the reactions: furthermore, the variation in the rate of reaction of the $Fe^{II}Z^{m-}$ with $Co(NH_3)_5Cl^{2+}$ were explained in terms of the steric, charge, and stabilization effects. For the reductions of the $Co(NH_3)_5Y^{2+}$ by the $Fe^{II}Z^{m-}$, it is suggested that the stabilization effect, the degree of which is expressed by the values of the logarithmic ratio of the stability constants ($\log K_{Fe^{III}Z}/K_{Fe^{II}Z}$), is the most important factor controlling the reaction rate.

A water-soluble polymer metal complex of *cis*-$[Co(en)_2PVPCl]Cl_2\cdot nH_2O$ (PVP=poly-4-vinylpyridine) was prepared,[3] and the specific rate and activation parameters for the ferrous-sulfate-ion reduction were determined in dilute sulfuric acid solution.[4] The rate of the reduction of the polymer complex ions is expected to be sensitive to the charge on the reductant species, since the polymer ion forms a "domain" with a greater charge density in the solution.

In the present study, the effects of the polymer ligand on the rate of the electron-transfer reactions were examined for the reduction of the polymer complex ion by ferrous chelate and aquo-ferrous ions.

Experimental

Materials. The *cis*-$[Co(en)_2Cl_2]Cl$[5] and *cis*-$[Co(en)_2pyCl]Cl_2$[6] were prepared by the procedures described in the references cited. Poly-4-vinylpyridines with degrees of polymerization (P_n) of 19 and 98 were prepared such as has been reported by Katchalsky *et al.*[7]

Preparations of cis-$[Co(en)_2PVPCl]Cl_2\cdot nH_2O$. $[Co(en)_2PVPCl]Cl_2\cdot nH_2O$ was prepared by means of substitution reaction between *cis*-$[Co(en)_2Cl_2]Cl$ and PVP in water-ethanol solution.[3] The identity and the purity of the *cis*-$[Co(en)_2PVPCl]Cl_2\cdot nH_2O$ were confirmed by the elementary analysis of C, H, and N, and the infrared and electronic spectra. The absorption peak at 1600 cm^{-1}, based on $\nu_{C=C,C=N}$ of the pyridine ring of the PVP, shifts to a wave number higher by about 20 cm^{-1} in the PVP complex. This indicates the coordination of the pendant pyridine to the Co(III). The absorption peaks due to the $\nu_{C=C}$, δ_{CH} (in plane) and the δ_{CH} (out of plane) also shift to a wave number higher by 2—10 cm^{-1} as a result of coordination. Some examples of the results of the elementary analysis are shown in Table 1. The degree of coordination (x) was determined from carbon content.[8] The absorption maximum and the molar extinction coefficient of the first absorption band of the $Co(en)_2$ $PVPCl^{2+}$ in the aqueous solution agree with those in the literature (λ_{max}=518 nm and $\varepsilon_{max}=72\pm2$).[3] The configuration of the *cis*-$[Co(en)_2$-$PVPCl]^{2+}$ is shown in Fig. 1. The *cis*-configuration of the $[Co(en)_2PVPCl]Cl_2\cdot nH_2O$ we prepared was ascertained from the sharp splitting of the $-CH_2$ rocking band (870—900

cm^{-1})[9] of the ethylenediamines in the complex.

Kinetic Measurements. The solution of the ferrous perchlorate was prepared by dissolving a known amount of analytical-grade iron wire, (Mallincroft Co.) in an excess of perchloric acid solution. The methods of determinations the ferrous, hydrogen and perchlorate ions in the ferrous perchlorate solution and the method of preparation for the ferrous chelate solutions were identical with those used in a previous work.[2]

The solution of the Co(III) complex was prepared by dissolving weighed amounts of the Co(III) complex into an acetate-buffered solution. The ionic strength of the reaction mixture was maintained at a constant value by the addition of sodium perchlorate. The reaction was followed spectrophotometrically at the wave-lengths in the vicinity of the first absorption maximum (—520 nm) of the Co(III) complex for higher concentrations of the complex and at the charge-transfer absorption maximum (~230 nm) of the Co(III) complex for lower Co(III) concentrations. The rate constants were calculated from the data which were obtained under pseudo-first-order conditions in which, in most cases, the concentration of the Fe(II) was in great excess over that of the Co(III). In some cases, the concentration of the Fe(II) was in not so great an excess over that of the Co(III): in such cases, then, the value of [Fe(II)] used for the calculation of the rate constant was an average value of the Fe(II) concentrations between the initial time and the half-life of the reaction. The values of k_{py} and k_{PVP} were obtained by means of this equation: $2.3\times m/[Fe(II)]$, where m is the slope of the straight line which was obtained from the slopes of the log (A_t-A_∞) *vs.* time plots, where A_t is the absorbance at time t, and A_∞, the absorbance after all the Co(III) has been reduced to Co(II).

Results

The rate equations for the reduction of $Co(en)_2pyCl^{2+}$ by Fe^{2+} and $Fe^{II}Z^{m-}$ and that of the $Co(en)_2PVPCl^{2+}$ by Fe^{2+} almost fit the second-order kinetics: $-d[Co(III)]/dt=k[Co(III)][Fe(II)]$ ($k=k_{py}$ or k_{PVP}), under the experimental conditions employed. The apparent second-order rate constant of k_{PVP} for the $Fe^{II}Z^{m-}$ reductions was calculated from the initial slopes of the log (A_t-A_∞) *vs.* time plots. In most cases, such plots give straight lines for about a half-life of the reaction.

Table 2 shows that the rate constant for the Fe^{2+} reduction of the polymer complex with $P_n=98$ is almost identical with that of the polymer complex with $P_n=19$ within the limits of experimental errors when the values of x are equal to each other ($x=0.68$ for $P_n=98$ and $x=0.65$ $P_n=19$). This indicates that the value of k_{PVP} for Fe^{2+} reduction is not so much affected by the chain length of the polymer ligand when the P_n value ranges between 19 and 98 under the experimental conditions given in Table 2. For the Fe^{2+} reduction, the reactivity of the polymer complex is lower than that of the monomeric one by about one-third.

TABLE 2. RATE CONSTANTS FOR THE Fe^{2+} REDUCTION OF $Co(en)_2ACl^{2+}$

A	P_n	x	k[a], $M^{-1}s^{-1}$
Py			1.1×10^{-3}
PVP	98	0.68	3.7×10^{-4}
PVP	19	0.65	3.7×10^{-4}

a) $[Co(III)]=4.0\times10^{-3}$ M, $[Fe(II)]=3.4\times10^{-2}$ M, $[Fe(II)]=3.4\times10^{-2}$ M, $[H^+]=2.0\times10^{-2}$ M, $\mu=0.12$, 40 °C.

Ferrous Chelate Reduction. All the reductions of the $Co(en)_2pyCl^{2+}$ and $Co(en)_2PVPCl^{2+}$ by $Fe^{II}Z^{m-}$ except for the Fe^{II}DTPA were followed in the solution of pH=5 in which the predominant species of Fe(II) are normal ferrous chelates. For the Fe^{II}DTPA reduction, the rate constants of Reactions (1) and (2) could be obtained separately from the pH dependence of the rate constant:

$$Co(en)_2ACl^{2+} + FeHDTPA^{2-} \rightarrow Co(II) + Fe(III) \quad (1)$$

$$Co(en)_2ACl^{2+} + FeDTPA^{3-} \rightarrow Co(II) + Fe(III) \quad (2)$$

where A=py or PVP. From Reactions (1) and (2), we obtaine:

$$k_a(1+K_{FeHZ}[H^+]) = k_1 + k_2K_{FeHZ}[H^+] \quad (3)$$

In this equation, k_1 and k_2 are the rate constants of Reactions (1) and (2) respectively, while K_{FeHZ} is the formation constant of the protonated chelate, $FeHDTPA^{2-}$, and k_a is k_{py} or k_{PVP}. The value of K_{FeHZ} was $10^{5.4}$ ($\mu=0.1$ and at 25 °C).[10] As is shown in Fig. 2, the plots of $k_a(1+K_{FeHZ}[H^+])$ *vs.* $[H^+]$ become linear in both cases. The slopes and intercepts of these lines give the values of k_2K_{FeHZ} and k_1 respectively.

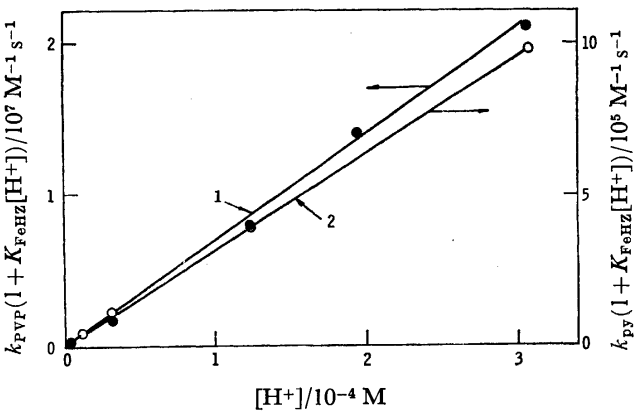

Fig. 2. Plots of $k_a(1+K_{FeHZ}[H^+])$ *vs.* $[H^+]$.
$[Co(III)]=1.0\times10^{-5}$ M, $[Fe^{II}DTPA]=5.1\times10^{-5}$ M, $\mu=0.02$, 25 °C,
1, $Co(en)_2PVPCl^{2+}$, 2, $Co(en)_2pyCl^{2+}$.

Unfortunately, the intercepts of such plots were too small for us to determine the values of k_1 for the $Co(en)_2pyCl^{2+}$ and the $Co(en)_2PVPCl^{2+}$. The values of k_1 were, however, estimated to be smaller than corresponding k_2 values by at least one-tenth in both cases. The rate constants for the reductions of $Co(en)_2pyCl^{2+}$ and $Co(en)_2PVPCl^{2+}$ by several ferrous chelates are summarized in Table 3.

The effects of the conentration of the ferrous chelate and the degree of the coordination and that of the polymerization on the rate of the reduction of the polymer complex are represented in Fig. 3 and Table 4 respectively. For the $Fe^{II}Z^{m-}$ reduction, The apparent rate constant is affected by the degree of coordination, x, in

the polymer complex and by the degree of polymerization of the polymer ligand: the rate constant increases with an increase in the value of x and the rate constant in the complex of PVP with P_n=98 is greater than that for P_n=19 when the values of x are almost the same. A comparison the rate constants for the $Co(en)_2pyCl^{2+}$ and $Co(en)_2PVPCl^{2+}$ complexes at different ionic strengths is also shown in Table 5.

Discussion

It may be reasonable to assume that the reductions of the $Co(en)_2PVPCl^{2+}$ and $Co(en)_2pyCl^{2+}$ complexes by Fe^{2+}, $FeSO_4$,[11] and $Fe^{II}Z^{m-}$ proceed through a chloride-bridged mechanism, since it has been suggested that $Co(NH_3)_5Cl^{2+}$ reacts with Fe^{2+},[12] $FeEDTA^{2-}$,[12] and $FePDTA^{2-}$[13] *via* the chloride-bridged activated state.

The rate of reaction between two cationic species in an aqueous solution, for example, the reaction of $Co(NH_3)_5Cl^{2+}$ with Fe^{2+}, is markedly accelerated in the presence of small amounts of polyions, such as polyvinylsulfonate or polymethacryloxyethylsulfonate anions.[14-17] In dilute solution of a polyelectrolyte, the damains occupied by the polyions contain very high density of the ionized group, while the space between the domains has only a very low concentration of ionic species.[14] It was also demonstrated by means of several experimental techniques, such as electronic mobility,[18,19] osmotic pressure,[20] and potentiometric titration,[21,22] that appreciable amounts of the counter ions are fixed near the polyion structure in an aqueous solution of polyelectrolytes due to Coulombic attraction between the polyion and the counter ion. The polycation domain consisting of the $Co(en)_2PVPCl^{2+}$ also tends to concentrate the opposite-charged $Fe^{II}Z^{m-}$ species. This causes an increase in the local concentration of the $Fe^{II}Z^{m-}$ species, thus promotes the reduction rate. The results listed in Table 6 qualitatively support this electrostatic explanation: the results show that the acceleration factor depends essentially on the charges of the reductant. The reduction of the activity coefficient of the multiplycharged activated complex in the strong field of the polyion domain[23] is considered to be another factor controlling the rates of polyion catalyzed reactions. Among the reactions investigated, the latter factor, however, seems to be less important than the former, since the acceleration factor for the Fe^{2+} reduction of the $Co(en)_2PVPCl^{2+}$, in which the reaction takes place through the multiply positive-charged activated complex, is not so far from unity. The specific rate for the $FeEDTA^{2-}$ reduction of the $Co(en)_2PVPCl^{2+}$ complex increases as the degree of coordination increases (Table 5). This could also be explained in terms of the accumulation of the $FeEDTA^{2-}$ in the polycation doamin as the degree of

Table 6. Acceleration factors for the Fe(II) reduction of $Co(en)_2PVPCl^{2+}$

Reductant	Acceleration factor k_{PVP}/k_{py}
Fe^{2+}	0.33[a]
$FeSO_4$	0.59[b]
$FeEDTAOH^-$	3.7[c]
$FeEDTA^{2-}$	21[c]
$FeCyDTA^{2-}$	16[c]
$FeHDTPA^{2-}$	22[c]

a) μ=0.12, 40 °C, P_n=98, x=0.45, in 0.1 M $HClO_4$.
b) $\Sigma[SO_4^{2-}]=1.25$, $[H^+]=1.0$ M, P_n=98, x=0.45.[4]
c) μ=0.02, P_n=19, x=0.64.

coordination increases, since it is considered that the charge density of the polymer domain becomes larger with the degree of coordination. For a $FeEDTA^{2-}$ reduction, the pseudo-first order rate constant, k_p, increases with the concentration of the reductant, but the relationship between the rate constant and the $[FeEDTA^{2-}]/[Co(III)]$ is not linear as is shown in Fig. 3. This seems to suggest the existence of an equilibrium between the $FeEDTA^{2-}$ in the bulk and that in the domain in the polyion-$FeEDTA^{2-}$ system.

The greater influence of the ionic strength or the concentration of the nonparticipating salts on the specific rate of the $FeEDTA^{2-}$ reduction of the $Co(en)_2PVPCl^{2+}$ than the influence of the $Co(en)_2pyCl^{2+}$ (Table 5) also indicates greater effect of the Coulombic force between the polycations and the nonparticipating anions. As the amounts of the nonparticipating anions in the solution increase, their concentrations in the domain would increase also, this causing a partial neutralizing of the positive charges carring on the polyion domain. Therefore, the amounts of the $FeEDTA^{2-}$ will tend to be diluted in the polyion domains, resulting in a lower collision frequency.

The Thermal Decomposition and Reduction of Silver(I) Oxide

Issei NAKAMORI, Hidetsugu NAKAMURA, Toshiyuki HAYANO, and Shuichi KAGAWA*

Department of Chemical Engineering, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received October 5, 1973)

The thermal decomposition of silver(I) oxide and its reduction with reductive gases, such as ethylene, hydrogen, and carbon monoxide, have been studied by using a fixed-bed flow reactor. Under isothermal conditions, each reaction gave a sigmoidal shape to the fractional decomposition *vs.* time curves, and these curves were in good agreement with Avrami's equation. The temperature at which the reaction commenced corresponded well to the chemical affinity of the reaction, and a linear free-energy relationship holds between the apparent activation energy and the standard enthalpy change of the reaction. In the thermal decomposition, an enlargement in particle size resulting from the melting and sintering of the product silver was recognized, but in the reduction the particle size scarcely varied during the reaction. On the basis of these results, the mechanism of each reaction was discussed.

The thermal decomposition of silver(I) oxide has been investigated by various workers, but no reasonable explanation of the decomposition rate equation and the reaction mechanism were obtained. With regard to the fractional decomposition (α) *vs.* reaction time (t) curves, both sigmoidal and nonsigmoidal curves have been reported. Sigmoidal curves have been reported by Lewis[1] and by Hood and Murphy,[2] who proposed that the reaction proceeded autocatalytically obeying by Ostwald's equation: $d\alpha/dt=k\alpha(1-\alpha)$. Recently, Tobisawa[3] and Herley and Prout[4] have proposed a topochemical approach to these observed sigmoidal curves. Nonsigmoidal curves which have a maximum rate at the initial stage of the decomposition have been reported by Pavluchenko and Gurevich[5] and by Garner and Leaves.[6] Kato *et al.*[7] observed nonsigmoidal curves which showed that the reaction proceeded linearly with the time up to a great extent of the fractional decomposition. However, almost all the samples which have not shown sigmoidal curves have undergone grinding or preheating. These treatments may have an effect on the physical and chemical properties of the samples.

On the other hand, the reduction of silver oxide with ethylene has been studied in order to examine the role of silver as a catalyst in the direct oxidation of ethylene.[8-10] Kagawa *et al.*[9] found that, both in the thermal decomposition of silver oxide and in its reduction with ethylene, the reactions proceeded obeying Ostwald's equation and suggested that the two mechanisms of reactions were similar.

In this paper, on the basis of a comparison of the thermal decomposition with the reduction with several reductive gases, the reaction mechanisms will be discussed.

Experimental

Preparation of Silver(I) Oxide. The sample of silver oxide was prepared from silver nitrate and sodium hydroxide. In order to eliminate the silver carbonate formed at the surface of the silver oxide, the specimen was treated in a carbon dioxide-free nitrogen stream at 60—120 °C for 48—72 hr and stored *in vacuo* over silica gel under dark-room conditions. By a chemical analysis of the silver, the sample gave 100±0.2% as silver(I) oxide and was confirmed gas-chromatographically not to evolve oxygen gas below 250 °C, while the X ray diffraction patterns did not show any line of silver or of silver carbonate.

Apparatus and Procedure. The reaction was carried out in a fixed-bed flow reactor using a Pyrex tube 1 cm in inside diameter. A given amount of the silver oxide sample was packed in the reactor. In the case of the thermal decomposition, the nitrogen used as a carrier gas was passed through at a constant flow rate. The reactor was immersed in a fused-salts bath and heated; then the reaction commenced. The product oxygen in the effluent gas was analyzed by gas-chromatography. The reaction rate was determined from the flow rate of the carrier gas and from the oxygen concentration in the effluent gas. In the cases of the reductions with ethylene, hydrogen, and carbon monoxide, pure reactant gases and mixtures of them with nitrogen gas were passed through the reactor at a constant flow rate and the reaction product gases, such as ethylene oxide, carbon dioxide, and water vapour, were analyzed gas-chromatographically. In each reduction, no oxygen gas evolution as a result of the thermal decomposition was detected. One of the baths of the oil, the water or the water-methanol, was selected as a thermostat according to the reaction temperature.

Experiments were carried out both isothermally and dynamically. In the case of a dynamical operation, the heating rate was 2 °C/min. In the case of an isothermal operation, the required temperature could be obtained within 5 minutes and the temperature was controlled within ±0.5 °C during the course of the reaction. At slow flow rates up to 80 cm^3/min, the effect of the flow rate on the rates of the thermal decomposition and the reduction was observed. Therefore, experiments were carried out at flow rates above 80 cm^3/min. The sample weight did not effect the reaction rate. Considering the accuracy of analysis and the elimination of the heat of reaction, the sample weight was determined to be 0.5—1.5 g for the thermal decomposition and for the reduction with ethylene, and about 0.15 g for the reductions with hydrogen and carbon monoxide.

Results

Reaction under Dynamical Conditions. As is shown in Fig. 1, the thermal decomposition of silver oxide began at 330 °C, reached a maximum rate at about 440 °C, and was completed at 500 °C. On the other hand, the reduction with ethylene occurred over the range of temperature of 110—210 °C, that with hydrogen, at 10—130 °C, and that with carbon monoxide, at −40—30 °C. By balancing the oxygen atoms in

product gases with those in silver oxide used, the reaction equations were determined. The results are shown in the fifth column of Table 1. In the reduction of silver oxide with ethylene, two reactions occurred competitively and the selectivity of ethylene oxide based on the ethylene reacted was about 37%. In the sixth and seventh columns of Table 1 respectively, the temperature at which the reaction commenced (T_c) and the standard free energy change of the reaction (ΔG°_{298}) are described. Between T_c and ΔG°_{298} a fairly good correspondence is found; the smaller (the more negative) the ΔG°_{298}, the lower the T_c.

Reaction under Isothermal Conditions. The thermal decomposition under isothermal conditions was carried out between 410—430 °C. The fractional decomposition *vs.* time curves are shown in Fig. 2. These curves, which showed an accelerated period, gave a sigmoidal shape characteristic of a solid reaction. The reductions of silver oxide with ethylene, hydrogen, and carbon monoxide were carried out at the temperature ranges of 136—145 °C, 65—75 °C, and −8—10 °C respectively. The results[11] are shown in Figs. 3, 4 and 5. Although the reaction temperatures were different from each other, the shapes of the curves were sigmoidal, similar to those of the thermal decomposition in nitrogen.

In the case of the reduction with ethylene, the effect of the partial pressure of ethylene on the reduction rate is illustrated in Fig. 6.[12] The partial pressure of

ethylene below 0.4 atm had a considerable influence on the reaction rate constant, but above 0.4 atm the effect was negligible. For the other reductive gases, similar results were obtained.

Scanning-Electron-Microscope Observation. The sample of silver oxide consisted of opaque polycrystalline particles. From scanning electron micrographs it was observed that some dozens of primary particles about 0.1 μ in size aggregate to form a secondary particle several ten microns in size. Some examples of scanning electron micrographs are shown in Fig. 7. In the case of the thermal decomposition, the product silver somewhat melted in the course of the reaction. After the completion of the decomposition, the particle size of silver came to about several ten times larger than that of the sample of silver oxide.

On the other hand, in the case of the reduction, the primary particle decreased in size as the density changed from oxide to metallic silver, and no enlargement in size as a result of sintering was observed. From this result an enlargement in size resulting from the aggregation or sintering of primary particles does not seems to affect the fractional decomposition *vs.* time curves or, therefore, the reaction mechanism.

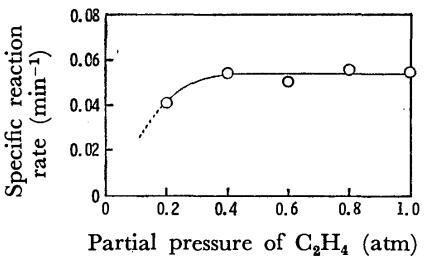

Fig. 6. Effect of partial pressure of C_2H_4 on reaction rate at 138 °C.

Discussion

The overall reaction of the thermal decomposition and reduction of silver(I) oxide can be written commonly by this equation:

$$Ag_2O(solid) + Reactant(gas) \rightarrow Ag(Solid) + Product(gas) \quad (1)$$

In the thermal decomposition, there is nothing corresponding to the reactant in Eq. (1), and the product is oxygen. The results in these experiments showed that, in a series of reactions, the thermal decomposition

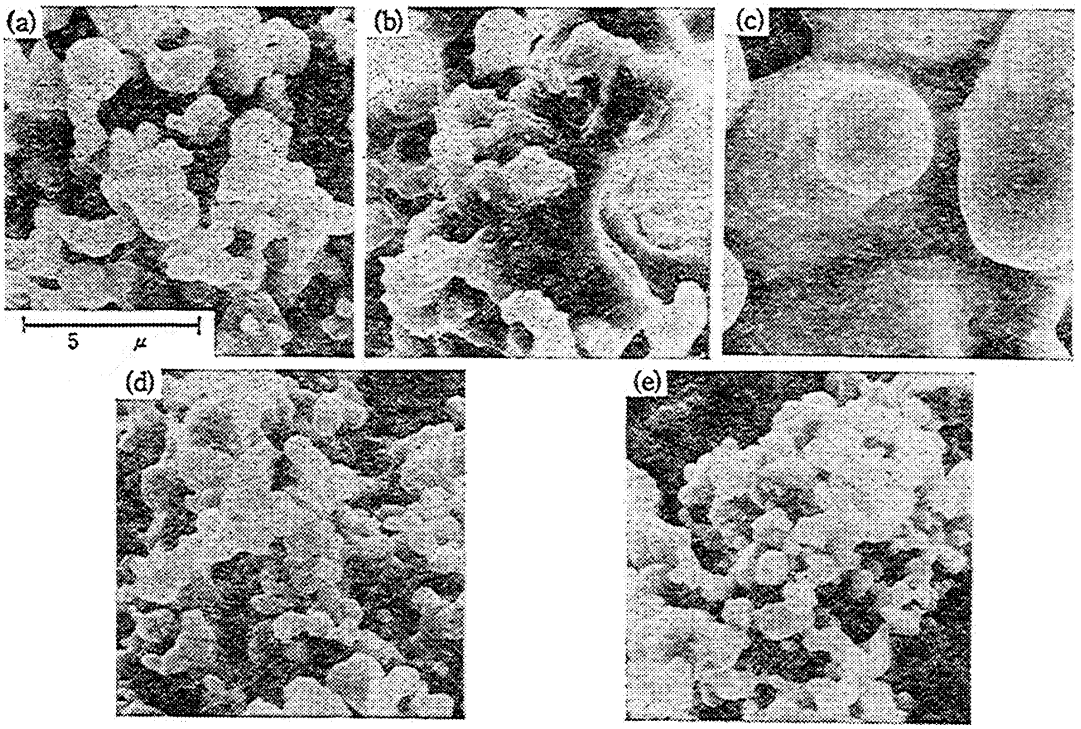

Fig. 7. Scanning electron micrographs of some selected samples.
a) Silver(I) oxide undecomposed. b) Sample at fractional decomposition of 0.5 in the thermal decomposition. c) Sample at complete decomposition in the thermal decomposition. d) Sample at fractional decomposition of 0.5 in the reduction with C_2H_4. e) Sample at complete decomposition in the reduction with C_2H_4.

occurred at the highest temperature (330 °C) and that the reduction with carbon monoxide occurred at the lowest temperature (−40 °C). The temperature at which the reaction commenced varied approximately linearly with ΔG°_{298}. It is interesting that each of these reactions gave the same sigmoidal shape to the fractional decomposition *vs.* time curves, although these reactions occurred at different temperatures, extending over a wide range.

Two kinds of theories to explain sigmoidal curves in a phase transformation and a thermal decomposition have been proposed. One kind is exemplified by those of Garner and of Prout and Tompkin, which explain the growth of nuclei in terms of the branching chain-reaction mechanism; the other kind is exemplified by Avrami, Mampel, Erofeev, and Cahn's theories, which take into account the overlapping of growing nuclei. Prout and Tompkin's rate equation is identical with Ostwald's equation, which was used by Lewis and by Hood and Murphy. However, it is unreasonable to apply this equation over the entire range of decomposition, because an equation of this form requires that all the solid product be in a position to catalyse all the particles of the solid reactant equally throughout the complete course of the reaction. In a solid decomposition where the mobility of the reacting constituents is low, such a situation is not feasible.[13] Besides, the results of this experiment did not fit in well with Prout-Tompkin's equation.

On the other hand, the latter contains complicated equations, none of which can be applied to any practical problem. However either of the following approximate equations can be utilized:

$$\alpha/(1-\alpha) = Bt^k \tag{2}$$

$$\alpha = 1 - \exp(-Bt^k) \tag{3}$$

where α is the fractional decomposition; t, the reaction time, and B and K, the constants characteristic of the reaction system.

As is shown in Figs. 8—11, the present experimental results fit in well with Eq. (3) except in the case of the

reduction with hydrogen, where the range of applicability of Eq. (3) is somewhat small. From these figures, the values of k and B were determined. They are shown in Table 2. The values of k, being within 2.00—2.81, were approximately constant in all the reaction systems. From the finding that the thermal decomposition and the reduction occur obeying the same rate equation, it can be considered that the rate-determining step is similar. Plots of log B against $1/T$ (K^{-1}) gave straight lines, and from their slopes the apparent activation energies (E_a) were determined. The plot of this activation energy against the standard enthalpy change of the reaction at the average temperature investigated (ΔH°_T) gave a fairly good straight line (Fig. 12). Let us now discuss this free-energy relationship.

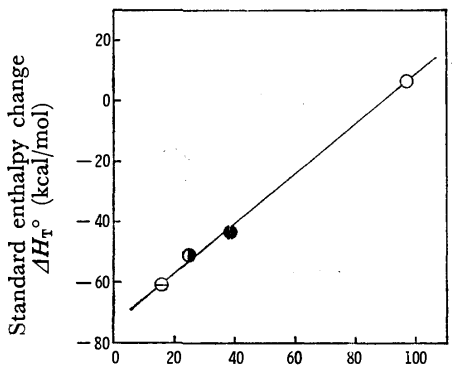

Fig. 12. Linear free energy relationship.
⊖ reduction with CO, ◑ reduction with H_2, ● reduction with C_2H_4. ○ thermal decomposition in N_2

Although the mechanism of Reaction (1) is not yet known in detail, generally the following steps may be considered: Silver oxide decomposes at the active point which exists in the interior of crystal or on the surface layer, thus producing silver and oxygen atoms. Then this oxygen atom diffuses to the outer surface to react with the reactant gas, and the silver atom diffuses to the interface between metallic silver and silver oxide to form a silver crystal.

Since the fractional decomposition *vs.* time curves gave a sigmoidal shape, the diffusion step may not be the rate-determining step. If the chemical reaction of an oxygen atom with a reactant gas occurs at the surface of silver oxide, the reaction rate depends upon the surface area of the silver oxide and on the partial pressure of the reactant gas. Since the surface area of silver oxide decreases as the reaction proceeds, the reaction rate must decrease monotonously and does not have an accelerated period. Even if this chemical reaction occurs over the whole surface of both silver oxide and silver, the sigmoidal curves cannot be explained, for the total surface area either remains constant (in the case of the reduction) or decreases gradually (in the case of the thermal decomposition), as may be seen in scanning electron micrographs. Moreover, the rate of the reaction is not first-order with respect to the partial pressure of reductive gas. Thus, the chemical reaction may not be the rate-determining step.

From Allen's[14] study it is reasonable to consider that silver-oxygen bond secession occurs at the initial stage of the reaction. However this step may not be the rate-determining step, for if it is so, the activation energies of each reaction must be constant in all the reaction systems, while in reality the apparent activation energy of each reaction, as calculated from the initial reaction rate, varied with the reaction system—the higher the reaction temperature, the larger this value.

Dubinin *et al.*[15] and Kato *et al.*[7] have reported that the thin layer silver coating on silver oxide and silver produced by the reduction with ethylene considerably increases the reaction rate. From these reports, and the finding that a series of these reactions occur obeying the same rate equation, similar to the equation of an ordinary phase transformation, it is more reasonable to consider that the step of the nucleation of silver and its development is the rate-determining step.

Though the results of this experiment can not reveal the detailed reaction mechanisms, from the above considerations we can estimate Eqs. (4) and (5) to be:

$$Ag_2O(solid) + Reactant(gas) \rightarrow Ag(interface) + Product(gas) \quad (4)$$

$$Ag(interface) \rightarrow Ag(solid) \quad (5)$$

From the previous discussion it can be considered that Reaction (4) steadily occurs in a preliminary equilibrium, and that Reaction (5) is rate-determining. Therefore:

$$\Delta G^\circ_{(1)} = \Delta G^\circ_{(4)} + \Delta G^\circ_{(5)} \quad (6)$$

$$\Delta G^\circ_{(4)} = -RT\ln(C_{Ag}\cdot C_{prod.}/C_{react.}) \quad (7)$$

The B is Avrami's rate equation is some function of the formation rate of the nuclei ($\dot{N}$) and the growth rate of the nuclei (G).[16] Though the form of this function depends upon the dimensionality of the development of the nuclei, in general it takes the form of const$\cdot G^a\cdot \dot{N}^b$.

The volume nucleation rate is approximately[16]:

$$\dot{N}_j = vn(\delta/D)^{3-j}\exp\{-(\Delta G_j^* + \Delta G_A^*)/RT\} \quad (8)$$

where j is the dimensionality of the nucleation site; v, a frequency factor; n, the number of atoms per unit volume; δ, an effective grain boundary thickness; D, the grain diameter; ΔG_j^*, the minimum free energy required to form a nucleus, and ΔG_A^*, the free energy of activation for a nucleus to continue to grow.

The linear growth rate would be:

$$G = v\delta(n/s)\exp(-\Delta G_A^*/RT) \quad (9)$$

where n/s is the density of atoms per unit area of the reactive molecules.

By rearranging Eqs. (1), (4) and (5), we get:

$$C_{Ag} = (C_{react.}/C_{prod.})\exp\{-(\Delta G^\circ_{(1)} - \Delta G^\circ_{(5)})/RT\} \quad (10)$$

where C_{Ag} is the concentration of silver atoms and is proportional to n.

Since the experiments in this study were carried out under similar conditions, the values of ($C_{react.}/C_{prod.}$) during the course of the reaction are equal in each reaction; thus, the apparent activation energy obtained from the Arrhenius plot of B becomes:

$$E_a = b\Delta H_j^* + (a+b)(\Delta H_A^* + \Delta H^\circ_{(1)} - \Delta H^\circ_{(5)}) \quad (11)$$

where ΔH° is an enthalpy change term corresponding to a free-energy change term. Since ΔH_j^*, ΔH_A^*, and $\Delta H^\circ_{(5)}$ are considered to be constant in all the reaction systems, we can understand that the plot of the apparent activation energy against $\Delta H^\circ_{(1)}$ should be a straight line.

From the above discussion, we may conclude that, since the chemical reaction process is very rapid, and since the process of the crystallization of new-phase silver is the rate-determining step, the thermal decomposition and reduction of silver oxide show the same kinetic behaviour as a phase transformation.

About the thermal decomposition of silver oxide, Allen[14] reported that the activation energy calculated from the reaction rate and the reaction temperature was 36 kcal/mol. A differentiation of Eq. (3) with t yields:

$$d\alpha/dt = kB^{1/k}f(\alpha) \quad (12)$$

Thus, the activation energy determined by Allen must be equal to $1/k$ times our apparent activation energy. Actually, the two give approximately equal values.

In this study, it is difficult to discuss the sites of nucleation and the dimensionality of the growth of the nuclei in detail considering the accuracy of our experiments. Moreover, whether or not the sites where the bond secession of silver oxide occurs are identical with the sites where the nuclei of a silver crystal generates is an interesting problem for future study.

An Infrared Study of the Steric Effects of Alkyl Substituents on the N–H Stretching Absorptions of *sym*-Dialkylureas

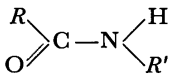
Yoshiyuki MIDO

Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657

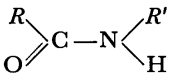
(Received October 6, 1973)

By examining their N–H stretching absorptions in the hydrogen-bonding system, the steric effects of the substituent on the C=O or N–H group have been studied for *sym*-disubstituted alkylureas of the *R*HNCONH*R'* type in carbon tetrachloride. By comparing the estimated percentage of the monomer, it is concluded that the steric effects are not large enough to convert the *trans* conformation into the *cis* conformation, though the branched alkyl groups may prevent another molecule from approaching more strongly than the normal alkyl groups. Correlations among some spectral parameters have been examined, such as the estimated percentage of the monomer, the frequency shift upon hydrogen-bond formation, the apparent integrated absorption intensity, and the half-intensity width of the associated band.

The peptide group in secondary amides has been shown to adopt possibly the *trans* and/or *cis* conformation under certain conditions:[1,2]



trans

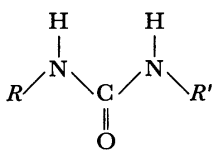


cis

The more favorable conformation and its percentage in solution are mainly decided by the steric factor between the substituents, *R* and *R'*, and the C=O group.[1-6] The steric factor can affect the intensity of the associated band; that is, the larger the size of the *R* and *R'* groups, the weaker the intensity.[5,6] The N–H stretching frequencies characteristic of their conformations have been established.[1-6]

As *sym*-dialkylureas have the –CO–NH– structure, such as in secondary amides, it seemed that it would be interesting to examine the relationships between the size of *N*-alkyl substituents and the intensity of the associated N–H stretching band in solution, and to estimate the limit of the size which can convert the dominant *trans* conformation into the *cis* conformation, if the steric hindrance of a bulky group such as *tert*-butyl can convert in that manner.

We have studied various alkylureas by infrared spectrometry and have shown that *sym*-dialkylureas are dominantly in the *trans-trans* conformation in the solid[7,8] and liquid states,[7] and in solutions.[9,10]



trans-trans

However, our conclusion regarding *sym*-di-*tert*-butylurea (*s*-D*t*BU) in solutions did not agree with that of Rao *et al.*,[11] suggesting that, of the two closely-spaced monomeric N–H stretching bands, the stronger band, at 3437 cm^{-1}, arises from the *cis* rotamer.[12] The other band, at 3469 cm^{-1} (indicated as a weak band by an arrow sign in Fig. 1) could be interpreted as being due to the *cis* conformation; we do not, however, have any conclusive evidence yet, though it is certain that the 3469 cm^{-1} band does not originate from the *trans* conformation.

The purposes of the present study are: (1) to examine whether or not the steric hindrance of a bulky group or groups such as *tert*-butyl is large enough to convert the *trans* conformation into the *cis* conformation, and (2) to establish possible correlations among the spectral parameters obtained from the N–H stretching absorptions for various *sym*-dialkylureas in a dilute carbon tetrachloride solution.

Experimental

All the dialkylureas used had already been identified in our previous studies.[7,8] Carbon tetrachloride for spectroscopy was used. The spectra (3600—3200 cm^{-1}) were recorded with solvent compensation at a slow speed and using a five-fold-scale expansion in frequency. The measurements were made at 27°±2 °C with a Hitachi EPI-G2 Infrared Grating Spectrophotometer.

The 0.0025 M solutions in carbon tetrachloride were examined using a 2.0-cm NaCl cell. Some typical spectra are shown in Fig. 1. The apparent molar extinction coefficient, ε, for the monomeric N–H stretching band of each sample was determined by measuring its apparent optical density, $O.D._{mono}$ of a 0.0005 M solution (using a 5.0-cm NaCl cell), in which the associated band no longer appears. The ε is defined as:

$$\varepsilon = \frac{1}{CL}\log_{10}\left(\frac{T_0}{T}\right)_{\nu_{max}}$$

where C is the concentration of the solute in moles per liter, L is the cell length in cm, and T_0 and T are the apparent intensities of the incident and transmitted radiation at the maximum wave number respectively.

In order to obtain reliable data, three or more samples were independently prepared for each of the dialkylureas, and their spectra were recorded. The spectral parameters were independently estimated from three or four of their reproducible spectra. The average value of the estimations is listed in Table 1. As the monomeric and associated bands significantly overlap one another, and as the latter band is much broader, as is shown in Fig. 1, the average values are considered to have some certainty. Therefore, the $O.D._{mono}$, the $O.D._{asso}$, and the frequency shift, $\Delta\nu$, were obtained from the band-contours before the graphical separation by Jones' method,[6] while the apparent integrated absorption intensity, B, and the half-intensity width, $\nu_{1/2}$, of the associated band were obtained from the band contours after the graphical separation. The estimated concentration percentage of the monomer, C_{mono}/C, was calculated from the $O.D._{mono}$ and

a) Point number in figures. b) Apparent molar extinction coefficient ($mol^{-1}\cdot l\cdot cm^{-1}$). c) $B=\int\frac{1}{CL}\log_e\left(\frac{T_0}{T}\right)d\nu$ ($mol^{-1}\cdot l\cdot cm^{-2}$). d) $\Delta\nu=\nu_{mono}-\nu_{asso}$, see Ref. 9 for ν_{mono}. e) Side band (monomer), see Experimental. f) The average value, see Experimental.

ε values. The B is defined as:

$$B=\frac{1}{CL}\int\log_e\left(\frac{T_0}{T}\right)d\nu$$

where $d\nu$ is the differential of the wave number.

In a special case with such a band-splitting as is seen in MU*i*P, MU*s*B and MU*t*B, when the values of parameters are as plotted in Figs. 2—7, the average value of two for the splitting in a spectral parameter was used except in C_{mono}/C and the corresponding ε in Figs. 2 and 4 respectively, since, generally, the N–H vibrations, which derive from two components due to two N–H groups on dialkylurea, appear as only one band. The exceptional C_{mono}/C in Fig. 2 for the special three was estimated for only the higher component in splitting because the intensity of the lower component is considerably affected by the neighboring associated band.

The uncertainties of C_{mono}/C, B, $\nu_{1/2}$, and $\Delta\nu$ may be estimated to be about 4%, 0.5×10^3 $mol^{-1}\cdot cm^{-2}$, 7 cm^{-1}, and 5 cm^{-1} respectively.

Results and Discussion

It is expected that the bulkier the effective size of alkyl substituents on dialkylureas is, the larger the steric hindrance between the C=O and the substituents will be, and the harder the intermolecular association through hydrogen bond will be, thus weakening the intensities of associated bands. Figure 1 shows the expected spectral behavior of the broader associated N–H band in dialkylureas; in their associated band-intensities, *s*-DMU, with the smallest methyl groups, is the strongest, while *s*-D*t*BU, with the largest *tert*-butyl groups, is the weakest, the other two being in the middle.

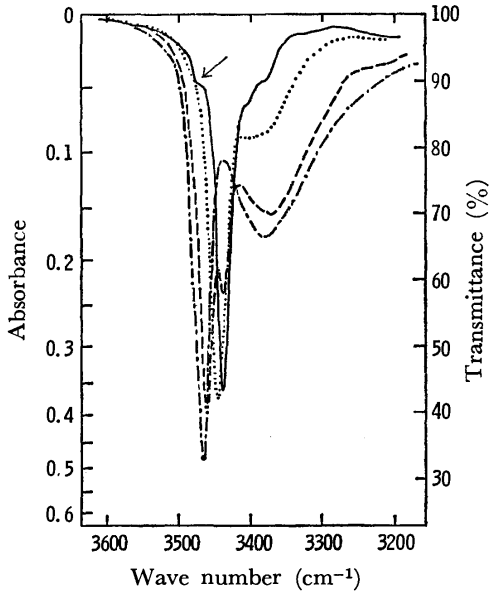

Fig. 1. Infrared spectra, N-H stretching region, of dialkylureas in CCl_4 (0.0025 M), ——————: *s*-DMU (1), ------: MU*i*P (4), ·····: EU*t*B (13), ——: *s*-D*t*BU (26). An arrow sign indicates the questionable band, which was assigned to the *trans* ν(N-H) vibration by Rao *et al.*[1]

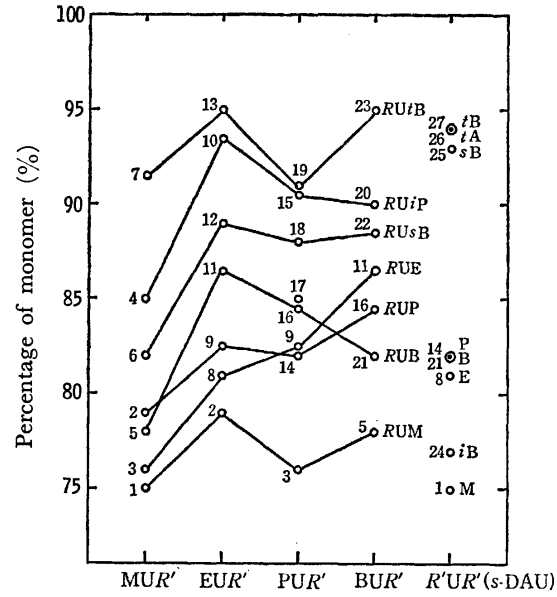

Fig. 2. The estimated percentage of monomer of dialkylureas in CCl_4 (0.0025 M). The points are numbered as in Table 1, column 1 (as in Figs. 3—7). The observed data for dialkylureas with the same *R*′ group are connected by a line.

The band-splitting of the monomeric absorption in MU*i*P (as well as in MU*s*B and MU*t*B) results from two different types of N-H groups, the higher component resulting from the methyl group, and the lower component, from the branched alkyl group, but not from rotational isomerism.[9,10] As the above monomeric band has been already assigned to the *trans* conformation except for the 3469 cm^{-1} band in *s*-D*t*BU,[9,10] it is also reasonable to similarly assign the associated band to the *trans* conformation.[13] Several spectral data obtained quantitatively are summarized in Table 1.

The estimated percentage of the monomer is plotted in Fig. 2 for four series of *R*HNCONH*R*′ (*RUR*′) according to the *R* group and a series with the same substituents (*s*-DAU). As may be seen in Fig. 2, the percentages are sensitive to the alkyl substituent and may be classified into three groups; the derivatives with a methyl group (*R*UM) have the lowest value, those with another primary alkyl group have a middle value, while those with such a branched alkyl group as isopropyl, *sec*- and *tert*-butyl have the highest value. The values for *s*-DAU are more sensitive to the alkyl substituents.

This suggests that the percentage roughly differentiates the alkyl substituent on dialkylurea. Also, the monomeric N-H stretching frequency of dialkylurea has been found to differentiate the alkyl substituent.[9,10] Therefore, we examined the correlation between the frequency and the percentage (Fig. 3). Figure 3 shows that the larger the percentage, the lower the frequency. It is interesting to note that the hydrogen-bonding formation ability of dialkylurea may, qualitatively but directly, be deduced from its monomeric N-H stretching frequency itself, though it can also, of course, be deduced from the well-established correlations of the frequency shift, $\Delta\nu$, with the physical properties.[14]

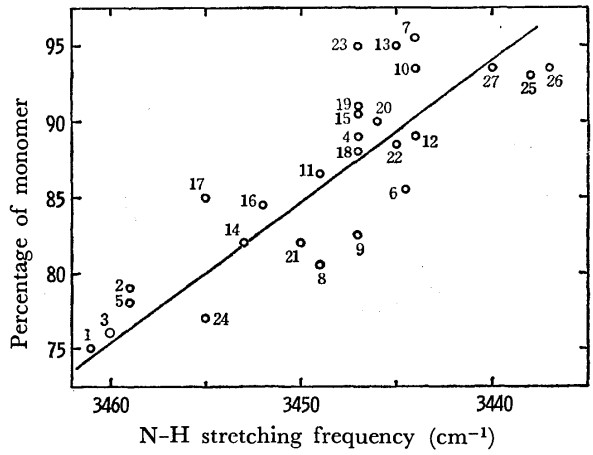

Fig. 3. The correlation between the monomeric N-H stretching frequency and the percentage of monomer.

Among the percentages of dialkylureas with a branched alkyl group or groups, there is no drastic difference, though there is a slightly increasing inclination in the percentage order: *RUs*B<*RUi*P<*RUt*B. This indicates that the steric hindrance between C=O and a *tert*-butyl group or groups is not large enough to drastically convert the *trans* conformation into the *cis* conformation. The indication adds support to our conclusions[9,10] that the dialkylureas examined exist dominantly in the *trans-trans* conformation in solution and that the stronger band at 3437 cm^{-1} of the two monomeric N-H stretching bands of *s*-D*t*BU arises from the *trans* conformation, contrary to the assignment by Rao *et al.*[11]

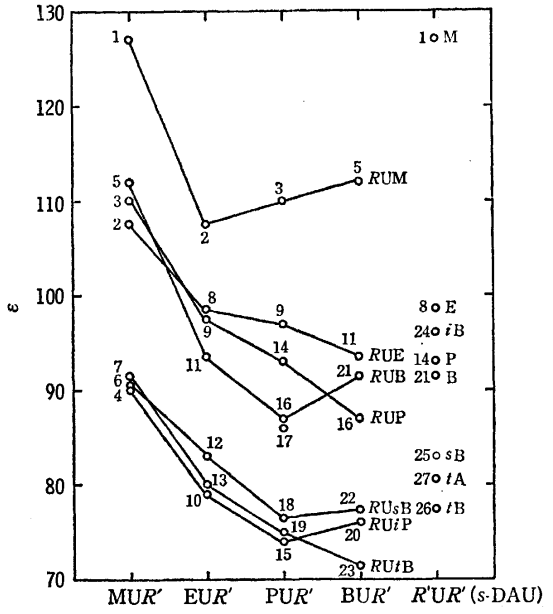

Fig. 4. The apparent molar extinction coefficient ε of dialkylureas in CCl_4 (0.0005 M, 5 cm).

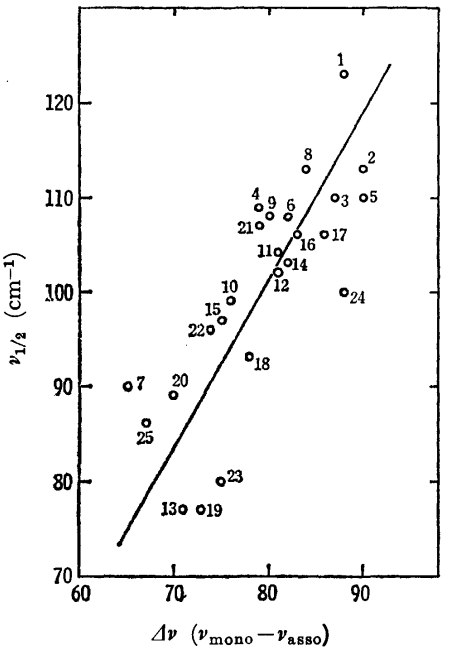

Fig. 5. The correlation between the frequency shift $\Delta\nu$ and the half-intensity width $\nu_{1/2}$.

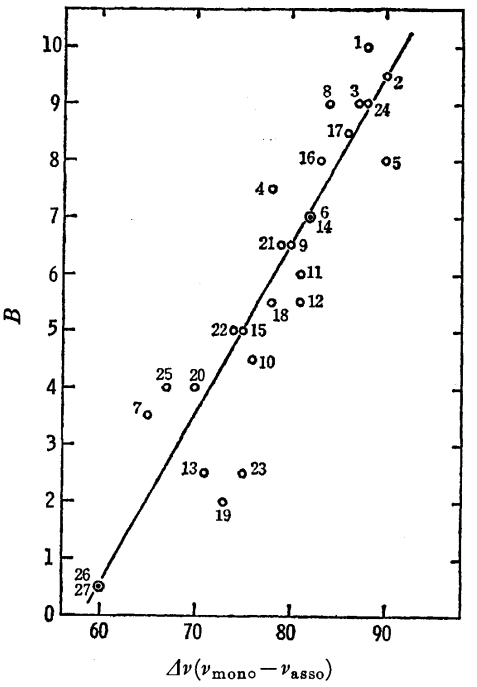

Fig. 6. The correlation between the frequency shift $\Delta\nu$ and the apparent integrated absorption intensity B.

The zig-zag-like line-plots in Fig. 2 seem to stem from the steric effect characteristic of the substituent on the hydrogen bond. The fact that no line-plots of the apparent molar extinction coefficients, ε, shown in Fig. 4 are zig-zag suggests that the steric effect affects the hydrogen-bonding formation and that the effect of the ethyl group is quite effective. Similar studies of *N*-alkylamides *R*CONH*R'* have shown that, of the *n*-alkyl groups, the ethyl group most greatly hinders the hydrogen-bonding formation, and that the effects of the longer-chain alkyl group are constant.[5,6]

The plots for ε may also be classified into three groups according to the *R'* group in *RUR'*. As there are large differences in ε among the three groups, it must be emphasized that when a hydrogen-bonding system is quantitatively studied, an examination should be made not only of the intensity of the associated band, but also of that of the monomeric band.

The amount of the X–H stretching frequency shift, $\Delta\nu$, upon a hydrogen-bonding system (X–H···Y) has generally been accepted as a measure of the strength of the hydrogen bond, and it has been directly related to the half-intensity width, $\nu_{1/2}$, and the intensity, B, of the associated band, the enthalpy of the hydrogen-bonding formation, and the X–H distance, but inversely related to the X···Y distance and the Hammett sigma function.[14,15]

In the present study, some correlations among spectral parameters have been examined for the hydrogen-bonding system of dialkylureas in a 0.0025 M carbon tetrachloride solution. It is quite evident from Table 1 and Fig. 1 that the bulkier the *R* and *R'* groups in *RUR'*, the smaller the $\Delta\nu$, $\nu_{1/2}$, or B value. The correlations between $\Delta\nu$ and $\nu_{1/2}$ or B were found to be linear (Figs. 5 and 6). A similar correlation was established between B and the estimated percentage of the associated species, C_{asso}/C (Fig. 7). The remarkable deviation of Points 26 (for *s*-D*t*BU) and 27 (*s*-D*t*AU) in Fig. 7 is considered to arise because their percentages of associated species were overestimated, since the questionable band at 3469 cm^{-1} in *s*-D*t*BU and the corresponding band in *s*-D*t*AU, which are also monomeric bands, as described, were not estimated to be added to their percentages of the monomer.

It is natural that the bulkier the alkyl substituents of dialkylureas are, the smaller the values of the $\Delta\nu$, $\nu_{1/2}$, B and C_{asso}/C become and, accordingly, the more closely the points approach to the original in Figs. 5—7.

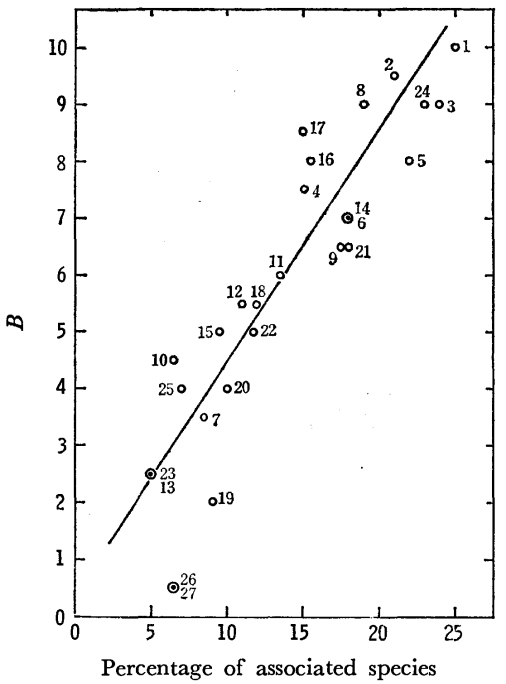

Fig. 7. The correlation between the estimated percentage of associated species C_{asso}/C and the apparent integrated absorption intensity B.

A comparison of the spectra of dialkylureas and *N*-alkylamides[6] shows clear differences in their spectral properties: (1) The $\Delta\nu$ values of the latter (*N*-alkylamides), when estimated from the spectra with N–H stretching band-intensities similar to those of the former, are approximately one and a half times as large as those of the former. (2) The former can form hydrogen bonds in a solution at a lower concentration than the latter. Probably, those spectral differences originate mainly from the differences in the electronic structure and the number of N–H groups per molecule. This consideration is supported by the facts that the C=O stretching frequencies of the former are generally higher than those of the latter, indicating the stronger tendency in the former to impart a double-bond character to the C=O bond, and that trialkylureas with only one N–H group give spectra with band-intensities similar to the latter at the same concentration.[16]

The author wishes to express his deep gratitude to Dr. Hiroatsu Matsuura of the Institute for Protein Research of Osaka University for his kind advice and to Prof. Hiromu Murata of Hiroshima University for his encouragement.

12) For dialkylureas, Rao *et al.* did not define the term "*cis* rotamer" with regard to the two C–N rotational axes. Three forms could be considered: the *trans-trans*, the *trans-cis*, and the *cis-cis* forms, but the *cis-cis* form is unlikely on steric grounds.[9] It is possible that there is no difference in the N–H frequency for the *trans* conformation between the *trans-trans* and the *trans-cis* forms. We propose that the *cis* conformation represents only a *cis* relation between an N–H group and a C=O group about the C–N rotational axis.
13) If the associated band of the *cis* conformation is considered in relation to the case of secondary amides, it must appear 100—150 cm^{-1} lower than that of the *trans* conformation.[1,4,5]

The Molar Volume and Entropy of Adsorbed Methane on Porasil

Yoshio HORI* and Riki KOBAYASHI

Department of Chemical Engineering, Rice University, Houston, Texas 77001, U. S. A.

(Received October 25, 1973)

With the use of high-precision gas-chromatography, the multilayer adsorption of methane on fused silica beads was precisely measured between 145.0 K and 213.6 K. The molar volume and the partial molar entropy of the adsorbed methane were determined as a function of the temperature. The molar volume in the monolayer region depends much less on the temperature than that of the bulk liquid. However, the molar volume of multilayer adsorbed methane shows a dependence on the temperature similar to that of bulk liquid, which is at a lower temperature. The volume of the monolayer is practically constant under the present experimental conditions. The apparent thickness of the adsorbed monolayer was interpreted in terms of a simple collision model. The partial molar entropy of the adsorbed phase is much lower than that of the saturated bulk liquid. The lower dependence of the molar volume on the temperature and the lower entropy suggest that the freedom of motion of the adsorbed molecules is restricted as compared with those in bulk liquid.

The series perturbation technique,[1] a refined form of "Hypothetical perfect gas perturbation,"[2] was described in a previous paper and shown to be useful in the study of adsorption. The absolute adsorption and the molar volume of adsorbed methane can be measured by means of this technique. The molar volume of adsorbed methane was verified by the analysis of the dependence of Gibbs adsorption on the gas phase density, which was discussed previously.[1]

In order to measure the precise values of the molar volume of the adsorbed phase, a high-precision gas-chromatography was developed. The apparatus was equipped with a high-precision flow meter described elsewhere.[3] In addition to the molar volume of the adsorbed phase, the entropy of the adsorbed phase will be presented here.

Experimental

Apparatus. The high-pressure gas-chromatographic apparatus[1] was modified for the precise measurement of the retention volume. The apparatus consists of two sets of the ordinary gas-chromatographic apparatus. One has a column packed with an adsorbent for the measurement of the physical adsorption. The other is connected to the outlet of the former one and is used as a flow meter. A differentiator and a high-precision timer are combined with the latter chromatographic apparatus to give precise measurements of the flow rate of the carrier gas.[3] The general features of the apparatus are similar to the one described previously.[1] Therefore, only the modifications for precise measurement will be described here.

The pressure of the perturbation gases was kept equal to that of the carrier gas. The volume of the loop of the sample injection valve (a dose of perturbation gas) was about 50 μl. The carrier gas and all the perturbation gases were dried with magnesium perchlorate before entering the system. The column packed with the adsorbent was immersed in a thermostat filled with isohexane or isopentane. The thermostat was cooled by liquid nitrogen, and the temperature was maintained as constant as ±0.02° by means of a Thermotrol, Model 1053 A, manufactured by Hallikainen Instruments. The temperature distribution in the thermostat was uniform at any temperature in the present study in the range of ±4 inches from the column position. A flow-through thermal conductivity cell, Model 10-460 by Gow-Mac, was used. The gas volume of the thermal conductivity cell was 0.35 ml. The signal was recorded by means of a recorder, Speedomax W/L, made by Leeds & Northrup. The response time (full span) of the recorder was 0.5 s. The thermal conductivity cell and the expansion valves were immersed in the thermostat at 35.0 °C.

Materials. All the gases except radioactive methane and the adsorbent Porasil are the same as those used in the previous study.[1] The tritiated methane was purchased from New England Nuclear. The perturbation gases were diluted with the carrier gas (methane) in the following ratios: helium 1/32, neon 1/16, argon 1/32, and tritiated methane 0.5 curie in 560 ml of methane at 130 atm. The diluted perturbation gases were stored in 560 ml cylinders made of stainless steel.

Determination of Retention Time. The shape of an elution peak corresponds to the concentration distribution of a perturbation gas in the eluted carrier gas. The retention time is defined as the value averaged over this distribution curve:

$$t_r = \int_0^\infty y \cdot t dt \Big/ \int_0^\infty y dt$$

Here, y is the height of the elution peak at time t. When a perturbation gas is injected, a precision timer is triggered by a microswitch attached to the sample injection valve. The precision timer is turned off manually in the vicinity of the top of the elution peak, and this turn-off signal is marked on the recorder chart by an event marker. The precision timer is used to minimize the effect of any possible shrinkage or expansion of the chart paper.

The retention time, t (min), was calculated as below:

$$t_r = t_0 + \frac{l_c - l_m}{u}$$

t_0 (min) is the time elapsed between the turning on and off of the timer described above. l_m (cm) is the position of the turn-off mark on the recorder chart with reference to the outset of the elution peak. u (cm/min) is the chart speed of the recorder. u was taken at 10.16 cm/min during the course of this work. l_c is the center of gravity of the eluted peak:

$$l_c = \int_0^{l_2} y \cdot x dx \Big/ \int_0^{l_2} y dx = \sum_{i=0}^{s} x_i \cdot y_i \cdot \Delta x \Big/ \sum_{i=0}^{s} y_i \cdot \Delta x$$

where x (cm) is the position in the chart with reference to the outset of the peak and where l_2 is the position of the end of the peak. The other values follow the usual substitution

* Present address: Research Department, Kikumoto Works, Sumitomo Chemical Co., Ltd., Niihama, Ehime 792

of an integration with summation. The value of s was taken between 25 and 40 for an elution peak.

Source of Experimental Error. The retention times for He, Ne, Ar, and CH_3T were reproducible within 0.1% in any experimental run in this apparatus. The precision of the flow meter was 0.06% as has been discussed elsewhere.[3] Therefore, there must be other sources of experimental error. As a matter of fact, the flow rate was found to change when an eluted perturbation gas passed through the expansion valve. The carrier gas flows through the expansion valve in a viscous flow across a great difference of pressure. On the other hand, the composition of the part of the carrier gas including an eluted perturbation gas is a little different from pure carrier gas. This difference in composition gives rise to a change in the viscosity, resulting in the slight change in the flow rate mentioned above. Since the retention volume is calculated as the difference between the column value and the by-pass one (see Eq. (1) in Ref. 1), the viscosity effect will be cancelled out in the first order approximation. However, a delicate difference in flow pattern may bring about some scattering of the retention volumes. This viscosity effect will cause the sample-size effect, which was minimized in the present study by choosing the concentration of the perturbation gases stated above.

Results and Discussion

Adsorption Isotherm. The experimental data obtained by means of present apparatus were treated according to the series perturbation method previously reported.[1] The values of the absolute adsorption* of methane on Porasil between 145.0 K and 213.16 K are tabulated in Table 1. The isotherms show typical multilayer adsorption.

Molar Volume of the Adsorbed Methane. The free gas volume of the chromatographic column varies with the amount of adsorption. Figure 1 shows this relation in the present study after the correction of the thermal expansion of the stainless steel column and Porasil. In the interests of simplicity, the results at 193.16 K and 181.23 K are not shown in Fig. 1. The free gas volume decreases linearly up to 7 mmol/g,

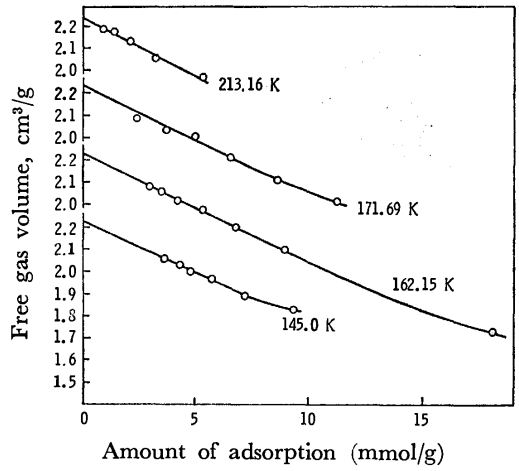

Fig. 1. Dependence of the free gas volume upon the amount of adsorption.

* The amount of adsorption discussed in this paper is the "absolute adsorption" described previously.[1]

Table 1. Absolute adsorption of methane on porasil

but the plots become curved near 10 mmol/g. The slopes of the straight lines were computed by the least-squares method between 0 and 7 mmol/g. The results, shown in Fig. 2, show the molar volume of the adsorbed phase between 0 and 7 mmol/g, V_a. The average molar volume, V_m, of the adsorbed phase near 10 mmol/g was estimated by means of:

$$V_m = \{V_g(0) - V_g(N_A)\}/N_A$$

where $V_g(0)$ and $V_g(N_A)$ are the free gas volume at the amount of adsorption 0 and N_A mmol/g. The value of $V_g(0)$ was estimated from the extrapolation linearly to zero adsorption in Fig. 1. The molar volume, V_m, is also plotted against the temperature in Fig. 2, with the molar volume of saturated liquid methane[4] shown for comparison. The data obtained from the previous paper are indicated by closed circles. The V_a is higher than that of liquid methane at lower temperatures and changes slowly with the temperature. On the other hand, V_m increases with the temperature in the linear extension of liquid methane at lower temperatures. These facts suggest that the adsorbed phase

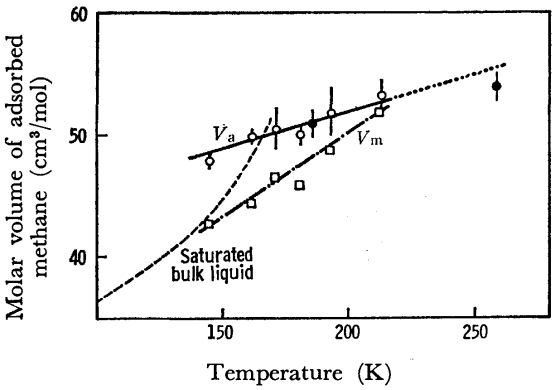

Fig. 2. Change of molar volumes of adsorbed methane with temperature. V_a is the molar volume near monolayer, and V_m is that averaged over 10 mmol/g of adsorption.

near the monolayer is quite different from the liquid phase, but that the multilayer adsorbed phase would be similar to the liquid phase at lower temperatures.

Temperature Dependence of the Monolayer Capacity. The adsorption data were processed according to a modified BET method which has three parameters:[5]

$$\Phi/N_A = 1/(N_0 \cdot C) + \Theta/N_0$$
$$\Phi \equiv x[(1-x^n)-nx^n(1-x)]/(1-x)^2$$
$$\Theta \equiv x(1-x^n)/(1-x)$$
$$x \equiv P/P_0$$

N_0 is the monolayer capacity (mmol/g). P and P_0 are the adsorption pressure and the saturation pressure of the bulk liquid at the same temperature. n is a parameter adjustable so as to give the best straight line in the Φ/N_A *vs.* Θ plot. Straight lines were obtained where x was less than 0.6. The values of n lie between 5.5 and 6. In Table 2 are tabulated the values of N_0 obtained by this procedure. It is remarkable that the monolayer capacity changes very slowly with the temperature. The volume of the monolayer, V_0, can be evaluated by means of:

$$V_0 = V_a \cdot N_0$$

with the V_a as shown in Fig. 2. The V_0 value appears in the third column of Table 2. The monolayer volumes are apparently independent of the temperature.

Apparent Thickness of the Monolayer. One can estimate the apparent thickness of the monolayer, h_0, from this relationship:

Table 2. The monolayer properties of adsorbed methane on porasil

T K	N_0 mmol/g	V_0 cm³/g	h_0 Å
213.16	3.04±0.02	0.161	3.34
193.16	3.13±0.01	0.162	3.36
181.23	3.17±0.01	0.159	3.30
171.69	3.18±0.02	0.161	3.34
162.15	3.23±0.01	0.161	3.34
145.00	3.28±0.02	0.157	3.26

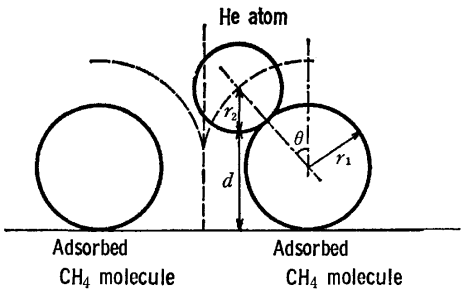

Fig. 3. A collision model of a perturbation gas atom and adsorbed methane molecules.

$$h_0 = V_0/A$$

where A is the surface area of the adsorbent, 482 m²/g according to conventional BET, using nitrogen with molecular cross-sectional area of 16.2 Å². The thickness of the monolayer, shown in the fourth column of Table 2, is virtually constant.

Since an adsorbed molecule will vibrate normal to the surface, the thickness of the monolayer must be larger than the collision diameter of the adsorbate molecule. Therefore, it seems to be contradictory that the apparent thickness of the monolayer is 3.31 Å, while the collision dimaeter of methane is 3.817 Å.[6] This will now be explained. Let us take an example of a helium atom moving normal toward the surface (Fig. 3). The helium atom will hit an adsorbed methane molecule and fly back to the gas phase again. The distance between the center of the helium atom and the surface is r_2+d when a helium atom is in contact with a methane molecule (Fig. 3), where r_1 and r_2 are 1/2 of the collision diameters of methane and helium respectively. The contribution of r_2 has already been corrected to the steric effect in the series-perturbation theory by adding $A \cdot r_2$ to the retention volume of helium,[1] where A is the surface area of the adsorbent. Thus, the thickness of the adsorbed layer may be observed to be d in that collision. The apparent thickness of the adsorbed layer can be estimated by averaging the d values over the surface of the adsorbed methane molecule. If adsorbed methane molecules are arranged in a hexagonal closed packing position, and if the monolayer capacity is assumed to be 3.20 mmol/g, the apparent thickness of the adsorbed layer can be estimated to be 3.0 Å by a simple calculation. In this estimation, the collision diameters of helium and methane are taken to be 2.56 Å and 3.82 Å respectively.[6] If the helium atom moves parallel to the surface, the apparent thickness will be observed to be equal to 3.82 Å. Therefore, the actual value of the apparent thickness must be a certain value between 3.0 Å and 3.82 Å. If one takes into account the vibrational motion of adsorbed methane normal to the surface, the observed apparent thickness (3.31 Å) is in good agreement with the value estimated above.

Entropy of the Adsorbed Methane. The experimental data were treated according to a procedure described previously.[7] Figure 4 shows the plots of $\log f$ *vs.* $1/T$ at fixed amounts of adsorption, where f

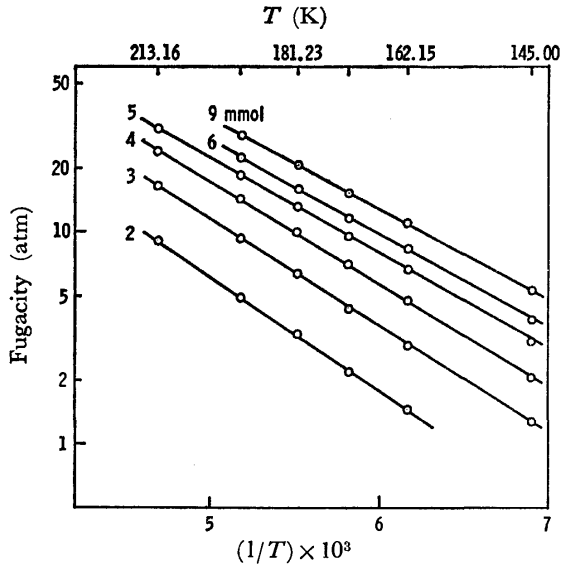

Fig. 4. Plots of $\log f$ *vs.* $1/T$ at fixed amounts of adsorption.

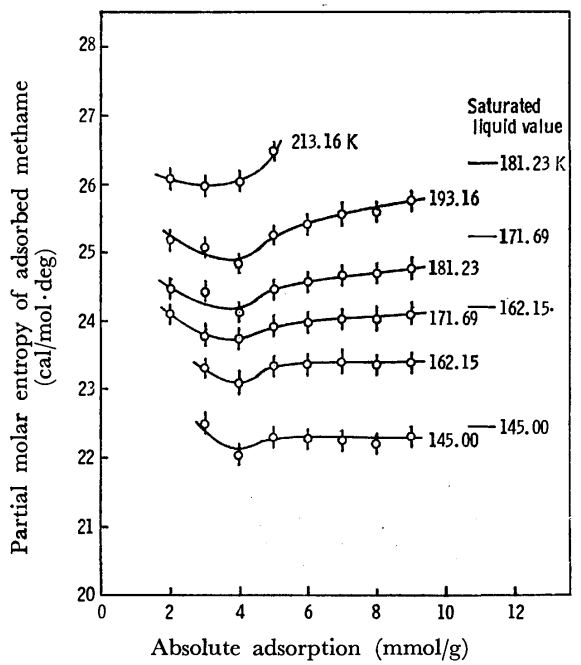

Fig. 5. Entropy of saturated liquid methane is indicated in the right-hand side.

is the equilibrium fugacity. The experimental points for 7 and 8 mmol/g are not shown for the sake of simplicity. Single straight lines can be drawn over all the range of temperatures. The slopes of the straight lines were determined by the least-squares method.

The partial molar entropy of the adsorbed methane was also calculated; it is shown in Fig. 5.** In Fig. 5 the molar entropy of saturated liquid methane is also shown at various temperatures. The partial molar entropy of the adsorbed phase at 145 K is nearly equal to the molar entropy of saturated liquid at the same temperature.*** However, above 145 K the partial molar entropy of the adsorbed methane is much lower than the molar entropy of the saturated liquid. As has been mentioned above, the temperature dependence of the molar volume of the adsorbed methane, V_m, is much lower than that of the bulk liquid (Fig. 2). V_m increases linearly with the temperature near the critical temperature (190.9 K[8]), like an extension of the molar volume of saturated liquid methane at lower temperatures. This may be explained as follows. The surface will attract adsorbate molecules and prevent the intermolecular distance from increasing steeply near the critical temperature. These facts suggest that the freedom of motion of the adsorbed molecules is restricted above 145 K as compared with that in bulk liquid.

Grant and Manes[9] stated that the liquidlike state may persist on the adsorbent at temperatures far above the critical temperature of the free liquid. Their assumption was previously verified by the present authors.[7]

Brunauer[10] suggested that multilayer adsorption probably occurs at temperatures where molecular clusters can exist in the gas phase, *i. e.*, for temperatures up to 10 to 15° above the critical. However, the present authors investigated the high-pressure adsorption of methane on Porasil, and found that multilayer adsorption takes place as much as 40° above the critical temperature. The −19.9 °C isotherm, 60° higher than the critical, reaches about 1.6 times the monolayer coverage.[1]

These findings indicate that the surface attracts adsorbate molecules very strongly, even over the monolayer coverage, and that multilayer adsorbed molecules possess less freedom of motion than those of bulk liquid at the same temperature.

Financial support was supplied by the U. S. National Science Foundation.

** The values of entropy above 4 mmol/g of adsorption at 213.16 K and 193.16 K differ somewhat from those reported in the previous paper.[7] This disagreement comes from the different temperature ranges of measurement in the two studies. It is impossible at present to tell whether or not the discrepancy is meaningful.

*** The measurement could not be made below 145.0 K for the following reason. In order to obtain precise values of the retention time, the flow rate must not be two low at the detectors. On the other hand the pressure drop across the column is to be low enough to be negligible. Therefore the pressure should be appreciably higher inside the column than at the detector. (*i.e.* 1 atm) However, the vapor pressure of methane becomes very low below 145.0 K (for example, 2.67 atm at 125 K). Consequently, it is impossible to measure an appropriate adsorption isotherm.

The Electro-Initiated Polymerization of Acrylamide in an Aqueous Solution of Trifluoroacetic Acid and Potassium Trifluoroacetate*

Zenpachi OGUMI, Isao TARI,** Zenichiro TAKEHARA, and Shiro YOSHIZAWA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received November 2, 1973)

The electro-initiated polymerization of acrylamide was investigated in an aqueous solution of trifluoroacetic acid and potassium trifluoroacetate. An oligomer with a molecular weight of 4000—6000 was thus obtained. The initiating ability of Kolbe's intermediate radicals was recognized by an analysis of the fluorine contained in the polymerized products as the end group. Kolbe's intermediate radicals, R·, react with monomers, M, to form RM·, which takes the paths of polymerization and other reactions. The rate of reaction to form RM· is so fast that no Kolbe's dimer, C_2F_6, is obtained. Gas analysis clarified the ratio of $CF_3COO\cdot$ to $CF_3\cdot$, which reacted with the monomer. The comparison of the molecular weights as measured by the two different methods suggests that the coupling reaction of radical ends terminates the propagation reaction. The rate of oligomer production was independent of the current density.

Over a period of years, much interest has been shown in electrolytic methods of initiating a polymerization, the so-called electro-initiated polymerization. A few papers have been reported concerning utilizing Kolbe's electrolysis as a source of free radicals for initiating polymerization. Yoshizawa *et al.*[1] obtained a polymerized acrylamide with a molecular weight of 700—1500 by the electro-initiated polymerization of acrylamide in an aqueous solution of acetic acid and potassium acetate. In this paper, the polymerization of acrylamide in an aqueous solution of trifluoroacetic acid and potassium trifluoroacetate was examined. The use of trifluoroacetate instead of acetate allows us to make sure whether Kolbe's radicals initiate the polymerization or produce the initiating species from an analysis of fluorine, which is considered to be present as the end group. From the results of the current efficiency of the production of oligomer and the relation between the rate of electrode reaction and that of polymerization, a path of the production of the oligomer may be suggested. Furthermore, information about Kolbe's intermediate radicals may be obtained.

Experimental

An H-shaped glass fitted with a fine fritted glass filter as a diaphragm was used as the electrolysis cell. Smooth platinum plates (3×3 cm^2) were used as electrodes. One of them was coated on one side with silicon resin for use as a working electrode, and this one was electrolyzed anodically and cathodically, alternately, and finally cathodically in 0.5 M H_2SO_4 at 20 mA/cm^2 as pretreatment. After that, it was washed with distilled water and electrolytes and then used immediately. Trifluoroacetic acid (commercial G.R. grade) was used.

The content of iron compound in it, which is known to affect the polymerization of acrylamide,[2] was less than 0.003 %, and this is low enough to have no effect on this experiment. Four mol of this reagent and 2 mol of potassium hydroxide (comercial G.R. grade) were dissolved in distilled water to 1 liter. This solution will be designated as TFA+TFK 4M from now on. The monomer of acrylamide was recrystallized from benzene and dried under air. The acrylamide thus refined, which will be designated as AAM, was stored in a dark and cold place and used within a week. The anolyte was prepared by dissolving a given amount of AAM in 100 ml of TFA+TFK 4M. TFA+TFK 4M was used as a catholyte without any addition of AAM. Electrolysis was carried out in an ice-water bath. Nitrogen was bubbled from 30 min before the beginning of the electrolysis to its end. The potential-current curve was potentiostatically obtained by the use of a rotating disk electrode (the surface area was 1 cm^2) in order to prevent the working electrode from being covered by the gas evolved. When the anolyte was poured into 1 liter of methanol after electrolysis, a white precipitate of an insoluble polymerized product came out. This was filtered through a #4 glass filter, dried at 60—80 °C under reduced pressure, and weighed. The viscosities were determined in an Ubellohde viscometer mounted in a thermostated bath held at 30.00±0.05 °C. The intrinsic viscosities were determined by means of the usual graphic plots. The weight-average molecular weight was calculated by means of the equation: $[\eta]=3.73\times10^{-4}\times M_w^{0.66}$.[3] To examine the possibility of the hydrolysis of the amide group to acid, the pH titration of the aqueous solution of the product was carried out. The results showed no hydrolysis occurring.

Results

Fluorine Content in Polymerized Products. The polymerized product obtained by the electrolysis of TFA+TFK 4M 100 ml+AAM 20 g at the anodic current of 400 mA/9 cm^2 was dissolved into the distilled water; this solution was poured into methanol in order to free the occluded fluorine from the product. The fluorine content in the product purified by repeating this process five times was examined by elemental analysis. Its content was between 2 and 3 percent. On the other hand, the polymerized product obtained by the electrolysis of a solution of acetic acid and its potassium salt was dissolved into TFA+TFK 4M, and then the fluorine content of this sample was examined. However, only a trace of fluorine was detected. These results clearly indicate that fluorine was included in the product *via* electrode processes.

Potential-current Relationship. The steady-state potential-current relationship was potentiostatically obtained. In this experiment, a rotating disk electrode

---: ohmic drop corrected

was used for the reason described above. The ohmic drop between the working and reference electrodes was not corrected in Fig. 1. This correction would cause Curve 2, measured in the solution containing AAM, to be almost the same as Curve 1, measured in the solution containing no AAM, as is shown by the dotted line. These curves show a current plateau which is characteristic of the Kolbe reaction.

Relationship between the Electrolysis Time and the Yield of an Oligomer. As is shown in Fig. 2, the yields of the oligomer increase linearly with the electrolysis time until four hours. This shows that the yield can be normalized independent of the electrolysis time, so that the induction period of oligomer production can be very short and the conditions can be kept constant during the electrolysis. Lying for eight hours under the same conditions except for a current passing through gave no polymerized product.

The Effect of the AAM Concentration on the Yields. The dependence of the yields on the concentration of AAM was examined at a current of 440 mA/9 cm².

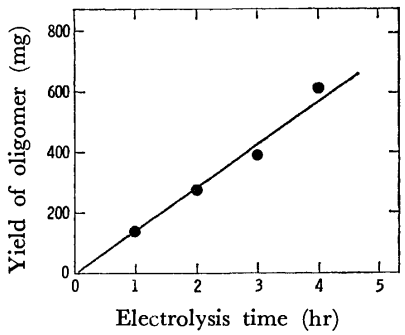

Fig. 2. Dependence of yields on electrolysis time in the solution of TFA+TFK 100 ml+AAM 20 g.
Current: 400 mA/9 cm²

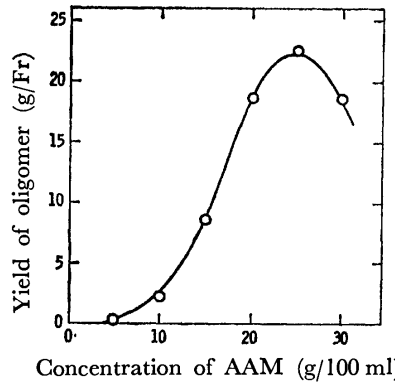

Fig. 3. Dependence of yields on the concentration of AAM in the solution of TFA+TFK 4M
Current: 400 mA/9 cm²

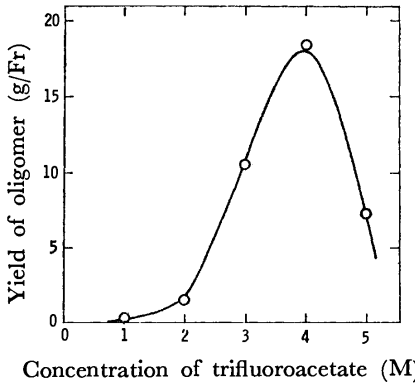

Fig. 4. Dependence of yields on the concentration of trifluoroacetate.
AAM 20 g per 100 ml of solution
Current: 400 mA/9 cm², $CF_3COOH:CF_3COOK=1:1$

The results are presented in Fig. 3.

The Effect of the Concentration of Trifluoroacetate on the Yields. The dependence of the yields on the concentration of trifluoroacetate was examined at the current of 400 mA/9 cm². In these experiments, the ratio of trifluoroacetic acid to potassium trifluoroacetate was kept constant at 1 : 1. The results shown in Fig. 4 show the maximum and the disagreement with the results obtained in the case of acetate, which shows a linear dependence.[1)]

The Effect of the Current Density on the Yield. In order to investigate the effect of the current density on the yield, electrolysis was carried out at different current densities under the conditions of TFA+TFK 4M 100 ml+AAM 20 g. The results are shown in Fig. 5.

Analysis of Evolved Gases. A gas chromatographic technique was utilized to determine the gaseous products which were formed during electrolysis. The oxygen, tetrafluoromethane, hexafluoroethane, and carbon dioxide were analyzed by using the stationary phase of silica gel, Porapak K, and molecular-sieve 5A. The retention time was used for the qualitative analysis. The relative sensitivities, $N_2 : O_2 : CO_2 : CF_4 : C_2F_6 = 1.00 : 1.05 : 0.872 : 0.541 : 0.485$, were used for the quantitative analysis. Table 1 shows that both carbon dioxide and hexafluoroehane were evolved at high current efficiencies when no AAM was added, while,

Table 1. Current efficiency of gaseous products
Solution: TFA+TFK 4 M, Platinum electrode

AAM (g/100 ml)		0			20		
C. D. (mA/cm²)		20	30	40	20	30	40

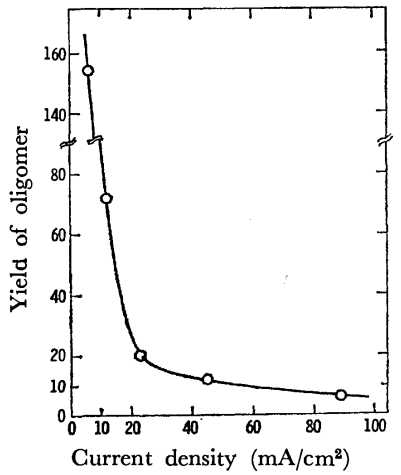

Fig. 5. Dependence of yields on current density in the solution TFA+TFK 4 M 100 ml+AAM 20 g.

on the other hand, the addition of AAM to anolyte caused a significant decrease in the current efficiency of the evolution of carbon dioxide and allowed the production of only a trace of hexafluoroethane. These results indicate that the intermediate radicals produced (R·) by electrolysis on the electrode do not further the normal coupling process of Kolbe's reaction, but react with the monomer (M) to form RM·. Whether CF_3COO· or CF_3· of the intermediate radicals reacts with the monomer was determined by a comparison of the current efficiencies of the evolution of gases between the cases without and with the addition of AAM. The results are shown in Table 2.

40	37	52

Molecular Weight. The molecular weight was determined by means of two methods, one was based on viscosity measurements, and the other one, on a quantitative analysis of the end groups of the product by measuring the fluorine content. The results calculated by the two different measurements are listed in Table 3. The calculation in the latter method was carried out on the assumption that both ends of a product had a trifluoromethyl group. This table shows that the molecular weight does not depend on the current density.

Discussion

The facts that fluorine was detected in the polymerized products and that the molecular weights calculated from the fluorine contents were almost equal to those obtained by means of viscosity measurements indicate that Kolbe's electrochemical reaction produces the initiating species of polymerization and that termination is caused by a coupling reaction of radicals. It had previously been certified that the charge transfer of monomeric acrylamide on the anode does not take place under the experimental conditions adopted here. It has been reported that, in an experiment using acetic acid and potassium acetate, the oligomer with a molecular weight of about 1000 was produced.[1] On the other hand, in this experiment an oligomer with a molecular weight of 4000—6000 was obtained. This may be considered because of the difference in the possibilities of chain transfer to species in the electrolyte. The polymerized product was identified by means of IR spectroscopy as the oligomer of acrylamide. The electrochemical reaction of trifluoroacetate was extensively investigated in detail by Conway *et al.*[4] They proposed that trifluoroacetate furthers the process of Kolbe's reaction on the platiniumine electrode as follows, in the same way as in the case of acetate:

$$CF_3COO^- \longrightarrow CF_3COO\cdot + e \qquad (1)$$

Table 3. The effect of current density on the products

$$CF_3COO\cdot \longrightarrow CF_3\cdot + CO_2 \quad (2)$$

$$CF_3\cdot \longrightarrow 1/2C_2F_6 \quad (3)$$

or

$$CF_3COO\cdot \longrightarrow 1/2C_2F_6 + CO_2 \quad (4)$$

Many workers have proposed different mechanisms for Kolbe's reaction. We consider that the free radical mechanism is most reasonable. In this work, however, gas analysis has clearly shown that the addition of AAM to the anolyte resulted in preventing the evolution of Kolbe's coupling product, C_2F_6. This indicates that the intermediate species, $CF_3COO\cdot$ and/or $CF_3\cdot$, produced by the charge transfer of trifluoroacetate on the anode react with the monomeric acrylamide existing near the anode much faster than they react in the path of Kolbe's coupling process which produces C_2F_6 and forms RM·. The radicals, RM·, produces in this way react among themselves or with R· and monomers. The current efficiencies of the production of oligomers can be calculated from the yields and molecular weights of oligomers. As is shown in Fig. 6, a straight-line relation on logarithmic coordinates was obtained. This means that the rate of the production of the oligomer is independent of the rate of the electrode process and becomes a very slow and almost constant value compared with the latter. All this indicates that most of the RM· produced disappeared without furthering the polymerization. This result can be explained by considering in the same way as in the "cage effect theory," which is extensively used on the discussion of polymer chemistry. The RM· produced exists on the electrode surface or in the vicinity of the electrode, where the concentration of radicals is so high that the coupling reaction occurs easily. This is why the initiating efficiency of R· becomes very low. Thus, the polymerization may proceed as follows.

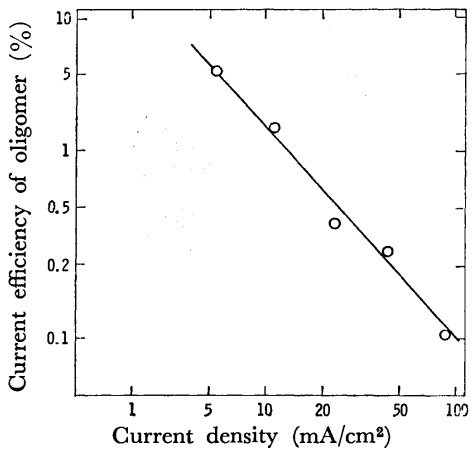

Fig. 6. Dependence of current efficiencies for polymerization on current density.

$$R\cdot + M \xrightarrow{\text{fast}} RM\cdot \quad (5)$$

$$2RM\cdot \longrightarrow RMMR \quad (6)$$

$$RM\cdot + R\cdot \longrightarrow RMR \quad (7)$$

$$RM\cdot + M \xrightarrow{\text{slow}} RMM\cdot \dashrightarrow \text{oligomer} \quad (8)$$

R· is $CF_3COO\cdot$ and/or $CF_3\cdot$, and the ratio of $CF_3COO\cdot$ to $CF_3\cdot$ can be calculated from the gas analysis, as is shown in Table 2. The production of the high polymer of acrylamide caused by the addition of iron compounds to the solution adopted here has already been reported.[2] With reference to this evidence, intermediate radicals, RM·, and Kolbe's radicals can not exist as literally "free" radicals, because, if so, they would react to the high polymer, instead, they interact with the electrode. The region where polymerization takes place will be discussed in detail in following papers.

Force Field of Allene

Kazutoshi TANABE and Shinnosuke SAËKI

National Chemical Laboratory for Industry, Honmachi, Shibuyaku, Tokyo 151

(Received November 5, 1973)

The force constants based on the simple or modified Urey-Bradley, and the general force fields have been determined from the observed fundamental frequencies, Coriolis coupling constants and centrifugal distortion constants of allene C_3H_4, C_3D_4 and $C_3H_2D_2$ by the damped least-squares method. It is concluded that the simple or modified UBFF is not suitable for reproducing the observed data. In order to attain the best fit between the observed and calculated values, new bond-angle interaction constants q(CH, CCC) and q(CC, HCH) as well as the bond-bond and angle-angle interaction constants p and l should be added to the simple UBFF.

The intramolecular force field of an allene molecule is of interest in connection with the electronic structure of the adjacent double bond system in the molecule. Although there are many papers on the measurements and analysis of infrared or Raman spectra,[1-19] calculation of the force constants for the allene molecule has not yet been thoroughly accomplished.

Shuler and Fletcher[8] observed the infrared spectrum of allene-d_2 and calculated the force constants from the observed frequencies of allene-h_4 and -d_4 to support the assignment of the fundamental frequencies of allene-d_2. Sverdlov and Borisov[20,21] determined the force constants and calculated the normal frequencies allene-h_4, -d_1, -1,1-d_2, -1,3-d_2, -d_3 and -d_4 in order to to elucidate the peculiarity of the vibrational spectra of compounds with cumulated double bonds. Venkateswarlu and Pillai[22] determined the force constants from the observed Raman and infrared data, and compared these results with those of molecules having similar chemical bonds. Cyvin,[23] and Andersen *et al.*[24] determined the force constants in order to evaluate the mean amplitudes of vibration for allene-h_4, -d_1, -1,1-d_2, -1,3-d_2, -d_3, -d_4 and -t_4. Fletcher and Thompson[25] applied the Hybrid Orbital Force Fiele (HOFF) to the allene molecule, and determined the force constants from the vibrational frequencies and Coriolis coupling constants of allene-h_4, -d_4 and -1,1-d_2.

However, according to latest studies, some of the observed vibrational frequencies or Coriolis coupling constants used in these papers are proved to be based on erroneous assignment. Nemes *et al.*[26] determined the force constants from the observed data of the fundamental frequencies and the Coriolis zeta constants of allene-h_4, -d_4 and -d_2, but their analysis was made only on the E species vibrations of the allene molecule.

Very recently, the centrifugal distortion constants of allene-d_2 has been obtained from the analysis of microwave spectrum.[27] For allene-h_4 and -d_4, Maki and Toth[17] measured the vibration-rotation spectra with a high resolution, and obtained the values of D_J and D_{JK}. Inclusion of these centrifugal distortion constants into the calculation of the force constants will lead to a better determination of the force field of the allene molecule.

We have determined the force constants of the allene molecule in order to attain the best fit between the observed and calculated values of the thirty-seven fundamental frequencies, ten Coriolis coupling constants and five centrifugal distortion constants of allene-h_4, -d_4 and -1,1-d_2. From the values of the force constants based on the simple or modified Urey-Bradley, and the more general force field, the intramolecular force field of the allene molecule has been discussed in relation to the electronic structure of the adjacent double bond system in the molecule.

Calculation

The observed data of the fundamental frequencies, the Coriolis coupling constants and the centrifugal distortion constants of allene-h_4, -d_4, and -d_2 have been taken from the literature where the correct band assignment was made. Since the ν_7 and ν_{10} bands of allene-d_2 have not been observed in the spectra, their frequencies have roughly been estimated by the frequency product rule.[5,26] For the ν_{11} and ν_{15} bands of allene-d_2, the frequencies estimated from the combination bands have been adopted.[8]

In calculating the force constants from the observed data of the fundamental frequencies, the Coriolis coupling constants and the centrifugal distortion constants, the statistical weights for these data are of much significance in the least-squares determination. The final results are very sensitive to the allocation of the statistical weights for the observed data. We have taken the statistical weight of a given observed datum as the squared reciprocal of its experimental uncertainty, in accordance with Nemes *et al.*[26] and Aldous and Mills.[28]

For the experimental uncertainty of a fundamental frequency, 1% of the observed wave number has been taken, the vibrational anharmonicity or any resonance effect being taken into consideration. The value 0.02 has been taken for the uncertainty of a Coriolis coupling constant. The uncertainty of a centrifugal distortion constant has been taken from the experimental error given in the literature.[17,27] The uncertainty for the estimated vibrational frequencies of allene-d_2 (ν_7, ν_{10}, ν_{11} and ν_{15}) has been taken to be 15 cm^{-1} according to Nemes *et al.*[26] The observed data and their uncertainties used in the least squares calculation are summarized in Table 1.

The computation of normal frequencies by means of Wilson's GF matrix method and the refinement of force constants by the least squares method have been carried out using a FACOM Model 270-30 electronic computer system. The molecular structure parameters used in the computations are taken from the work of Maki and Toth[17] as follows: r(C–H)=1.087(A), R(C=C)=1.308, and $\angle$HCH=118°10′. The internal

coordinates and the symmetry coordinates of the allene molecules are given in Tables 2 and 3, respectively.

The force constants have been adjusted by the damped least-squares method by the equation

$$\Delta K = (\tilde{J}WJ)^{-1}\tilde{J}W\Delta\nu,$$

where J and W are the Jacobian and weight matrices, respectively, and ΔK and $\Delta\nu$(obsd−calcd) are the column matrices. The standard deviations of the force constants have been evaluated by the equations

$$\sigma(K) = (\sigma_1^2+\sigma_2^2)^{1/2},$$

$$\sigma_1 = \left[\frac{N}{N-k}(\tilde{J}WJ)^{-1}\right]_{ii}^{1/2},$$

and

$$\sigma_2 = \left[\frac{N}{N-k}(\tilde{J}WJ)^{-1}(\tilde{J}W\Delta\nu)(\tilde{J}W\Delta\nu)(\tilde{J}WJ)^{-1}\right]_{ii}^{1/2},$$

where N, k denote the numbers of the available observed data and the adjusted force constants, respectively.[29]

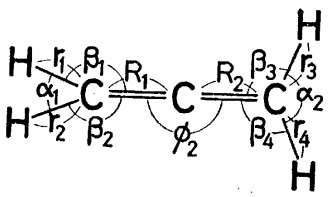
ϕ_1, ϕ_2	CCC bending
τ	Torsion



Results and Discussion

First, in order to confirm the validity of the simple Urey-Bradley force field (UBFF),

$$2V = \sum K_i(\Delta r_i)^2 + \sum H_{ij} r_i r_j (\Delta\phi_{ij})^2 + 2\sum F'_{ij} q^\circ_{ij} (\Delta q_{ij}) + \sum F_{ij}(\Delta q_{ij})^2 + \sum \pi(\Delta\gamma)^2 + Y(\Delta\tau)^2,$$

where K, H, F, π, Y are the stretching, bending, repulsive, out-of-plane bending, and torsional force constants, respectively, we determined these force constants by the least-squares method using the observed data. The converged values and their standard deviations of the UBFF force constants are given in Table 4. The calculated values of the normal frequencies, the Coriolis coupling constants and the centrifugal distortion constants of the allene molecules are given in Table 1 in comparison with the observed data.

Although the nine UBFF force constants were de-

a) In units of mdyn/Å. b) In units of mdyn·Å. c) In units of mdyn.

termined (Table 4), the agreement between the observed and calculated values is not satisfactory as a whole. In particular, the disagreement in the normal frequencies ν_9 and ν_{10} of allene-h_4 and -d_4, ν_{13} and D_{JK} of allene-d_2, and the Coriolis coupling constants ζ_9, ζ_{10}, ζ_{11}, $|\zeta_{9,10}|$ is much larger than experimental uncertainty. The weighted sum of squared errors, a residual 389 in this case indicates the average difference between the observed and calculated values

$$\sqrt{389/52} = 2.7$$

is about three times larger than the experimental uncertainty. A disagreement to this extent cannot be ignored. Therefore, in order to reduce it, several other interaction force constants have been added to the above simple UBFF.

Shimanouchi[30] introduced several new interaction force constants for the purpose of revising the simple Urey-Bradley force field, and determined their values for various molecules:

$p : p(\Delta r_i)(\Delta r_j)$	bond-bond interaction (SiX_4)
$\rho : \rho(\Delta r_i)(\Delta r_j)$	resonance interaction (CO_3^{--})
$t : t(\Delta\phi_{ij})(\Delta\phi_{kl})$	trans interaction (CH_3CH_3)
$g : g(\Delta\phi_{ij})(\Delta\phi_{kl})$	gauche interaction (CH_3CH_3)
$l : l(\Delta\phi_{ij})(\Delta\phi_{ik})$	angle-angle interaction (CH_2X_2).

The bond-bond interaction force constants p(CH,CH), p(CH,CC), and, in particular, p(CC,CC) are considered to take important roles in the force field of the allene molecule. Thus we added the three force constants p to the UBFF, and determined the twelve MUBFF force constants by the least-squares method. Converged values are compared with those of the simple UBFF in Table 4, the calculated values of ν, ζ, D being given in Table 1.

Although the new interaction force constants p converged to have appreciable values (Table 4), the effect of introducing such force constants on the calculated values (Table 1) is not striking. The residual in this case is 376, and thus the average difference

$$\sqrt{376/52} = 2.7$$

is about three times larger than experimental uncertainty. This agreement is slightly better than in the case of the above simple UBFF. However, the disagreement cannot be overlooked, and the force field sould be improved.

For this purpose, we determined the force constants based on the more general force field (GFF), and transformed the converged values of the GFF force constants into the UBFF force constants. A modification of the Urey-Bradley force field was discussed.

The twenty-three force constants based on the general force field were adjusted by the least-squares method from the total fifty-two observed data. A refinement of all the GFF force constants led to large standard deviations for some force constants. Hence, in order to reduce them, and to determine individual force constants definitely, the number of adjusted force constants was reduced, on the assumption that interaction between non-adjacent bonds in the allene molecule can well be neglected.

Though the force constant $F(3,3)$ in the A_1 symmetry species of allene-h_4 or -d_4 still differs from $F(6,6)$ in B_2, the other five force constants in B_2 are equal to those in A_1, and the two force constants $F(8,9)$ and $F(9,10)$ in the E species are equal to zero. Thus the sixteen independent GFF force constants were adjusted by the least squares method from the observed ν, ζ, D data. The converged values and standard deviations of the GFF force constants are listed in Table 5.

The agreement between the observed and calculated values in this case is satisfactory as a whole. The residual is 34.1, hence the average difference between the observed and calculated values

$$\sqrt{34.1/52} = 0.81$$

is even smaller than experimental uncertainty. The disagreement between the observed and calculated

values mentioned above in the case of UBFF and MUBFF is now well resolved in terms of the GFF force constants (Table 1). The agreement is satisfactory, and the GFF force constants (Table 5) are qualified as pertinent to the representation of the force field of the allene molecule.

They were thus converted into the UBFF force constants, and several interaction constants which should be added to the Urey-Bradley force field were determined. (See Table 4 for a comparison with force constants of UBFF and MUBFF). Some remarks are given concerning the results obtained for the MUBFF force constants derived from the GFF.

As new interaction force constants which should be added to the UBFF, in addition to the bond-bond interaction term p and the angle-angle interaction term l proposed by Shimanouchi, the necessity of introducing the bond-angle interaction term q should be stressed. The constant q(CC, HCH) is important for describing the normal frequencies of the A_1 and B_2 type vibrations.

The bond-angle interaction term q(CH,CCC) as well as the angle-angle interaction term l(HCC,CCC) and l(CCC,γ) are important for describing the normal frequencies and the Coriolis coupling constants of the E type vibrations. The necessity of introducing the term l was stressed by Shimanouchi for molecules such as methylene halides. The fact that the term l is also of significance in molecules containing double bonds such as allene is interesting in relation to the intramolecular force field.

The bond-bond interaction terms p(CH,CH), p(CH, CC) and p(CC,CC) suggest an electronic interaction between the bonds in the allene molecule. The strong electronic interaction between the adjacent double bonds in the allene molecule may give rise to the effectiveness of the value for p(CC,CC).

The authors thank Professor Eiji Hirota, Department of Chemistry, Kyushu University, and Dr. Chi Matsumura, National Chemical Laboratory for Industry, for their valuable discussions and suggestions.

The Kinetics and Mechanism of Hydrogen Adsorption and Hydrogen–Deuterium Equilibration on the Copper Surface

Makoto KIYOMIYA, Naohiro MOMMA, and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received November 13, 1973)

The mechanism of H_2–D_2 equilibration reaction over the copper surface was studied in the 40—90 °C range of temperature and in the pressure range of 4—45 Torr. From the studies of the hydrogen adsorption and the reaction between gaseous deuterium and preadsorbed hydrogen, the reaction was confirmed to proceed *via* combination between hydrogen and deuterium atoms on the surface. The rate constants for the adsorption and the desorption were optimized by a computer simulation of the reaction-time course and were found to be in satisfactory agreement with the observed results. A marked isotope effect was found in these rates; its influence on the partial pressure dependence of the reaction was discussed.

It has been known that copper, a typical "s-metal," is different from a "d-metal" in its catalytic activity for reactions such as the hydrogenation of olefins and the decomposition of alcohols or formic acid. Surface hydrogen is supposed to play an important role in these reactions. However, there have been few detailed reports on the adsorption and reaction of hydrogen on the copper surface.

Allen and Mitchell[1] have reported that hydrogen is not chemisorbed on the evaporated film of copper in the temperature range from 90 to 273 K. On the other hand, Prichard and Alexander[2] have found, from their measurements of the surface potential, that hydrogen is chemisorbed spontaneously on the evaporated film between 242 and 337 K. Though Shield and Russell[3] suggested that the adsorption of hydrogen is due to transition-metal impurities, Cadenhead and Wagner[4] have found that carefully reduced copper powder can adsorb approximately 0.4 of a monolayer of hydrogen at 77 K. Recently, Momma and Yasumori[5] have found, from a thermal desorption study, that there is only one dissociative state for the adsorbed hydrogen on copper powder.

In this work, we studied in detail the kinetics of the H_2-D_2 equilibration reaction in order to ascertain the behavior of adsorbed hydrogen on the copper surface.

Experimental

A circulating system of about 500 ml was used for the studies of adsorption and kinetics. This apparatus was incorporated with a reaction vessel, an inductance Bourdon gauge,[6] gas reservoirs, and a high-vacuum line. The temperature of the reaction vessel was controlled within ±0.5 °C. Isotopes of hydrogen were analyzed by the use of a gas chromatograph with a column of Mn^{2+} coated γ-alumina.[7]

The kinetics of the equilibration reaction was studied using an equimolar mixture of H_2 and D_2 in the temperature range of 40—90 °C at total pressures between 4 and 45 Torr. The dependences of the reaction rate on the partial pressures of H_2 and D_2 were also examined. Two series of experiments were carried out; in the first series, the initial pressure of H_2 (or D_2) was varied, while that of D_2 (or H_2) was kept constant, and in the second series, the fraction of hydrogen was varied under a constant total pressure.

During the course of the equilibration, the amounts of hydrogen and deuterium adsorbed on the surface were estimated from the introduced amounts and from the partial pressure of each isotopic molecule. The pressure change due to adsorption during the course of reaction was continuously followed by means of a Bourdon gauge. The rates of the adsorption and desorption of hydrogen and deuterium and the adsorption isotherms were determined using the same reaction vessel.

Copper powder, used as a catalyst, was prepared by the following procedure: cupric oxide was precipitated from an aqueous solution of copper nitrate by adding sodium hydroxide and was reduced with circulating hydrogen of 50—100 Torr at 180 °C. Guaranteed-reagent cupric nitrate was obtained from Wako-Pure Chemical Industries, Ltd. The reduction was continued for 50 hr until no decrease in the hydrogen or no trace of water could be found. The reduced copper powder was evacuated at the same temperature for several hours. The surface area of the catalyst was estimated as 4.4 m^2/g by means of the BET method using krypton at 77 K.

Transition-metal impurities in the cupric oxide were examined by emission spectroanalysis; the amounts of Fe and Ni were less than 5 ppm, and those of Co and Mn were less than 10 ppm. As for non-transition-metal impurities, the amounts of Al and Na were less than 2 and 0.5 ppm respectively, while those of Si and Mg slightly exceeded the limit of detection.

High-purity hydrogen, deuterium (HD less than 0.5%), and krypton purchased from the Takachiho Co., Ltd., were used without further purification.

In annealing, the copper powder was heated at definite temperatures up to 500 °C *in vacuo* below 10^{-5} Torr for an hour. Prior to each kinetic run, the annealed catalyst was evacuated again at room temperature for several hours.

The simulation and the numerical analysis of the reaction-time course were carried out by means of the Runge-Kutta-Gill method with the aid of a computer, HITAC 8700.

Results

The Adsorption of Hydrogen and Deuterium. The adsorption of hydrogen proceeded at a measurable speed at room temperature. Figures 1 and 2 show the time courses of the chemisorption of H_2 and D_2 respectively in the temperature range of 30—170 °C. It is evident that the chemisorption requires an activation energy. A marked isotope effect in the adsorption rate was found; the rate of hydrogen adsorption was about six times as fast as that of deuterium adsorption at room temperature. Figure 3 shows a linear relationship[8] between the rate of adsorption and the pressure, where the points on each line were obtained as those

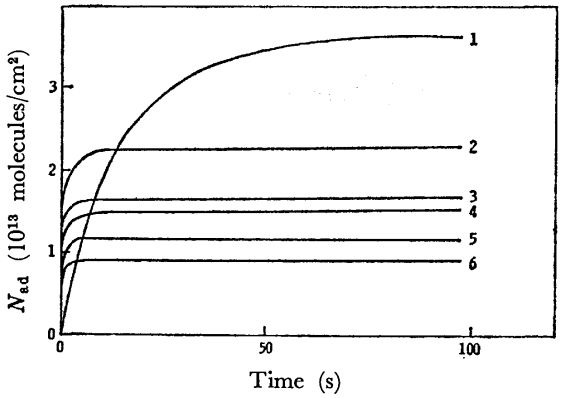

Fig. 1. Time course of hydrogen adsorption on copper at various temperatures.

for the same amount of adsorbed hydrogen from various time curves at 20 °C. The intercepts correspond to the desorption rates, which increase with the amount of adsorbed hydrogen. This result suggests that the adsorption is not controlled by any process such as diffusion in the gas phase or in surface migration, but by the simple collision of gaseous molecules with the surface.

The adsorption isotherms of hydrogen and deuterium were obtained in the temperature region from 0 to 60 °C and at pressures from 4 to 45 Torr. The adsorption of hydrogen was found to be reversible under these conditions. Plots of the reciprocal of $\sqrt{P_e}$ against the reciprocal of N^s_{ad} showed a linear relationship, where P_e is the equilibrium pressure and N^s_{ad} is the amount of adsorbed hydrogen. This result indicates that the adsorption isotherm obeys the Langmuir equation for dissociative adsorption. The monolayer capacity was evaluated as 2.8×10^{14} H atoms/cm^2. This value corresponds to approximately 20% of the surface copper atoms, 1.6×10^{15} atoms/cm^2, taken as the average of the (111) and (100) planes. The heats of adsorption of hydrogen and deuterium were determined to be 9.2±1.0 kcal/mol and 10.3±2.0 kcal/mol respectively.

The overall rate of adsorption may, therefore, reasonably be expressed as:

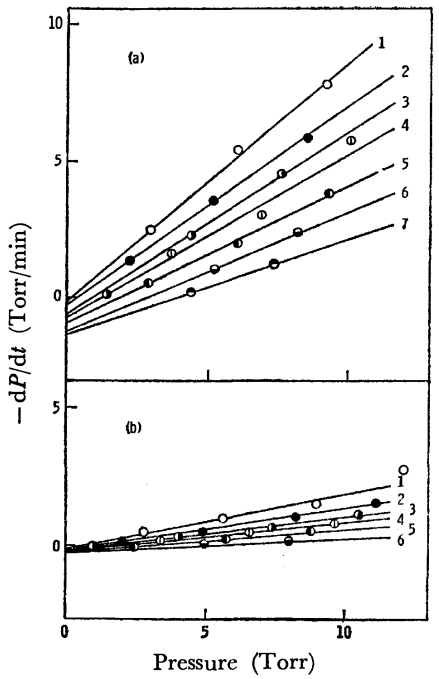

Fig. 3. Relationship between the net rate of adsorption and pressure at constant amount of adsorption at 20 °C.
a: H_2, b: D_2; 1: 0.306, 2: 0.612, 3: 0.918, 4: 1.22, 5: 1.53, 6: 1.84, 7: 2.14×10^{13} molecules/cm^2.

$$KV/\sigma_0^2 S\cdot dP/dt = -k_a P(1-\theta)^2 + k_d\theta^2 \qquad (1)$$

where K is the conversion factor (molecules/ml·Torr), V is the volume of the reaction system, σ_0 is the monolayer capacity, S is the surface area, and k_a and k_d are the rate constants for adsorption and desorption respectively.

Adsorption Measurements during H_2-D_2 *Equilibration.* The change in the adsorption during the H_2-D_2 equilibration was followed volumetrically; the results at 14 °C are shown in Fig. 4. The amount of adsorbed hydrogen or deuterium is conventionally expressed by the virtual pressure of H_2 or D_2 which would be

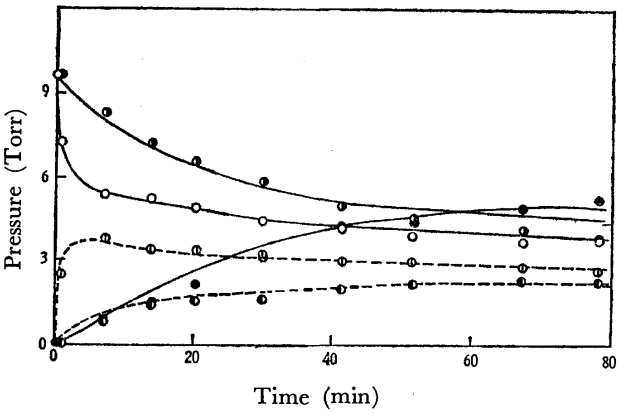

Fig. 4. Adsorption during the course of H_2-D_2 equilibration on copper at 14 °C. Lines indicate the best fitting curves obtained by computer simulation.
○: H_2(g), ◑: D_2(g), ●: HD(g), ⓘ: H_2(a), ◐: D_2(a).

expected if the adsorbed species were all present in the gas phase. When an equimolar mixture of H_2 and D_2 was introduced into the reaction system, the hydrogen in the gas phase decreased more rapidly than the deuterium. The adsorbed amount of hydrogen reached a maximum about ten minutes after the start of the reaction. As the reaction proceeded, the amount of adsorbed hydrogen decreased, whereas that of the adsorbed deuterium increased until it reached an amount similar to that of adsorbed hydrogen, their sum being almost kept constant after the maximum.

Exchange Reaction. In order to get information on the mechanism of the H_2-D_2 equilibration, the exchange reaction between the adsorbed hydrogen and gaseous deuterium was examined. Figure 5 shows the behavior of hydrogen species during the course of the exchange. In this case, H_2 was preadsorbed on the copper surface; then, the hydrogen in the circulating system was quickly replaced by deuterium except for the small amount of hydrogen in the catalyst vessel. An induction period for the HD formation and a maximum in the rate appeared, and the surface hydrogen was gradually displaced by deuterium.

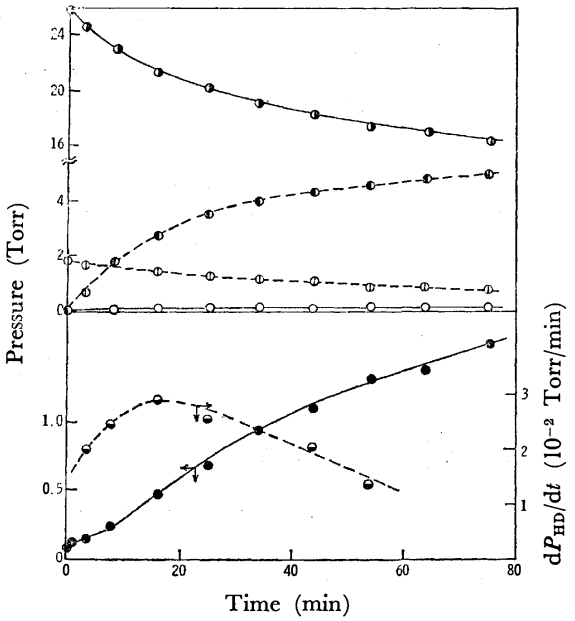

Fig. 5. Adsorption during the course of exchange reaction at 20 °C.
○: H_2(g), ◑: D_2(g), ●: HD(g), ◒: the rate of HD formation, ⓘ: H_2(a), ◐: D_2(a).

These results suggest that the equilibration takes place through the repetition of the dissociative adsorption of H_2 and D_2 and the desorption of HD. Hydrogen deuteride is formed from the recombination between the chemisorbed hydrogen and deuterium atoms; the rate of HD formation in this case should be proportional to the respective concentrations of adsorbed species. This view was further supported by a similar finding for the exchange between adsorbed D atoms and gaseous H_2 molecules.

If a reaction between adsorbed hydrogen atoms and gaseous deuterium molecules, $H(a)+D_2 \rightarrow HD+D(a)$,

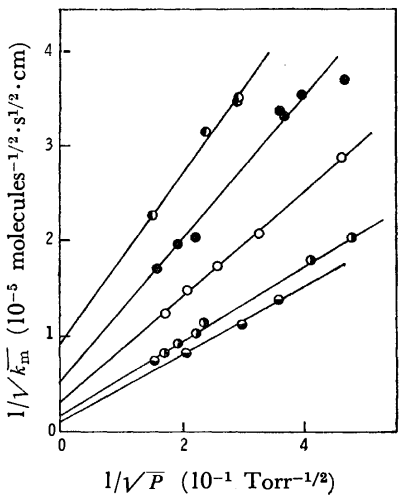

Fig. 6. Dependence of $1/\sqrt{k_m}$ on $1/\sqrt{P}$ at various temperatures.
◐: 43.5, ●: 51, ○: 64, ◑: 75.5, ◒: 85 °C,

occurs, a monotonous decrease in the rate may be observed, since the rate is expressed as $dP_{HD}/dt = k\theta_H P_{D_2}$.

Kinetics of H_2-D_2 Equilibration. The rate of the equilibration in an equimolar mixture of H_2 and D_2 obeyed the usual first-order equation:

$$k_e = 1/t \cdot \ln(x_0 - x_e)/(x_0 - x_t) \qquad (s^{-1}) \qquad (2)$$

where x_0, x_t, and x_e represent the fraction of hydrogen deuteride at the beginning, at time t, and at equilibrium respectively. The absolute rate, k_m, is derived from the constant, k_e, as:

$$k_m = nk_e/S \qquad (\text{molecules/cm}^2\cdot\text{s}) \qquad (3)$$

where n is the total number of hydrogen molecules in the reaction system and where S is the surface area of copper.

The dependences of the absolute rate on the pressure and the temperature were studied in the ranges from 4 to 45 Torr and from 40 to 90 °C. The apparent order of the reaction was 0.8 with respect to the total pressure of hydrogen. Since a linear relationship holds between the reciprocals of $\sqrt{k_m}$ and $\sqrt{P}$, as is shown in Fig. 6, the rate may be represented by the equation:

$$k_m = k_0(\sqrt{KP}/1 + \sqrt{KP})^2 \qquad (4)$$

where k_0 is the rate constant and is estimated as an extrapolated value of k_m when the pressure rises to infinity. The apparent activation energy and the heat of adsorption were evaluated as 17.9±1.5 kcal/mol and 9.7±1.5 kcal/mol respectively.

Dependence of the Rate on the Composition of the Reactant. In order to ascertain the dependence of the rate on the partial pressures of H_2 and D_2, two series of experiments were carried out. Figure 7 shows the initial rate of HD formation obtained at 79 °C, where the partial pressure of H_2 or D_2 was kept constant. A marked isotope effect was observed; when the partial pressure was lower than 3.2 Torr, the rate of reaction under a constant D_2 pressure was faster than that under a constant H_2 pressure. Plot of log P_{H_2} or log P_{D_2}

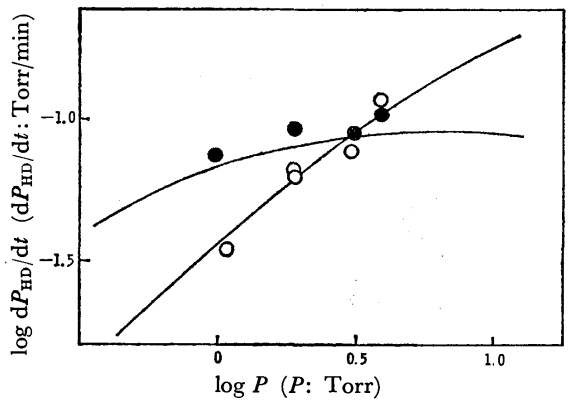

Fig. 7. Variation of initial rate of HD formation with hydrogen or deuterium pressure. Initial pressure was 3.2 Torr. Solid lines show theoretical curves. ○: initial P_{H_2}=3.2 Torr, ●: initial P_{D_2}=3.2 Torr.

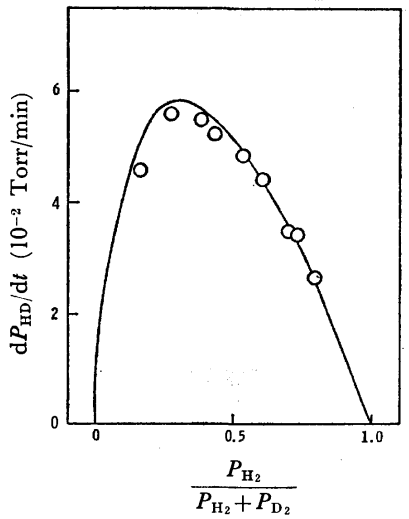

Fig. 8. Variation of initial rate of HD formation with the fraction of hydrogen. Total pressure was kept constant at 6.2 Torr. Solid line shows a theoretical curve.

against the logarithm of the initial rate of HD formation gives the apparent reaction order of 0.8±0.1 in deuterium and that of 0.2±0.1 in hydrogen within these pressure limits.

Figure 8 shows the correlation between the initial rate of HD formation and the fraction of hydrogen under a constant total pressure of 6.2 Torr at 84 °C. The maximum in the rate appears at a hydrogen fraction of 0.3—0.4; it deviates from the point of an equimolar composition. This result can be attributed to the kinetic isotope effect in the adsorption and desorption processes.

Effect of Annealing. The dependences of the reaction velocity and the apparent activation energy on the annealing temperature are shown in Table 1; the activity per unit of weight of copper decreased on annealing. However, it was found that the annealing also decreased the surface area of copper and that the reaction rate per unit of surface area remained almost unchanged.

Table 1. Effect of annealing on catalytic activity

Annealing temp. (°C)	Surface area (m^2/g)	Specific activity (molecules/s·g)	k_m (molecules/s·cm^2)	E_{ap} (kcal/mol)
180	4.4	2.48×10^{14}	5.6×10^{9}	12.6
280	4.1	2.15×10^{14}	5.2×10^{9}	12.6
380	3.4	1.72×10^{14}	5.1×10^{9}	12.2
480	2.2	0.69×10^{14}	4.4×10^{9}	11.9

Discussion

In the present study, it is revealed that hydrogen is dissociatively adsorbed on the copper surface and that an activation energy is needed for this process. The results obtained from the adsorption measurements during the course of the exchange reaction confirm that the equilibration reaction occurs *via* the dissociative adsorption of H_2 and D_2 and the desorption of HD as a result of a recombination of the chemisorbed hydrogen and deuterium atoms.[9] A recent study of the thermal desorption supports this mechanism; the desorption spectra showed only one dissociatively-adsorbed state for hydrogen on the reduced copper powder. The desorption was found, from the dependence of the peak shift on the amount of adsorption, to be second-order with respect to the surface concentration of hydrogen; further, the complete mixing of the hydrogen and deuterium atoms was observed.

There is no alternative mechanism for explaining the equilibration reaction. Since the Rideal-Eley mechanism[10] involves a surface reaction between the chemisorbed hydrogen atom and the physically-adsorbed molecule as the rate-controlling step, it does not accord with the present results on the exchange reaction. The Schwab-Killmann mechanism,[11] which presumes a molecular adsorption of H_2 and D_2 and a bimolecular rearrangement between them on the surface, also does not hold because the adsorbed hydrogen is in a dissociative state, as has been discussed above.

Subsequently, the results of the adsorption measurements during the H_2-D_2 equilibration can be analyzed according to the following scheme:

$$H_2 \underset{k_d^H}{\overset{k_a^H}{\rightleftharpoons}} 2H(a) \quad \text{(I)}$$

$$HD \underset{k_d^{HD}}{\overset{k_a^{HD}}{\rightleftharpoons}} H(a) + D(a) \quad \text{(II)}$$

$$D_2 \underset{k_d^D}{\overset{k_a^D}{\rightleftharpoons}} 2D(a) \quad \text{(III)}$$

where k_a and k_d are the rate constants for the adsorption and the desorption respectively, as defined above.

The rates are expressed in the same way as in Eq. (1):

$$KV/\sigma_0^2 S\cdot dP_H/dt = -k_a^H P_H(1-\theta_H-\theta_D)^2 + k_d^H\theta_H^2 \quad (5)$$

$$KV/\sigma_0^2 S\cdot dP_{HD}/dt = -k_a^{HD} P_{HD}(1-\theta_H-\theta_D)^2 + k_d^{HD}\theta_H\theta_D \quad (6)$$

$$KV/\sigma_0^2 S\cdot dP_D/dt = -k_a^D P_D(1-\theta_H-\theta_D)^2 + k_d^D\theta_D^2 \quad (7)$$

This set of simultaneous differential equations was solved numerically by applying the Runge-Kutta-Gill

TABLE 2. RATE CONSTANTS FOR DESORPTION AND ADSORPTION AT 14°C

	k_d (cm²/molecules·s)	k_a (cm²/molecules·Torr·s)
H_2	7.9×10^{-17}	5.4×10^{-18}
HD	7.0×10^{-17}	3.0×10^{-18}
D_2	1.7×10^{-17}	7.2×10^{-19}

method with the aid of a computer. The rate constants as parameters were chosen so as to obtain the best-fitting curves to the experimental time course by using the least-squares method. The rate constants thus determined are listed in Table 2; the coincidence of the theoretical curves with the experimental results is evident, as is shown in Fig. 4. The rate constants at 0 and 89 °C were also evaluated from the results of adsorption during the equilibration by means of the computer simulation procedure. The activation energies for the adsorption and desorption were determined from these constants at 0, 14, and 89 °C by combining the separate data of the adsorption rates of H_2 and D_2 at temperatures between 0 and 20 °C. These values are summarized in Table 3. The rate constants estimated from the adsorption and desorption rates of H_2 and D_2 at 20 °C are compared with those determined by the simulation in Table 4. The agreement between the calculated and the observed values offers an additional evidence for the validity of computer simulation. Therefore, it is confirmed that the reaction proceeds *via* the so-called Bonhoeffer-Farkas mechanism.

TABLE 3. ACTIVATION ENERGIES FOR DESORPTION AND ADSORPTION

	E_a (kcal/mol)	E_d (kcal/mol)
H_2	9±1	17±1
HD	9±1	17±2
D_2	10±1	18±2

TABLE 4. RATE CONSTANTS FOR DESORPTION AND ADSORPTION AT 20°C

	k_d (cm²/molecules·s)		k_a (cm²/molecules·Torr·s)	
	Obsd	Calcd	Obsd	Calcd
H_2	1.5×10^{-16}	1.5×10^{-16}	5.5×10^{-18}	7.4×10^{-18}
D_2	4.2×10^{-17}	3.6×10^{-17}	1.1×10^{-18}	1.0×10^{-18}

It may be seen that the rates are empirically represented by Eq. (4), which is derived on the basis of this mechanism by neglecting the isotope effect. The linear relationship shown in Fig. 6 is, however, rather accidental; Eq. (4) predicts that the reaction order of H_2 or D_2 must not exceed 0.5. The solid lines in Figs. 7 and 8 were obtained by the use of evaluated rate constants involving the isotope effect and were in good agreement with the experimental results.

Accordingly, the considerations given above indicate that the isotope effect can not be ignored in interpreting the pressure dependence of the reaction.

The equilibration reaction can now be precisely analyzed on the basis of the present results and the transition-state theory. It can easily be shown that the rate constants of adsorption, k_a, and desorption, k_d, are given by:

$$k_a = kT/h\cdot F^{\ddagger}/F_g F_{s_2}\cdot\exp(-E_a/RT)\cdot k'/T\cdot s/2L \quad (8)$$

$$k_d = kT/h\cdot F^{\ddagger}/F_{H(a)}{}^2\cdot\exp(-E_d/RT)\cdot s/2L \quad (9)$$

where L is the total number of sites per unit area of copper, s is the number of adjacent sites, and F_g, $F_{H(a)}$, F_{s_2}, and $F^{\ddagger}$ are the partition functions of gaseous hydrogen, the adsorbed hydrogen atom, the dual sites, and the activated complex respectively. The constant, k', in Eq. (8) is the conversion factor in unit of molecules·deg/Torr·ml. The transmission coefficient is assumed to be unity. The rates at 14 °C were evaluated by assuming F_{s_2}, $F^{\ddagger}$, and $F_{H(a)}$ to be unity, and s to be 6, and by assuming L as 2.8×10^{14} sites/cm². The results for hydrogen were:

$$k_a = 6.0\times10^{-18} \quad \text{(cm²/molecules·Torr·s)}$$

$$k_d = 7.9\times10^{-15} \quad \text{(cm²/molecules·s)}.$$

As is shown in Table 2, the calculated rate constant of adsorption is in satisfactory agreement with the experimental value. However, in the case of desorption, the theoretical value is larger than the experimental value by a factor of 10^2. This discrepancy is presumably a result of the low vibrational frequencies of the adsorbed hydrogen atom on the real surface.

By combining the difference between the zero-point energies of the molecular vibrations of H_2 and D_2, 1.8 kcal/mol with the values of the activation energies shown in Table 3, it is possible to estimate the difference between the zero-point energies of the Cu-H and Cu-D vibrations on the surface. The value, 0.9 kcal/mol, obtained for this difference seems reasonable in comparison with the value, 0.92 kcal/mol, of that between the dissociation energies of diatomic molecules, CuH and CuD.

It has been considered by several investigators that defect structures in metal surface may play an important role in heterogeneous catalysis. Uhara *et al.*[12] studied the effect of annealing on the catalytic activity of copper for the decomposition of benzene diazonium chloride and suggested that the fall in catalytic activity was attributable to a decrease in the concentration of dislocation which occurred around 400 °C. In the present study, the total activity per unit of weight decreased upon annealing in a way similar to that observed by them. However, the surface area also decreased upon annealing, and the reaction rate per unit of surface area was almost unvaried. Therefore, this reaction is not structurally sensitive, but belongs to a category of "facile" reaction[13] which depends only on the degree of exposure of metal atoms. Besides, it is known that the points or lines of the emergence of defects at silver films[14] and the lattice imperfection on silver crystals[15] are unimportant for the decomposition of formic acid. Woodward *et al.*[16] indicated that dislocations on silver do not act as active sites for the oxidation of ethylene. The present findings, together with these observations, lead us to conclude that the structural defects in s-metals do not play a dominant role in heterogeneous catalysis.

The Crystal Structure of (+)-2,5-Dimethoxy-8-Chlorotriptycene

Tsuguhiro KANEDA,* Noriyoshi SAKABE, and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received November 16, 1973)

The crystal structure of (+)-2,5-dimethoxy-8-chlorotriptycene has been investigated by the X-ray method. The crystal system is monoclinic, and the space group is $P2_1$. The cell dimensions are $a=8.231$, $b=13.320$, $c=8.156$ Å, and $\beta=96.49°$. The structure was deduced from the Patterson map and from the calculation of the R-factor minimized by varying the rotational and translational parameters. The structure parameters were refined by the block-diagonal least-squares method by using 1227 independent reflections; the final R-value was 0.073. The absolute configuration was determined to be 1R6S from the Cu$K\alpha$ anomalous scattering of the chlorine atom.

Triptycene has a rigid molecular skeleton, with a three-fold symmetry axis. The crystal structures of several triptycene derivatives have been investigated,[1-5] and the high symmetry of the molecular structure has been characterized. A series of optically-active substituted triptycenes were synthesized by Ogura, Nakagawa, and their co-workers,[6-8] and the theoretical analysis of their circular dichroism spectra was carried out by the exciton method.[9-11] It was found that the absolute configuration of (+)-2,5-dimethoxy-7-dimethylaminotriptycene hydrobromide, as determined by the X-ray method, was not in agreement with that deduced by the analysis of the CD spectra.[5,9-11] The disagreement between the X-ray and CD analysis is serious problem for the foundation of stereochemistry; further investigation with other derivatives is earnestly desired.

The triptycene derivatives thus far studied have substitutents at the 2, 5, and 7-carbon atoms; however, other derivatives with substituents at different positions are also of much interest. The present investigation was undertaken in order to determine the absolute configuration of (+)-2,5-dimethoxy-8-chlorotriptycene in order to confirm the absolute configuration by the X-ray method.

Experimental

The (+)-2,5-dimethoxy-8-chlorotriptycene was synthesized and crystallized from the petroleum ether by Dr. Ogura.

The space group was determined from oscillation and Weissenberg photographs. The density was measured by the flotation method in a mixed solution of cyclohexane and carbon tetrachloride. The cell dimensions were determined by the least-squares method, using 12 reflections which had been carefully measured on a Hilger-Watts four-circule diffractometer with Ni-filtered Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). The intensity data were also measured on the diffractometer in the ω-2θ scanning mode ($\theta\leq 72°$) with the same radiation, using a crystal whose size was $0.3\times0.3\times0.5$ mm^3.

1378 independent reflections were obtained, and no correction was made for absorption or extinction. The crystal data are shown in Table 1.

TABLE 1. CRYSTAL DATA

$M.\ F.$: $C_{22}H_{17}O_2Cl$
$M.\ W.=348.83$
Crystal system: monoclinic
Systematic absences: $0k0$ when k is odd.
Space group: $P2_1$
$a=8.231\pm0.002$, $b=13.320\pm0.002$,
$c=8.156\pm0.001$ Å; $\beta=96.49\pm0.01°$
$V=886.5$ Å^3, $Z=2$,
$D_m=1.280$, $D_c=1.284$ g·cm^{-3},
$F(000)=364$, $\mu=21.29$ cm^{-1} (for Cu$K\alpha$)

Structure Analysis

Since the molecule is rigid and since the bond lengths of related molecules are known,[5] the position of each atom may be easily estimated when the translational and rotational parameters of the molecule in the unit cell can be determined. The direction of the pseudo-three-fold axis could be easily found from the Patterson map, because the carbon-carbon vectors with lengths of ~1.4 Å and ~2.8 Å were superposed six and four times respectively along the axis. This implies that two of the rotational parameters, ω and χ, can be determined and that only the ϕ parameter remains to fix the rotational freedom (see Fig. 1).

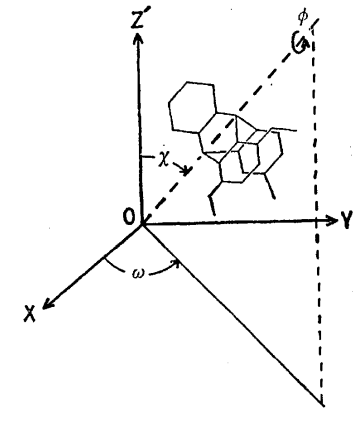

Fig. 1. Definition of rotational parameters with respect to the Cartesian coordinate axes.[12]

The translational and rotational searches were performed by the calculation of the R-values on the basis of the assumed model, which is rotated around the ϕ-axis and translated in the ac plane. Twenty-three $h0l$ reflections within $\theta<30°$ were selected for this calculation. The angle of the ϕ parameter was changed in the range from 0 to 2π with an interval of $\pi/90$ radian. At each setting of ϕ, the molecule was successively

translated in the *ac* plane by 1/50 for both Δx and Δz, and the *R*-value was calculated at each point. The position of the minimum *R*-value(0.30) was easily found on the *R*-map thus prepared. The calculation could be done within ten minutes machine time on the FACOM 230-60. Further refinement, using all the three-dimensional reflection data, confirmed that the position was actually adequate. The origin was adjusted so as to put all the *y*-parameters of atoms belonging to one molecule in the range from 0 to one.

The diagonal least-squares method was applied for the refinement of structure parameters by using 1227

independent reflections with $|F^0|>6\sigma$, and the R-index was reduced to 0.130. Additional block-diagonal least-squares refinement was carried out with anisotropic thermal factors, and the R-index was converged to 0.097. The hydrogen atoms attached to the benzene rings and those attached to the bridge-head carbons were found on the difference Fourier map. Further refinement, including these hydrogen positions, resulted in the final R-value of 0.073, with an equal weight for each reflection. No other significant peaks were found in the final Fourier and difference Fourier maps.

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[13] The computation was carried out with the programs of UNICS coded by Dr. Ashida and those coded by ourselves on FACOM 230-60 at the Nagoya University Computation Center.

The atomic coordinates, with their standard deviations, and the anisotropic thermal factors, with their standard deviations, are listed in Table 2 and Table 3 respectively. The observed and calculated structure factors are listed in Table 4.[14]

Results and Discussion

(+)-2,5-Dimethoxy-8-chlorotriptycene is actually a rigid molecule with a pseudo-three-fold axis. The bond lengths and angles are shown in Table 5 and Table 6 respectively. The average bond length around the C(1) and C(6) of the bridge head carbons, 1.52 Å, is in good agreement with the expected value for an sp^2-sp^3 carbon bond.[15] The bonds which form the bicyclo-2,2,2-octatriene ring are longer than the normal value of the benzene ring by 0.02~0.04 Å. The tetrahedral angles around the bridge-head carbons are smaller by 2.4~4.6° than the normal tetrahedral angle. The external angles made by the bicyclo-2,2,2-octatriene ring and the benzenoid ring are about 127°, while the internal angles are about 113°. These results mean that a significant strain is exerted on the part of the

bicyclo-2,2,2-octatriene ring of the triptycene skeleton. A similar trend is found in the results of previous studies.[1-5]

The least-squares planes of three benzene rings are given by the following equations;

(1) Benzene ring:
$0.8201X+0.4291Y-0.3786Z'-4.0490=0$

(2) Chlorobenzene ring:
$0.8823X-0.4620Y+0.0906Z'-0.3395=0$

(3) Dimethoxybenzene ring:
$-0.0524X+0.8942Y-0.4446Z'-3.8398=0$

where X, Y, and Z' are coordinates in Å along the a, b, and c* axes respectively. The deviations of atoms from these planes are shown in Table 7. The planarity of the three benzene rings is remarkably good. The chlorine atom is nearly on the ring plane, and bridgehead carbons are on nearly three planes, but C(21) deviates from the dimethoxybenzene-ring plane by 0.13 Å.

a) Atoms not included in the least-squares plane calculation.

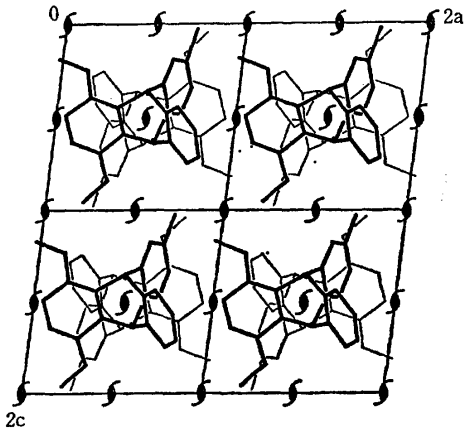

Fig. 2. Projection along the b axis.

The crystal structures as projected along the b axis and the c axis are shown in Figs. 2 and 3 respectively. The intermolecular distances within 3.6 Å are listed in Table 8. The closest distance occurs at 3.29 Å between the chlorine atom and the oxygen atom of the methoxyl group (O(2)).

The absolute configuration was determined by the Bijvoet method using the anomalous scattering of Cu$K\alpha$ radiation by the chlorine atom. The $\Delta f'$ and $\Delta f''$ values were taken from the International Tables for X-ray Crystallography.[13] The observed intensity differences and calculated ones between the Bijvoet pair for twenty reflections are listed in Table 9. The signs of the observed values are in good agreement with those calculated based on the positional parameters of Table 2 in the right-handed coordinate system. The absolute configuration thus determined is 1R6S, as is illustrated in Fig. 4. This result is in good agreement with the chemical correlation of (+)-2,5-dimethoxy-8-

The Microwave Spectrum of 3,3,3-Trifluoropropene

Shuji SAITO and Fumio MAKINO
Sagami Chemical Research Center, Sagamihara, Kanagawa 229
(Received December 10, 1973)

The microwave spectra of normal, 2-^{13}C, and three monodeuterated isotopic species of 3,3,3-trifluoropropene have been studied. The combined structure of r_0 and r_s was obtained from the rotational constants observed. It has been necessary to take account of a tilt angle of the symmetry axis of the trifluoromethyl group. The following structural parameters have been determined: r(C–C)=1.489±0.002 Å, r(C=C)=1.312±0.010 Å, r(C–H$_1$)=1.085±0.011 Å, r(C–H$_2$)=1.092±0.009 Å, r(C–H$_3$)=1.109±0.003 Å, ∠F–C–F=106.8±0.3°, ∠C–C=C=124.8±0.4°, ∠C=C–H$_1$=120.6±1.0°, ∠C=C–H$_2$=122.8±1.0°, ∠C=C–H$_3$=121.2±1.0°, and θ_t=1.0±0.8° on the assumption that r(C–F)=1.345±0.003 Å, where θ_t denotes the tilt angle of the CF$_3$ top axis relative to the C–C bond away from the double bond of the vinyl group. The components of the electric dipole moment have been determined to be μ_a=2.331±0.014 D and μ_b=0.698±0.025 D; these values give a total dipole moment of 2.433±0.020 D at an angle of 7±1° with the symmetry axis of the trifluoromethyl group. The relative intensity between the rotational transitions in the ground state and in the first torsionally-excited state has been measured. The torsional frequency has been determined to be 88±25 cm^{-1}.

When a trifluoromethyl group, CF_3, is substituted in a molecule, a significant structural change can be expected because fluorine is the most electronegative element. There have been several studies of the structural determination of molecules containing the trifluoromethyl group by means of microwave spectroscopy or other methods. The results thus far have not, however, shown definitely the trend of the structural change upon trifluoromethyl substitution. Hilderbrandt *et al.*[1] studied hexafluoroacetone, hexafluoropropylimine, and hexafluoroisobutene by means of the electron-diffraction method and revealed that, upon fluorine substitution, the C-C bond length of the molecules studied increased, contrary to the trend previously observed in pairs of ethane[2] and 1,1,1-trifluoroethane,[3] ethylene[4] and 1,1-difluoroethylene,[5] and so on.

The real structural change upon fluorine substitution should be extractable from the accurately-determined structures of the fundamental and simplest molecules, in which such other effects as steric repulsion are not conspicuous. The pair of propene and 3,3,3-trifluoropropene is a good example for study. Recently, Tokue, Fukuyama and Kuchitsu[6] studied both the molecules by the electron-diffraction method. Making a joint analysis using the electron-diffraction intensities and the results of our microwave spectroscopic study which we will report in this paper, they determined the average structure of 3,3,3-trifluoropropene and found that the molecule follows the trend previously observed. The infrared spectrum of 3,3,3-trifluoropropene has been observed in the gas phase and assigned except for the torsional mode of the CF_3 top.[7] The dipole moment of this molecule in the gas phase was determined to be 2.45 D by the dielectric-constant method.[8]

In this paper we will report the microwave spectrum of 3,3,3-trifluoropropene, including one ^{13}C isotopic species and three monodeuterated species, and the determination of the molecular structural parameters, the dipole moment, the torsional frequency, and the barrier to internal rotation. While this work was in progress, Mukhtarov and Kuliev[9] reported the rotational constants of 3,3,3-trifluoropropene in the ground and torsionally-excited states, and its dipole moment.

Experimental

The spectra were observed with a conventional 110 KHz Stark-modulation spectrometer.[10] The measurements were carried out at the temperature of dry ice. The accuracy of the frequencies measured was estimated to be better than 0.1 MHz. Normal 3,3,3-trifluoropropene was obtained from the K & K Co. and was used without further purification. A mixture of three monodeuterated isotopic species was kindly provided by Y. Nakano. A deuterated sample was prepared by a hydrogen-exchange reaction of normal species with the deuterium gas on a powdered nickel catalyst. The product was purified by gas chromatography.

Microwave Spectrum

The spectra of the normal 3,3,3-trifluoropropene observed in the X to K bands consisted of a strong *a*-type *R*-branch and weak *b*-type *R*- and *Q*-branch transitions, characteristic of a nearly prolate symmetric top. Their assignment was made on the basis of the Stark effect on each transition. The weak *b*-type *R*-branch transitions were measured by means of a recorder. The frequencies of the observed transitions are listed in Table 1. The rotational constants of the normal species were determined by a least-squares fitting of the lowest fifteen transitions, as is shown in Table 4. The centrifugal distortion effect was discarded in the analysis, because only low-J transitions were measured.

The strong satellite lines in the vicinity of the ground-state transitions and showing similar Stark effect behavior were found at slightly higher frequencies with regularly varying intensities. These were assigned to the transitions in the first and second torsionally-excited states, since their intensities indicated that the states belong to the vibrations of very low frequencies which were not observed in the infrared spectrum.[7] The frequencies of the observed transitions are listed in Table 2. The rotational constants in the torsionally-excited states were obtained in the same way as those of the ground state. These results are also given in Table 4. The obtained B and C rotational constants in the ground and torsionally-excited states are nearly equal to those reported by Mukhtarov and Kuliev.[9]

a) Accuracy better than ±0.1 MHz, unless otherwise indicated, b) ±0.2 MHz. c) Calculated frequencies were obtained using the rotational constants in Table 4.

Their values of the A rotational constants are quite different from ours. This difference is due to the fact that we have observed both the *a*- and *b*-type spectra in the ground and torsionally-excited states.

Though all three ^{13}C isotopically-substituted species were searched for in their natural abundances (1.1%), most of the lines were masked or disturbed by other strong lines. Only the *a*-type spectrum of the 2-^{13}C species was assigned and measured, as is shown in Table 3.

a) Accuracy better than ±0.1 MHz, unless otherwise indicated. b) ±0.2 MHz. c) Calculated frequencies were obtained using the rotational constants in Table 4.

There are three isotopic isomers of monodeuterated species. For the sake of simplicity, each isomer is designated by the number of the substituted atom, as given in Fig. 1. Also, only *a*-type *R*-branch transitions were observed for these species because of the low enrichment of the deuterium atom. The results are shown in Table 3. The rotational constants of the 2-^{13}C and monodeuterated species were determined

from a few adequate transitions. The observed rotational constants and moments of intertia are given in Table 4. The large errors associated with the A rotational constants for the 2-^{13}C and monodeuterated species resulted from a lack of observation on b-type transitions.

Dipole Moment

The second-order Stark effect was measured for four transitions, as is shown in Table 5. The electrode spacing was calibrated using the $J=1\leftarrow0$ transition of OCS.[11] From the Stark coefficients, μ_a was determined to be 2.331±0.014 D, and μ_b, to be 0.698±0.025 D; these values gave a value of 2.433±0.020 D for the total dipole moment, where the error quoted was 2.5 times the standard deviation. The total dipole moment made an angle of 16°40′±40′ with the a principal axis. The orientation of the dipole moment relative to the molecular framework is not uniquely determined. It is reasonable to consider that the dipole moment

a) Values in 10^{-5} MHz(V/cm)$^{-2}$

of 3,3,3-trifluoropropene is mainly made up of the group moment of the CF_3 top. The angle between the direction of μ_{total} and the symmetry axis of the CF_3 top was determined to be 7±1° on the basis of the structure determined in the following section. The dipole moment obtained in this study is in agreement with the value ($\mu=2.45$ D) obtained by the dielectric-constant measurement.[8] Mukhtarov and Kuliev[9] gave slightly different values for the components of the dipole moment: $\mu_a=2.17\pm0.05$ D and $\mu_b=0.42\pm0.05$ D.

Molecular Structure

When the symmetry axis of the trifluoromethyl group is assumed to be colinear with the C–C single bond, there are eleven independent parameters specifying the structure of 3,3,3-trifluoropropene. As 2-^{13}C and three monodeuterated species were observed, the r_s coordinates of the center carbon atom and three hydrogen atoms were calculated to be as listed in Table 6. Three moments of inertia for the normal species are not enough to determine the remaining six parameters. We assume that the C–F bond distance is 1.345±0.003 Å,

Table 6. The r_s coordinates of atoms in 3,3,3-trifluoropropene (Å)

Atom	a_s	b_s
2-C	1.0655±0.0023	0.6605±0.0039
H_1	2.2022±0.0011	−1.0868±0.0025
H_2	3.1732±0.0007	0.4899±0.0056
H_3	1.0499±0.0023	1.7699±0.0015

the value obtained by the electron-diffraction method[6] and the most precise among the observed parameters. Moreover, we made full use of two moments of intertia for the 2-^{13}C species. Assuming the proper values for the parameters concerning three hydrogen atoms, four skeletal parameters, r(C–C), r(C=C), ∠F–C–F, and ∠C–C=C, were calculated by using three moments of inertia for the normal species and the I_b and I_c of the 2-^{13}C species. The results thus obtained were unreasonable, however, even if the effect of the zero-point vibrations was assumed to be rather large. It was found that five moments of inertia were never reconciled to the parameters of the vinyl group within any reasonable range, because the structure of the CF_3 group was strictly conditioned by the assumed value of the r(C–F) bond and the following equation;

$$\Delta I = I_a + I_b - I_c = 4m_F r_{CF}^2 \sin^2 \theta_{FCF}/2 + \Delta_0 \qquad (1)$$

This means that it is necessary to consider a relative configuration between the trifluoromethyl group and the vinyl group. Therefore, we recalculated the structure by taking account of the tilt of the symmetry axis of the trifluoromethyl group relative to the C–C single bond. About a one-degree tilt of the symmetry axis from the C–C single bond outward from the C–C=C angle was enough to explain five moments of inertia. The results are shown in Table 7. The remaining six parameters concerning the three hydrogen atoms were fitted to give their r_s coordinate as is given in Table 6. The obtained structural parameters are also shown in Table 7. The a and b coordinates of the C_2 atom in the molecular structure determined were calculated to be 1.0667 Å and 0.6613 Å respectively; these values were in agreement with the r_s coordinates given in Table 6.

Internal Rotation

No splitting due to internal rotation was observed in any of the spectral lines in the torsionally-excited states up to $v=2$. The frequency of the torsional vibration was obtained from the relative intensities of the transitions in the ground state and in the first torsionally-excited state by the use of the method of Esbitt and Wilson.[12] Nine transitions of $J=2\leftarrow1$, $3\leftarrow2$, and $4\leftarrow3$ with $K_{-1}=0$ and 1 were investigated, but only three were suitable for measurement. The difficulties arose from the richness of the lines. The results for the three transitions which had the least interference are shown in Table 8. From the average relative intensity, the torsional frequency was found to be:

Table 8. Relative intensities of the transitions in the ground state and the $v_t=1$ torsional state of 3,3,3-trifluoropropene at 294 K

Transition	$I(v_t=1)/I(G.S.)$
$3_{03} \leftarrow 2_{02}$	0.66±0.01
$3_{12} \leftarrow 2_{11}$	0.72±0.03
$4_{04} \leftarrow 3_{03}$	0.57±0.03
Average	0.65±0.08

$$\nu_t = 88 \pm 25 \text{ cm}^{-1}.$$

This value is in good agreement with the frequency reported by Mukhtarov and Kuliev.[9] After the well-known method of the internal rotation analysis[13,14] and the molecular structure obtained, the three-fold barrier to the internal rotation of the trifluoromethyl top with respect to the vinyl group was calculated to be:

$$V_3 = 1640 \pm 800 \text{ cm}^{-1}.$$

The large uncertainty is due to the experimental error.

Discussion

The molecular structure of 3,3,3-trifluoropropene is conspicuous in a tilted trifluoromethyl group. Methyl group tilt has been found in several molecules from an analysis of the internal rotation or by structural analysis.[15] Tilted trifluoromethyl groups have not been reported since splittings due to the internal rotation are scarcely observed, and the detailed structures of the molecules containing a CF_3 top have rarely been determined. Though the magnitude of the tilt observed in this study is small, the heavy mass of the CF_3 top causes the effect to be noticeable, shifting the total moments of inertia. As has been described above, the moments of inertia including these shifts can never be explained within the plausible values of other skeletal parameters.

The tilt of the methyl group attached to an unsaturated carbon atom has not shown any definite direction,

such as is observed in propene,[16] acetone,[17] and methylketene.[18] It is not easy to find why the tilt of 3,3,3-trifluoropropene is away from the double bond of the vinyl group. In this connection, though, it should be noted that the distance between the H_1 atom and the fluorine atom in the plane of symmetry is 2.45 Å, slightly less than the sum of the atomic van der Waals radii, 2.55 Å.[19]

Tokue *et al.*[6] determined the average structure of 3,3,3-trifluoropropene by a joint analysis using the electron-diffraction intensities and our rotational constants. Their results agree with ours within the range of experimental error except for the C=C–H angle. The three C=C–H angles of 3,3,3-trifluoropropene have been determined separately in this study; their average is 121.5±1.0°. The corresponding value obtained by Tokue *et al.* is significantly small, 111.3±4.0°. Tokue *et al.* noticed that the C=C–H angle obtained in the joint analysis always became small if the weight of the rotational constants was increased relative to the diffraction intensities, while, inversely, if this angle was fixed to the r_α° parameter, 119.0°, some of the skeletal parameters were shifted appreciably. A similar situation was encountered in our structural analysis when the tilt of CF_3 top was not considered. It will be interesting to carry out the joint analysis with a tilted trifluoromethyl top.

When compared with the structures of related molecules, the partial structure of the CF_3 group of 3,3,3-trifluoropropene is very similar to those of analogous compounds.[3,20] The vinyl group of $CF_3CH{=}CH_2$ is slightly different from those of propene[21] and *cis*-3-fluoropropene.[22] The C–C single and C=C double bonds of 3,3,3-trifluoropropene are compared with those of related molecules in Table 9, which shows a systematic change in the bond distances upon trifluoromethyl substitution; a change in the C–C single bond connecting the methyl group and the rest of the molecule, which is brought about by the trifluoromethyl substitution, depends inversely on the electron-withdrawing force of the rest of the molecule. The molecules studied by Hilderbrandt *et al.*[1] may not act thus or may be influenced by other kinds of forces.

The Reaction of β-Hydroxyalkylmercuric Perchlorate with Sodium Formate in an Aqueous Solution

Sumio SHINODA and Yasukazu SAITO

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 21, 1973)

The reaction of 2-hydroxy-1-propylmercuric perchlorate with sodium formate in an aqueous solution was found to be a redox-type reaction: $CH_3CH(OH)CH_2HgClO_4+HCOONa=CH_3CH=CH_2+Hg(0)+CO_2+H_2O+NaClO_4$. The concentration of the mercurial coordinated by the formate ion was determined *in situ* by analyzing the geminal ^{199}Hg–^1H spin-coupling constant. By changing the ratio of $[CH_3CH(OH)CH_2HgClO_4]/[HCOONa]$, the initial reaction rate was confirmed to be first-order with respect to the formato-mercurial: $v=k[CH_3CH(OH)CH_2HgOCOH]$. From the variation in k with the temperature, the values of $E_a=17.5$ kcal mol^{-1} and $A=4.0\times10^8$ s^{-1} were obtained. On the grounds of the kinetic isotope effect for DCOONa and the stereochemical study with *threo*- and *erythro*-$CH_3CH(OH)CHCH_3HgClO_4$, a mechanism is proposed in which the reaction proceeds solely through the unimolecular redox-decomposition of the formato-mercurial, involving an anti-elimination of olefin coupled with a two-electron transfer from the formate ligand to the mercurial.

A number of inorganic ions are known to oxidize formic acid in solution, and various mechanisms have been postulated for the redox processes.[1–5] In view of the ready redox-decomposition of β-hydroxyalkylmercurials,[6–9] it seemed of interest to investigate further the reactivity of the organomercurials through reactions with formate ions in aqueous media.

One of the unique features of the organomercurial is that it exhibits satellite peaks in the PMR spectra due to proton-mercury (^{199}Hg; $I=1/2$, natural abundance 16.84%) spin-spin interactions. In particular, the geminal proton-mercury coupling constants are useful in discriminating the dissociation or coordination of ligands, since they depend characteristically on the ligand species.[10–13] Accordingly, a quantitative analysis of formate-ion coordination during the reaction becomes possible. In the present work, we wish to report the application of geminal coupling constants of organomercurials to reaction kinetics, together with an elucidation of the reaction mechanism on the grounds of the rate expression, the isotope effect, and the stereochemistry of the reaction.

Experimental

Reagent. A mercuric solution was prepared by adding 28.703 g of 70% perchloric acid (0.20 mol) to 21.659 g of mercuric oxide (0.10 mol) suspended in 50 ml of water. Hydroxymercuration was effected by bubbling propene through the mercuric solution at 0 °C to obtain an aqueous 2-hydroxy-1-propylmercuric perchlorate solution quantitatively. Perchloric acid, formed stoichiometrically by the hydroxymercuration, was neutralized by an equivalent amount of sodium carbonate (5.299 g; 0.05 mol). The stock solution was prepared by diluting the solution to 100 ml with water (1.00 M; pH 0.75); the solution was then stored in a refrigerator. Aqueous *threo*- and *erythro*-3-hydroxy-2-butylmercuric perchlorate solutions were prepared in a similar manner using *cis*- and *trans*-2-butenes respectively. An aliquot of these solutions (2 to 10 ml) was used in each experiment. Sodium deuteroformate (DCOONa) of a minimum isotopic purity (atom % D) of 99% was obtained from Merck, Sharp, and Dohme of Canada, Ltd. The other chemicals were the G. R. grade, prepared by the Tokyo Kasei Co., Ltd. (Tokyo).

Experimental Procedure. A calculated amount of sodium formate (0.30 to 2.00 M) was added to 2 ml of the 2-hydroxy-1-propylmercuric perchlorate stock solution at 0 °C. A part of the solution maintained at 0 °C was quickly transferred to a PMR sample tube and put in the probe of the spectrometer kept at an adjusted temperature. The temperatures (45.2 to 63.2 °C) were calibrated by the relative chemical shifts of ethyleneglycol. The reaction was pursued by taking spectra in sequence with a JEOL PS-100 or a Hitachi R-20B PMR spectrometer.

In the determination of the amount of gas evolution, the solution of the reactants was introduced into a 100-ml flask connected to a vacuum line, and the amount was determined manometrically. A Hitachi RMU-6 mass spectrometer was used for the analysis of the gas-phase components. The amounts of *cis*- and *trans*-2-butenes were determined by gas chromatography using a column of 20% dimethylsulfolane on Celite.

Results and Discussion

Stoichiometry of the Reaction of $CH_3CH(OH)CH_2HgClO_4$ with Sodium Formate. The aqueous solution of 2-hydroxy-1-propylmercuric perchlorate (**1**) mixed with an equimolar amount of sodium formate was stable at 0 °C, but both the evolution of gas and the precipitation of elemental mercury were observed at *ca.* 50 °C. The reaction was pursued by taking the PMR spectra of a solution containing various concentrations (0.30 to 2.00 M) of sodium formate *in situ* after the temperature of the solution had been abruptly raised from 0 °C. The concentrations of the reactants were determined from the doublet peak (CH_3-; δ 1.21) for the mercurials and the singlet peak (HCO-; δ 9.12) for the formate ions respectively, in comparison with the peak intensity of the external tetramethylsilane reference. Some typical representative spectra are shown in Fig. 1, in which no other absorption peaks are obviously detected.

The time-course of the respective concentrations of the reactants is presented in Fig. 2, which evidently confirms the following equations:

$$[CH_3CH(OH)CH_2Hg^+]_0 - [CH_3CH(OH)CH_2Hg^+] = [HCOO^-]_0 - [HCOO^-] \quad (1)$$

$$d[CH_3CH(OH)CH_2Hg^+]/dt = d[HCOO^-]/dt \quad (2)$$

A mass-spectrometric analysis of the evolved gas showed that the gas-phase composition was an equi-

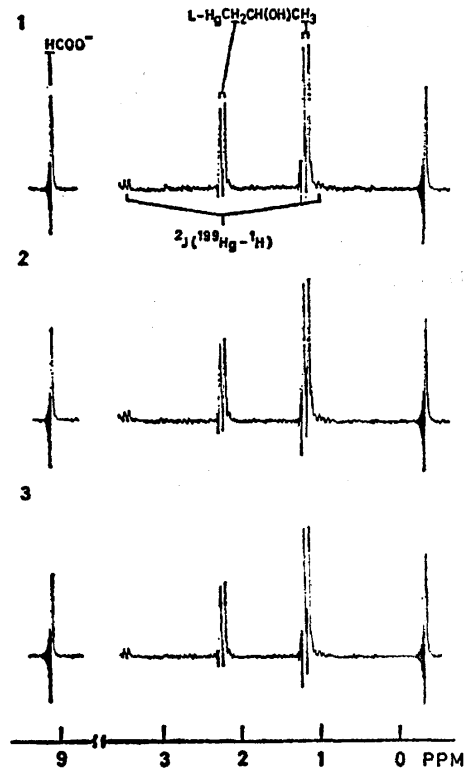

Fig. 1. The time-sequential PMR spectra obtained *in situ* for the reaction of 2-hydroxy-1-propylmercuric perchlorate with sodium formate in an aqueous solution at 51.0 °C. The unchanged singlet peak at −0.32 ppm is an absorption due to an external tetramethylsilane reference. Initial concentrations of the mercurial and sodium formate were 1.00 M and 0.70 M, respectively. These spectra were taken after (1) 14.0 min, (2) 37.0 min, (3) 136.3 min from the moment of raising the solution temperature.

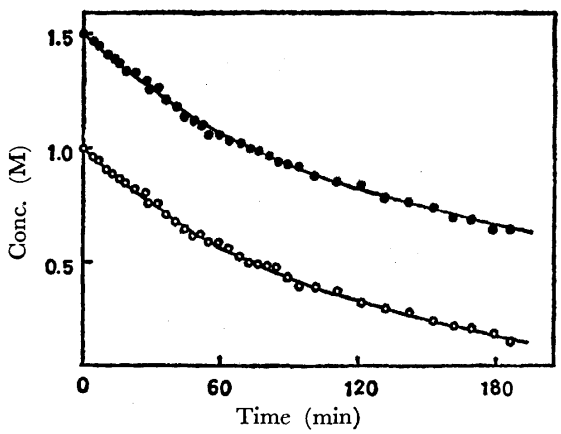

Fig. 2. The time-course of concentrations of the reactants for the reaction of 2-hydroxy-1-propylmercuric perchlorate with sodium formate in an aqueous solution at 63.2 °C. ○ and ● correspond to the mercurial and formate ions, respectively.

molar mixture of propene and carbon dioxide. No other gas, such as hydrogen or carbon monoxide, was detected by either mass-spectroscopic or gas-chromatographic analysis. It was also found by manometric measurement that the amounts of propene and carbon dioxide formed coincided (within 2%) with those of decomposed mercurials and formate ions. The stoichiometry of the reaction can, therefore, be expressed by Eq. (3), which obviously shows a redox-type reaction:

$$CH_3CH(OH)CH_2HgClO_4 + HCOONa = CH_3CH{=}CH_2 + Hg(0) + CO_2 + H_2O + NaClO_4 \quad (3)$$

Rate Equation for the Reaction of $CH_3CH(OH)CH_2HgClO_4$ with Sodium Formate. In the solution of the reactants, mercurials are present in the forms of both an aquo-complex, $CH_3CH(OH)CH_2HgOH_2^+$ (**2**),[14] and a formato-complex, $CH_3CH(OH)CH_2HgOCOH$ (**3**),[15] which are equilibrated as Eq. (4). Their ratio is reflected in the apparent value of the geminal ^{199}Hg-^1H spin-coupling constant, $^2J_{HgH}$, of the mercurial. Formate ions are found in the forms of ligands, free ions, and formic acid, which exchange with each other rapidly on the PMR time-scale. The peak intensities in Fig. 1 show the total amounts of the mercurials and formate ions respectively.

$$\underset{\mathbf{2}}{CH_3CH(OH)CH_2HgOH_2^+} + HCOO^- \rightleftharpoons \underset{\mathbf{3}}{CH_3CH(OH)CH_2HgOCOH} + H_2O \quad (4)$$

Since any observed value of $^2J_{HgH}$, J_{obs}, is expressed as a function of the molar fractions (Eq. (5)), the amounts of both **2** and **3** can be adequately evaluated through the use of Eq. (6) by monitoring the value of J_{obs} *in situ*, if the inherent values of $^2J_{HgH}$ for **2** and **3** (J_a and J_f, respectively) are properly determined:

$$J_{obs} = J_a x + J_f(1-x) \quad (5)$$

$$\left.\begin{aligned} x &= (J_{obs}-J_f)/(J_a-J_f) \\ 1-x &= (J_a-J_{obs})/(J_a-J_f) \end{aligned}\right\} \quad (6)$$

where x and $(1-x)$ are molar fractions of **2** and **3** respectively. As the complete dissociation of **1** had been confirmed,[14] it was possible to determine the value of J_a by simply measuring the $^2J_{HgH}$ for the aqueous solution of **1** (258.0 Hz). The increase in the added amount of sodium formate caused the decrease in the value of $^2J_{HgH}$ (Fig. 3). In the presence of a

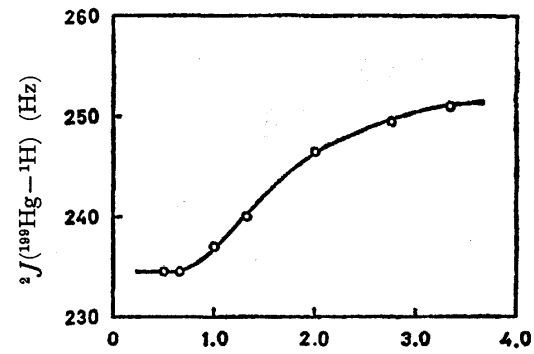

Fig. 3. Variation of geminal ^{199}Hg-^1H spin-coupling constant with the amount of added sodium formate. The concentration of $CH_3CH(OH)CH_2HgClO_4$ was commonly chosen as 1.00 M.

sufficient excess of sodium formate, the value became apparently constant. By extrapolating the plot to the intercept, the value of J_f was determined to be 234.5 Hz. The difference in value between J_a and J_f is large enough for us to determine x and $(1-x)$ with sufficient precision.

The reaction rates were determined for the solutions of the reactants with various ratios of [$CH_3CH(OH)CH_2HgClO_4$] to [HCOONa], where the initial concentrations of the mercurial were commonly chosen as 1.00 M. The increase in the amount of added sodium formate accelerated the reaction. Further, as is shown in Fig. 4, a plot of the initial rate against the concentration of **3**, as evaluated by Eq. (6), is linear. Each of the double circles represents three experimental values of the initial rates determined for solutions with different pH values, which were controlled by added amounts of both sodium formate and perchloric acid.

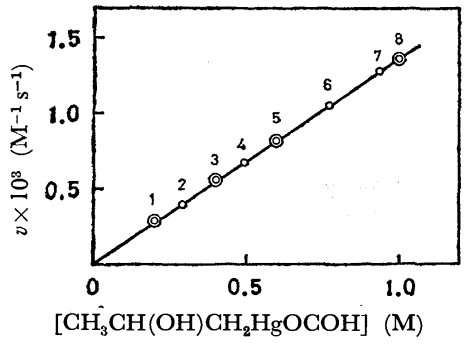

Fig. 4. Plot of initial rate *vs.* concentration of 2-hydroxy-1-propylmercuric formate at 63.2 °C.
Each point corresponds to the composition (HCOONa (M), $HClO_4$ (M)) of the solution: 1 (0.29, 0.10; pH 0.77. 0.58, 0.41; pH 0.52. 0.95, 0.82; pH 0.20), 2(0.30, 0.00; pH 1.60), 3(0.50, 0.10; pH 1.08. 0.79, 0.40; pH 0.85. 1.18, 0.80; pH 0.57), 4(0.50, 0.00; pH 1.80), 5(0.71, 0.10; pH 1.59. 1.02, 0.41; pH 1.34. 1.41, 0.81; pH 1.05), 6(0.80, 0.00; pH 2.27), 7(1.07, 0.00; pH 2.39), 8(1.50, 0.00; pH 3.41. 1.80, 0.00; pH 3.88. 2.00, 0.00; pH 4.20), where the concentration of $CH_3CH(OH)CH_2HgClO_4$ was commonly chosen as 1.00 M. Initial rates were calculated from the initial linear slopes of the plots of the conversion (below 5%) *vs.* time.

The observed absence of any appreciable variation in the rate with the pH evidently shows that the reaction is zero-order in proton activity in the pH range studied.

The rate equation for the reaction of **1** with sodium formate in an aqueous solution is, therefore, given by Eq. (7). This equation shows that the reaction proceeds only when the formate ligand is coordinated:

$$v = -d[CH_3CH(OH)CH_2Hg^+]/dt = -d[HCOO^-]/dt = k[CH_3CH(OH)CH_2HgOCOH] \quad (7)$$
$$(k = 1.35\times10^{-3}\ s^{-1} \text{ at } 63.2\ ^\circ C)$$

Kinetic Isotope Effect for the Reaction of $CH_3CH(OH)CH_2HgClO_4$ with Sodium Formate. Experiments with DCOONa indicated a kinetic isotope effect, k_H/k_D, of 2.1±0.1 (the mean of three experimental values), at 51.0 °C. This effect is similar in magnitude to those for the inorganic ions,[1,2] although considerably smaller than that for Hg^{2+} (3.4 at 46.5 °C).[2] The existence of the kinetic isotope effect confirms that the C–H bond of the formate ion is actually broken in the rate-determining step. Therefore, we can exclude a possible alternative path in which the slow deoxymercuration of the mercurial is succeeded by the fast oxidation of the formate ion by the free mercuric ion formed, even though this path is consistent with the data in Fig. 2. In fact, oxy-ligands are far less effective for the deoxymercuration than halo-ligands;[16] moreover, the reaction rate has been claimed to be first-order in proton activity in the case of deoxymercuration.[17,18]

Stereochemistry of the Reactions of $CH_3CH(OH)CHCH_3HgClO_4$ with Sodium Formate. *Threo-* and *erythro-*3-hydroxy-2-butylmercuric perchlorate, obtained by the hydroxymercuration of *cis-* and *trans-*2-butenes[19] respectively, were used to determine the stereochemical nature of the reaction. Both the evolution of gas and the precipitation of elemental mercury were also observed for the reactions of these mercurials with sodium formate. The gas-chromatographic analyses of the evolved 2-butenes showed that the stereo-isomerism was completely retained in comparison with the respective starting 2-butenes. This clearly indicates that the reaction involves the stereospecific anti-elimination of olefins.

Activation Parameters for the Decomposition of $CH_3CH(OH)CH_2HgOCOH$. From the variation in k in Eq. (7) with the temperature (45.2 to 63.2 °C), the values of E_a=17.5 (±0.5) kcal mol^{-1} and A=4.0 (±0.9)×10^8 s^{-1} were obtained as activation parameters for the unimolecular decomposition of **3**. The activation energy, E_a, is of a magnitude similar to those for the inorganic ions.[1,2] The value of the pre-exponential factor, A, reported for the unimolecular decomposition of the Tl^{3+}-formate ion adduct,[2] lies near to the normal magnitude of A ($\sim10^{13}$ s^{-1}) for simple unimolecular reactions in solutions.[20] Therefore, the comparatively large reduction of A for the unimolecular decomposition of **3** strongly suggests a restricted structure of the transition state.

Structural Consideration of the Activated Complex. Taking into consideration the results of the kinetic isotope effect and stereochemistry, the structure of the activated complex represented in Fig. 5 is proposed for the decomposition of the formato-mercurial, where the hydroxyl ion and the elemental mercury are eliminated in an anti-manner, coupled with two-electron transfer processes. The magnitude of A seems to be

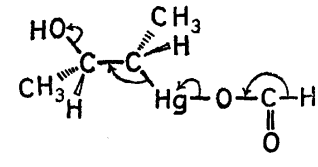

Fig. 5. Proposed structure of the activated complex for the redox decomposition of *threo*-3-hydroxy-2-butylmercuric formate.

compatible with this sterically-restricted structure. The observed stereospecificity of the reaction may be correlated with the predominant preference of antiperiplanar elimination in the *E*2 reactions.[21]

The authors wish to express their gratitude to Professor Yukio Yoneda for his helpful discussions and encouragement. They would also like to acknowledge the financial support received from the Kawakami Memorial Fund.

The Crystal and Molecular Structure of β-Lactose

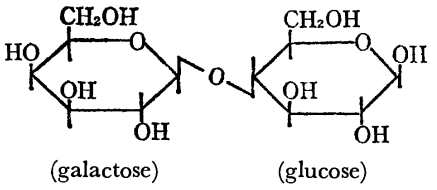
Ken HIROTSU and Akira SHIMADA†

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received December 24, 1973)

The crystal structure of β-lactose ($C_{12}H_{22}O_{11}$) was solved by direct phasing methods with integrated photographic intensity data. The structure was refined by the anisotropic least-squares method to give a final R value of 0.068 for the observed reflections. The space group is $P2_1$, with $Z=2$ and with unit cell dimensions of $a=10.839$ (6), $b=13.349$ (6), $c=4.954$ (5) Å, and $\beta=91.31$ (9)°. All the hydrogen atoms were located on different syntheses. The crystals are nearly isostructural with those of β-cellobiose except for the axial O(4) atom. The exocyclic C(5)–C(6) and C(5′)–C(6′) bonds are significantly shorter than the other C–C bonds. The lengths of the two ring C–O bonds are unequal in the galactose unit and equal in the glucose unit. The C(1)–O(1) and C(1′)–O(1′) bond lengths are shorter by 0.015 Å and 0.030 Å than the mean exocyclic C–O length of 1.417 Å. The structure contains an intramolecular hydrogen bond and exhibits an asymmetrical twist about the bridge bond. All the oxygen atoms, except the bridge oxygen atom, are involved in the hydrogen-bonding network, which comprises two terminating chains.

The crystal structure of β-lactose has been determined as a part of a series of X-ray diffraction studies of carbohydrates in this laboratory.[1] β-Lactose (*O*-β-D-galactopyranosyl-(1→4)-β-D-glucopyranoside) is a disaccharide which consists of glucose and galactose units, as is shown in (I):



(galactose) (glucose)

(I)

The crystal structure of α-lactose monohydrate[2] was determined by Fries, Rao, and Sundaralingam. The main purpose of our investigation was to compare precisely the bond lengths and angles of β-lactose with those of α-lactose,[2] β-cellobiose,[3–5] and methyl β-cellobioside.[6] The conformation of the (β-1,4) glycosidic bond, which is present in a variety of natural polysaccharides, and the hydrogen-bond scheme in crystal was also of interest.

Experimental

Suitable crystals were prepared from a hot aqueous solution by the method reported by Tsuzuki and Mori.[7] The cell dimensions were measured from zero-layer Weissenberg photographs, which were calibrated with superimposed Al powder lines ($a=4.04934$ Å). The density was determined by the flotation technique using a mixture of cylohexane and carbon tetrachloride. The crystal data are summarized in Table 1. A crystal with the dimensions of $0.2\times0.2\times0.3$ mm was used for all the intensity measurements. The intensity data were recorded on multiple film, equi-inclination integrating Weissenberg photographs using Cu$K\alpha$ radiation. Layers from $h0l$ to $h2l$ and from $hk0$ to $hk5$ were obtained. The intensities were estimated visually by comparison with a calibrated intensity standard. No correction was applied for absorption and extinction. All the intensity data were corrected for spot shape and for Lorentz and polarization factors. The resulting data were correlated and reduced to the relative structure factor amplitudes using the method of Hamilton, Rollet, and Sparks.[8] A total of 1595 structure factors were evaluated; 129 were too weak to be measured. Finally, a Wilson plot was made estimating an approximate absolute scale and an overall temperature factor, in order to calculate normalized structure factor magnitudes, $|E|$.

† Deceased August 5, 1973.

Structure Determination and Refinement

The crystal structure of β-lactose was solved by the multisolution method described by Woolfson and Germain.[9] The starting set of phases is listed in Table 2. In order to apply the tangent formula,[10] numerical phases from 45° to 315° (=−45°) in steps of 90° were assigned to the A and B symbols. Tangent refinement was carried out for each of the 16 possible phase combinations, and the number of reflections included was gradually increased from 100 with $E>1.70$ to 350 with $E>1.22$. The values of R_{Karle}[11] ranged from 0.27 to 0.31, and those of Z[12], from 8842 to 10882. All sixteen E-maps were calculated in increasing order of R_{Karle} value. A cursory inspection revealed the site of the glucose unit in several of the E-maps, and so the unit was chosen as a trial partial structure.[13] How-

TABLE 2. THE STARTING SET OF PHASES

h	k	l	E	ϕ	
3	9	−2	2.85	0°	
4	0	3	2.14	0°	origin and enantiomorph

7	7	−1	2.87	B	(90° → 115.7°)

ever, this partial structure could not be developed into a complete structure by means of tangent refinement. After completing the structure, it turned out that the unit was actually properly oriented, but not placed in the right position in the unit cell. After this initial failure, the following new sets of phases were assigned to the A and B symbols. Tangent refinement was again carried out for each of the additional 20 possible phase combinations: (A=±90°, B=±45°, ±135°), (B=±90°, A=±45°, ±135°), (A=±90°, B=±90°). A solution was finally obtained from an *E*-map calculated by means of the phases in the most consistent set (R_{Karle}=0.21 and Z=10470). The initial and refined phases in this set are shown in Table 2. The positions of all the non-hydrogen atoms were easily located and further confirmed by a least-squares refinement. Seven cycles of isotropic block-diagonal least-squares refinement resulted in an R ($=\Sigma||F_o|-|F_c||/\Sigma|F_o|$) value of 12.5%. Six more cycles of anisotropic block-diagonal least-squares and two difference-map calculations were necessary to locate the 22 hydrogen atoms. The isotropic thermal parameters of the hydrogen atoms were assumed to be equal to those of the parent atoms, which were obtained from the last stage of isotropic refinement (R=12.5%). These hydrogen atoms were included in the refinement, in which positional parameters were varied but thermal parameters were fixed. Additional cycles of refinement resulted in an R value of 7.4%. At this point, seven reflections with very large structure-factor amplitudes were removed from the data because they appeared to be affected by secondary extinction. Four final cycles of block-diagonal refinement gave an R of 6.8% for the observed reflections and one of 7.7% for all the reflections. Throughout the refinements,

Table 3. Fractional atomic coordinates and thermal parameters in β-lactose

Key to atomic numbering is given in Fig. 1. The temperature factor expression used was

$$\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+hk\beta_{12}+hl\beta_{13}++kl\beta_{23})].$$

Numbers in parentheses refer to standard deviations of the last place.

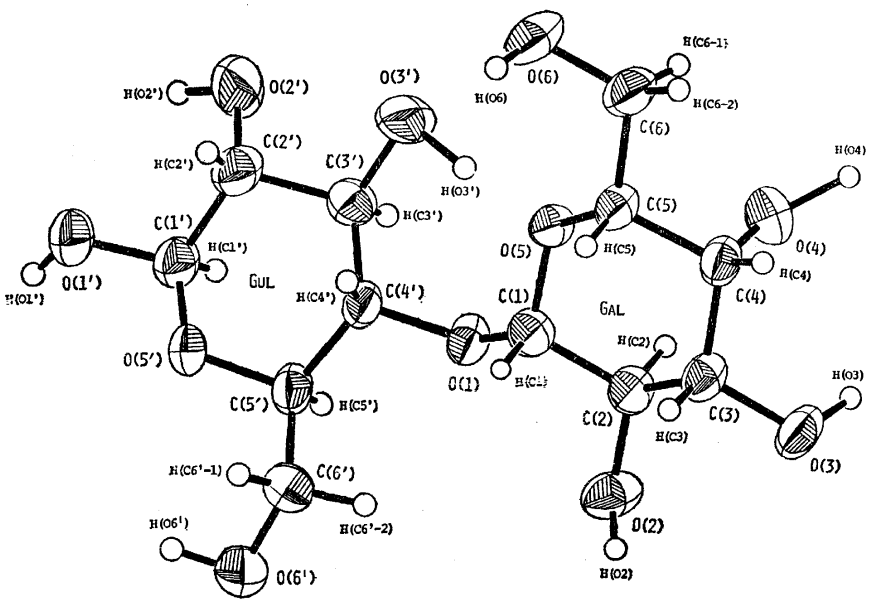

Fig. 1. Molecular conformation and atomic numbering in β-lactose.
The 74% probability thermal ellipsoids are shown for carbon and oxygen atoms.

the following weighting scheme was used:

$$w = 0.15 \text{ for } |F_o| < 1.4$$
$$w = (1.4/F_o)^2 \text{ for } |F_o| \geq 1.4.$$

The final atomic parameters are listed in Table 3. The atomic scattering factors used for the carbon and oxygen atoms were those of the International Tables for X-ray Crystallography,[14] and for the hydrogen atoms, those of Stewart, Davidson, and Simpson (1965).[15] The final structure factors are given in Table 4.*

After the completion of this work, this structure was found to be nearly isomorphous with β-cellobiose except for the atomic position of O(4).

Discussion

Figure 1 illustrates the conformation of the molecule of β-lactose, with the standard numbering for carbohydrates.

Bond Lengths and Angles. The bond lengths and angles involving carbon and oxygen atoms are shown in Fig. 2. The standard deviations are 0.005~0.006 Å for the carbon-carbon bonds and the carbon-oxygen bonds, and 0.3°~0.4° for the valence-bond angles. The bond lengths and angles in the β-galactosyl and β-glucosyl moieties agree well with the values previously reported by Berman, Chu, and Jeffrey.[16]

The carbon-carbon distances found in the unprimed ring (galactosyl moiety) range from 1.508 Å to 1.531 Å, with an average value of 1.524 Å, while those found in the primed ring (glucosyl moiety) range from 1.510 Å to 1.538 Å, with an average value of 1.530 Å. The average values of the corresponding ring C–C bonds in the four disaccharides listed in Table 5 range from 1.521 Å (C(1)–C(2)) to 1.533 Å (C(3')–C(4')) and are normal

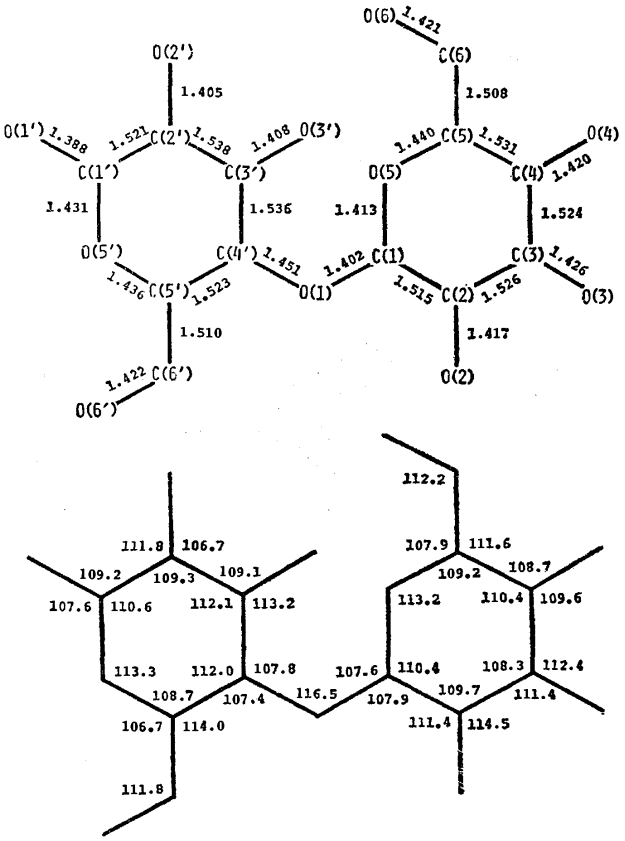

Fig. 2. Bond lengths(Å) and bond angles(°) in β-lactose.

values for carbohydrates, although C(1)–C(2) and C(1')–C(2') seem to be slightly short. The exocyclic C(5)–C(6) and C(5')–C(6') bonds are significantly shorter than the ring C–C bonds in all four disaccharides. The average value of the C(5)–C(6) bond is 1.514 Å, and that of C(5')–C(6') is 1.508 Å. This slight shortening with respect to the average ring C–C bonds has been

* Table 4 has been submitted to, and is kept by the office of the Chemical Society of Japan, 1-5 Kanda-Surugadai, Chiyoda-ku, Tokyo 113. (Document No. 7417).

pointed out by Ham and Williams.[6]

Two endocyclic C–O bonds [C(1)–O(5) and C(5)–O(5)] in the unprimed ring of β-lactose are found at 1.413 Å and 1.440 Å, the latter bond being about 5σ longer than the former. In the primed ring, the corresponding distances [C(1')–O(5') and C(5')–O(5')] are nearly equal: C(1')–O(5')=1.431 Å *versus* C(5')–O(5')=1.436 Å. The same trend was observed in β-cellobiose: C(1)–O(5)=1.425 Å *versus* C(5)–O(5)=1.436 Å and C(1')–O(5')=1.435 Å *versus* C(5')–O(5')=1.437 Å. However, the two endocyclic C–O bonds in methyl β-cellobioside[6] are nearly equal in the primed and the unprimed rings. In α-lactose,[2] the same pattern, C(1)–O(5)<C(5)–O(5), as in β-cellobiose and β-lactose was found in the unprimed ring, while the reverse trend, C(1')–O(5')<C(5')–O(5'), was found in the primed ring. These differences and the greater variation of C–O bond lengths may be significant and may be associated with the type of hydrogen bond involved, but no correlation is apparent.

The exocyclic C–O bonds in β-lactose range from 1.405 Å to 1.426 Å, with a mean value of 1.417 Å, excluding the anomeric and bridge C–O bonds. The corresponding average lengths of α-lactose, β-cellobiose, and methyl β-cellobioside are 1.427 Å with a spead of 0.018 Å, 1.419 Å with a spread of 0.017 Å, and 1.428 Å with a spread of 0.030 Å, respectively. There are no significant differences among these average values. The means value of the C(2)–O(2) bonds in the four compounds listed in Table 5 is 1.419 Å. The corresponding average values of C(3)–O(3), C(4)–O(4), C(6)–O(6), C(2')–O(2'), C(3')–O(3'), and C(6')–O(6') are shown in the 7th column of Table 5. There are no significant differences among these average values.

The C(1)–O(1) and C(1')–O(1') bond lengths in the anomeric positions of β-lactose are significantly shorter, by 0.015 Å and by 0.030 Å respectively, than the mean exocyclic C–O length of 1.417 Å. This shortening effect has been found in disaccharides in Table 5 and many other related compounds. The C(1)–O(1) bonds in the unprimed rings of α-lactose, β-cellobiose, and methyl β-cellobioside are all greater than the C(1')–O(1') bonds in the primed rings, as is shown in Table 5. The bridge C(4')–O(1) bond distance (1.451 Å) of β-lactose is in good agreement with the corresponding length (1.446 Å) in β-cellobiose. The average C(4')–O(1) bond length of four disaccharides in Table 5 is 1.443 Å, significantly longer than the normal C–O distance for carbohydrates.

The bond angles of four disaccharides with (β-1,4) linkage have been tabulated in Table 6. The average carbon valence-bond angle within the rings of β-lactose is 110.1° with a spread of 3.8°. The average deviations from the corresponding angles in β-cellobiose, α-lactose, and methyl β-cellobioside are 1.0°, 1.2°, and 2.2° respectively. The C–O–C ring angles are the largest among the ring angles in β-lactose, α-lactose, and β-cellobiose, but not in the primed ring of methyl

a) This value was not included in the calculation of the mean value, since the oxygen atom is in an axial position.

β-cellobioside.

In β-lactose, the exocyclic angles range widely from 106.7° to 114.5°, with an average value of 110.0°, excluding the valence-bond angle at the glycosidic oxygen atom. The average difference in the corresponding exocyclic bond angles between β-lactose and β-cellobiose is 0.8°, which is significantly small compared with the other two average differences (1.6° and 1.8°) between β-lactose and α-lactose, and between β-lactose and methyl β-cellobioside. This may be because β-lactose is nearly isostructural with β-cellobiose. The exocyclic bond angles are strongly affected by intermolecular forces, especially by the formation of hydrogen bonds. The larger differences in the average values found between β-lactose and α-lactose, and between β-lactose and methyl β-cellobioside, are caused by the different molecular packing, *i.e.*, the different hydrogen-bonding scheme.

The bond angle of 116.5° at the bridge oxygen atom of β-lactose agrees with the corresponding angles found in the crystal structures of β-cellobiose (116.1°), α-lactose (117.1°), methyl β-cellobioside (115.8°), lactose–calcium bromide heptahydrate (115.6°),[17] and lactose–calcium chloride heptahydrate (116.0°).[18]

Molecular Conformation. The conformational angles in the pyranose rings of β-lactose, α-lactose, β-cellobiose, and methyl β-cellobioside are listed in Table 7. The torsional angles in the galactose unit of β-lactose range only from 55.9° to 61.2°, with an average value of 58.2°. On the other hand, those of the glucose unit range more widely, from 48.9° to 65.0°, with a mean value of 55.7°. In the four disaccharides listed in Table 7, the torsional angles around the ring C–O bonds are generally the largest, while those around C(2)–C(3), C(3)–C(4), C(2′)–C(3′), and C(3′)–C(4′), which are at the position opposite to the ring C–O

bonds, are the smallest, although there are some exceptions. This trend may be due to the smaller puckering around the C(2)-C(3) and C(3)-C(4) bonds and the larger puckering around the C(5)-O(5) and C(1)-O(5) bonds. The torsional angles involving exocyclic atoms in β-lactose are shown in Table 8. The exocyclic torsional angles around C(1')-C(2'), C(2')-C(3'), C(3')-C(4'), and C(4')-C(5') in the β-glucose residue of β-lactose are considerably larger than those in the galactose residue.

Both C(5)-C(6) and C(5')-C(6') bonds have the+ *synclinal* conformation.

The conformational twists about the C(1)-O(1) and C(4')-O(1) bonds are of interest in comparison with the models for cellulose. The torsional and pseudotorsional angles[19] of the (β-1,4) linkage in the five determined structures and the present one are given in Table 9. Because of the isomorphous structures, the torsional and pseudotorsional angles of β-lactose are approximately equal to those of β-cellobiose. These two molecules exhibit an asymmetrical twist about the bridge bond, $\Psi_1=-70.7°$ and $\Psi_2=108.0°$ in β-lactose, and $\Psi_1=-76.3°$ and $\Psi_2=106.4°$[20] in β-cellobiose. The two isostructural lactose complexes, lactose–calcium bromide heptahydrate and lactose–calcium chloride heptahydrate, also exhibit an asymmetrical twist. The conformations around the bridge bonds of these two complexes are very similar to those of β-lactose and β-cellobiose, as is shown in Table 9. In contrast to the above four structures, a symmetrical twist about the bridge bond is found in α-lactose: $\Psi_1=-92.6°$ and $\Psi_2=94.6°$. In methyl β-cellobioside, the conformation around the bridge bond is close to that of α-lactose, but it is not symmetrical. The conformations about the bridge bonds in disaccharides with (β-1,4) linkage are affected by the intermolecular forces in the crystal, especially hydrogen bonding, but, roughly speaking, the same conformation is maintained. This similarity in conformation about the bridge bond is caused by the fact that, in these molecules, the intramolecular hydrogen bond, O(3')···O(5), is always formed and plays an important role in determining the molecular conformation.

Hydrogen Bonding. The molecular packing and

k	2−*x*,	1/2+*y*,	−1−*z*

the hydrogen-bonding scheme are shown in Figs. 3 and 4. The hydrogen-bonding distances and angles are listed in Table 10. The crystal structure of β-lactose is nearly isomorphous with β-cellobiose. However, the hydrogen-bonding scheme around the axial O(4) atom is different from that of β-cellobiose. When the equatorial O(4) atom in the crystalline β-cellobiose is assumed to be replaced by the axial O(4) atom and the intermolecular distances are subsequently calculated, two hydrogen bonds, O(6)···O(4) and O(4)···O(2′), are missing and only one short contact, O(4)···O(3′), of 2.30 Å is found. This short contact can be lengthened to correspond to the hydrogen-bond length by slight changes in the atomic positions, and one more hydrogen bond can be formed between O(6) and O(3′), as is shown in Figs. 3 and 4. Therefore, crystalline β-lactose is isomorphous with β-cellobiose. β-Epicellobiose (*O*-β-D-glucopyranosyl-(1→4)-β-D-mannopyranoside) is different from β-cellobiose only in that the O(2′) atom is in an axial position. In a similar manner, the equatorial oxygen atom O(2′) in the crystalline β-cellobiose is assumed to be replaced by the axial O(2′). As a result, one short contact of 3.18 Å is found between O(2′) and O(6′). Although two hydrogen bonds, O(2′)–H···O(6′) and O(4)–H···O(2′), are missing, there appear to be two compensating hydrogen bonds, which are perhaps formed between axial O(2′) and O(6′) and between O(4) and O(3′) by slight changes

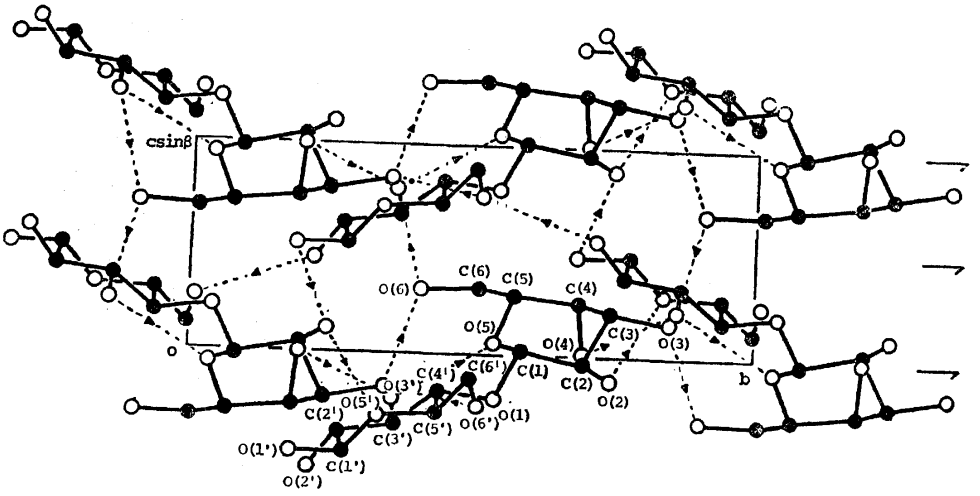

Fig. 4. Packing of the structure viewed down the *a* axis.

in atomic positions. Hence, crystalline anhydrous β-epi-cellobiose, as well as β-lactose, might be isomorphous with β-cellobiose.

Each of four hydroxyl groups, O(2)–H, O(3)–H, O(6)–H, and O(6′)–H, participates in hydrogen bonds as both one donor and one acceptor. O(4)–H, O(1′)–H, and O(2′)–H serve as donors only. O(3′)–H serves as one donor and two acceptors. Two ring oxygens, O(5) and O(5′), take part in hydrogen bonds as acceptors. The glycosidic linkage oxygen atom is not involved in hydrogen bonds, just as in all crystal structures of di- and tri-saccharides. The hydrogen-bond system comprises two terminated chains:

$$\begin{aligned} &O(2', g) \rightarrow O(6', h) \rightarrow O(3, i) \rightarrow \\ &\quad O(6, a) \rightarrow O(3', d) \rightarrow O(5, d) \\ &\qquad\qquad \uparrow \\ &\qquad\qquad O(4, j) \end{aligned}$$

$$O(1', d) \rightarrow O(2, f) \rightarrow O(5', a)$$

where → indicates the donor direction and where the small letter refers to the symmetry operations given in Table 10. The intramolecular hydrogen bond, O(3′)⋯O(5)=2.707 Å, is significantly short compared with that of 2.811 Å in α-lactose, that of 2.767 Å in cellobiose, that of 2.762 Å in methyl β-cellobioside, that of 2.76 Å in lactose–calcium bromide heptahydrate, and that of 2.75 Å in lactose–calcium chloride heptahydrate.

Computer Programs

All the calculations were performed on a FACOM 270/30 computer at the Computer Center of Osaka City University using the following programs: RSLC-3,[21] RSSFR-3,[21] HBLS-IV,[21] SCALE (film factor, Lp, and layer scaling),[22] DEAM,[23] PHASE-I, II, and III (direct method),[24] and BOND (bond length and angle, best plane, dihedral angle, and intermolecular distance).[25]

The Reaction of Hot Deuterium Atoms with *cis*-2-Butene

Shin SATO, Seishi NISHIDA, and Kiyoshi HOSOYA

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 25, 1973)

The photolysis of deuterium iodide at the wavelength of 2288 Å was carried out in the presence of *cis*-2-butene and iodine at 40 °C. Among the products, hydrogen (D_2 and HD), methane (CH_3D), propylene ($CH_3CH{=}CHD$), *n*-butane ($CH_3CHDCHDCH_3$), and 1-butene were measured as a function of the pressure of *cis*-2-butene. The formation of HD at higher pressures of *cis*-2-butene was attributed to the abstruction of H atoms from *cis*-2-butene-by hot D atoms. This reaction accounted for 8% of the total D atom-reaction. The formations of CH_3D, C_3H_5D, and $C_4H_8D_2$ were well explained by the successive reactions of hot butyl radicals, $C_4H_8D^*$.

In the reaction of recoil-tritium atoms with a saturated hydrocarbon,[1] the substitution reaction is well known to occur together with the abstraction reaction:

$$T^* + RH \begin{cases} \nearrow RT + H \\ \searrow HT + R \end{cases}$$

In a previous paper,[2] we reported that, when hot deuterium atoms were produced by the photolysis of DI at 2288 Å in the presence of ethylene, a large amount of HD was formed, and that the pressure dependence of this HD formation could be well explained in terms of the following reaction scheme:

$$D^* + C_2H_4 \rightarrow C_2H_4D^* \rightarrow \begin{cases} H + C_2H_3D \\ \xrightarrow{+DI} HD \end{cases}$$

The so-called "billiard-like" substitution reaction and also the abstraction reaction do not seem to occur with ethylene.[3] In the case of propylene, on the other hand, more than 10% of the reaction of hot deuterium atoms is attributable to the abstraction reaction producing HD.

In order to substantiate these findings, we have studied the reaction between hot deuterium atoms and *cis*-2-butene after a slight modification of the reaction system.

Experimental

The deuterium iodide and hydrogen iodide were prepared in a manner described previously.[2] The *cis*-2-butene was purchased from the Takachiho Shoji Co., which showed no impurity on gas chromatographic analysis. To keep the reaction system at 40 °C, a small air bath box was made. The temperature inside was kept within ±1 °C by using a modified Beckmann thermometer. The irradiation by a cadmium resonance lamp was performed through a quartz window attached to the box. In each experiment, the cell was saturated with iodine vapor before deuterium iodide and *cis*-2-butene were introduced.

The non-condensable products at 77 K were collected by means of Toepler pump equipped with a cuprous oxide furnace, which was used to combust hydrogen into water when the amount of methane produced was measured. Among the condensable products at 77 K, hydrocarbons were analyzed on the gas chromatograph of a 20-m-long dimethyl sulforane column. The D-content in the product was measured by mass spectrometry after each component had been separated by gas chromatography. Many kinds of alkyl iodides were found to be formed, but they were not analyzed quantitatively.

Results

The photolysis results are summarized in Fig. 1. All the data were obtained when the pressures of DI and I_2 were 10.3 and 1.1 Torr respectively, in a 120-ml reaction vessel; the irradiation time was 6 min. Experiments with HI in place of DI were also carried out. Those results are not shown here, because the curves for each product almost coincided with those for the corresponding products shown in Fig. 1. The plots for HD and D_2 were obtained after a correction was made for the initially-present impurity, HI, in the DI gas. The correction method has been previously described.[2]

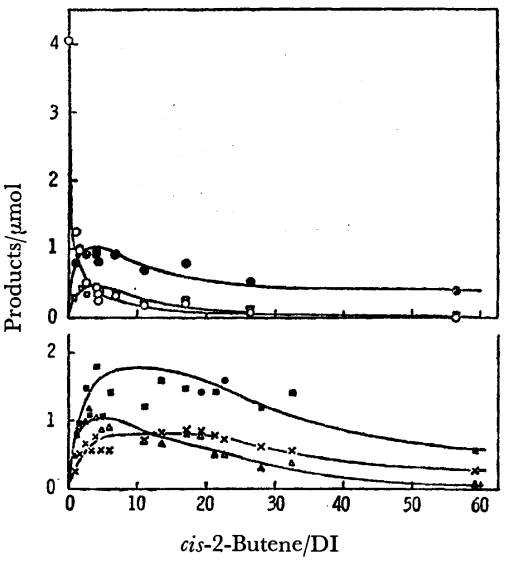

Fig. 1. The photolysis products as a function of the *cis*-2-butene/DI ratio. ○, D_2; ●, HD; □, CH_3D; ■, *n*-butane; △, propylene; ×, 1-butene.

Mass-spectrometric analysis showed that the methane formed in the present system consisted of CH_3D and CH_4. By estimating the contribution of the HI initially present in the DI gas, and that of the abstraction reaction of CH_3 from butene, to the formation of CH_4,[4] it was concluded that, if pure DI was used, all of the methane produced must be CH_3D. When a similar correction was applied to the mass spectra of propylene and *n*-butane, it was found that they were $CH_3CH{=}CHD$ and $CH_3CHDCHDCH_3$ respectively. In the case of 1-butene, however, no unique conclusion could be obtained.

According to Back and Cvetanović, iodine atoms initiate the *cis-trans* isomerization of 2-butene, and also the isomerization to 1-butene, although the latter process is very slow.[5] In the present system, obviously, these reactions are overlapped with the reactions initiated by the D atoms. Therefore, we will not discuss the formation of 1-butene in the present system, although it is itself of much interest.

Discussion

Abstraction Reaction of Hot D Atoms. As Fig. 1 shows, the amounts of HD, CH_3D, and $CH_3CH{=}CHD$ increase with the increase in the ratio of *cis*-2-butene/DI up to about 3, where the total pressure is 40 Torr. At the pressures higher than that, the three products gradually decrease with the increase in pressure. The curve for HD levels off at about 0.4 μmol, while those for CH_3D and $CH_3CH{=}CHD$ approach zero. The curve for HD is very similar to that obtained in the DI–C_3H_6 system.[2] These results may be interpreted in terms of the following reaction scheme:

$$DI + h\nu \longrightarrow D^* + I \quad (1)$$

$$D^* + DI \longrightarrow D_2 + I \quad (2)$$

$$D^* + I_2 \longrightarrow DI + I \quad (3)$$

$$D^* + C_4H_8 \longrightarrow \begin{cases} D + C_4H_8 & (4) \\ HD + C_4H_7 & (5) \\ C_4H_8D^* & (6) \end{cases}$$

$$C_4H_8D^* \longrightarrow \begin{cases} CH_3 + CH_3CH{=}CHD & (7) \\ H + C_4H_7D & (8) \\ D + C_4H_8 & (9) \end{cases}$$

$$C_4H_8D^* + M \longrightarrow C_4H_8D + M \quad (10)$$

$$C_4H_8D + DI \longrightarrow C_4H_8D_2 + I \quad (11)$$

$$C_4H_8D + I_2 \longrightarrow C_4H_8DI + I \quad (12)$$

$$CH_3 + DI \longrightarrow CH_3D + I \quad (13)$$

$$CH_3 + I_2 \longrightarrow CH_3I + I \quad (14)$$

$$CH_3 + C_4H_8 \longrightarrow C_5H_{11} \quad (15)$$

$$H(D) + DI \longrightarrow HD(D_2) + I \quad (16)$$

$$H(D) + I_2 \longrightarrow HI(DI) + I \quad (17)$$

$$H(D) + C_4H_8 \longrightarrow C_4H_9(C_4H_8D) \quad (18)$$

$$I + I + M \longrightarrow I_2 + M \quad (19)$$

In the presence of a large amount of *cis*-2-butene, all of the thermalized atoms and radicals are captured by *cis*-2-butene or I_2 and do not contribute to the formation of HD and CH_3D. Therefore, the HD formation observed at the higher pressures must be due to Reaction (5). In the absence of *cis*-2-butene, the amount of D_2 produced was 4.02 μmol. Using this value and assuming $k_1/k_2=3$,[6] the ratio of $k_5/(k_4+k_5+k_6)$ may be estimated to be as follows: $0.4/4.02(1+3\times1.1/10.3)=0.075$. This value, about 8%, is smaller than that previously obtained as the fraction of the abstraction reaction in the hot D atom reaction in the DI–C_3H_6 system (more than 10%). By comparing the curves of HD in both experiments, we feel that the figure of more than 10% previously obtained may be a little overestimated. However, the exact determination of these values is not feasible by the present technique.

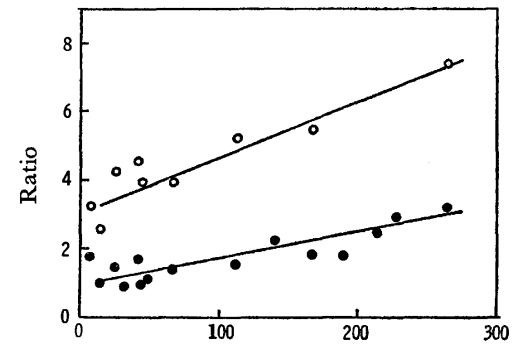

Fig. 2. The ratios of *n*-butane/methane (○) and *n*-butane/propylene (●) as a function of the *cis*-2-butene pressure.

Formation of CH_3D. Figure 2 shows the ratios of propylene/*n*-butane and methane/*n*-butane as a function of the pressure of *cis*-2-butene. On the appropriate assumption, the steady-state treatment of the reaction mechanism proposed above can predict these linear relationships.

In a previous paper, we concluded that the D* atoms produced in the photolysis of DI at 2288 Å did not give rise to the direct substitution reaction:

$$D^* + CH_2{=}CH_2 \longrightarrow CHD{=}CH_2 + H$$

The mechanism of the methane formation discussed above may be taken as one of the evidences supporting this conclusion.

Reaction (7) is a unimolecular reaction which competes with Reactions (8) and (9). If the hot radical has a lifetime long enough for the distribution of its excess energy to the vibrational freedom of the radical, Reaction (7) may predominate over Reactions (8) and (9), because the excess energy retained in the radical is only 50 kcal/mol. However, the pressure-dependent curve of HD in the range of the C_4H_8/DI ratios, 0∼10, is similar to that of CH_3D, as is shown in Fig. 1. There are two possible explanations for this similarity. One is that the lifetime of the hot radical is not long enough for the distribution of the excess energy, upon which Reaction (8) depends. The other is the participation of the substitution reaction of hot D atoms, such as

$$D^* + CH_3CH{=}CHCH_3 \longrightarrow CH_2DCH{=}CHCH_3 + H,$$

which may be possible, because the C–H bond, which is substituted, is aliphatic. Since we could not analyze the D content in *cis*-2-butene, though, no precise conclusion could be drawn.

General Discussion. The hot D atoms obtained in the present experiment are retained most at 2.4 eV.[2] According to the estimation of Wolfgang,[1] the characteristic hot atom reactions take place at more than 5 eV. The reactions reported here, therefore, are largely explainable by a small extension of the thermal reactions.

The decomposition of the *sec*-butyl radicals produced by the addition of hydrogen atoms to 2-butene has been extensively studied by Rabinovitch and his coworkers,[7]

and chemical activation is a well-known method of obtaining the hot radicals. For the production of hydrogen atoms, they used an electric discharge under a low pressure of hydrogen. Their data were mainly obtained at pressures lower than 1 Torr. Therefore, the results obtained here cannot be compared directly with theirs. According to their data on the D+*cis*-2-butene system,[8] k_a is about 2.0×10^7 s^{-1} at the pressure of 0.3 Torr. k_a is defined as follows:

$$k_a = \omega\frac{D}{S}$$

Here, ω is the collision frequency, while D and S are the fractions of the decomposition and of the stabilization of hot radicals. A rough estimation may be made in the present system as follows:

$$\frac{\text{methane}}{n\text{-butane}} \simeq \frac{D}{S} = k_a'/\omega$$

Using the data shown in Fig. 2, the value of k_a' could be calculated to be in the range of 10^8 s^{-1}, which is a little larger than the k_a value reported for the thermal D atom reaction. This difference may be attributed to the difference in the initial energy of the D atoms.

Calculation of the Widths for Isotropic Parts of Highly-polarized Raman Lines: Vibrational Relaxation of Infrared-inactive Levels

Masao KAKIMOTO and Tsunetake FUJIYAMA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

**Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158*

(Received December 25, 1973)

A theoretical calculation is made to explain the widths of the isotropic parts of polarized Raman lines in liquids. The calculation is based on the model of the intermolecular resonance-type vibrational relaxation through the vibration-dependent term of the Lennard-Jones atom-atom interaction. The result is applied to the Raman lines of liquid nitrogen, oxygen, and carbon disulfide, and compared with the experimental data.

It is known that a polarized Raman line consists of two parts, the isotropic and anisotropic parts, and that the former originates from the trace, and the latter, from the anisotropy, of a scattering tensor.[1,2] Because the trace of a tensor is independent of any rotation of coordinates, the isotropic part does not reflect the rotational motion of molecules. The widths of the isotropic parts are very narrow in general and are considered to be related to the decay of the vibrationally-excited state or the vibrational relaxation. The anisotropic part, on the other hand, contains information not only about the vibrational relaxation, but about the molecular rotational motion (or the reorientational motion in the case of condensed phases). The line-shape of the anisotropic part is expressed as a convolution of two curves which give the line-shapes due to vibrational relaxation and rotational motion respectively. Many authors have tried, both from theoretical[2-6] and experimental[2,7-12] aspects, to extract information about the reorientational motion of molecules in liquids from the observed line-shape of a Raman line. However, very few but Valiev[13] have reported any theoretical evaluation of the widths of the isotropic part. The present work will be concerned with the calculation of the width of the isotropic part of a highly-polarized Raman line which is infrared-inactive, or with the calculation of the transition probability for vibrational relaxation of an infrared-inactive level.

Previously, the present authors[14] reported a theoretical evaluation of the vibrational-relaxation widths appearing in the infrared spectra. Those results were, however, confined to infrared-active vibrational levels, because dipole matrix elements are necessary to cause transitions. In the present case, a similar model is not applicable since a vibrational transition has no transition moment. Any attempt to seek an interaction which causes vibrational relaxation ends to failure so long as we confine ourselves to *molecule-to-molecule*-type interactions. Valiev[13] used an exchange interaction *between atoms* which participate in a molecular vibration and estimated only the order of magnitude for the vibrational-relaxation width. Our model is similar to that of Valiev, but differs in the following two points: first, the use of a more realistic potential function of the Lennard-Jones type for an interatomic interaction, and second, the use of a model of the resonance exchange of vibrational quanta between two molecules.

Theory

Consider a pair of two homonuclear diatomic molecules, the interaction geometry of which is shown in Fig. 1. The interaction potential between two atoms,

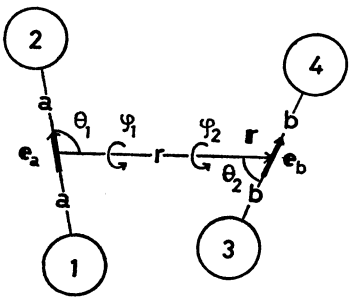

Fig. 1. A diagram showing a geometry of interacting two diatomic molecules.
1, 2, 3, and 4 indicate the atoms. $\mathbf{e}_a$ and $\mathbf{e}_b$ are unit vectors.

i and j, is written as $V(r_{ij})$, since the interaction, for which the Lennard-Jones potential is anticipated, is a function of the interatomic distance, r_{ij}, alone. Then the total intermolecular interaction, V, is:

$$V = \sum_{(i,j)} V(r_{ij}) \tag{1}$$

where (i, j) means all the pairs of interacting atoms, (1,3), (1,4), (2,3), and (2,4). The interatomic distances, r_{ij}'s, are the functions of r, θ_1, θ_2, φ_1, φ_2, a, and b (see Fig. 1):

$$r_{24} = r\left[1-\frac{2}{r}(a\cos\theta_1 - b\cos\theta_2) + \frac{1}{r^2}\{a^2+b^2 - 2ab(\sin\theta_1\cos\varphi_1\sin\theta_2\cos\varphi_2 + \sin\theta_1\sin\varphi_1\sin\theta_2\sin\varphi_2 + \cos\theta_1\cos\theta_2)\}\right]^{1/2} \tag{2}$$

and similar equations for the others.[15] As the molecules undergo vibrations, a and b, and hence r_{ij}'s also, change in magnitude. Therefore, we expand V in a series of the small changes of the bond distances, Δa and Δb, and retain only the term which is bilinear on Δa and Δb:

$$V' = \frac{\partial^2 V}{\partial a \partial b}\Delta a \Delta b \tag{3}$$

which, by virtue of Eq. (1), yields:

$$V' = \sum_{(i,j)} \left[\frac{\partial^2 V(r_{ij})}{\partial r_{ij}^2} \frac{\partial r_{ij}}{\partial a} \frac{\partial r_{ij}}{\partial b} + \frac{\partial V(r_{ij})}{\partial r_{ij}} \frac{\partial^2 r_{ij}}{\partial a \partial b} \right] \Delta a \Delta b \quad (4)$$

Note that $\frac{\partial^2 V(r_{ij})}{\partial r_{ij}^2}$ and $\frac{\partial V(r_{ij})}{\partial r_{ij}}$ are common for all the (i,j) pairs. Therefore, they are written simply as $\frac{d^2V}{dr^2}$ and $\frac{dV}{dr}$ respectively. On calculating the differentials in Eq. (4), we expand the square bracket in Eq. (2) in powers of $1/r$ and neglect the terms of orders higher than $(1/r)^2$. This approximation, and hence its validity, are similar to those of a dipole-dipole interaction.[15] Some manipulation leads to:

$$V' = \left[\frac{d^2V}{dr^2} \frac{4ab}{r^2} X + \frac{dV}{dr} \frac{4ab}{r^3} Y \right] \Delta a \Delta b \quad (5)$$

where:[16]

$$X = 1 + (\mathbf{e}_a \cdot \mathbf{e}_b)^2 + 8\left(\mathbf{e}_a \cdot \frac{\mathbf{r}}{r}\right)^2 \left(\mathbf{e}_b \cdot \frac{\mathbf{r}}{r}\right)^2 - 6(\mathbf{e}_a \cdot \mathbf{e}_b)\left(\mathbf{e}_a \cdot \frac{\mathbf{r}}{r}\right)\left(\mathbf{e}_b \cdot \frac{\mathbf{r}}{r}\right) - 2\left(\mathbf{e}_a \cdot \frac{\mathbf{r}}{r}\right)^2 - 2\left(\mathbf{e}_b \cdot \frac{\mathbf{r}}{r}\right)^2 \quad (5a)$$

and:

$$Y = -1 - 2(\mathbf{e}_a \cdot \mathbf{e}_b)^2 - 15\left(\mathbf{e}_a \cdot \frac{\mathbf{r}}{r}\right)^2 \left(\mathbf{e}_b \cdot \frac{\mathbf{r}}{r}\right)^2 + 12(\mathbf{e}_a \cdot \mathbf{e}_b)\left(\mathbf{e}_a \cdot \frac{\mathbf{r}}{r}\right)\left(\mathbf{e}_b \cdot \frac{\mathbf{r}}{r}\right) + 3\left(\mathbf{e}_a \cdot \frac{\mathbf{r}}{r}\right)^2 + 3\left(\mathbf{e}_b \cdot \frac{\mathbf{r}}{r}\right)^2 \quad (5b)$$

The vector products appearing in Eqs. (5a) and (5b), and hence X and Y, are written in terms of the spherical harmonics normalized to unity, $Y_l^m(\theta_a,\varphi_a)$, $Y_l^m(\theta_b,\varphi_b)$, and $Y_l^m(\theta_r,\varphi_r)$, where (θ_a,φ_a), (θ_b,φ_b), and (θ_r,φ_r) are the polar coordinates of $\mathbf{e}_a$, $\mathbf{e}_b$, and $\mathbf{r}$ respectively in a laboratory-fixed coordinate system. Though these expressions are too lenghty to be written here, the following relations will be necessary later:

$$\int X^2 d\tau' = \frac{2^{10}}{5^2}\pi^3$$
$$\int Y^2 d\tau' = \frac{2^{13}}{3 \times 5^2}\pi^3 \quad (6)$$
$$\int XY d\tau' = -\frac{2^{11} \times 7}{3^2 \times 5^2}\pi^3$$

where $d\tau' = \sin\theta_a \sin\theta_b \sin\theta_r d\theta_a d\varphi_a d\theta_b d\varphi_b d\theta_r d\varphi_r$, and where integrations are carried out over the entire configuration space.

Now, consider that the two molecules are initially on the vibrational states of $v_a=1$ and $v_b=0$ respectively, where v_a and v_b are the vibrational quantum numbers. Then, the transition probability for a coupled transition, $(v_a, v_b)=(1, 0)\rightarrow(0, 1)$, is given by:[17]

$$\frac{1}{\hbar^2}\int_{-\infty}^{\infty} \langle M(0)M(t)\rangle_{av} e^{-i(\omega_a-\omega_b)t} dt \quad (7)$$

where ω_a and ω_b are the vibrational angular-frequencies and where M means the matrix element of V':

$$M = \langle 01 | V' | 10 \rangle \quad (8)$$

The average, denoted by $\langle\ \rangle_{av}$ in Eq. (7), may be regarded either as a time-average or, if M is ergodic, as an ensemble average. The latter concept is used later in calculating the average. To obtain a probability, $P(1\rightarrow0)$ for ,one of the interacting molecules undergoing a transition, $1\rightarrow0$, one integrates Eq. (7) over ω_b and takes the square root:[18]

$$P(1\rightarrow0) = \frac{1}{\hbar}\left[\langle |M|^2\rangle_{av}\right]^{1/2} \quad (9)$$

We then insert Eq. (5) into Eq. (9), keeping in mind that $2\Delta a$ and $2\Delta b$ are the normal coordinates, Q_a and Q_b respectively, of vibrations. Further, when the interacting two molecules are of the same species, we can write:

$$a = b$$

and:

$$\langle 1|Q_a|0\rangle = \langle 1|Q_b|0\rangle = \sqrt{\frac{\hbar}{2m\omega}} \quad (10)$$

where m is the reduced mass and where $\omega=\omega_a=\omega_b$. Thus,

$$P(1\rightarrow0) = \frac{a^2}{2m\omega}\left[\left\langle\left(\frac{d^2V}{dr^2}\right)^2 \cdot \frac{1}{r^4}X^2\right\rangle_{av} + 2\left\langle \frac{d^2V}{dr^2}\frac{dV}{dr}\frac{1}{r^4}XY\right\rangle + \left\langle\left(\frac{dV}{dr}\right)^2 \cdot \frac{1}{r^6}Y^2\right\rangle_{av}\right]^{1/2} \quad (11)$$

To proceed further, an analytical expression for V is necessary. The best that is available, that has a simple form and whose parameters are determined well, may be the Lennard-Jones potential:

$$V(r) = 4\varepsilon\left[\left(\frac{r_0}{r}\right)^{12} - \left(\frac{r_0}{r}\right)^6\right] \quad (12)$$

The averages of Eq. (11) are calculated as:

$$\langle F\rangle_{av} = W\int F d\tau \quad (13)$$

where:

$$d\tau = r^2 dr d\tau'$$

and where W is a normalization constant which is determined, from the condition that n molecules are contained in 1 cm^3, to be:

$$W = \frac{n}{(4\pi)^2} \quad (14)$$

A lower limit, a_0, exists for the parameter, r, the physical meaning of which is that no two molecules can come closer than a_0. Remembering the relations of Eq. (6), we finally obtain:

$$P(1\rightarrow0) = \frac{8}{5}\frac{a^2}{m\omega}\sqrt{n\pi}\,4\varepsilon\left[A\frac{r_0^{24}}{a_0^{29}} - B\frac{r_0^{18}}{a_0^{23}} + C\frac{r_0^{12}}{a_0^{17}}\right]^{1/2} \quad (15)$$

where

$$A = \frac{4\times1909}{29},\quad B = \frac{4\times1123}{23},\quad \text{and}\quad C = \frac{661}{17}.$$

Comparison with the Experimental Data

To check the validity of our model as used in the present theory, the widths of the isotropic Raman lines of liquid N_2 and O_2 were calculated by means of Eq.

Table 1.

Molecule	$(cm^{-1})^{b)}$	FWHM[a] (cm^{-1})		Used parameters		
		Obsd[b]	Calcd	$2a$ (Å)[c]	ε/k (K)[d]	r_0 (Å)[d]
N_2	2331	0.067±0.004	0.037	1.0976	35.7	2.789
O_2	1555	0.117±0.008	0.067	1.2074	35.7	2.789
CS_2	656	0.50 ±0.02	0.72	3.108	124.0	3.418

a) Full-width at half-maximum, calculated from Eq. (15) through the relation; FWHM$=P(1\rightarrow0)/\pi c$, where c is the velocity of light. b) See Ref. 19. c) See Ref. 22. d) See Ref. 23.

(15) and compared with the observed ones.

The Raman lines of liquid N_2 and O_2 are extremely narrow; therefore, the widths cannot be measured precisely with a conventional grating spectrometer. Clements and Stoicheff[19] have reported the most reliable data to date; they made their observations by the use of a Fabry-Perot interferometer.

In the calculations of the theoretical widths, the values of n are estimated from the values of the molecular weight and density.[20] Since the Lennard-Jones parameters, ε and r_0, are not available for an N···N or O···O pair, they are transferred from those for an Ne pair. The estimation of a_0 is the most difficult problem, although the results are rather sensitive to it. We arbitrarily, mainly because of the ease of calculation, put a_0 equal to r_0.[21] The results are shown in Table 1.

The conclusion of Eq. (15) is also applicable to the estimation of the width for the totally-symmetric vibration of CS_2, although it is a triatomic molecule. In this case, Q_a is $\sqrt{2}\Delta a$ instead of $2\Delta a$; therefore Eq. (15) should be multiplied by a factor of two. The values of ε and r_0 are transferred from those of Ar. The result for CS_2 is also included in Table 1.

As may be seen from Table 1, the agreement between the calculated and the experimental values is fairly good. This agreement may confirm the validity of the model used in the present theory. There may be many causes for the broadening of the isotropic part of a Raman line, but it can be concluded that the resonance exchange of the vibrational quanta through the interatomic interaction is the most important.

The authors are indebted to all the members of the Shimanouchi Laboratory for their helpful correspondence about this work. They are particularly grateful to Professor Takehiko Shimanouchi of the University of Tokyo for giving them the opportunity of publishing this work.

16) All the quantities subscripted with a or b in the text hereafter correspond to the left and the right molecules, respectively, in Fig. 1.

17) See, for example, R. Zwanzig, *J. Chem. Phys.*, **34**, 1931 (1961), Eqs. (3)—(9).

18) K. A. Valiev, *Opt. Spectrosc.*, **11**, 253 (1961), Eq. (24). The integration over ω_b must be carried out only within a certain limited range, $[\omega_a-\alpha, \omega_a+\alpha]$, because ω_b cannot spread over so widely. In obtaining Eq. (9) of the text, one is putting the integral

$$\int_{\omega_a-\alpha}^{\omega_a+\alpha}\int_{-\infty}^{\infty}\frac{\langle M(0)M(t)\rangle_{av}}{\langle|M|^2\rangle_{av}}e^{-t(\omega_a-\omega_b)t}dtd\omega_b$$

equal to 1. Although there is no theoretical reason to choose the value of 1, this simplification is permissible because we concern here only with the order of magnitude and because there is no way to estimate the correct value for α. In the limit of $\alpha\rightarrow\infty$, the final result (Eq. (11) or (15)) becomes about 2.5 (*i.e.* $\sqrt{2\pi}$) times larger.

19) W. R. L. Clements and B. P. Stoicheff, *Appl. Phys. Lett.*, **12**, 246 (1968): Though the spectra they measured contain not only isotropic but anisotropic parts, the widths reported may be regarded as those of isotropic parts, because of very low depolarization degrees.

20) "International Critical Tables," National Research Council, McGraw-Hill, New York (1928).

21) r_0 is the distance at which the potential has the value zero. If we choose, instead, a_0 to be the distance at which the potential has the value $(3/2)kT$ the results become about 3.3 times larger for N_2 and O_2, and about 3.6 times larger for CS_2. This may be an overestimation, since we do not take a radial distribution function into account. Anyhow, the present model gives the correct order of magnitude.

(Received January 14, 1974)

The electrical properties of evaporated thin films of copper phthalocyanine(CuPc) were investigated by the ac method. The frequency dependence of conductivity and capacitance, and the activation energy for dc conductivity in α- and β-CuPc were determined. No significant variation in the electrical properties was observed with the difference in the phases of CuPc films *in vacuo*. The frequency dependence of conductivity and capacitance can be explained in terms of the simultaneous hopping and band conduction, *viz.*, $\sigma=\sigma_{dc}+A_1\cdot\omega^n$ and $C=C_\infty+A_2\cdot\omega^{1-n}$. The energy gap for α- and β-CuPc *in vacuo* is 1.80 eV and 1.89 eV, respectively. The adsorbed O_2 gas has a great effect on the dc conductivity but little on the ac conductivity of α-CuPc film. The adsorption of oxygen on α-phase CuPc might be the cause of high dc conductivity and low activation energy(0.5—0.7 eV) as compared with those *in vacuo*.

It is known that copper phthalocyanine(CuPc) can be obtained in two crystallographic modifications(α and β). Wihksne and Newkirk[1] found that the conductivity of form α is greater than that of form β by a factor of 10^5, the activation energies being 0.25 eV and 0.9 eV, respectively. On the other hand, Harrison and Ludewig[2] claimed that the difference in conductivity is due to the greater adsorptivity for oxygen on α-phase CuPc, and found that the conductivity of the α-phase film is similar to that of the β-phase one when the oxygen has been eliminated. Eley and Parfitt[3] studied the ac conductivity of aromatic compounds. They explained the frequency dependence of conductivity in a compressed powder disk in terms of contact resistance and contact capacitance(Maxwell-Wagner type dispersion). The frequency dependence of the conductivity in aromatic compounds can be explained in terms of the hopping conduction mechanism rather than the Maxwell-Wagner type dispersion.[4,5] We have studied the frequency and temperature dependence of conductivity as well as the capacitance of α- and β-phase CuPc films.

Experimental

Electrical measurements were carried out on evaporated thin α- and β-phase CuPc films, the surface of the film being expected to be in alignment with its *ab*-plane. An ac bridge TR 10C(Ando Electrics Co., Ltd.) was used to measure the conductivity and capacitance. The sample was held in O_2 or H_2 atmosphere or *in vacuo*(about 10^{-2} Torr). A sandwich type cell of thin film was prepared by evaporation on a microscope slide. The evaporation was carried out in a vacuum of the order of 10^{-6} Torr, the rate of deposition of CuPc being approximately 10^{-7} mm/s. The bottom electrode was an evaporated silver layer covered with an evaporated thin film of CuPc. The CuPc thickness was about 10^{-3} mm. The top electrode was also prepared by the evaporation of silver. The cell constant was determined to be about 2×10^3 cm. The β-phase CuPc was obtained by annealing the evaporated film at 320 °C for 30 min in N_2 atmosphere.[1,2] The transition from α to β-phase on annealing was confirmed by the IR spectrum of the CuPc film which was deposited on a KBr disk. This was also confirmed by the change of electrical conductivity, the result being similar to that obtained by Wihksne and Newkirk[1] as well as by Harrison and Ludewig.[2] Measurements of the conductivity and the capacitance were carried out at temperatures 13—130 °C (±2 °C). The frequency was varied from 30 Hz to 1 MHz. The amplitude of the alternating voltage amounted to 20 V.

Results and Discussion

Ebert and Gottlieb[6] studied the X-ray diffraction and IR spectra of α- and β-CuPc. Their results indicate that the IR spectrum of α-CuPc differs from that of β-CuPc at the wavelengths 7.6, 9.2, 11.4, 13 and 14 μm. The spectra of the deposited CuPc film on a KBr disk and the annealed one were found to be similar to those obtained by Ebert and Gottlieb, indicating that the evaporated film of CuPc on a slide glass is in the α-phase while the annealed one is in the β-phase.[2]

The frequency dependence of conductivity for the α- and β-CuPc films *in vacuo* at various temperatures is shown in Figs. 1 and 2. The temperature and the frequency dependences of the electrical properties for both α- and β-CuPc *in vacuo* were found to be similar, indicating that there is no significant difference between the two phases. In the high frequency region, it was found that the conductivity of both α- and β-CuPc is proportional to ω^n:

$$\sigma_{ac} = A_1\cdot\omega^n \qquad (1)$$

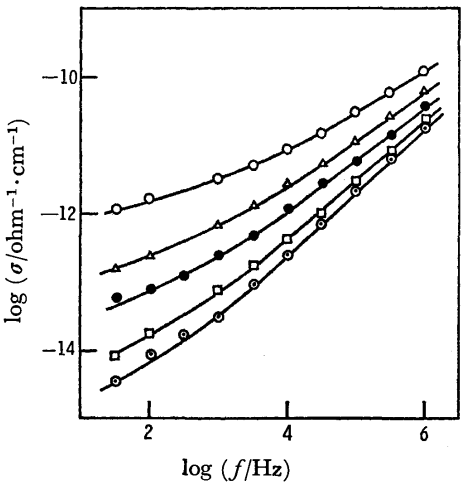

Fig. 1. Frequency dependence of conductivity of α-CuPc film *in vacuo*.
(○) 124 °C, (△) 98 °C, (●) 74 °C, (□) 47 °C, (⊙) 27 °C.

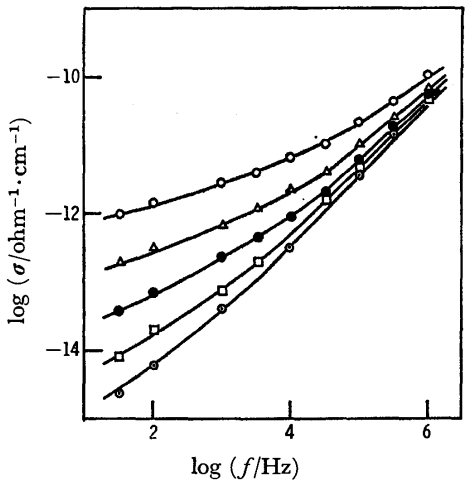

Fig. 2. Frequency dependence of conductivity of β-CuPc film *in vacuo*.
(○) 127 °C, (△) 99 °C, (●) 76 °C, (□) 45 °C, (⊙) 18 °C.

where ω is the angular frequency. The value of n decreases from 1.0 to 0.5 with an increase in temperature. σ_{ac} at low frequencies was calculated by extrapolation from the high frequency region on the assumption that σ_{ac} obeys Eq. (1) over the whole range of frequency. In the low frequency region the difference between σ_{ac} value thus obtained and the observed conductivity increases with an increase in temperature.

We have studied the frequency and temperature dependence of conductivity of aromatic compounds in both an evaporated thin film and a compressed powder disk and have found that the observed conductivity can be expressed as the sum of two terms, the band conduction and the hopping conduction.[4,5] The latter strongly depends on frequency, but not the former. Thus we have

$$\sigma = \sigma_{ac} + \sigma_{dc} = A\cdot\omega^n\cdot\exp[-E(T\cdot\omega)/kT] + \sigma_0\cdot\exp(-E/kT) \quad (2)$$

where σ_{ac} is the frequency dependent conductivity, σ_{dc} is the frequency independent conductivity, $E(T\cdot\omega)$, the apparent activation energy for hopping from one localized state to another, is a function of both temperature[7-9] and frequency, and E is the activation energy of the band conduction. When the conductivity is given by Eq. (2), the Kramers-Kronig relation[10] can be used to determine the frequency dependence of the capacitance:

$$C = C_\infty + A_2\cdot\omega^{1-n} \quad (3)$$

The values of n for conductivity and capacitance were obtained at various temperatures by use of Eqs. (2) and (3). It was assumed that C_∞ is roughly equal to the value of C at 1MHz. The values of n thus obtained are given in Table 1. The values of n in C are in fair agreement with those in σ_{ac}. The results indicate that the frequency dependence of conductivity and capacitance can be expressed by Eqs. (2) and (3) within experimental error. We see that σ_{ac} of α-CuPc and that of β-CuPc do not differ greatly (Fig. 3). The apparent activation energy of ac conductivity decreases with the increase in frequency and the decrease in temperature for both α- and β-CuPc *in vacuo*.

Table 1. Values of n for α-CuPc and β-CuPc films *in vacuo* and in H_2 atmosphere

Phase	Temp. °C	n in σ_{ac}	n in C
β *in vacuo*	127	0.4_9	0.5_2
	99	0.5_4	0.5_7
	76	0.6_8	0.6_4
	45	0.8_3	—
α *in vacuo*	124	0.5_0	0.5_7
	98	0.6_3	0.5_9
	74	0.6_9	0.7_5
	47	0.8_1	0.7_6
	27	0.8_3	0.7_6
α in H_2	122	0.5_0	0.5_0
	99	0.5_5	0.5_4
	73	0.6_5	0.5_9
	54	0.7_2	0.6_6
	31	0.8_4	—

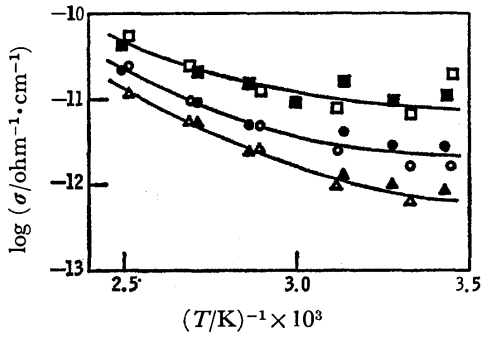

Fig. 3. Temperature dependence of conductivity in the high frequency region of α- and β-CuPc films *in vacuo*.
(□, ○, △) α-CuPc, (■, ●, ▲) β-CuPc, (□, ■) 300 kHz, (○, ●) 100 kHz, (△, ▲) 30 kHz.

The temperature dependence of σ_{dc} ($=\sigma - A_1\cdot\omega^n$) was obtained for both α- and β-CuPc (Fig. 4). The activation energy of σ_{dc} is 0.90 eV and 0.94 eV for the α-CuPc and the β-CuPc film *in vacuo*, respectively. These are in fair agreement with those obtained by Harrison and Ludewig.[2]

The effect of adsorbed O_2 gas on the electrical properties was investigated. The frequency dependence of conductivity for α-CuPc film in H_2 and O_2 is shown in Figs. 5 and 6. The frequency dependence of conductivity and capacitance in H_2 is similar to that *in vacuo* (Table 1) but the activation energy of dc conductivity is slightly larger than that *in vacuo*. In the low frequency range, the conductivity of α-CuPc in O_2 is larger than that *in vacuo* by a factor of 10^4 at room temperature. The magnitude of σ_{dc} was poorly reproducible, being strongly affected by the condition of O_2 gas adsorption. The activation energy was found to be 0.5—0.7 eV. When the contribution of σ_{dc} component is large, the frequency dependence of σ_{ac} can be obtained by subtracting σ_{dc} from σ on the assumption that the value of σ_{dc} is approximately equal to that of σ in the low

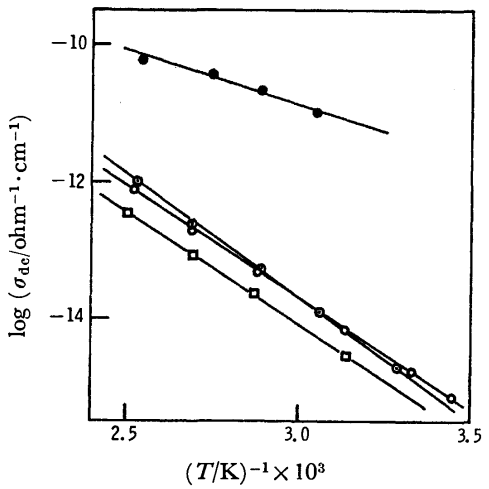

Fig. 4. Temperature dependence of dc conductivity of CuPc film in various conditions.

frequency region. The frequency dependence of σ_{ac} is shown in Fig. 7. It can thus be said that the σ_{ac} is little affected by the adsorbed O_2.

The band conduction σ_{dc} becomes gradually predominant at low frequency range with temperature rise, so that in the high temperature region the conductivity depends little on the frequency. Such a remarkable tendency is observed in particular in α-CuPc under O_2 atmosphere. It seems that the hopping conduction σ_{ac} is mainly based on the localized state (and/or shallow traps) which might be produced by crystal

defects but not adsorbed oxygen, and the band conduction σ_{dc} is due to electrons excited to the conduction band and/or holes to the valence band. Since the frequency at which traps produced by adsorbed oxygen are filled and emptied is greater than the applied field frequencies, the adsorbed oxygen has no effect on thermally and frequency assisted hopping conduction.

The Radiolytic-chain Dechlorination of Polychlorinated Biphenyls in Alkaline 2-Propanol Solutions

Takeshi SAWAI, Toshinari SHIMOKAWA, and Yoshiharu SHINOZAKI

Tokyo Metropolitan Isotope Research Center, Fukazawa, Setagaya, Tokyo 158

(Received January 17, 1974)

The radiolysis of solutions of polychlorinated biphenyls(PCB's) and potassium hydroxide in simple aliphatic alcohols was studied. The major products in alkaline 2-propanol solutions were potassium chloride, acetone, lower chlorinated biphenyls, and biphenyl. Their yields increased and the concentration of the hydroxide ions decreased with the dose. Acetone and potassium chloride were formed in high yields, and their concentrations were almost equal to the diminution in the hydroxide ions. The dechlorination yield was determined as a function of the dose, the dose rate, and the concentrations of PCB's, potassium hydroxide, and organic solutes. The chain-dechlorination reaction proceeded in the alkaline 2-propanol solution, but not in alkaline methanol, ethanol, 1-propanol, and butanols. The 2-propoxide radical anion, which is formed by the electron transfer from the hydroxide ion to the 2-propanol radical, is the chain carrier for the dechlorination reaction of PCB's in alkaline 2-propanol solutions. The mechanism is discussed in detail.

In neutral or alkaline aliphatic alcohol solutions, carbon tetrachloride,[1] 1,1,1-trichloro-2,2-*bis*(*p*-chlorophenyl)ethane,[2] nitrous oxide, [3] and methyl halide[4] undergo radiolytic decomposition with high yields. For example, in alkaline alcoholic solutions of methyl halide, methane is produced in a high yield on exposure to ^{60}Co γ-rays, but the yields can be changed by varying the kinds of alcohol and solutes; *e.g.*, the dehalogenation yields of CH_3Cl, CH_3Br, and CH_3I in alkaline 2-propanol were 2.2, 130, and 179, respectively. Sherman has proposed the following reactions for the most important propagation steps in the chain decomposition in alkaline alcoholic solutions:[4]

$$R\cdot + \overset{|}{C}HOH \longrightarrow RH + -\overset{\cdot}{C}OH \ (I) \quad (1)$$

$$I + B^- \rightleftharpoons -\overset{|}{C}O^- \ (II) + BH \quad (2)$$

$$MX + II \longrightarrow M\cdot + X^- + -\overset{|}{C}O \quad (3)$$

$$N_2O + II \longrightarrow O^- + N_2 + -\overset{|}{C}O \quad (3')$$

$$M\cdot(\text{or } O^-) + \overset{|}{C}HOH \longrightarrow MH(\text{or } OH^-) + I \quad (4)$$

where R·, B^-, and MX are the radical, the base, and alkyl halide, respectively. Moreover, it has been suggested that the radical-induced chain decomposition of some compounds in the alkaline alcohol solution can be observed under the following conditions: 1. MX should have a sufficiently high electron affinity, so that electron transfer from the alcohol radical anion-(II) is an efficient process, and 2. the compound produced by the electron-transfer reaction (3) is able to abstract a carbinol hydrogen from alcohol, thus giving the alcohol radical (I).

In general, it is well known that organic halides have a very high reactivity toward hydrated electrons and form halide ions by dissociative electron attachment. The rate constants of hydrated electrons for monofluoro- or monochlorobenzene and polyfluorobenzenes are $5\times10^8\ M^{-1}s^{-1}$ and $10^9\sim10^{10}\ M^{-1}s^{-1}$.[5,6] Therefore, it may be expected that the reactivity for polychlorinated biphenyls (PCB's) is relatively high. The study of the dechlorination reactions of aromatic polychlorides in organic solutions, especially in alkaline alcoholic solutions, is very interesting. In a preliminary experiment,[7] it was found that the chain dechlorination of PCB's proceeded and yielded potassium or sodium chloride and biphenyl with high *G*-values in the alkaline 2-propanol solutions, but not in the neutral 2-propanol and the alkaline methanol. The authors suggested that the chain-propagation steps in the dechlorination of PCB's must be similar to that proposed by Sherman.[3,4] This radiolytic-chain dechlorination of PCB's in 2-propanol-alcoholate solutions has also been found independently by Arai *et al.*[8]

The present paper is concerned with a more detailed study of the chain-dechlorination reaction of PCB's.

Experimental

Sample. PCB's dissolved in alkaline alcohol solutions were placed in a Pyrex irradiation vessel 12 mm in o.d. The solutions were irradiated with 3K Ci ^{60}Co γ-rays at room temperature after having been purged with pure nitrogen gas for about 30 min or after having been degassed by freeze-pump-thaw cycles. The dose rate was determined by means of a ferrous sulfate solution, and the energy absorbed in the samples was corrected with the electron density of the solutions.

The PCB's (Kanechlor-300, 400, 500*), alcohols, and potassium hydroxide (special grade, from Wako Pure Chemical Co.) were used without further purification. As the PCB's used in our experiments consist of mixtures of various chlorinated biphenyls, the contents of chlorine were analyzed by means of elemental analysis with a Shimadzu UM-2 element analyzer.

Analysis. The potassium chloride produced by irradiation was dissolved in water and was determined by Mohr's method.[9] The hydroxide-ion concentration was measured by means of acid-base titration, with phenolphthalein as an indicator. The PCB's remaining in the solutions after irradiation were analysed with a Shimadzu 4B gas chromatograph with an electron-capture-type detector and using a 2 m glass column of SE-30 at 190—210 °C. The acetone and biphenyl were determined by means of a Shimadzu 4A gas chromatograph with a hydrogen flame detector at 60

* Kanechlor (identified as KC for short) is a commercial name of the PCB's manufactured by the Kanegafuchi Chemical Industrial Co., Ltd. The numeral indicates the average number of substituted chlorine; *e.g.*, 400 shows a PCB containing 4 chlorines as the average.

and 220 °C respectively; for these analyses, a 2 m stainless steel column of 20% polyethylene glycol 20 M on chromosorb was used. A gas chromatograph-mass spectrometer (Shimadzu LKB-9000) was also used for the confirmation of the PCB's, acetone, and biphenyl.

Results and Discussion

Yield of Chloride Ion, Acetone, and Biphenyl. As has been shown in the previous paper,[7] the chloride ion was effectively liberated from the PCB's in the alkaline 2-propanol solutions purged with nitrogen gas, and a complementary amount of the hydroxide ion was consumed on exposure to ^{60}Co γ-rays at room temperature; the dechlorination was completely suppressed when the OH^- was almost consumed. In the case of 2-propanol solution containing 0.05 M potassium hydroxide and 1% KC-400, the initial yield of the chloride ion ($G(Cl^-)$) was ~450; meanwhile, the decreasing yield of the hydroxide ion was equal to that of the dechlorination. These high yields suggest that the radiolytic-chain dechlorination reaction apparently occurred, because the radical yield in the radiolysis of 2-propanol was only ~7.[10] The chain dechlorination, on the other hand, did not occur in the presence of dissolved oxygen. In the presence of an excess of potassium hydroxide in relation to the PCB's, the formation of chloride ions and the decrease in the quantity of hydroxide ions with the dose are shown in Fig. 1. The formation and the consumption were almost equal in each dose, and these rates decreased with the dose. The acetone and biphenyl also increased with an increase in the dose in a 0.2 M alkaline 2-propanol solution of 0.5% KC-300, as is shown in Fig. 2. The yield of acetone was almost the same as that of the chloride ion, and the rate was also suppressed with the dose. The formation of biphenyl increased sharply at a dose between 6×10^{18} and 2×10^{19} eV/g. At a dose of 3.2×10^{19} eV/g, the dechlorination of PCB's

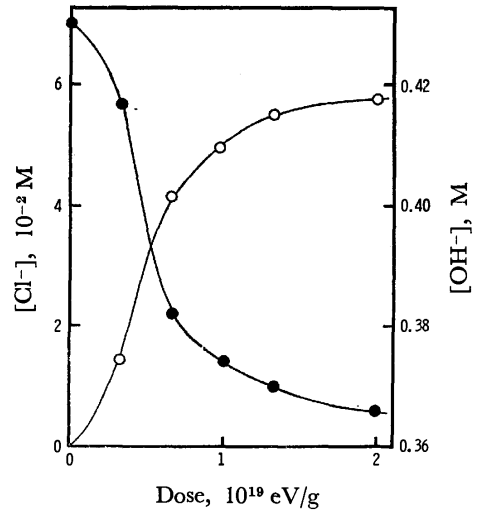

Fig. 1. Increase of chloride ion and decrease of hydroxide ion at various dose in 0.42 M KOH-2-propanol solutions of 0.3% KC-400.
○: chloride ion, ●: hydroxide ion
dose rate: 6.6×10^{18} eV/g hr

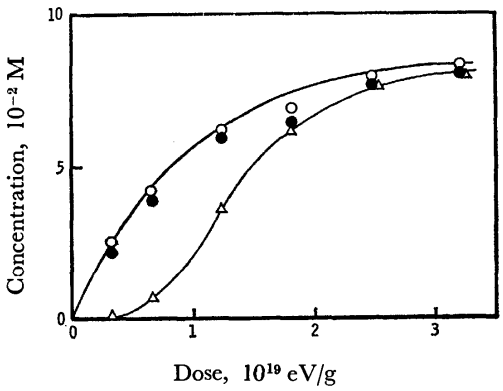

Fig. 2. Yields of products in 0.2 M KOH-2-propanol solutions of 0.5% KC-300.
○: chloride ion, ●: acetone, △: biphenyl
dose rate: 1.1×10^{19} eV/g hr

was found to reach about 100%, as calculated from the chlorine content. The amount of biphenyl multiplied by a factor of 3.2** was almost equal to the chloride-ion concentration at a dose of 3.2×10^{19} eV/g. This fact suggests that the dechlorination reaction of PCB's is predominant and that other reactions, such as C–C bond dissociation, the dimerization of PCB's, or the addition of radicals to a benzene ring, scarcely proceed. Pinacol was not detected.

The initial yields of the dechlorination and of the decrease in the quantity of hydroxide ions were affected by the alkaline concentration. These results are summarized in Table 1. As can be seen from Table 1, the yield obviously increased with the hydroxide-ion concentration; however, the effect of the PCB concentrations from 1% to 10% on the $G(Cl^-)$ value was small: we found no remarkable difference between KC-300, -400, and -500.

On irradiating 0.2 M alkaline 2-propanol solutions containing 0.5% KC-300 at a dose rate of $6.94\sim244\times10^{17}$ eV/g hr, the initial yields of Cl^- were found to be as given in Table 2. As is shown in Table 2, the yield

Table 1. Initial yields in alkaline 2-propanol solutions

PCB's	OH⁻/M	$G(Cl^-)$	$G(-OH^-)$	Dose rate eV/g hr
1% KC-400	1×10^{-2} a)	170	180	4.0×10^{18}
	5×10^{-2}	450	420

(2): 0.5% KC-400, dose rate 6.7×10^{18} eV/g hr, 1.5 hr
(3, 4): 0.5% KC-300, dose rate 8.4×10^{17} eV/g hr, 17 hr

increased with a decrease in the dose rate.

The dechlorination has to depend on additives such as electron acceptors or radical scavengers if the initiation step is Reaction (1) and if the chain-propagation steps are Reactions (3) and (4). Table 3 shows the effects of various additives on the chloride-ion concentration. The presence of a small amount of these electron acceptors inhibited the formation of chloride ions, this effect was especially notable in nitrobenzene. The addition of *n*-hexane had no particular effect, though. The reactivity of PCB's towards the solvated electrons has not been established, but it may be at least of the order of $10^9\sim10^{10}$ $M^{-1}s^{-1}$ in view of the facts that the rate constants of hydrated electrons for halogenated benzenes in aqueous solutions were 5×10^8 in monochlorobenzene,[5] $6\sim7\times10^7$ in monofluorobenzene,[5,6] $1\sim2\times10^9$ in difluorobenzene,[6] and $\sim2\times10^{10}$ $M^{-1}s^{-1}$ in tetra and hexafluorobenzene.[6] On the other hand, the rate constants were 5×10^9 for acetone or biphenyl and 3×10^{10} $M^{-1}s^{-1}$ for nitrobenzene.[5] The almost complete suppression of the dechlorination by the presence of these electron acceptors, in the case of nitrobenzene particularly, cannot be explained only by the competition reaction of electrons with the dissociative electron attachment for PCB's, because $G(e^-_{solv})$ was only 0.9~1.0, while $G(H)$, $G(H_2)$, and $G(CH_3)$ were 2.6, 1.27, and 1.06, respectively.[10-12] A simple explanation of the suppression of the dechlorination is to inhibit the charge-transfer reaction in the propagation steps. The inhibition may involve the competition for an intermediate in one of the propagation steps, as has been mentioned by Sherman:[3]

$$-\overset{|}{C}O^- + S \longrightarrow -\overset{|}{C}O + S^- \quad (9)$$

The effect of the irradiation temperature on the dechlorination was studied at ~20 °C, 60 °C, and 90 °C. The samples were irradiated in an oil bath with a regulator, and the temperature was monitored by means of a thermocouple on a recorder. The dechlorination yield at 60 °C showed an increase of ~30%, but there was a small decrease at 90 °C in comparison with the value at ~20 °C. Arai *et al.*[8] has shown that the yield decreased at higher temperatures in alcoholate solutions and that phenylcyclohexadiene instead of biphenyl was the main product at 200 °C. They presumed that a different reaction might occur at higher temperatures, *e.g.*, the decomposition of radicals or addition to a benzene ring.

Dechlorination of PCB's. In irradiating the PCB's in alkaline 2-propanol solutions, each peak height on the gas chromatogram varied with the dose. The gas chromatograms of the KC-300 solutions, irradiated and unirradiated, are shown in Fig. 3. From the analysis with the gas chromatograph-mass spectrometer, it was deduced that the peak numbers of 1, 2-3, 4-6, and 7 in Fig. 3 were identified with mono-, di-, tri-, and tetrachlorobiphenyl respectively. However, no special attention was paid to the concentration of each PCB and isomer. Figure 4 shows the effect of the dose on these peak heights. The yields of chloride ion are also plotted in Fig. 4. As the chloride ion was formed, the tetra- and trichlorobiphenyl decreased quickly, while the di- and monochlorobiphenyl decreased after having

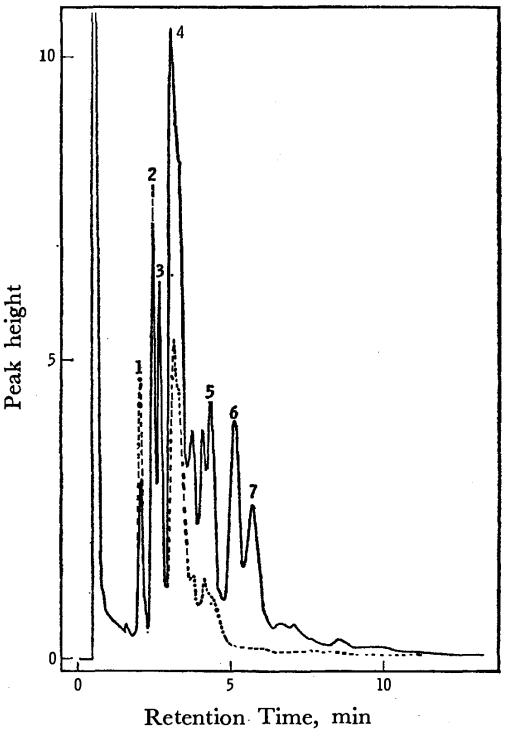

Fig. 3. Gas chromatogram of unirradiated and irradiated 0.2 M KOH-2-propanol solutions of 0.5% KC-300.
solid line: unirradiated solution

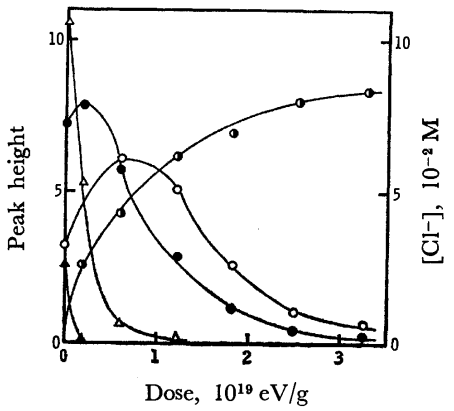

Fig. 4. Effect of irradiation dose on peak heights of chlorinated biphenyls in 0.2 M KOH-2-propanol solutions of 0.5% KC-300.
▲: tetrachlorobiphenyl, △: trichlorobiphenyl
●: dichlorobiphenyl, ○: monochlorobiphenyl
◑: chloride ion
dose rate: 1.1×10^{19} eV/g hr

increased temporarily. The facts indicate that the PCB's were dechlorinated by irradiation to form the less chlorinated biphenyls and were then finally converted to biphenyl *via* monochlorobiphenyl. It is well known that biphenyl is very stable to ionizing radiations. The variation in each peak height of the KC-400 and KC-500 solutions with the dose was similar to that of KC-300, but was a little more complicated.

Reaction of Chain Dechlorination. The radiolytic chain dechlorination of PCB's in the alkaline 2-propanol solution must be similar to the mechanism suggested by Sherman[3,4] for the decomposition of N_2O or of bromo- and iodobenzene in alkaline aliphatic alcohols.

In the dechlorination of PCB's: 1) Chain dechlorination did not occur in neutral alcohols but occurred in alkaline 2-propanol solutions and the $G(Cl^-)$ value depended on the concentration of the hydroxide ion. 2) The amounts of chloride ion and acetone formed, and the decrease in the hydroxide-ion concentration upon irradiation, were almost equal at each radiation dose. 3) The formation of the radical ion ($(CH_3)_2CO^-$) is known in alkaline aqueous solutions of 2-propanol,[13,14] and the rate of Reaction (2) was relatively fast and the pK-value was 12.2.[13] 4) The charge-transfer process was very important in the propagation steps of the chain-dechlorination reactions, because the dechlorination was effectively suppressed in the presence of a small amount of an electron acceptor such as nitrobenzene. 5) The dechlorination from highly chlorinated biphenyls was a predominant reaction in the first stage, and then the lowly chlorinated biphenyls were converted to biphenyl *via* monochlorobiphenyl.

On the basis of the above facts, the radiolytic-chain dechlorination of PCB's in deoxygenated alkaline 2-propanol solutions can be represented as follows:

$$(CH_3)_2CHOH \xrightarrow{\sim\sim} R\cdot,\ e^-_{solv},\ \text{other products} \quad (5)$$

$$C_{12}H_{10-n}Cl_n + e^-_{solv} \longrightarrow \cdot C_{12}H_{10-n}Cl_{n-1} + Cl^- \quad (6)$$

$$R\cdot + (CH_3)_2CHOH \longrightarrow (CH_3)_2\dot{C}OH + RH \quad (7)$$

$$\cdot C_{12}H_{10-n}Cl_{n-1} + (CH_3)_2CHOH \longrightarrow C_{12}H_{10-n+1}Cl_{n-1} + (CH_3)_2\dot{C}OH \quad (8)$$

$$(CH_3)_2\dot{C}OH + OH^- \rightleftharpoons (CH_3)_2CO^- + H_2O^{13)} \quad (9)$$

$$(CH_3)_2CO^- + C_{12}H_{10-n}Cl_n \longrightarrow (CH_3)_2CO + \cdot C_{12}H_{10-n}Cl_{n-1} + Cl^- \quad (10)$$

As Reactions (8), (9), and (10) proceed, n decreases to $n-1$, $n-2$, ···, and finally biphenyl is produced:

$$(CH_3)_2CO^- + C_{12}H_9Cl \longrightarrow (CH_3)_2CO + \cdot C_{12}H_9 + Cl^- \quad (11)$$

$$\cdot C_{12}H_9 + (CH_3)_2CHOH \longrightarrow C_{12}H_{10} + (CH_3)_2\dot{C}OH \quad (12)$$

The rate of the dechlorination, on the other hand, decreased with the dose, as is shown in Figs. 1, 2, and 4. This can be accounted for by the following reactions: 1. An electron acceptor such as biphenyl was formed. Indeed, the presence of a small amount of biphenyl decreased the $G(Cl^-)$. 2. The concentration of the hydroxide ion decreased with the dose. 3. Highly chlorinated PCB's changed into lowly chlorinated PCB's. The rate constant of Reaction (10) in the lowly chlorinated compounds may be lower than that in the highly chlorinated compounds, because the dechlorination yield of trichlorobenzene in the alkaline 2-propanol was higher than those of di- and monochlorobenzene.[15]

Assuming the initiation by Reactions (5)—(9), the propagation by (8)—(10), and a biomlecular termination by Reaction (13)[3];

$$2(CH_3)_2CO^- \xrightarrow[(CH_3)_2CHOH]{} (CH_3)_2CO + 2(CH_3)_2CHO\cdot \quad (13)$$

the initial yield of the dechlorination is given by Expression (I):

$$G(Cl^-) = G_e + k_{10}[\text{PCB's}]\{(G_e+G_R)/k_{13}\times D]\}^{1/2} \quad (I)$$

where G_e: yield of scavengable electrons by PCB's
G_R: yield of the radical R
D: dose rate

A straight line is obtained in a plot of $G(Cl^-)$ *vs.* $(1/D)^{1/2}$ as is shown in Fig. 5. The bimolecular reaction (13) should be very important in the chain dechlorination; however, the positive intercept at $(1/D)^{1/2}=0$ may

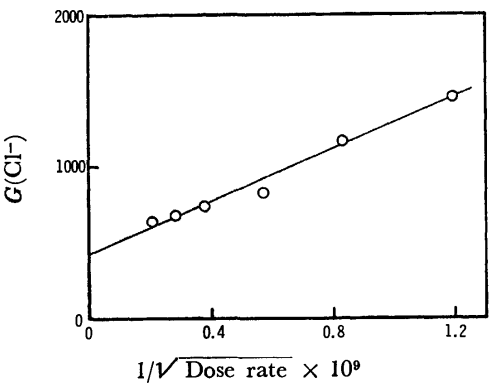

Fig. 5. Dechlorination yield as a function of dose rate.

Table 4. Dechlorination yields of PCB's in various alcohol solutions of 0.2 M KOH-0.5% KC-300

Solvent	$G(Cl^-)$	pK[13]
Methanol	4.2	10.7
Ethanol	4.9	11.6
1-Propanol	3.2	11.5
2-Propanol	700	12.2
n-Butanol	6.5	11.5
i-Butanol	9.0[a]	11.6
sec-Butyl alcohol	40	
t-Butyl alcohol	4.9	b)

Dose rate: 1.2×10^{19} eV/g hr. a) Dose rate 1.4×10^{18} eV/g hr. b) No observable dissociations up to pH 13.5.[14]

indicate an additional termination process.

Dechlorination of PCB's in Other Alcohols. It was found that the radiolytic dechlorination of PCB's in the alkaline 2-propanol solutions occurred efficiently. We studied whether a similar reaction proceeded in other simple aliphatic alcohols. The $G(Cl^-)$ values in various alcohols containing 0.5% KC-300 and 0.2 M KOH are shown in Table 4. The $G(Cl^-)$ in the solution of *sec*-butanol was relatively high, but it was only 4~9 in the other alcohols.

In alkaline alcohol solutions, the G(dechlorination) value of carbon tetrachloride were 270, 62, and 7.7 in 2-propanol, 1-propanol, and *tert*-butyl alcohol respectively.[1] The magnitude in 1-propanol was indicative of a chain reaction. Moreover, the $G(Cl^-)$ of DDT in neutral alcohols showed the same tendency.[2] The order of decreasing yield paralleled the order of increased C–H bond strength of the alcohols.

In our experiments, the chain-dechlorination reaction did not involve any alcohols other than 2-propanol and *sec*-butyl alcohol. It is known that in the pulsed radiolysis of alkaline aqueous solutions of aliphatic alcohol, the α-hydroxyl radicals dissociate to the transient RO^- and that the pK-value of the reversible reaction (9) in 2-propanol is 12.2, while the others are lower, as is shown in Table 4.[13,14] Therefore, the equilibrium in Reaction (9) apparently shifts to the right-hand side except for the case of *sec*- and *tert*-butyl alcohol. The fact that PCB's in alcoholic solutions other than 2-propanol did not undergo the radiolytic chain dechlorination may be attributed to either the fact that the electron-transfer process to PCB's from RO^- is inefficient or to the fact that the PCB radical cannot abstract the α-hydrogen of alcohols. We cannot decide which is the case. The 2-propoxide radical ion may release an electron more easily than the ions of other alcohols: also, the bond strength of α-hydrogen in 2-propanol is smaller than that of methanol, ethanol, 1-propanol, *n*-butanol, and isobutyl alcohol.

The authors are indebted to Mr. Nobuo Ito, Tokyo Metropolitan Research Institute for Environmental Protection, for his help in the analysis using a gas chromatograph-mass spectrometer.

Vibrational Energy Transfer of Some X_2CO-type Molecules on Collision with Argon

Yoshiro YONEZAWA* and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 5, 1974)

Vibrational excitation of X_2CO-type polyatomic molecules (X=F, Cl, Br, and H) on collision with an argon atom at temperatures 1000—3000 K was treated by the SSH-Tanczos method with a more tractable formula of average vibrational factor. Bending modes are more easily excited than bond-stretching modes in carbonyl halides. Excitation of the carbonyl stretching mode, the most difficult to occur in T–V process, becomes realizable when coupled with other modes to satisfy the near-resonance conditions.

Energy transfer involved in molecular collision is of importance in chemical reactions. Theories have been developed considerably for diatomic molecules[1-6] but not much for polyatomic molecules. An approximation method was given by Schwartz, Slawsky, and Herzfeld (SSH[4,5]), and Tanczos.[6] Though it is based on the two-state distorted-wave approximation by the harmonic oscillator model, useful results can be deduced for the energy transfer process of vibrationally excited molecules.

We have applied this method to the vibrational excitation of X_2CO-type polyatomic molecules (X=F, Cl, Br, and H) on collision with an argon atom. From the results, the kinetic data of the thermal decomposition of carbonyl fluoride reported by Modica[7] are discussed.

Method of Calculation

According to the SSH theory,[4,5] the probability that a pair of molecules originally in vibrational states i_a and i_b will arrive at vibrational states f_a and f_b after a collision at temperature T K is given by

$$\langle P(a,b)\rangle = \tilde{p}\,p_0(a)p_0(b)V^2(a)V^2(b) \times 8\sqrt{\frac{\mu}{2kT}}\exp(\varepsilon_0/kT)\left(\frac{8\pi^3\mu\Delta E}{h^2}\right)^2 \times \int_0^\infty F(u)\mathrm{d}u \quad (1)$$

with

$$F(u) = \frac{u}{\alpha^4}(r_c/r_0)^2\exp\left(-\frac{\mu u^2}{2kT}\right)\frac{\exp(H-H')}{[1-\exp(H-H')]^2} \quad (2)$$

and

$$H = \frac{4\pi^2\mu u}{\alpha h}, \quad H' = \frac{4\pi^2\mu v}{\alpha h} \quad (3)$$

where μ is the reduced mass of the collision pair which approach each other with an effective relative velocity u and recede with a velocity v; ΔE is the net total change in translational energy involved during the collision, *i. e.*,

$$\Delta E = h\nu_a(i_a-f_a) + h\nu_b(i_b-f_b) = \mu(v^2-u^2)/2\ ; \quad (4)$$

ε_0 is the minimum value of the Lennard-Jones potential

$$\varepsilon(r) = 4\varepsilon_0[(r/r_0)^{12} - (r/r_0)^6]\ ; \quad (5)$$

α is an intermolecular force constant in reciprocal length units, for the repulsive exponential potential function

$$V(r) = V_0\exp(-\alpha r) - \varepsilon_0 \quad (6)$$

evaluated so as to best fit Eq. (5) at $r=r_0$ and $r=r_c$, where r_c is the distance between molecular centers at the classical turning point for each u; p_0 is the geometrical factor required for the orientation consideration, $p_0(i_a\to f_a)=2/3$ being assumed herewith, and $\tilde{p}$ is a cross-section factor which is approximated by

$$\tilde{p} = 1.364/(1+1.1\,\varepsilon_0/kT) \quad (7)$$

The average vibrational factor V^2 in Eq. (1) for polyatomic molecules has been given by Tanczos[6] as follows:

$$V^2(a) = V^2(i_a\to i_a\pm1) = \frac{h\left(i_a+\frac{1}{2}\pm\frac{1}{2}\right)}{8\pi^2\nu_a}\frac{(\alpha^*)^2}{N_s}\sum_s\frac{A_{sa}^2}{m_s} \quad (8)$$

where s denotes the atom to be taken into account in the breathing sphere model, N_s the number of atoms, $N_s=4$ being assumed herewith, m_s an atomic mass, and A_{sa} the Cartesian displacement coefficient of s in the normal vibration Γ_a whose vibrational frequency is ν_a. α^* is evaluated at $u=u^*$, the most favorable velocity for the vibrational transition involving a particular value of ΔE:

$$\alpha^* = \frac{1}{r_0-r_c}\ln\left(1+\frac{E_m}{\varepsilon_0}\right) \quad (9)$$

where

$$E_m = \mu(u^*)^2/2 = kT\left[\frac{2\pi^4\mu(\Delta E)^2}{(\alpha^*)^2h^2kT}\right]^{1/3} \quad (10)$$

Following the method of a normal coordinate analysis by Stretton,[8] we can express the summation in Eq. (8) in a compact form as follows:

$$\sum_s A_{sa}^2/m_s = (\tilde{L}_X L_X)_{a,a} \quad (11)$$

where L_X is a transformation matrix between the orthogonal coordinate X and normal coordinate Q, and the product $(\tilde{L}_X L_X)_{a,a}$ is to be taken over the matrix elements corresponding to Γ_a only. L_X can be determined by means of the GF matrix treatment of molecular vibrations.[9]

$$L_X = M^{-1}\tilde{B}L_G\Lambda_G^{-1/2}L_c \quad (12)$$

* Present Address: Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606.

where definitions of the matrices, M^{-1}, $\tilde{B}$, L_G, $\Lambda_G^{-1/2}$, and L_c are the same as in Ref. 9.

For the sake of convenience, we introduce the average amplitude factor $Y(X_s;\Gamma_a)$ for atom s in Γ_a:

$$Y(X_s;\Gamma_a) = (\tilde{L}_X)_{a,x_s}(L_X)_{x_s,a} + (\tilde{L}_X)_{a,y_s}(L_X)_{y_s,a} + (\tilde{L}_X)_{a,z_s}(L_X)_{z_s,a} \quad (13)$$

The right-hand side of Eq. (11) can thus be written as

$$(\tilde{L}_X L_X)_{a,a} = \sum_s Y(X_s;\ \Gamma_a) \quad (14)$$

We analyzed the in-plane vibrational motion of carbonyl halides and formaldehyde by using the potential function of Miyazawa.[10] We have omitted the mode Γ_6 (B_2 symmetry) throughout the calculation. Since it is the only mode corresponding to the out-of-plane motion, it cannot be mixed with the other five modes. Its omission does not affect our calculations. Molecular geometries were obtained from the literature.[11] Relevant Urey-Bradley force constants are summarized in Table 1.[12,13]

Vibrational transition probabilities of those molecules by translational-vibrational (T–V) or vibrational-vibrational (V–V) process on collision with an argon atom at T=1000—3000 K have been calculated by the above method. Relevant constants of the Lennard-Jones potentials for the collision pairs are given in Table 2. Calculations were carried out on a FACOM Computer at the Kyoto University Computation Center.

Table 1. Urey-Bradley force constants of X_2CO molecules in md/Å[a]

Molecule	Force constants					
	K_{CX}	K_{CO}	H_{XX}	H_{OX}	F_{OX}	F_{XX}
F_2CO	4.528	12.85	0.450	0.294	1.578	1.120
Cl_2CO	1.99	12.61	0.11	0.218	0.860	0.523
Br_2CO	1.565	12.83	0.060	0.189	0.631	0.528
H_2CO	3.842	11.044	0.349	0.338	0.88	0.0

a) The symbols K, H, and F denote the force constants for the bond-stretchings, bond-bendings, and nonbond interactions, respectively. The coefficients for the energy terms linear with respect to displacements were all assumed to be one-tenth the force constants.

Table 2. Lennard-Jones potential parameters[a] and reduced masses of the collision pairs

Collision pair	r_0 (Å)	ε_0/k (K)	μ (10^{-23} g)
F_2CO-Ar	5.331	117.8	4.166
Cl_2CO-Ar	5.562	210.4	4.763
Br_2CO-Ar	5.638	253.9	5.448
H_2CO-Ar	4.988	116.8	2.869
CO-Ar	3.504	116.8	2.756

a) Potential parameters of carbonyl halides-argon systems were approximated by

$r_0=[r_0(\text{CO-CO})+r_0(X_2-X_2)+r_0(\text{Ar}-\text{Ar})]/2$

$\varepsilon_0=\sqrt{\varepsilon_0(X_2-X_2)\varepsilon_0(\text{Ar}-\text{Ar})}$.

Parameter values of r_0(M−M) and ε_0(M−M) were taken from J. O. Hirschfelder, C. F. Curtiss, and R. B. Bird, "Molecular Theory of Gases and Liquids," John Wiley & Sons, New York, N. Y. (1954), Appendix.

Results and Discussion

Fundamental frequencies and average amplitude factors of all the molecules are summarized in Table 3.

Table 3. Fundamental frequencies[a] and average amplitude factors[b]

a) Calculated and observed wavenumbers $\bar{\nu}$ in cm^{-1}. The experimental values for carbonyl halides (taken from Ref. 12) and formaldehyde (I. C. Hisatsune and D. F. Eggers, Jr., *J. Chem. Phys.*, **23**, 487 (1955)) are given in parentheses. b) $Y(X_s;\Gamma_a)$ given in units of 10^{23} g^{-1}.

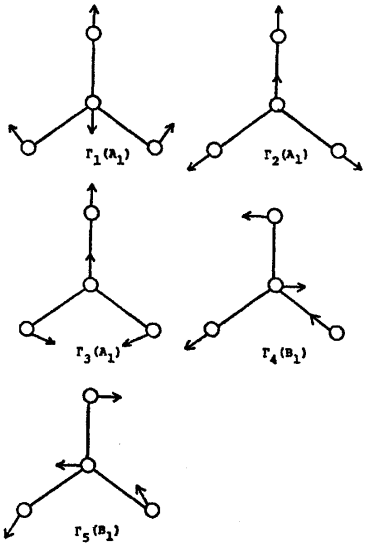

Fig. 1. The normal modes of F_2CO in Cartesian displacements.
The magnitude of the displacement vectors are arbitrary.

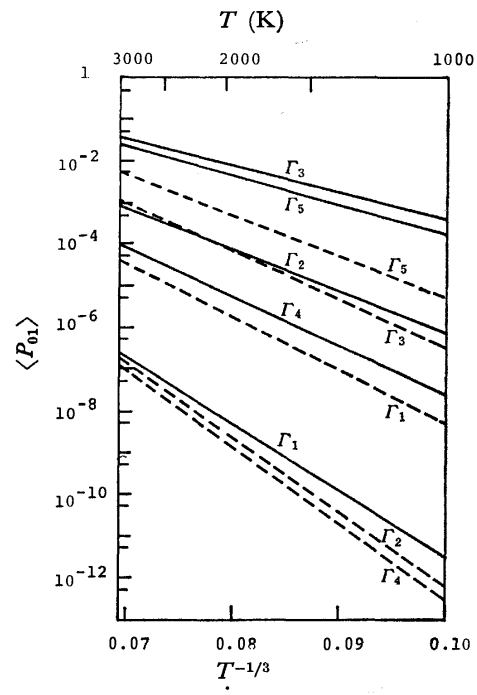

Fig. 2. Temperature dependences of the T-V vibrational transition probabilities, $\langle P_{01}\rangle$, of all the normal modes of F_2CO (solid line) and H_2CO (broken line).

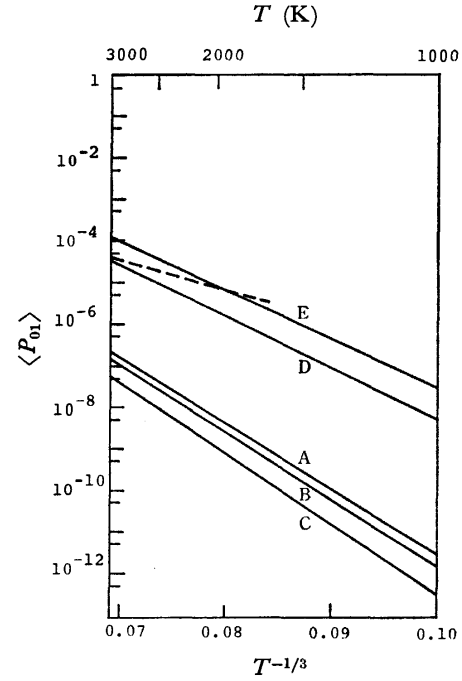

Fig. 3. Temperature dependences of the T-V vibrational transition probabilities, $\langle P_{01}\rangle$, of the carbonyl stretching mode (Γ_1) of X_2CO. The broken line represents the values calculated for CO from Eq. (15) with the aid of

$\langle P_{01}\rangle = \exp(h\nu/kT)/\{\tau Z_c[1-\exp(-h\nu/kT)]\}$

where Z_c denotes the average number of collisions which a CO molecule experiences per second under 1 atmospheric pressure.

A, F_2CO; B, Cl_2CO; C, Br_2CO; D, H_2CO; E, CO.

The normal modes of carbonyl fluoride in Cartesian displacements are represented in Fig. 1. There are three A_1 modes: carbonyl stretching Γ_1, symmetric CX stretching Γ_2, XCX bending Γ_3, and two B_1 modes: asymmetric CX stretching Γ_4, CO rocking Γ_5. It can be seen that vibrational wave numbers increase in the order $\bar{\nu}_3<\bar{\nu}_5<\bar{\nu}_2<\bar{\nu}_4<\bar{\nu}_1$ for carbonyl halides and in $\bar{\nu}_5<\bar{\nu}_3<\bar{\nu}_1<\bar{\nu}_2\leqq\bar{\nu}_4$ for formaldehyde.

Transition probabilities $\langle P_{01}\rangle$ for the 0—1 excitation of the various normal modes of carbonyl fluoride and formaldehyde by T-V process are plotted as functions of $T^{-1/3}$ in Fig. 2. As was the case with the vibrational excitation of diatomic molecules studied by Landau-Teller,[14] all the $\langle P_{01}\rangle$ are proportional to $\exp(-T^{-1/3})$. Transition probabilities of X_2CO molecules increase in the reverse order to that of the magnitude of vibrational wave numbers, *viz.*, $\langle P_{01}(\Gamma_1)\rangle<\langle P_{01}(\Gamma_4)\rangle<\langle P_{01}(\Gamma_2)\rangle<\langle P_{01}(\Gamma_5)\rangle<\langle P_{01}(\Gamma_3)\rangle$ for carbonyl halides, and $\langle P_{01}(\Gamma_4)\rangle\leqq\langle P_{01}(\Gamma_2)\rangle<\langle P_{01}(\Gamma_1)\rangle<\langle P_{01}(\Gamma_3)\rangle<\langle P_{01}(\Gamma_5)\rangle$ for formaldehyde. The results are due primarily to the decrease of ΔE in these orders.

Transition probabilities for the 0—1 excitation of carbonyl stretching modes (Γ_1) of carbonyl halides, formaldehyde, and carbon monoxide are shown in Fig. 3. As the vibrational wave number of carbon monoxide, we have assumed 2143 cm^{-1}.[13] Millikan *et al.* have observed that, in carbon monoxide–argon system, the vibrational relaxation time τ over 1700—3000 K is expressed by

$$\ln(p\tau) = \gamma T^{-1/3} + \delta \qquad (15)$$

with $\gamma=182$ and $\delta=-22.4$, where p is in atm, τ in second, and T in K.[15,16] $\langle P_{01}\rangle$ of carbon monoxide obtained from this equation is also given in Fig. 3. The two values agree with each other especially near 2000 K. The $\langle P_{01}\rangle$ value for carbon monoxide is larger than the values for carbonyl halides by a few order of magnitude, despite its larger value of ΔE.

The average vibrational factors $V^2(0\rightarrow1)$ of the Γ_1 mode are given in Table 4. The V^2 values for carbon monoxide and formaldehyde are several times greater than those for carbonyl halides. This is ascribable to the larger values of α^* and smaller reduced masses of this mode for these two molecules. The reduced mass of the carbonyl stretching mode is indicated by $[(\tilde{L}_X L_X)_{\Gamma_1,\Gamma_1}]^{-1}$ for carbonyl halides as well as formaldehyde and $[m_C m_O/(m_C+m_O)]$ for carbon monoxide, where m_C and m_O denote the mass of the carbon and oxygen atoms, respectively.

TABLE 4. AVERAGE VIBRATIONAL FACTORS $V^2(0\rightarrow1)$ OF THE CARBONYL STRETCHING MODE

Molecule	$V^2(0\rightarrow1)\times10^3$				
	T=1000	1500	2000	2500	3000 K
F_2CO	2.01	1.99	1.99	1.98	1.98
Cl_2CO	1.96	1.94	1.93	1.92	1.92
Br_2CO	1.92	1.90	1.88	1.88	1.87
H_2CO	7.08	7.02	6.99	6.97	6.96
CO	9.30	9.22	9.18	9.15	9.13

However, with V^2 alone we cannot account for the large $\langle P_{01} \rangle$ value for carbon monoxide. An even more important contribution to $\langle P_{01} \rangle$ is derived from the reduced mass μ involved in Eq. (2); the $F(u)$ becomes greater in magnitude as the reduced mass decreases. The relatively large $\langle P_{01} \rangle$ for formaldehyde can be interpreted in the same way. All the results emphasize the concurrent importance of small ΔE and μ as well as large V^2 in order that vibrational energy transfer proceeds more effectively. The intramolecular motion of halogen atom in carbonyl halides hardly affects the vibrational excitation of carbonyl stretching mode; the amplitude factors of the halogen atoms in Γ_1 are negligibly small as compared with those for the carbon and oxygen atoms (Table 3).

Transition probabilities were calculated for the 0—1 excitation of carbonyl stretching mode by V-V processes coupled with the 1—0 de-excitation of the other modes $\langle P_{01}^{10} \rangle$, with the 2—0 de-excitation of the Γ_2 mode $\langle P_{01}^{20} \rangle$, and with the 1—0 de-excitation of both the Γ_3 and Γ_5 modes $\langle P_{10}^{01,10} \rangle$. The results for carbonyl fluoride are plotted as functions of $T^{-1/3}$ in Fig. 4.

We see that the transition probabilities $\langle P_{01}^{10} \rangle$ increase in the reverse order to that of the magnitude of ΔE, *viz.*, $\langle P_{01}^{10}(\Gamma_1-\Gamma_3) \rangle < \langle P_{01}^{10}(\Gamma_1-\Gamma_5) \rangle < \langle P_{01}^{10}(\Gamma_1-\Gamma_2) \rangle < \langle P_{01}^{10}(\Gamma_1-\Gamma_4) \rangle$. A similar trend is also found in the case of formaldehyde: $\langle P_{01}^{10}(\Gamma_1-\Gamma_4) \rangle \leqq \langle P_{01}^{10}(\Gamma_1-\Gamma_2) \rangle < \langle P_{01}^{10}(\Gamma_1-\Gamma_5) \rangle < \langle P_{01}^{10}(\Gamma_1-\Gamma_3) \rangle$. Likewise, $\langle P_{01}^{20} \rangle$ is far larger than the corresponding $\langle P_{01} \rangle$ and $\langle P_{01}^{10} \rangle$ in the temperature range of our study. However, $\langle P_{01}^{10,10} \rangle$ is not so large as $\langle P_{01}^{20} \rangle$.

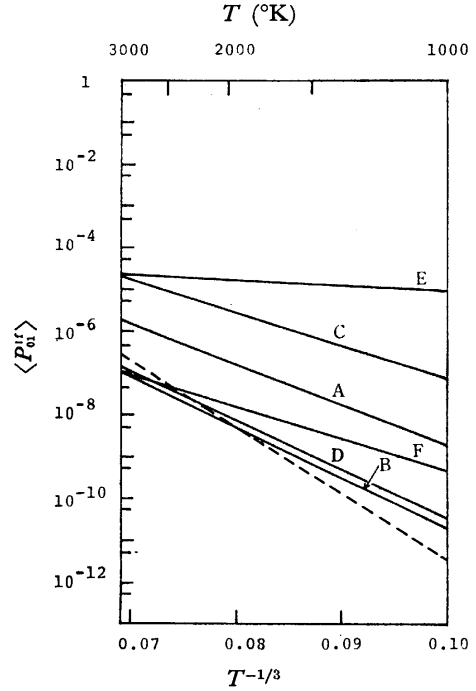

Fig. 4. Temperature dependences of the V-V vibrational transition probabilities, $\langle P_{01}^{10} \rangle$, $\langle P_{01}^{20} \rangle$, and $\langle P_{01}^{10,10} \rangle$ of F_2CO.
A, $\langle P_{01}^{10}(\Gamma_1-\Gamma_2) \rangle$; B, $\langle P_{01}^{10}(\Gamma_1-\Gamma_3) \rangle$; C, $\langle P_{01}^{10}(\Gamma_1-\Gamma_4) \rangle$; D, $\langle P_{01}^{10}(\Gamma_1-\Gamma_5) \rangle$; E, $\langle P_{01}^{20}(\Gamma_1-\Gamma_2) \rangle$; F, $\langle P_{01}^{10,10}(\Gamma_1-\Gamma_3,\ \Gamma_5) \rangle$.
The broken line indicates $\langle P_{01} \rangle$ for the T-V process.

In short, the transition probability for the 0—1 excitation of Γ_1 at lower temperature markedly increases on near-resonance coupling with another mode. Thus, it is probable that under the usual experimental conditions, vibrational excitation of a normal mode is caused mainly by a V-V process. At higher temperature ($T > 2000$ K), however, none of the V-V processes are more efficient than the T-V process.

Modica[7] has studied the kinetics of shock-tube decomposition of carbonyl fluoride in argon at 2200—3600 K:

$$F_2CO + Ar \longrightarrow FCO + F + Ar.$$

He concluded that in the transition state the bending modes (Γ_3, Γ_5, and Γ_6) are considerably deformed in constrast to the relatively insensitive bond-stretching modes (Γ_1, Γ_2, and Γ_4). Our present calculations show the relative ease of the vibrational excitation of Γ_3 and Γ_5. The Γ_6 mode should also be as easily excited as these two modes because of its small vibrational wave number (774 cm^{-1}).[12] The decomposition reaction might proceed through the V-V energy transfer from these bending modes to the C-F bond-stretching modes.

Magnetic Properties of Nonbenzenoid Aromatic Hydrocarbons

Hiroyuki YAMAGUCHI* and Takeshi NAKAJIMA
Department of Chemistry, Tohoku University, Sendai 980
(Received March 18, 1974)

The magnetic susceptibilities for nonbenzenoid aromatic hydrocarbons have been examined by using the modified London-Hoarau method in the framework of the Wheland-Mann-type SCF MO approximation. By taking into account the double-bond fixation quite common in these molecules, we obtained a general agreement between the calculated results and the available experimental values.

The diamagnetic delocalization susceptibility of a ring π-electron system, attributable to induced ring currents in its π-electron network, is one of the important quantities indicative of π-electron delocalization. A quantum-mechanical theory for the diamagnetic delocalization susceptibility was first developed by London.[1] His method is based on the Hückel LCAO MO theory and has extensively been used for a variety of aromatic hydrocarbons.[2,3] The calculated diamagnetic anisotropies for benzenoid hydrocarbons are usually in quite good agreement with the experimental values. On the other hand, the direct application o London's technique to nonbenzenoid aromatic hydrocarbons[4,5] often brings about unsatisfactory results in view of the recently-reported experimental data.[15]

It is probable that such unsatisfactory results arise mainly from the employment of molecular orbitals obtained using the simple Hückel MO theory which does not take into account the double-bond fixation quite common in nonbenzenoid hydrocarbons and, hence, proves to be less reliable when applied to these molecules, and partly from the shortcomings inherent in London's original theory. Hoarau[6] has made improvements on the London theory by refining the calculation of the gauge factors.

It is the purpose of this paper to calculate the magnetic susceptibilities of several nonalternant hydrocarbons by using the modified London-Hoarau method in the framework of the Wheland-Mann-type SCF MO approximation.[7] This approximation allows us to obtain equilibrium geometrical structures with respect to the C–C bond lengths of these molecules.

Method of Calculation

London's theory is not necessarily related to the simple Hückel MO approximation. It can naturally be extended to the Wheland-Mann-type SCF LCAO MO method.[7] In this method, the Coulomb integral, α_μ, and the resonance integral, $\beta_{\mu\nu}$, are given by the following formulas, respectively:

$$\alpha_\mu = \alpha_0 + \omega(1-q_\mu)\beta_0 \quad (1)$$

where q_μ is the electron density and ω is taken to be unity, and:

$$\beta_{\mu\nu} = \beta_0 \exp[a(1.397-r_{\mu\nu})] \quad (2)$$

where $r_{\mu\nu}$ is the bond length and is correlated with the bond order, $p_{\mu\nu}$, by Eq. (3):[8]

$$r_{\mu\nu} = 1.520 - 0.186p_{\mu\nu} \quad (3)$$

The value of a in Eq. (2) is taken to be 4.4 Å^{-1}. This value was determined so as to reproduce the observed C–C bond lengths of butadiene[9] and naphthalene[10] and the dipole moments of pentafulvene[11] and heptafulvene.[12]

Improving the correlation between the experimental and calculated relative anisotropies of diamagnetic susceptibility, Hoarau proposed an expression for the molar susceptibility which includes a dependence on the delocalization energy, DE:[7]

$$\Delta K = \Delta K_L/3 + A\times 10^{-18}DE \quad (4)$$

where ΔK_L is the molar susceptibility according to London's theory.[1] The A parameter was fitted to ensure the best agreement with the experimental results; the value of 0.776 for the case of Hückel basis was found. Nakajima and Kohda[13] proposed a different value for A, 0.940. However, in both papers rather inaccurate experimental values of diamagnetic susceptibility were used. Reconsidering their procedure by the use of the more recent experimental values of the diamagnetic susceptibilities given in Ref. 14, we obtain a different least-squares fit:**

$$\Delta K = \Delta K_{SCF}/3 + 0.359\times 10^{-18}DE \quad (5)$$

where ΔK_{SCF} is the magnetic susceptibility calculated by using the Wheland-Mann-type SCF LCAO MO basis. Equation (5) can be used to calculate the magnetic susceptibilities of several nonbenzenoid aromatic hydrocarbons (Fig. 1).

Results and Discussion

In Table 1, the theoretical diamagnetic susceptibilities, ΔK, for nonalternant hydrocarbons are listed (in units of $\Delta K_{benzene}$) and compared with the experimental exaltations (in units of $\Lambda_{benzene}$).[15] The theoretical values are in good agreement with the experimental data, except for the case of aceheptylene (IX), whose experimental exaltation has been reported, unbelievably, to be zero. Recently, using the coupled perturbed Hartree-Fock method, Mikami *et al.*[16] have calculated the magnetic susceptibility of IX. The calculated value is almost the same as that obtained in this paper. It is, therefore, hoped that the experimental value of this molecule should be re-examined. In pentalene (I), heptalene (II), *s*-indacene (III), py-

* Present address: Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto 860.

** We have re-examined the A value using the experimental values of benzene, naphthalene, anthracene, naphthacene, phenanthrene, chrysene, pyrene, perylene, triphenylene, and coronene, which do not exhibit any significant bond-length variation.

racylene (IV), and dipleiadiene (V), the last of which is yet unknown, the magnetic susceptibilities are predicted to be negative. Such an anomalously-reduced diamagnetism may be interpreted as an induced paramagnetism.[13,17–19]

Molecules I, II, and III are predicted to possess two equilibrium geometrical structures, one belonging to the molecular symmetry, D_{2h}, and the other to C_{2h}.[20] In the former, the C–C bond lengths are quite equalized, while in the latter there is a considerable double-bond fixation. The equilibrium structures with the reduced-molecular symmetry (C_{2h}) were obtained by taking a distorted C nuclear arrangement with the C_{2h} symmetry as the starting geometry for the iterative calculation. It has been shown that, as a result of the *pseudo*-Jahn-Teller effect, in such a case the structure with reduced symmetry is energetically more stable than the fully-symmetrical one. We calculated the magnetic susceptibilities for two molecular symmetries of these molecules. It can be seen that the double-bond fixation brings about a considerable decrease in the paramagnetic susceptibility. The good agreement with theory and experiment in heptalene (II) provides further support for the molecular-symmetry reduction occurring in this molecule and in Molecules I and III as well.

In Molecules IV, V, and VI, it is predicted that the calculated bond lengths of the naphthalene core are almost the same as those in the free naphthalene molecule and that there are marked double-bond fixations in the other region of the periphery.[21] The periphery of IV and V may give a paramagnetic ring current characteristic of the $4n$ perimeter.[18] On the other hand, naphthalene core in IV and V may exhibit a diamagnetic ring current to the same extent as that of a free naphthalene molecule. Therefore, it may be expected that the paramagnetic ring current and the diamagnetic ring current cancel each other out to give a small magnetic susceptibility in IV and V.

It may be concluded that the magnetically-induced ring currents decrease sensitively with the double-bond fixation, and that in I, II, III, IV, and V they are extremely impeded. Part of the evidence for these reduced magnetic susceptibilities is given by the NMR spectra of II,[22] III,[23] and IV,[24] which show the proton signals in the olefinic region.

Ligand-Ligand Interaction in the β-Diketonato Complexes of Be^{2+}, Al^{3+}, and Zn^{2+}

Takeshi OHNO and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received September 13, 1973)

The fluorescence yield (Φ_F) and the phosphorescence yield (Φ_P) of acetylacetone, benzoylacetone, and dibenzoylmethane were enhanced by coordination of Zn^{2+}, Al^{3+}, and Be^{2+} in an increasing order. In the bis- and the tris-bidentate complexes, not only did the ratios of Φ_P to Φ_F increase, but also the lifetimes of the phosphorescences became a little longer than that of the corresponding mono-bidentate complex. This change originates from some kinds of interaction between the ligands in the excited and ground states. Such an inter-ligand interaction was supported by the measurement of the polarization. However, the interaction energy is smaller than the expected values in the analyses of the absorption spectra and the circular dichroism in the region of the ligand band. A difference in the absorption spectra between the mono- and the bis- or the tris-bidentate complexes was seen only in the Franck-Condon factors; this finding supports the extension of the excited state through the two or the three ligands due to the weak inter-ligand interaction.

It can be easily expected that an excited state of a ligand in a coordination compound has a different character from that of the free ligand because of the coordination bond and the other ligand(s) in close proximity. An enhancement of the ligand-triplet yield is caused by spin-orbit interaction due to a heavy metal ion,[1] and the excitation in the ligand is transferred to that in the metal ion,[2] with an excited state below that of the ligand. Further, the circular dichroism due to intra-ligand transition in some tris-bidentate complexes implies the presence of an inter-ligand effect through dipole-dipole interaction. However, effect of inter-ligand interaction on the excited state of ligand has been examined, through many types of inter-molecular interaction—redox reaction, dimer formation, luminescence quenching, and energy transfer—have been reported between molecules in the excited state and in the ground state. Because such a type of reaction has been known to depend on the extent of interaction between the molecules (see Table 1), one may ascertain the extent of the inter-ligand interaction by exploring the photochemistry of ligand. Consequently, each ligand in the bis- and tris-bidentate complexes suffers from ligand-ligand interaction and coordination effects; first, we examined the corresponding mono-bidentate complex, in which the coordination effect was revealed, and then the bis- and the tris-bidentate complexes were compared with it.

TABLE 1. PHENOMENA CAUSED BY INTERACTION BETWEEN MOLECULES IN THE EXCITED STATE AND THE GROUND STATE

Interaction	Phenomena
Strong	Excimer formation[3] Electron transfer[3]
Intermediate	Splitting of the vibronic band in the absorption spectrum[4]
Weak	Change of emission yield and lifetime[5] Energy transfer[6]

Three kinds of metal ions—beryllium(II), zinc(II), and aluminium(III)—were chosen as central metal ions, as they are practically inactive to electron-transfer reaction on photoexcitation and have no excited state below 45×10^3 cm^{-1}. Because these three metal ions arrange ligands in different conformations, the magnitudes and the characters of ligand-ligand interactions can be expected to be different. All the metal ions were easily chelated by various β-diketones, which showed strong luminescences at lower temperatures.[7] The acetylacetonato complexes emitted phosphorescence only, whereas the complexes of dibenzoylmethane and benzoylacetone emitted both fluorescence and phosphorescence. Therefore, some characteristics (yield, lifetime, and spectrum) of the emission in addition to the absorption spectrum were measured in order to ascertain the interaction between ligands in the excited state and the ground state.

Experimental

Materials. *Free Ligands*: The acetylacetone(AcAc), benzoylacetone(Ba), and dibenzoylmethane (Dbm) were purified in the following ways: vacuum distilation for AcAc, three recrystallizations from ethanol for Ba, and four recrystallizations from ethanol and benzene for Dbm.

Metal Complexes and Metal Salts: The metal complexes were prepared in the usual ways except of $Be(AcAc)_2$, which was obtained from Wako Pure Chemical Industries. The complexes of zinc prepared had the following molecular formula: $Zn(AcAc)_2(H_2O)$, $Zn(Ba)_2\cdot C_2H_5OH$, $Zn(Dbm)_2(H_2O)_2$. In aluminium and beryllium complexes, three β-diketones coordinate to Al^{3+}, and two, to Be^{2+}. The results of the elementary analyses agreed with the theoretical values within a deviation of 0.58% for carbon and that of 0.14% for hydrogen. The purifications of the metal salts, $BeSO_4$, $Zn(NO_3)_2$, $KAl(SO_4)_2\cdot12H_2O$, and H_3BO_3, were carried out through two recrystallizations from aqueous solutions.

Solvents: The ethanol was refluxed with silver nitrate and over calcium oxide, and then distilled. The methanol was purified in a similar way without drying. The water was distilled two times. The ether and isopentane were dried over calcium chloride and distilled over metalic sodium.

Procedure. All the solutions were buffered by 0.2 M borate at pH=8.0. The bis-bidentate and tris-bidentate complexes were examined soon after preparation, because, in solution, 10% of the complex was dissociated in a day. The spectrum of the mono-bidentate complex was measured for the solution containing β-diketone (10^{-5} M), together with a large excess of a metal ion ($10^{-4}\sim10^{-3}$ M), in which only the mono-β-diketonato complex was expected to exist.

This was supported by the set of successive formation constants,[8] by the changes in both the absorption and emission spectra and in the lifetime in the presence of excess metal ions. We used a mixture of water and methanol (1 : 4 by volume) as the solvent.

Measurements. The absorption spectra were measured by means of a Shimadzu MPS-50L spectrophotometer. For the measurements at the temperature of boiling nitrogen (77.4 K), a quartz Dewar vessel (diameter : 55 mm) filled with liquid nitrogen was set very near to the wide aperture of the head-on type photomultiplier in order to diminish the error due to light scattering.

For the luminescence studies, all the complexes and ligands were studied at 77 K at a concentration of about 10^{-5} M. The emission spectra were obtained by using MPF-2A Hitachi fluorescence spectrophotometer with a band-width of 2~8 nm; it had been calibrated by the method of Lippert[9] against the fluorescence of β-naphthol. The emission yields were determined relative to an EPA solution of benzophenone with a band-width of 6 nm.[10]

To measure the polarization of the emission, a Polacoat film (105 UV), put between two quartz plates, or a Gram-Thomson prism was used as the polarizer, and a Toshiba polarizing filter, as the analyzer. The emission monochromator, which had different transmittance with polarized lights perpendicular to each other, was corrected by means of unpolarized light scattered from a frosted glass.

Results and Discussion

Semi-empirical calculations have shown that the absorption band of AcAc in the near ultraviolet region is attributable to the π-π* transition[11] with a transition moment along the x-axis, as is shown in Fig. 1.

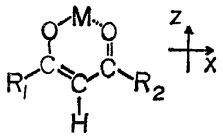

Fig 1. Structure of the ligand.
AcAc: $R_1=R_2=CH_3$
Ba: $R_1=CH_3$, $R_2=C_6H_5$
Dbm: $R_1=R_2=C_6H_5$

For Ba and Dbm, the intense band observed in a frequency region a little lower than AcAc can safely be assigned to the π-π* transition. Although the n-π* transitions are hidden by the strong π-π* transition, one of n-π* transitions may be shifted to a higher frequency because of the formation of an enol form†, this lifting one of the non-bonding orbitals. It is certain that, just as with the hydrogen bond, coordination to the metal ion makes a six-membered ring. However, because neither coordination nor protonation greatly changes the energy level of the other non-bonding orbital in the ring comformation, the non-bonding orbital may interact with the π-orbital of the neighboring ligand(s) in the complexes of aluminium, as will be discussed below.

† Burdett and Rogers reported, on the basis of PMR analysis, that 80% of the free AcAc, 100% of the Ba and 100% of the Dbm exists as the enol form in $CHCl_3$ or CCl_4.[12]

Effect of Coordination on the Excited States of β-Diketones. Absorption and Emission Spectra: A broad absorption band was observed at room temperature in the near-ultraviolet region for all the β-diketones examined, independent of the presence or absence of

metal ions. Each of the mono-bidentate complexes had a broad absorption band, not greatly different from the free β-diketone. At 77 K, the fine structure of the absorption spectra emerged as is shown in Fig. 2—4; one may easily recognize that the peaks and shoulders of the coordinating β-diketones shift to a lower frequency than those of the free β-diketones (see Table 2). However, an exception is found in the case of $Al(Dbm)^{2+}$, in which a new band is weakly observed on the lower-frequency side of the 0—0′ band.

Coordination enhanced the emission intensity of β-diketones in all cases at 77 K, as is shown in Fig. 2. The fluorescence spectra of these mono-coordinated complexes have a well-resolved structure at 77 K and are practically independent of the metal ions (Fig. 2). The numerical data on the peaks and shoulders are shown in Table 2. As Fig. 2 shows, there are mirror-image relations between the absorption and the fluorescence spectra. Therefore, all of the peaks and the shoulders of the absorption may be regarded as 0—0′ bands or vibronic bands. However, $Al(Dbm)^{2+}$ is an exception; it is different from the others in its absorption spectrum, though similar in its fluorescence spectrum.

On the basis of rough analyses of the fine structures of the spectra, symmetric vibrations coupled with the π-π^* transition are assigned to C–C stretching in the six-membered ring and to C–R (R : CH_3 or C_6H_5) stretching (1300 cm^{-1}) (except for the case of $Be(AcAc)^+$) on the basis of Nakamoto's assignment of $Al(AcAc)_3$.[13]

Yields and Polarizations of Emission: All the free β-diketones showed a weak emission with quantum yields below 0.008 at 77 K. Fluorescence was observed only for Dbm. However, the coordination increased the emission very much, as has been mentioned above, and the fluorescence was easily observed even in the case of Ba. In view of all the emission yields listed in Table 3, it is noticeable that the emission yield was enhanced with the coordination in the following order: Be>Al>Zn. The simultaneous enhancement of the fluorescence and phosphorescence yields indicates that the strong metal-ligand bond restricts the internal rotation of the ligand in the singlet excited state and prevents it from making a radiationless transition. In fact, the fluorescence yields increase in an order of that of the ionic radii of metal ions (Be^{2+}: 0.34, Al^{3+}: 0.57, Zn^{2+}: 0.69 Å). Further, this presump-

tion is supported by the fact that an intense fluorescence is observed at low temperatures for all the complexes which have no emission at room temperature.

It is important that beryllium complexes do not have the smallest ratio of the phosphorescence yields to the fluorescence yield, contrary to the expectation that the ratio in the lightest metal complex would be the smallest on account of having the smallest spin-orbit interaction. This abnormality will be discussed later.

The polarization of emission is defined by Eq. (1) when excited with polarized light:

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \quad (1)$$

where $I_{\parallel}$ and $I_{\perp}$ are the emission intensities with electric vectors parallel and perpendicular to that of the exciting light respectively. When the emission moment at an angle(θ) with the absorption one, P is written as Eq. (2), assuming the random orientation of a solute in the solution:

$$P = \frac{3\cos^2\theta - 1}{\cos^2\theta + 1} \quad (2)$$

Moreover, the polarization is calculated to be 1/2 when the transition moment of the emission is the same in direction as that of absorption (θ=0°), and −1/3 when it is perpendicular (θ=90°). The fluorescence polarizations obtained have a small deviation from the ideal value (1/2) and are independent of the excitation light throughout the near-ultraviolet region for all the samples except Al(Dbm)$^{2+}$, as Table 4 shows. Phosphorescence polarizations have negative or small positive values, depending on the metal ions, for all the series of β-diketones; they are also independent of excitation wavelength except for the dibenzoylmethanato complex of aluminium. The independence of P for the mono-β-diketonato complex suggests that the broad absorption band in the near-ultraviolet region consists of one kind of transition except for the case of dibenzoylmethanato complexes, one of which has a new and weak absorption band in the lower frequency region, as has been mentioned above. The negative and small positive values of the phosphorescences indicate that the lowest triplet state is a π-π^* state in all cases, just as McGlynn *et al.* reported.[14] The assignment of the phosphorescence is supported by both the semi-empirical calculation of acetylacetone[13] and the relatively longer lives of the phosphorescences. The shortest lifetime, 0.1 s, which was found for Be(AcAc)$^+$, was longer than any other reported life-times of the n-π^* triplet state.

a) The values were obtained on the excitation of the 0—1′ or 0—2′ band; they were different from the value on the excitation of the 0—0′.

It is interesting that the shortest lifetimes of the AcAc and Dbm complexes were found not for the zinc complexes but for the beryllium complexes, contrary to the expectation based on the spin-orbit coupling through the metal-ligand bond. Because the shortest lifetimes were accompanied by extraordinary enhancements of the yields in all the beryllium complexes, it is probable that the intersystem crossing rates ($S_1 \rightarrow T_0$, $T_0 \rightarrow S_0$) increase with the strength of the metal-ligand bond.

After all, the metal-ligand bond in a complex brings about: (i) a small radiationless transition rate in the singlet excited state, resulting in increasing yields of emission, and (ii) a large intersystem crossing rate, resulting in a larger yield and the shortest lifetime of the phosphorescence.

Ligand-ligand Interactions in Bis- and Tris-bidentate Complexes. Conformations of Ligands in Bis- and Tris-bidentate Complexes: The conformations of the coordinating β-diketones are different depending on the metal ions. In beryllium complexes, the six-membered rings of two ligands hold planes which are vertical with each other, so that the Coulomb exchange interaction of π-π electrons (inter-ligand π-π) between two ligands

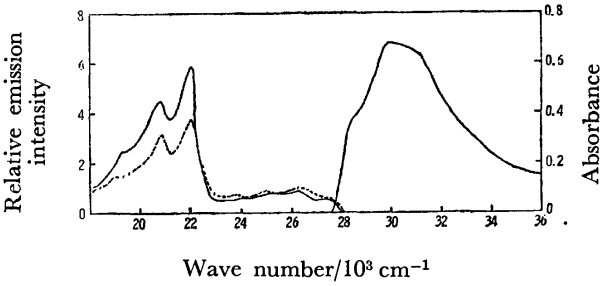

Fig. 5. Absorption and emission spectra of Be(Ba)$_2$ (solid line) and Be(Ba)$^+$ (broken line) at 77 K in methanol and water (4 : 1 by volume).

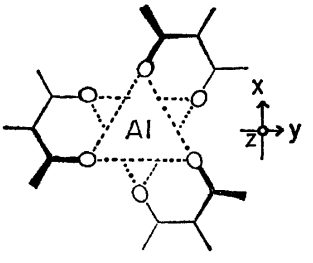

Fig. 6. Comformation of the tris-acetylacetonato complex of aluminium(III).

is impossible as the first approximation. However, weak interactions of two types cannot be ignored. One is the dipole-dipole interaction due to a weak component of the transition moment along the z-axis. The other is the interaction between non-bonding electrons localized on the oxygen atoms of one ligand and the π-electrons on the six-membered ring of the other ligand (inter-ligand n-π).

Aluminium complexes with the three same ligands have a conformation as in Fig. 6, belonging to the D_3 group. In these complexes, both Coulomb exchange interaction (inter-ligand π-π and n-π) and dipole-dipole interaction may be operative between the ligands. Especially, the circular dichroism of tris-(acetylacetonato)-silicon(IV) in the near-ultraviolet region has been understood on the basis of the dipole-dipole interaction,[15] which splitted the triply-degenerated state into two exciton-like state with A_2 and E symmetry with an allowed transition.

As for zinc complexes—$Zn(AcAc)_2 \cdot (H_2O)$[16] and $Zn(Ba)_2 \cdot C_2H_5OH$,[17] X-ray analysis has shown that two ligands of AcAc or Ba are approximately coplanar and that H_2O or C_2H_5OH is located at an apical position. It is probable that $Zn(Dbm)_2 \cdot (H_2O)_2$ has a similar structure, with two Dbm in the same plane and two H_2O at apical positions. Such a structure has also been reported in the case of Zn(8-hydroxyquinolinato)$_2(H_2O)_2$.[18] Two ligands in the same plane may interact with each other through both Coulomb-exchange (π-π and n-π) and dipole-dipole interactions; the latter produces a lower symmetric state with a forbidden transition and an antisymmetric higher one with an allowed transition.

Absorption Spectra and Emission Spectra: Each of the bis- and the tris-β-diketonato complexes has an absorption spectrum similar to that of the corresponding mono-β-diketonato complex, as is shown in Figs. 2—4. Although they are not finely resolved, some peaks and shoulders of the absorption spectra of the bis- and the tris-β-diketonato complexes can be assigned to a vibrational structure, just as those of the corresponding mono-β-diketonato complexes are (see Table 2). This assignment is supported by the fluorescence spectra in the case of the dibenzoylmethanato complexes (see Fig. 2). The fluorescence spectra of the bis-β-diketonato complexes, whose peaks and shoulders can be assigned to one kind of progression without ambiguity, have a good mirror image with the absorption spectra. After all, it is reasonable to say that there is not so strong an interaction between ligands in the bis- and tris-bidentate complexes as to produce a distinct new electronic transition.

This is contrary to the proposition which explains the absorption spectra and the circular dichroism of some tris-acetylacetonato complexes. Hanazaki *et al.*[11] have regarded the separation (1500 cm^{-1}) between the absorption maximum and the shoulder on the lower-frequency side observed at room temperature as the energy difference between the A_2 and E states for $Al(AcAc)_3$. For $Si(AcAc)_3^+$, 1500 cm^{-1} has been obtained in a similar way to that reported by Mason and Searle.[15] However, there remain some ambiguities in the assignments which are deduced without considering that the vibrational structure might appear as some sub-bands in the absorption spectra. Moreover, it must be recalled that the dipole-dipole interaction comes vibronically into play, according to Simpson,[19] when the vibrational interval (1300 cm^{-1}) is larger than the interaction energy (850 $cm^{-1} = 1/3 \times$ (the energy difference between E and A_2 states), which has been calculated by the method of P-P-P SCF-CI[11]). The splitting of the individual sub-band is calculated approximately to be one fourth of 2560 cm^{-1}, on the average, if the absorption spectrum is considered to consist of four sub-bands. Therefore, the absorption spectrum becomes more complex and broader, so that small splitting cannot be observe deasily. Moreover, if the dipole-dipole interaction in $Al(AcAc)_3$ is retained in the case of $Al(Dbm)_2^+$, which has a less broad absorption spectrum, a splitting of the individual sub-band should be observed.

In the case of α,α′-bipyridyl complexes of nickel(III) whose absorption spectra are well resolved into several sharp sub-bands, the splitting of the sharp individual sub-band may be expected to be visible since the total dipole-dipole interaction in $[Ni(\alpha,\alpha'\text{-bipyridyl})_3]^{2+}$ has been calculated to be 2680 cm^{-1}.[20] However, Bray *et al.* observed no difference between the well-resolved spectra of the mono- and the tris-α,α′-bipyridyl complexes at 77 K.[21] After all, then it is not improbable that the dipole-dipole interaction in the tris-β-diketonato complexes is smaller than the calculated values in the cases of $Al(AcAc)_3$ and $Si(AcAc)_3^+$.

However, in the relative intensities of the sub-bands of the absorption spectra, a distinct difference is observed between the bis- or the tris-bidentate complexes and the mono-bidentate complexes (Figs. 3 and 4). The intensities of the 0—0′ and 0—1′ bands are higher, and those of the 0—2′ and 0—3′ bands are a little lower, for $Al(AcAc)_3$ and $Al(Ba)_3$ than for the respective monobidentate complexes. As for the fluorescence, the intensity ratios of the vibronic bands to the 0—0′ band for the bis- and the tris-bidentate complexes in

Table 5. Relative intensities of the vibronic bands of emission normalized to the intensity of the 0′—0 or 0″—0 band

Compound	Fluorescence		Phosphorescence	
	0′—1	0′—2	0″—1	0″—2
$Be(AcAc)^+$	—		1.10	0.90
$Be(AcAc)_2$	—		1.07	0.87
$Al(AcAc)^{2+}$	—		0.92	
$Al(AcAc)_3$	—		0.88	
$Be(Ba)^+$	—		0.65	
$Be(Ba)_2$	—		0.62	
$Al(Ba)^{2+}$	1.88	1.95	0.96	
$Al(Ba)_3$	1.87	1.92	0.95	
$Be(Dbm)^+$	1.56	0.84	0.42	
$Be(Dbm)_2$	1.55	0.77	0.41	
$Al(Dbm)^{2+}$	1.30	0.72	0.74	0.68
$Al(Dbm)_2^+$	1.19	0.66	0.69	0.64
$Zn(Dbm)^+$	1.20	0.77	0.48	
$Zn(Dbm)_2$	1.15	0.65	0.42	

any case, are lower than those for the mono-bidentate complexes as is shown in Table 5; for instance, the ratio of the 0′—1 is 1.30 for $Al(Dbm)^{2+}$ while it is 1.19 for $Al(Dbm)_2^+$. A similar situation is also seen in the phosphorescence. The intensity ratios of the vibronic bands are lower for the bis- and the tris-bidentate complexes than for the mono-bidentate complexes except in the case of $Al(Ba)_3$.

These changes in the spectral pattern are reduced to the change in the Franck-Condon factors ($\langle 0|v'\rangle^2$, $\langle 0'|v\rangle^2$ and $\langle 0''|v\rangle^2$ where v and v' are zero or near to zero). The situation in which the Franck-Condon factors for the sub-bands of the bis- and the tris-bidentate complexes decrease compared to that of the mono-bidentate complexes may correspond to the reduction of the configurational deformation or displacement in the excited state with the bis- and the tris-bidentate complexes. Since a smaller deformation or displacement can be expected when a ligand-ligand interaction causes an extended excited state, the variation in the Franck-Condon factors can be understood in terms of ligand-ligand interaction. Further, it may be expected that the Franck-Condon factors of phosphorescence ($\langle 0''|v\rangle^2$, v: much higher) are smaller in the bis- and the tris-bidentate complexes. If this is the case, the phosphorescence may also be expected to have a larger yield and a longer lifetime, because smaller Franck-Condon factors with higher v-values reduce the rate of the radiationless transition for polyatomic molecules.[22]

Yields and Polarizations of Emissions: The sharing of excitation and emission by two or three ligands results in a depolarization of the emission. When the excited state of the bis-bidentate complexes of beryllium is a doubly degenerate state of E symmetry, with a transition moment of two components, the fluorescence polarization is calculated to be 0.14 (see Table 6). The polarizations measured for $Be(Ba)_2$ and $Be(Dbm)_2$ were nearly 0.14 as Table 4 shows*. Though these results do not enable us to decide what kind of inter-ligand interaction is operative, they support the idea that an interaction exists between ligands in the excited state and in the ground state. As for the tris-β-diketonato complexes belonging to the D_3 group, it can easily be seen that the transition moments of the three ligands couple to give a transition (z-polarized) with the A_2 symmetry and a transition (x- and y-polarized) with the E symmetry. Since the splitting of the two states is too small to be observed in the spectra, it is plausible that both of the states fluoresce at 77 K. In that case, the fluorescence polarization can be calculated to be 0.09 on excitation to both states. In fact, the measured polarization (0.03) of $Al(Ba)_3$ was near to the ideal value. Therefore, these results confirm the existence of the excited state extending through three ligands which has been proposed on the basis of the changes in the sub-band intensities.

* The polarization of $Be(Dbm)_2$ was different between the 0′—0 excitation and the 0—1′ or 0—2′ excitation. It is probable that ligand-ligand interaction produces such a splitting as was observed in the case of $Al(Dbm)_3^{2+}$ as has been described.

TABLE 6. IDEAL VALUES OF THE FLUORESCENCES OF BIS AND TRIS-BIDENTATE COMPLEXES[a]

Complex (symmetry group)	Absorption (moment)	Fluorescence (moment)	Polarization
Tris-bidentate (D_3)	$A_1 \rightarrow A_2$, E (x, y, z)	$A_2 \rightarrow A_1$ (z)	0.22
	$A_1 \rightarrow A_2$, E (x, y, z)	$E \rightarrow A_1$ (x, y)	−0.17
	$A_1 \rightarrow A_2$, E (x, y, z)	A_2, $E \rightarrow A_1$ (x, y, z)	0.09
Bis-bidentate (D_{2d})	$E \rightarrow E$ (x, y)	$E \rightarrow E$ (x, y)	0.14

a) The ideal values are calculated on the following conditions in the case of tris-β-diketonato complexes: (i) the ratio of the transition probability of $A_2 \leftrightarrow A_1$ to that of $E \leftrightarrow A_1$ is two, and (ii) the internal conversion rate between A_2 and E is very rapid.

No difference in fluorescence polarization between the mono- and bis-β-diketonato form was observed for zinc complexes. However, this does not imply that no delocalization of the excited state occurs through the two ligands of zinc complexes, because the two ligands have parallel transition moments.

As for the phosphorescence, the bis- and tris-β-diketonato complexes have longer lifetimes than the corresponding mono-β-diketonato complexes except for zinc complexes, as Table 3 shows. These changes may be caused by a decrease in the radiationless transition rate, because the rate is reduced with the decrease in Franck-Condon factors for higher v'-values which was expected from the change in the vibronic band intensities of the phosphorescences mentioned above.

There was a distinct change in the emission yields from the mono-β-diketonato complexes to the bis- and tris-β-diketonato ones (see Table 3). The fluorescence yields of the latter decreased, while the phosphorescence yields increased. The increase in the phosphorescence yields seems to arise from the same origin (a decrease in the radiationless transition rate of the triplet state) as the longer lifetime. However, because the increase in the yield was much larger than that in the lifetime, it may be assumed that it is mainly due to the increase in the intersystem crossing rate of the singlet-excited state and partially due to a decrease in the radiationless transition rate of the triplet state. This assumption is supported by the fact that the fluorescence yields decrease in the case of the bis- and tris-β-diketonato complexes. It is reasonable that the increase in the intersystem crossing rate is brought about by the spin-orbit coupling through the inter-ligand interaction as well as by inter-phenyl interaction in diphenylmethane and triphenylmethane.[5]

Studies of the Chemiluminescence of Several Xanthene Dyes. VI. A Kinetic Analysis of a Blue-fluorescent Product in the Chemiluminescent Reaction of Eosin Y with Hydrogen Peroxide

Isao KAMIYA and Keizo AOKI

Department of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received November 29, 1973)

In the present study, we found that the absorbance at 395 nm of the chemiluminescent reaction system of eosin Y with hydrogen peroxide initially increased to a maximum, and then gradually decreased. From the finding that the absorption spectrum of a chromatographically-isolated blue-fluorescent product (M_E) showed a peak at the same wavelength (395 nm), we could confirm that the increment of the absorbance at 395 nm (Δ_{395}) was mainly due to the generation of M_E; we then extended the investigation of the mechanism for the chemiluminescent reaction by a kinetic analysis of M_E. The observed value of Δ_{395} could be approximately calculated by the expression of $[M_E]$, which was derived from a kinetic scheme proposed in the previous paper.[1] The ratio of the generation rates of M_E in different media, which was calculated from the observed values of Δ_{395}, was in good agreement with that estimated from the curves of the chemiluminescence emission intensity *versus* the time measured in the media. These results gave additional evidence in support of the view that the blue-fluorescent species is the primary excited product in the reaction.

In the previous paper,[1] Kamiya and Kato showed that the chemiluminescence emission (CL-emission) in the reaction of such a xanthene dye as eosin Y with hydrogen peroxide in an alkaline solution was composed of two emission components: a greenish-yellow emission whose spectral distribution was similar to that of the fluorescence emission (FL-emission) of the dye, and a blue emission similar to the fluorescence band which appeared during the course of the reaction. The observed characteristics of the emission components indicated that the generation of an excited species which fluoresces blue light, and an energy-transfer process from the exicted product to an unoxidized dye were likely to be part of the mechanism for the chemiluminescent reaction.

In the present study, we found that the absorbance at 395 nm of the reaction system initially increased to a maximum, and then gradually decreased. From the finding that the absorption spectrum of a chromatographically-isolated blue-fluorescent product showed a peak at the same wavelength (395 nm), we could confirm that the increment of the absorbance at 395 nm (Δ_{395}) was mainly due to the generation of the blue-fluorescent product (M_E); we then extended the investigation of the mechanism for the chemiluminescent reaction by a kinetic analysis of M_E. The details of the experimental results and a discussion based on the results will be presented in this paper.

Experimental

The luminescent reaction was performed by adding 0.5 ml of a 20% aqueous solution of hydrogen peroxide to a mixture of 1 ml of a 0.3 M aqueous solution of sodium hydroxide and 3 ml of a 1.3×10^{-3} M eosin Y solution in 50% dimethylsulfoxide, in 50% ethanol, or in water, in a quartz cell ($10\times10\times45$ mm) at 40 °C.

The FL-emission spectra were measured on a Hitachi MPF-2A-type recording fluorescence spectrophotometer. With the exciting source turned off, the intensities of the CL-emission were measured on the same apparatus equipped with a thermostatic cell assembly. The absorption spectrum and the changes in the absorbances at 395 nm and 517 nm with the reaction time were measured on a Hitachi 124-type recording spectrophotometer. The temperature of the reaction system was maintained at 40 °C in a Komatsu SPR-D Coolnics cell holder.

The separation of the blue-fluorescent product from the reaction mixture could be performed by thin-layer chromatography (Silica Gel G on a glass plate; chloroform–acetic acid, 1 : 1, or acetone–benzene–acetic acid, 2 : 7 : 1, for development), as well as by paper chromatography (Toyo Filter Paper No. 50; 25% aqueous ethanol solution–5% aqueous ammonia solution, 1 : 1, for development). A part of the blue-fluorescent spot on the plate was scraped off, and the blue-fluorescent product was extracted with ethanol.

The spent reaction mixture was neutralized with dilute hydrochloric acid and evaporated to dryness; then the main product of the reaction was extracted with ethanol. The identification of the main product with an authentic sample of phthalic acid was performed on a Yanagimoto GCG-550-type gas chromatograph, in which nitrogen gas was used as carrier gas, and on a Hitachi EPI-G-type infrared spectrophotometer (KBr-disk method).

Results and Discussion

Figure 1 shows the change in the absorption spectrum of the chemiluminescent reaction system of eosin Y with hydrogen peroxide (50% dimethyl sulfoxide system) in the region of 330—470 nm.[2] This figure indicates that the absorbance at 395 nm initially increases to a maximum, and then gradually decreases. Figure 2 illustrates the curves of the absorbance at 395 nm *versus* the reaction time (Δ_{395}–t curves) for the reaction in three media: a 50% aqueous solution of dimethyl sulfoxide (50% DMSO), a 50% aqueous ethanol solution (50% EtOH), and water (H_2O). The results clearly demonstrate that the Δ_{395}–t curves are strongly characterized by the media; that is, Δ_{395} is remarkable in 50% DMSO, prolonged but not so remarkable in 50% EtOH, and slight in H_2O. It was found that the absorption spectrum of an ethanol solution of the isolated blue-fluorescent product showed a peak at 395 nm, as is illustrated in Fig. 3. This result strongly suggests that the change in the absorbance at

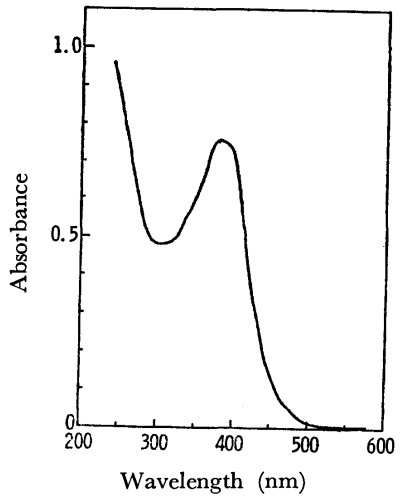

Fig. 3. Absorption spectrum of a ethanol solution of isolated blue-fluorescent product.

395 nm is mainly due to the generation of the blue-fluorescent product.

The overall reaction in the chemiluminescent system seems to be complicated, since several spots of minor unknown reaction products other than the main product (phthalic acid) and the blue-fluorescent product were separated by chromatography. However, without regard to the details, it has been found that the experimental results in the previous studies are consistent with the following kinetic scheme.[1,3]

Radical generation from the decomposition of hydrogen peroxide in an alkaline solution:

$$H_2O_2 \longrightarrow R^{\cdot}\ (O_2H^{\cdot} \text{ or } OH^{\cdot})$$

The generation of an excited (blue-fluorescent) species (M_E) by the decomposition of a short-lived energy-rich intermediate (M) which will be produced by the reaction of eosin Y (E) with R·:

$$E + R^{\cdot} \longrightarrow M \longrightarrow M_E^* \quad \text{(reaction rate } k_1') \quad \text{(i)}$$

An energy-transfer process:

$$M_E^* + E \longrightarrow M_E + E^* \quad (k_2) \quad \text{(ii)}$$

Blue FL-emission from M_E^*:

$$M_E^* \longrightarrow M_E + h\nu_1 \quad (k_3) \quad \text{(iii)}$$

Greenish-yellow FL-emission from E*:

$$E^* \longrightarrow E + h\nu_2 \quad (k_4) \quad \text{(iv)}$$

Radiationless deactivation of E*:

$$E^* \longrightarrow E + \text{heat} \quad (k_4') \quad \text{(iv')}$$

Self-quenching:

$$E^* + E \longrightarrow E + E \quad (k_5) \quad \text{(v)}$$

Since the Δ_{395}–t curve decreased in the course of the reaction,[4] the decomposition step of M_E may be taken into account:

$$M_E + R^{\cdot} \longrightarrow Q \quad (k_6) \quad \text{(vi)}$$

The quantity of blue-fluorescent species (M_E) produced must be small because of the low quantum yield of this chemiluminescent reaction.[5] Product Q, therefore, seems not to be the main reaction product (phthalic acid, P), since the yield of P (based on eosin Y consumed) was about 40%; therefore a further generation step of P which competes with reaction (i) must be present:

$$E + R^{\cdot} \rightarrow\rightarrow P \quad (k_7') \quad \text{(vii)}$$

According to the reaction scheme, the intensity of the greenish-yellow CL-emission ($h\nu_2$, I_E) is given by:

$$I_E = k_1'[R^{\cdot}]k_2k_4[E]^2/(k_2[E]+k_3)(k_4+k_4'+k_5[E]) \quad (1)$$

where [E] is the concentration of E at time t.

Since the intensity of blue CL-emission ($h\nu_1$), which is given by $k_1'[R^{\cdot}][E]k_3/(k_2[E]+k_3)$, and the fluorescence efficiency of eosin Y did not vary much with the change in [E] in the systems, assuming that $k_2[E] \gg k_3$ and $k_4+k_4' \gg k_5[E]$, and further assuming that the reactions of (i) and (vii) obey the pseudo-first order reaction in view of the previous result, that [R·] did not vary during the reaction provided [H_2O_2] was high (excess), we can write:

$$I_E = \{k_1k_4/(k_4+k_4')\}[E]_0 \exp\{-(k_1+k_7)t\} \quad (2)$$

where $k_1=k_1'[R^{\cdot}]$, $k_7=k_7'[R^{\cdot}]$, and where $[E]_0$ is the initial concentration of E.

The straight lines for the plots of log I_E(the lograithm of the CL-emission peak at 560 nm) *versus* the reaction time shown in Fig. 4 indicate that Eq. (2) is acceptable, and from the lines the values of k_1+k_7 in

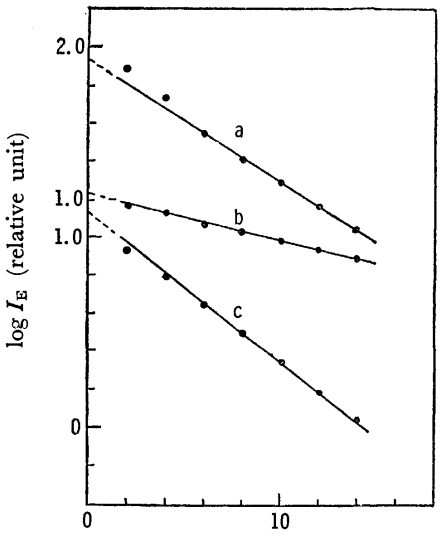

Fig. 4. Log plots of the relative intensities of emission peak (I_E) at 560 nm *versus* reaction time for the chemiluminescent reaction of eosin Y in 50% DMSO (a), 50% EtOH (b), and H_2O (c) at 40 °C.

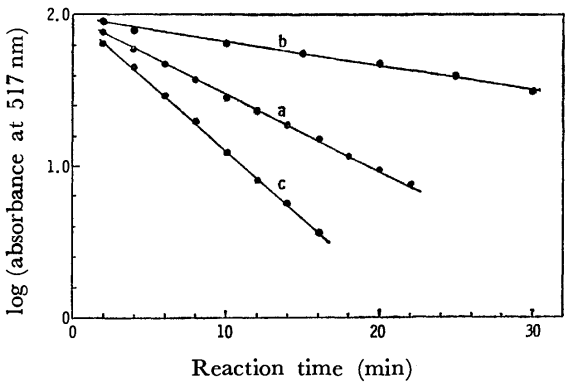

Fig. 5. Log plots of the absorbance at 517 nm of eosin Y (decomposed during the course of the chemiluminescent reaction) *versus* reaction time in 50% DMSO (a), 50% EtOH (b), and H_2O (c) at 40 °C.

50% DMSO, 50% EtOH, and H_2O are estimated to be 0.14, 0.05, and 0.19 min^{-1} respectively under the experimental conditions employed in the study. The same values of k_1+k_7 could be found from the lines for the log plots of the absorbance at 517 nm (the absorption peak of eosin Y) *versus* the reaction time (see Fig. 5).

The decomposition path of E being summarized by the following competitive and consecutive reaction diagram:

$$E + R^{\cdot} \begin{cases} \xrightarrow{k_1'} M_E^* \xrightarrow{\text{(fast)}} M_E \xrightarrow{k_6'} Q \\ \xrightarrow{k_7'} P \end{cases}$$

the concentration of the blue-fluorescent product ($[M_E]$) at time t can be given by:

$$[M_E] = \{k_1[E]_0/(k_1+k_7-k_6)\}[\exp(-k_6t) - \exp\{-(k_1+k_7)t\}] \quad (3)$$

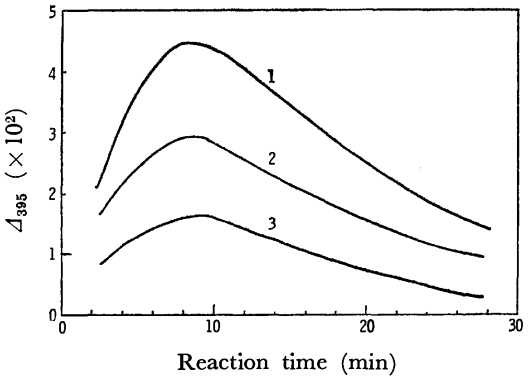

Fig. 6. Δ_{395}-t curves measured in 50% DMSO systems of different initial concentrations of eosin Y. 1: 8.7×10^{-4} M, 2: 5.8×10^{-4} M., 3: 4.3×10^{-4} M (40 °C).

where $k_6'[R\cdot]$ is put to k_6 by assuming that Reaction (vi) also obeys the pseudo-first order reaction.

Figure 6 shows Δ_{395}-t curves measured in 50% DMSO systems of different initial concentrations of eosin Y($[E]_0$). The results indicate that the value of Δ_{395} is strongly proportional to $[E]_0$, and so is proportional to $[M_E]$, if Eq. (3) is acceptable. From this argument, and recalling the results shown in Fig. 3, even though Δ_{395} may be changed a little by the decomposition of eosin Y and the generation of other minor, unknown reaction products, it seems reasonable to assume that:

$$\Delta_{395} \fallingdotseq \varepsilon_{395}[M_E] \quad (4)$$

where ε_{395} is the molar extinction coefficient of M_E at 395 nm. From Eq. (4), we can write:

$$\Delta_{395} = \{k_1\varepsilon_{395}[E]_0/(k_1+k_7-k_6)\}[\exp(-k_6t) - \exp\{-(k_1+k_7)t\}] \quad (5)$$

From Eqs. (3) and (4), putting t_m as the time required the reach to maximum of Δ_{395}, we can derive the following equation:

$$k_6\exp(-k_6t_m) = (k_1+k_7)\exp\{-(k_1+k_7)t_m\} \quad (6)$$

since $d[\Delta_{395}]/dt=0$; therefore $d[M_E]/dt=0$ at $t=t_m$. From the curves shown in Fig. 2, t_m being found to be 8, 12, and 2 min in 50% DMSO, 50% EtOH, and H_2O respectively, we can calculate the values of k_6 to be 0.10, 0.13, and 1.1 min^{-1} in 50% DMSO, 50% EtOH, and H_2O respectively, using the values of k_1+k_7 and t_m. From Eq. (6), the maximum value of $[M_E]$ at t_m ($[M_E]_m$) is given by:

$$[M_E]_m = (k_1/k_6)[E]_0\exp\{-(k_1+k_7)t_m\}$$

So that the maximum value of $\Delta_{395}(\Delta_m)$ is given by:

$$\Delta_m = \varepsilon_{395}(k_1/k_6)[E]_0\exp\{-(k_1+k_7)t_m\} \quad (7)$$

From Eqs. (5) and (7), we can finally write:

$$\Delta_{395} = \Delta_m[k_6/(k_1+k_7-k_6)\exp\{-(k_1+k_7)t_m] \times[\exp(-k_6t) - \exp\{-(k_1+k_7)t\}] \quad (8)$$

From the curves shown in Fig. 2, Δ_m being found to be 45×10^{-2}, 11×10^{-2}, and 4×10^{-2} in 50% DMSO, 50% EtOH, and H_2O respectively, the Δ_{395} values in these media can be calculated by the following numerical equations:

In 50% DMSO;

$$\Delta_{395} = \{0.10\times45\times10^{-2}/(0.14-0.10)\exp(-0.14\times8)\} \times\{\exp(-0.10t)-\exp(-0.14t)\}$$
$$= 3.45\{\exp(-0.10t)-\exp(-0.14t)\} \quad (9)$$

In 50% EtOH:

$$\Delta_{395} = \{0.13\times11\times10^{-2}/(0.05-0.13)\exp(-0.05\times12)\} \times\{\exp(-0.13t)-\exp(-0.05t)\}$$
$$= -0.325\{\exp(-0.13t)-\exp(-0.05t)\} \quad (10)$$

In H_2O:

$$\Delta_{395} = \{1.1\times4\times10^{-2}/(0.19-1.1)\exp(-0.19\times2)\} \times\{\exp(-1.1t)-\exp(-0.19t)\}$$
$$= -0.07\exp\{(-1.1t)-\exp(-0.19t)\} \quad (11)$$

In Table 1, the value of Δ_{395} in 50% DMSO, and 50% EtOH calculated using Eqs. (9) and (10) are tabulated, together with the observed values in the media. It can be seen from the table that the calculated Δ_{395} values are in fairly good agreement with the observed Δ_{395} values. The observed values of Δ_{395} in H_2O were, however, too small to make such a comparison.

Assuming that the value of ε_{395} does not appreciably vary in these media, we can calculate the ratio of k_1 (the generation rate of M_E) in the media from Eq. (7):

$$k_1(\text{DMSO}) : k_1(\text{EtOH}) : k_1(H_2O) = 0.10\times45\times10^{-2}/\exp(-0.14\times8) : 0.13\times11\times10^{-2}/\exp(-0.05\times12)$$
$$: 1.1\times4\times10^{-2}/\exp(-0.19\times2) = 5.3 : 1 : 2.47 \quad (12)$$

Table 1. Observed and calculated values of Δ_{395} in 50% DMSO and 50% EtOH

Reaction time (min)	50% DMSO		50% EtOH	
	Δ_{395} (obsd)	Δ_{395} (calcd)	Δ_{395} (obsd)	Δ_{395} (calcd)
2	10×10^{-2}	22.4×10^{-2}		
4	31	34.1		
5			8×10^{-2}	9×10^{-2}
6	41	40.3		
8	45	42.4		
10	44	41.7	10.5	10.8
12	41	39.7	11	11.2
14	37	36.6		
16	34	33.1		
18	30	29.3		
20	26	25.5	9	9.7
22	24	22.4		
24	21	19.3		
26	18	16.5		
28	16	14.1		
30	14	12.0	6	6.7
40			3.5	4.1
50			2	2.6

On the other hand, as Eq. (2) indicates that:

$$I_{E_0} = \{k_1k_4/(k_4+k_4')\}[E]_0$$

at $t=0$, the relative values of I_{E_0} in 50% DMSO, 50% EtOH, and H_2O can be estimated to be 87, 17, and 14 respectively by the extrapolation of the log plot of I_E (shown as relative intensities in Fig. 4) to zero-time. The ratio of the apparent efficiencies of the FL-emission ($k_4/(k_4+k_4')$) in the media was found to be 75 : 73 : 25, so we can also calculate the ratio of k_1 as follows:

$$k_1(\text{DMSO}) : k_1(\text{EtOH}) : k_1(H_2O) = 87/75 : 17/73 : 14/25 = 5.0 : 1 : 2.43 \quad (13)$$

The ratio in Eq. (13) is in good agreement with that in Eq. (12).

All of the results provide additional support for the view that the blue-fluorescent species is the primary excited product.

Unfortunately, the quantity of the isolated blue-fluorescent product was too small for it to be weighed or identified. 3,5-Dibromo-2,4-dihydroxybenzoate-2, which was produced when eosin Y was hydrolized in a 50% aqueous solution of sodium hydroxide for five hours at 140 °C,[6] showed no fluorescence at 480 nm. The fluorescence spectrum of 3,6-dihydroxyxanthone, which has been identified as the emitting species in the chemiluminescent reaction of succinylfluorescein, showed a peak at 410 nm.[7] The question as to the identification of the blue-fluorescent product, therefore, remains unanswered.

This work was supported in part by a Scientific Research Grant of the Ministry of Education.

The Electronic Spectra of Diphenylacetylene and 1,3-Butadiyne

Tetsuko TAKABE, Masashi TANAKA, and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received February 4, 1974)

The electronic absorption spectra of 2,4-hexadiyne-1,6-diol, diphenylacetylene, and diphenyldiacetylene were measured in a single crystalline state with a polarized light. The results of the polarization measurement and the theoretical calculations gave confirmative assignments of the electronic transitions of these molecules.

The electronic structures and electronic spectra of acetylene and poly-acetylenes have previously been investigated and have attracted considerable attention because of the simple molecular structures and the diveristy of electronic energy levels. Earlier extensive investigations of acetylene by Ingold *et al.*[1] and Innes[2] have revealed that the shape of the molecule in the excited state is not linear. The assignments of the electronic transitions of acetylene and poly-acetylenes have been discussed by many people.[3-9] The electronic spectra of diacetylene were studied by Woo and Chu[7] and by Price and Walsh,[8] and the bending of the excited state was suggested. Beer[9] investigated poly-acetylenes and classified the excited levels on the basis of the intensities of the electronic bands and the phosphorescence spectra. The polarization of band was measured on the crystal of dimethyldiacetylene, but the details of the analysis have not appeared. In this paper the polarization measurements in the near UV region of the derivatives of diacetylene, 2,4-hexadiyne-1,6-diol, diphenylacetylene and diphenyldiacetylene will be reported. The theoretical calculations of the energy levels of diacetylene and diphenylacetylene will also be presented in order to explain the observed spectra.

Experimental

2,4-Hexadiyne-1,6-diol was synthesized from propargyl alcohol.[10] The crystal for spectral measurements was obtained from a chloroform solution, and it was developed on the ac plane. The crystalline data will be reported in the Appendix. The projection of the molecules on the ac plane is shown in Fig. 1. The diphenylacetylene was obtained from the Tokyo Kasei Co. and was purified by recrystallization from methanol. The thin crystals for spectral measurement were obtained by sublimation; they were developed on the ab plane. The crystal structure was analyzed by Robertson and Woodward.[11] The diphenyldiacetylene was synthesized from phenylacetylene and was recrystallized from acetic acid. The crystal structure was analyzed by Wiebenga.[13] The crystalline absorption measurements were done with a microspectrophotometer.

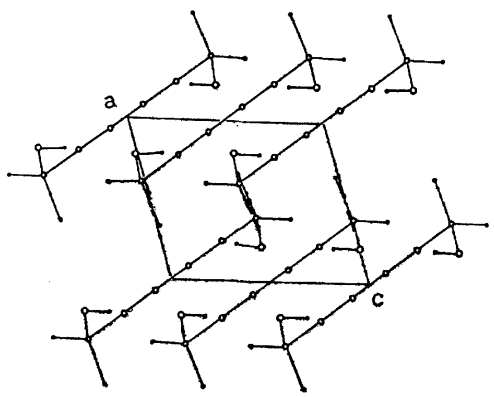

Fig. 1. Projection of 2,4-hexadiyne-1,6-diol crystal onto the ac plane.

Theoretical Calculations

The electronic energy levels of the diacetylene group and diphenylacetylene were calculated by a modification of the Pariser-Parr-Pople method, in which all the π and $\bar{\pi}$ electrons in the triple bonds are considered. The orthogonal MO sets, composed of $2p\pi$ and $2p\bar{\pi}$ atomic orbitals of carbon atoms, are calculated by the SCF method. The Hartree-Fock matrix elements are given as;

$$\begin{aligned}(\pi_\mu|\mathbf{F}|\pi_\mu) &= W_\mu + (\pi_\mu\pi_\mu|\pi_\mu\pi_\mu) - \sum_{\nu}^{m}(\pi_\nu\pi_\nu|\pi_\mu\pi_\mu) \\ &\quad - \sum_{\eta}^{n}(\bar{\pi}_\eta\bar{\pi}_\eta|\pi_\mu\pi_\mu) \\ &\quad + \sum_{\nu}^{m}\sum_{j}^{m}\{2C^*_{j\nu}C_{j\nu}(\pi_\nu\pi_\nu|\pi_\mu\pi_\mu) - C^*_{j\mu}C_{j\mu}(\pi_\mu\pi_\nu|\pi_\mu\pi_\nu)\} \\ &\quad + \sum_{\eta}^{n}\sum_{j}^{m}\{2C^*_{j\eta}C_{j\eta}(\bar{\pi}_\eta\bar{\pi}_\eta|\pi_\mu\pi_\mu) - C^*_{j\mu}C_{j\mu}(\bar{\pi}_\eta\pi_\mu|\bar{\pi}_\eta\pi_\mu)\} \\ (\pi_\mu|\mathbf{F}|\pi_\nu) &= \beta_{\mu\nu} - \sum_{j}^{m}C^*_{j\mu}C_{j\nu}(\pi_\mu\pi_\mu|\pi_\nu\pi_\nu) \\ (\pi_\mu|\mathbf{F}|\bar{\pi}_\eta) &= 0 \end{aligned} \quad (1)$$

where the subscript j denotes the filled MO, which varies from 1 to m, and where μ, ν, and η designate carbon atoms with orthogonal $2p\pi$ orbitals, π and $\bar{\pi}$. The one-electron Coulomb integrals are taken as:

$$(\pi_\mu\pi_\mu|\pi_\mu\pi_\mu) = (\bar{\pi}_\mu\bar{\pi}_\mu|\bar{\pi}_\mu\bar{\pi}_\mu) = 10.53 \text{ eV}$$

and

$$(\pi_\mu\pi_\mu|\bar{\pi}_\mu\bar{\pi}_\mu) = (\pi_\mu\pi_\mu|\pi_\mu\pi_\mu) - 1/2(\pi_\mu\bar{\pi}_\mu|\pi_\mu\bar{\pi}_\mu)$$

where

$$(\pi_\mu\bar{\pi}_\mu|\pi_\mu\bar{\pi}_\mu) = 0.91 \text{ eV}.$$

The valence-state ionization potential, W_p, is taken as -11.24 eV for the sp hybridized state and as -11.22 eV for the sp^2 hybridized state. The resonance integrals, β, were taken only for nearest neighbors; they were calculated by

$$\beta = -2.38\exp(2.375 - 1.7r) \text{ eV}.$$

All the calculations were based on the structure data determined by the X-ray crystal analysis. The configurational interaction of one-electron excited states were calculated with the SCF MO. The calculation for diphenylacetylene was performed similarly. The

Results and Discussion

2,4-Hexadiyne-1,6-diol. The electronic absorption spectra in an ethanol solution are shown in Fig. 2. Two different series of absorption bands have been observed, one with a very weak intensity in the 30000—37000 cm^{-1} region and another with a medium intensity in the 37000—48000 cm^{-1} region. Both series are accompanied by vibrational progressions of 2200—2300 cm^{-1}, which can reasonably be correlated with the total symmetric vibration of the triple bonds. Because the intensities of these bands are rather weak, both series may be regarded as having a forbidden character.

The crystalline absorption spectra on the ac plane are presented in Fig. 3. Although the 0-0 band origin was not confirmed for this spectra, nevertheless the spectral pattern was clearly resolved, showing some vibrational progressions. The weakest and lowest transition starts at 30400 cm^{-1} and extends to 37000 cm^{-1}. The two band maxima at 33900 and 36100 cm^{-1} are separated by 2200 cm^{-1}, which is regarded as the total

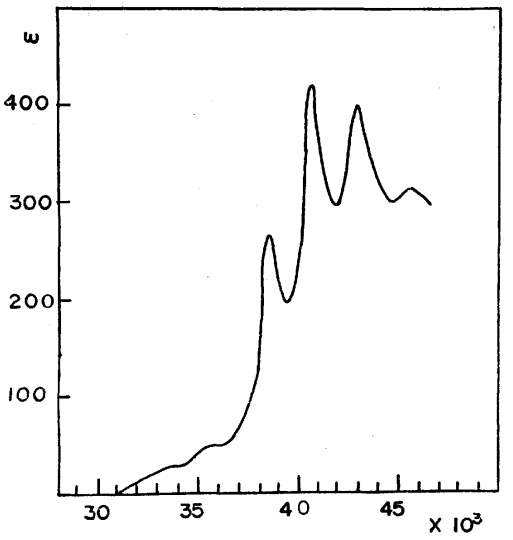

Fig. 2. Electronic absorption spectrum of 2,4-hexadiyne-1,6-diol in ethanol solution measured with Carl Zeiss spectrophotometer PMQ-II.

symmetric stretching vibration of the carbon-carbon triple bond. Taking the 0-0 band origin of the series as at 30400 cm^{-1}, one may suppose the presence of a coupled asymmetric mode which makes the forbidden transition active. For instance, the first vibronic allowed level may be assumed at 31700 cm^{-1}; therefore, a coupled frequency must be about 1300 cm^{-1} at its maximum.

The second, stronger series starts at 38500 cm^{-1}, followed by the vibrational progressions given by $38500+2200n$ cm^{-1} ($n=1,2,\cdots$). The dichroic intensity ratios for these two band series are estimated by taking the intensity ratio from the areas of these observed bands; they are tabulated in Table 1. The calculated value (1.63) is obtained from the crystal structure data by assuming that the electronic transitions are polarized parallel to the long axis of the molecule. With the second stronger transition, the observed value (1.5) is in good agreement with the predicted value of the long-axis polarization. For the first band, the polarization seems to be along the short-axis, because the observed intensity ratio (1.1) deviates from the value of the long-axis. As regards the transition polarized perpendicular to the long-axis, the direction could not be determined in $D_{\infty h}$ symmetry, but the dissimilar polarization ratio may be considered as proof of a different polarization character.

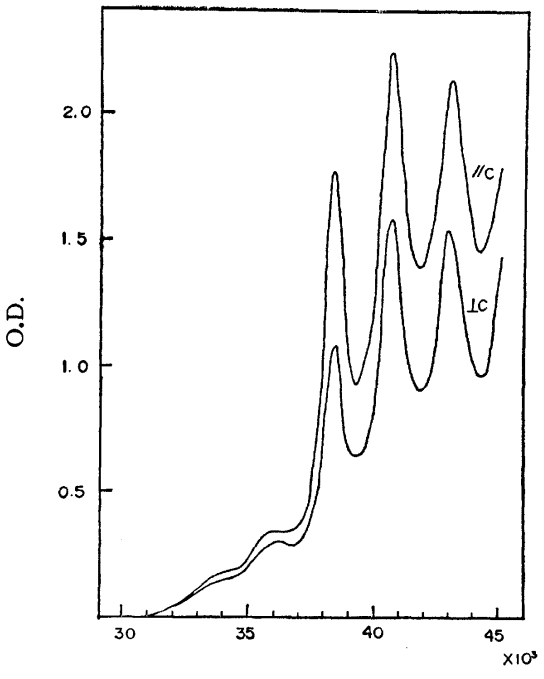

Fig. 3. Crystalline absorption spectra of 2,4-hexadiyne-1,6-diol for ac plane with the light polarized parallel and perpendicular to the c-axis.

Following the results of the theoretical calculations, the first forbidden band is assigned to the $^1A_{1u}$ state; it is shown that the transition is a $\pi \rightarrow \bar{\pi}^*$ type and is strictly forbidden. In the symmetry of the $D_{\infty h}$ of the linear system, the band is not active and it should appear when the excited state is deformed to the *trans*-form and/or when the molecule is coupled with the e_{1g}-type vibration. The vibronic analysis suggests that the observed vibronic excited state may be bent by a coupling with an asymmetric vibrational mode.

The second band is assigned to the transition to the $^1E_{2u}$ state, which is also forbidden but which has a mixed character of $\pi \rightarrow \pi^*$ and $\pi \rightarrow \bar{\pi}^*$-type transitions. The calculated energy values are in good agreement with the observed value. The $^1E_{2u}$ state of the linear system is changed to the ^1B_u state in the *trans*-form and to the $^1B_1$ state in the *cis*-form. The transition to these states will be allowed along the direction of the triple bond.[3-9] The presence of two band systems in the near UV region is in good agreement with the results of Woo and Chu,[7] who found a very weak system at 33700—37730 cm^{-1} and a diffuse and stronger band in the 38460 cm^{-1} region.

The results of polarization measurements on the crystalline spectra are in good agreement with the theoretical predictions of the transition directions. Thus, the assignments have been established for the first and second bands.

Diphenylacetylene. The UV spectrum in the ethanol solution is shown in Fig. 2. The first absorption band, starting at 33800 cm^{-1}, shows vibrational progressions of 2000 cm^{-1} and 950 cm^{-1}. The former is regarded as a totally symmetric vibration of the

carbon-carbon triple bond, while the latter may be a vibration of the benzene ring. The results of the calculation show that the first band is the long-axis-polarized allowed transition. The crystalline absorption spectra are shown in Fig. 5. While the projection of molecules onto the developed ab plane is illustrated in Fig. 6. The intensity ratio observed on the crystalline spectra can reasonably be explained by the oriented gas model, and the first absorption band has been shown to be polarized parallel to the long-axis. These results support the earlier investigation by Mikailenko *et al.*[12] of the polarization study of the fluorescence.

Diphenyldiacetylene: The UV spectrum in the ethanol solution is shown in Fig. 7. The observed bands are very broad, and they seem to be composed of two or three band series starting at 30700 cm^{-1} and at 38500 cm^{-1}. The crystalline spectra are recorded with the ab plane, as is shown in Fig. 8. Following the crystalline structure data of Wiebenga,[13] the projection of molecules onto the ab plane is shown in Fig. 9. It will be easily found that the long-axis of the molecule is slightly more inclined to the a-axis than to the b-axis, and that the intensity ratio by the oriented gas model is $I_a/I_b=$ 1.4 : 1, while the observed value is 1.25 : 1 for both the first and second bands. Those results show that the polarization of the first and second bands are both along the long-axis.

Appendix

Crystalline Data of 2,4-Hexadiyne-1,6-diol. After the completion of our crystalline structure analysis, we found that an independent research has already been published.[14] However, the atomic coordinates were not given, and so we briefly describe our own results.

Crystal Data. From Weissenberg photographs and single-crystal diffractometry on a Hilger-Watt Four-circle diffractometer with Cu$K\alpha$, $\lambda=1.5418$ Å, $a=4.083(1)$, $b=16.000(1)$, $c=4.764(1)$ Å, $\beta=106.3°$, $Z=2$. $d_{obsd}=1.14$ g/cm³, and $d_{calcd}=1.19$ g/cm³. Space group $P2_1/c$. When the intensity data were collected on the diffractometer, 360 independent reflections were obtained. The data were corrected by the Lorentz and polarization factors. The absorption correction was not applied since the crystal size was so small as $0.1\times0.5\times$ 1 mm. The center of the molecule is coincident with the origin of the crystal for symmetry reasons. The molecule is linear, and the direction of the molecular axis can easily be found in the Patterson map. The refinement of the structure was performed by the block-diagonal least-squares method and by Fourier synthesis. A program of the UNICS written by Dr. Ashida was employed. The calculation was performed on the Hitac 5020 at Computer Centre, the University of Tokyo. The final R-index including hydrogen atoms was 0.107.

The Electronic Spectra of Paracyclophadiynes

Tetsuko TAKABE, Masashi TANAKA, and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 19, 1974)

The electronic absorption spectra of [3,3]-paracyclophadiyne and [4,4]-paracyclophadiyne have been investigated in solution and in the crystalline state. A *trans*-annular interaction between the diacetylene group and the benzene ring has been found, and a theoretical study has been made to confirm the assignment. The bathochromic shift and the CT band from the benzene ring to the diacetylene group are particularly noticeable for [3,3]-paracyclophadiyne, where the inter-group distance is significantly shorter than the normal van der Waals distance.

The *trans*-annular interaction between the different groups in composite molecules is a problem of great interest, because the mechanism of the electronic interaction between contact groups at close distances is not yet fully elucidated. A well-known case is that of [2,2]-paracyclophane, where a bathochromic shift of the UV absorption is observed. The CT bands of the complexes between TCNE and cyclophanes are also red-shifted by the *trans*-annular layer interaction.[1] The electronic structure and spectrum of [2,2]-paracyclophane were investigated by Vala *et al.*[2] and by Iwata *et al.*[3] and a significant change in spectrum from that of benzene was interpreted in terms of the presence of the CT transition between the benzene rings.

Recently a series of paracyclophadiynes were synthesized by Misumi and his collaborators;[4] a crystallographic study was carried out on one of these compounds in this laboratory. Each of the molecules consists of a diacetylene group and a benzene ring (Fig. 1), and the CT effect can be expected between the two groups. In this paper the electronic absorption spectra of 4,6-[10]-paracyclophadiyne ([3,3]-paracyclophadiyne) and 5,7-[12]-paracyclophadiyne ([4,4]-paracyclophadiyne) will be investigated in order to ascertain the *trans*-annular effect on the UV spectra. The inter-group CT transition is observed in [3,3]-paracyclophadiyne, while it is not found in [4,4]-paracyclophadiyne. A theoretical calculation for interpreting these spectra will be presented, and the assignment of the spectra will be presented in detail.

Experimental

The samples of [3,3]-paracyclophadiyne and [4,4]-paracyclophadiyne were gifts from Professor Misumi of Osaka University. The absorption spectra in solution were measured by means of a Carl Zeiss spectrophotometer, PMQ II. The crystalline absorption spectra of [3,3]-paracyclophadiyne were measured by means of thin crystals obtained by sublimation. A microspectrophotometer, composed of a Carl Zeiss monochromator and an Olympus microscope, was used for the crystalline spectral measurements. The crystal structure of [3,3]-paracyclophadiyne will be described in a separate paper. The crystalline data are as follows: monoclinic; space group $P2_1/a$; $a=14.509$; $b=8.539$, $c=10.623$ Å, and $\beta=112.37°$.[5] The crystal develops the ab plane by sublimation. The thin crystal of [4,4]-paracyclophadiyne were obtained from an acetone-water solution and were used for spectral measurements. The crystalline data were obtained by oscillation and Weissenberg photographs; $a=8.441\pm0.03$, $b=13.14\pm0.03$, $c=12.73\pm0.03$ Å, $\alpha=90.4\pm0.3°$, $\beta=90.4\pm0.3°$, and $\gamma=92.8\pm0.3°$. The crystal develops the ac plane.

Theoretical Calculations

The electronic energy levels of [3,3]-paracyclophadiyne are calculated by the molecular orbital method. The orthogonalized SCF MO for the diacetylene group, ϕ_{aj}, and the benzene ring, ϕ_{bi}, are calculated, and the ground configuration of the molecule is given as;

$$\Phi_0 = |\phi_{a1}(1)\cdots\bar{\phi}_{an}(2n)\phi_{b1}(2n+1)\cdots\bar{\phi}_{bm}(2n+2m)| \quad (1)$$

The excited configurations of each group will be denoted as $\Phi_{ai\to aj}$ and $\Phi_{bi\to bj}$. The singlet configuration of the charge transfer from the benzene ring to the diacetylene group may be described as;

$$\Phi_{bi\to aj} = \frac{1}{\sqrt{2}}\{|\cdots\phi_{bi}(2n+2i-1)\bar{\phi}_{aj}(2n+2i)\cdots| \pm|\cdots\phi_{aj}(2n+2i-1)\bar{\phi}_{bi}(2n+2i)\cdots|\} \quad (2)$$

The configurational energies and the matrix elements are calculated by using the Hamiltonian including the inter-group interaction:

$$\mathscr{H} = \sum_i\left\{-\frac{\hbar^2}{2\mu}\nabla_i^2 + V(\mathbf{r}_{ai}) + V(\mathbf{r}_{bi})\right\} + 1/2\sum_{i,j}e^2/r_{ij}. \quad (3)$$

The calculation of the excited energy levels is carried out by the composite molecule method. That is, the matrix elements between Φ_0, $\Phi_{ai\to aj}$ and $\Phi_{bi\to aj}$ are given in the zero-differential overlap approximation as follows:

$$\begin{aligned}
&(\Phi_{ai\to aj}|\mathscr{H}|\Phi_{ai\to aj}) = E_0 + \varepsilon_{aj} - \varepsilon_{ai} - (\phi_{ai}\phi_{ai}|\phi_{aj}\phi_{aj}) + 2(\phi_{ai}\phi_{aj}|\phi_{ai}\phi_{aj})\\
&(\Phi_{bi\to aj}|\mathscr{H}|\Phi_{bi\to aj}) = E_0 + \varepsilon_{aj} - \varepsilon_{bi} - (\phi_{bi}\phi_{bi}|\phi_{aj}\phi_{aj})\\
&(\Phi_{ai\to aj}|\mathscr{H}|\Phi_{ak\to al}) = 2(\phi_{ai}\phi_{aj}|\phi_{ak}\phi_{al}) - (\phi_{ai}\phi_{ak}|\phi_{aj}\phi_{al})\\
&(\Phi_{ai\to aj}|\mathscr{H}|\Phi_{bk\to bl}) = 2(\phi_{ai}\phi_{aj}|\phi_{bk}\phi_{bl})\\
&(\Phi_{ai\to bj}|\mathscr{H}|\Phi_{ak\to bl}) = -(\phi_{ai}\phi_{ak}|\phi_{bj}\phi_{bl})\\
&(\Phi_{bi\to aj}|\mathscr{H}|\Phi_0) = -\sqrt{2}\left(\phi_{bi}\left|-\frac{\hbar^2}{2\mu}\nabla^2\right|\phi_{aj}\right)\\
&(\Phi_{ai\to aj}|\mathscr{H}|\Phi_{ai\to bl}) = -\left(\phi_{aj}\left|-\frac{\hbar^2}{2\mu}\nabla^2\right|\phi_{bl}\right)\\
&(\Phi_{ai\to aj}|\mathscr{H}|\Phi_{bk\to aj}) = \left(\phi_{ai}\left|-\frac{\hbar^2}{2\mu}\nabla^2\right|\phi_{bk}\right)\\
&(\Phi_0|\mathscr{H}|\Phi_{ai\to aj}) = (\Phi_{ai\to aj}|\mathscr{H}|\Phi_{ak\to bl}) = (\Phi_{ai\to bj}|\mathscr{H}|\Phi_{bk\to al}) = 0
\end{aligned} \quad (4)$$

Here, the intermolecular kinetic and Coulomb integrals

are exactly calculated; the molecular orbitals, ϕ_{ai}, and the orbital energies, ε_{ai}, were given in a previous paper.[6] The results of the calculation are shown in Tables 1 and 2, where the polarization directions are described by the coordinates shown in Fig. 1.

It may be seen from Table 2 that the lower CT transitions are mostly of the $\phi_{bi}\rightarrow\phi_{aj}$ type, which implies that the donor property of the benzene ring exceeds that of the diacetylene group.

Results and Discussion

[4,4]-Paracyclophadiyne. The electronic absorption spectrum in solution is shown in Fig. 2, while that in a crystal is shown in Fig. 3. The spectra are considered to be superpositions of those of the two chromophores, the benzene and diacetylene groups, and a red shift of the $^1E_{1u}$-type band of benzene is observed. In the crystalline spectra, the weakest $^1A_{1u}$-type band of the diacetylene group is observed in the 33500—35500 cm^{-1} region, and the second transition, starting at 36700 cm^{-1}, may be reasonably correlated with the band at 38500 cm^{-1} of the diacetylene group, because it shows the vibrational progressions characteristic of the diacetylene group. Overlapping with this band series, the $^1B_{2u}$ parentage band of the benzene ring may exist in this region. Since the crystal structure is not known for this molecule, an extensive argument on the polarization and assignment can not be developed, but the band at 44500 cm^{-1} may be regarded as originating from the $^1E_{1u}$ level of the benzene group. The red shift of this band as compared to that of benzene may be caused by the CT-type interaction, which indicates that the level may be located in the higher energy region. The

inter-group distance, separated by four methylene groups, will be larger than 3.3 Å, and the electronic overlap between the groups is not so effective that the CT transition may not appear at lower energies with a noticeable intensity.

[3,3]-Paracyclophadiyne. In the solution spectra of [3,3]-paracyclophadiyne (Fig. 2), a bathochromic shift of the UV absorption is apparent. The first absorption band in the 34500—37500 cm^{-1} region may be related to the diacetylene group,[6] but the transition to the $^1B_{2u}$ state of the benzene ring may overlap in this region. In the crystalline spectra (Fig. 4), a broad band with vibrational structures are observed in the 33500—37000 cm^{-1} region, and the band intensities along the a- and b-axes are nearly the same throughout this spectral region. These results seem consistent with the assignment of the $^1B_2(y)$-type transition, since the crystal structure analysis shows that the y-polarized band should give a nearly equal intensity along the a- and b-axes. If the $^1B_{2u}$-type transition of the benzene ring dominates in this region, the intensity should be predominant along the b-axis rather than distributed equally between the two axes; hence, the contribution of the $^1B_{2u}$-type band may not be so significant in the 38500—40000 cm^{-1} region.

Several CT transitions from the benzene ring to the diacetylene group are calculated to exist in this region, although they have weak intensities. In the shorter-wavelength region, a sharp prominent transition is observed at 42700 cm^{-1}; it is an extra band not belonging to either of the component chromophores. Following the theoretical calculation, a CT transition of the $^1B_2(y)$ type may be responsible for this transition, in which the charge transfer from the benzene ring to the diacetylene group is predominant. The polarization characteristic of this transition is that of the y-axis. However, the direction of the transition moment could

not unambiguously be determined by the observed polarization ratio (I_b/I_a), because the possibility of z polarization still remains to be solved.

According to the crystal-structure analysis, the inteatomic distances between the diacetylene group and the benzene-ring plane are in the range of 3.1—3.2 Å; a significant electronic interaction can be expected at such a short interatomic distance. Although the CT transition does not appear with strong intensities in the near UV region, the spectrum shows a bathochromic shift of the first band as large as 1300 cm^{-1}, in contrast to the case of [4,4]-paracyclophadiyne. The vibrational structure of the band is also blurred off. Moreover, the $^1E_{1u}$-type band of the benzene ring is blue-shifted in contrast to [4,4]-paracyclophadiyne because of the presence of the CT state at 42700 cm^{-1}, below the original position of the $^1E_{1u}$ level. The influence of the CT transition is thus shown to be important in determining the spectral properties of the system, with chromophores interacting through *trans*-annular interactions.

The authors are grateful to Professor Soichi Misumi and Drs. Yoshiteru Sakata and Takahiro Matsuoka of Osaka University for the gift of samples.

Estimation of Individual Ionic Activity Coefficients from Conductivity Data on Strong Electrolytes in Dilute Aqueous Solutions

Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Hirosawa, Wako-shi, Saitama 351

(Received April 22, 1974)

The individual ionic activity coefficients of strong electrolytes in dilute aqueous solutions are derived from the ionic conductivity data, using the Debye-Hückel-Onsager theory of strong electrolyte solutions. The mean activity coefficients computed by the present method are in good agreement with the experimental values in most of the uni-univalent and some of the uni-multivalent electrolytes studied, which demonstrates the validity of the method in deriving the individual ionic activity coefficients. Comparisons are made of the values of individual activity coefficients of various ions in dilute aqueous solutions of strong electrolytes, as determined by different methods including measurements of potential differences across membranes at varying concentrations. The influence of the ion of opposite sign on the individual ionic activity coefficient has been observed.

The individual ionic activity coefficient is an important and useful quantity in the study of various phenomena in electrolyte solutions. Thermodynamics provides methods of determining mean activity coefficients of electrolytes, but it can offer no theoretical or experimental approach to the determination of individual ionic activity coefficients. Non-thermodynamic assumptions must be introduced in the calculation of individual ionic activity coefficients. Typical conventions used for computing ionic activities have been discussed in detail by Bates and Alfenaar.[1]

In solutions of low ionic strength ($I \leq 0.1$ M), individual ionic activity coefficients can be calculated with reasonable accuracy from the Debye-Hückel equation, if appropriate ion-size parameters are assumed. In his classical tabulation of ion-size parameters, Kielland[2] employed the so-called Stokes radius calculated from the ionic conductivity at infinite dilution. The application of conductivity data to the determination of ion-size parameters in the activity equation was suggested by Fuoss and Accascina.[3] Justice *et al.*[4] discussed the self-consistency of the Debye-Hückel theory of activity coefficients and the Fuoss-Onsager theory of electrolytic conductivity, and justified the use of conductivity data in the estimation of activity coefficients of electrolytes in dilute solutions ($I \leq 0.1$ M). Their study, however, was restricted to mean activity coefficients of electrolytes. The possibility of computing individual ionic activity coefficients from conductivity data has not been discussed.

In this paper, individual ionic activity coefficients are derived from ionic conductivity data, based upon the Debye-Hückel-Onsager theory of strong electrolyte solutions. The results are compared with the individual ionic activity coefficients calculated by various conventions[1] and with some experimental values obtained from membrane-potential measurements.

Theoretical

The Debye-Hückel-Onsager theory[5] of strong electrolyte solutions gives the following expressions for the individual ionic activity coefficient $\gamma_{+(-)}$ and ionic conductivity $\lambda_{+(-)}$, respectively, of the cation (anion) in a solution of a single electrolyte*:

$$\log \gamma_{+(-)} = -A^* z^2_{+(-)} \chi^{-1}_{+(-)} \tag{1}$$

$$\lambda_{+(-)} = \lambda^{\infty}_{+(-)} - (\alpha^* \lambda^{\infty}_{+(-)} + \beta^* |z_{+(-)}|) \chi^{-1}_{+(-)} \tag{2}$$

where $z_{+(-)}$ is the charge number, $\lambda^{\infty}_{+(-)}$ the ionic conductivity at infinite dilution, the coefficients A^*, α^*, and β^* are given in Table 1, and $\chi_{+(-)}$ is the distance parameter that determines the potential due to the environment of the given central ion. According to the Debye-Hückel theory, $\chi_{+(-)}$ is given by

$$\chi_{+(-)} = a_{+(-)} + \kappa^{-1} \tag{3}$$

where $a_{+(-)}$ is the distance of closest approach and κ^{-1} is often called the thickness of the ionic atmosphere. In the following treatment, however, it is not necessary to know the explicit expression for the quantity $\chi_{+(-)}$.

Eliminating $\chi_{+(-)}$ from Eqs. (1) and (2), we obtain

$$\log \gamma_{+(-)} = -\frac{A^* z^2_{+(-)}}{\alpha^* \lambda^{\infty}_{+(-)} + \beta^* |z_{+(-)}|} (\lambda^{\infty}_{+(-)} - \lambda_{+(-)}) \tag{4}$$

which relates the individual ionic activity coefficient to the ionic conductivity. Similarly, for the mean activity coefficient $\gamma_{\pm}$ of a completely dissociated electrolyte, we obtain

$$\log \gamma_{\pm} = -\frac{A^* |z_+ z_-|}{\alpha^* \Lambda^{\infty} + \beta^* (z_+ + |z_-|)} (\Lambda^{\infty} - \Lambda) \tag{5}$$

where Λ is the equivalent conductivity of the electrolyte.

Eq. (1) (the Debye-Hückel approach) and Eq. (2) (the Onsager-Robinson-Stokes approach) are less rigorous than more advanced theoretical expressions,[5] but do fit with reasonable accuracy the experimental data on mean activity coefficients and conductivities of completely dissociated electrolytes in aqueous solutions of ionic strengths below 0.1 M. The use of Eqs. (1) and (2) also has the following practical advantages for the present purpose:

(i) The equations can be combined in a straightforward way to give the expressions (4) and (5) for activity coefficients in terms of conductivity data.

(ii) The application of Eq. (2) is not restricted to solutions of symmetrical electrolytes, whereas some advanced conductivity equations (such as the Fuoss-Onsager equation) can be used only in solutions of

* The difference in activity coefficients due to the different concentration scales is ignored throughout the present paper.

TABLE 1. EXPRESSIONS FOR A^*, α^* AND β^* IN Eqs. (1) AND (2), AND THEIR NUMERICAL VALUES IN AQUEOUS SOLUTIONS OF 25 °C ($\varepsilon=78.30$, $\eta=0.008903$ poise)

a) Equivalent concentration c^* is defined by $c^*=\nu zc$, where c is the molarity and $\nu z=\nu_+z_+=\nu_-\lvert z_-\rvert$.
b) Interpolated values.

symmetrical electrolytes.

In this connection, it is important to remember that the formal expression for χ is not required in the derivation of Eqs. (4) and (5); these relations are satisfied if the effect of ionic interaction (considering only the Debye-Hückel type) on the activity and conductivity is expressed by the common parameter χ in Eqs. (1) and (2).

Results and Discussion

Equivalent Conductivities and Transport Numbers. Knowledge of equivalent conductivities and transport numbers is necessary in order to determine activity coefficients by using Eqs. (4) and (5). Ionic conductivities $\lambda_{+(-)}$ can be obtained from the equivalent conductivity Λ of the electrolyte and the transport numbers $t_{+(-)}$ of the ions according to the equation

$$\lambda_{+(-)} = t_{+(-)}\Lambda \qquad (6)$$

In the following calculations we used the conductivities and transport numbers reported by Spedding and Atkinson[6] (for the lanthanum salts) and those given in the Landolt-Börnstein Tables[7] (for the other electrolytes).

Mean Activity Coefficients of Strong Electrolytes. The validity of the present method of computing activity coefficients from conductivity data was examined by comparing the mean activity coefficients calculated by using Eq. (5) with the experimental data available in literature.[5,6,8] The results obtained with a variety of strong electrolytes are given in Table 2.

It is seen that the calculated activity coefficients o the majority of uni-univalent electrolytes are in good agreement with the experimental values at ionic strengths below 0.1 M. The agreement is also good for calcium chloride and for lanthanum chloride and bromide in solutions where $I \leq 0.1$ M. Some deviation of the calculated values from the experimental data is observed in solutions of hydrochloric and nitric acids. From the 62 sets of data in Table 2, the correlation between $\gamma_{\pm\text{calc}}$ and $\gamma_{\pm\text{exp}}$ is given by

$$\gamma_{\pm\text{calc}} = -0.00193 + 0.993\ \gamma_{\pm\text{exp}}$$

with

$$S = 0.0112,\ S_a = 0.00858,\ S_b = 0.0111$$

where S, S_a, and S_b are the standard deviations for $\gamma_\pm$, the intercept, and the slope, respectively.

Individual Activity Coefficients of Ions. Examination of the results given in Table 2 shows Eq. (4) to give reasonably good estimates of individual ionic activity coefficients in dilute solutions ($I \leq 0.1$ M). Table 3 presents the individual activity coefficients of various ions calculated by using Eq. (4) in aqueous electrolyte solutions of 25 °C.

It follows from the results in Table 3 that:

(i) In chloride solutions the individual activity coefficients of univalent cations increase in the order $H^+ < NH_4^+ < K^+ < Na^+ < Li^+$. This sequence of the alkali-metal cations is consistent with that obtained from potential measurements using a permselective membrane.[9] The activities of calcium and magnesium ions are almost the same in chloride solutions.

(ii) The values of $\gamma(H^+)$ are practically equal in chloride and nitrate solutions.

(iii) In solutions of a given ionic strength, $\gamma(K^+)$ varies with the nature of the anion, increasing in the order $SO_4^{2-} < NO_3^- < Cl^- < Br^- \lesssim CH_3COO^- < I^-$.

(iv) The values of $\gamma(La^{3+})$ increase in the following order: $NO_3^- \simeq Cl^- < Br^- < ClO_4^-$.

(v) The individual activity coefficient of chloride ion is almost the same in solutions of HCl, LiCl, NaCl, KCl, NH_4Cl, $CaCl_2$ and $MgCl_2$ of a given ionic strength ($I \leq 0.1$ M). In Fig. 1, $\log \gamma(Cl^-)$ is plotted as a function of $I^{1/2}$; the theoretical lines calculated from the Debye-Hückel limiting equation and from the Scatchard equation (*cf.* Eq. (8)) are also shown. Smaller values of $\gamma(Cl^-)$ observed in $LaCl_3$-solutions suggest the existence of some specific interaction between La^{3+} and Cl^-.

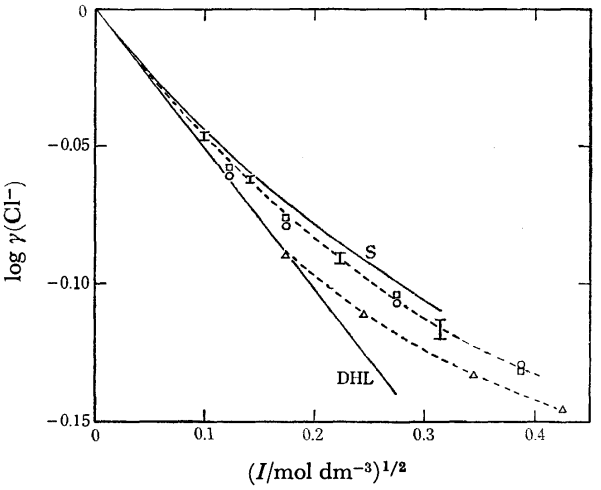

Fig. 1. Individual activity coefficients of chloride ion as a function of $I^{1/2}$ in aqueous solutions of uni-univalent and uni-multivalent electrolytes at 25 °C. I, uni-univalent electrolytes (HCl, LiCl, NaCl, KCl and NH_4Cl); O, $CaCl_2$; □, $MgCl_2$; △, $LaCl_3$. DHL, Debye-Hückel limiting slope; S, theoretical line by the Scatchard equation.

(vi) The values of $\gamma(NO_3^-)$ increase in the order $Ag^+ < K^+ < H^+$.

(vii) The activity of sulfate ion is almost the same in solutions of Na_2SO_4 and K_2SO_4 ($I \leq 0.15$ M).

Comparison of Individual Ionic Activity Coefficients Calculated by Different Methods. The following non-thermodynamic conventions have been commonly adopted in the estimation of individual ionic activities.[1]

The MacInnes Convention. MacInnes[10] assumes that

$$\gamma(K^+) = \gamma(Cl^-) = \gamma_\pm(KCl) \qquad (7)$$

in aqueous solutions of potassium chloride. It is also assumed that the activity of chloride ion in the presence of various univalent cations is independent of the nature of the cation at any concentration.

The pH Convention. In this convention[1,11] the individual activity coefficient of chloride ion in dilute aqueous solutions ($I \leq 0.1$ M) is assumed to be given by the Scatchard equation[12]

TABLE 3. INDIVIDUAL ACTIVITY COEFFICIENTS OF IONS IN AQUEOUS SOLUTIONS OF STRONG ELECTROLYTES AT 25 °C, AS COMPUTED FROM THE IONIC CONDUCTIVITY DATA

		(c^*=0.015)	(c^*=0.03)	(c^*=0.06)	(c^*=0.09)
CH_3COO^-	$Na(CH_3COO)$	0.901	0.869	0.816	0.770
	$K(CH_3COO)$	0.915	0.883	0.833	0.782
SO_4^{2-}	Na_2SO_4	0.591	0.503	0.383	0.303
	K_2SO_4	0.586	0.490	0.376	0.300

$$\log \gamma(Cl^-) = -\frac{A\sqrt{I}}{1+1.5\sqrt{I}} \quad (8)$$

where A is the Debye-Hückel limiting slope.

The Valance-relationship Convention. According to this convention,[1] the activity coefficients of ions are related as in the Debye-Hückel limiting law. In the case of an unsymmetrical electrolyte MA_2, for example, the relationship between $\gamma(M^{2+})$, $\gamma(A^-)$ and $\gamma_\pm(MA_2)$ is given by

$$\gamma(M^{2+}) = \gamma(A^-)^4 = \gamma_\pm(MA_2)^2 \quad (9)$$

For uni-univalent electrolytes the relationship is simply

$$\gamma_+ = \gamma_- = \gamma_\pm \quad (10)$$

which is equivalent to the assumption proposed by Guggenheim.[13]

If the individual activity coefficients of chloride ion at varying ionic strengths are defined either by the MacInnes convention or by the pH convention, the individual activity coefficients of other ions can be calculated in the following way:[1] *e.g.*, for the univalent cation M^+ and anion A^- of the electrolyte MA

$$\log \gamma(M^+) = 2 \log \gamma_\pm(MCl) - \log \gamma(Cl^-)$$

$$\log \gamma(A^-) = \log \gamma(Cl^-) + 2 \log \frac{\gamma_\pm(MA)}{\gamma_\pm(MCl)}$$

and for the univalent anion A^- of the salt MA_2

Table 4. Comparison of individual activity coefficients of various ions in aqueous solutions of strong electrolytes at ionic strength of 0.1 M and at 25 °C, as computed by different methods

a) Estimated from the figure given in Ref. 1.

$$\log \gamma(A^-) = \log \gamma(Cl^-) + \frac{3}{2} \log \frac{\gamma_\pm(MA_2)}{\gamma_\pm(MCl_2)}$$

In this derivation of individual ionic activity coefficients, it is assumed that $\gamma(Cl^-)$ and $\gamma(M^+$ or $M^{2+})$ are independent of the nature of the ions of opposite sign present in the solution.

Application of all the conventions mentioned above more or less ignores the nature of the ions. On the other hand, the present method takes into account the nature of the ions as revealed by their characteristic ionic conductivities, and should give more reasonable estimates of individual ionic activity coefficients.

Table 4 compares the activity coefficients of various ions in aqueous solutions at ionic strength of 0.1 M, as determined by the different methods discussed earlier. The experimental values for cations in Table 4 were derived from potential measurements with a perm-selective membrane[9]; the experimental data were standardized at an ionic strength of 0.01 M or 0.015 M (in case of Na_2SO_4 and K_2SO_4). The experimental values for anions were calculated from those for the cations and those for the mean activity coefficients of the corresponding electrolytes. The membrane-potential measurements involve some error due to the difficulty of eliminating liquid-junction potentials; the uncertainty in the present experimental values is estimated to be between 1 and 5% most in cases.

Further experimental data will be required before it can be decided whether the present method gives more reliable estimates of individual ionic activity coefficients than the other conventions. From Table 4, however, it is already seen that the present method gives the best fit to the experimental values in the cases of calcium chloride and of sodium and potassium sulfates, where the other conventions result in appreciably different values.

The Catalytic Activity of Some Mixed Oxides for Depolymerization of Paraldehyde

S. P. WALVEKAR* and A. B. HALGERI

Department of Chemistry, Central College, Bangalore University, Bangalore-560001, India

(Received August 28, 1972)

Depolymerization of paraldehyde in benzene catalyzed by SiO_2–ZrO_2, SiO_2–TiO_2, Al_2O_3–ZrO_2, TiO_2–ZrO_2, Al_2O_3–TiO_2 (calcined at various temperatures) has been studied. It is observed that in all the cases the catalytic activity (first order rate constant, k) exhibited a maximum against the temperature of heat treatment of the catalyst. The acid sites at $pK_a \leqq -3.0$ correlate best with catalytic activity for depolymerization of paraldehyde.

It has been observed previously that mixed oxides show fairly strong acidic property on their surface and that the acidity changes remarkably on subjecting the samples to heat treatment.[1] In the present work an attempt has been made to study the depolymerization of paraldehyde in presence of some of these solid acids.

Depolymerization of paraldehyde proceeds in presence of mineral acids and carboxylic acids in non-aqueous media and can be followed by an accurate and easy method of analysis.[2,3] Depolymerization of paraldehyde in presence of solid acids like metal sulphates has been reported by Tanabe *et al.*[4,5] It was considered of interest to study this reaction in presence of mixed oxide catalysts for which no data exists. The rate constants have been correlated with the acidity of the catalysts.

Experimental

Materials. Paraldehyde and pure quality benzene were dried over sodium, distilled and used in this work. All other chemicals were extra pure grade reagents and were used as received.

Preparation of Catalysts. Silica gel was prepared by hydrolysis of dilute sodium silicate solution with 10% HCl.[6] Alumina was prepared from $Al(NO_3)_3 \cdot 9H_2O$ by precipitating $Al(OH)_3$ using ammonia water.[7] The precipitates obtained in the above two cases were heated for an hour and then filtered off and washed with distilled water till it was free from chloride and nitrate ions respectively. Finally the precipitates were dried at 100 °C for 20 hr and preserved. The binary oxides were prepared as follows.

1) Silica–titania: 85 g of SiO_2 gel prepared as above was suspended in 500 ml of distilled water and 18 ml of $TiCl_4$ was added. The mixture was boiled on a water bath for 1 hr and 50 ml of 28% ammonia water was added drop by drop to form the precipitate of titanic acid (H_4TiO_4). The final pH of the solution was near about 7.5. The mixture was heated for about an hour with continuous stirring and then the precipitate was filtered off and washed thoroughly with distilled water till it was free from chloride ions. The precipitate was dried at 100 °C for 20 hr and preserved. The weight % of TiO_2 in the mixture was calculated to be 15.

2) Silica–zirconia: 89 g of silica was suspended in 250 ml of distilled water and a solution of 26.9 g of $Zr(SO_4)_2 \cdot H_2O$ in 500 ml of water was added and to this mixture 46 ml of 28% ammonia was added dropwise with vigorous stirring. The mixture was heated for 2 hr. The final pH of the solution was 7.6. The precipitate was filtered off, washed with water until no sulfate ions were detected in the washings. The precipitate was dried as in 1). The weight % of ZrO_2 in the mixture was calculated to be 11.

3) Alumina–zirconia: This catalyst was prepared by the precipitation technique described above. 80 g of alumina prepared as above was suspended in 250 ml of distilled water and a solution of 48.9 g of $Zr(SO_4)_2 \cdot H_2O$ in 500 ml of water was added. The mixture was boiled on a water bath for 1 hr and 83 ml of 28% ammonia water was added dropwise until the pH of the solution was near about 7.2. The precipitate was washed and dried as in 1). The weight % of ZrO_2 in the mixture was calculated to be 20.

4) Titania–zirconia: The coprecipitated mixture of TiO_2–ZrO_2 was prepared as follows. 19.6 g of $Zr(SO_4)_2 \cdot H_2O$ was dissolved in 500 ml of distilled water and 20.5 ml of $TiCl_4$ was added to this solution. The solution was heated on a water bath for 2 hr and 322 ml of 28% ammonia water was added slowly with vigorous stirring to form a coprecipitate of the mixture. The final pH of the solution was near about 7.5. The precipitate was heated for 1 hr and was filtered off and washed thoroughly with distilled water until no chloride and sulfate ions were detected in the washings. The precipitate was dried at 120 °C for 20 hr. The weight % of ZrO_2 in the mixture was calculated to be 32.

5) Alumina–titania: 48.5 g of $AlCl_3 \cdot 6H_2O$ was dissolved in 360 ml of water and 7.8 ml of $TiCl_4$ was added. The solution was heated on a water bath for 1 hr and 290 ml of 28% ammonia water was added to the mixture in lots of 50 ml at a time. The last lot of ammonia water was added dropwise with continuous stirring until the pH of the solution was around 7.2. The mixture was boiled to complete the coprecipitation. The precipitate was washed and dried as in 4). The weight % of TiO_2 in the mixture was calculated to be 26.

The samples thus obtained in the above cases were powdered and only such samples collected between 100 and 150 mesh sieves were used. The powders were subjected to heat treatment in the temperature range of 120 to 1050 °C by heating for 6 hr in an electrical muffle furnace with temperature control arrangement. The samples after heat treatment were cooled in a desiccator and preserved in covered glass tubes, under vacuum.

Measurement of Surface Acidity and Acid Strength. The acidity (the number of acid sites) having an acid strength H_0 equal to or lower than the pK_a value of the indicator used were determined by using the amine titration method.[8,9]

Kinetic Studies. The procedure adopted was essentially the same as described by the earlier authors.[4,5] The reaction was studied at 25 °C by analyzing the acetaldehyde formed at various intervals of time by the bisulfite method.[10] Tests showed that none of the catalysts used, interfered with the determination of acetaldehyde by the above method.

Sufficient precautions were taken to study these reactions

* To whom all the correspondence has to be made.

in the absence of moisture, since even traces of moisture could greatly retard or even stop the reaction altogether, especially when very effective catalysts were being used in low concentrations. Since the reaction is heterogeneous and the rate depends upon the condition of the experiment, the experiments were carried out under similar conditions throughout this investigation.

Results and Discussion

It has been observed that the rate of depolymerization of paraldehyde catalyzed by metal sulphates[4] is of the first order and similarly with mixed oxides the rate was found to be of the first order with respect to paraldehyde concentration, as straight line graphs were obtained for the log $(a-x)$ against time 't' plots.

The results of the depolymerization of paraldehyde catalyzed by SiO_2–ZrO_2, SiO_2–TiO_2, Al_2O_3–ZrO_2, TiO_2–ZrO_2, and Al_2O_3–TiO_2 are presented in Tables 1 and 2. It is seen from these tables that the acidity at $pK_a \leqq -3.0$, increases with increasing temperature of heat treatment and attains a maximum and then decreases with further rise in temperature. A reference to the rate constant value, k, in these tables indicates that there exists a correlation between acidity and the catalytic activity. When the catalyst was poisoned by dicinnamal acetone ($pK_a = -3.0$), it could not depolymerize paraldehyde. Therefore acid sites having an acid strength of $pK_a \leqq -3.0$ correlate best with catalytic activity for depolymerization of paraldehyde. This conclusion is in agreement with the one obtained by us in case of some silica and alumina based binary oxide catalysts[11-13] and also with the one obtained by other workers with metal sulphates.[5] The dependence of catalytic activity on the temperature of heat treatment of catalyst is shown in Tables 1 and 2. It is observed that in all cases the catalytic activity (first order rate constant, k) exhibited a maximum against the temperature of heat treatment of the catalyst. The decrease in the catalytic activity of these mixed oxides after heat treatment at elevated temperatures is due to a decrease in the number of acid sites and acid strength rather than to a decrease in their surface area.[14]

It is interesting to note from the results presented in Tables 1 and 2 that acidity of 0.05 mmol/g or less at $pK_a \leqq -3.0$ is not effective for catalyzing this reaction. In case of Al_2O_3–ZrO_2 samples heat-treated at 260 and 800 °C have an acid value of 0.02 and 0.04 mmol/g respectively but these show no catalytic activity. Similarly in case of TiO_2–ZrO_2 and Al_2O_3–TiO_2 samples calcined at 120 and 220 °C have an acid value of 0.03 mmol/g but have no catalytic activity. It is further observed in case of SiO_2–TiO_2 that samples heat-treated at 120, 800, and 1000 °C have a number of acid sites having an acid strength of $pK_a \leqq +3.3$, but these samples show no catalytic activity. Similarly in case of Al_2O_3–TiO_2, TiO_2–ZrO_2 samples heat-treated at 120 and 800 °C have a number of acid sites having an acid strength of $pK_a \leqq +3.3$, but have no catalytic activity. A similar observation is made in case of Al_2O_3–ZrO_2 and Al_2O_3–TiO_2 for samples heat-treated at 260 and 220 °C respectively. Therefore even those relatively few acid sites at $pK_a \leqq -3.0$ (0.05 mmol/g or less) and those at $pK_a \leqq +3.3$ are catalytically inactive.

The reason for the ineffectiveness of acid sites with weaker acid strength than $pK_a = -3.0$ is probably to be found in the fact that no paraldehyde molecule will give a conjugated acid at any of these weaker sites, since the pK_a value of paraldehyde is about -3.3.[15] Similar correlations between activity and acid amount over limited ranges of acid strength were evident in both the hydration of propylene,[16] polymerization of isobutyl vinyl ether[17] catalyzed by various sulphates, and also hydrolysis of aliphatic esters catalyzed by

mixed oxides.[18] In these cases catalytic activities were found to be proportional to the activities at $-3.0 \leqq H_0 \leqq +1.5$, at $-5.6 \leqq H_0 \leqq -3.0$ and at $H_0 \leqq -3.0$ respectively.[16-18]

These observations show that every reaction requires acid sites of a particular acid strength for a particular reaction and hence it can be concluded that acidity and acid strength play an important role in every acid catalyzed reaction.

Authors wish to express their thanks to Professors M. Shadaksharaswamy and T. D. Bhaskar for providing research facilities and encouragement.

The Telomerization of Methyl Acetate and Methyl Cyanoacetate with Ethylene

Tsutomu FUJIMOTO and Ichiro HIRAO

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-kyushu 804

(Received August 4, 1973)

The telomerization of methyl acetate and cyanoacetate with ethylene initiated by di-*tert*-butyl peroxide was investigated. Methyl esters of linear and α-branched alkanoic acids, and linear and α-branched alkyl acetates, as well as hydrocarbons, were identified in the system of methyl acetate. The methyl esters of linear and α-branched α-cyanoalkanoic acids were identified in the system of methyl cyanoacetate, but no alkyl cyanoacetates could be found. It was suggested that intramolecular 1,5-hydrogen transfer in telomer radicals with two ethylene units and a chain-transfer reaction to the telomers gave the branched telomers. The chain-transfer constants were estimated in the system of methyl cyanoacetate. The introduction of the cyano group to methyl acetate at the α-position gave a favorable system for chain-transfer reactions and facilitated intramolecular 1,5-hydrogen transfer in the telomer radicals. The relatively higher relative reactivity of the methoxy group to the acetyl group in methyl acetate in the telomerization with ethylene was discussed.

It is well known that a homolytic abstraction of an α-hydrogen atom from acetic and α-substituted acetic acids and their esters preferentially give the carboxymethyl radical and its homologous radicals.[1-3] The radicals react with olefins to give telomeric products.[4] The telomerization of ethylene with acetic acid and its derivatives is accompanied by 1,5-hydrogen transfer in telomer radicals, α-branched telomers being formed together with linear telomers.[5-7] Propagation, chain-transfer, and intramolecular hydrogen-transfer reactions of methoxycarbonylalkyl and cyanomethoxycarbonylalkyl radicals may be expected in the telomerization of methyl acetate and cyanoacetate with ethylene. An elucidation of the behavior of these radicals will give information of interest with regard to the reactivity of substituted alkyl radicals.

Some homologous series of telomers may be expected in the telomerization of methyl acetate with ethylene, but only linear aliphatic acids have been isolated from the telomerization products.[8] Free radical additions of ethyl cyanoacetate to unsaturated compounds have also been investigated,[9-14] but there has been no report on the telomerization of methyl cyanoacetate with ethylene. This paper will describe the telomerization products and the chain-transfer and intramolecular-rearrangement reactions of the telomer radicals in the telomerization of methyl acetate and cyanoacetate with ethylene.

Results and Discussion

Telomerization Products of Methyl Acetate with Ethylene. The telomerization was carried out in the presence of radical initiators in an autoclave. The product of the telomerization was fractionated into three fractions: I (insoluble in hot methyl acetate), II (soluble in hot methyl acetate, but insoluble at room temperature), and III (soluble in methyl acetate at room temperature). A product with a high molecular weight was obtained under an initial ethylene pressure of 40 kg/cm², but a product with a mean molecular weight of 235 was obtained using di-*tert*-butyl peroxide (DTBP) when ethylene was introduced to keep a pressure of 20 kg/cm² at 140 °C during the reaction. The product thus obtained was further fractionated to three fractions, III-1 (bp 60—150 °C/60 mmHg), III-2 (bp 150/60—170 °C/5 mmHg), and the residue (III-3). The compositions and molecular weights of the fractions are given in Table 1.

TABLE 1. COMPOSITION AND MOLECULAR WEIGHT OF THE FRACTIONS OF METHYL ACETATE TELOMER

Initiator	AIBN	DTBP	DTBP

III-3	—	—	22.8 (384)

a) Pressure of 20 kg/cm² was kept at 140 °C. b) Molecular weights are given in parentheses.

The gas chromatogram of lower boiling products is shown in Fig. 1. The identification of the products was carried out by gas chromatography (glc) and by a study of the IR, NMR, and mass spectra (see Experimental). The a_n peaks (n=1—7) were identified with methyl butanoate (LA_1), hexanoate (LA_2), octanoate (LA_3), decanoate (LA_4), dodecanoate (LA_5), tetradecanoate (LA_6), and hexadecanoate (LA_7) respectively. The b_n peaks (n=1—7) were identified with propyl (LM_1), pentyl (LM_2), heptyl (LM_3), nonyl (LM_4), undecyl (LM_5), tridecyl (LM_6), and pentadecyl (LM_7) acetates respectively. The c_n peaks (n=1—5) were identified with methyl 2-ethylbutanoate (BA_1), 2-ethylhexanoate (BA_2), 2-butylhexanoate (BA_3), 2-ethyloctanoate (BA_4), and 2-butyloctanoate (BA_5) respectively. The d_n peaks (n=1—3) were identified with

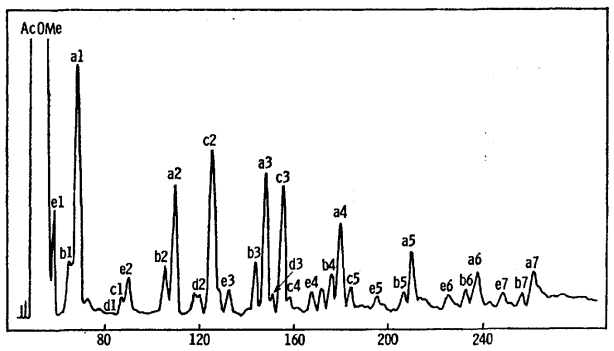

Fig. 1. Gas chromatogram of the telomerization product of methyl acetate with ethylene.

1-ethylpropyl (BM_1), 1-ethylpentyl (BM_2), and 1-butylpentyl(BM_3) acetates respectively. Although a peak which corresponds to 1-butylheptyl acetate in the retention time could not be detected because of the overlap of other peaks, the presence of the acetate was suggested by the formation of undecan-5-ol after the saponification of the telomerization product. The e_n peaks (n=1—7) were hydrocarbon homologues with an odd number of carbon atoms, from nonane to heneicosane respectively. The hydrocarbons were presumably formed by the addition of methyl radicals to ethylene. The result of silica-gel-column chromatography showed that hydrocarbons were included (at least 12% by weight) in the product obtained under a pressure of 20 kg/cm² at 140 °C. Chiang and Li have isolated and identified only linear acids from the same telomerization,[8] but the telomerization product was a complex mixture containing methyl esters of α-branched alkanoic acids (BA), linear alkyl (LM), and α-branched alkyl (BM) acetates and hydrocarbons in addition to methyl esters of linear alkanoic acids (LA).

The amounts of telomers relative to the amount of BA_2 were determined by glc because no suitable internal standard could be found. The results are given in Table 2. The content of the LA_1 telomer was 42% at 160 °C, while the contents of LA, BA, LM, and BM were 46—57, 24—29, 18—21, and 2—5% respectively in the telomers detectable by glc (Table 3).

Full lines indicate butyl branched telomers.

The distributions of the telomers were almost unaffected by the reaction time. The effects of the pressure of ethylene on the distributions of LA, LM, BA, and BM are shown in Figs. 2, 3, and 4. In the distribution of LA, a remarkable minimum was found at two ethylene units, while a maximum at four ethylene units in the distribution of the methyl ester telomers with a branch of the butyl group under a high pressure of ethylene.

Telomerization Products of Methyl Cyanoacetate with Ethylene. The telomerization was carried out in the presence of DTBP at 140 °C in an autoclave. Ethylene was introduced into the autoclave to keep the prescribed pressure during the reaction. The gas chromatogram of the reaction mixture is shown in Fig. 5. The reaction products were identified by glc and by mass spectrometry (see Experimental). The 1, 4, and 6 peaks were identified with methyl 2-cyanobutanoate (N_1), 2-cyanohexanoate (N_2), and 2-cyanooctanoate (N_3) respectively. The 2, 5, 7, 8, and 9 peaks were identified with methyl 2-cyano-2-ethylbutanoate (B_1), 2-cyano-2-ethylhexanoate (B_2), 2-butyl-2-cyanohexanoate (B_3), 2-cyano-2-ethyloctanoate (B_4), and 2-butyl-2-cyanooctanoate (B_5) respectively. No propyl and pentyl cyanoacetates, which were expected to be formed *via* cyanoacetoxymethyl radicals, could be detected by glc. The component of the 3 peak was confirmed to be methyl 2-cyano-3-methyl-2-butenoate, which was a product of the thermal decomposition of DTBP in methyl cyanoacetate without ethylene, by a study of the IR, NMR, and mass spectra. A small amount of higher-boiling materials (bp> 110 °C/1 mmHg) was also obtained; however, the IR and NMR spectra showed the presence in the fraction of a few telomers with higher ethylene units.

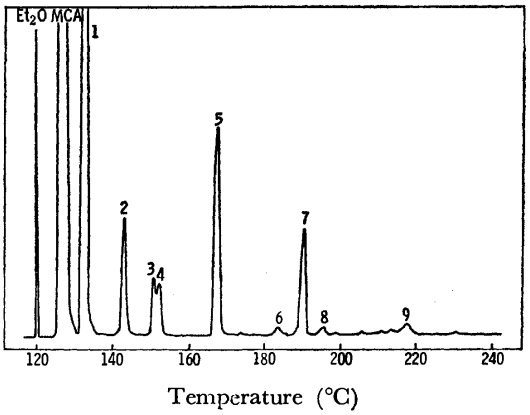

Fig. 5. Gas chromatogram of the telomerization product of methyl cyanoacetate with ethylene.

The analysis of the telomerization products was carried out by means of glc. The results are given in Table 4. The content of the N_1 telomer was over 50%, and a remarkable formation of the branched telomers, especially B_2, was observed in this system.

Chain-transfer Reactions in Telomerization of Methyl Cyanoacetate with Ethylene. In the telomerization, linear telomers, N_n, may be formed by the chain-transfer reaction of linear telomer radicals formed from cyanomethoxycarbonylmethyl radicals. The branched telomer, B_1, may be formed *via* the addition of ethylene to 1-cyano-1-methoxycarbonylpropyl radicals. The increase in the amount of B_1 with the reaction time suggests that the radicals were produced by the abstraction of a hydrogen atom at the α-position in the linear telomer N_1. The formation of the radicals by 1,3-hydrogen transfer in 3-cyano-3-methoxycarbonylpropyl radicals is presumed to be negligible because of the small possibility of 1,3-hydrogen transfer.[15] The formation of B_1, therefore, suggests that a part of the branched telomers may be formed by chain transfer to linear

telomers.

The B_2 telomer may be formed by Reaction et2 from 5-cyano-5-methoxycarbonylheptyl radicals and by Reaction bt1 from 3-cyano-3-methoxycarbonylheptyl radicals (Chart 1). A part of the latter radicals may be formed through chain-transfer reaction to N_2 (a2); however, most of the radicals may be formed *via* intramolecular 1,5-hydrogen transfer in 5-cyano-5-methoxycarbonylpentyl radicals, which are telomer radicals with two ethylene units. The intramolecular 1,5-hydrogen transfer was suggested by the remarkable formation of the B_2 telomer, even at an initial stage of the reaction. Intramolecular 1,5-hydrogen transfer reaction is known in alkyl radicals in the gas phase[15] and has been suggested in the telomerization of ethylene with acetic acid and its derivatives.[5-7] Therefore, most of the telomers with a branch of the butyl group at the α-position may be formed from the radicals produced by the intramolecular hydrogen transfer. The possible formation pathways of the telomers identified in the system are summarized in Chart 1.

An estimation of the conversions (A_n and R) of the linear telomer N_n to branched telomers *via* chain-transfer to the telomer and of 5-cyano-5-methoxycarbonylpentyl radicals to branched telomers *via* intramolecular 1,5-hydrogen transfer in the radicals was attempted on the basis of the yields of telomers. For the estimation, it was necessary to determine the yields of branched telomers in each pathway. The yields were estimated from the following relations by assuming the same chain-transfer constant for the telomer radical, $RC(CN)(COOCH_3)\dot{E}_n$ (R=Et, Bu, and hexyl; E represents an ethylene unit), with the same n;

$$\frac{[B_2]_{et2}}{[B_1]_{et1}} = \frac{[B_3]_{bt2}}{[B_2]_{bt1}} = \frac{[B_5]_{ht2}}{[B_4]_{ht1}}$$

$$\frac{[B_4]_{et3}}{[B_2]_{et2}} = \frac{[B_5]_{bt3}}{[B_3]_{bt2}}$$

where $[B_n]_{etn}$, $[B_n]_{btn}$, and $[B_n]_{htn}$ represent the yields of branched telomers formed in the et$n$, bt$n$, and ht$n$ pathways respectively. There is no information on the chain-transfer constants of the branched telomer radicals; however, we may expect little change in the constants caused by the difference in alkyl groups, such as ethyl, butyl, and hexyl, in the telomer radical. A slight change may also be expected from the ratios (1.0—1.5)[6,7] of the chain-transfer constant of the branched telomer radical $BuC(X)(COOCH_3)\dot{E}_n$ to that of the linear telomer radical $CH(X)(COOCH_3)\dot{E}_n$ in the telomerizations of methyl propionate (X=CH_3) and methyl chloroacetate (X=Cl) with ethylene. The results, and the estimated conversions of linear telomer radicals with ethylene units of n by Reaction tn (T_n) and of branched telomer radicals $HE_2C(CN)(COOCH_3)\dot{E}_n$ by Reaction bt$n$ (T_{bn}), are given in Table 5. The mean value of A_1 and A_3 was used for A_2 in the estimation of the conversion, R. It was found that 5-cyano-5-methoxycarbonylpentyl radicals gave branched telomers in conversions of 75—79% under the present conditions.

TABLE 5. CONVERSION OF TELOMER RADICALS

Press. (kg/cm²)	20	30	30	30	40
Time (hr)	8	1	3	8	8
T_1[a]	77.4	70.4	68.7	68.3	61.1

a) Conversions are given in percentage.

The chain-transfer constants, C_n (k_{tn}/k_{pn}), for a linear telomer radical, $\dot{E}_nCH(CN)COOCH_3$, and C_{bn} (k_{btn}/k_{bpn}) for a branched telomer radical, $HE_2C(CN)(COOCH_3)\dot{E}_n$, were estimated by Mayo's equation[16] from the estimated yields of the telomers and from the average ratio of the ethylene and methyl cyanoacetate concentrations. The C_{rp} ratio of the rate constants, k_r (Reaction r) to k_{p2} (Reaction p2), was evaluated from the estimated yields of the branched telomers formed *via* Reaction r ($[B_n]_r$) and those of all of the linear and branched telomers formed *via* Reaction p2 ($[N_n+B_n]_{p2}$), and from the average concentration of ethylene;[7]

$$C_{rp} = \frac{k_r}{k_{p2}} = \frac{[B_n]_r[E]}{[N_n+B_n]_{p2}}$$

The estimated chain-transfer constants and C_{rp} values are given in Table 6. In the estimation, the formation of N_2 from 1-cyano-1-methoxycarbonylpentyl radicals by hydrogen abstraction was neglected.[6,7] Although the chain-transfer constant of the radical cannot be estimated, it should be much smaller than C_1 for the radicals stabilized by cyano and methoxycarbonyl groups. If the constant is not negligible, some higher value may be estimated for C_{rp} and some lower value for C_2. The estimated chain-transfer contants and C_{rp} values were larger than those in the telomerization

of methyl propionate and methyl chloroacetate with ethylene.[6,7]

Chain-transfer Reactions in the Telomerization of Methyl Acetate with Ethylene. In the telomerization product, telomers of methyl esters and acetates were found. The formation of these telomers suggests that hydrogen atoms of acetyl and methoxy groups in methyl acetate were abstracted to give methoxycarbonylmethyl and acetoxymethyl radicals. The formation of branched methyl ester telomers BA by chain transfer to linear telomers LA was also suggested by the formation of the BA_1 branched telomer. Intramolecular 1,5-hydrogen transfer in 5-methoxycarbonylpentyl radicals was also suggested by the minimum in the distribution of the LA telomer at two ethylene units (Fig. 2) and by the remarkable formations of BA_2 and of branched methyl ester telomers with a butyl group at the α-position. The formation of branched acetate telomers may be similar to that of methyl ester telomers, BA, as the formation of BM_1 and the amount of BM_2 suggest. These pathways of the formation of branched telomers are the same in manner as those in the system of methyl cyanoacetate.

The degree of chain transfer to linear telomers, LA, cannot be estimated because not all of the telomers could be analyzed by glc, but a convresion of more than 9% of the LA_1 formed during the reaction to the branched telomers was evaluated from the ratio of the amount of BA_1 to the sum of the amounts of LA_1 and BA_1 for 8 hr under a pressure of 20 kg/cm² at 140 °C. A considerable extent of the intramolecular hydrogen transfer in 5-methoxycarbonylpentyl radicals was also suggested by the ratio (1.6) of the sum of the amounts of BA_2, BA_3, and BA_5 to that of LA_3, LA_4, and LA_5, although it means only a rough measure.

A significant degree of the formation of branched telomers was also shown by the compositions of the series of telomers in the entire product (Table 7).

Table 7. Relative ratio of series of the telomers

Temp. (°C)	20	130	140	150	160
LA	—	1.00	1.00	1.00	1.00
LM	—	0.41	0.37	0.36	0.33
BA	—	0.74	0.61	0.47	0.32
BM	—	0.12	0.10	0.04	0.02
BA/LA	—	0.74	0.61	0.47	0.32
BM/LM	—	0.29	0.27	0.11	0.06
$(M/A)_t$	—	0.30	0.29	0.27	0.26
$(M/A)_d$	1.47	0.93	0.83	0.80	—
$(M/A)_0$	1.15	—	0.26	—	—

The compositions were obtained by means of NMR as follows:

$$LA = H_d - H_e/3$$
$$LM = H_f/2$$
$$BA = 2H_e/3 - H_d$$
$$BM = H_e/3 - H_f/2$$

where H_c, H_e, H_f, and H_d represent the relative intensities of the protons of CH_3COO–, –$COOCH_3$, –$COOCH_2$–, and of the sum of the protons of –CH_2COO– and >$CHCOO$– respectively. The high ratio of the branched telomer, BA, to the linear telomer, LA, was observed under a pressure of 20 kg/cm² at 130—140 °C, and the ratio decreased with a rise in the reaction temperature. In acetate telomers, the ratio (BM/LM) of branched to linear telomers also shows a tendency similar to that of methyl ester telomers. However, the lower ratio of BM/LM suggests that the α-hydrogen of the alkoxy moiety in the acetates is less reactive as a whole for homolytic hydrogen abstraction than that of the carboxylic moiety in the methyl esters.

The chain-transfer constants of the telomer radicals in this system could not be evaluated, but the broad distributions of the LA and LM telomers suggest quite small-chain-transfer constants of ω-methoxycarbonylalkyl and ω-acetoxyalkyl radicals (Figs. 2 and 3). A lower reactivity of ω-acetoxyalkyl radicals in the chain-transfer reaction than that of the ω-methoxycarbonylalkyl radicals was also suggested by the broader distribution in the acetate telomers, LM. The sharp distribution of the cyanoacetate telomers, N_n, compared with that of the methyl ester telomers, LA, shows that the introduction of the cyano group to methyl acetate at the α-position gave a favorable system for a chain-transfer reaction.

Relative Reactivity of the Methoxy Group to the Acetyl Group. In the telomerization of methyl acetate with ethylene, the abstraction of a hydrogen atom from methoxy and acetyl moieties in methyl acetate was indicated by the formation of acetate and methyl ester telomers. The relative reactivity of the methoxy group to the acetyl group in methyl acetate for hydrogen abstraction was estimated by means of the ratio ($(M/A)_t$) of the amounts of acetate telomers to that of methyl ester telomers in the telomerization. The ratio was 0.30 at 130 °C; it was slightly decreased with a rise in the reaction temperature (Table 7). The ratio suggests that the relative reactivity of the methoxy group is higher than that of the alkoxy moiety to the acetyl group in ethyl and isopropyl acetates.[17] Therefore, it was compared with the ratio ($(M/A)_d$) of the amount of the acetoxy group to that of the methoxycarbonyl group in the product of the decomposition of DTBP in methyl acetate, and with the formation ratio ($(M/A)_0$) of nonyl acetate to methyl decanoate in the addition of methyl acetate to 1-octene initiated by DTBP. The $(M/A)_d$ ratio was estimated from the ratio of the proton intensity of the acetyl group to that of the methoxy group in the product, which contained mainly methyl succinate, ethylene diacetate, and methyl 3-acetoxypropionate. The $(M/A)_0$ ratio was measured by means of glc. The ratios of $(M/A)_d$ and $(M/A)_0$ are given in Table 7.

The $(M/A)_d$ and $(M/A)_0$ ratios suggest that the methoxy group is more reactive for hydrogen abstraction than the acetyl group at 20 °C, and that the relative reactivity of the methoxy group decreases with a rise in the temperature. The value of $(M/A)_0$ was the same as that of $(M/A)_t$ at 140 °C; it was presumed to be higher than that in the addition of 1-octene with

methyl acetate initiated by di-isopropyl peroxydicarbonate.[18]. The $(M/A)_d$ ratio at the same temperature showed that the relative reactivity of the methoxy group was higher in the absence of ethylene or 1-octene. The difference in the relative reactivity of the methoxy group may be caused by a difference in the extent of contributions of the *tert*-butoxy, methyl, and telomer radicals to hydrogen abstraction from methyl acetate. In the decomposition of DTBP in methyl acetate, a hydrogen atom of methyl acetate may be abstracted by the methyl and *tert*-butoxy radicals formed by the decomposition of DTBP. Methyl radicals predominantly abstract a hydrogen atom from the acetyl group in methyl acetate,[19] whereas a hydrogen atom of the methoxy group in methyl acetate may be abstracted mainly by electrophilic *tert*-butoxy radicals.[20] Therefore, the high value of $(M/A)_d$ may be attributed to the large extent of the contribution of *tert*-butoxy radicals to the hydrogen abstraction. In the presence of olefins, the relative reactivity of the methoxy group may be apparently decreased by the contribution of additional hydrogen abstraction by telomer radicals, which are expected to be similar reactive with alkyl radicals in hydrogen abstraction. The relatively higher values of $(M/A)_t$ and $(M/A)_0$ may be caused by some contribution of *tert*-butoxy radicals to the hydrogen abstraction in the telomerizations with short kinetic chain lengths.

Experimental

Materials. Commercial methyl acetate was treated with acetic anhydride and with potassium carbonate in the usual way, then distilled. Commercial methyl cyanoacetate was dried over anhydrous magnesium sulfate, then distilled. Commercial 1-octene was distilled. The DTBP, ethylene, and methyl esters of linear alkanoic acids were obtained commercially. The methyl esters of α-branched alkanoic acids were prepared from the corresponding acids and methanol. The methyl 2-cyanoalkanoates and 2-alkyl-2-cyanoalkanoates were prepared from alkyl bromides and methyl cyanoacetate or the corresponding methyl 2-cyanoalkanoates.[21] Acetates and cyanoacetates were prepared from the corresponding alcohols and acetyl chloride or cyanoacetic acid. These reference samples were confirmed by elemental analyses and by a study of the IR and NMR spectra.

Telomerization. *Procedure A*: A mixture of methyl acetate (100 g) and an initiator (0.015 mol/mol) was placed in a 300 ml stainless-steel autoclave, air was displaced with ethylene, and ethylene was introduced until a pressure of 40 kg/cm² was reached at room temperature. The mixture was then heated at the prescribed temperature with stirring. *Procedure B*: A mixture of 150 g of methyl acetate and 7.5 g of DTBP was heated at the prescribed temperature in the autoclave. During the reaction, ethylene was introduced to keep the pressure prescribed for that temperature.

The telomerization of methyl cyanoacetate with ethylene was carried out by Procedure B, using 150 g of methyl cyanoacetate and 4.4 g of DTBP.

Hydrolysis of Telomers. A mixture of 7.6 g of the telomerization product of methyl acetate with ethylene, 5.0 g of potassium hydroxide, and 50 ml of ethanol was heated at 180 °C for 8 hr in an autoclave. The aicd (5.0 g) and the neutral fractions (1.9 g) were subsequently separated in the usual way.

Separation of Hydrocarbons. Hydrocarbons (0.127 g) were separated from the telomerization product (1.014 g) of methyl acetate with ethylene using a silica-gel-column with petroleum ether.

Identification of the Products. A gas chromatographic determination was made on 2.25 m and 4.0 m columns packed with PEG-20M (30% on Celite 545) for the telomerization products of methyl acetate with ethylene, and on a 2.25 m column packed with Apiezone Grease L (30% on Celite 545) for the telomerization products of methyl cyanoacetate with ethylene, with helium as the carrier gas. The IR and NMR spectra were measured on JASCO IR-A2 and JEOL JNM-C-60HL spectrometers respectively. The mass spectra were measured on a Hitachi RMU-6L mass spectrometer combined with a gas chromatograph. The reaction mixture was fractionated by the use of a spinning-band column.

Methyl Alkanoates LA_n: The retention times (min) of LA_1—LA_4, measured using a 4.0 m column at 140 °C and of LA_5—LA_7, measured using a 2.25 m column at 240 °C, agreed with those of authentic methyl esters as follows (LA_n, the retention time, reffered to methyl ester, and its retention time): LA_1, 1.75, butanoate, 1.72; LA_2, 4.45, hexanoate, 4.40; LA_3, 11.10, octanoate, 11.06; LA_4, 27.76, decanoate, 27.75; LA_5, 3.01, dodecanoate, 2.99; LA_6, 5.21, tetradecanoate, 5.22; LA_7, 9.02, hexadecanoate, 8.97. The IR and NMR spectra of LA_n (n=1—5), which were collected by preparative glc, and the mass spectra of LA_n(n=1—7) also supported the above identification. The signals in the NMR spectra were as follows (signal, τ value, and assignment): a, 9.07—9.15(t), CH_3–; b, 8.35—8.77 (m), $-CH_2-$; c, 7.82—7.84 (t), $-CH_2COO-$; d, 6.48—6.49 (s), $-COOCH_3$.

Alkyl Acetates LM_n: The retention times of LM_n (n=1—4), measured using a 4.0 m column at 140 °C, and of LM_n (n=5—7), measured using a 2.25 m column at 240 °C, agreed with those of authentic acetates as follows (LM_n, retention time, referred to acetate, and its retention time): LM_1, 1.66, propyl, 1.57; LM_2, 4.07, pentyl, 4.09; LM_3, 10.20, heptyl, 10.11; LM_4, 25.39, nonyl, 25.34; LM_5, 2.76, undecyl, 2.80; LM_6, 4.87, tridecyl, 4.90; LM_7, 8.44, pentadecyl, 8.50. The retention times of tridecyl and pentadecyl acetates were estimated using the relation between the retention times and the number of carbon atoms in the homologues. The mass spectra of LM_n (n=1—7) also supported the above identification.

Methyl α-Branched Alkanoates BA_n: The retention times of BA_n (n=1—5), measured using a 4.0 m column at 140 °C, agreed with those of authentic esters as follows (BA_n, retention time, referred methyl ester, and its retention time): BA_1, 2.86, 2-ethylbutanoate, 2.79; BA_2, 6.22, 2-ethylhexanoate, 6.17; BA_3, 13.16, 2-butylhexanoate, 13.10; BA_4, 14.70, 2-ethyloctanoate, 14.74; BA_5, 31.08, 2-butyloctanoate, 30.9. The retention time of methyl 2-butyloctanoate was estimated from those of the homologues. The IR and NMR spectra of BA_n (n=1—3), which were collected by preparative glc, and the mass spectra of BA_n (n=1—4) also supported the above identification. The signals in the NMR spectra were as follows (signal, τ value and assignment): a, 9.10—9.15 (t), CH_3–; b, 8.56—8.74 (m), $-CH_2-$; c, 7.82—7.87 (m), $>CHCOO-$; d, 6.38—6.47 (s), $-COOCH_3$.

α-Branched Alkyl Acetates BM_n: The retention times of BM_1, measured using a 2.25 m column at 80 °C, and of BM_2 and BM_3, measured using a 4.0 m column at 150 °C, agreed with those of authentic acetates as follows (BM_n, retention time, referred acetate, and its retention time): BM_1, 8.12, 1-ethylpropyl, 8.19; BM_2, 5.53, 1-ethylpentyl,

5.52; BM_3, 11.30, 1-butylpentyl, 11.31. BM_2 and BM_3 were also confirmed by mass spectrometry. The nonan-5-ol (with a retention time of 9.92 min at 150 °C using a 4.0 m column) in the neutral fraction was detected by glc, as were the alcohols corresponding to LM_n (n=1—7) and BM_n (n=1—3).

Hydrocarbons: The retention times of the e_1—e_4 peaks and of the e_5—e_7 peaks were measured at 140 °C with a 4.0 m column and at 240 °C with a 2.25 m column respectively. The retention times and the *m/e* of the parent ion peaks of the components of the e_n peaks (n=1—7) were as follows (e_n, retention time, *m/e* of parent ion peak, and n in CH_3-$(CH_2CH_2)_nH$): e_1, 1.13, 128, 4; e_2, 2.85, 156, 5; e_3, 7.02, 184, 6; e_4, 17.48, 212, 7; e_5, 2.17, 240, 8; e_6, 3.74, 268, 9; e_7, 6.50, —, 10.

Methyl α-Cyanoalkanoates N_n and B_n: The retention times of N_n (n=1—3) and B_n (n=1—5) at 190 °C agreed with those of authentic esters as follows (N_n or B_n, retention time, referred to methyl ester, and its retention time): N_1, 0.97, 2-cyanobutanoate, 0.96; N_2, 2.24, 2-cyanohexanoate, 2.24; N_3, 5.44, 2-cyanooctanoate, 5.45; B_1, 1.56, 2-cyano-2-ethylbutanoate, 1.57; B_2, 3.33, 2-cyano-2-ethylhexanoate, 3.32; B_3, 6.74, 2-butyl-2-cyanohexanoate, 6.72; B_4, 7.87, 2-cyano-2-ethyloctanoate, 7.85; B_5, 15.84, 2-butyl-2-cyano-octanoate, 15.83. The mass spectra of N_n (n=1—3) and B_n (n=1—5) also supported the above identification.

Propyl (1.18 min at 190 °C) and pentyl (2.97 min at 190 °C) cyanoacetates could not be detected by glc. Methyl 2-cyano-3-methyl-2-butenoate which had been collected by the use of a silica-gel-column with benzene was confirmed by elemental analysis, and by a study of its IR, NMR, and mass spectra.

Gas Chromatographic Analysis of Products. The gas chromatographic analysis of the telomerization products of methyl acetate with ethylene was made on a 2.25 m colum (PEG-20M, 30%). The column temperature was programed to rise at a rate of 4 °C/min from 80 °C to 240 °C. The amounts of the telomers relative to those of methyl 2-ethylhexanoate were determined by the use of calibration curves. The analysis of the telomerization products of methyl cyanoacetate with ethylene was made on a 2.25 m, column (Apiezone Grease L, 30%). The column temperature was programed to rise at a rate of 4 °C/min from 140 °C to 240 °C. Cyclododecane was used as the internal standard.

Determination of the Relative Ratios (M/A). Methyl acetate was removed from the reaction mixture of the telomerization of methyl acetate with ethylene by the use of a spinning-band column. The NMR spectra of the residues were measured in carbon tetrachloride.

The decomposition of DTBP (3.7 g) in methyl acetate (74 g) was carried out in an autoclave. The treatment of the reaction mixture was similar to that described above. The reaction of 1-octene (5.6 g) with methyl acetate (74 g) in the presence of DTBP was carried out much like the telomerization procedure. The ratio of the yield of nonyl acetate to that of methyl decanoate was determined by glc. In the experiments at 20 °C, the reaction mixture was irradiated with a high-pressure mercury lamp (UM-102).

The authors wish to thank Mr. Toshinori Shiraki, Mr. Keizo Fujiyama, Mr. Koichi Sonoda, Mr. Akira Morinaga, and Mr. Fumio Harada for their assistance in the experimental work.

Studies of Tritylated Sucroses. III. NMR Studies of Tritylacetylsucroses

Toshiki Otake

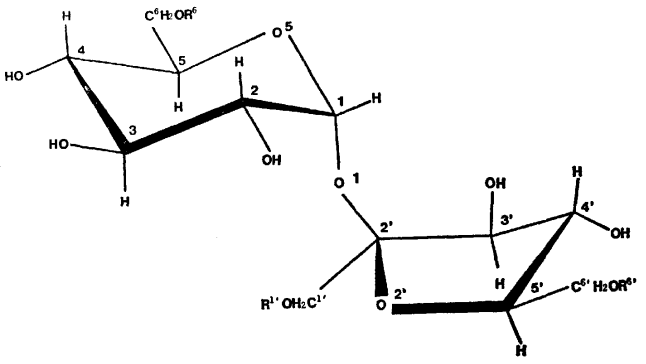
Nippon Electric Varian, Ltd., Azabu Iigura-machi, Minato-ku, Tokyo 106

(Received October 22, 1973)

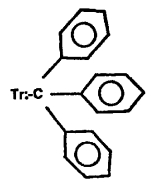
Seven tritylated derivatives have been synthesized by the tritylation of the primary hydroxyl group of sucrose. The ^{1}H NMR spectra of their peracetyl derivatives have been determined at 100 MHz and 220 MHz in order to assign the sugar-ring-proton signals with the aid of the double-resonance technique and NMR spin simulation. The relationship between the chemical shifts of their methine protons and the substituted position of the bonded trityl groups is discussed. Crystalline 1′-mono-*O*-tritylsucrose derived from 6,6′-di-*O*-palmitolysucrose is also described.

The preparations and the structures of two mono-*O*-tritylsucroses, 6′- (I) and 6-mono-*O*-tritylsucrose (II), and of 1′, 6-di-*O*-tritylsucrose (VI) were reported in previous papers.[1,2] The structures were mainly elucidated by ^{1}H NMR studies of the corresponding peracetyl derivatives and by gas-chromatographic studies of their partially-methylated derivatives. The structure of the tri-*O*-trityl derivative, 1′,6,6′-tri-*O*-tritylsucrose (VII), was established through complicated reaction routes without refering to the NMR spectra.[3-5]

In the NMR spectra of the tritylacetylsucroses, signals of protons on methylene carbons directly bearing an *O*-trityl group were observed in the region between δ 2 and 3.5. However, the author did not assign the



I $R^{6'}=Tr$ $R^{1'}=R^{6}=OH$
II $R^{6}=Tr$ $R^{1'}=R^{6'}=OH$
III $R^{1'}=Tr$ $R^{6}=R^{6'}=OH$
IV $R^{6}=R^{6'}=Tr$ $R^{1'}=OH$
V $R^{1'}=R^{6'}=Tr$ $R^{6}=OH$
VI $R^{1'}=R^{6}=Tr$ $R^{6'}=OH$
VII $R^{1'}=R^{6}=R^{6'}=Tr$



methine proton signals which appear in the region between δ 4.5 and 6.0; these signals show characteristic patterns according to the number and positions of trityl groups on a sucrose molecule. The chemical shifts and coupling constants for the methine and methylene protons of octa-*O*-acetylsucrose (VIII) had already been determined with the aid of the double-resonance technique and the multi solvent method.[6]

This paper will deal with the assignment of methine-proton signals in the tritylacetylsucroses and with the relationship between the methine chemical shifts and the anisotropic effects exerted by a trityl group. Further, it is suggested that the difference in the chemical shifts of methine or methylene protons between a tritylacetyl and a peracetyl derivative of an oligosaccharide provides valuable information about its stereostructure or conformation in solution.

Results and Discussion

As has been described in previous papers,[1,2] 1′-mono-*O*-tritylsucrose (III) was not found in the reaction product of sucrose with trityl chloride in pyridine, although di- and tri-*O*-tritylsucroses with a trityl group at the 1′-position were found in the product. The reaction of 6,6′-di-*O*-palmitoylsucrose[7] with trityl chloride in a 1 : 2 mole ratio in pyridine gave 1′-mono-*O*-trityl-di-*O*-palmitoylsucrose (IX) as the main product. In the reaction solution, the presence of unreacted trityl chloride and di-*O*-palmitoylsucrose, and a minor amount of poly-*O*-trityldi-*O*-palmitoylsucroses were also observed by thin-layer chromatography. Compound IX which had been isolated by column chromatography, was deacylated to give III. The procedure used to prepare the remaining six tritylacetylsucroses was described in the previous papers.[1,2] Recently, Buchanan[8] and Suami and Ikeda[9] have reported the synthesis of 6′-mono-*O*-tritylhepta-*O*-acetylsucrose (I′) and a peracetyl derivative of 1′,6′-di-*O*-tritylsucrose (V′) from 2,3,6,3′,4′-penta-*O*-acetylsucrose.

Figure 1 shows parts of the 220 MHz NMR spectrum of III′, which gives the expected seven signals of acetylmethyl-protons at δ 1.85 (3H), 1.97 (3H), 1.99(3H), 2.02(3H), 2.03(3H), 2.08(3H), and 2.10(3H), and also an AB-type quartet at δ 3.17 and 3.24 which arises from the isolated oxymethylene protons at the 1′-position. These signals together with the relative integrated intensity of the trityl group which corresponds to 14.83 protons (theory, 15 protons), and that of the acetyl groups, which corresponds to 20.96 protons (theory, 21 protons), account for the expected structure of III′.

In the NMR spectra of the tritylacetylsucroses with an acetyl group at the 6-position, such as 1′-mono- (III′), 6′-mono- (I′), and 1′,6′-di-*O*-tritylacetylsucrose (V′), all the methine-proton signals except those due to H-5 and H-5′ were readily assigned with the aid of the double-resonance technique, the results are shown in Figs. 1, 2, and 3. The analysis of the complicated signals between δ 5.2 and 5.6 in the spectrum of I′ was made by the spin-simulation method; these results are also shown in Fig. 2.

When a trityl group is situated at the 6-position, as in

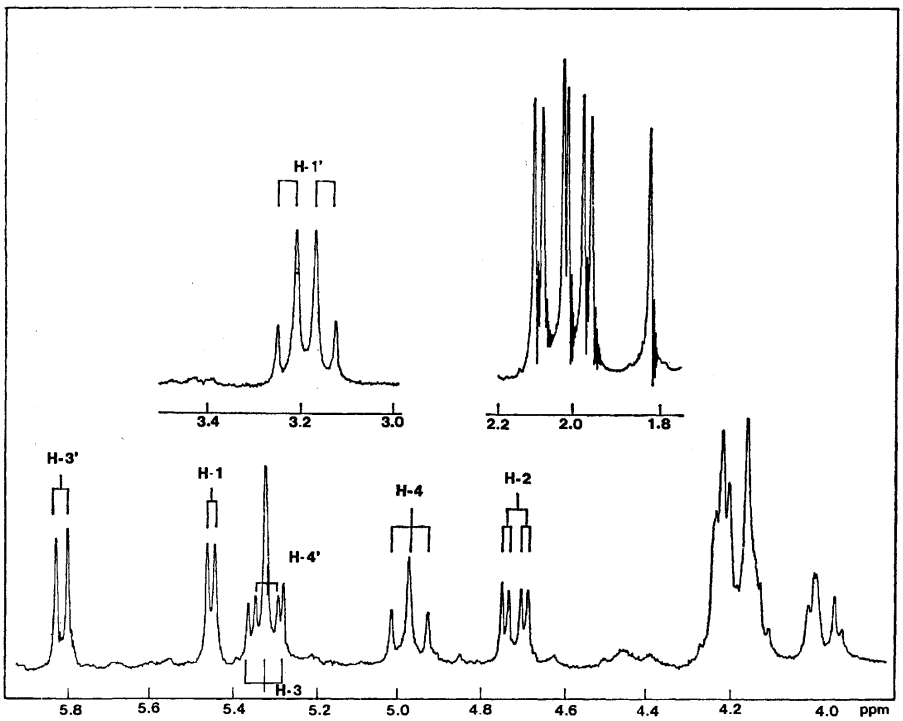


Fig. 1. Parts of the NMR spectrum at 220 MHz of III'.

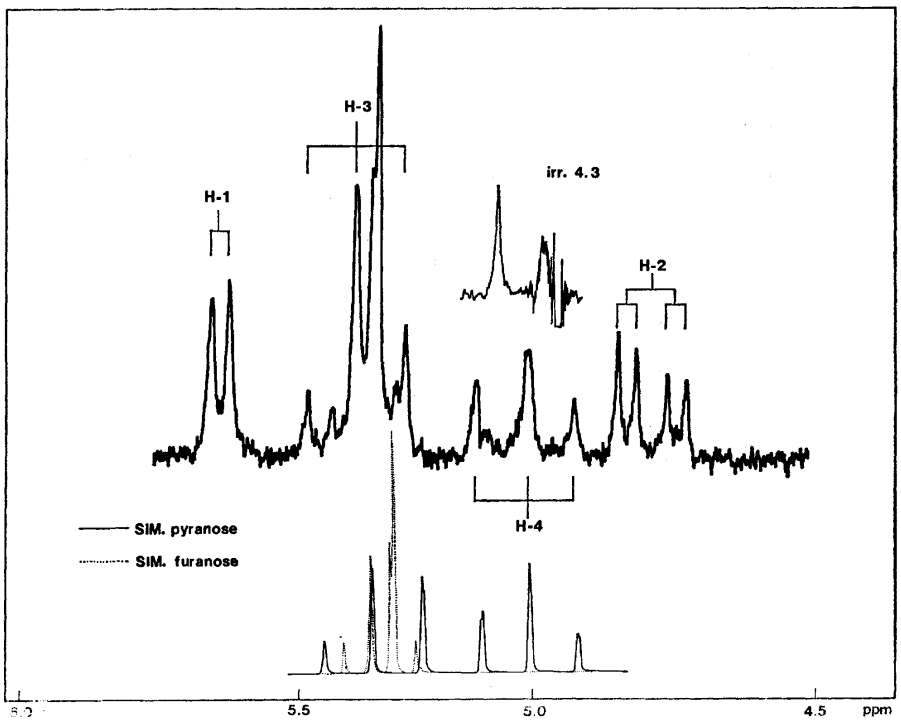

Fig. 2. A part of the NMR spectrum at 100 MHz of I'

the cases of 6-mono- (II'), 6,6'-di- (IV'), I',6-di- (VI'), and 1',6,6'-tri-*O*-tritylacetylsucrose (VII'), the access of the H-3 and H-4 signals and the overlapping of other signals make their assignments difficult, especially at 100 MHz. An approximate first-order analysis was applied to the methine-proton signals in the 220 MHz spectrum of II', which was confirmed by a spin simulation; the results are shown in Fig. 4. The signals due to H-3 and H-4 in IV' and VII' show symmetrical, but overlapping patterns near δ 5.2 in their 220 MHz spectra and correspond to the AB part of an ABXY system, where J_{AX} equal J_{BY}. They were simulated using appropriate parameters, as is shown in Figs. 5 and 6. In the 220 MHz spectrum of VI', the signals due to H-3 and H-4 lie between δ 5.20 and 5.35 (Fig. 7). By analogy with the cases of IV' and VII', the chemical shifts of H-3 and H-4 may have a value almost equal to that corresponding to

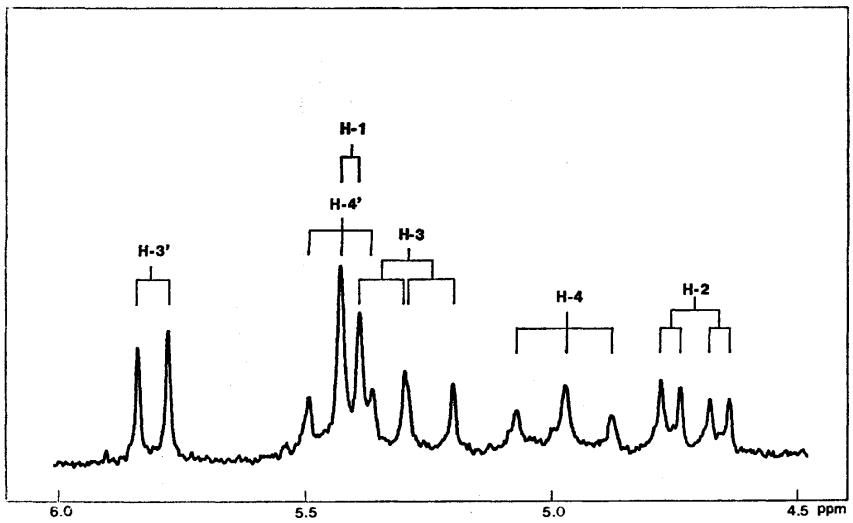

Fig. 3. A part of the NMR spectrum at 100 MHz of V'.

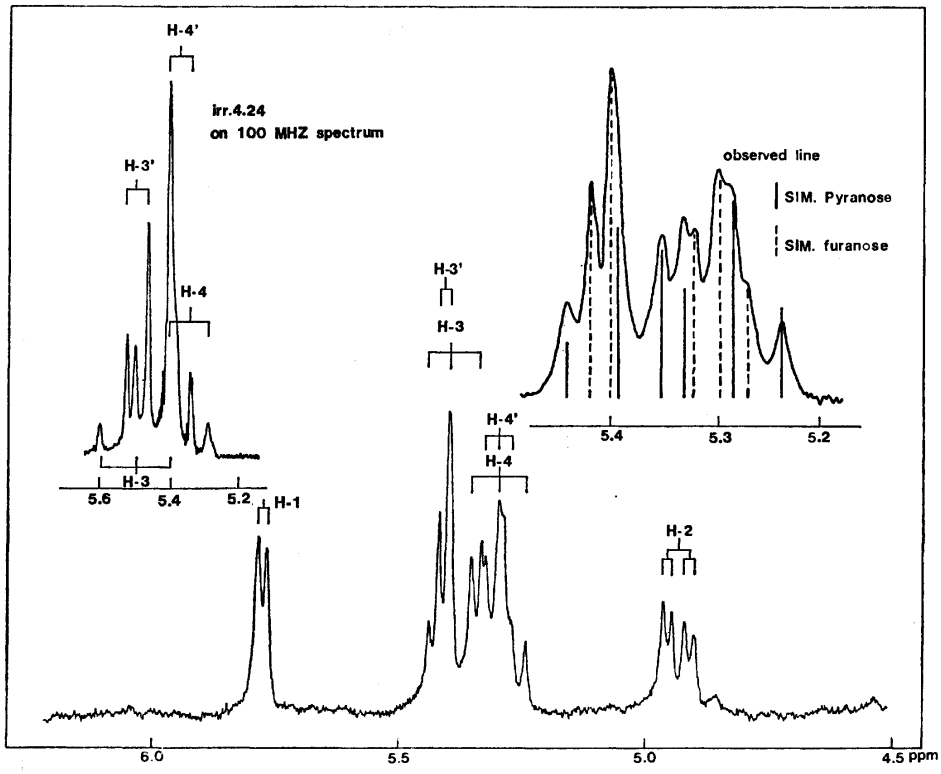

Fig. 4. Parts of the NMR spectrum at 220 MHz of II'.

the frequency of either of the two intense signals appearing in this region, that is, δ 5.31 or 5.27. The remaining methine-proton signals of this group of compounds, II', IV', VII', and VI' are well resolved and were readily assigned at 220 MHz.

The assignment of the signals of H-4 by irradiating H-5 signals was achieved only in the case of II'. For the other compounds of this group, the assignment of the H-4 signals was unsuccessful, because the chemical shifts of H-3 are too close to those of H-4.

The coupling constants applied to NMR spin simulation are listed in Table 1. The chemical shifts of all the methine protons except those of H-5 and H-5' in the tritylacetylsucroses examined are listed in Table 2.

Table 1. Coupling constants (Hz) applied to NMR spin simulation for tritylacetylsucroses

Compound	$J_{2,3}$	$J_{3,4}$	$J_{4,5}$	$J_{3',4'}$	$J_{4'5'}$
I'	9.5	10.0	10.0	5.3	5.5
II'	9.5	10.0	10.0	5.0	5.0
IV'	10.0	10.0	10.0	—	—
VII'	10.0	10.0	10.0	—	—

The differences in chemical shifts between a methine proton of octa-*O*-acetylsucrose (VIII) and the cor-

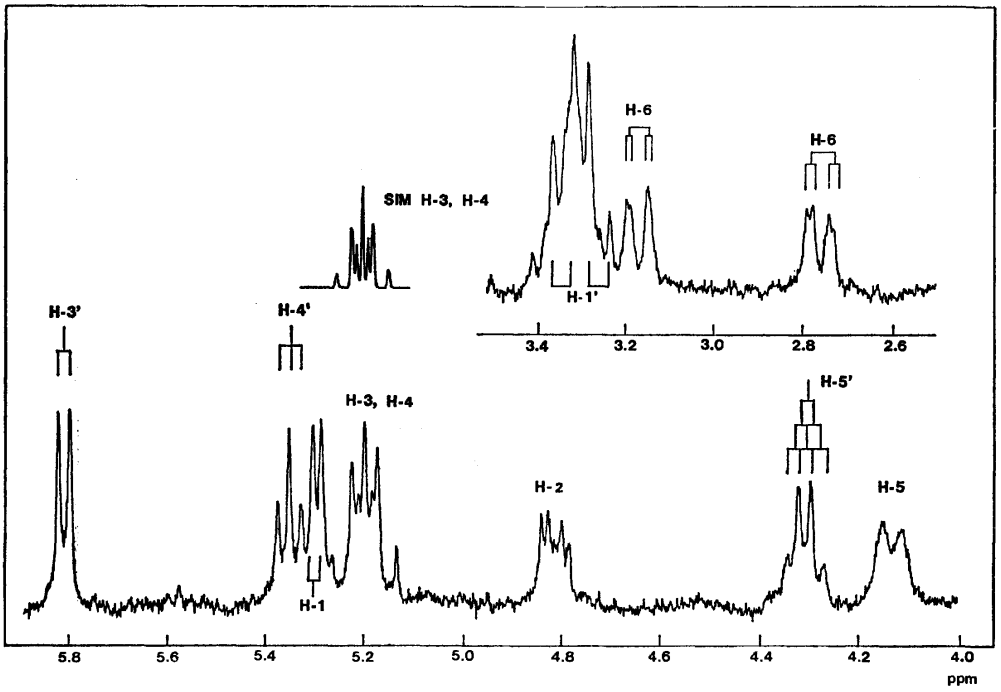

Fig. 5. Parts of the NMR spectrum at 220 MHz of VII'.

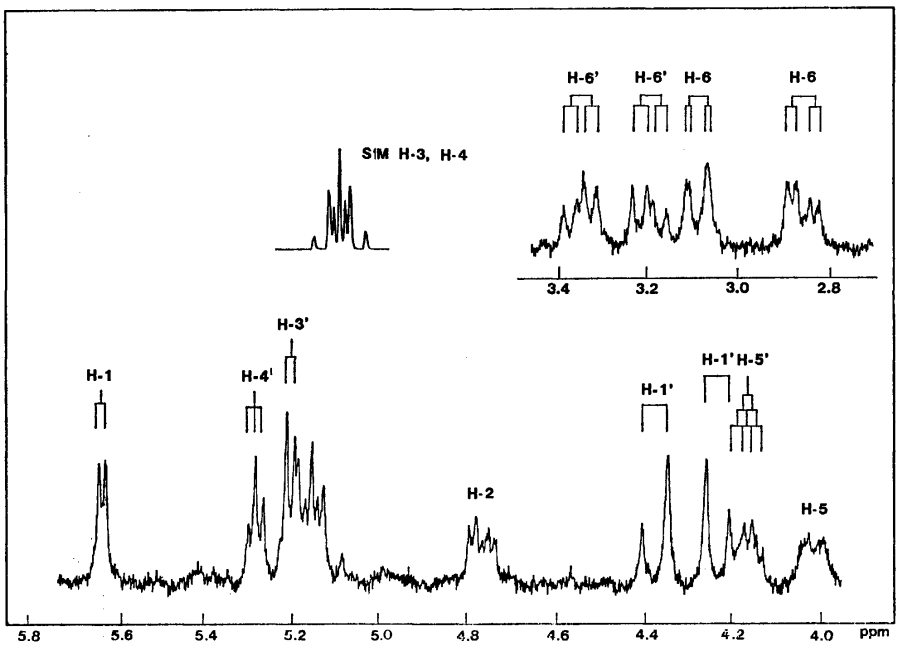

Fig. 6. Parts of the NMR spectrum at 220 MHz of V'.

responding proton of each tritylacetylsucrose (Δ) are listed in Table 3. A positive Δ value represents a downfield shift of a proton signal from VIII to a tritylacetylsucrose.

Each compound has its characteristic set of Δ values. The protons, H-3' in III', H-4 in II', and H-4' in I', resonate at lower fields than the corresponding protons in VIII. In spite of the similarity in the positional relationship between each proton and the trityl group, as will be shown below, the difference in the magnitude of the deshielding effects upon these protons should be considerable.

When a methine proton shares a hexose ring with a trityl group, it generally suffers a deshielding effect as in the cases of H-2 and H-3 in II', and that of H-4' in III', but not the case of H-3' in I'. In all the mono-*O*-tritylacetylsucroses, the methine protons bonded to the hexose ring with no trityl group resonate at a slightly higher field than the corresponding protons in VIII.

The anisotropic shielding effect, σ (expressed in ppm), that is, the ring-current effect of a benzene ring, is well known.[10] The surface where $\sigma=0$ is approximated by a double cone, the axis of which is shared

VI'	−0.23	−0.15	−0.16	−0.10	+0.36	+0.06
VII'	−0.38	−0.06	−0.23 or −0.28	+0.11 or +0.16	+0.37	−0.01

with the hexad axis of the ring; the inside of the cone is the shielding region, and the outside, the deshielding region. The rotation of a phenyl of a trityl group about the bond to the methane carbon # (C_{TM}) is sterically hindered, while the trityl group as a whole can rotate around the C–O bond (TOB), thus dividing the space into several regions, as is shown in Fig. 8. A proton in the P region surrounding the TOB bond

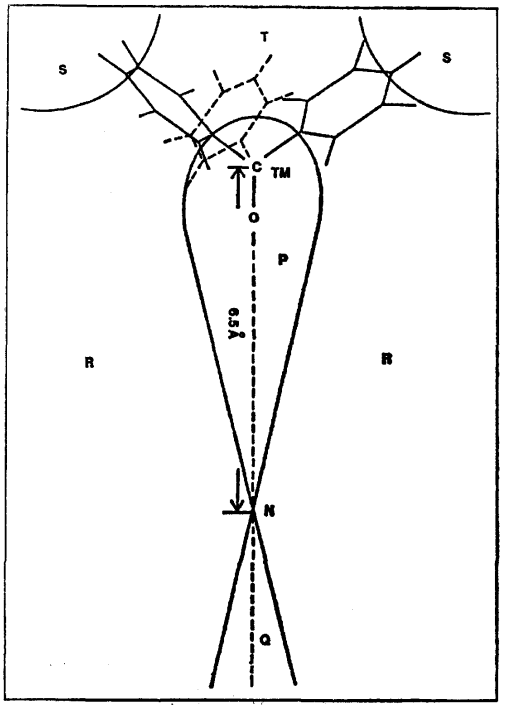

Fig. 8. A schematic representation of the anisotropic shielding effects exerted by a trityl group.

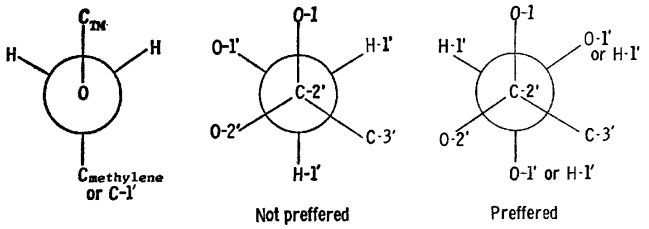
always suffers a deshielding effect, while that in the Q region suffers a shielding effect. The distance between C_{TM} and the node, N, of P and Q is estimated to be about 6.5 Å, with reference to the structure of triphenylmethane in the gas phase, as determined by the electron-diffraction method.[11] In the R region, the outside of the P and Q cores, the sign of the shielding effect, σ, is not clear. However, in view of the cancellation of a positive with a negative effect, the magnitude of σ in this region could not be very large. The methine protons in the tritylacetylsucroses should never be included in the S and T regions.

Thus, rotation about the bond which bears a trityl group causes a wide range of shielding or deshielding effects on a proton near this group. In all the tritylacetylsucroses, the rotation about the bond between the methylene carbon and the oxygen atom is appreciably restricted in such a conformation as (A). Any other conformations about the $C_{methylene}$–O bond make the distance between a phenyl group and various parts of the sucrose moiety too short. In III′, such a conformation as (B) is avoided, as by the Δ-2 effect in the case of glycopyranosides,[12] and the conformation illustrated as (C) is perferred. The trityl group is almost fixed; therefore, H-3′ may mostly be included in the P core, the deshielding region.



(A) (B) (C)

The C-5′ in I′ and C-5 in II′ are both attached with only one oxygen atom, and so the conformational restriction about C-5′–C-6′ or C-5–C-6 may be less than that about C-2′–C-1′. Then, H-4′ in I′ and H-4 in II′ may experience a shielding-deshielding averaging effect more than does H-3′ in III′. A proton on a ring with no trityl group may be included in the Q core, the shielding region which extends from the node, N.

The applicability of the additive rule for the Δ-value of di-*O*- and tri-*O*-tritylacetylsucroses has been examined. Each Δ value for a certain methine proton in a poly-*O*-tritylacetyl derivative agrees, in general, with the sum of the corresponding Δ values of mono-*O*-trityl derivatives, although there are some exceptions. This fact suggests that the disposition of a trityl group or the conformation of a sucrose moiety remains almost unchanged.

Experimental

General Methods. The NMR spectra were recorded on a Varian HA-100D (100 MHz) and an HR-220 (220 MHz) spectrometer, using chloroform-*d* solutions and with tetramethylsilane as the internal reference. The chemical shifts are expressed in δ. The NMR simulation was accomplished by means of a Varian Spectro System SS-100 equipped with a Varian 620/i computer. Thin-layer chromatography was carried out using Merck silica gel G as an adsorbent in a thickness of 0.25 mm. The developed plate was sprayed with 50% sulfuric acid and heated at 120 °C. Column chromatography was carried out using silica gel, 60—80 mesh (Kanto Chemical Co.).

1′-*Mono*-O-*tritylsucrose* (III). Crystalline 6,6′-di-*O*-palmitoylsucrose (1.278 g, mp 108—109 °C) which had been extracted from commercial sucrose palmitate, followed by crystallization, was reacted with recrystallized trityl chloride (0.834 g) which has twice the molarity of the ester, in dry pyridine (5 ml) at room temperature. Then the solution was allowed to stand for 96 hr. At the end of the reaction period, the solution was concentrated *in vacuo* at 40 °C until it became a hard syrup. Then the syrup was chromatographed on 10 g of silica gel. After the column had been washed with chloroform (200 ml) and 3% methanol–chloroform (70 ml), 6,6′-di-*O*-palmitoyl 1′-mono-*O*-tritylsucrose (IX) was eluted with 5% methanol–chloroform (200 ml). The evaporation of the last solution left 441 mg of IX as an amorphous solid. The thin-layer chromatogram developed by an admixture of methanol–tetrahydrofuran–water–methylene chloride 5 : 7 : 0.2 : 88 (vol/vol/vol/vol) showed the residue to be homogeneous, with an R_f value of 0.59. After the IX (400 mg) had then been dissolved by 5% ammoniac methanol (20 ml), the solution was allowed to stand for 24 hr at room temperature to remove the palmitoyl group. Then the solution was dried *in vacuo*, followed by the addition of methanol and reconcentration. The residue was chromatographed on a silica gel (10 g) column. After washing with 5% methanol–chloroform, III was eluted with 10% methanol–chloroform (200 ml). The residue of evaporation gave 201 mg of III.

Repeated crystallization from a 20% methanol–chloroform solution gave needles which melted at 193—196 °C and which had an $[\alpha]_D^{23}$ of +70.4° (*c* 1, methanol).

Found: C, 63.11; H, 6.40%. Calcd for $C_{31}H_{26}O_{11}$: C, 63.69; H, 6.21%.

1′-*Mono*-O-*tritylhepta*-O-*acetylsucrose(III′)*. 1′-Mono-*O*-tritylsucrose, III (100 mg), was dissolved in 2 ml of dry pyridine and then acetylated with acetic anhydride (0.3 ml) for 24 hr. The residue of evaporation *in vacuo* was chromatographed on silica gel (10 g) by washing the gel with 200 ml of toluene and 200 ml of 10% methyl ethyl ketone–toluene. The evaporation of the last washings gave 121 mg of III′, which had an $[\alpha]_D^{20}$ of +76.5° (*c* 1.59, $CHCl_3$).

Found: C, 61.67; H, 5.44%. Calcd for $C_{45}H_{50}O_{18}$: C, 61.50; H, 5.73%.

Other Materials. All the mono- and di-*O*-tritylacetylsucroses except III′ and V′ were prepared by the methods reported previously.[1,2] The tri-O-trityl derivative(VII′) was prepared by the method of Bredereck and his-co-workers. The authentic sample of V′ was synthesized by Suami and Ikeda through 2,3,6,3′,4′-penta-*O*-acetylsucrose; it melted at 100.0—102.0 °C and had an $[\alpha]_D^{20}$ of +58.4° (*c* 2.49, $CHCl_3$).

Found: C, 69.17; H, 5.70%. Calcd for $C_{62}H_{62}O_{17}$: C, 69.01; H, 5.79%.

The author wishes to thank Rrof. T. Suami, Keio University, for providing him with an authentic sample of 1′,6′-di-*O*-tritylhexa-*O*-acetylsucrose, Dr. T. Nishida for determining the 220 MHz NMR spectra, and Mr. K. Kushida for the 100 MHz NMR spectra.

Asymmetric Synthesis in the Oxymercuration Reaction Using Optically Active Mercuric Salts[1)]

Toshio SUGITA, Yasuo YAMASAKI, Osamu ITOH, and Katsuhiko ICHIKAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 5, 1973)

The oxymercuration-demercuration of styrene with optically active mercuric tartrate, 2-phenylpropionate, mandelate, camphorate, menthoxyacetate, and monomethyl tartrate resulted in a partial asymmetric synthesis of 1-phenylethanol. When mercuric tartrate was used, exceptionally high optical yields (25—32%) were observed. The mechanisms for the asymmetric synthesis are discussed.

In many stereochemical investigations of the oxymercuration of olefins, asymmetric syntheses have recently been reported. Partial asymmetric syntheses were achieved in the methoxymercuration of the menthol and sugar esters of $\alpha\beta$-unsaturated acids.[2)] In these investigations, the chiral moiety resided in the olefinic part. As part of an investigation of asymmetric oxymercuration using optically active mercuric salt as a chiral center, Wright[3)] reported that two diastereomeric methoxymercurials were obtained in unequal amounts by the methoxymercuration of cyclohexene with mercuric (+)-lactate. After we had presented the results of asymmetric oxymercuration which would be included in the present paper, Carlson and Funk[4)] reported similar results using decene, octene, heptene, and allylbenzene as the olefinic substrates. However, the author did not refer to the stereochemical reaction mechanisms at all.

The present paper will deal with the results of the asymmetric synthesis of 1-phenylethanol (**3**) *via* the oxymercuration of styrene (**1**) with mercuric salts of chiral acids, utilizing the convenient and mild oxymercuration-demercuration procedure developed by Brown.[5)]

Styrene (**1**) was subjected to an oxymercuration reaction with an equivalent amount of mercuric salts in 50% aqueous tetrahydrofuran (THF) at 25 °C, and the resulting oxymercurials were submitted to demercuration *in situ* with alkaline sodium borohydride. The resulting **3** was purified by means of fractional distillation and, in some cases, by preparative vapor phase chromatography (vpc). The possibility of racemization of the reaction products during demercuration was safely excluded by the confirmation of the constant optical purity of chiral **3** in an alkaline medium. The results are summarized in Table 1.

$$\underset{(1)}{C_6H_5\text{-}CH{=}CH_2} \xrightarrow[H_2O\text{-}THF]{Hg(OCO\overset{*}{R})_2\ (2)} \xrightarrow{NaBH_4} \underset{OH}{C_6H_5\text{-}\overset{*}{C}H\text{-}CH_3}\quad (3)$$

As is shown in Table 1, an exceptionally high optical yield of **3** was observed when mercuric tartrate (**2a**) was used. On the contrary, the other chiral mercuric salts (**2b-g**) gave very low or no measurable optical yields.

It is well known in oxymercuration that the addition of perchloric acid or Lewis acids such as boron trifluoride effectively accelerates the reaction. Inouye[2a)] reported that the methoxymercurations of (−)-menthyl crotonate, cinnamate, and β-methylcinnamate were accelerated by boron trifluoride etherate, and that the optical yields of these reactions were comparable to those without the catalyst. In the present system, the addition of boron trifluoride accelerated the reaction; however, only a slight asymmetric induction was achieved and the predominant product was (−)-**3**, which was enantiomeric to that without the catalyst.

The role of the acid catalyst is looked upon as promoting the dissociation of mercuric salts leading to the highly active acyloxymercuric cation, which then added to the olefin to yield the mercurinium ion.

$$(RCOO)_2Hg \overset{H^+}{\rightleftharpoons} RCOOHg^+ + RCOOH$$

$$\text{>C=C<} + RCOOHg^+ \rightleftharpoons \text{>C(HgOCOR)C<}$$

The chiral environment which the mercury atom of the mercuric tartrate cation, HOOC·CHOH·CHOH·COOHg$^+$, experiences seems to be similar to that of mercuric methyl tartrate (**2g**). Therefore, it is conceivable, on the basis of assumptions described above, that low asymmetric induction was observed in either case.

On the other hand, the oxymercuration proceeds very smoothly in methanol solvent, under such neutral conditions, the dissociation of usual mercuric salts cannot be considered so favorable, and the reacting species seems not to be the acyloxymercuric cation but mercuric salt itself. In this case, a molecular adduct

$$\text{>C=C<} + Hg(OCOR)_2 \rightleftharpoons \text{>C(Hg(OCOR)}_2\text{)C<} \rightleftharpoons \text{>C(HgOCOR)C<}$$

or π-complex is formed at first, and the configuration of the product is determined at this stage if the product is formed by the attack of the solvent molecule in *trans* fashion on the π-complex or mercurinium ion formed subsequently, as is generally accepted. The oxymercuration with **2a** was very slow as compared with the reaction using the other salts such as **2h**. This fact also seems to indicate that the tartrate anion

a) The reaction was carried on at 25 °C. b) The optical rotations were measured as pure liquid using 0.5 dm cell. c) Calculated from the value of α_D^{17} −11.0° (neat, l=0.25 dm): E. Downer and J. Kenyon, *J. Chem. Soc.*, **1939**, 1156. d) When the reaction was carried out for 1 day, no **3** was obtained. e) Under nitrogen atmosphere. f) BF_3-etherate (5 ml) was added. g) Equivalent amount of (+)-diethyl tartrate was added. h) Five equivalent amounts of (+)-diethyl tartrate were added.

strongly combines with mercury, and that the **2a** molecule adds to the olefinic double bond, making a molecular complex.

It is also interesting to note that the oxymercuration with mercuric acetate (**2h**) in a solvent containing (+)-diethyl tartrate produced asymmetric induction to some extent. Henbest[6] reported that, in the methoxymercurials obtained from 4-cyclohexenol and its derivatives, the mercury atom was oriented *cis* relative to the hydroxyl substituent, and he suggested that the coordination between the mercury atom and the substituent oxygen determined the stereochemical course of the addition. Although the complex-forming tendency of mercury toward oxygen is usually considered to be rather weak, it may be suggested that the glycol structure operates to endow a chiral environment to the mercury atom. Consequently, the mercury atom of **2a** becomes chiral by salt forming bonds as well as by coordinating bonds between mercury and hydroxyl oxygen, and it is likely that the complex-formation between **2a** and **1** is the stage of asymmetric synthesis.

When the mercury atom of **2a**, already coordinated by two carboxyl and two hydroxyl groups, makes a molecular complex with olefin, the mercury should have a coordination number more than four. Although the tetrahedral four-coordination is more common for mercury complexes, the six-coordinated mercury was suggested in an aqueous solution[7] and octahedral complexes of the type $(HgL_6)(ClO_4)_2$ were obtained when the donor atom was oxygen.[8] If octahedral six-coordination is assumed for mercuric (+)-(*R*,*R*)-tartrate (**2a**), the molecular complex of **2a** and **1** can be depicted as **4**, in which **1** favorably coordinates in the sterically less-hindered orientation. Mercuric (+)-tartrate (**2a**) in **4** has a C_2 chirality as a whole. Chiral complexes are usually more effective than simple chiral atoms in asymmetric inductions. It seems, therefore, to be a natural outcome that **2a** produces exceptionally high optical yields compared with **2b–g**, which is seemingly incapable of forming such a chiral complex. The S_N2-like attack of water on **4** or on the mercurinium ion derived from **4** gives (+)-(*R*)-**3**, which is the predominant isomer actually obtained. The results with **2a** reported by Carlson[4] are consistent with this mechanistic assumption.

Experimental

All the boiling and melting points are uncorrected. The optical activity measurements were carried out on a Zeiss polarimeter and a Yanagimoto ORD-185 recording spectropolarimeter.

Materials. Commercially-available (+)-tartaric acid, (−)-malic acid (mp 105.5—106.5 °C; $[\alpha]_D^{28}$ −1.48°, c=8.29, H_2O), and (+)-camphoric acid (mp 189—193 °C; $[\alpha]_D^{20}$ +47.8°, EtOH) were used without further purification. (+)-Mandelic acid (mp 134—134.5 °C; $[\alpha]_D^{20}$ +155.3°, H_2O) and (−)-2-phenylpropionic acid[9] (bp 133—135 °C/6 mmHg; $[\alpha]_D^{21}$ +73.1°, $CHCl_3$) were obtained by the resolution of each racemic acid with cinchonine and (−)-1-phenylethylamine respectively. (−)-Menthoxyacetic acid[10] (bp 161—169 °C/7 mmHg; $[\alpha]_D^{20}$ −94.9°, MeOH), (+)-methyl hydrogen tartrate[11] (mp 54.5—55.5 °C (monohydrate); $[\alpha]_D^{18}$ +14.7°,

c=21, H_2O), and (+)-diethyl tartrate (bp 140—141 °C/7 mmHg; $[\alpha]_D^{20}$ +7.66°, neat) were prepared by the known procedures. Some of these acids were not completely optically pure; however, the optical purities of the resulting **3** are listed in Table 1 without corrections.

Styrene and THF were distilled before use in each experiment.

Preparations of Mercuric Salts. (+)-Tartaric acid (50.0 g, 0.33 mol) in 150 ml of water was added slowly to a stirred clear solution of mercuric acetate (95.7 g, 0.30 mol) in 400 ml of water. After the mixture was stirred for a while, the resulting white precipitates were washed with water until the filtrate became neutral. After drying under reduced pressure, 98.2 g (94%) of mercuric (+)-tartrate (**2a**) were obtained. Mp>200 °C, no clear mp indicated. Found: Hg, 57.7%. Calcd for $C_4H_4O_6Hg$: Hg, 57.5%.

Mercuric (−)-2-phenylpropionate (**2b**); mp 94—95 °C (recrystallized from EtOH); $[\alpha]_D^{24}$ −59.1° ($CHCl_3$); yield, 70.2%. Found: Hg, 39.0%. Calcd for $(C_9H_9O_2)_2Hg$: Hg, 40.2%. Mercuric (+)-mandelate (**2c**); mp 172—172.5 °C; yield, 95.3%. Found: Hg, 39.9%. Calcd for $(C_8H_7O_3)_2Hg$: Hg, 39.9%. Mercuric (−)-malate (**2d**); mp>200 °C, no clear mp indicated; yield, 86.5%. Found: Hg, 57.2%. Calcd for $C_4H_4O_5Hg$: Hg, 60.3%. Mercuric (+)-camphorate (**2e**); mp 266 °C (decomp.); yield, 95.6%. Found: Hg, 49.3%. Calcd for $C_{10}H_{14}O_4Hg$: Hg, 50.3%. Mercuric (−)-menthoxyacetate (**2f**); mp 64—66 °C (recrystallized from EtOH-H_2O), $[\alpha]_D^{20}$ −59.8° ($CHCl_3$); yield, 66.8%. Found: Hg, 30.8%. Calcd for $(C_{12}H_{21}O_3)_2Hg$: Hg, 32.0%. Methyl mercuric (+)-tartrate (**2g**); mp 171—172 °C (decomp.); $[\alpha]_D^{18}$ +27.4° (H_2O); quantitative yield. Found: Hg, 35.7%. Calcd for $(C_5H_7O_6)_2Hg$: Hg, 38.1 %; for $(C_5H_7O_6)_2Hg\cdot 2H_2O$: Hg, 35.6%.

Analysis of Mercury. Adams' procedure[12] was modified. To 0.2 g of the mercuric salt were added 10 ml of 7% fuming sulfuric acid and 5 ml of fuming nitric acid. The mixture was heated until reflux, and to it was added water sufficient to dissolve the mercuric salt. Refluxing was continued with the addition of water in small portions until the evolution of NO_2 gas ceased. To the cooled, colorless, clear solution was added 1 drop of 4% potassium permanganate solution, the color of which persisted for 5 min. The excess permanganate was removed by means of 5% ferrous sulfate solution. The mercury in the prepared sample was titrated with 0.05 N KSCN solution, using ferric alum as an indicator (Volhard method).[13]

General Method of Oxymercuration-demercuration. Mercuric (+)-tartrate (**2a**, 17.5 g, 50.2 mmol) was suspended in 50 ml of water, to which was added 50 ml of THF. Styrene (**1**, 5.23 g, 50.2 mmol) was then added dropwise to the suspension under well-stirring at 25 °C, and the reaction mixture was stirred in dark at that temperature for 7.5 day. To the mixture were added 50 ml of 3.0 M NaOH and then sodium borohydride (0.90 g, 23.8 mmol) in 50 ml of 3.0 M NaOH, and the mixture was stirred for 15 min. The resulting metallic mercury was filtered off and the filtrate was saturated with NaCl and extracted with ether. The ether extract was washed with water and dried over Na_2SO_4. Distillation under reduced pressure gave 1.03 g (16.8%) of crude **3** (bp 84—85 °C/8 mmHg, n_D^{20} 1.5292), which contained **1**, acetophenone, benzaldehyde, and benzyl alcohol up to a total of 5%. The crude product was purified by preparative vpc (PEG-20M 25% on C-22 fire-brick, 3 m column), and submitted to optical rotation measurements, α_D^{20} +6.66° (neat, l=0.50 dm). The product was identified by elemental analysis and by comparisons of the vpc retention time and the IR and NMR spectra with those of an authentic sample.

In the cases of **2b**, **2c**, **2e**, and **2f** the starting acids were recovered without racemization from the aqueous layer of ether extraction.

*Treatment of **3** in an Alkaline Medium.* (+)-1-Phenylethanol (**3**, α_D^{19} +6.41°, neat, l=0.50 dm; 0.61 g) was stirred with 20 ml of 3.0 M NaOH, 10 ml of water, and 10 ml of THF at 25 °C for 19 hr. After work-up and distillation, 0.40 g of **3** (α_D^{19} +6.40°, neat, l=0.50 dm) was recovered.

Catalytic Hydration of Pyridinecarbonitriles in the Presence of $[Cu(en)_2]Cl_2 \cdot 2H_2O$ and $CuCl_2 \cdot 2H_2O$

Ken-ichi WATANABE and Kiyoshi MURAYAMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received December 25, 1973)

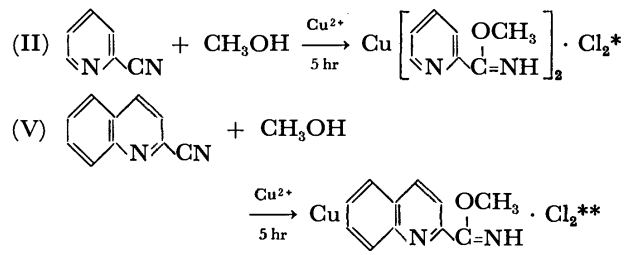
Spectrophotometric studies on the catalytic hydration of 2-pyridinecarbonitrile derivatives in the presence of $[Cu(en)_2]Cl_2 \cdot 2H_2O$ and $CuCl_2 \cdot 2H_2O$ under nearly neutral conditions revealed that the products are their amides. In some cases, the yields were calculated from the weight of amides obtained. The hydration of the nitrile group was influenced by electronic and steric effects. Selective hydration of the nitrile group in α-position was observed in the case of dinitrile. The selectivity was applied to hydrolysis of nitriles to carboxylic acids.

It has been reported[1] that 2-pyridinecarbonitrile is easily hydrated to 2-pyridinecarboxamide in the presence of various complexes of Cu(II), Ni(II), and Co(II) in neutral solution at 60 °C. The nitrile group in α-position is presumed to interact with metal ions coordinated to the ring nitrogen and the activated nitrile group undergoes hydration to afford the free amide through ligand exchange. In order to elucidate the phenomenon, we studied the hydration of some 2-pyridinecarbonitrile derivatives (Table 1) in the presence of $[Cu(en)_2]Cl_2 \cdot 2H_2O$ and $CuCl_2 \cdot 2H_2O$. The results are given in this paper together with a discussion from theoretical and synthetic viewpoints.

Aqueous solutions of the nitriles containing the catalysts were kept at 60 °C (or 80 °C) for 5 hr in a sealed glass tube. The reactions were followed spectrophotometrically[1] and the yields of the reaction products were calculated.

Results and Discussion

The reaction conditions and main results are summarized in Tables 2 and 3. The UV analytical method could not be applied to compound III. No reaction occurred in IV and V at 60 °C even with a large amount of catalyst and an elongated reaction time of 20 hr. They were thus treated at 80 °C and the yields were calculated from the weight of free amides obtained (Table 3). I was a little more reactive than II as observed in the reactions with a large amount of the catalyst(Table 2). It was assumed that the higher basicity of I than II due to the methyl group made the pyridine ring easy to undergo coordination. On the other hand, II was more reactive than III presumably by electronic effect of the cyano group in 4-position(Table 3). The low reactivity of IV and V was attributed to steric hindrance in the coordination to the catalysts. In their Cu(II) ion catalyzed reactions, the amide complexes were not obtained, presumably for the same reason. In order to examine the reactivity of V, it was refluxed 5 hr with both catalysts and about 10% of the amide was obtained. We tried the addition of methanol to II and V in the presence of Cu(II) ion under reflux as follows:



The reaction product from V was *O*-methyl-2-quinolinecarboximidate copper(II) chloride instead of bis-coordinated ligand complex. This also suggests a

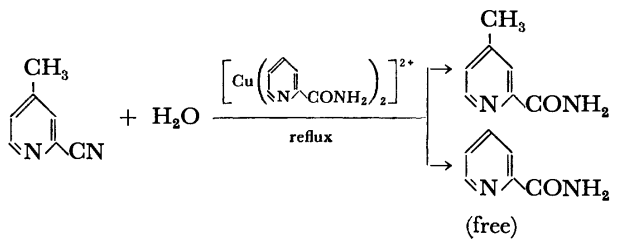
a) Product: 4-cyano-2-pyridinecarboxamide. b) Product: 2,6-pyridinedicarboxamide.

steric hindrance in the coordination of the bulky ligand.

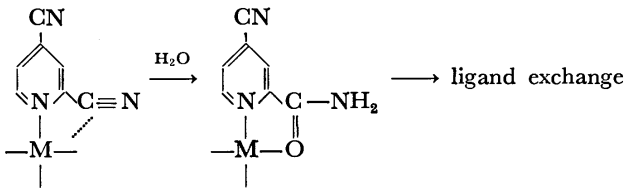
Thus, the electronic and steric effects of substituents were observed apparently in these catalytic hydration. The reactivity of compounds I–V was in the order: I>II>III>IV>V. This is attributed to their coordination ability caused by an electronic or steric factor which would also influence the mode of the reaction of IV.

In the reaction with $[Cu(en)_2]Cl_2\cdot 2H_2O$, all the reaction products, amides, were obtained in free form (Table 3). On the other hand, in the reaction with Cu(II) ion, I and II afforded stable copper(II) complexes of their amides. Thus, the net yield of amide from II should be estimated to be greater than 49% (free amide). However, III afforded scarcely any copper(II) complex of the amide, although free amide was obtained to some extent. The amide complexes obtained from I and II were found to have excellent catalytic ability. We examined the ligand exchange of the complex catalysts and found the formation of mixed amides in free form as follows:



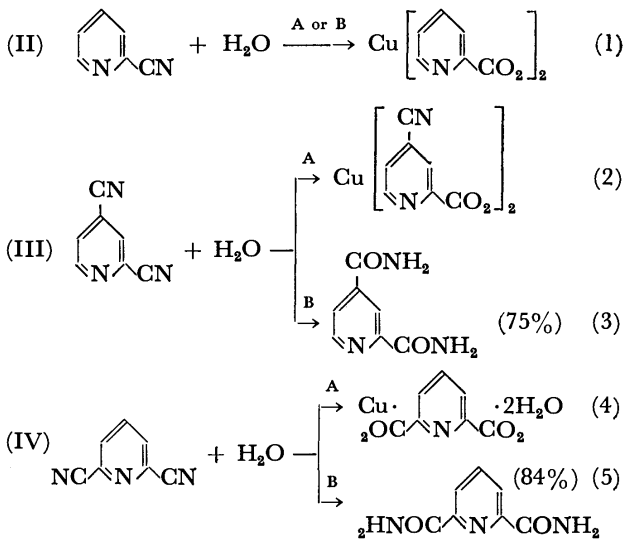
This suggested a catalytic function of labile metal complexes through ligand exchange.[1]

Remarkable selective hydration of the nitrile group in α-position was observed in dinitrile III to give 4-cyano-2-pyridinecarboxamide (Tables 1 and 3). In contrast, no selectivity was observed in the reaction with dinitrile IV. This indicates a particular interaction of metal ion with nitrile group in α-position.



Such selectivity was not observed in the reaction in the presence of catalysts such as mineral acids, alkali, metals, or metal oxides.

For the synthetic application of this catalytic hydration, we tried selective hydrolysis of III with Cu(II) ion and nickel oxide catalysts under neutral conditions. For the sake of comparison, reactions of II and IV were also examined. It was found that selective hydrolysis of dinitrile III occurrs with Cu(II) ion, and simultaneous hydration occurrs in the presence of Ni-(or Cu) oxide catalyst. The results are summarized as follows:



Method A: Cu(II) excess, pH *ca.* 4.5, reflux 15 hr
Method B: Ni-oxide(black), pyridine, reflux 2—5 hr

Use of an excess Cu(II) ion with a long reflux caused the hydrolysis of the nitrile group in α-position to afford copper(II) complexes of acids (Method A). In this case, III gave a 2 : 1 complex of 4-cyano-2-pyridinecarboxylic acid by selective hydrolysis(2), while IV gave 1 : 1 complex of diacid(4). The use of metal oxides[2] or metal[3] catalysts is excellent for the purpose of synthesizing amides from nitriles under neutral conditions, but the method lacks selectivity. Thus, III and IV gave free diamides in good yields(3 and 5, respectively) in contrast to the metal ion catalyzed reactions. II undergoes hydrolysis with metal oxide to afford copper(II) complex of 2-pyridinecarboxylic acid as in the case of Cu(II) ion catalyzed reactions(1). Although 4-carbamoyl-2-pyridinecarboxylic acid complex was expected, no selective hydrolysis of α-nitrile group in III was observed.

Exprimental

Materials. 4-Methyl-2-pyridinecarbonitrile was prepared[4] from 4-methylpyridine, recrystallized from ethanol

mp 88—89 °C. Commercial 2-pyridinecarbonitrile was recrystallized from ether, mp 28—29 °C. 2,4-Pyridinedicarbonitrile: 4-pyridinecarbonitrile-*N*-oxide was prepared[5] from 4-pyridinecarbonitrile and hydrogen peroxide solution, mp 206—215 °C. This was heated with dimethylsufonic acid and potassium cyanide to give 2,4-pyridinedicarbonitrile.[6] The crude dinitrile was purified by means of column chromatography(alumina) with benzene, mp 91—92 °C. 2,6-Pyridinedicarbonitrile was prepared[5,6] from 2-pyridinecarbonitrile by a similar method, mp 126—127 °C. 2-Quinolinecarbonitrile was prepared[7] from quinoline and recrystallized from methanol, mp 93—94 °C. $[Cu(en)_2]Cl_2 \cdot 2H_2O$ was prepared and recrystallized several times. Commercial extra-pure $CuCl_2 \cdot 2H_2O$ was used. Nickel oxide (black) was prepared by the decomposition of nickel carbonate at 250—300 °C.

Spectrophotometry (Table 2). In a sealed glass tube was placed 10 ml of a solution containing nitrile (5×10^{-3} mol/l) and catalyst, and the reaction mixture was kept at 60 °C for 5 hr. After the reaction, an aliquot quantity of the reaction mixture was poured into a column packed with ion exchange resin (Dowex 50, 2 × H-type) and developed with water (resin in column: diameter 1 cm, length 3 cm). The elute was a solution of unreacted pure nitrile which was separated completely from the reaction mixture. The decrease in the amount of starting material was followed spectrophotometrically (I: 274 nm, II: 265 nm, IV: 225 nm, V: 303 nm), and the yield of the reaction products, amides, was calculated. Yield(%) = 100 − unreacted nitrile. The separation was examined by the blank test. In the case of V, a water–ethanol mixture(2 : 1) was used for development.

Synthetic Method (Table 3). In a sealed flask was placed 50 ml of a solution containing nitrile (7.8×10^{-3} mol) and catalyst(9.7×10^{-4} mol) and the reaction mixture was kept at 80 °C for 5 hr. In the cases of III, IV, and V, deposition of white crystals was observed during the course of the reaction. After the reaction, the mixture was cooled and the precipitate was filtered off, dried and washed with benzene. The amide crystals thus obtained were recrystallized from acetic acid.

4-Cyano-2-pyridinecarboxamide. Mp 255—256 °C(dec), lit,[5] 256—258 °C. IR: νN-H 3410, νC≡N 2245, νC=O 1700 cm^{-1}, (KBr). Found: C, 56.87; H, 3.37; N, 28.38%. Calcd for $C_7H_5N_3O$: C, 57.14; H, 3.43; N, 28.56 %.

2,6-Pyridindiecarboxamide. Mp 298—302 °C(dec), lit,[6] 295—297 °C. IR: νN-H 3410, νC=O 1680 cm^{-1} (KBr). Found: C, 50.97; H, 4.32; N, 25.28%. Calcd for $C_7H_7N_3O_2$: C, 50.90; H, 4.28; N, 25.45%.

2-Quinolinecarboxamide(trace). Mp 129—131 °C, lit,[7] 132—133 °C. Determined by mixed melting point method and IR: νN-H 3440, νC=O 1680 cm^{-1}(KBr).

Hydration with Nickel Oxide Catalyst(black). Fifty ml of an aqueous solution containing nitrile(1g), II, III, or IV, and nickel oxide(0.1 g) was refluxed for 2—5 hr. In the reaction with IV, pyridine was added in order to dissolve the nitrile completely. After the reaction, the catalyst was filtered while hot and the filtrate was cooled. Amide crystals were precipitated, and were then filtered and recrystallized from water.

2,4-Dipyridinecarboxamide. Mp 256 °C, lit,[8] 258 °C. IR: νN-H 3450, 3310, νC=O 1715, 1695 cm^{-1} (KBr). Found: C, 50.97; H, 4.25; N, 25.33%. Calcd for $C_7H_7N_3O_2$: C, 50.90; H, 4.28; N, 25.45%.

Hydrolysis with Copper(II) Ion. A solution(100 ml) containing nitrile(1g), II, III, or IV, and $CuCl_2 \cdot 2H_2O$ (1.32 g) was refluxed for 15 hr(homogeneous, pH *ca.* 4.5). After the reaction, the reaction mixture was concentrated to a small quantity under reduced pressure, and then cooled. Crystals deposited were filtered, washed with ethanol, and recrystallized from water, dried *in vacuo*.

Copper (II) complex of 4-cyano-2-pyridinecarboxylic acid. IR: νC≡N 2240, νC=O 1650 cm^{-1}. Found: C, 46.76; H, 1.79; N, 16.17; Cl, 0%. Calcd for $C_{17}H_6O_4N_4Cu$: C, 46.99; H, 1.68; N, 15.67; Cl, 0%.

Copper(II) complex of 2,6-pyridinedicarboxylic acid. IR: νO-H 3440, νC=O 1160 cm^{-1}. Found: C, 31.80; H, 2.57; N, 5.38; Cl, 0%. Calcd for $C_7H_7NO_6Cu$: C, 31.76; H, 2.65; N, 5.29; Cl, 0%. When 2,6-pyridinedicarboxamide was treated similarly, the same complex was obtained.

The authors wish to express their hearty thanks to Dr. Shinnichiro Suzuki, Osaka University, for his valuable advice.

Syntheses of Pyrrolotropone Derivatives from Benzocycloheptene-5,6-dione Monoarylhydrazones. II.[1,2] Syntheses of Benzo[5,6]cyclohept[1,2-*b*]-indole-6,11,12-triones

Kunihide FUJIMORI and Kameji YAMANE

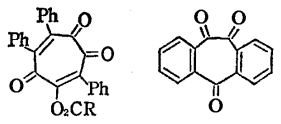
Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto 390

(Received January 16, 1974)

Benzo[5,6]cyclohept[1,2-*b*]indole-6,11,12-triones (benzoindolotropoquinones) (VIIIa—c) were prepared by the oxidation of 11,12-dihydrobenzo[5,6]cyclohept[1,2-*b*]indol-6-ones (Va—c) with sodium dichromate in acetic acid. Compound VIIIa was rearranged by means of a concd sodium hydroxide solution into a known benzocarbazole-1,4-quinone. The pyrrolotropolone derivative (VII) was also obtained through the ring closure of the 5-hydrazinotropolone derivative (VI).

Cyclohepta-3,6-diene-1,2,5-trione(*p*-tropoquinone) has been of interest as an *o*- and *p*-quinone-type compound with a seven-membered ring, but it was not successfuly synthesized until quite recently in spite of many attempts to do so.[3]

5-Nitrosotropolone and 5-arylazotropolone, however, have long been known to have the structures of monooxime and monoarylhydrazone respectively, and tropoquinone trioxime has been obtained from the former.[3]



(I) (II)

Wittmann *et al.*[4] prepared the triphenylhydroxy derivative (I) and Ito *et al.*[5a] performed a successful synthesis of tropoquinone itself by the photosensitized oxidation of 2,5-substituted tropones. Improving its synthetic procedure, the latter[5b] later obtained tropoquinone quantitatively by the oxidation of 5-hydroxytropolone with DDQ in absolute methanol.

On the other hand, dibenzotropoquinone (II) had been obtained earlier.[6]

The present authors will describe the syntheses of benzoindolotropoquinones (VIII) by means of the oxidation of 11,12-dihydrobenzo[5,6]cyclohept[1,2-*b*]indol-6-ones (V) with dichromate.

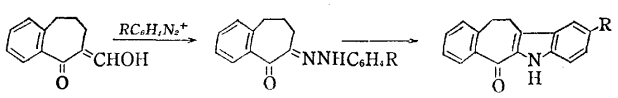
Results and Discussion

Benzocycloheptene-5,6-dione monoarylhydrazones (IV) were obtained by treating a hydroxymethylene compound (III) of benzosuberone with a solution of aryldiazonium salts (Japp-Klingermann reaction). It was described in a previous paper[7] that those hydrazones (IV) could also be obtained by the reaction of benzocycloheptene-5,6-dione with arylhydrazines.

The resulting hydrazones (IVc and IVe), by analogy with IVa, *etc.*,[7] underwent Fischer indolization to form 11,12-dihydrobenzo[5,6]indol-6-ones (Vc and Ve).

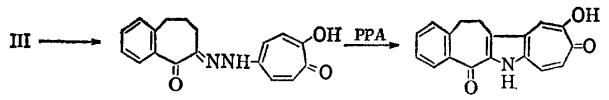
The reaction of Compound III with diazonium salt from 5-aminotropolone led to the corresponding hydrazone (VI), which was then converted into the pyrrolotropolone derivative (VII) by ring closure with PPA.

The Oxidation of V with Sodium Dichromate. On treatment with NBS, Compounds Va—d were converted into benzo[5,6]cyclohept[1,2-*b*]indol-6-ones(ben-



(III) (IV) (V)

a: R=H, b: R=Br, c: R=Cl, d: R=CH_3, e: R=NO_2



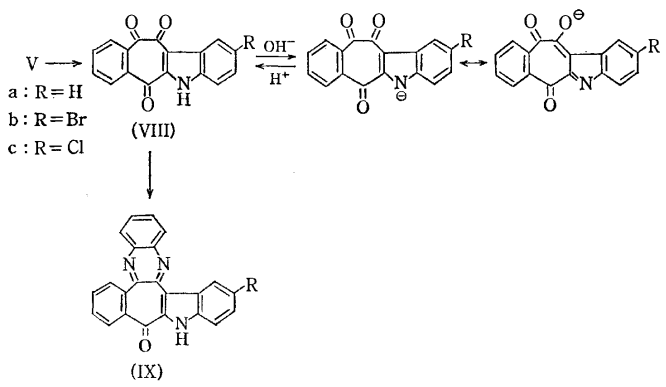
(VI) (VII)

zoindolotropones),[7] but the oxidation of V with selenium dioxide or chloranil resulted in the recovery of the unchanged starting materials. However, when Compound Va was treated with sodium dichromate in acetic acid, orange micro needles (mp 318—320 °C (dec)) were obtained.

The IR spectrum shows absorption bands at 3290 cm^{-1} (NH st.), and at 1680, 1641, and 1623 cm^{-1} (C–O st.). The elemental analysis revealed a composition with the formula of $C_{17}H_9NO_3$.

Further, the compound reacted with *o*-phenylenediamine to give the corresponding quinoxaline derivative. Therefore, the compound may be considered to have the structure of benzo[5,6]cyclohept[1,2-*b*]indole-6,11,12-trione(benzoindolotropoquinone) (VIIIa).

In the same way as with Compound VIIIa, VIIIb, and VIIIc were prepared by the dichromate oxidation of Vb and Vc; those compounds gave the corresponding quinoxaline derivatives, IXb and IXc respectively.



The UV spectra of VIIIa–c display the same absorption pattern in neutral and acidic media, but in an

alkaline medium they show more yellow color and the absorption maxima are shifted to longer wave lengths than in neutral and acidic media.

On changing to an acidic medium from an alkaline medium, the spectra returned to that in neutral and acidic media.

It was, therefore, supposed that VIIIa—c exsited in enolate ions in an alkaline medium.

The absorption spectra in an aprotic solvent such as chloroform or dimethyl sulfoxide are different from those in a protic solvent such as alcohol, so the formation of hemiketal can be taken into consideration in alcohol, by analogy with tropoquinone.[5]

TABLE 1. ULTRAVIOLET AND VISIBLE ABSORPTION MAXIMA

Compound	λ_{max}, nm(log ε)
VIII a	257(4.40), 265^{sh}(4.39), 295(3.85), 351(4.01)
VIII b	252(4.42), 257^{sh}(4.41), 269^{sh}(4.38), 356(4.05)
VIII c	252(4.42), 257^{sh}(4.42), 266^{sh}(4.39), 355(4.06)
	in CH_3OH or CH_3OH-0.1M HCl
VIII a	270(4.35), 285^{sh}(4.30), 375(3.89)
VIII b	276(4.37), 287^{sh}(4.36), 387(3.97)
VIII c	275(4.38), 286^{sh}(4.37), 387(3.97)
	in CH_3OH-0.1M NaOH

The NMR spectra were unable to measure since VIIIa—c were only slightly soluble in common organic solvents.

The Treatment of VIIIa with a Concd Sodium Hydroxide Solution. As has been mentioned above, VIIIa–c are considered to exist as enolate ions in slightly alkaline conditions. When VIIIa was heated in concd sodium hydroxide solution, the solution turned a greenish purple and gave orange micro needles (mp 280 °C). The results of the elemental analysis of the compound accord with the formula of $C_{16}H_9O_2N$, and the IR spectrum is identical with that for the known benzocarbazole-1,4-quinone (X).

The reaction process is supposed to cause a benzilic-acid rearrangement, followed by its decarboxylation and oxidation as well, thus producing stable benzocarbazole-1,4-quinone.

Experimental*

All the melting points are uncorrected.

General Procedure for the Preparation of Benzocycloheptene-5,6-dione Monoarylhydrazones(IV). Into a solution of aryldiazonium salt, prepared from arylamine and sodium nitrite in dilute sulfuric acid, the hydroxymethylene derivative (III) of benzocyclohepten-5-one was stirred, drop by drop, at 0 °C. When the stirring was continued, oily products solidified.

The resulting solid was collected and recrystallized from ethanol.

Benzocycloheptene-5,6-dione Monophenylhydrazone(IVa). Orange needles; yield, 44%; mp 111—112 °C. The mixed melting point with monophenylhydrazone, obtained by the reaction of benzocycloheptene-5,6-dione with phenylhydrazine, was not depressed.

Benzocycloheptene-5,6-dione Mono-p-tolylhydrazone(IVb). Orange needles; yield, 22%; mp 160—161 °C. The mixed melting point with mono-*p*-tolylhydrazone, obtained by the reaction of benzocycloheptene-5,6-dione with *p*-tolylhydrazine, was not depressed.

Benzocycloheptene-5,6-dione Mono-p-bromophenylhydrazone(IVc). Orange needles; yield, 36%; mp 160—161 °C. The mixed melting point with mono-*p*-bromophenylhydrazone, obtained by the reaction of benzocycloheptene-5,6-dione with *p*-bromophenylhydrazine, was not depressed.

Benzocycloheptene-5,6-dione Mono-p-chlorophenylhydrazone(IVd). Orange needles; yield, 69%; mp 165—166 °C. Found: C, 68.42; H, 5.16; N, 9.66%. Calcd for $C_{17}H_{15}ON_2Cl$: C, 68.34; H, 5.06; N, 9.38%.

Benzocycloheptene-5,6-dione Mono-p-nitrophenylhydrazone(IVe). Yellow needles; yield, 46%; mp 205—207 °C. Found: C 66.11; H, 4.87; N, 13.99%. Calcd for $C_{17}H_{15}N_3O_3$: C, 66.00; H, 4.89; N, 13.59%.

2-Chloro-11,12-dihydrobenzo[5,6]cyclohept[1,2-b]indol-6-one(Vc). A mixture of IVc (2.0 g) and concd hydrochloric acid (3 ml) in acetic acid (50 ml) was refluxed for 3 hr. After cooling, the reaction mixture was diluted with water and the resulting material was collected by filtration. Recrystallization from ethanol gave yellow micro needles (1.7 g, 90%); mp 232—233 °C. IR(KBr): ν_{NH} 3305, $\nu_{conjugated\ C=O}$ 1612 cm^{-1}. UV: $\lambda_{max}^{CH_3OH}$ 258(log ε=4.08) and 339(4.33) nm. Found: C, 72.69; H, 4.27; N, 5.13%. Calcd for $C_{17}H_{12}ONCl$: C, 72.47; H, 4.29; N, 4.97%.

2-Nitro-11,12-dihydrobenzo[5,6]cyclohept[1,2-b]indol-6-one(Ve). A mixture of IVe (0.19 g) and PPA (2 ml) was heated at 100 °C for 3 hr. After cooling, the reaction mixture was diluted with water. The resulting material was collected by filtration and dried. Recrystallization from acetic acid gave yellow needles (0.16 g, 89%); mp 280—282 °C. IR (KBr): ν_{NH} 3296, $\nu_{conjugated\ C=O}$ 1615 cm^{-1}. UV: $\lambda_{max}^{CH_3OH}$ 236(log ε=4.03), 260(3.96), and 313(4.49) nm. Found: C, 70.05; H, 4.18; N, 9.84%. Calcd for $C_{17}H_{12}N_2O_3$: C, 69.85; H, 4.14; N, 9.58%.

Benzocycloheptene-5,6-dione Mono-4,5-tropolonylhydrazone(VI). Into a solution of diazonium salt, prepared from 5-aminotropolone (1.0 g), III (1.4 g) was stirred, drop by drop, at 0 °C. The reaction mixture was then extracted with benzene, and the extract was dried over anhydrous sodium sulfate and condensed to leave a residue. Recrystallization from ethanol gave deep ruby red, scale-like crystals (0.28 g, 12%); mp 185—186 °C.

* The authors are grateful to the Sankyo Co., Ltd., for carrying out a part of the elemental analysis.

Found: C, 70.16; H, 5.28; N, 9.08%. Calcd for $C_{18}H_{16}N_2O_3$: C, 70.11; H, 5.23; N, 9.09%.

Pyrrolotropolone Derivative(VII). A mixture of the hydrazone (0.1 g) described above and PPA (2 ml) was heated at 120 °C for 3 hr. After cooling, the reaction mixture was diluted with water. The resulting material was collected by filtration and recrystallized to give yellowish-green micro crystals (0.05 g, 53%); mp>280 °C. UV: $\lambda_{max}^{CH_3OH}$ 240(log ε=4.19), 271(4.34), 299(4.37), 320(4.27), and 288 (4.27) nm. IR(KBr): ν_{OH} 3283, ν_{NH} 3258, $\nu_{conjugated\ C=O}$ 1611, 1591 cm^{-1}.

Found: C, 74.15; H, 4.70; N, 4.76%. Calcd for $C_{18}H_{13}O_3N$: C, 74.21; H, 4.50; N, 4.81%.

*Benzo[5,6]cyclohept[1,2-*b*]indole-6,11,12-trione(VIIIa).* A solution of Va (1.0 g) in acetic acid (30 ml) was heated at 100 °C, and then sodium dichromate (2.3 g) was added little by little. After the mixture has been refluxed for 30 min, the reaction mixture was stirred at room temperature for 2 hr. Water (5 ml) was then added, and the resulting material was collected by filtration. Recrystallization from acetic acid gave orange micro needles (0.24 g, 22%); mp 318—320 °C (dec).

Found: C, 74.15; H, 3.38; N, 4.56%. Calcd for $C_{17}H_9NO_3$: C, 74.18; H, 3.30; N, 5.09%.

Monophenylhydrazone: Reddish-brown needles; mp>280 °C IR(KBr): ν_{NH} 3283, 3238 cm^{-1}. Found: C, 75.69; H, 4.16; N, 11.30%. Calcd for $C_{23}H_{15}N_3O_2$: C, 75.60; H, 4.14; N, 11.50%.

Quinoxaline Derivative: Orange micro needles; mp>280 °C. UV: $\lambda_{max}^{CH_3OH}$ 242(log ε=4.49), 253(4.48), 277(4.58), and 427(4.09) nm. IR(KBr): ν_{NH} 3311, $\nu_{conjugated\ C=O\ or\ C=C}$ 1611, 1593 cm^{-1}. Found: C, 79.77; H, 3.85; N, 12.02%. Calcd for $C_{23}H_{13}N_3O$: C, 79.52; H, 3.77; N, 12.10%.

*2-Bromobenzo[5,6]cyclohept[1,2-*b*]indole-6,11,12-trione(VIIIb).* Compound was obtained from Vb (1.0 g) in acetic acid (60 ml) and sodium dichromate (1.89 g) by a method similar to that used for the preparation of VIIIa.

Recrystallization from acetic acid gave orange-yellow micro needles (0.26 g, 24%); mp>280 °C. UV: $\lambda_{max}^{CH_3OH}$ 242 (log ε=4.39), 253(4.40), 277(4.46), and 420(3.99) nm. IR(KBr): ν_{NH} 3305, $\nu_{conjugated\ C=O}$ 1680, 1638, and 1633 cm^{-1}.

Found: C, 57.67; H, 2.33; N, 4.15%. Calcd for $C_{17}H_8O_3NBr$: C, 57.65; H, 2.28; N, 3.96%.

Quinoxaline Derivative: Yellow micro needles; mp>280 °C. IR(KBr): ν_{NH} 3305, $\nu_{conjugated\ C=O\ or\ C=C}$ 1622 and 1590 cm^{-1}. Found: C, 64.88; H, 3.11; N, 9.68%. Calcd for $C_{23}H_{12}ON_3Br$: C, 64.80; H, 2.84; N, 9.86%.

*2-Chlorobenzo[5,6]cyclohept[1,2-*b*]indole-6,11,12-trione(VIIIc).* Compound was obtained from Vc (1.0 g) in acetic acid (50 ml) and sodium dichromate (2.6 g) by a method similar to that used for the preparation of VIIIa. Recrystallization from acetic acid gave yellow micro needles (0.26 g, 24%); mp>280 °C. UV: $\lambda_{max}^{CH_3OH}$ 242(log ε=4.41), 253(4.43), 277 (4.49), and 422(4.03) nm. IR(KBr): ν_{NH} 3236, $\nu_{C=O}$ 1683, 1643, and 1633 cm^{-1}. Found: C, 66.10; H, 2.64; N, 4.82%. Calcd for $C_{17}H_8O_3NCl$: C, 65.92; H, 2.60; N, 4.52%.

Quinoxaline Derivative: Yellow micro needles; mp>280 °C. Found: C, 72.42; H, 3.18; N, 10.96%. Calcd for $C_{23}H_{12}ON_3Cl$: C, 72.35; H, 3.17; N, 11.01%.

The Treatment of VIIIa with a Concd Sodium Hydroxide Solution. A suspension of VIIIa (1.0 g) in a 50% sodium hydroxide solution (50 ml) was heated on a water bath for 15 min. The reaction mixture turned a greenish purple and gave orange crystals. The resulting crystals were collected by filtration and recrystallized from ethanol to give orange prisms (0.05 g, 56%); mp 280 °C. The IR spectrum was identical with that of benzocarbazole-1,4-quinone which had been obtained by the oxidation of benzocarbazole with chromic anhydride. Found: C, 77.45; H, 3.65; N, 5.76%. Calcd for $C_{16}H_9O_2N$: C, 77.72; H, 3.67; N, 5.67%.

The authors wish to express their thanks to Professor Emeritus Tetsuo Nozoe of Tohoku University for his kind guidance. This research was supported by a grant from the Ministry of Education.

Attempted Synthesis of Diphenylmethylenecyclobutanetrione and the Anomalous Behavior of Its Monoacetal, 4,4-Dimethoxy-2-diphenylmethylenecyclobutane-1,3-dione

Fumio Toda and Koji Yuwami

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790

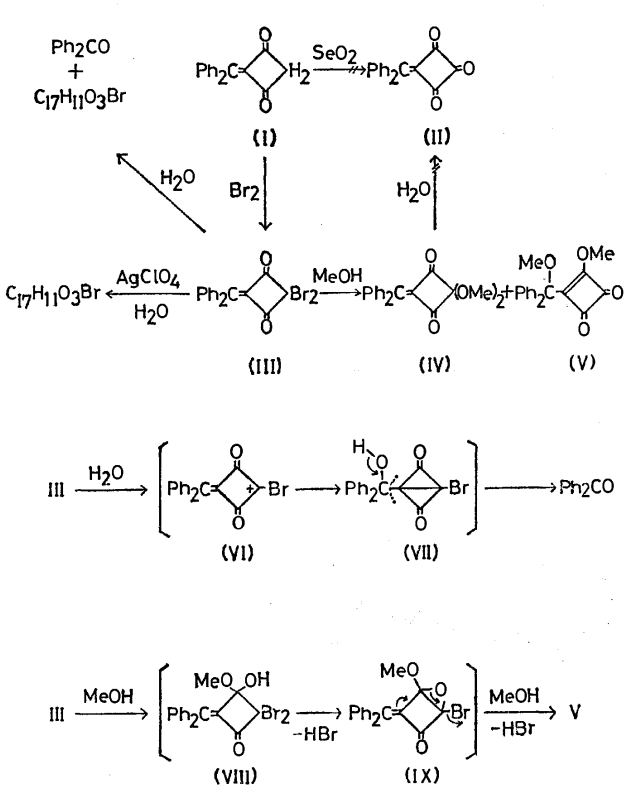
(Received January 21, 1974)

Neither the oxidation of 2-diphenylmethylenecyclobutane-1,3-dione (I) with SeO_2 nor the hydrolysis of 4,4-dibromo- (III) and 4,4-dimethoxy-2-diphenylmethylenecyclobutane-1,3-dione (IV) afforded the title cyclobutanetrione (II). The title acetal (IV) was dissolved in concd HCl-MeOH without hydrolysis, probably in the protonated form (X) on its carbonyl oxygen. The basification of a solution of IV in concd HCl-MeOH-d_4 recovered the IV undeuterated. On the other hand, IV was dissolved in KOH-MeOH in the form of the enolate anion (XII). The acidification of a solution of IV in KOH-MeOH-d_4 afforded the deuterated acetal (IV-d_6).

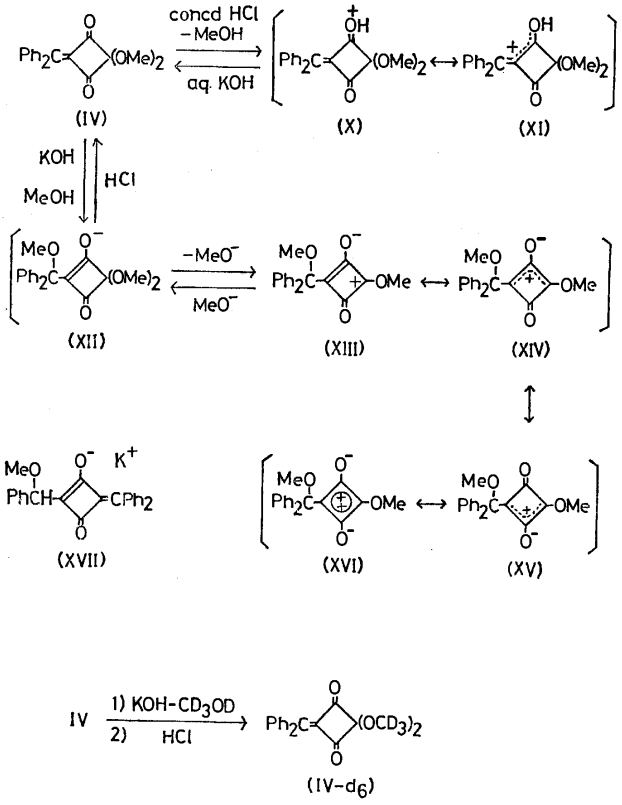
No derivative of methylenecyclobutanetrione has yet been reported, even though derivatives of 3,4-dimethylenecyclobutane-1,2-dione,[1] 2,4-dimethylenecyclobutane 1,3-dione,[2] and trimethylenecyclobutanone[3] have been prepared. All our attempts to prepare diphenylmethylenecyclobutanetrione (II) by the oxidation of 2-diphenylmethylenecyclobutane-1,3-dione (I) and by the hydrolysis of 4,4-dibromo- (III) and 4,4-dimethoxy-2-diphenylmethylenecyclobutane-1,3-dione (IV) failed. During the course of these attempts, however, we have found some anomalous behavior of IV in reaction to acid and base.

The treatment of I[2] with two molar amounts of Br_2 in $CHCl_3$ at room temperature afforded III in a 92% yield. The heating of III in MeOH under reflux for 2 hr afforded IV and 4-diphenylmethoxymethyl-3-methoxycyclobut-3-ene-1,2-dione (V) in 39 and 10% yields respectively. Because the reaction of III with MeOH in the presence of pyridine afforded IV in a 52% yield, but no any detectable amount of V, the HBr initially evolved by the methanolysis of III, thus leading to IV, is essential for the production of V. Therefore, a plausible pathway of the formation of V is as follows: a HBr-catalyzed addition of MeOH to the carbonyl of III gives VIII. The ketonization, accompanied by the attack of the methoxide ion on the diphenylmethyl carbon of the epoxide intermediate (IX) which is derived from VIII, affords V (Scheme 1).

The oxidation of I with SeO_2 in dioxane gave only a resinous material. The hydrolysis of III in boiling aqueous MeCN afforded benzophenone and an unidentified carboxylic acid ($C_{17}H_{11}O_3Br$) in 30 and 31% yields respectively. The formation of the benzophenone can be interpreted by assuming such an interme-



Scheme 1.



Scheme 2.

diate bearing diphenylhydroxymethyl moiety as VII. The formation of VII can be formulated by a homoallylic rearrangement across the four-membered ring (1,3-interaction), accompanied by the attack of the hydroxy ion on the diphenylmethyl carbon of VI initially produced from III (Scheme 1). The treatment of III with $AgClO_4$ in aqueous THF afforded the carboxylic acid in a 50% yield, but no II.

In contrast with usual acetals, IV was dissolved in concd HCl–MeOH without hydrolysis into the ketone (II), and the basification of the solution recovered the IV quantitatively. Because IV is almost insoluble in MeOH at room temperature, it is clear that HCl has a role in dissolving IV in MeOH. Because the basification of a solution of IV in concd HCl–MeOH-d_4 recovered the IV undeuterated, and because the UV spectral data of IV in concd HCl–MeOH are comparable to those of IV in MeOH (Table 1), the form of IV in the acidic media must be one derived by a protonation on its carbonyl oxygen (X). The contribution of XI to the resonance of X is considerable. However, it is not clear why the ε decreases as the concentration of concd HCl increases.

Table 1. The UV spectra of IV

Solvent	λ_{max} nm ($\varepsilon \times 10^{-2}$)		
MeOH	247 (94)	330 (69)	392 (128)
5% concd HCl–MeOH		331 (67)	393 (127)
20% concd HCl–MeOH		332 (39)	394 (83)
50% concd HCl–MeOH		332 (25)	400 (54)
5% KOH–MeOH	241 (107)		

In a similar manner, IV was dissolved in KOH–MeOH, and the acidification of the solution recovered the IV quantitatively. However, the UV spectrum of IV in 5% KOH–MeOH differs widely from that of IV in MeOH (Table 1). The IR spectrum of IV in 5% KOH–MeOH showed a very strong ν(C–O$^-$) band at such lower frequencies (1560 cm^{-1}) as does the carboxylate ion (1600—1540 cm^{-1}). The data are comparable to those of the potassium salt of the analogous enolate anion (XVII), which has been prepared by the reaction of 4-diphenylmethylene-2-benzylidenecyclobutane-1,3-dione with KOH–MeOH,[2] thus showing

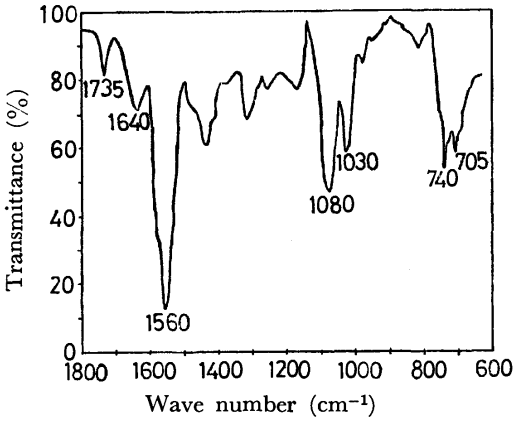


Fig. 1. The IR spectrum of IV in 5% KOH–MeOH (polyethylene-film window cell).

a very strong ν(C–O$^-$) band at 1580—1540 cm^{-1}. Therefore, it is reasonable to consider that the enolate anion (XII) is formed when the IV is dissolved in KOH–MeOH.

Nevertheless, the acidification of a solution of IV in KOH–MeOH-d_4 afforded the fully deuterated acetal (IV-d_6). The exchange of the two MeO with the CD_3O of the solvent can be interpreted by assuming an equilibrium between XII and XIII (Scheme 2). If the presence of XIII in the media is correct, the contribution of XIV and XV to its resonance is considerable. However, the contribution of the cyclobutadiene dication (XVI) to the resonance is doubtful, because even the tetraphenylcyclobutadiene dication is unstable and has been observed only at temperatures below —40 °C.[4]

Experimental

Reaction of I with Br_2. Into a solution of I (2.48 g) in $CHCl_3$ (100 ml), Br_2 (3.2 g) was stirred over a period of 10 min under cooling with an ice bath. The subsequent evaporation of the solvent left crude crystals. Recrystallization from acetone afforded III as red-prisms; 3.74 g (92%); mp 191 °C. IR (Nujol): 1790 (m), 1710 (vs), and 1505 cm^{-1} (vs); $\lambda_{max}^{CHCl_3}$: 246 sh (6300), 336 (9800), 407 (20700), and 425 sh nm (ε, 19600); NMR ($CDCl_3$): 2.45 τ (s, Ph).

Found: C, 50.54; H, 2.54%. Calcd for $C_{17}H_{10}O_2Br_2$: C, 50.29; H, 2.46%.

Reaction of III with MeOH. A solution of III (2.03 g) in MeOH (20 ml) was heated under reflux for 2 hr. The subsequent evaporation of the solvent left a mixture of purple rhombs and colorless needles, which were separated mechanically. The recrystallization of the purple rhombs from MeOH afforded IV; 0.6 g (39%); mp 129—130 °C. IR (Nujol): 1790 (m), 1700 (vs), 1085 (s), and 1040 cm^{-1} (vs); NMR ($CDCl_3$): 2.50 (s, Ph, 10H) and 6.36 τ (s, OMe, 6H).

Found: C, 73.88; H, 5.00%. Calcd for $C_{19}H_{16}O_4$: C, 74.01; H, 5.23%.

The recrystallization of the colorless needles from MeOH afforded V; 0.15 g (10%); mp 209—210 °C. IR (Nujol): 1790 (s), 1750 (m), 1585 (s), and 1360 cm^{-1} (s); λ_{max}^{MeOH}: 230 nm (ε, 23700); NMR ($CDCl_3$): 2.63 (s, Ph, 10H), 5.45 (s, OMe, 3H), and 6.87 τ (s, OMe, 3H).

Found: C, 73.87; H, 5.26%. Calcd for $C_{19}H_{16}O_4$: C, 74.01; H, 5.23%.

When the reaction of III (1.15 g) with MeOH (10 ml) was carried out in the presence of pyridine (0.1 g) by the same procedure as above, 0.4 g (52%) of IV was obtained.

Hydrolysis of III. A solution of III (0.406 g) in 5% aqueous MeCN (10 ml) was heated under reflux for 1 hr. After cooling, the reaction mixture was diluted with ether (100 ml). The ether solution was washed with dil KOH and water, and then dried over anhydrous Na_2SO_4. The evaporation of the solvent left benzophenone; 0.55 g (30%). The crude crystals obtained by the acidification of the alkaline extract were recrystallized from MeOH to afford an unidentified compound ($C_{17}H_{11}O_3Br$) as colorless needles; 0.106 g (31%); mp 189—190 °C. Mass spectrum *m/e*: 344 and 342 (M^+); IR (Nujol): 1690 (vs), 1625 (m), 1530 (m), and 1175 cm^{-1} (m); $\lambda_{max}^{CHCl_3}$: 330 nm (ε,←12100); NMR ($CDCl_3$): 2.5—2.9 τ (m, Ph).

Found: C, 59.56; H, 3.28%. Calcd for $C_{17}H_{11}O_3Br$: C, 59.50; H, 3.23%.

Reaction of III with $AgClO_4$. A mixture of III (0.406 g), $AgClO_4$ (0.45 g), and 10% aqueous THF (10 ml) was

kept at 0 °C for 5 min. Aqueous NaCl was then added to the reaction mixture. After the precipitates had been filtered off, the filtrate was diluted with ether (50 ml). The ether solution was washed with water and dried over anhydrous Na_2SO_4. The recrystallization from MeOH of the crude crystals left by the evaporation of the solvent afforded an unidentified compound ($C_{17}H_{11}O_3Br$): 0.17 g (50%).

The Formation of IV-d_6. The addition of dil HCl to a solution of IV (0.1 g) in 5% KOH-MeOH (10 ml) afforded IV-d_6; 0.1 g (100%). IR (Nujol): 2100 (w), 1790 (m), 1700 (vs), and 1525 cm^{-1} (vs); NMR ($CDCl_3$): 2.5 τ (s, Ph).

This work was supported by a grant from the Ministry of Education.

Dopaquinone and Related Compounds: Reactions with *o*-Phenylenediamine

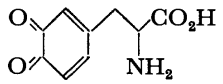
Yoshimori OMOTE, Tokuo HIRAMA, and Toshihiko KOMATSU

Department of Chemistry, Tokyo Kyoiku University, Bunkyo-ku Otsuka, Tokyo 112

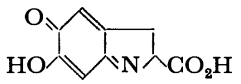
(Received January 22, 1974)

The oxidation of 4-substituted catechols including DOPA with *o*-chloranil or cerium(IV) sulfate to give the corresponding *o*-benzoquinones was examined. The trapping of *o*-benzoquinones with *o*-phenylenediamine immediately after oxidation was successfully used to isolate 2-substituted phenazines, the substituents being $-CH_3$, $-CH(CH_3)_2$, $-(CH_2)_2CO_2H$, $-(CH_2)_2CO_2CH_3$, $-CH{=}CHCO_2H$, $-CH{=}CHCO_2CH_3$, $-(CH_2)_2NHCOC_6H_5$, and $-CH_2CH(NHCOC_6H_5)CO_2CH_3$. Dopaquinone was identified in a protected form.

Raper[1] suggested the intermediacy of dopaquinone (I) in the melanogenesis of DOPA, and later Bu'Lock and Harley-Mason[2] reported the formation of dopachrome (II) based on the ultraviolet absorption spectrum. These intermediates are very unstable and have never been synthesized or trapped in spite of many reports on *o*-benzoquinones.[3-5]



I



II

Recently Horspool *et al.* have shown that 4-substituted *o*-benzoquinones react with arylamines at the 4- and 5-positions.[6] Also, it is known that dopamine or 5-hydroxydopamine is easily cyclized into the corresponding indoline derivative by mild oxidation. Thus, it was of interest to synthesize and trap dopaquinone or dopachrome. This paper will be concerned with the synthesis of dopaquinone and related compounds in neutral or acidic media as well as with their reactions with *o*-phenylenediamine.

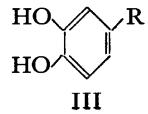
Results and Discussion

UV Spectral Studies. The oxidation of DOPA and related catechols were examined by means of the UV spectrum. Several oxidants are known to convert catechols to the corresponding *o*-benzoquinones: *e.g.*, *o*-chloranil,[3a] silver oxide,[7] cerium(IV) sulfate,[8] and potassium nitrosodisulfonate,[4a] among which *o*-chloranil is the best for the UV spectral studies. Equimolar solution of catechol and *o*-chloranil in ethanol were mixed, and the absorbance of the mixture was measured. The absorption maxima of the mixtures indicate that, in the case of catechols with no free amino group, the absorption of the corresponding quinone appears between 380—390 nm (Table 1). The absorbance of tetrachlorocatechol at 300 nm increased, while those of *o*-chloranil at 350 and 410 nm and catechol at 280 nm decreased. The isosbestic points were observed near 290 and 380 nm.

TABLE 1. THE ABSORPTION MAXIMA OF THE REACTION PRODUCTS OF 4-SUBSTITUTED CATECHOLS (IIIa—IIIh) WITH *o*-CHLORANIL

	λ_{max} (nm)		λ_{max} (nm)
IIIa	370	IIIe	385
IIIb	380	IIIf	384
IIIc	385	IIIg	—
IIId	386	IIIh	—

The final concentration of a substrate was 5×10^{-4} mol/l.



III

R

a : H
b : CH_3
c : $C(CH_3)_3$
d : $CH(CH_3)_2$
e : $(CH_2)_2CO_2H$
f : $(CH_2)_2NHCOC_6H_5$
g : $(CH_2)_2NH_2$
h : $CH_2CH(NH_2)CO_2H$

In the case of catechols with a free amino group, however, no absorption of *o*-benzoquinone appeared near 390 nm, while the absorptions at 350 and 410 nm of *o*-chloranil disappeared. These facts suggest that the oxidation by *o*-chloranil did not yield the corresponding *o*-benzoquinone. Dopamine (IIIg) did not show any absorption of *o*-benzoquinone after oxidation, but after 20 hr it showed an absorption at 470 nm which is similar to that of dopachrome.[9] DOPA (IIIh) itself did not show any absorption at 470—500 nm under similar oxidation conditions. Considering that dihydrocaffeic acid (IIIe), a desamino DOPA, gave a typical quinoid spectrum on oxidation, it could be concluded that a carboxyl group of DOPA has no relation to the instability of dopaquinone, but that an amino group contributes toward the cyclization of dopaquinone into an indoline derivative or an unidentified product.

Oxidation of 4-Substituted Catechols to o-Benzoquinone. 4-Isopropylcatechol (IIId), as a model compound of DOPA, was oxidized by *o*-chloranil according to the method which Horner *et al.*[3a] used in the oxidation of homocatechol, but 4-isopropyl-*o*-benzoquinone was an oily product and could not be obtained in a pure state. Therefore, cerium(IV) sulfate[8] was used as the oxidant. The acidic media are favorable for the stability of the quinone produced. The *o*-benzoquinone was obtained as a dark red oil which showed UV absorption band at 390 and 540 nm and an NMR spectrum characteristic of 4-substituted *o*-benzoquinone ring[10] (see Experimental), but an attempt at purification was unsuccessful. Therefore, it became necessary to trap such an unstable *o*-benzoquinone as a stable crystalline compound.

Reaction of o-Benzoquinones with o-Phenylenediamine. One of the most common methods of trapping *o*-benzoquinones is the reaction with *o*-phenylenediamine to give a phenazine derivative.[3a] On the other hand, Horspool *et al.*[6] have pointed out the possibility of substitution on the 4- or 5-position of *o*-benzoquinone upon treatment with arylamine. However, when the oily 4-isopropyl-*o*-benzoquinone was treated with *o*-phenylenediamine, 2-isopropylphenazine(Vb) was obtained in a 53% yield as yellow needles (Table 2).

TABLE 2. PHENAZINES (V) DERIVED FROM 4-SUBSTITUTED *o*-BENZOQUINONES (IV)

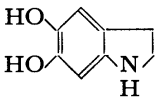
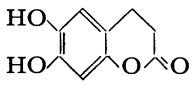
IV V

The quinones (IVc and IVd) from dihydrocaffeic acid and its methyl ester were also oily substances, but their corresponding phenazines (Vc and Vd) were crystals. The quinone from dihydrocaffeic acid is an isomer of a catechol (VII),[11] just as VI is a formal isomer of the unisolable dopamine quinone. However, the presence of these compounds could not be detected among the oxidation products. The quinone from caffeic acid was very unstable and could not be identified even by the NMR spectrum, but the trapping of this quinone to give the phenazine derivative (Vf) was successful. As is shown in Table 2, the method of trapping unstable *o*-benzoquinone by *o*-phenylenediamine is useful for the identification of dopaquinone related compound.



VI



VII

Finally, DOPA was protected by methylation and benzoylation and then oxidized by cerium(IV) sulfate to give a dark red oil showing the UV and NMR spectra characteristic of 4-substituted *o*-benzoquinone, which was then converted into the crystalline phenazine derivative.

Experimental

Oxidation of 4-Isopropylcatechol (IIId). To a solution of IIId (137 mg) in chloroform (7 ml), we poured an ice-cooled solution of cerium(IV) sulfate (aq. 734 mg) in 20% sulfuric acid (13 ml), after which the mixture was stirred for 5 min. Then a solution of cerium(IV) sulfate (aq. 73.4 mg) in 20% sulfuric acid (2 ml) was added and the mixture was stirred for 1 min. The organic layer was washed three times with 0.01 M sulfuric acid, dried over anhydrous sodium sulfate, and then concentrated to give a red oil.

UV $\lambda_{max}^{CHCl_3}$: 390 and 580 nm; NMR ($CDCl_3$): δ 1.23 (d, J=7 Hz, 6H), 2.65 (septet, J=7 Hz, 1H), 6.2 (broad s, 1H), 6.4 (d, J=11 Hz, 1H), and 7.0 (dd, J=11 and 2 Hz, 1H); IR (film): 2940, 1735, 1680, 1665, 1280, 815, and 755 cm^{-1}.

Found: C, 71.40; H, 6.77%. Calcd for $C_9H_{10}O_2$: C, 71.98; H, 6.71%. R_f: 0.705(*n*-butyl acetate-heptane 1 : 1, DMF impregnated paper.[12]

Oxidation of N-Benzoyl DOPA Methyl Ester (IIIi). To a solution of IIIi (60 mg) in methanol-ethyl acetate (1 : 5) we added an ice-cooled solution of cerium(IV) sulfate (170 mg) in 20% sulfuric acid (4 ml) after which the mixture was vigorously stirred for 1 min. Then a solution of cerium(IV) sulfate (2 mg) in sulfuric acid was added to complete the reaction. The organic layer was washed three times with dilute sulfuric acid, dried over anhydrous sodium sulfate, and then concentrated to afford a dark red oil.

UV $\lambda_{max}^{CHCl_3}$: 386 and 580 nm; NMR ($CDCl_3$): δ 3.0 (broad d, J=7 Hz, 2H), 5.0 (broad t, J=7 Hz, 1H), 6.2 (broad s, 1H), 6.3 (d, J=10 Hz, 1H), and 7.0 (dd, J=10 and 2 Hz, 1H).

Phenazines. A typical example is shown below in the case of 2-methylphenazine.

2-Methylphenazine (IV).[13] A solution of 4-methylcatechol (IIIb) (170 mg) in chloroform was mixed with a solution of cerium(IV) sulfate in 20% sulfuric acid and stirred for 1 min. The organic layer was washed, dried and transferred into an ethereal solution of *o*-phenylenediamine with stirring at room temperature. After the mixture had stood for six days, the ether was distilled off and a mixture of acetic anhydride and pyridine (1 : 1, v/v) was added to the residue. After standing overnight, the reaction mixture was heated *in vacuo* to remove the acetic anhydride and pyridine. The residue was purified by column chromatography(benzene-ethyl acetate 5 : 1, silica gel) to give a yellow powder, which was recrystallized from ethanol to give yellow needles; 161 mg (76%), mp 116—116.5 °C (lit,[4] 117 °C).

2-Isopropylphenazine (Vb). 4-Isopropylcatechol (IIId) (150 mg) gave 115 mg (54%) of Vb; yellow needles, mp 90—91 °C; UV λ_{max}^{MeOH} (ε): 252 (124000) and 365 nm (13800); NMR ($CDCl_3$): δ 1.43 (d, J=7 Hz, 6H), 3.20 (septet, J=7 Hz, 1H), and 7.6—8.3 (m, 7H); IR (KBr): 1643, 1512, 1370, 835, and 758 cm^{-1}. Found: C, 81.22; H, 6.41; N, 12.55%. Calcd for $C_{15}H_{14}N_2$: C, 81.05; H, 6.35; N, 12.60%.

3-(2-Phenazinyl)propionic Acid (Vc). Dihydrocaffeic acid (IIIe) (364 mg) gave 338 mg (67%) of Vc; yellow prisms, mp 186—188 °C (dec): UV λ_{max}^{MeOH} (ε): 254 (124000) and 363 nm (15300); NMR (CF_3CO_2H): δ 3.16 (t, J=7 Hz, 2H), 3.50 (t, J=7 Hz, 2H), and 8.2—8.8 (m, 7H); IR (KBr): 1720, 1640, 825, and 775 cm^{-1}. Found: C, 71.19; H, 4.90; N, 11.08%. Calcd for $C_{15}H_{12}N_2O_2$: C, 71.41; G, 4.80; N, 11.11%.

Methyl 3-(1-Phenazinyl)propionate (Vd). The methyl ester of dihydrocaffeic acid (392 mg) gave 235 mg (44%) of Vd; yellow sticks, mp 92—93 °C; UV λ_{max}^{EtOH} (ε): 253 (143000) and 364 nm (20500); NMR ($CDCl_3$): δ 2.81 (t, J=7 Hz, 2H), 3.24 (t, J=7 Hz, 2H), 3.69 (s, 3H), and 7.5—8.3 (m, 7H): IR (KBr): 1740, 1640, 840, and 760 cm^{-1}. Found: C, 71.94; H, 5.23; N, 10.52%. Calcd for $C_{16}H_{14}N_2O_2$: C, 72.16; H, 5.30; N, 10.52%.

3-(2-Phenazinyl)-2-propenoic Acid (Ve). Caffeic acid (900 mg) gave 150 mg (12%) of Ve; dark yellow needles, mp 257—258 °C (dec); UV λ_{max}^{MeOH} (ε): 238 (21000), 282 (62000), 358 (7200), 380 (11000), and 395 nm (13000); NMR (CF_3CO_2H): δ 7.04 (d, J=15.6 Hz, 1H), 8.03 (d, J=15.6 Hz, 1H), and 8.3—8.8 (m, 7H); IR (KBr): 1690, 1620, 1290, 820, and 740 cm^{-1}. Found: C, 70.80; H, 4.06; N, 11.08%. Calcd for $C_{15}H_{10}N_2O_2$: C, 70.26; H, 4.03; N, 11.20%.

Methyl 3-(2-Phenazinyl)-2-propenoate (Vf). The methyl ester caffeic acid (388 mg) gave 68 mg (13%) of Vf; yellow needles, mp 152—154 °C; UV λ_{max}^{EtOH} (ε): 238 (19900) 285 (83500), 377 (16900), and 395 nm (15500); NMR

($CDCl_3$): δ 3.82 (s, 3H), 6.57 (d, J=16 Hz, 1H), and 7.6—8.3 (m, 8H); IR (KBr): 1725, 1630, 1312, 1290, 820, and 750 cm^{-1}. Found: C, 72.20; H, 4.60; N, 10.55%. Calcd for $C_{16}H_{12}N_2O_2$: C, 72.71; H, 4.58; N, 10.60%.

N-Benzoyl-3-(2-phenazinyl)ethylamine (Vg). *N*-Benzoyldopamine (IIIf) (376 mg) gave 178 mg (37%) of Vg; yellow needles, mp 171—172 °C; UV λ_{max}^{MeOH} (ε): 253 (107000) and 365 nm (13400); NMR ($CDCl_3$): δ 3.17 (t, J=7 Hz, 2H), 3.85 (q, J=7 Hz, 2H), 6.60 (broad s, 1H), and 7.2—83. (m, 12H); IR (KBr): 3320, 1640, 1550, 820, and 750 cm^{-1}. Found: C, 76.80; H, 5.25;N, 13.03%. Calcd for $C_{21}H_{17}N_3O$: C, 77.04; H, 5.23; N, 12.84%.

Methyl 3-(2-Phenazinyl)-2-benzoylaminopropionate (Vh). The methyl ester of N-benzoyldopa (IIIi) (100 mg) gave 38 mg (31%) of Vh; yellow needles, mp 211—212 °C; UV λ_{max}^{EtOH} (ε): 225 (25500), 254 (127000), and 363 nm (16800); IR(KBr): 3270, 1745, 1640, 815, and 760 cm^{-1}. Found: C, 71.83; H, 5.09; N, 11.16%. Calcd for $C_{23}H_{19}N_3O_3$: C, 71.67; H, 4.97; N, 10.90%.

The Photochemical Reaction of 1,4-Naphthoquinone Derivatives with Hydrogen Donors

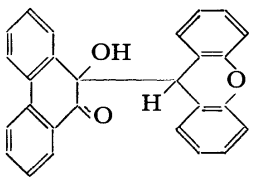
Kazuhiro MARUYAMA and Seiichi ARAKAWA

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

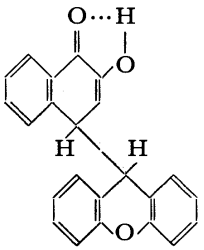
(Received February 5, 1974)

The reaction products of the photochemical reactions of 1,4-naphthoquinone and its methyl- or halogeno-derivatives with xanthene were investigated. Methyl-substituted 1,4-naphthoquinones produce the corresponding 1,4-naphthohydroquinones, but naphthoquinone and its halogeno-derivatives react to give substituted or added products by the xanthyl group in addition to the hydroquinone derivatives. Stable free radicals, which remain unchanged under atmospheric pressure, are also obtained in the latter reactions. The courses of the photochemical reactions were investigated by means of the CIDNP technique, and the reaction mechanism was discussed.

The photochemical reaction of quinones has received extensive interests by many investigators.[1] According to Pfundt,[2] the irradiation of 9,10-phenanthraquinone with xanthene gave the "1,2-adduct", **1**, the reaction was reinvestigated by Maruyama and his co-workers.[3]



1



2

The irradiation of 1,2-naphthoquinone with xanthene, however, gave a different type of photo-adduct, **2**.[4] Recently the present authors have examined the photochemical reactions of *p*-quinones with xanthene by means of the CIDNP technique[5] and pointed out the formation of unstable intermediates in the course of reactions. Stable products such as hydroquinones and 9,9′-bixanthyl are also formed in the reactions.

In this work, the photochemical reactions of 1,4-naphthoquinone, 2-methyl-1,4-naphthoquinone, 2,3-dimethyl-1,4-naphthoquinone, 2,6-dimethyl-1,4-naphthoquinone, 2-chloro-1,4-naphthoquinone, 2,3-dichloro-1,4-naphthoquinone, 2-bromo-1,4-naphthoquinone, 2,3-dibromo-1,4-naphthoquinone with xanthene dissolved in benzene were mainly studied from the standpoint of stableproduct analyses. Examinations by means of the CIDNP technique were also extended to the above reactions in order to investigate the reaction mechanism.

Results and Discussion

In all of the photochemical reactions described below, a benzene solution of 1,4-naphthoquinone derivatives and xanthene sealed in a glass tube was irradiated by means of a 400W high-pressure mercury arc lamp from the outer side through a 5-cm-thick water layer under ice-water cooling or at room temperature.

Methyl-substituted 1,4-Naphthoquinones. The irradiation for about eight hours of the benzene solution of 2-methyl-1,4-naphthoquinone, **3a**, and xanthene gave 2-methyl-1,4-naphthohydroquinone, **4a**, and 9,9′-bixanthyl in a 70—80% yield. 2,3-Dimethyl-1,4-naphthoquinone, **3b**, and 2,6-dimethyl-1,4-naphthoquinone, **3c**, reacted as well as the **3a** with xanthene to give the corresponding 1,4-naphthohydroquinone derivatives and 9,9′-bixanthyl in good yields. The quantum yields of the naphthoquinone disappearance are tabulated in Table 1.

TABLE 1. QUANTUM YIELDS OF THE DISAPPEARANCE OF 1,4-NAPHTHOQUINONE DERIVATIVES

Quinones	Quantum yields[a]
1,4-Naphthoquinone	0.39
2-Methyl-1,4-naphthoquinone	0.29
2,3-Dimethyl-1,4-naphoquinone	0.12
2-Chloro-1,4-naphthoquinone	0.41

a) Non-degassed benzene solutions were used for the determination. Wavelength of light for excitation was longer than 400 nm.

1,4-Naphthoquinone and Its Halogeno-derivatives. In the photochemical reactions of 1,4-naphthoquinone and its halogeno-derivatives, other products of the **6** and **7** types, were obtained in addition to the corresponding hydroquinones and 9,9′-bixanthyl. Moreover, stable radicals could be isolated in the reaction of the halogeno-derivatives with xanthene. The relative yields of the respective compounds in the reaction products are profoundly dependent on the temperature, as is shown in Table 2. For example, under ice-water cooling compounds of the **8**, **9**, and **7** types were produced as the main products, but at room temperature

Table 2. Products in the photochemical reaction of 1,4-naphthoquinone derivatives with xanthene[a)]

8 (or quinhydrone) **9**

6 **7**

stable radical **10**

(*ca.* 25 °C) the principal products were of the **8**, **7**, and **10** types and the yield of **9** was considerably reduced. The reactions of **5d** and **5e** followed the same trend. The structures of the **6**—**9** products were determined by means of IR, PMR, mass, and elemental analyses.

Structure of Stable Radicals ***10***. In the photochemical reaction of halogeno-derivatives of 1,4-naphthoquinone with xanthene at room temperature, stable, greenish free radicals could be obtained in fairly high yields. The radicals show a well-resolved ESR hyperfine structure in a tetrahydrofuran solution. The typical ESR spectra of the radicals, which are obtained in the photochemical reaction of 2,3-dichloro- and 2,3-dibromo-1,4-naphthoquinone with xanthene, are shown in Fig. 1.

The analyses of the spectra are straightforward; five groups of lines split further to a quintet. This means that the radical center is at position 9' and almost all of the unpaired electrons delocalize on the xanthyl moiety. The physical properties of the stable radicals obtained are summarized in Table 3.

When the radicals were then submitted to chromic acid oxidation (or ferric chloride oxidation), they gave

Table 3. Physical properties of stable free radicals

Free radicals	**11a**[a)]	**11b**[a)]	**11c**[a)]
Color	green	dark green	black

ESR coupling constants (gauss) $a_{H_3',6'}$	3.90	3.60	3.81
ESR coupling constants (gauss) $a_{H_2',4',5',7'}$	0.79	0.74	0.76
g-Values	2.0029	2.0030	2.0034

a) The structures **11a**, **11b**, and **11c** correspond to the stable radicals **10b**, **10c**, and **10d** respectively.

9'-hydroxyderivatives, **12**. Reaction with zinc dust-hydrochloric acid, on the other hand, resulted in the corresponding 2-halogeno-3-[9'-xanthyl]-1,4-naphtho-hydroquinones, which were subsequently autoxidized in the air to the corresponding naphthoquinone derivatives, **6**. The radicals showed a broad IR absorption due to the hydroxy group in the region of ν_{OH}: 3000—3200 cm^{-1}. Therefore, the radicals were assigned to structure **10**.

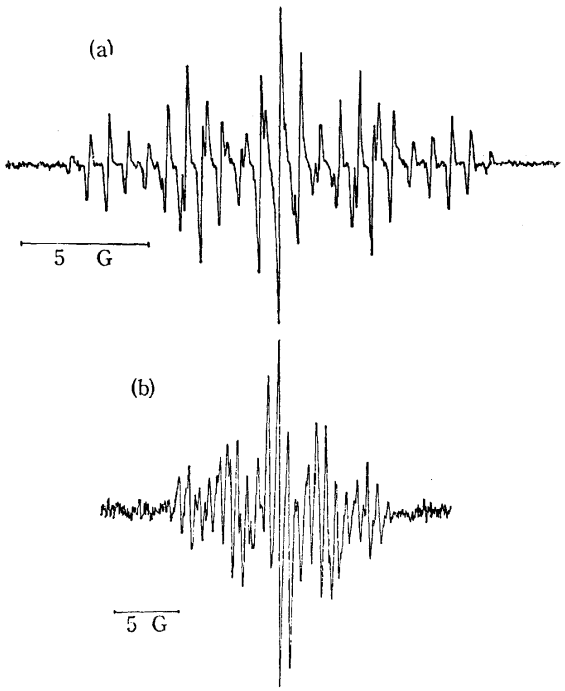

Fig. 1. ESR spectrum of stable radical (**10c**) obtained in the reaction of 2,3-dichloro-1,4-naphthoquinone with xanthene(a) and in the reaction of 2,3-dibromo-1,4-naphthoquinone with xanthene(b).

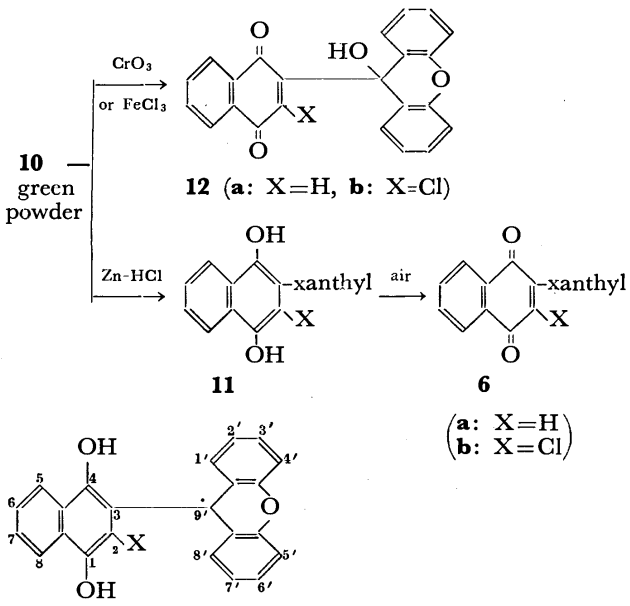
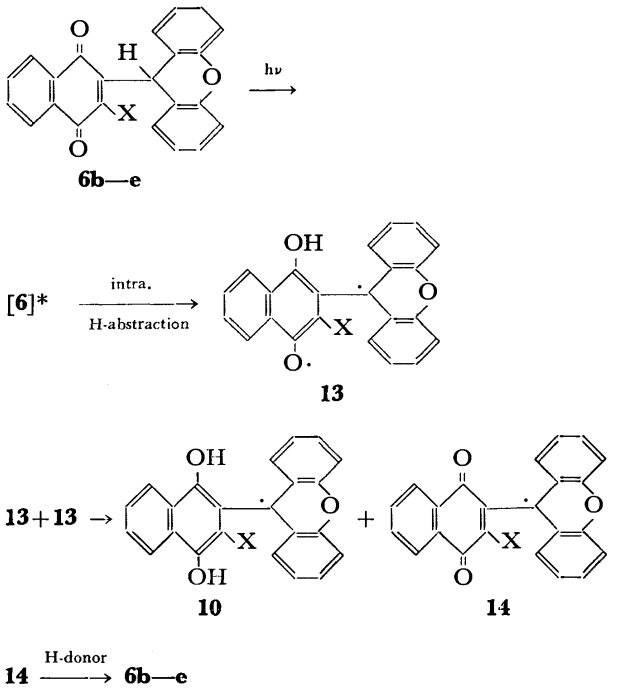
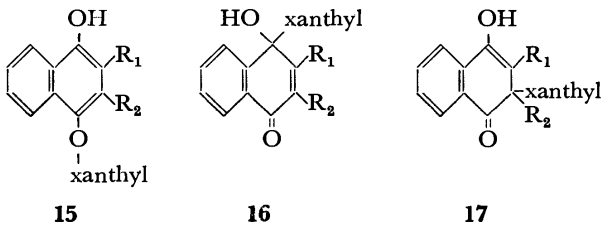


Thus, **5b** and **5d** convert to the same product, **10a**; **5c**, to **10b**, and **5e**, to **10c**. The radicals are stable in the solid state, but they gradually change to non-radical substances in a solution (*e.g.*, solvent THF). These radicals may be produced *via* photo-induced intramolecular hydrogen abstraction of the primary products, **6b—e**, accumulated in the reacting system, as is shown in the following equations;



CIDNP Measurements and Reaction Mechanism. 1,4-Naphthoquinone derivatives examined in this work have n→π* absorption bands in the region of λ_{max}: 420—440 nm (ε: 20—60). The molecules of 1,4-naphthoquinone derivatives excited by the n→π* transition could be converted to the triplet state via inter-system crossing. The excited molecules in the triplet state can abstract hydrogen from xanthene to give the triplet radical pair, **18**—radical pair consisting of a semiquinone radical and a xanthyl radical—in the solvent cage. By means of the CIDNP technique we have previously investigated the photochemical reactions of 1,4-naphthoquinone derivatives with xanthene and pointed out the formation of the **15**, **16**, and **17** reaction intermediates.[5] These reaction intermediates decomposed thermally to give a solvent-separated semiquinone radical and xanthyl radical.



In addition to the strongly polarized PMR signals due to these intermediates, other polarized PMR signals corresponding to the isolated stable products could be observed. The PMR spectra observed during the course of the photochemical reactions of 1,4-naphthoquinone and its halogeno-derivatives with xanthene are shown in Figs. 2—4; Fig. 2 shows the PMR polarized signals observed in the reactions of 1,4-naphthoquinone with xanthene, Fig. 3, those of 2-chloro-1,4-naphthoquinone, and Fig. 4, those of 2,3-dichloro-1,4-naphthoquinone. The polarized PMR signals due to the stable products could be easily assigned to the

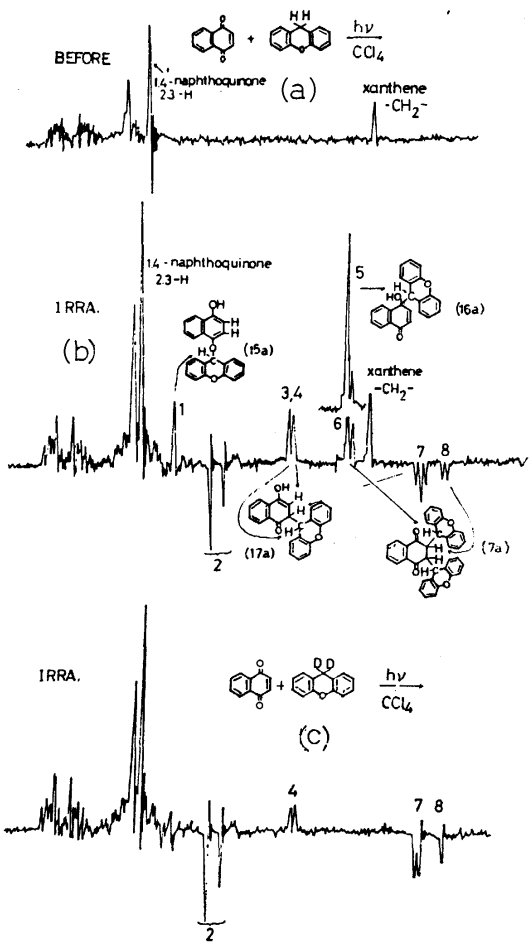


Fig. 2. PMR spectra observed in the photochemical reaction of 1,4-naphthoquinone with xanthene.
(a): before irradiation, (b): during irradiation; (c): during irradiation, when xanthene-9-d_2 was used.
Signals 2 in the Figure should be assigned to 2,3-protons of **16a**[15].

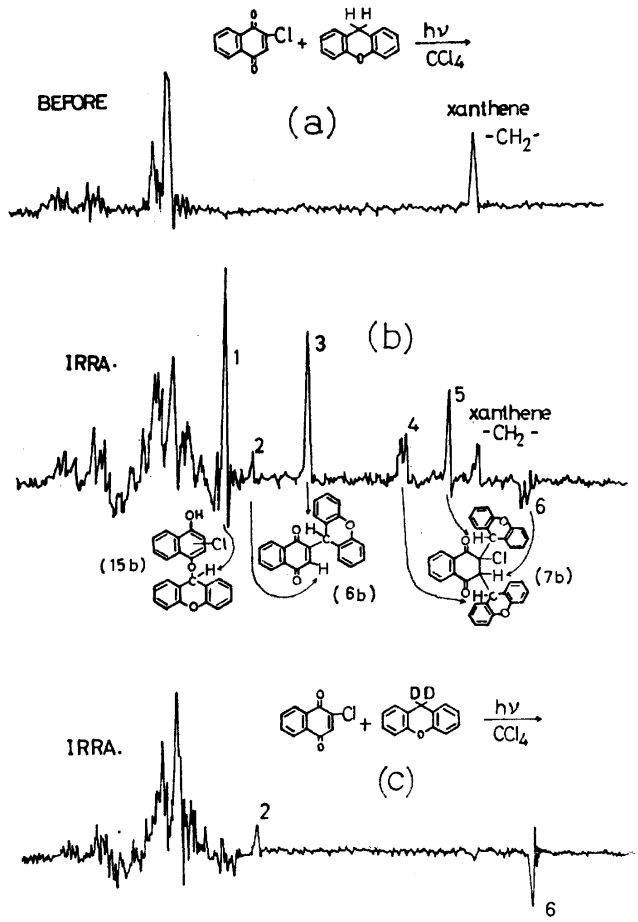

Fig. 3. PMR spectra observed in the photochemical reaction of 2-chloro-1,4-naphthoquinone with xanthene.
(a): before irradiation, (b): during irradiation, (c): during irradiation, when xanthene-9-d_2 was used.

respective compounds by comparison with the PMR spectra of the isolated products, but one can determine those due to reaction intermediates by comparison with the polarized PMR signals observed in the reaction of the corresponding quinones with xanthene-9-d_2 and their chemical shifts. The structures thus determined are indicated in Figs. 2—4. According to the CKO theory,[6] the polarized signals are developed by the reaction products formed through a radical process, regardless of their stabilities. Although these photochemical reactions obviously proceed through radical processes, fairly vigorous liberation of hydrogen halides could be observed in the course of the reactions of **5b**, **5c**, **5d**, and **5e**. This may be interpreted in terms of the decomposition of the thermally-unstable intermediates to give the substituted derivatives of 1,4-naphthoquinone by means of the xanthyl group. Since the structure of the reaction intermediates formed in the reacting system, as well as the stable products, could be determined by means of the CIDNP technique and by stable-product analyses, the following possible reaction scheme can be proposed. The disproportionation of the semiquinone radical (Step iv) was unambiguously confirmed by means of the CIDNP technique, the details were reported in a previous report.[5] The temperature dependence of the stable-product distributions described in Table 2 can be ingeniously interpreted by taking into consideration Steps v and vi; at higher temperatures the yield of 9,9′-bixanthyl is considerably reduced, and that of the stable radical is increased. The process of the stable free radical formation has already been considered in Section 3. In the photochemical reaction of 1,4-naphthoquinone with xanthene, Steps vii, viii, and ix might be unimportant.

The photochemical reactions of 1,4-naphthoquinone derivatives with thioxanthene proceeded quite smoothly, as those with xanthene, but the products were the corresponding hydroquinones, quinhydrones and 9,9′-bithioxanthyl, with the exceptions of **5b** and **5d**. In the phothochemical reactions of **5b** or **5d** with thioxanthene, a small amount of the adduct corresponding to **6b** was isolated in addition to the compounds described above.

Experimental

Materials. 1,4-Naphthoquinone (mp 125—126 °C) commercially available was further purified by sublimation.

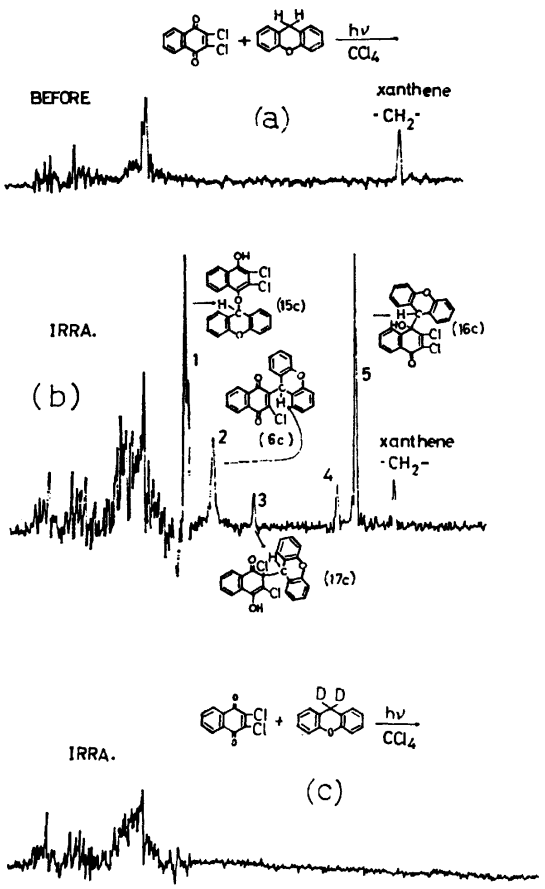

Fig. 4. PMR spectra observed in the photochemical reaction of 2,3-dichloro-1,4-naphthoquinone.
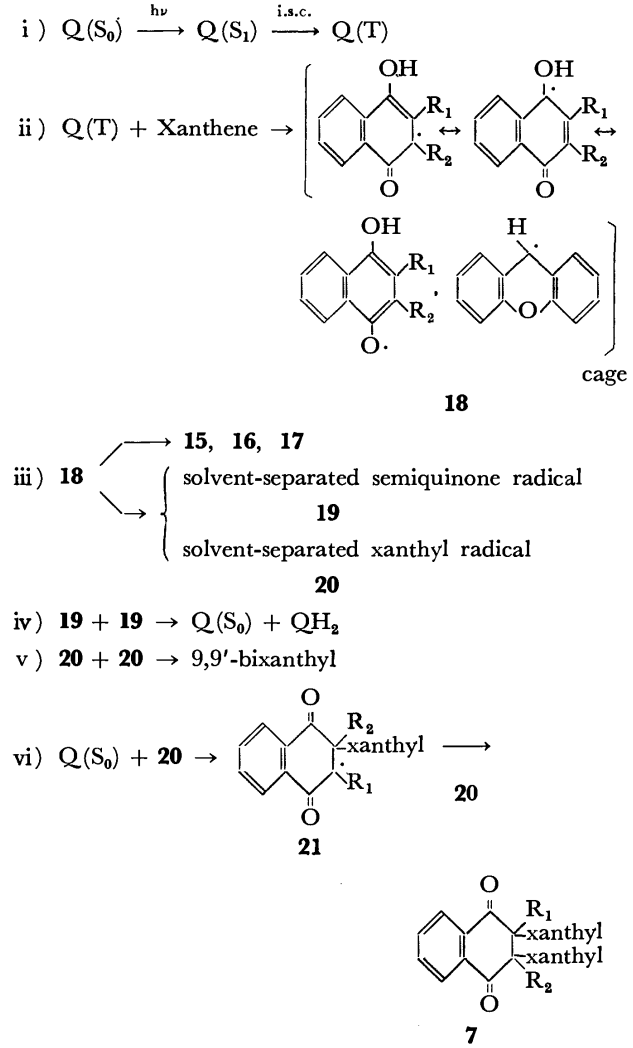
(a): before irradiation, (b): during irradiation, (c): during irradiation, when xanthene-9-d_2 was used.

2-Methyl-1,4-naphthoquinone (mp 104—105 °C),[7] 2,3-dimethyl-1,4-naphthoquinone (mp 126—127 °C),[8] and 2,6-dimethyl-1,4-naphthoquinone (mp 139 °C),[9] were prepared by the oxidation of the corresponding methylnaphthalenes with chromic acid. 2-Chloro-1,4-naphthoquinone (mp 116—117 °C) was prepared by the oxidation of 2,4-dichloronaphthol with chromic acid.[10] 2,3-Dichloro-1,4-naphthoquinone (mp 197—198 °C) commercially available was further purified by recrystallization. 2-Bromo-1,4-naphthoquinone (mp 135 °C) was prepared by the dibromination of 1,4-naphthoquinone, followed by dehydrobromination with sodium acetate.[11] 2,3-Dibromo-1,4-naphthoquinone (mp 220 °C) was prepared by the bromination of 2-bromo-1,4-naphthoquinone.[11] Xanthene commercially available was further purified by recrystallization. Thioxanthene (mp 130—131 °C) was prepared by the reduction of thioxanthone with lithium alminium hydride.[12] Thioxanthone was prepared by heating thiosalicyclic acid and benzene in conc. sulfuric acid.[13] Xanthene-9-d_2 was prepared with lithium aluminium deuteride.

Spectra. Infrared spectra were taken with a JASCO IR-G spectrophotometer, using a KBr disc. PMR spectra were observed with a JEOL PS-100 100 Hz spectrometer in suitable solvents using TMS as the internal standard. Ultraviolet spectra were recorded by means of a Shimadzu UV-200 spectrophotometer. ESR spectra were measured at room temperature using a JEOL X-band PE-3X spectrometer in THF.



Reaction Scheme.

Photochemical Reactions. A typical photochemical reaction was performed as follows; 1,4-naphthoquinone derivatives (1—2 mmol) and one or two equivalents of xanthene were dissolved in 30 ml of benzene, and the solution was irradiated in an ordinary glass tube from outside by a 400W high-pressure mercury arc lamp through a water layer 5—10 cm thick under ice-water cooling or at room temperature.

i) Photochemical Reactions of Methyl-substituted 1,4-Naphthoquinone, 3, with Xanthene. A soluiton of 2-methyl-1,4-naphthoquinone, **3a** (300 mg, 1.7 mmol), and two equivalents of xanthene was irradiated for 8 hr. 2-Methyl-1,4-naphthohydroquinone, **4a**, thus deposited was filtered off, washed with benzene, and recrystallized from acetic acid. The filtrate was evaporated under reduced pressure and the residue was chromatographed on silica gel. Elution with light petroleum gave 9,9′-bixanthyl in 70—80% yield. 2,3-Dimethyl-1,4-

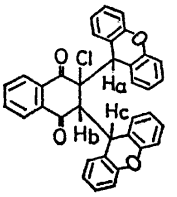
naphthoquinone, **3b**, and 2,6-dimethyl-1,4-naphthoquinone, **3c**, reacted with xanthene as smoothly as **3a** to give **4b**, **4c**, and 9,9′-bixanthyl. 2-Methyl-1,4-naphthohydroquinone, **4a**; white needles(readily turned violet in the air), mp 152 °C; ν_{OH} 3320 cm^{-1}. 2,3-Dimethyl-1,4-naphthohydroquinone, **4b**; white crystals (readily turned black), mp 141 °C; IR(KBr): ν_{OH} 3300 cm^{-1}, 2,6-Dimethyl-1,4-naphthohydroquinone, **4c**; white crystals tinged with violet; mp 175—176 °C; IR(KBr): ν_{OH} 3260 cm^{-1}. 9,9′-Bixanthyl; colorless needles; mp 211—211.5 °C.

*ii) Photochemical Reaction of 1,4-Naphthoquinone, **5a**, with Xanthene.* A solution of **5a** (632 mg, 4 mmol) and xanthene (4 mmol) in 30 ml of benzene was irradiated under ice-water cooling (at 0—5 °C) for hr 5. Dark violet needles of quinhydrone, **8a**, (195 mg, 31%) were deposited and then filtered off. The filtrate was evaporated under reduced pressure, and the residue was chromatographed on a column of florisil. Elution with light petroleum gave 9,9′-bixanthyl (120 mg, 17%). Elution with light petroleum–benzene (1 : 1 v/v) gave unreacted 1,4-naphthoquinone. Elution with benzene gave white crystals of 2,3-dixanthyl-2,3-dihydro-1,4-naphthoquinone, **7a** (31 mg, 1.5%). Quihydrone, **8a**; mp 165—166 °C, IR (KBr): ν_{OH} 3250 cm^{-1}. 2,3-Dixanthyl-2,3-dihydro-1,4-naphthoquinone, **7a**; mp 196 °C, IR(KBr): $\nu_{C=O}$ 1675 cm^{-1}, $\nu_{=C-O-}$ 1250 cm^{-1}. PMR($CDCl_3$) δ: 7.8—6.1(m, 20H), 4.30(d, 2H, methine protons of the xanthyl moleties), 3.12(d, 2H, 2,3-protons of the quinone moiety), J=4.0 Hz. Found: C, 83.20; H, 4.54%. Calcd for $C_{36}H_{24}O_4$: C, 83.06; H, 4.65%. Mass *m/e*: 520(M^+), 362, 338, 181.

*iii) Photochemical Reactions of 2-Chloro-1,4-naphthoquinone, **5b**, with Xanthene.* A solution of **5b** (964 mg, 5 mmol) and xanthene (5 mmol) in 60 ml of benzene was irradiated for 4 hr under ice-water cooling(at 0—5 °C). The violet leaflets quinhydrone, **8b**, (470 mg, 48%) thus deposited were filtered off, washed with petroleum-benzene, and recrystallized from petroleum–benzene(4 : 1 v/v). The filtrate was evaporated under reduced pressure to *ca.* 3 ml. Petroleum ether was added to the resulting solution, and crude solids were filtered off and recrystallized from peroleum–benzene to give colorless crystals of 2-chloro-2,3-dixanthyl-2,3-dihydro-1,4-naphthoquinone, **7b** (110 mg, 4%). The mother liquors from the filtration of **7a** were evaporated under reduced pressure, and the resulting residue was chromatographed on silica gel. Elution with petroleum gave 9,9′-bixanthyl (203 mg, 23%). Elution with petroleum–benzene(5 : 1 v/v) gave yellow needles of 2-xanthyl-1,4-naphthoquinone, **6b** (9 mg, 0.8%).

In the photochemical reaction of **5b** at room temperature, a solution of **5b** (385 mg, 2 mmol) and the equivalent mol of xanthene was irradiated for 5 hr. Greenish solids of **10b** (107 mg, 14%) were deposited, and filtered off, washed with petroleum-benzene. The greenish solids were proved to consist of free radicals by means of ESR spectroscopy. The filtrate was evaporated under reduced pressure to *ca.* 3 ml, and treated with petroleum; then the quinhydrone, **8b**, and **7b** deposited were collected and dissolved in petroleum-benzene (5 : 1 v/v) under heating. The quinhydrone was dissolved, and insoluble **7b** was separated out. The recrystallization of crude **7b** gave pure crystals (95 mg, 9%). When a hot solution containing quinhydrone was cooled, violet leaflets of quinhydrone, **8b** (94 mg, 24%), were obtained. The mother liquors left after the filtration of **8b** and **7b** were evaporated, and the resulting residue was chromatographed on silica gel. 17 mg of 9,9′-bixanthyl (5%) and 14 mg of **6b** (2.1%) were thus obtained.

Quinhydrone, **8b**; mp 141—142 °C, IR(KBr): ν_{OH}

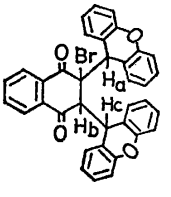


7b

3360 cm^{-1}. 2-Chloro-2,3-dixanthyl-2,3-dihydro-1,4-naphthoquinone, **7b**; mp 186 °C(decomp.), IR(KBr): $\nu_{C=O}$ 1700 cm^{-1} (due to carbonyl group bearing a chlorine atom at the equatorial position), 1675 cm^{-1}. PMR($CDCl_3$) δ: 8.08—6.36(m, 20H), 4.98(d, H_c), 4.43(s, H_a), 3.76(d, H_b), J_{bc}=4.0 Hz. In the PMR spectrum of the adduct corresponding to **7b** obtained from the photochemical reaction of **5b** with xanthene-9-d_2, the two signals at δ: 4.98 and 4.43 disappeared and the signal at δ: 3.76 changed to a singlet. Found: C, 78.11; H, 4.19; Cl, 6.12%. Calcd for $C_{36}H_{23}O_4Cl$: C, 77.90; H, 4.18; Cl, 6.39%. 2-Xanthyl-1,4-naphthoquinone **6b**; mp 196 °C, IR(KBr): $\nu_{C=O}$ 1650 cm^{-1}. PMR(CCl_4) δ: 7.0—8.3 (m, 12H), 6.31(s, 1H, proton at position 3 of the quinone moiety), 5.76(s, 1H, methine proton of the xanthene moiety). UV($CHCl_2$): λ_{max} (log ε), 430 nm(1.43), 340 nm(3.60), 286 nm(3.88), 254 nm(4.46). Found: C, 81.72; H, 4.06%. Calcd for $C_{23}H_{14}O_3$: C, 81.64; H, 4.17%. Stable radical, **10b**; greenish powder; mp 105—107 °C(decomp.), IR(KBr): ν_{OH} 3200 cm^{-1}.

*iv) Photochemical Reaction of 2-Bromo-1,4-naphthoquionne, **5d**, with Xanthene.* A solution of **5d** (1165 mg, 5 mmol) and xanthene (5 mmol) in 60 mg of benzene was irradiated for 5 hr under ice-water cooling (at 0—5 °C). Four products were isolated by the same treatment as in the case of **5b**. 250 mg (21%) of quinhydrone, **8d**, 210 mg(23%) of 9,9′-bixanthyl, 35 mg(2.1%) of **6b**, and 25 mg(0.8%) of 2-bromo-2,3-dixanthyl-2,3-dihydro-1,4-naphthoquinone **7d** were obtained. In the photochemical reaction of **5d** at room temperature, a solution of **5d** (354 mg, 1.5 mmol) and xanthene (1.5 mmol) was irradiated for 5 hr. The greenish solids, **10d**, deposited (117 mg, 23%) were filtered off, and washed with benzene–petroleum ether. The greenish solids were proved to be free radicals by means of ESR spectroscopy. The filtrate was evaporated under reduced pressure, and the resulting residue was chromatographed on silica gel. Small amounts 9,9′-bixanthyl and 25 mg(5%) of **6b** were thus obtained.

Quinydrone, **8d**; dark-violet leaflets; mp 113—115 °C, IR(KBr): ν_{OH} 3400 cm^{-1}. 2-Bromo-2,3-dixanthyl-2,3-dihydro-1,4-naphthoquinone, **7d**; white crystals; mp 151—152 °C, IR(KBr): $\nu_{C=O}$ 1700, 1780 cm^{-1}. PMR($CDCl_3$) δ: (m, 20H), 5.16(d, H), 4.56(s, H), 3.93(d, H), J_{bc}=4.0 Hz. Elemental and mass analyses could not be done, because **7d** was unstable and gradually decomposed. However, IR and PMR spectra showed the same patterns as those of **7b**. Stable radical, **10d**; greenish powder; mp *ca.* 110 °C (decomp.). **10d** and **10b** had almost the same decomposing points, and their chromic-acid oxidations gave the same



7d

product. Their ESR and IR spectra were, then, quite similar.

*v) Photochemical Reaction of 2,3-Dichloro-1,4-naphthoquinone, **5c**, with Xanthene.* A solution of **5c** (454 mg, 2 mmol) and xanthene (2 mmol) was irradiated for 11 hr. The dark-greenish solids thus deposited were filtered off, and washed with benzene. 130 mg(17%) of dark-greenish solids, **10c**, were thus obtained. The filtrate was evaporated under reduced pressure, and the resulting residue was chromatographed on silica gel. Elution with benzene gave red needles of 2-chloro-3-xanthylnaphthoquinone, **6c**, (178 mg, 24%). The dark-greenish solids were proved to be free radicals by means of ESR spectroscopy.

Stable radical, **10c**; dark-greenish powder; mp 135—140 °C(decomp.), IR(KBr): ν_{OH} 3050 cm^{-1}. 2-Chloro-3-xanthyl-1,4-naphthoquinone **6c**; PMR($CDCl_3$) δ: 7.5—8.2 (m, 4H), 6.7—7.3(m, 8H), 6.16(s, 1H), IR(KBr): $\nu_{C=O}$ 1660 cm^{-1}. UV($CHCl_3$): λ_{max} (log ε) 483 nm(1.80), 3.40 nm(3.75), 280 nm(4.18), 252 nm(4.30). Found: C, 73.98; H, 3.38; Cl, 9.77%. Calcd for $C_{23}H_{13}O_3Cl$: C, 74.11; H, 3.51; Cl, 9.51%. Mass *m/e*: 372(M$^+$), 337, 181.

*vi) Photochemical Reaction of 2,3-Dibromo-1,4-naphthoquinone, **5e**, with Xanthene.* A solution of **5e** (632 mg, 2 mmol) and xanthene (2 mmol) in 60 ml of benzene was irradiated for 10 hr. The black solids deposited were filtered off, and washed with benzene. 53 mg(5.3%) of black solids, **10d**, were thus obtained. The solids were proved to consist of free radicals by means of ESR spectroscopy. The filtrate was evaporated, and the resulting residue was chromatographed on silica gel. Elution with benzene gave red needles, which proved to be 2-bromo-3-xanthyl-1,4-naphthoquinone **6e** (107 mg, 11%).

Stable radical, **10e**; black powder; mp 181—182 °C(decomp.), IR(KBr): ν_{OH} 3050 cm^{-1}. 2-Bromo-3-xanthyl-1,4-naphthoquinone, **6e**; mp 210 °C(decomp.), IR(KBr): $\nu_{C=O}$ 1667 cm^{-1}. UV($CHCl_3$): λ_{max} (log ε) 490 nm(1.85), 340 nm (3.54), 290 nm(4.23), 254 nm(4.29). PMR($CDCl_3$) δ: 7.0—8.4(m, 12H), 6.36(s, 1H): Found: C, 66.49; H, 3.08; Br, 19.02%. Calcd for $C_{23}H_{13}O_3Br$: C, 66.20; H, 3.14; Br, 19.14%.

vii) Photochemical Reactions of 1,4-Naphthoquinone Derivatives with Thioxanthene. A solution of 1,4-naphthoquinone derivatives, **3a** and **5a**—**e** (2 mmol), and thioxanthene(4 mmol) in 30 ml of benzene was irradiated for 6—8 hr. Naphthohydroquinones, quinhydrones, and 9,9'-bithioxanthyl were thus obtained in nearly quantitative yields. In the photochemical reaction of **5b** or **5d** with thioxanthene, small amounts of the adduct corresponding to **6b** were isolated. 9,9'-Bithioxanthyl; white needles; mp>300 °C. 2-Thioxanthyl-1,4-naphthoquinone; orange needles; mp 236—237 °C, IR(KBr): $\nu_{C=O}$ 1650 cm^{-1}. PMR($CDCl_3$) δ: 7.04—8.0(m, 12H), 6.36(s, 1H), 5.74(s, 1H). Mass *m/e*: 354(M$^+$), 337, 197.

*Oxidation of Stable Free Radicals, **10b—d**.* A dilute aqueous chromic acid solution was added to a solution of stable free radicals, **10b, 10c,** or **10d** (100 mg), in acetic acid(30 ml) until the green solution turned reddish yellow. A 100-ml portion of water was then added to the solution, and it was extracted with ether. The dried extract was evaporated, and resulting residue was separated on thin-layer chromatography. 2-[9'-Hydroxyxanthyl]-1,4-naphthoquinone, **12a**, from **10b** and **10d**, and 2-chloro-3-[9'-hydroxyxanthyl]-1,4-naphthoquinone, **12b**, from **10c**, in about 30% yield.

2-[9'-Hydroxyxanthyl]-1,4-naphthoquinone, **12a**; red needles; mp 226—227 °C, IR(KBr): ν_{OH} 3490 cm^{-1}, $\nu_{C=O}$ 1660 cm^{-1}. PMR($CDCl_3$) δ: 6.92—8.10(m, 13H), 3.20 (s, 1H, –OH). Found: C, 78.25; H, 4.05%. Calcd for $C_{23}H_{14}O_4$: C, 77.96; H, 3.98%. Mass *m/e*: 354(M$^+$), 337, 197. 2-Chloro-3-[9'-hydroxyxanthyl]-1,4-naphthoquinone, **12b**; orange yellow needles; mp 165 °C (decomp.), IR(KBr): ν_{OH} 3370 cm^{-1}. $\nu_{C=O}$ 1680, 1640 cm^{-1} (the two IR absorptions due to carbonyl groups indicate the existence of chelated and non-chelated carbonyl groups, coinciding with the existence of an intramolecularly-hydrogen-bonded hydroxyl group). PMR($CDCl_3$) δ: 8.22—6.88(m, 12H), 6.84(s, 1H, –OH). Found: C, 71.38; H, 3.40; Cl, 9.35%. Calcd for $C_{23}H_{13}O_4Cl$: C, 71.04; H, 3.38; Cl, 9.12%. Mass *m/e*: 388(M$^+$), 371, 352, 336, 279, 197.

ESR Spectroscopy. ESR spectra of **10b—e** were observed at room temperature by the use of a JEOL X-band PE-3X spectrometer. THF used as a solvent was dried with metallic sodium and purified by distillation. Samples dissolved in THF were thoroughly degassed by four freeze-pump-thaw cycles and sealed. The ESR coupling constants and *g*-values of **10b—e** were measured by using Fremy's salt (a_N: 13.0 gauss, *g*: 2.0055) as a standard.

CIDNP Examinations. An investigation of these photochemical reactions by the CIDNP technique was performed using a JEOL C-60 HL spectrometer, equipped with a modified NMR probe for the photo-irradiation. The details of the method used were previously described in this Bulletin by Maruyama and his co-workers.[3]

Determination of Quantum Yields. A solution of 1,4-naphthoquinone derivatives(0.1 M) and xanthene(0.2 M) was irradiated with a 400W high-pressure mercury arc lamp through a uv-cut filter (Toshiba VY-42). The intensity was determined by means of a potassium ferrioxalate actinometer.[14] The rate of quinone disappearance was determined spectroscopically.

(Received February 8, 1974)

1,5-Cyclooctdiene reacted with phenylpalladium chloride to give di-μ-chloro-bis-(1-phenylcyclooct-4-ene-8σ,4π)-dipalladium(II). Similarly, the reaction of *endo*-dicyclo-pentadiene with phenylpalladium chloride led to di-μ-chloro-bis-[*endo*-6-phenyl-3a,4,5,6,7,7a-hexahydro-*endo*-4,7-methanoindene-*endo*-5σ,(2—3)π]-dipalladium (II). The σ-bonded structures of these complexes have been confirmed by studies of the IR and NMR spectra.

Heck[1] has previously reported that the reaction of 1,3-diolefins with arylpalladium chloride gave 1-arylmethyl-π-allylpalladium chloride dimers in moderate yields. In this paper, we wish to report that 1,5-cyclooctadiene (**1**) and *endo*-dicyclopentadiene (**2**) react with arylpalladium chloride to form complexes containing a carbon–palladium σ bond.

Experimental

Materials. All the melting points are uncorrected. The arylmercuric chlorides were prepared by the methods described in the literature: *p*-tolylmercuric chloride,[2] mp 232—233 °C; *p*-anisylmercuric chloride,[3] mp 173—174 °C. The phenylmercuric chloride, 1,5-cyclooctadiene (**1**), and *endo*-dicyclopentadiene (**2**) were of a commercial grade and were used after purification.

*The General Procedure for The Preparation of Di-μ-chloro-bis-(1-arylcyclooct-4-ene-8σ,4π)-dipalladium(II) (**3a—c**) and Di-μ-chloro-bis-*[endo-*6-aryl-3a,4,5,6,7,7a-hexahydro-*endo-*4,7-methano-indene-*endo-*5σ,(2—3)π]-dipalladium(II) (**3d—f**).* A lithium chloropalladite solution was prepared by stirring 0.42 g (10 mmol) of anhydrous lithium chloride and 1.77 g (10 mmol) of anhydrous palladium chloride overnight at room temperature in 100 ml of acetonitrile. Into the lithium chloropalladite solution, arylmercuric chloride(10 mmol) was then added with stirring at room temperature for ten min, after which 12 mmol of **1** or **2** was added in one portion. After the mixture had been stirred at room temperature for 6 hr, the solution was filtered and evaporated to dryness. The residue was dissolved in chloroform and chromatographed on neutral alumina. The first elution with chloroform and recrystallization from methanol afforded colorless crystals, which were identified as biphenyls (**4a—c**). Further elution with chloroform and recrystallization from chloroform–cyclohexane afforded yellow products (**3a—f**). The results are summarized in Table 1.

*The Preparation of Chloro-(1-arylcyclooct-4-ene-8σ,4π)-pyridine-palladium Complexes (**5a—c**)* and *Chloro-*[endo-*6-aryl*]-*3a,4,5,6,7,7a-hexahydro-*endo-*4,7-methano-indene-*endo-*5σ,(2—3)π]-pyridine-palladium Complexes (**5d—f**).* A solution of the palladium complex (**3a—f**) (0.10 g) in methylene chloride was treated with a solution of pyridine (5% excess) in ether. After 30 min, the solvent was removed under reduced pressure; the residue was then recrystallized from benzene-cyclohexane to give yellow crystals. The results are summarized in Table 2.

*Sodium Borohydride or Deuteride Reductions of Arylated σ-Complexes (**3a—f**).* Into a suspension of sodium borohydride or deuteride in 50—70 ml of dry monoglyme **3a—f** was added with stirring over a period of 30 min (molar ratio of 2 : 1, hydride to complex). After the solution has been stirred at room temperature for 1 hr, an exual volume of water was added and the solution was heated on a steam bath for 1 hr. The reaction was heated on a steam bath for 1 hr. The reaction mixture was then cooled, and the palladium precipitate which had formed was collected on a filter. The filtrate was extracted with three 75-ml portions of *n*-hexane. The combined extracts were dried over anhydrous magnesium sulfate and then fractionally distilled to afford to product, **6a—f** or **7a—c** (see Table 3). The products were identified by comparison with authentic samples and by the observation of the NMR spectra.

Results and Discussion

At room temperature, **1** reacted with phenylpalladium chloride to give yellow di-μ-chloro-bis-(1-phenylcyclooct-4-ene-8σ,4π)-dipalladium(II) (**3a**) in a 28% yield, accompanied by a small amount of biphenyl (**4a**). *p*-Tolyl- and *p*-anisylpalladium chloride also reacted to afford yellow σ-complexes (**3b—c**).

The reduction of **3a** with sodium borohydride in monoglyme to afford phenylcyclooctane (**6a**) showed that the addition of the phenyl group occurred at an olefinic bond by means of the formation of a new carbon-carbon bond and that the reaction occurred without any rearrangement of the carbon skeleton. The σ-bonded structure of the complex (**3a**) was supported by the molecular-weight measurements and by the bridged splitting reaction with pyridine to give a readily soluble monomeric derivative (**5a**). Moreover, the far-infrared spectrum of **3a** showed a bridged Pd–Cl stretching absorption at about 278 and 227 cm^{-1}. The NMR spectrum of **3a** was consistent with the four resonances at 1.18—2.75 (the protons of methylene and methine groups), 6.09 (the olefinic proton), 6.46 (the olefinic proton), and 7.25 ppm (the phenyl protons), and was in agreement with the proposed structure. Similarly, in the NMR spectra of **3b—c**, all the resonances can be satisfactorily accounted for by the presence of the σ-bond.

In the presence of lithium chloropalladite, the reaction of **2** with arylmercuric chloride in acetonitrile also gave the yellow chloro-bridged complex, di-μ-chloro-bis[*endo*-6-aryl-3a,4,5,6,7,7a-hexahydro-*endo*-4,7-methanoindene-*endo*-5σ,(2—3)π]-dipalladium(II) (**3d—f**), accompanied by a small amount of **4a—c**. The molecular-weight measurements, the observation of far-infrared spectra, and the bridge-splitting reaction with pyridine supported the chloro-bridged binuclear structures for **3d—f**. Furthermore, the NMR spectra of **3d—f** were in agreement with the proposed structures.

TABLE 1. THE REACTION OF ARYLPALLADIUM CHLORIDE WITH 1,5-CYCLOOCTADIENE (**1**) AND *endo*-DICYCLOPENTADIENE (**2**)

Arylating Agent ArHgCl	Product	Yield (%)[a]	Mp °C (lit.)	Found % (Calcd) and mol wt[b]	IR (cm^{-1}) and NMR (δ, ppm) spectra.

a) Yields are based upon the arylmercuric chloride. b) IR spectra were measured on KBr disks (4000—650 cm^{-1}) or in Nujol mulls mounted on thin polythene windows (700—200 cm^{-1}). NMR spectra were observed in $CDCl_3$ by means of a Hitachi R-22 NMR spectrometer at 90 MHz, using TMS as an internal standard. The chemical shifts were followed by the splitting pattern (s, singlet; q, quartet; m, multiplet) and the relative strengths. Molecular weight was determined in $CHCl_3$, using a Hitachi 115 vapor-pressure osmometer. c) E. Müller and T. Topel, *Ber.*, **72**, 273 (1939).

TABLE 3. REDUCTION OF ARYLATED σ-COMPLEXES (**3a—f**) WITH $NaBH_4$ OR $NaBD_4$

Product[a]	Yield %	Bp °C/mmHg (lit.)	NMR spectra (δ, ppm).
6a (Ar=Ph)	68	110—115/1 (100—102/0.55—0.6[b])	
6b (Ar=*p*-tolyl)	70	123—125/1	1.38—1.81 (m, 14H, -CH_2-), 2.28 (s, 3H, CH_3), 2.80 (m, 1H, -CH-), and 7.22 (q, 4H, tolyl protons).
6c (Ar=*p*-anisyl)	71	118—121/1	1.40—1.79 (m, 14H, -CH_2-), 2.83 (m, 1H, -CH-Ar), 3.71 (s, 3H, CH_3O-), and 7.18 (q, 4H, anisyl protons).
6d (Ar=Ph)	75	134—136/2	1.36—1.90 (m, 14H, -CH_2-+-CH-), 3.03 (d-q, 1H, H_A, $J_{A,X}$=8.5 Hz, $J_{A,B}$=2.0 Hz, $J_{A,7}$=3.5 Hz), and 7.23 (m, 5H, phenyl protons).
7a (Ar=Ph)	70	132—135/2	1.35—1.90 (m, 11H, -CH_2-+-CH- -CHD-), 3.04 (q, 1H, H_A, $J_{A,X}$ =8.5 Hz, $J_{A,7}$=3.6 Hz), and 7.23 (m, 5H, phenyl protons).
6e (Ar=*p*-tolyl)	68	144—147/2	1.30—1.96 (m, 14H, -CH_2-+-CH-), 2.30 (s, 3H, CH_3-), 2.97 (d-q, 1H, H_A, $J_{A,X}$=8.4 Hz, $J_{A,B}$=2.1 Hz, $J_{A,7}$=3.6 Hz), and 7.11 (m, 4H, tolyl protons).
7b (Ar=*p*-tolyl)	65	144—148/2	1.34—1.93 (m, 11H, -CH_2-+-CH-+-CHD-), 2.29 (q, 1H, H_A, $J_{A,X}$ =8.6 Hz, $J_{A,7}$=3.6 Hz), and 7.13 (m, 4H, tolyl protons).
6f (Ar=*p*-anisyl)	65	150—151/3	1.30—1.98 (m, 14H, -CH_2-+-CH-), 2.96 (d-q, 1H, H_A, $J_{A,X}$=8.0 Hz, $J_{A,B}$=2.0 Hz, $J_{A,7}$=3.5 Hz), 3.74 (s, 3H, CH_3O-), and 7.25 (m, 4H, anisyl protons).
7c (Ar=*p*-anisyl)	68	148—150/3	1.28—1.98 (m, 11H, -CH_2-+-CH-+-CHD-), 2.94 (q, 1H, H_A, $J_{A,X}$ =8.2 Hz, $J_{A,7}$=3.5 Hz), 3.74 (s, 3H, CH_3O-), and 7.28 (q, 4H, anisyl protons).

a) The elemental analyses were consistent with the assigned structures and the deuterium-content of the products was calculated from the mass-spectral results. b) A. C. Cope and E. C. Hermann, *J. Amer. Chem. Soc.*, **72**, 3405 (1950).

For example, the NMR spectrum of **3e** consists of six groups of bands centered at δ 1.01—2.05 (the methylene and methine protons), 2.28 (the methyl protons), 2.85 (H_X proton), 3.23 (H_A proton), 6.50 (the olefinic protons), and 7.32 ppm (the tolyl protons), with relative intensities of 8 : 3 : 1 : 1 : 2 : 4. The quartet peak (J=10 and 4 Hz) at δ 3.23 ppm is assigned to the proton (H_A) on the aryl-bearing carbon, and the coupling of 10 Hz between the (CH-*p*-tolyl) and (CH-Pd) protons is a result of a coupling to a vicinal proton with a 0° dihedral angle ($J\simeq$7—9 Hz).[4] The palladium-carbon bond must be *endo* so that palladium can remain coordinated to the double bond; the *p*-tolyl moiety is, therefore, *endo*. In addition, the reduction of **3e** with sodium borohydride or deuteride gave a saturated hydrocarbon, $C_{17}H_{22}$ (**6e**) or $C_{17}H_{19}D_3$ (**7b**). The NMR spectrum of **6e** shows a very characteristic pair of quartets ($J_{A,X}$=8.4 Hz, $J_{A,B}$=2.1 Hz, $J_{A,7}$= 3.6 Hz) for the H_A proton at 2.97 ppm. The coupling constant of $J_{A,X}$ correlates with the calculated value ($J\simeq$7—9 Hz) between H_A and a proton at a 0° angle, and the coupling constant of $J_{A,B}$ is that expected for a 120° dihedral angle ($J\simeq$2 Hz). Furthermore, the NMR spectrum of deuterated hydrocarbon (**7b**) was very similar to that of **6e**, and the *endo*-configuration of the deuterium was established by the H_A quartet ($J_{A,X}$=8.6 Hz, $J_{A,7}$=3.6 Hz). These results support the proposed structure for **3e**. Similarly, in the NMR spectra for **3d** and **3f** and monomeric pyridine derivatives (**5d—f**), all the resonances can be satisfactorily accounted for by the proposed structures.

Recently, Maitlis[5] has reported that the reaction of diphenylmercury with dichloronorbornadiene palladium gave di-μ-chloro-bis-(*endo*-3-phenylnorbornen-2-yl-*endo*-palladium) and that the reaction proceeds *via* an *endo*-attack on co-ordinated norbornadiene. In the reaction of **1** or **2** with arylpalladium chloride, the reaction undoubtedly proceeds by means of *cis* arylpalladation at the double bond.

The Stereochemistry of the Addition of Trimethylaluminum to Decalones and Methyl-substituted Cyclohexanones

Toshimitsu SUZUKI, Toshiaki KOBAYASHI, Yoshinobu TAKEGAMI, and Yuzo KAWASAKI*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received March 11, 1974)

The addition to the methyl-substituted 4-*t*-butylcyclohexanone was studied, providing that the β-axial methyl and α-axial methyl groups hindered the axial and equatorial attacks respectively. The results obtained with fused-ring system ketones (four decalones) were explained by considering the similar stereochemical influence of 2- and 3-methylene substituents as corresponding methyl substituents. A rapid conformation equilibrium was also considered for *cis*-decalones. In addition, the axial attack, especially at a molar ratio of two or more, was found to be hindered by the α-equatorial methyl group. This hindrance was explained by assuming the half-chair form of the cyclohexanone ring in the transition state.

The stereochemical factors of nucleophilic addition to cyclohexanone derivatives were reported for the first time by Dauben *et al.*[1] for the reduction by hydride, and two concepts, *i.e.*, "Steric Approach Control" and "Product Development Control", were proposed to explain the observed results.

Richer[2] excluded the concept of "Product Development Control" from his results on the addition reaction of small or rod-like reagents (*e.g.*, H^-, CN^-, $HC{\equiv}C^-$) to 4-*t*-butylcyclohexanone, and proposed that the steric course was determined by the relative seriousness of interactions between the entering group and 3,5-axial hydrogens. This concept was clarified by Marshall and Carroll,[3] considering the geometry of transition states.

On the other hand, Chérest and Felkin[4] considered "Steric strain" in the transition state of axial attack and "Torsional strain" in the transition state of equatorial attack, and proposed that the steric course of the reaction was controlled by the relative amounts of these strains.

Recently, the stereochemistry of the addition reaction of trialkylaluminum to substituted cyclohexanones was investigated by Ashby[5a] and our group. In these reactions, the steric course of the addition reaction was greatly dependent on the molar ratio of ketone to alkylaluminum. That is, in the reactions with the hydrocarbon solvent, it was found that the stereoselectivity changed with the reactant molar ratio. For example, in the cases of 4-*t*-butylcyclohexanone and trimethylaluminum in the benzene solvent, it was found that the amount of axial alcohol was about 75% of alcoholic products when the reactant molar ratio (Al/K) was one or less, and that the amount of equatorial alcohol was about 90% when the molar ratio was two or more.

Fig. 1.

The reaction of benzophenone with trimethylaluminum in benzene was investigated kinetically by Ashby *et al.*[6] They concluded that the reaction mechanism depended on the reactant molar ratio. When the molar ratio (Al/K) was unity, a slow unimolecular reaction proceeded through an intramolecular rearrangement of the ketone-Al complex, and when the molar ratio was two or more, a rapid bimolecular reaction took place between a second trimethylaluminum and a ketone-Al complex. 4-Centered and 6-centered transition states were proposed respectively. The relationship between the change in stereoselectivity in the cyclohexanone derivatives and the difference in mechanisms indicated by Ashby *et al.* is very interesting; it may be assumed that the equatorial attack corresponds to the unimolecular reaction, and the axial attack, to the bimolecular reaction.

In this paper, the reactions of fused-ring-system ketones (four decalones) with trimethylaluminum in a hydrocarbon solvent were investigated in order to clarify the stereochemistry of the addition reaction of trialkylaluminum to cyclohexanone derivatives. The reactions of several 2-alkylcyclohexanones with trimethylaluminum were also investigated in order to learn more details of the stereochemistry of this reaction.

Experimental

Materials. trans-*2-Decalone*:[7] $\Delta^{1(9)}$-Octalone-2 was synthesized by the method described in the literature. The reduction of $\Delta^{1(9)}$-octalone-2 (10 g) by liq. NH_3 and Li (2.5 g) gave *trans*-2-decalone. Quantitative analysis was carried out by GC. (Hitachi F6D model. Golay R45 column). Purity, 97%.

cis-*2-Decalone*: $\Delta^{1(9)}$-Octalone-2 (24.5 g) was hydrogenated in slightly acidic (HCl) aqueous ethanol on 2.5 g of a palladium-carbon (5%) catalyst.[8] The hydrogenation product was vacuum-distilled to give 19.7 g of a mixture of 90% *cis*-2-decalone and 10% *trans*-2-decalone (22 mmHg 126~127 °C). The mixture was purified by the recrystallization from *n*-pentane at about −100 °C. Purity, 99.2%.

cis-*1-Decalone*:[9] α-Naphthol, purified by vacuum distillation, was hydrogenated in acetic acid on platinum dioxide. *Cis-cis*-1-decalol (white solid, mp 89—90 °C. lit 88—89 °C) was obtained by the recrystallization of the hydrogenation product from *n*-hexane. A solution of 18.5 g of *cis-cis*-1-decalol in acetic acid (75 ml) was oxidized by a solution of 9 g of chromic acid in water. The subsequent vacuum distillation of the oxidation product afforded 88% *cis*-1-decalone. Purity, 88%. The only impurity was *trans*-1-decalone.

* Present address: Tokuyama Soda Co. Ltd., Tokuyama 745.

trans-*1-Decalone*: The mother solution of the above-mentioned recrystallization (containing decalin, decalones, and decalols) was oxidized in acetone by a solution of chromic acid and sulfuric acid. The oxidation product, which contained decalin, *trans*-1-decalone, and *cis*-1-decalone (*trans* : *cis*~1 : 1), was chromatographed on activated alumina to afford sufficiently pure *trans*-1-decalone (*cis*-1-decalone isomerizes to *trans*-1-decalone on activated alumina). Purity, 92%.

cis-*2,6-Dimethylcyclohexanone*: A solution of 29 g of 2,6-xylenol (purified by recrystallization from *n*-hexane) in 75 ml of acetic acid was hydrogenated on 0.67 g of platinum dioxide. The hydrogenation product was oxidized in acetone by the use of chromic acid and sulfuric acid. Vacuum distillation afforded 87% *cis*-2,6-dimethylcyclohexanone (69.5—70 °C/23 mmHg). The only impurity was the *trans* isomer. The structure of the product was checked by 220 MHz NMR. Purity, 87%.

cis-*2-Methyl-4-t-butylcyclohexanone*: Essentially pure *cis*-2-methyl-*4-t*-butylcyclohexanone was obtained from 2-methyl-4-*t*-butylphenol by the procedure described above. Purity, 96%.

trans-2-*Methyl-4-t-butylcyclohexanone*: *Trans*-2-methyl-4-*t*-butylcyclohexanone was obtained by the isomerization of *cis*-2-methyl-4-*t*-butylcyclohexanone following the procedure described by Huff *et al.*[10] The product thus obtained contained about 70% *trans* isomer and 30% *cis* isomer.

4-t-Butylcyclohexanone: 4-*t*-butylcyclohexanone was synthesized by the oxidation of 4-*t*-butylcyclohexanol with chromic acid and sulfuric acid. Purity, nearly 100%.

2-Methylcyclohexanone, 2,2,6-trimethylcyclohexanone, 3,3,5-trimethylcyclohexanone: Commercially-available reagents were used without further purification.

The toluene was purified by distillation after reflux on lithium aluminum hydride under an argon atmosphere for one day.

The trimethylaluminum was obtained from the Ethyl Corporation and was used without further purification. The concentration of the trimethylaluminum solution (in toluene) was determined by the volume of methane evolved on treating an aliquot of the solution with water.

All the ketones were used as 1 mol/l solutions prepared by weighing out the calculated amount of ketone in a volumetric flask and by subsequently diluting with toluene.

Procedure: A three-necked flask equipped with a magnetic stirrer, a gas inlet, a self-sealing rubber cap, and a gas outlet connected to a bubbler was flushed with argon. Toluene (about 9 ml) and 1 ml of a ketone solution was flushed with argon. Toluene (about 9 ml) and 1 ml of a ketone solution were introduced into the flask at the reaction temperature, and then a calculated amount of trimethylaluminum solution was stirred in. After a four-hour reaction, the solution was hydrolyzed with a small piece of ice and then 1 ml of an ammonium chloride solution (1M). The solution was washed with water to remove the aluminum hydroxide and then dried over calcium sulfate. A Hitachi model F6D gas liquid chromatograph with a Golay R45 column was employed for the qualitative and quantitative analyses. 220 MHz NMR was also employed to determine the configurations of the products.

Results and Discussion

Reactions of Three Cyclohexanones with Trimethylaluminum. The results are summarized in Table 1. In the case of 4-*t*-butylcyclohexanone, which has no substituent on the 3,5- or 2,6-position, the stereoselectivity is reversed, depending on the reactant molar ratio of ketone to trimethylaluminum (Al/K), indicating that the equatorial attack is the main course when the molar ratio is one or less, while the axial attack is the main course when the molar ratio is two or more. On the other hand, the results obtained from the reaction of trimethylaluminum with *trans*-2-methyl-4-*t*-butylcyclohexanone show a different steric course from that of 4-*t*-butylcyclohexanone. In this ketone, the 2-methyl group occupies the axial position, so the attack of trimethylaluminum from the equatorial side is blocked, resulting in the higher yield of equatorial alcohol. As has been shown in a previous paper, in the reaction of 3,5,5-trimethylcyclohexanone, the 3-axial methyl group hinders the trimethylaluminum attacking from the axial side. Therefore, these two cyclohexanones show steric courses different from that of 4-*t*-butylcyclohexanone.

The Reactions of Decalones. The results are summarized in Table 2.

trans-2-Decalone: The steric requirement of the carbonyl group in this ketone is the same as that of 4-*t*-butylcyclohexanone, so the results are almost the same as those of 4-*t*-butylcyclohexanone.

trans-1-Decalone: Although a reversal of the stereoselectivity depending on the ketone to aluminum molar ratio is observed, axial alcohol is formed in an amount of more than 40% even when the ratio (Al/K) is two, indicating that the axial attack is depressed to some extent. This might be explained by the presence of three axial

hydrogens (3, 8, and 10 positions) corresponding to the 3,5-axial hydrogens in cyclohexanone, which are believed to hinder the axial attack at a molar ratio of two or more. However, this ketone can be considered to be 2,3-di-equatorial-substituted cyclohexanone. It is known that the 3-equatorial substituent does not play any role in determining the stereoselectivity, so we should consider some effect of the 2-equatorial substituent. The effect of the 2-equatorial methyl substituent will be discussed below.

cis-Decalones:

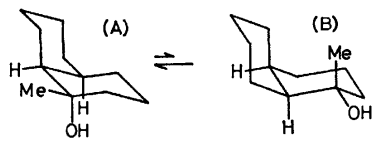

Fig. 4. Two conformations of *cis-cis*-alcohol produced by the reaction of *cis*-1-decalone and trimethylaluminum.

In the *cis*-decalone system, there exist two conformations, (A) and (B), which are believed to reach a very fast equilibrium, as is depicted in Figs. 5 and 6. The notations of the produced alcohols are as follows: in *cis-cis*-alcohol the hydroxyl group and bridge hydrogens are on the same side with the carbonyl-containing ring. On the other hand, in the *cis-trans*-alcohol they are on the opposite side. Therefore, in the case of *cis*-1-decalone, for example, as is depicted in Fig. 4, *cis-cis*-alcohol has an axial hydroxyl group in (A) and an equatorial hydroxyl group in (B) respectively.

cis-1-decalone: As is shown in Table 2, *cis-trans*-

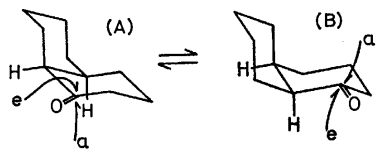

Fig. 5. *cis*-1-decalone, a; axial attack, e; equatorial attack.

alcohol is the predominant product at any molar ratio, and the steric course of the reaction apparently does not depend on the molar ratio. However, these results can be explained by the rapid conformation equilibrium between (A) and (B), considering the same steric course as in the case of 4-*t*-butylcyclohexanone.

At molar ratios of one or less, judging from the results of the reaction of trimethylaluminum with 4-*t*-butylcyclohexanone, the equatorial attack is predominant. The equatorial attack of trimethylaluminum on the (B) conformer gives *cis-trans*-alcohol. However, the equatorial attack on the (A) conformer is sterically hindered by the axial substituent (ring component). Thus, at molar ratios of one or less, the predominant reaction can be considered to be the equatorial attack of trimethylaluminum on the (B) conformer giving mainly *cis-trans*-alcohol.

At molar ratios of two or more, the prevailing attack on the cyclohexanone ring is an axial one. Accordingly, the (A) conformer gives *cis-trans*-alcohol by

the axial attack of trimethylaluminum; on the other hand, the axial attack on the (B) conformer is difficult by the presence of the 3-axial ring component.

The results can also be explained as follows: At any reactant molar ratio, trimethylaluminum attacks *cis*-1-decalone from the less hindered side (*i.e.*, the axial side in the (A) conformer and the equatorial side in the (B) conformer), so the product distribution is not affected by the reactant molar ratio. However, the axial attack at the molar ratio of unity is shown to be slow or difficult by the results obtained with *trans*-2-methyl-4-*t*-butylcyclohexanone. As is shown in Table 1, the reactivity of this ketone at the molar ratio of unity is very low (18.3%), even though the axial attack is the predominant steric course because of the fixed 2-axial methyl substituent. In addition, the equatorial attack at a molar ratio of two or more is the minor reaction path in most cases; it can become the major one only if the cyclohexanone ring contains a substituent which hinders the axial attack greatly, such as 3-axial methyl group in 3,3,5-trimethylcyclohexanone. Therefore, the latter explanation is not adequate.

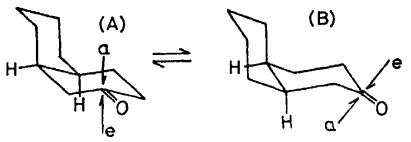

Fig. 6. *cis*-2-decalone, a; axial attack, e; equatorial attack.

cis-2-Decalone: When the molar ratio of ketone to aluminum is one or less, *cis-cis*-alcohol and *cis-trans*-alcohol are formed in nearly equal amounts; however, with an increase in the molar ratio, the *cis-trans*-alcohol increases to a large extent.

At a molar ratio of one or less, the equatorial attacks on the (A) and (B) conformers are equally favored, so *cis-trans*-alcohol and *cis-cis*-alcohol are produced from (A) and (B) respectively by the equatorial attack. Therefore, the two epimers are produced in almost equal amounts.

At a molar ratio of two or more, an axial attack on the (A) conformer is hindered by the presence of a 3-axial ring component. On the (B) conformer, however, an axial attack normally takes place and produces *cis-trans*-alcohol.

The results with four decalone isomers can be explained using the same concepts which were used in discussing the ketones listed in Table 1, considering the rapid conformation equilibrium of each isomer. Therefore, it may be concluded that, in these fused-ring-system ketones, the reactions proceed by means of the same steric course as in the monocyclic ketones.

From the results obtained by the reaction with *trans*-1-decalone, however, further study about cyclohexanones having 2-equatorial substituent is considered to be important.

Reactions of Cyclohexanones with an α-Equatorial Methyl Substituent. The results are summarized in Table 3. When the molar ratio (Al/K) is one, axial alcohols are produced in quantities of more than 96% in all the ketones investigated except 2,2,6-trimethylcyclohexanone, indicating that the stereoselectivity is greatly enhanced compared with the case of 4-*t*-butylcyclohexanone. The results for 2,2,6-trimethylcyclohexanone are anomolous. This ketone has a 2-axial methyl substituent, so the equatorial attack should be hindered. However, axial alcohol is still the main product, even though its percentage is about 10% smaller than those with other ketones.

At the reactant molar ratio of two, the extent of axial attack decreases in the order of 4-*t*-butylcyclohexanone, 2-methylcyclohexanone, and *cis*-2,6-dimethylcyclohexanone, as is shown in Table 3. It is known, therefore, that the axial attack decreases with the successive replacement of 2,6-equatorial hydrogens by methyl groups. In addition, a similar decrease in the axial attack is seen with a decrease in the flexibility of the ring system in the order of 2-methylcyclohexanone, *cis*-2-methyl-4-*t*-butylcyclohexanone, and *trans*-1-decalone. The results for *cis*-2,6-dimethylcyclohexanone and 2,2,6-trimethylcyclohexanone show that the 2-axial-methyl group plays a minor role in stereoselectivity at molar ratios of two or more. This may also be seen in the results for 4-*t*-butylcyclohexanone and *trans*-2-methyl-4-*t*-butylcyclohexanone (cf. Run 3 and Run 8 in Table 1).

Until now, the effect of the 2,6-equatorial substituent

Temp. 0°C Time 4 hr, in toluene

on the stereoselectivity of the nucleophilic addition of an organometallic compound has not received any attention. However, as has been shown in the results obtained here, the 2,6-equatorial methyl groups causes a steric hindrance of the axial attack of trialkylaluminum at molar ratios of two or more.

Recently, Ashby *et al.*[5b] proposed the "Compression effect" to explain the reversal of stereoselectivity depending on the reactant molar ratio. Although the effect will be valid for the reversal of selectivity, it may be insufficient to explain the results for 2-alkylsubstituted cyclohexanones. If the "Compression effect" is enhanced through the replacement of 2,6-equatorial hydrogens by methyl groups, the axial attack should be more favored. On the contrary, the axial attack was decreased greatly by the 2,6-equatorial methyl substituent. Therefore, in working out a mechanism to explain the stereochemical effect of the 2,6-equatorial methyl group on the axial attack, one must consider the flexibility of the cyclohexanone ring.

At molar ratios of two or more, the trialkylaluminum complexed with ketone further complexed with a second trialkylaluminum moiety. The exact structure of this ketone : Al=1 : 2 complex cannot be depicted. However, as is to be expected from the amine trialkylaluminum complex, the distance between oxygen and trialkylaluminum is about 2 Å.[11] As has already been clarified, the distance between carbon and aluminum is about 2 Å. Such a structure as is shown in Fig. 7 may be considered. In this complex, the alkyl group of the first aluminum complexed to ketone has a very low activity toward carbonyl addition. Therefore the alkyl group of the second aluminum may attack the carbonyl group. In the transition state, the carbonyl plane will be distorted from the chair form to the half-chair form; consequently, the 2,6-equatorial substituent will come up to the carbonyl plane. This causes a large steric hindrance of the axial attack of

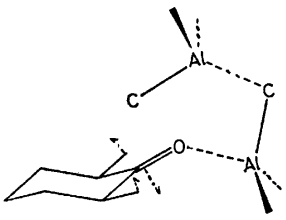

Fig. 7. ketone : $AlMe_3$=1 : 2 complex.

3,5 Me(a)	−	++	−	++

+: having hindrance on the attack, —: little or no effect on the attack,

trialkylaluminum at molar ratios of two or more. In connection with this, the fact that *trans*-1-decalone gave a smaller amount of the axial attack product than did 2-methyl- or *cis*-2-methyl-4-*t*-butylcyclohexanone can be explained by the fact that the flexibility of carbonyl plane is depressed by the fused-ring system. This mechanism, which assumes the importance of the flexibility of the carbonyl group, explains the low reactivity of trimethylaluminum toward adamantanone. The reaction of trimethylaluminum with adamantanone at a molar ratio of two was carried out. It was found that the reactivity of this ketone was very low. Only a 20% conversion was observed in the reaction with trimethylaluminum at 0 °C for 4 hr. Adamantanone has so very rigid a cyclic system that it is difficult for the carbonyl plane to be distorted to the half-chair form. Table 4 summarizes the effects of hydrogens or methyl groups, which affect the direction of the attack of trimethylaluminum on cyclohexanone derivatives.

Temperature Dependence of the Product Distribution. In the case of 4-*t*-butylcyclohexanone, the product ratio (axial alcohol to equatorial alcohol) is not altered with the reaction temperature. However, it is affected by the reaction temperature in the cases of ketones containing 2-equatorial methyl substituents (listed in Table 3) or 3,3,5-trimethylcyclohexanone. Table 5 illustrates the results for 2,2,6-trimethylcyclohexanone, which showed the largest temperature dependence of the product distribution of all the ketones investigated.

A linear relationship is observed between the plot of log (-OHax./-OHeq.) *vs.* $1/T$ at Al/K=2. The dif-

Difference of activation energies; $E_{eq.}-E_{ax.}=4.06$ kcal/mol

ference between the activation energies was calculated to be about 4 kcal/mol. The difference in activation energy suggests a difference in mechanisms between axial and equatorial attacks. In addition, it should be noted that the results in $AlMe_3/K=2$ approach the results obtained at a molar ratio of one when the reaction temperature is elevated. From these two facts, it was considered that, in these ketones, the unimolecular reaction from the equatorial side contributed greatly even when the reactant ratio was two.

In these ketones, because of the large steric requirement, the rate of bimolecular axial attack decreased so as to be comparable with the rate of equatorial attack by the unimolecular process; therefore, the temperature dependence of the product distribution is observed.

On the other hand, in the case of 4-*t*-butylcyclohexanone, the rate of axial attack is sufficiently large and the temperature dependence is not observed.

Reaction of Biguanides and Related Compounds. X.[1] The Cyclization of Arylbiguanides with Acyl Isothiocyanates

Mitsuru FURUKAWA, Motoo GOTO, and Seigoro HAYASHI

Faculty of Pharmaceutical Sciences, Kumamoto University, Oe-hon Machi, Kumamoto 862

(Received March 12, 1974)

The reactions of arylbiguanides with benzoyl and ethoxycarbonyl isothiocyanates gave 4(or 2)-arylguanidino-2(or 4)-phenyl-6-thioxo-1,6-dihydro-*s*-triazines and 4-arylguanidino-2-oxo-6-thioxo-1,4,5,6(or 1,2,3,6)-tetrahydro-*s*-triazines respectively, both of which were then converted into the corresponding oxo compounds, in which the thioxo group was converted into the oxo group, by oxidation with hydrogen peroxide. The condensation of 3-amidino-1-aryl-2-thioureas with aryl isothiocyanates afforded 1-aryl-2-arylimino-4-imino-6-thioxo-1,4,5,6-tetrahydro-*s*-triazines, which were also formed by the pyrolysis of 3-amidino-1-aryl-2-thioureas.

It has been reported by Somogyi[2] that the reaction of phenylbiguanide with an equimolar quantity of phenyl isothiocyanate gave 4,6-diimino-1-phenyl-2-phenyliminohexahydro-*s*-triazine, 6-amino-2,4-dianilino-*s*-triazine, and 4-imino-1-phenyl-2-phenylimino-6-thioxohexahydro-*s*-triazine in 29, 14—16, and 19% yields respectively, all *via* the same intermediate addition product. The interaction of biguanide and phenyl isothiocyanate has also been reported by Kurzer[3] to afford an excellent yield of 4,6-diimino-1-phenyl-2-thioxohexahydro-*s*-triazine, though no unequivocal evidence for its structure was provided. As an extension of our work on the reaction of biguanides with carbonyl compounds, we investigated the reaction of arylbiguanides with benzoyl and ethoxycarbonyl isothiocyanates, in both of which a carbonyl group is involved in the position adjacent to the isothiocyanate group.

Reaction of Arylbiguanides with Benzoyl Isothiocyanate. By analogy with the reaction of phenylbiguanide with phenyl isothiocyanate, several cyclization products are possible in the reaction between arylbiguanides (**1**) and benzoyl isothiocyanate (**2**). In addition, the participation of the carbonyl group in the cyclization is also possible.

When equimolar quantities of **1** and **2** were heated in ethanol for 4 hr, one product was obtained in a low yield. The product was positive in a lead acetate test for the sulfur atom. The infrared (IR) absorption spectra of the product exhibited the characteristic absorptions assignable to amino and imino groups near 3340 and 3140 cm^{-1} and that due to the thiocarbonyl group near 1250 cm^{-1}, but no absorption assignable to the carbonyl group was observed. Although the absorption assigned to the thiocarbonyl group was at a higher frequency than the normal absorption band of a thiocarbonyl group, its identity was confirmed by the fact that the absorption disappeared upon conversion to the carbonyl group by oxidation. The ultraviolet (UV) absorption spectra showed the maximum absorption at 265 nm. On the basis of these results and the analytical data, the product is presumed to be 4(or 2)-arylguanidino-2(or 4)-phenyl-6-thioxo-1,6-dihydro-*s*-triazines (**3**). A similar cyclization reaction has been known in the condensations of *N*-unsubstituted amidino compounds with aroyl isothiocyanates[4] and with substituted imidoyl isothiocyanates.[5] Support for the assigned structure **3** was provided by the mass spectra, in which the molecular ion and the fragment ion peaks

due to arylamidyl and arylamino ions were observed as an abundant peak.

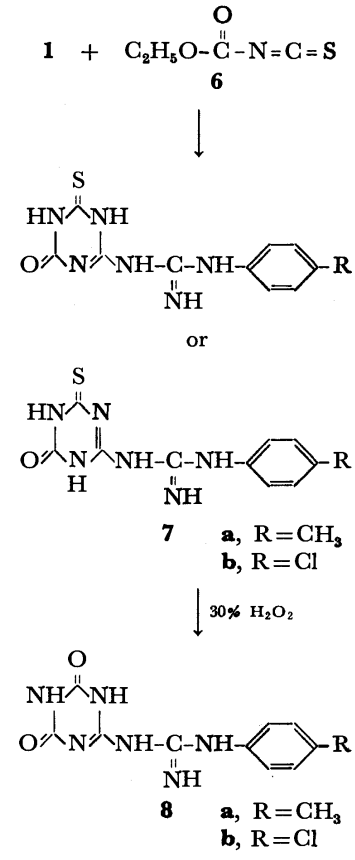
In order to further elucidate the assigned structure, the product was converted into 4(or 2)-arylguanidino-2 (or 4)-phenyl-6-oxo-1,6-dihydro-*s*-triazines (**4**). The conversion was successfully carried out by heating with a 30% aqueous hydrogen peroxide solution in acetic acid at 80 °C for 30 min. The structure of **4** was established by the good agreement of the elemental analyses and by the IR spectra, in which the absorption of the thiocarbonyl group disappeared and the absorption assignable to the carbonyl group was observed near 1680 cm^{-1}. The absorption pattern was quite similar to that of **3**.

Somogyi[2] has reported that the cyclization reaction of phenylbiguanide with phenyl isothiocyanate proceeds through the intermediate addition product which is formed by the addition of the terminal amino group of phenylbiguanide to the isothiocyanate group. In view of the resonance formula of **2**, it seems that the initial addition of **1** to **2** would analogously occur at the positive carbon atom of the isothiocyanate group, but not at the adjacent carbonyl carbon atom, to form a similar intermediate (**5**), followed by cyclization to **3** by dehydration, though all efforts to isolate the intermediate under milder reaction conditions failed. The results are summarized in Table 1.

Reaction of Arylbiguanides with Ethoxycarbonyl Isothiocyanate. Recently Goerdeler and Neuffer[6] have reported that the amidino compounds, such as isoureas, isothioureas[7] and guanidines, reacted with ethoxycarbonyl isothiocyanate, with the elimination of ethanol, to give oxothioxotetrahydro-*s*-triazines. Compound **1** is also presumed to behave similarly toward ethoxycarbonyl isothiocyanate, because an amidino moiety is involved in the molecule.

When equimolecular quantities of **1** and ethoxycarbonyl isothiocyanate (**6**) were treated in ethanol at room temperature, 4-arylguanidino-2-oxo-6-thioxo-1,4, 5,6(or 1,2,3,6)-tetrahydro-*s*-triazines (**7**) were obtained in comparatively good yields, as had been expected.

The structure of **7** was assigned on the basis of the results of elemental analyses and the spectral data. The IR spectra exhibited characteristic absorptions assignable to amino and imino groups near 3450 and 3300 cm^{-1} and that due to the thiocarbonyl group near 1235 cm^{-1}. The mass spectra showed the molecular ion peak as an abundant peak. Fragment ion



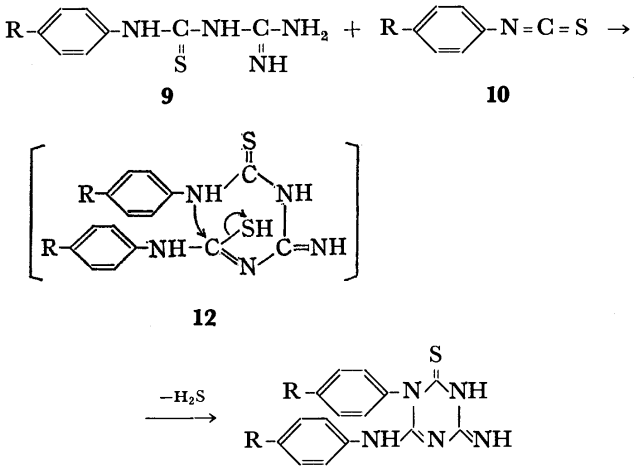
Scheme 2.

peaks presumably corresponding to the arylamidyl ion, the arylamino ion, and arylcyanamide were also observed. The UV spectra indicated the maximum absorption bands at 270 nm in a 0.01 M hydrochloric acid solution and at 275 and 250 nm in a 0.01 M sodium hydroxide solution; they must be due to the keto and enol forms respectively. Evidence for the structure was achieved by conversion with hydrogen peroxide into 4-arylguanidino-2,6-dioxo-1,2,5,6-tetrahydro-*s*-triazines (**8**), whose structures were established on the basis of the results of elemental analyses and the spectral data.

Reaction of 3-Amidino-1-aryl-2-thioureas with Phenyl Isothiocyanate. Because of the structural similarity, 3-aminido-1-aryl-2-thioureas (**9**) may be expected to behave much like **1** toward isothiocyanates. Crowther *et al.*[8] have reported that, in the preparation of 3-alkyl-

amidino-1-*p*-chlorophenyl-2-thioureas from alkylguanidines and *p*-chlorophenyl isothiocyanate, 4-alkylamino-2-*p*-chloroanilino-1-*p*-chlorophenyl-6-thioxo-1,6-dihydro-*s*-triazines were formed as by-products. This cyclization is presumed to proceed through the intermediate addition product which is formed by addition of 3-alkylamidino-1-*p*-chlorophenyl-2-thiourea, alone with further *p*-chlorophenyl isothiocyanate. Thus the condensation of **9** with several aryl isothiocyanates (**10**) was examined.

When equimolecular quantities of **9** and **10** were heated in dimethylformamide (DMF) at 110 °C, 1-aryl-2-arylamino-4-imino-6-thioxo-1,4,5,6-tetrahydro-*s*-triazines (**11**) were obtained in moderate yields.



a, R=H **c**, R=C_2H_5O
b, R=CH_3 **d**, R=Cl

Scheme 3.

The structure of **11** was assigned on the basis of the results of elemental analyses and the spectral data. The IR spectrum exhibited absorptions assignable to amino and imino groups near 3430, 3370, and 3280 cm^{-1} and that due to the thiocarbonyl group near 1150 cm^{-1}. In the mass spectrum, the corresponding molecular ion was observed as the most abundant peak. Fragment ion peaks corresponding to the elimination of NCS group from the molecular ion and to arylamine were also observed. The reaction probably proceeds through the intermediate addition product (**12**), followed by the elimination of hydrogen sulfide, though attempts to isolate the intermediate were unsuccessful. The liberation of hydrogen sulfide was actually confirmed by the positive lead acetate test. Compound **11** was also obtained in a lower yield by the pyrolysis of **9** in DMF at 110 °C. It is probably formed by condensation of **9** with the **10** formed by the decomposition of **9**. The formation of **10** from **9** is detected in the mass spectrum of **9**.[9] The results are summarized in Table 2.

Contrary to expectations, however, the reactions of **9** with **2** and **6** resulted in failure, a small amount of the **9** being recovered unchanged and no anticipated product being isolated.

Experimental

*4(or 2)-Arylguanidino-2(or 4)-phenyl-6-thioxo-1,6-dihydro-s-triazine (**3**).* General Procedure: A solution of arylbiguanide (10 mmol) and benzoyl isothiocyanate (10 mmol) in ethanol (20 ml) was heated for 4 hr under reflux. The precipitates deposited during heating were collected by filtration. The filtrate was concentrated under reduced pressure, and the precipitates deposited on cooling were collected by filtration. The combined precipitates were recrystallized from a suitable solvent. The detailed data are summarized in Table 1. These compounds exhibited the corresponding molecular ion as an abundant peak in the mass spectra.

*2(or 4)-Phenyl-4(or 2)-p-tolylguanidino-6-oxo-1,6-dihydro-s-triazine (**4a**).* Into a suspension of 2(or 4)-phenyl-4(or 2)-*p*-tolylguanidino-6-thioxo-1,6-dihydro-*s*-triazine (0.6 g, 1.8 mmol) in acetic acid (7 ml), we stirred, drop by drop, a 30% aqueous hydrogen peroxide solution (0.3 ml) at 80 °C over a 5-min period. Stirring was continued for an additional 30 min, keeping the temperature at 80 °C, and then the insoluble parts were filtered off. The filtrate was basified with concentrated aqueous ammonia. The precipitates deposited upon cooling were collected by filtration, washed with water, and recrystallized from DMF-water to give colorless prisms (0.15 g, 26.3%) melting at 304—305 °C. IR(KBr): 1680 cm^{-1} (C=O). MS: 320 (M^+). Found: C, 63.34; H, 5.24; H, 25.84%. Calcd for $C_{17}H_{16}ON_6$: C, 63.73; H, 5.04; N, 25.84%.

*4(or 2)-p-Chlorophenylguanidino-2(or 4)-phenyl-6-oxo-1,6-dihydro-s-triazine (**4b**).* Into a suspension of 4(or 2)-*p*-chlorophenylguanidino-2(or 4)-phenyl-6-thioxo-1,6-dihydro-*s*-triazine (0.8 g, 2.24 mmol) in acetic acid (8.2 ml), we stirred, drop by drop, a 30% aqueous hydrogen peroxide solution (0.7 ml) at 80 °C over a 5-min period. The reaction mixture was then treated by the same procedure as that described above. The resulting product was recrystallized from DMF

*4-p-Tolylguanidino-2-oxo-6-thioxo-1,4,5,6(or 1,2,3,6)-tetrahydro-s-triazine (**7a**).* Into a solution of *p*-tolylbiguanide (1.9 g, 10 mmol) in ethanol (20 ml), we stirred, drop by drop, ethoxycarbonyl isothiocyanate (1.3 g, 10 mmol) at 0 °C under a stream of nitrogen gas. Stirring was continued for an additional 24 hr at room temperature under a nitrogen stream. The precipitates which were gradually deposited in the course of the reaction were collected by filtration, washed with water, dried, and recrystallized from DMF to give colorless prisms (1.86 g, 67.5%); mp>360 °C. IR (KBr): 1680 (C=O) and 1235 (C=S) cm^{-1}. UV $\lambda_{max}^{0.01M\ HCl}$ nm (log ε): 271 (4.42). UV $\lambda_{max}^{0.01M\ NaOH}$ nm (log ε): 248 (4.44) and 275 (4.44). Found: C, 47.99; H, 4.23; N, 29.95 %. Calcd for $C_{11}H_{12}ON_6S$: C, 47.82; H, 4.38; N, 30.42%.

*4-p-Chlorophenylguanidino-2-oxo-6-thioxo-1,4,5,6(or 1,2,3,6)-tetrahydro-s-triazine (**7b**).* Into a solution of *p*-chlorophenylbiguanide (2.12 g, 10 mmol) in ethanol (20 ml), we stirred, drop by drop, ethoxycarbonyl isothiocyanate (1.31 g, 10 mmol) at 0 °C under a stream of nitrogen gas. The reaction mixture was then treated by the same procedure as that described above to give colorless prisms (1.84 g, 62.0%); mp>360 °C. IR (KBr): 1680 (C=O) and 1235 (C=S) cm^{-1}. UV $\lambda_{max}^{0.01M\ HCl}$ nm (log ε): 270 (4.47). UV $\lambda_{max}^{0.01M\ NaOH}$ nm (log ε): 250 (4.37) and 275 (4.41). Found: C, 40.94; H, 3.08; N, 28.01%. Calcd for $C_{10}H_9ON_6SCl$: C, 40.47; H, 3.06; N, 28.32%.

*4-p-Tolylguanidino-2,6-dioxo-1,2,5,6-tetrahydro-s-triazine (**8a**).* Into a solution of 4-*p*-tolylguanidino-2-oxo-6-thioxo-1,4,5,6(or 1,2,3,6)-tetrahydro-*s*-triazine (0.5 g, 1.8 mmol) in an aqueous 1 M sodium hydroxide solution (16 ml), we stirred, drop by drop, an aqueous 30% hydrogen peroxide solution (4 ml) at 0 °C over a 20-min period. Stirring was continued for an additional 2 hr at room temperature. The precipitates which had been deposited were then collected by filtration. The filtrate was acidified with a 2 M sulfuric acid solution, and the precipitates thus deposited were collected by filtration. The combined precipitates were then washed with water, dried, and recrystallized from DMF to give colorless prisms (0.30 g, 64.1%); mp>360 °C. IR(KBr): 1720 and 1660 cm^{-1} (C=O). Found: C, 50.74; H, 4.72; N, 32.01%. Calcd for $C_{11}H_{12}O_2N_6$: C, 50.76; H, 4.65; N, 32.30%.

*4-p-Chlorophenylguanidino-2,6-dioxo-1,2,5,6-tetrahydro-s-triazine (**8b**).* Into a suspension of 4-*p*-chlorophenylguanidino-2-oxo-6-thioxo-1,4,5,6(or 1,2,3,6)-tetrahydro-*s*-triazine (0.8 g, 2.7 mmol) in an aqueous 1 M sodium hydroxide solution (20 ml), we added, drop by drop, an aqueous 30% hydrogen proxide solution (5.4 ml) at 0 °C over a 10-min period. Stirring was continued for an additional 1 hr at room tempreature, and then the insoluble part was filtered off and the filtrate was acidified with an aqueous 2 M sulfuric acid solution. The resulting precipitates were collected by filtration, washed with water, dried, and recrystallized from DMF to give colorless prisms (0.50 g, 65.8%) melting at 358—360 °C. IR(KBr): 1720 and 1660 cm^{-1} (C=O). Found: C, 42.92; H, 3.34; N, 29.73%. Calcd for $C_{10}H_9O_2N_6Cl$: C, 42.79; H, 3.23; N, 29.94%.

*1-Aryl-2-arylamino-4-imino-6-thioxo-1,4,5,6-tetrahydro-s-triazine (**11**).* General Procedure: a) A mixture of 3-amidino-1-aryl-2-thiourea (10 mmol), aryl isothiocyanate (10 mmol), and DMF (5 ml) was heated at 110 °C for 5 hr. After cooling, the mixture was poured into cold water and the precipitates thus deposited were collected by filtration, washed with water, and recrystallized from ethanol. The detailed data are summarized in Table 2. These compounds exhibited the corresponding molecular ions as the most abundant peak in the mass spectra. b) A solution of 3-amidino-1-aryl-2-thiourea (10 mmol) in DMF (5 ml) was heated at 110 °C for 10 hr. After cooling, the solution was poured into cold water and the resulting precipitates were collected by filtration, washed with water, and recrystallized from ethanol. The yield of the product is illustrated in Table 2. These compounds were identified with authentic samples obtained by the method described above by a mixed-melting-point determination and by an IR comparison.

Preparation and Thermal Decomposition of Acyl Carbamoyl Peroxides

Renji OKAZAKI and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received January 29, 1974)

Thirteen acyl carbamoyl peroxides, a new class of peroxides, were prepared by addition of peroxy-acids to organic isocyanates and their properties were examined. The thermal decompositions, especially of benzoyl *N*-(*p*-nitrophenyl)carbamoyl peroxide and benzoyl *N*-benzoylcarbamoyl peroxide, were studied in crystalline state and in solution, and it was shown that they decompose via three different mechanisms, involving either an amino-radical, a nitrene or a protonated nitrene, depending on reaction conditions.

Peroxides having active hydrogens, such as hydrogen peroxide and alkyl hydroperoxides are known to undergo addition reaction with isocyanates; hydrogen peroxide produces azo-compounds *via* dicarbamoyl peroxides which are too unstable to be isolated,[1] whereas hydroperoxides form considerably stable peroxycarbamates.[2,3] We have preliminarily communicated elsewhere[4] that peroxy-acids also react with isocyanates to give acyl carbamoyl peroxides, a new class of peroxides:

$$RN{=}C{=}O + R'C(=O)OOH \rightarrow RNHC(=O)OOC(=O)R'$$

The present paper presents detailed accounts of the preparation and thermal decomposition of these peroxides.

Results and Discussion

Acyl carbamoyl peroxides were prepared at $-10\sim-15$ °C by adding a peroxy-acid in ether to an ethereal solution of an isocyanate containing a trace of pyridine as catalyst. The peroxides thus obtained and their characteristic infrared absorption bands are listed in Tables 1 and 2, respectively.

Reaction between *N*-methyl-*N*-(*p*-nitrophenyl)carbamoyl chloride and peroxybenzoic acid with 30% potassium hydroxide as a base gave benzoyl *N*-methyl-*N*-(*p*-nitrophenyl)carbamoyl peroxide, which was found so unstable as to decompose readily at room temperature yielding carbon dioxide. In Table 3 are summarized attempted syntheses which did not give the peroxides expected.

Tables 1 and 3 show that in order for acyl carbamoyl peroxides to be prepared isocyanates must carry an electronegative substituent. With *p*-nitrophenyl isocyanate, all the peroxy-acids examined gave the corresponding peroxides irrespective of the nature of their substituents and the substituent in isocyanates appears to have to be more electronegative than, say, a *m*-chloro substituent. This trend is similar to that observed in the preparation of substituted *N*-phenylperoxycarbamates, of which the *p*-methyl and *p*-methoxy derivatives were not prepared.[3] The aliphatic isocyanate does not seem to give peroxides with peroxy-acids, although the aliphatic peroxy-acid reacts with appropriate aromatic isocyanates to yield peroxides. Replacement of a hydrogen on the nitrogen of the carbamoyl group by a methyl group makes the peroxide remarkably unstable.

The effect of an electron-withdrawing substituent in the isocyanate is explained because it increases the reactivity of an isocyanate towards addition[5] and at the same time seems to make it less vulnerable to oxidative attack by peroxy-acids. Further, an electro-

negative substituent seems to stabilize acyl carbamoyl peroxides as is observed with various types of peroxides, such as substituted benzoyl peroxides,[6] *t*-butyl *N*-phenylperoxycarbamates,[3] *t*-butyl peroxybenzoates[7] and *t*-butyl peroxyphenylacetates.[8] The destabilizing effect of a methyl group mentioned above seems to be due to its electron-releasing effect. Aliphatic isocyanates, which have low reactivity compared with aromatic ones,[5] do not yield acyl carbamoyl peroxides; on the other hand, benzoyl[9] and benzenesulfonyl[10] isocyanates, which are known for high reactivity, gave the corresponding peroxides in high yields.

The results of the thermal decompositions of benzoyl *N*-(*p*-nitrophenyl)carbamoyl peroxide in solutions as well as in crystalline state are summarized in Table 4. The yield of carbon dioxide exceeded 100 mol% by about 20% or more in benzene, chloroform and acetic acid, but it was about 100 mol% in the decomposition in crystalline state and in ethanol. Benzoic acid was produced in a relatively large amount in each case, but there was a definite difference in its yield between the decomposition in benzene, chloroform or acetic acid (about 50 mol%) on the one hand and that in crystalline state or in ethanol (70—80 mol%) on the other. Some products which appear to have been derived from phenyl radicals, such as biphenyl and benzene were formed in benzene, chloroform and acetic acid. The following nitrogen containing products were identified: *p,p'*-dinitroazobenzene in the decomposition in crystalline state; *p,p'*-dinitroazobenzene and *p*-nitroaniline in benzene and chloroform; *p*-nitroacetanilide in acetic acid; and 5-nitro-2-aminophenetole and 5-nitro-2-benzamidophenol in ethanol. Some of these findings strongly suggest a homolytic nature of the decomposition, but the concurrence of an ionic mechanism is very likely in view of the production of 5-nitro-2-aminophenetole and 5-nitro-2-benzamidophenol in ethanol.

The homolytic fission of the peroxidic linkage of benzoyl *N*-(*p*-nitrophenyl)carbamoyl peroxide would primarily produce an *N*-(*p*-nitrophenyl)-carbamoyloxy *p*-$O_2NC_6H_4NHCOO\cdot$ and a benzoyloxy $C_6H_5COO\cdot$ radicals. In order to know the behavior, under the prevailing conditions, of these radicals, *t*-butyl *N*-(*p*-nitrophenyl)peroxycarbamate[2,3] and benzoyl peroxide,[11] which are known to generate these radicals respectively, were separately decomposed in benzene and in ethanol and the products were examined. The results are summarized in Table 5. They show that the

Table 3. Attempted reactions[a] which gave no peroxides

Isocyanates	Peroxy-acids	Products isolated
p-ClC_6H_4NCO	$C_6H_5CO_3H$	*p,p'*-Dichloroazobenzene(10%) *p,p'*-Dichloroazoxybenzene(2%)
C_6H_5NCO	$C_6H_5CO_3H$	Nitrobenzene(1%), azobenzene(trace)
p-$O_2NC_6H_4NCO$	*o*-$HOOCC_6H_4CO_3H$	No reaction
$C_{11}H_{23}NCO$	$C_6H_5CO_3H$	No reaction
$C_{11}H_{23}NCO$	$C_{11}H_{23}CO_3H$	No reaction
p-$O_2NC_6H_4NCO$	H_2O_2	*p,p'*-Dinitroazobenzene(30%)
p-$OCNC_6H_4NCO$	$C_6H_5CO_3H$	Tarry material

a) Reactions were carried out by essentially the same procedure as described for the preparation of benzoyl *N*-(*p*-nitrophenyl)carbamoyl peroxide.

Table 4. Products of decomposition of benzoyl *N*-(*p*-nitrophenyl)carbamoyl peroxide

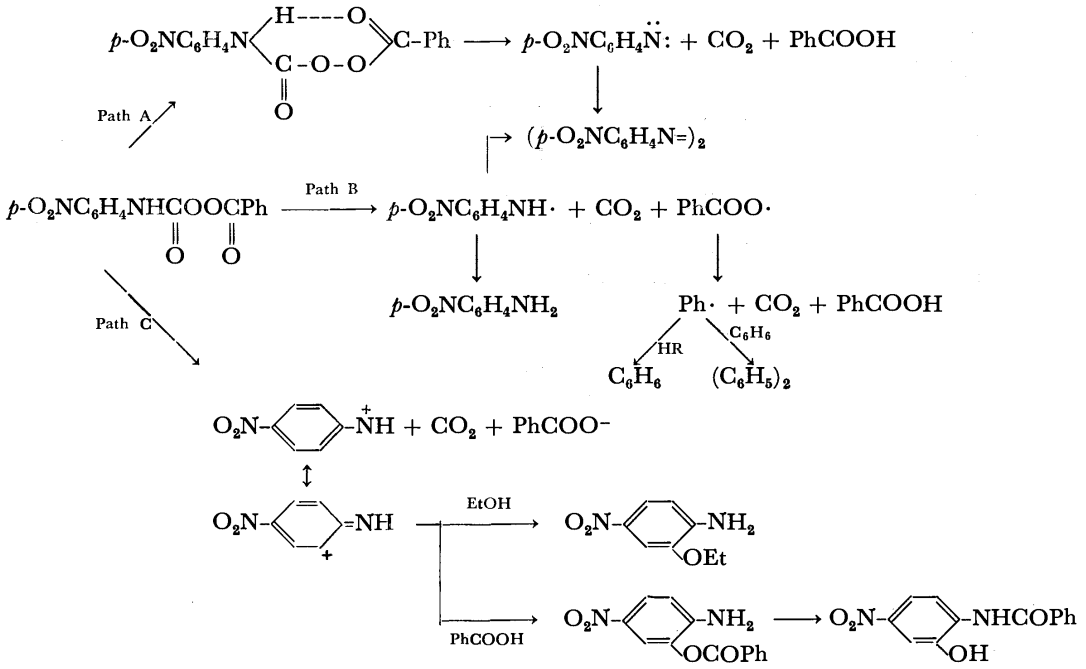
Reaction conditions		Products (yield in mol% of peroxide)[a]								
Solvent	Temp. °C	Carbon dioxide	Benzoic acid	Benzene	Biphenyl	*p*-Nitro-aniline	*p,p'*-Di-nitroazo-benzene	*p*-Nitro-acet-anilide	5-Nitro-2-benz-amido-phenol	5-Nitro-2-amino-phenetole
None	20	98	80			trace	15			
Benzene	80	117	48		20	15	12			
Chloroform	61	127	45	33		17	14			
Acetic acid	50	118	47	9				59		
Ethanol	78	96	68						10	63

a) The decomposition of benzoyl *N*-(*p*-nitrophenyl)carbamoyl peroxide usually gave a dark brown polymeric substance besides the compounds listed in this table.

TABLE 5. PRODUCTS OF DECOMPOSITION OF *t*-BUTYL *N*-(*p*-NITROPHENYL)PEROXYCARBAMATE AND BENZOYL PEROXIDE

Peroxide	Reaction conditions		Products (yield in mol% of peroxide)				
	Solvent	Temp. °C	Carbon dioxide	Benzoic acid	Biphenyl	*p,p'*-Dinitro-azobenzene	*p*-Nitro-aniline
Peroxycarbamate	Benzene	80	96		4	8	77
Peroxycarbamate	Ethanol	78	98			1	90
Benzoyl peroxide	Benzene	80	178	7	126[a]		

a) Biphenyl 90% and dihydrobiphenyl 36%.



Scheme 1.

carbamoyloxy radical, when generated in benzene or in ethanol, gives mainly carbon dioxide (96—98%) and *p*-nitroaniline (77—90%) with *p,p'*-dinitroazobenzene as a minor product, and that 89% of the benzoyloxy radical generated in benzene loses carbon dioxide before it engages in other reactions, finally to form 63% of biphenyl, and only 3.5% of benzoic acid was obtained. No trace of 5-nitro-2-aminophenetole was detected in the decomposition in ethanol.

On the basis of the results presented above, three pathways are proposed as shown in Scheme 1 for the thermal decomposition of benzoyl *N*-(*p*-nitrophenyl) carbamoyl peroxide. Path A is a concerted mechanism via a seven-membered cyclic transition state giving rise to *p*-nitrophenylnitrene; path B is a radical mechanism beginning with the homolysis of the oxygen-oxygen bond usually observed in the thermal decomposition of peroxides; and path C is an ionic mechanism. The extent to which each of these mechanisms is operative depends on the experimental conditions under which the peroxide is decomposed.

Path A is straightforward and best explains the decomposition in crystalline state, since carbon dioxide and benzoic acid were obtained in nearly 100% yield and the fact that 30% of the *p*-nitrophenylcarbamoyloxy moiety was accounted for as *p,p'*-dinitroazobenzene strongly suggests the intermediacy of *p*-nitrophenylnitrene.[12]

Since the *p*-nitrophenylcarbamoyloxy moiety will liberate 100% of carbon dioxide in any of the postulated pathways, the fact that the carbon dioxide was evolved in excess of 100% in the decomposition in benzene, chloroform or acetic acid indicates the involvement of path B, in which the benzoyloxy radical generated decomposes also to give carbon dioxide at the expense of benzoic acid. However, if path B were the only mechanism operative in these solvents, the yield of benzoic acid would have been much less than actually found and as much as 180% or more of carbon dioxide would have been obtained, since benzoyloxy radicals extensively decompose to give phenyl radicals and carbon dioxide (cf. Table 5). Thus, the results of product analyses indicate that the decomposition in benzene proceeds via both paths A and B to the exclusion of path C, *viz.*, about 25%[13] through path B and consequently about 75% through path A.

The mode of decomposition in chloroform appears to be similar to that in benzene, but benzene was formed instead of biphenyl, the intermediate phenyl radical abstracting a hydrogen atom from chloroform.

Some of the *p*-nitrophenylamino radical produced in path B may undergo dimerization followed by dehydrogenation under the prevailing oxidizing conditions finally to give *p,p'*-dinitroazobenzene; but obviously its chief reaction is abstraction of a hydrogen atom from an appropriate hydrogen-donating species to give *p*-nitroaniline (cf. Table 5 and Ref. 2). It can also arise, however, from *p*-nitrophenylnitrene,[14] although this mode of formation seems to be a remote possibility in benzene.

As regards the decomposition in ethanol, product analysis suggests that it proceeds chiefly by path C, in which a protonated *p*-nitrophenylnitrene or a *p*-nitrophenylnitrenium ion[15] is postulated; a polar protic solvent such as ethanol is likely to favor such an ionic process. The production of 5-nitro-2-aminophenetole in a yield of as high as 63% supports this view and is best explained by nucleophilic attack on a mesomeric form of the nitrenium ion $p\text{-}O_2NC_6H_4NH^+$ by a molecule of ethanol as shown in Scheme 1. The formation of 5-nitro-2-benzamidophenol is similarly explained in terms of nucleophilic attack on the ring by benzoic acid or benzoate ion followed by migration of the benzoyl group to the nitrogen.[16] If path B were also operative to any perceptible extent, benzene and *p*-nitroaniline would have been detected. The intermediacy of *p*-nitrophenylnitrene is excluded because neither nitrogen-containing products expected from it nor products of dehydrogenation of ethanol such as acetaldehyde[17] were found.

The decomposition pattern in acetic acid is different from that in ethanol, especially in that such a product as 5-nitro-2-acetamidophenol, which would have readily arisen by way of path C was not detected; the intermediacy of protonated nitrene (path C) is thus ruled out. It is similar to that in benzene or chloroform as far as the yields of carbon dioxide and benzoic acid concerned; accordingly, path B is undoubtedly operating in some measure, and path A must be the major one, although *p,p'*-dinitroazobenzene and *p*-nitroaniline were absent from the reaction mixture. It is worth noting that 59% of *p*-nitroacetanilide was obtained as the sole product which accounts for the *p*-nitrophenylcarbamoyl group. A small part of the anilide may have been produced by prolonged contact of the *p*-nitroaniline initially formed with hot acetic acid solvent during the period of the reaction and the subsequent work-up, as was shown to be the case by separate experiments. The mechanism by which most of the *p*-nitroacetanilide was formed from *p*-nitrophenylnitrene or *p*-nitrophenylamino radical with acetic acid remains unexplained.

The thermal decomposition of benzoyl *N*-benzoylcarbamoyl peroxide in crystalline state was examined by measuring its infrared spectrum in Nujol mull, in which the peroxide was hardly soluble. A freshly prepared mull showed a ν_{N-H} band at 3420 cm^{-1} and $\nu_{C=O}$ bands at 1765 and 1685 cm^{-1}. When the same sample was measured after being kept 30 minutes at room temperature, the ν_{N-H} band had almost disappeared and new bands had appeared at 2350 and 2260 cm^{-1}, which are attributable to carbon dioxide and phenyl isocyanate, respectively. The $\nu_{C=O}$ band at 1765 cm^{-1} had considerably decreased in intensity, whereas the $\nu_{C=O}$ band at 1685 cm^{-1} was almost unchanged, although its band width had slightly increased. These facts would suggest that this peroxide decomposes in crystalline state giving carbon dioxide, benzoic acid and transitory benzoylnitrene, which seems to rearrange immediately to phenyl isocyanate.

The results of decompositions of benzoyl *N*-benzoylcarbamoyl peroxide in solutions are summarized in Table 6. The yield of carbon dioxide was higher than 100% in benzene, but lower in ethanol. Benzoic acid was formed nearly quantitatively in ethanol. Biphenyl, which was found in benzene, is a product indicative of the operation of a radical mechanism but in ethanol no such products were detected; for example, benzene, which would have readily resulted from phenyl radicals by abstraction of a hydrogen atom from ethanol, was absent from the reaction mixture. Products containing nitrogen were: in benzene solution, benzamide, phenyl isocyanate, carbanilide and γ-triphenylbiuret, the last two being produced from the reaction of phenyl isocyanate with benzoic acid;[18] and in ethanol solution, ethyl benzhydroxamate.

These findings may be accommodated in the reaction sequences shown in Scheme 2, which are formulated by the analogy with Scheme 1.

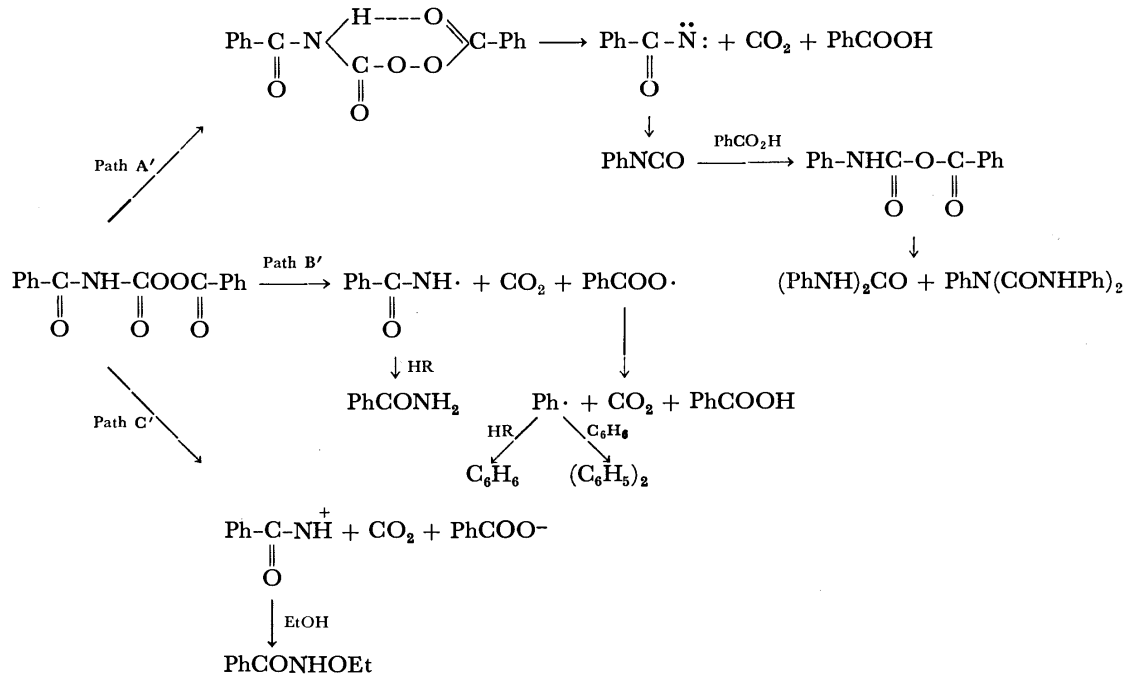
In path A', the intermediate formation of benzoylnitrene is postulated, which immediately rearranges to phenyl isocyanate,[19] and this in turn reacts with benzoic acid to give further products. Path B' represents a homolytic mechanism; the benzoyloxy radical will undergo a series of the usual reactions in benzene and the benzamido radical will abstract a hydrogen atom[20] from intermediate phenylcyclohexadienyl $C_6H_5C_6H_6\cdot$ radicals to give benzamide and biphenyl. Paths A' and B' are both operative in the decomposition in benzene; the former explains the formation of phenyl isocyanate and its subsequent reaction products with benzoic acid (carbanilide and γ-triphenylbiuret) and the latter that of biphenyl, benzamide, and more than 100 mol% of carbon dioxide.

Path C' postulated as a counterpart of path C in

Table 6. Products of decomposition of benzoyl *N*-benzoylcarbamoyl peroxide

Reaction conditions		Products (yield in mol% of peroxide)					
Solvent	Temp. (°C)	Carbon dioxide	Benzoic acid	Biphenyl	Benzamide	Phenyl isocyanate	Ethyl benzhydroxamate
Benzene[a]	80	124	28	34	34	2	
Ethanol	78	72	94				38

a) In addition to the products in this table carbanilide and γ-triphenylbiuret were isolated.



Scheme 2.

Scheme 1 involves protonated benzoylnitrene, which undergoes nucleophilic attack by ethanol, and best explains the formation of ethyl benzhydroxamate as the only isolable nitrogen containing compound in ethanol. It would seem possible that ethyl benzhydroxamate might have been formed by the action of solvent ethanol on benzoylnitrene produced by path A', thus,

$$C_6H_5CON: + EtOH \rightarrow C_6H_5CONHOEt.$$

Such a reaction is in fact reported by Horner, Bauer and Dorges,[21] but benzoylnitrene does not seem to be a proper intermediate in the present case, since no ethyl *N*-phenylcarbamate was detected, which ought to have been formed from ethanol and phenyl isocyanate, if benzoylnitrene had been involved, and which actually was obtained together with the benzhydroxamate.[21]

Experimental

Isocyanates and peroxy-acids were prepared by reported methods. *t*-Butyl *N*-(*p*-nitrophenyl)peroxycarbamate was prepared according to the directions given by O'Brien and his co-workers.[3]

Preparation of Acyl Carbamoyl Peroxides. A typical procedure is given below for the preparation of benzoyl *N*-(*p*-nitrophenyl)carbamoyl peroxide. Other peroxides were prepared similarly (see Table 1).

Benzoyl N-*(*p-*Nitrophenyl)carbamoyl Preoxide.* *p*-Nitrophenyl isocyanate (8.9 g, 0.055 mol) and two drops of pyridine were dissolved in 150 ml of absolute ether and to this solution, cooled to −15—−20 °C, was added slowly an ethereal solution (50 ml) of peroxybenzoic acid (purity 95%, 0.055 mol) with stirring while maintaining the temperature below −10 °C. The temperature was gradually raised to 0 °C after completion of the addition of the peroxy-acid. The precipitation of the peroxide set in after about 30 min. The mixture was stirred for a further 3 hr. The peroxide was filtered off and washed with cold ether three times (yield, 55%). The peroxide, at this stage, was almost pure and free from contamination with *p,p'*-dinitrodiphenylurea when pure starting materials were used. Recrystallization of 7.0 g of the peroxide from methylene chloride between 10 and −78 °C gave 4.0 g of almost white crystals, which explosively decomposed at 63 °C when heated at a rate of 4—5 °C per minute.

Benzoyl N-*(*m-Chlorophenyl)carbamoyl Peroxide.* Peroxybenzoic acid (3.2 g, 0.022 mol) in 20 ml of ether was added to 20 ml of an ethereal solution of *m*-chlorophenyl isocyanate according to the procedure described above for the *p*-nitro-derivative. After being stirred for 4 hr, the reaction mixture was added to 750 ml of petroleum ether (bp 35—40 °C) in order to precipitate the peroxide. Cooling the solution at −78 °C gave 3.3 g (55%) of a white solid material tinged with violet. This solid was certainly the desired peroxide, because it liberated iodine from an acetic acid solution of sodium iodide and violently detonated when allowed to stand for a few minutes at room temperature or heated on a spatula over a flame; it was too unstable to be submitted to elemental analysis and determination of active oxygen.

Benzoyl N-*Methyl*-N-*(*p-nitrophenyl)carbamoyl Peroxide.* An aqueous solution (30%) of potassium hydroxide (0.011 mol) was added dropwise with stirring to 170 ml of an ethereal solution of peroxybenzoic acid (1.7 g, 0.011 mole) and *N*-methyl-*N*-(*p*-nitrophenyl)carbamoyl chloride (2.2 g, 0.01 mole). After being stirred for 3 hr at −5 °C, the solution was kept at −78 °C for one day. Precipitated potassium chloride was filtered off and the filtrate was concentrated to 10 ml by evaporating the ether at −10 °C. Addition of cold petroleum ether to the concentrate gave a yellowish orange paste, which liberated iodine from an aqueous acetic acid solution of sodium iodide and decomposed even at 0 °C evolving carbon dioxide. The decomposition products of the peroxide at room temperature were *N*-methyl-*p*-nitroaniline (72%), mp and mixed mp 151 °C (lit,[22] 152 °C), benzoic acid (20%), and a trace of *N,N'*-bis-(p-nitrophenyl)ethylenediamine, mp 218—219°C (lit,[23] 220—221 °C), each of them being isolated by chromatography on alumina.

Thermal Decomposition of Peroxide. The decompositions

in solution were all performed under nitrogen or argon. Carbon dioxide evolved was measured by absorption in an Ascarite tube. Gas chromatographic analyses were carried out with a Perkin-Elmer Vapour Fractometer Model 154.

Decomposition of Benzoyl N-(p-Nitrophenyl)carbamoyl Peroxide in Crystalline State. The peroxide (1.839 g) was allowed to stand at room temperature (about 20 °C) for a week. The gas (0.261 g) evolved during the decomposition was shown to contain only carbon dioxide by mass spectrometric analysis. The residue was extracted with 400 ml of benzene for 13 hr in a Soxhlet extractor. From the benzene solution, benzoic acid (0.599 g) was recovered by using 5% sodium bicarbonate. The residual benzene solution was dried with anhydrous sodium sulfate, concentrated to 50 ml, and chromatographed on alumina to give *p,p'*-dinitroazobenzene (0.23 g), mp and mixed mp 218—219 °C (lit,[22] 220 °C), and a trace of *p*-nitroaniline, mp and mixed mp 147—148 °C (lit,[22] 148 °C).

Decomposition of Benzoyl N-(p-Nitrophenyl)carbamoyl Peroxide in Benzene. Benzene (900 ml) in a two-necked round-bottomed flask fitted with a gas inlet tube and a reflux condenser was flushed with a stream of nitrogen for an hour, and the peroxide (1.522 g, 5.03 mmol) was added quickly and dissolved by stirring. The solution was heated under reflux for 19 hr, nitrogen being slowly bubbled. Carbon dioxide (260 mg, 5.92 mmol) evolved. Removal of benzene by distillation gave 50 ml of a deep-red benzene solution. After the solution was shaken with 5% sodium bicarbonate to remove benzoic acid (297 mg, 2.43 mmol), it was dried with anhydrous sodium sulfate and analyzed; gas chromatography with an Apiezon grease column at 220 °C showed the presence of biphenyl only and chromatography on alumina and elution with benzene gave, in succession, biphenyl (152 mg, 0.99 mmol), *p,p'*-dinitroazobenzene (165 mg, 0.61 mmol), and unidentified brownish orange crystals (34 mg, mp 189—190 °C, from ethanol), and then elution with ether yielded *p*-nitroaniline (103 mg, 0.75 mmol).

Decomposition of Benzoyl N-(p-Nitrophenyl)carbamoyl Peroxide in Chloroform. The peroxide (2.673 g, 8.84 mmol) in 700 ml of chloroform was heated under reflux for 6 hr. The procedure was virtually the same as described above for the decomposition in benzene. The amount of carbon dioxide evolved was 494 mg (11.2 mmol). Chloroform was distilled from the reaction mixture through a concentric column of 80 cm in height to give 50 ml of a concentrated solution, a small portion of which was submitted to gas chromatographic analysis using an Apiezon grease column at 80 °C; it contained 227 mg (2.91 mmol) of benzene and no chlorobenzene. Isolation and identification of other products were carried out by chromatography on alumina as described above.

Decomposition of Benzoyl N-(p-Nitrophenyl)carbamoyl Peroxide in Acetic Acid. The peroxide (2.696 g, 8.94 mmol) in 665 ml of anhydrous acetic acid was decomposed at 50 °C for 12 hr. Acetic acid was carefully distilled through a 40 cm Vigreux column, an initial fraction (80 ml) boiling at 40—42 °C/35—38 mmHg being collected. This was fractionated through a concentric column of 80 cm in height under atmospheric pressure, an initial fraction (5 ml) being subjected to gas chromatographic analysis using a polyethylene glycol column at 100 °C to determine the quantity of benzene formed. The residual acetic acid solution in the first distillation was further concentrated almost to dryness at the same temperature and pressure as described above to give a brown solid, which was washed with 5% sodium bicarbonate to remove acidic compounds and then dissolved in a large amount of methylene chloride. The acid part extracted consisted of only benzoic acid (5.11 mg, 4.18 mmol), because methylation of the extract with diazomethane followed by gas chromatography showed the presence of methyl benzoate without any trace of other methyl esters such as methyl succinate which would have been formed from acetic acid solvent. Evaporation of the methylene dichloride solution gave only *p*-nitroacetanilide (952 mg, 5.29 mmol), which was identified by mixed melting point determination (213—215 °C, lit,[22] 215—216 °C) and comparison of the infrared spectrum.

Decomposition of Benzoyl N-(p-Nitrophenyl)carbamoyl Peroxide in Absolute Ethanol. The peroxide (1.409 g, 4.67 mmol) dissolved in 850 ml of absolute ethanol was heated under reflux for 24 hr. Carbon dioxide evolved weighed 196 mg (4.48 mmol). Removal of the solvent from the reaction mixture, an initial 100 ml of the distillate being retained for later examination, gave 70 ml of a deep-red solution, which was mixed with benzene and subjected to azeotropic distillation for complete removal of ethanol. The remaining benzene solution was filtered from insoluble dark brown precipitate, shaken with 5% sodium bicarbonate to extract benzoic acid (388 mg, 3.17 mmol), dried with anhydrous sodium sulfate and chromatographed on alumina, to give 5-nitro-2-aminophenetole (535 mg, 2.94 mmol) mp 90—91 °C (lit,[22] 91 °C). Found: C, 52.65; H, 5.72; N, 15.62%. Calcd for $C_8H_{10}N_2O_3$: C, 52.74; H, 5.53; N, 15.38%. Subsequent elution with benzene–ether mixture (1 : 9) gave two unidentified compounds in small amounts (20 mg and 30 mg). The dark brown precipitate insoluble in benzene mentioned above was recrystallized from ethanol and identified as 5-nitro-2-benzamidophenol (121 mg, 0.47 mmol), mp 266—267 °C. Found: C, 60.46; H, 4.07; N, 10.99%. Calcd for $C_{13}H_{10}N_2O_4$: C, 60.46; H, 3.90; N, 10.85%. The infrared spectrum in Nujol mull showed characteristic bands at 3340 (ν_{N-H}), 3110 (ν_{O-H}), and 1630 ($\nu_{C=O}$) cm^{-1}.

The initial fraction from the first distillation was submitted to gas chromatographic analysis for benzene using a polypropylene glycol column at 70 °C; but none was detected other than etanol.

Decomposition of Benzoyl N-benzoylcarbamoyl Peroxide in Benzene. The peroxide (2.846 g, 10.0 mmoles) was decomposed in 480 ml of benzene by heating under reflux for 49 hr. Carbon dioxide evolved weighed (544 mg 12.4 mmol). On cooling the solution, 0.0215 g of a light brown solid precipitated. It was filtered off and identified as a mixture of carbanilide (*sym*-diphenylurea) and γ-triphenylbiuret by comparing its infrared spectrum with those of authentic samples. The above filtrate, after being concentrated to 23 ml, was shown by gas chromatography (Apiezon grease L, at 150 °C) to contain biphenyl and phenyl isocyanate. The concentrate was shaken with 5% sodium bicarbonate, dried with anhydrous sodium sulphate and chromatographed on alumina to give biphenyl (402 mg), traces of carbanilide and γ-triphenylbiuret. The aqueous extract was dissolved in ether, methylated by diazomethane and submitted to gas chromatography using an Apiezon grease column at 161 °C; methyl benzoate (385 mg, 2.83 mmol) was detected. Evaporation of the ethereal solution and extraction of methyl benzoate from the residue with petroleum ether left benzamide (413 mg, 3.41 mmol), which was identified by the mixed mp (131—133 °C, lit,[22] 132.5—133.5 °C) and the infrared spectrum.

Decomposition of Benzoyl N-Benzoylcarbamoyl Peroxide in Absolute Ethanol. The peroxide (2.818 g, 9.89 mmol) was heated in ethanol (500 ml) under reflux for 20 hr, during which period 314 mg (7.13 mmol) of carbon dioxide evolved. The reaction mixture was concentrated to about 5 ml and

allowed to stand overnight in a refrigerator. After filtration of precipitated benzoic acid (266 mg), removal of the ethanol and addition of benzene, the solution was shaken with 5% sodium bicarbonate, dried with calcium chloride and evaporated to give 0.580 g of a light brown liquid residue. The acid portion extracted (1.937 g) with bicarbonate was methylated with diazomethane in ether and found to contain 0.861 g of benzoic acid by gas chromatographic determination of the methyl benzoate formed, and the remainder (1.112 g) of the aqueous extract, which was obtained of the extraction of the methyl benzoate with petroleum ether, was shown to be essentially identical with the above light brown liquid by comparison of the infrared spectra. A portion (0.417 g) of this liquid was dissolved in 3 ml of tetrahydrofuran and heated under reflux for 10 hr with 10 ml of 10% aqueous potassium hydroxide giving 0.152 g of benzoic acid and 0.151 g of ethyl benzhydroxamate, mp and mixed mp 63—64 °C (lit,[24] 64—65 °C), which is known to remain intact by treatment with alkali.[24] The light brown liquid was, therefore, considered to consist of ethyl benzhydroxamate (612 mg) and a compound which gave benzoic acid by alkaline hydrolysis.

Decomposition of t-*Butyl* N-*(*p-*Nitrophenyl)peroxycarbamate in Benzene.* Heating this peroxy-ester (1.282 g, 5.04 mmol) in benzene under reflux for 78 hr gave 213 mg (4.84 mmol) of carbon dioxide. The reaction mixture was concentrated to 29 ml and chromatographed on alumina to give biphenyl (29 mg 0.19 mmol), *p,p'*-dinitroazobenzene (103 mg, 0.38 mmol) and *p*-nitroaniline (536 mg, 3.88 mmol).

Decomposition of t-*Butyl* N-*(*p-*Nitrophenyl)peroxycarbamate in Ethanol.* The peroxy-ester (3.995 g, 15.7 mmol) was heated in ethanol (900 ml) under reflux for 22 hr to yield 681 mg (15.5 mmol) of carbon dioxide. Concentration of the reaction mixture to 70 ml and azeotropic distillation after addition of 150 ml of benzene gave 70 ml of a benzene solution and a precipitate (*p*-nitroaniline, 783 mg). The filtered benzene solution was chromatographed on alumina to give *p,p'*-dinitroazobenzene (35 mg, 0.13 mmol) and *p*-nitroaniline (1.145 g).

Decomposition of Benzoyl Peroxide in Benzene. Benzoyl peroxide (1.250 g, 5.17 mmol) was decomposed in boiling benzene for 46 hr to evolve 403 mg (9.18 mmol) of carbon dioxide. After the solution was concentrated to 26 ml, benzoic acid (46 mg, 0.38 mmol) was extracted with 5% sodium bicarbonate and the organic layer was submitted to gas chromatographic analysis for determination of biphenyl (716 mg) and dihydrobiphenyl (284 mg).

Crystal and Molecular Structure of ω-Amino Acids, ω-Amino-Sulfonic Acids and Their Derivatives. VII. The Crystal and Molecular Structure of DL-Carnitine Hydrochloride

Ken-ichi TOMITA, Keiko URABE, Yang Bae KIM,* and Takaji FUJIWARA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560

(Received April 24, 1974)

The crystal structure of DL-carnitine hydrochloride, $C_7H_{15}NO_3 \cdot HCl$, was determined by the heavy atom method using X-ray diffraction data on a Weissenberg photograph, and refined by the least-squares method to an *R*-factor of 0.13 for 1969 independent reflections. The crystals are monoclinic space group $P2_1/c$, $Z=4$, with $a=6.77(1)$, $b=11.41(2)$, $c=15.10(3)$ Å and $\beta=120.1(1)°$. By protonation at carboxyl oxygen atom, carnitine molecule has the cationic form, $N^+(CH_3)_3CH_2CH(OH)CH_2COOH$, with *trans-zigzag* skeletal configuration as similar as γ-amino-β-hydroxybutyric acid. The Cl^- ion mediates between adjacent carnitine cations by two O–H···Cl^- hydrogen bonds to form infinite chain elongated along the *c*-axis. The correlation between molecular structure and biological activity was also discussed.

Carnitine is a constituent of striated muscle and liver, being isolated from meat extract.[1] Its chemical structure was identified by M. Tomita et al. as L-γ-trimethylamino-β-hydroxybutyrobetaine by synthesis from L-γ-amino-β-hydroxybutyric acid.[2] Carnitine is well known as a vitamin B_T, a growth factor of certain insects, and medically used as a stimulant of gastric juice secretion. Furthermore, carnitine and its acetyl-derivatives have the muscarinic action in nervous system.[3] As its chemical structure is very similar to that of acetylchlorine and γ-amino-β-hydroxybutyric acid (GABOB), both chemical transmitters, we have carried out a single crystal X-ray analysis of DL-carnitine hydrochloride as a part of a series on the structural studies of ω-amino acids, and we also discuss very interesting correlation between structural specificity and biological activity.

Experimental

Using the commercial DL-carnitine hydrochloride, a colorless plate crystal was obtained from aqueous methanol solution by slow evaporation at room tempreature. The space group and cell constants were determined from precession photograph: the systematic absences of $0k0$ reflections with k odd and $h0l$ with l odd indicate that the space group is $P2_1/c$. The density was measured by flotation method using carbon tetrachloride-benzene mixture. The obtained crystallographic data are shown in Table 1. The intensities of 1969 independent reflections were collected from equi-inclination Weissenberg photographs around the *a*- and *b*-axes ($h=0$—5, $k=0$—3) with nickel-filtered Cu$K\alpha$ radiation and estimated by visual comparison with a calibrated scale. The usual corrections for Lorentz and polarization factors were made but none for absorption or extinction.

TABLE 1. CRYSTAL DATA

DL-Carnitine hydrochloride, $C_7H_{15}NO_3 \cdot HCl$	
Colorless transparent plates, Monoclinic system	
$a=6.77\pm0.01$ Å	$b=11.41\pm0.02$ Å
$c=15.10\pm0.03$ Å	$\beta=120.1\pm0.1°$
Volume of unit cell	1008.9 Å^3
Density (by flotation)	1.290 g/cm^3
Density (calculated)	1.301 g/cm^3
$Z=4$	$F(000)=428$
Space group: $P2_1/c$	

Structure Determination and Refinement

The structure was solved by heavy atom method. The position of the chlorine atom was easily determined from the inspection of sharpened Patterson map and all the non-hydrogen atoms were located by successive Fourier syntheses with phases based on the chlorine atom. By block-diagonal least-squares refinement with unit weight for the non-zero reflections and isotropic temperature factor, the initial *R*-factor, 0.26, was reduced to 0.19. Several cycles of refinement with anisotropic temperature factor for all non-hydrogen atoms were carried out to reduce *R*-factor to 0.17. The used anisotropic temperature factors are of the form: $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$.

A three-dimensional difference Fourier synthesis was then calculated and the positions of seven hydrogen atoms except those of methyl groups, were properly found. Each one hydrogen atom peak of three methyl groups having reasonable bond length and angle in the difference Fourier map was fixed and the remaining two hydrogen atom positions in each methyl group were calculated. The final cycles of refinement including the hydrogen atoms with isotropic temperature factors reduced *R*-factor to 0.13 (0.14 including $|F_0|=0$).

Observed and calculated structure factors for each reflection are listed in Table 2. The atomic scattering factors used in all calculations were taken from International Tables for X-ray Crystallography (1692).[4] The final positional and thermal parameters together with their estimated standard deviations are gived in Tables 3(a) and 3(b).

All the computations were carried out on an NEAC 2200—700 Computer at this University using the programs of UNICS system.

Results and Discussion

Molecular Dimensions. The bond lengths and angles are shown in Table 4 with their estimated stand-

ard deviations in parentheses, in which the atomic numbering corresponds to that in Fig. 1, the perspective drawing of the molecule of carnitine as observed in crystals of the hydrochloride. They are in good agreement with those reported in the literatures. It is evident, from the difference in bond length between C_7–O_2 and C_7–O_3, that the protonation occurs at O_3 atom, being confirmed by difference Fourier synthesis.

The carnitine molecule has two planes, one is defined by the skeletal carbon, C_4, C_5, and C_6, and nitrogen N (plane 1), and another one by C_6, C_7, O_2 and O_3 (plane 2). The equations of least squares planes and deviations of the individual atoms from each plane are listed in Table 5. The experimental value of the dihedral angle between these two planes is 29.2°, indicating that all the non-hydrogen atoms in main carnitine molecule compose roughly a *trans-zigzag* configuration except two methyl carbon and hydroxyl oxygen atoms. The torsion angles around relevant bonds are shown in Fig. 2, with which it will be discussed later.

The hydrogen atoms of the trimethylammonium group have been observed to be in a staggered conformation and the C_4–N–C_1–H_{14}, C_4–N–C_2–H_9 and C_4–N–C_3–H_{11} torsion angles are all nearly 180°. This staggered conformation is also observed in the crystal

structure of acetylcholine and its derivatives[5].

Molecular Enrivonment. Figure 3 shows the arrangement of the molecules in crystals as viewed along the *a*-axis. The chlorine ion mediates between adjacent carnitine cations by two O–H···Cl^- hydrogen bonds, $O_3H_1\cdots Cl^-$ (3.00 Å) and O_1–$H_5\cdots Cl^-$ (3.06 Å).

The contacts of the trimethylammonium group with the same group of neighboring molecules related by either a center of symmetry or two-fold screw axis have the normal van der Waals distances. There are no unusual short contacts in this crystal.

The Correlation between Molecular Structure and Biological Activity. As already mentioned in the introductory section, carnitine and its acetyl-derivatives have the muscarinic action in nervous system, and R. W. Baker *et al.* showed a strong correlation between structure and activity of muscarinic stimulants.[5] They pointed out that the torsion angles around relevant bonds and intramolecular distances between the nitrogen atom of trimethylammonium group and acetyl oxygen atom and so on in acetylcholine or its derivatives are of very important significance in performance of their activities. The torsion angle (τ) of the bonded group X–A–B–Y is defined as the angle between the plane X–A–B and the plane A–B–Y, and it is positive if clockwise and negative if anticlockwise from the near atom X to the further atom Y. As shown in Fig. 2, τ_1 of carnitine is +197.0°, τ_2 +174.8°, τ_3 +193.8° and τ_4 +203.3°, which correspond to all the anti-planar region of torsion angles defined by Klyne *et al.*[6] For comparison certain, torsion angles and interatomic distances observed in crystals of muscarinic stimulants are shown in Table 6(a) and (b), with that of carnitine hydrochloride and γ-amino-β-hydroxybutyric acid (GABOB). In this table, *ap*, *sc* or *ac* are the abbreviations of antiperiplanar, syn-clinal or anti-clinal, respectively. R. W. Baker *et al.* concluded that for potent muscarinic activity, τ_1 should be 180°, τ_2 in the range +73° to +137°,

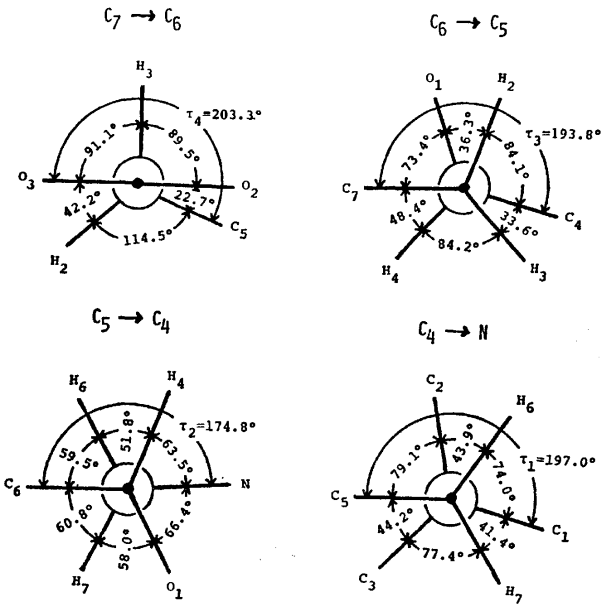

Fig. 2. The torsion angles around relevant bonds.

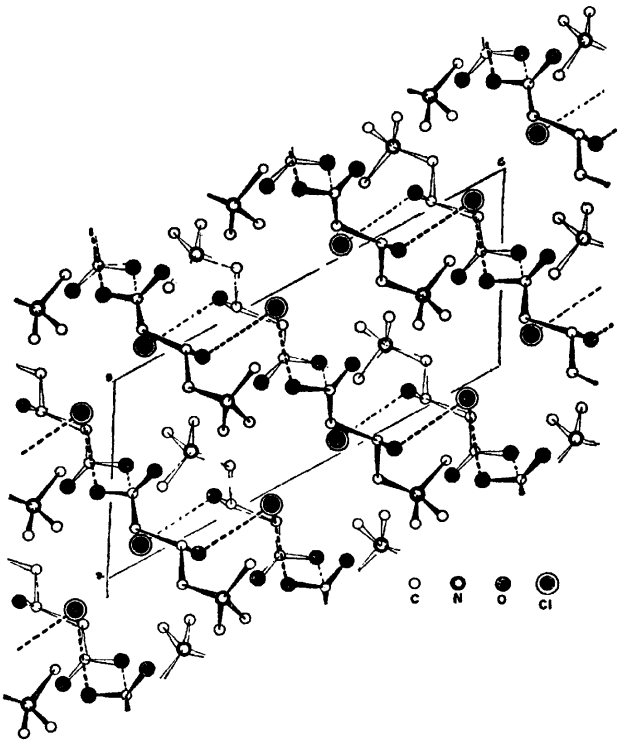

Fig. 3. The arrangement of the molecule in crystals as viewed along the *a*-axis.

τ_3 180±35° and τ_4 either 180° or −137°. The interatomic distances are: N^+–O (ester oxygen)=3.20 Å, N^+–C(carbonyl carbon)=4.50 Å and N^+–C(methyl carbon)=5.40 Å. Furthermore, the conformation of carbamoylcholine in crystals of its bromide is the only exceptional example of a potent muscarinic agonist with anti-periplanar conformation at τ_2(178°), and therefore, the relevant interatomic distances are significantly longer than those of the first three compounds in Table 6(b). On the other hand, the torsion angles and interatomic distances in crystals of carnitine hydrochloride and CABOB are very similar to those of carbamoylcholine because of having the *trans-zigzag* main chain configuration. It may be considered that there are two structurally different stimulants for muscarinic activity even if their conformations on interaction with the receptor molecule were modified from those observed in crystals. In other words, it may strongly suggest that the existence of two different receptor sites for muscarinic stimulants.

New Benzofuranosesquiterpenes from *Farfugium japonicum*. Farfugin A and Farfugin B[1]

Hajime NAGANO, Yoshihiko MORIYAMA, Yoshiaki TANAHASHI, and Takeyoshi TAKAHASHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received April 27, 1974)

Two new benzofuranosesquiterpenes, farfugin A and farfugin B, have been isolated from *Farfugium japonicum* (L.) Kitamura, and their structures have been determined as **1** and **2**, respectively.

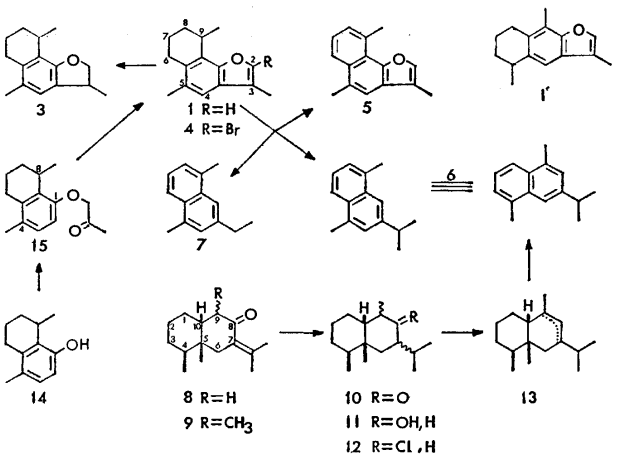
During chemical investigations on plants of the genus *Ligularia* (Compositae) and related plants,[2] two new sesquiterpenes, which we have named farfugin A and farfugin B, have been isolated from *Farfugium japonicum* (L.) Kitamura (=*Ligularia tussilaginea* Makino). We wish to report the structure determination leading to **1** and **2** for farfugin A and farfugin B, respectively.

A benzene extract of the rhizome of the plant was subjected to vacuum distillation and subsequent separation by column chromatography on silica gel to give farfugin A and farfugin B. Farfugin A (**1**) crystallized from methanol as colorless needles, mp 80.5—82.5 °C, $[\alpha]_D$+39°. The molecular formula of **1**, $C_{15}H_{18}O$, was determined by elemental analysis and the appearance of the molecular ion peak at *m/e* 214. Neither carbonyl nor hydroxyl absorption was observed in the IR spectrum. The UV and PMR spectra showed the presence of a β-methyl substituted benzofuran moiety with an α-proton,[3] an aromatic proton, an aromatic methyl, a secondary methyl spin coupled with a benzylic proton, two other benzylic protons, and four aliphatic protons (*Cf.* Experimental).

Hydrogenation of **1** over palladium–charcoal in methanol gave dihydrofurfugin A (**3**), whose PMR spectrum showed signals due to a part [$-OCH_2CH(CH_3)-$] of dihydrofuran moiety. An α-proton on the furan ring of **1** could be replaced by a bromine atom when **1** was treated with bromine in chloroform to afford bromofarfugin A (**4**).

Farfugin A (**1**) was dehydrogenated with palladium–charcoal to give a naphthofuran derivative (**5**) and a mixture of two naphthalene derivatives (**6** and **7**). Although a separation of the mixture failed due to paucity of the material, its UV, IR, and PMR spectra were closely related (*Cf.* Experimental) to those of 1,5-dimethyl-3-isopropylnaphthalene (**6**)[4] prepared from fukinone (**8**).[5] The sole difference between the two PMR spectra was that a *triplet* (J=7.5 Hz, $-CH_2\underline{CH}_3$) at δ 1.35 appeared in the spectrum of the mixture (**6** and **7**), while did not in that of **6** obtained from **8**. Combined glc-mass spectrometry of the mixture (**6** and **7**) revealed that it consisted of **6** [M^+ at *m/e* 198 ($C_{15}H_{18}$)] and **7**[M^+ at *m/e* 184 ($C_{14}H_{16}$)] in a ratio of 1 : 3. These observations showed that the mixture was composed of **6** and 1,5-dimethyl-3-ethylnaphthalene (**7**). The structure of the naphthofuran derivative (**5**) could be derived after completion of the structure determination of **1**.

The reference compound (**6**) was prepared as follows. Methylation of fukinone (**8**) with methyl iodide in a mixture of potassium *t*-butoxide and *t*-butyl alcohol gave 9-methylfukinone (**9**), which was hydrogenated over palladium–charcoal in ethanol to afford 9-methyldihydrofukinone (**10**). The ketone (**10**) was then reduced with lithium aluminium hydride to yield an alcohol (**11**). Treatment of **11** with phosphorus oxychloride in pyridine gave, besides a chloride (**12**), a mixture of hydrocarbons (**13**), which was subjected to dehydrogenation with palladium–charcoal to afford **6**[4] (Scheme 1).



Scheme 1.

The result of dehydrogenation experiments along with spectral data of farfugin A described as above led to two alternative structures (**1** and **1'**) for farfugin A. The presence of intramolecular nuclear Overhauser effects (NOE)[6] between the aromatic proton (at C-4) and the aromatic methyl (at C-5), and between the same aromatic proton (at C-4) and the methyl (at C-3), observed for bromofarfugin A (**4**), showed that the structure of farfugin A must be represented by **1** rather than by **1'** (Table 1). This was confirmed by the following synthesis.

Treatment of 4,8-dimethyl-1-hydroxy-5,6,7,8-tetrahydronaphthalene (**14**)[7] with chloroacetone, potassium iodide, and potassium carbonate in dry acetone under reflux gave 1-acetonyloxy-4,8-dimethyl-5,6,7,8-tetrahydronaphthalene (**15**). The ether (**15**) was then heated with polyphosphoric acid to afford (±)-**1**, mp 73—73.5 °C, identical with natural (+)-**1** in all respects [IR in Nujol (**1** was soluble in Nujol), UV, PMR, MS, and tlc] except mp and $[\alpha]_D$ data (Scheme 1).

Farfugin B (**2**) was isolated as a colorless oil. A molecular ion peak at *m/e* 214 ($C_{15}H_{18}O$) was observed in the mass spectrum. The presence of an α-proton and a β-methyl on the benzofuran moiety, two aromatic protons, an aromatic methyl, an olefinic methyl, and

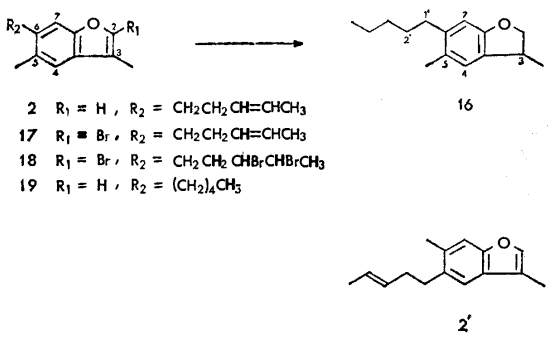
a) The NOE's are expressed as increases in integrated signal intensities in %. The other indications are given in Experimental.

two olefinic protons was shown from its UV and PMR spectral data (*Cf.* Experimental).

Hydrogenation of **2** over palladium-charcoal in ethanol gave tetrahydrofarfugin B (**16**), whose PMR spectrum showed a multiplet as AM part of an AMX system due to a methylene of dihydrofuran moiety, and two *singlets* at δ 6.58 and 6.88 due to two aromatic protons (*Cf.* Experimental).

These observations led to a 3-methylbenzofuran structure with an additional methyl and a C_5H_9 substituent on C-5 and C-6 (that is, either 2 or 2'; each with the side chain replaced by C_5H_9) for farfugin B.

A nature of the C_5H_9 group was shown to be *trans-n*-3-pentenyl from the following evidences. Bromination of **2** yielded bromofarfugin B (**17**) and tribromofarfugin **B** (**18**). A doublet (J=7.5 Hz, $C\underline{H}_3CHBr$-) appeared at δ 1.86 in the PMR spectrum of **18**, in place of the olefinic methyl signal at δ 1.65 in that of **2**. The PMR spectrum of dihydrofarfugin B (**19**), obtained by hydrogenation of **2** over platinum catalyst in methanol, showed signals at δ 0.91 due to a primary methyl. An IR absorption band at 965 cm^{-1} due to *trans*-olefinic linkage was absent in the IR spectra of **16**, **18**, and **19** (Scheme 2).



Scheme 2.

Two alternative structures of **2** and **2'** could thus be shown for farfugin B. The presence of NOE's between the aromatic proton (at C-4) and the aromatic methyl (at C-5), and between the other aromatic proton (at C-7) and the benzylic protons (at C-1'), observed for tetrahydrofarfugin B (**16**), favored the structure **2** over **2'** for farfugin B (Table 1). The structure of farfugin B should therefore be represented by 3,5-dimethyl-6-(*trans-n*-3-pentenyl)benzofuran (**2**). This received support from a recent synthesis of dihydrofarfugin B (**19**) from 1-methyl-2-bromo-4-methoxybenzene described elsewhere.[8]

Experimental

IR, UV, and mass spectra were measured using a Hitachi EPI-G2, a Hitachi EPS-3, and a Hitachi RMU-6-Tokugata spectrometers, respectively. A gas chromatograph, Hitachi K53, was equipped with this mass spectrometer for measurements by combined glc-mass spectrometry. Optical rotations, $[\alpha]_D$, were measured with a YANACO OR-50 spectrometer. PMR spectra were taken on a JEOL 4H-100 (100 MHz), a JEOL PS-100 (100 MHz), and a Hitachi R-20 (60 MHz) spectrometers. For the measurement of NOE's, the PMR spectra were taken with a Varian HA-100 spectrometer operating at 100 MHz in the frequency-swept and internal TMS-locked mode, for *ca.* 5% (w/v) degassed solution in $CDCl_3$. NOE experiments were performed with sweep rates of 0.4 Hz per sec for integration and 0.2 Hz per sec for signals on the spectrometer with a Hewlett-Packard HP-200ABR audio-oscillator and an HP-5212A electronic counter. Accuracies for NOE values are about ±2%. Chemical shifts are expressed in δ (TMS as internal standard), and coupling constants in Hz. All melting points were determined on a hot block and reported uncorrected. Merck Kieselgel G and Kieselgel 60 PF_{254} were used for analytical and preparative tlc, respectively. For column chromatography silica gel (Wakogel C-200) and neutral alumina (Showa Chemical Co.) were used.

Isolation of Farfugin A (1) and Farfugin B (2). The rhizomes of *Farfugium japonicum* (L.) Kitamura were extracted with hot benzene. The residue obtained (24 g) after evaporation of the solvent was subjected to distillation at 150 °C under 0.3 mmHg to give a brown oil (4 g), which, by repeated distillation, afforded a yellow oil(2.7 g). The oil was chromatographed on silica gel (150 g) using light petroleum as eluent (each 150 ml). The eluted fractions were collected and examined by tlc.

Fractions 6—8 were combined and the solvent was removed to give crude **1** (153 mg), which was further chromatographed on silica gel. Fractions eluted with light petroleum, on evaporation of the solvent, gave a residue, which afforded after crystallization from ethanol *farfugin A* (**1**; 102 mg), mp 80.5—82.5 °C, $[\alpha]_D^{20}$ +39° (c 0.34, in EtOH); UV (cyclohexane): λ_{max} 252.5 nm (ε 14500), 281 (2800), and 291 (3200); IR (Nujol): 1590 and 1540 cm^{-1}; PMR ($CDCl_3$): δ 1.37 (3H, d, J=7.5 Hz, $C_{(9)}$-CH_3), 2.16 (3H, d, J=1.2 Hz; $C_{(3)}$-CH_3), 2.27 (3H, s; $C_{(5)}$—CH_3), 2.63 (2H, m; $C_{(6)}$-H), 3.35 (1H, m; $C_{(9)}$-H), 7.05(1H, s; $C_{(4)}$-H), 7.20 (1H, m; $C_{(2)}$-H), and 1.5—2.0 (4H; $C_{(7)}$-H and $C_{(8)}$-H); MS: *m/e* 214 (relative intensity 79%, $M^+(C_{15}H_{18}O)$) and 199 (100%, $[M-CH_3]^+$). Found: C, 83.67; H, 8.24%. Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

Fractions 11—14 gave a residue (57 mg), which was chromatographed on silica gel. Fractions eluted with light petroleum were collected. Evaporation of the solvent gave

farfugin B (**2**; 49 mg), colorless liquid; UV (EtOH): λ_{max} 251.5 nm (ε 10500), 281.5 (3500), and 291.5 (3900); IR (liquid): 3020, 1575, and 965 cm^{-1}; PMR ($CDCl_3$): δ 1.65(3H, *m*; $-CH=CHC\underline{H}_3$), 2.19(3H, d, J=1.2 Hz; $C_{(3)}-C\underline{H}_3$), 2.37 (3H, s; $C_{(5)}-C\underline{H}_3$), 5.45 (2H, m; $-C\underline{H}=C\underline{H}-$), and 7.20 (3H, m; $C_{(2)}$-H, $C_{(4)}$-H, and $C_{(7)}$-H), and 2.5—3.0 (4H; $C_{(1')}$-H and $C_{(2')}$-H); MS: *m/e* 214 (37%, M^+ ($C_{15}H_{18}O$)) and 159 (100%).

*Hydrogenation of Farfugin A (**1**) over Palladium-Charcoal.* A solution of **1** (39 mg) in methanol (10 ml) was stirred with 10% palladium-charcoal (30 mg) in an atmosphere of hydrogen for 6 hr. Filtration of the catalyst and evaporation of the solvent under reduced pressure gave a crystalline product (32 mg), which was recrystallized from ethanol to give *dihydrofarfugin A* (**3**), mp 51—52 °C, UV (cyclohexane): λ_{max} 285 nm (ε 3200) and 292.5 (3500); IR (Nujol): 1610 and 1590 cm^{-1}; PMR ($CDCl_3$): δ 1.24 (3H, d, J=7 Hz; $C_{(9)}-CH_3$), 1.2 7(3H, d, J=6.5 Hz, $C_{(3)}-CH_3$), 2.15 (1H, s; $C_{(5)}-CH_3$), 2.55(2H, m; $C_{(6)}$-H), 3.00 (1H, m; $C_{(9)}$-H), 3.45 (1H, m; $C_{(3)}$-H), 4.03 (1H, dd, J=8 Hz and 7 Hz; $C_{(2)}$-H), 4.63 (1H, t, J=8 Hz; the other $C_{(2)}$-H), and 6.80 (1H, s; $C_{(4)}$-H); MS: *m/e* 216 (55%, M^+ ($C_{15}H_{20}O$)) and 201 (100%, $[M-CH_3]^+$).

*Bromination of Farfugin A (**1**).* A solution of bromine (23 mg) in chloroform (2 ml) was added dropwise to a solution of **1** (30 mg) in chloroform (5 ml) with stirring. The color of the solution disappeared immediately. Evaporation of the solvent gave a crystalline residue (40 mg), which was passed through a column of silica gel using light peroleum as eluent to afford *bromofarfugin A* (**4**; 38 mg), mp 99.5—100 °C (recrystallized from EtOH); IR (Nujol): 1590 cm^{-1}; PMR ($CDCl_3$): δ 1.38 (3H, d, J=7 Hz; $C_{(9)}-CH_3$), 2.12 (3H, s; $C_{(3)}-CH_3$), 2.27 (3H, s; $C_{(5)}-CH_3$), 2.63 (2H, m; $C_{(6)}$-H), 3.37 (1H, m; $C_{(9)}$-H), and 7.00 (1H, s; $C_{(4)}$-H); MS: *m/e* 294 (100%, M^+ ($C_{15}H_{17}OBr$)), 292 (100%, M^+), 279 (89%, $[M-CH_3]^+$), and 277 (90%, $[M-CH_3]^+$). Found: C, 61.66; H, 5.83%. Calcd for $C_{15}H_{17}OBr$: C, 61.44; H, 5.84%.

*Dehydrogenation of Farfugin A (**1**) over Palladium-Charcoal.* A mixture of **1** (51 mg) and 10% palladium-charcoal (53 mg) in a sealed tube under a nitrogen atmosphere was heated at 300 °C for 5 min. The reaction mixture was extracted with ether and evaporation of the solvent gave an oil (30 mg), which was submitted to separation by preparative tlc (silica gel impregnated with 1,3,5-trinitrobenzene, 10%; solvent: light petroleum). A silica gel layer (R_f 0.2) containing naphthofuran-trinitrobenzene adduct and that (R_f 0.4) containing naphthalene-trinitrobenzene adduct were collected respectively, and each of them was placed on the top of a column of alumina. Elution with benzene gave 3,5,9-trimethyl-naphtho[1,2-*b*]-furan (**5**; 7 mg), and a mixture (7 mg) of 1,5-dimethyl-3-isopropylnaphthalene (**6**) and 1,5-dimethyl-3-ethylnaphthalene (**7**), respectively. *3,5,9-trimethylnaphtho[1,2-b]furan* (**5**): mp 64.5—65.5 °C (recrystallized from EtOH); UV (MeOH): λ_{max} 248.5 nm (ε 49000), 253 (48000), 282.5 (5300, shoulder), 291 (5800), 302 (4300, shoulder), 324 (1800), and 339 (1500); IR (Nujol): 1570 cm^{-1}; MS: *m/e* 210 (100%, M^+($C_{15}H_{14}O$)), 209 (38%, $[M-H]^+$), and 195 (38%, $[M-CH_3]^+$).

Spectral data of the mixture of *naphthalene derivatives* (mixture of **6** and **7**) was as follows; UV (MeOH): λ_{max} 226 nm (ε 51700), 231 (72000), 278 (5100), 287 (5700), 293 (4800), and 324 (100) (ε was calculated based on assumption of molecular weight 198); IR (liquid): 1620, 1598, 865, 795, and 745 cm^{-1}; PMR ($CDCl_3$): δ 1.35 (t, J=7.5 Hz; $-CH_2C\underline{H}_3$), 1.37 (d, J=7.5 Hz; $-CH(C\underline{H}_3)_2$, 2.68 (s; aromatic $C\underline{H}_3$), and 7.2—8.0 (m, aromatic protons); glc (retention time): (i) 8.3 and 6.8 min (Diasolid H523 (2%), 1.5 m column, 160 °C, N_2 gas flow 80 ml/min); (ii) 17.0 min (Polydiethylene glycosuccinate on Chromosorb W (20%), 2 m column, 180 °C, N_2 gas flow 60 ml/min).

*Methylation of Fukinone (**8**).* To a solution of potassium *t*-butoxide in *t*-butanol, prepared from potassium (600 mg) and *t*-butanol (40 ml), a solution of fukinone[5] (**8**; 995 mg) in *t*-butanol (10 ml) and methyl iodide (6 g) were added dropwise under a nitrogen atmosphere. The reaction mixture was set aside for 5 hr at 25 °C. After neutralization with aqueous acetic acid (AcOH, 5 ml, and H_2O, 20 ml), the mixture was condensed under reduced pressure and extracted with ether. The extract was treated as usual and the resulting residue (1.97 g) was chromatographed on silica gel (150 g). Elution with light petroleum-ether (200 : 3; each fraction, 150 ml) gave an oil, 9-methylfukinone (**9**; 559 mg; from frs 15—19) and **8** (248 mg; from frs 22—25). *9-Methylfukinone* (**9**); UV (EtOH): λ_{max} 250 nm (ε 6500); IR (liquid): 1690 and 1630 cm^{-1}; PMR ($CDCl_3$): δ 0.81 (3H, d, J=7 Hz; $C_{(4)}-CH_3$), 0.94 (3H, s; $C_{(5)}-CH_3$). 1.07 (3H, d, J=7 Hz; $C_{(9)}-CH_3$), 1.80 (3H, s; $C=CCH_3$), and 1.91 (3H, s; $C=CCH_3$); MS: *m/e* 234 (30%, M^+ ($C_{16}H_{26}O$)), 219 (3%, $[M-CH_3]^+$), 187 (42%), 163 (39%), and 109 (100%).

*Hydrogenation of 9-Methylfukinone (**9**) over Palladium-Charcoal.* The methylated product (**9**; 559 mg) was hydrogenated with 10% palladium-charcoal (65 mg) in ethanol at room temperature. Filtration of the catalyst and evaporation of the solvent gave a residue (506 mg), which was passed through a column of silica gel (100 g) using light petroleum-ether (200 : 3) as eluent. The eluate was evaporated under reduced pressure to give oily *9-methyldihydrofukinone* (**10**; 402 mg), IR(liquid): 1710 cm^{-1}; MS: *m/e* 236 (31%, M^+ ($C_{16}H_{28}O$)), 221 (14%, $[M-CH_3]^+$), 194 (40%), 97 (52%), 84 (74%), 81 (51%). 69 (73%), 67 (55%), and 55 (100%).

*Reduction of **10** with Lithium Aluminium Hydride.* To a suspension of lithium aluminium hydride (464 mg) in dry ether (30 ml), a solution of **10** (403 mg) in dry ether was added and stirred for 4 hr at room tmeperature. The excess reagent was decomposed with water and the reaction mixture was extracted with ether. The extract was treated as usual to give an oily *9-methyldihydrofukinol* (**11**; 408mg), IR (liquid): 3450 cm^{-1}; MS: *m/e* 220 (6%, $[M-H_2O]^+$), 205 (24%, $[M-H_2O-CH_3]^+$) 177 (59%), 136 (75%), 109 (79%), 107 (66%), 95 (65%), 81 (56%), 67 (69%) and 55 (100%). A molecular ion peak at *m/e* 238 ($C_{16}H_{30}O$) was not observed.

*Dehydration of **11** with Phosphorus Oxychloride.* A solution of **11** (408 mg) and phosphorus oxychloride (2 ml) in pyridine (20 ml) was allowed to stand overnight at room temperature. The reaction mixture was poured into ice-water and extracted with ether. The extract was treated as usual to give a residue (341 mg), which was chromatographed on silica gel (100 g) using light petroleum as eluent (each fraction 20 ml). Fractions 10—12 gave a mixture of dehydrated products (**13**; 171 mg). Fractions 13—14 gave a residue, which was subjected to repeated chromatography on silica gel using light petroleum as eluent to afford the mixture of dehydrated products (**13**; 15 mg) and a chloride (**12**; 82 mg). The mixture of *9-methyleremophilenes* (**13**): colorless liquid, IR (liquid): 1650 cm^{-1}; PMR ($CDCl_3$): δ 5.16 (m, olefinic protons); MS: *m/e* 220 (5%, M^+ ($C_{16}H_{28}$)), 205 (4%, $[M-CH_3]^+$), 177 (70%), 109 (43%), 107 (44%), 97 (49%), 95 (100%), and 81 (71%). *Chloride* (**12**): colorless liquid, PMR ($CDCl_3$): δ 4.25 (m, $-CHCl-$); MS: *m/e* 258 (1.5%, M^+ ($C_{16}H_{29}OCl$)), 256 (2.5%, M^+), 221 (28%, $[M-Cl^+]$), 177 (57%), 109 (65%), 107 (96%), 81 (73%), 69 (65%), 67

(65%), and 55 (100%).

Dehydrogenation of ***13*** *over Palladium-Charcoal.* Dehydrated product (**13**; 60 mg) was heated with 10% palladium-charcoal (70 mg) at 300 °C for 5 min in a sealed tube under a nitrogen atmosphere. Another 60 mg of **13** was dehydrogenated described as above. The reaction mixtures were combined and extracted with ether. Evaporation of the solvent gave a residue (89 mg), which was submitted to preparative tlc. A diluted solution of 1,3,5-trinitrobenzene in methanol was sprayed on the plate. A zone developing a yellow color was collected and placed on the top of a column of alumina. The column was eluted with benzene to give oil 1,5-dimethyl-3-isopropylnaphthalene[4] (**6**; 24 mg). Picrate, orange needles, mp 110—113 °C (recrystallized from EtOH); trinitrobenzene-adduct, yellow needles, mp 139—141 °C (recrystallized from EtOH).

Spectral data of *1,5-dimethyl-3-isopropylnaphthalene* (**6**) were as follows; UV (EtOH): λ_{max} 225.5 nm (ε 49000), 231 (81000), 277.5 (4800), 287 (5700), 292.5 (4700), 318 (100), and 323 (100); IR (liquid): 1620, 1600, 865, 795, and 745 cm^{-1}; PMR ($CDCl_3$): δ 1.35 (6H, d, J=7.5 Hz; $-CH(C\underline{H}_3)_2$), 2.69 (6H, s, aromatic CH_3), and 7.2—8.0 (5H, m; aromatic protons); glc (retention time): (i) 8.3 min (Diasolid H523 (2%), 1.5 m column, 160 °C, N_2 gas flow 80 ml/min); (ii) 16.8 min (Polydiethylene glycosuccinate on Chromosorb W (20%), 2 m column, 180 °C, N_2 gas flow 60 ml/min).

*1-Acetonyloxy-4,8-dimethyl-5,6,7,8-tetrahydronaphthalene (****15****).* A solution of 1-hydroxy-4,8-dimethyl-5,6,7,8-tetrahydronaphtharene[7] (**14**; 896 mg) in dry acetone was refluxed with chloroacetone (964 mg), potassium iodide (314 mg), and potassium carbonate (2.50 g) for 6 hr. After the solvent was distilled off the residue was extracted with ether. The extract was washed, dried, and evaporated to afford a viscous oil (1.48 g), which was chromatographed on silica gel (75 g). Fraction eluted with benzene-light petroleum (2 : 1) gave *1-acetonyloxy-4,8-dimethyl-5,6,7,8-tetrahydronaphthalene* (**15**; 1.01 g), mp 50—51 °C (recrystallized from light petroleum); IR (Nujol): 1728, 1600, 1583, and 795 cm^{-1}; PMR ($CDCl_3$): δ 1.25 (3H, d, J=7 Hz; $C_{(8)}$–CH_3), 2.11 (3H, s; $C_{(4)}$–CH_3), 2.23 (3H, s; $-COCH_3$), 4.32 (2H, s; $-OCH_2CO-$), 6.32 (1H, d, J=9 Hz; $C_{(2)}$–H or $C_{(3)}$–H), and 6.78 (1H, d, J=9 Hz; $C_{(3)}$–H or $C_{(2)}$–H); MS: *m/e* 232 (20%, $M^+(C_{15}H_{20}O_2)$), 217 (10%, $[M-CH_3]^+$), 189 (20%, $[M-CH_3CO]^+$), 174 (100%), and 159 (88%). Found: C, 77.55; H, 8.64%. Calcd for $C_{15}H_{20}O_2$: C, 77.77; H, 8.77%.

*Cyclization of the Ether (****15****).* The ether (**15**; 971 mg) was heated with polyphosphoric acid (10 g) at 100 °C for 35 min under a nitrogen atmosphere. Ice-water was added and the reaction mixture was extracted with ether. The extract was washed with aqueous solution of sodium bicarbonate and then with water. After the solution was dried over anhydrous sodium sulfate, the solvent was removed to give a residue (860 mg), which was chromatographed on silica gel. Fractions eluted with light petroleum afforded a crystalline product, (±)-*farfugin A* (±**1**; 344 mg), mp 73—73.5 °C (recrystallized from EtOH); UV (cyclohexane): λ_{max} 253 nm (ε 13500), 281 (2800), and 290.5 (3000); IR (Nujol): 1590 and 1540 cm^{-1}; PMR ($CDCl_3$): δ 1.40 (3H, d, J=7 Hz; $C_{(9)}$–CH_3), 2.19 (3H, d, J=1 Hz; $C_{(3)}$–CH_3), 2.30 (3H, s; $C_{(5)}$–CH_3), 2.65 (2H, m; $C_{(6)}$–H), 3.37 (1H, m; $C_{(9)}$–H), 7.13 (1H, s; $C_{(4)}$–H), and 7.29 (1H, m; $C_{(2)}$–H); MS: *m/e* 214 (47%, $M^+(C_{15}H_{18}O)$), and 199 (100%, $[M-CH_3]^+$). Found: C, 84.02; H, 8.42%. Calcd for $C_{15}H_{18}O$: C, 84.07; H, 8.47%.

*Hydrogenation of Farfugin B (****2****) over Palladium-Charcoal.* A solution of **2** (29 mg) in ethanol was stirred with 10% palladium-charcoal (28 mg) for 5.5 hr under an atmosphere of hydrogen. Filtration of the catalyst and evaporation of the solvent gave a residue (22 mg), which was passed through a column of silica gel using light petroleum as eluent to afford oily *tetrahydrofarfugin B* (**16**; 19 mg); IR (liquid): 3020, 1618, and 1580 cm^{-1}; PMR ($CDCl_3$): δ 0.89 (3H, m; terminal CH_3 on the side chain), 1.29 (3H, d; J=7 Hz; $C_{(3)}$–CH_3), 2.23 (3H, s; $C_{(5)}$–CH_3), 2.52 (2H, m; benzyl) protons), 3.45 (1H, m; $C_{(3)}$–H), 4.01 (1H, dd, J=8 Hz and 7 Hz; $C_{(2)}$–H, 4.63 (1H, t, J=8 Hz; the other $C_{(2)}$–H), 6.58 (1H, s; $C_{(7)}$–H), and 6.88 (1H, s; $C_{(4)}$–H); MS: *m/e* 218 (100%, M^+ ($C_{15}H_{22}O$)), 203 (49%, $[M-CH_3]^+$), 162 (59%), and 161 (64%).

*Bromination of Farfugin B (****2****).* To a solution of **2** (36 mg) in carbon tetrachloride (5 ml), a solution of bromine (40 mg) in carbon tetrachloride (2 ml) was added dropwise with stirring and the resulting solution was allowed to stand at room temperature for 30 min. The products were examined by tlc. Evaporation of the solvent gave a residue (60 mg), which was chromatographed on silica gel using light petroleum as eluent to afford bromofarfugin B (**17**; 18 mg) and tribromofarfugin B (**18**; 36 mg). *Bromofarfugin B* (**17**): mp 36—37 °C (recrystallized from EtOH); IR (liquid): 3070, 3020, 1635, 1595, 1575, and 965 cm^{-1}; PMR ($CDCl_3$): δ 1.65 (3H, m; terminal CH_3), 2.12 (3H, s; $C_{(3)}$–CH_3), 2.34 (3H, s; $C_{(5)}$–CH_3), 5.45 (2H, m; $-C\underline{H}=C\underline{H}-$), and 7.13 (2H, s; $C_{(4)}$–H and $C_{(7)}$–H); MS: *m/e* 294 (71%, M^+ ($C_{15}H_{17}OBr$)), 292 (71%, M^+), 239 (100%), and 237 (100%). *Tribromofarfugin B* (**18**): mp 74—74.5 °C (recrystallized from EtOH); IR (Nujol): 1590, 1575, and 870 cm^{-1}; PMR ($CDCl_3$): δ 1.86 (3H, d, J=7.5 Hz; $-CHBr-C\underline{H}_3$), 2.13 (3H, s; $C_{(3)}$–CH_3), 2.40 (3H, s; $C_{(5)}$–CH_3), 4.20 (2H, m; $-C\underline{H}Br-C\underline{H}Br-$), 7.17 (1H, s; $C_{(4)}$–H or $C_{(7)}$–H), and 7.19 (1H, s; $C_{(7)}$–H or $C_{(4)}$–H); MS: *m/e* 456 (15%, $M^+(C_{15}H_{17}OBr_3)$), 454 (44%, M^+), 452 (44%, M^+), 450 (16%, M^+), 239 (100%), and 237 (100%). Found: C, 39.93; H, 3.77%. Calcd for $C_{15}H_{17}OBr_3$: C, 39.77; H, 3.78%.

*Hydrogenation of Farfugin B (****2****) over Paltinum Oxide.* Hydrogenation of **2** (8 mg) was effected over platinum oxide (8 mg) in methanol (2 ml) with stirring for 14 hr at 30 °C. Filtration of the catalyst and evaporation of the solvent gave oily *dihydrofarfugin B* (**19**; 8 mg), IR (liquid): 1575, 860, and 775 cm^{-1}; PMR ($CDCl_3$): δ 0.91 (3H, m; terminal CH_3), 2.23 (3H, d, J=1 Hz; $C_{(3)}$–CH_3), 2.42 (3H, s; $C_{(5)}$–CH_3), and 7.30 (3H, m; $C_{(2)}$–H, $C_{(4)}$–H, and $C_{(7)}$–H); MS: *m/e* 216 (19%, M^+ ($C_{15}H_{20}O$)) and 159 (100%).

The authors wish to thank Dr. M. Fukuyama and Mr. K. Sato, Sagami Chemical Research Center, Sagamihara-shi, for the measurements of NOE's.

Furanoeremophilane-6β,10β-diol and Its Derivatives. New Furanosesquiterpenes from *Ligularia japonica* LESS[1]

Masahiro TADA, Yoshihiko MORIYAMA, Yoshiaki TANAHASHI, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received May 2, 1974)

Three new furanosesquiterpenes have been isolated from *Ligularia japonica* LESS., and their structures including absolute configurations have been determined as furanoeremophilane-6β,10β-diol (**1**), 10β-hydroxyfuranoeremophilan-6β-yl 2'ξ-methylbutanoate (**2**), and 10β-hydroxy-6β-methoxyfuranoeremophilane (**3**).

In connection with structural studies on constituents of the genus *Ligularia* (Compositae),[2] three new furanoereomophilane derivatives have been isolated from *Ligularia japonica* LESS. We wish to describe the structure determination leading to furanoeremophilane-6β,10β-diol (**1**), 10β-hydroxyfuranoeremophilan-6β-yl 2'ξ-methylbutanoate (**2**), and 10β-hydroxy-6β-methoxyfuranoeremophilane (**3**) for these sesquiterpenes.

A benzene extract of the roots of the plant was subjected to separation by column chromatography on silica gel to give **1** and **2**. Compound **1**, mp 120—122 °C, $[\alpha]_D$+33° (EtOH),* was positive to the Ehrlich test. The molecular formula of **1**, $C_{15}H_{22}O_3$, was determined by elemental analysis and the appearance of the molecular ion peak at *m/e* 250. The IR, UV, and PMR spectra showed the presence of a secondary methyl, a tertiary methyl, a β-methyl-substituted furan moiety with an α-proton,[2] an allylic methylene linked to carbon with no proton, and of hydroxyl group(s) (cf. Experimental). A monoacetate (**4**), obtained by acetylation of **1** with acetic anhydride in pyridine exhibited an absorption due to an additional hydroxyl group in its IR spectrum. In the PMR spectrum of **1** in benzene, on addition of deuterium oxide, a doublet at δ 4.41 (J=7.5 Hz) due to a proton on a hydroxyl-bearing carbon changed into a singlet, while both of a doublet at δ 2.72 (J=7.5 Hz) due to a secondary hydroxyl proton and a singlet at δ 2.93 due to a tertiary hydroxyl proton disappeared. The presence in **1** of a secondary and a tertiary hydroxyl group could thus be shown.

The presence of intramolecular nuclear Overhauser effects (NOE)[3] between a β-methyl (at C-11) on the furan ring and a proton (at C-6) on an acetoxyl-bearing carbon, as well as between the same methyl (at C-11) and an α-proton (at C-12) on the furan ring (Table 1), observed for **4**, showed that a secondary hydroxyl-bearing carbon (C-6) of **1** must be located on a β'-position (that is C-7) on the furan ring. This received support from an upfield shift[4,5] by 0.12 ppm of a doublet at δ 2.03 (in deuteriochloroform; J=1.5 Hz) due to a β-methyl on the furan ring, when **1** was acetylated. As a nature of three (at α, β, and β') of the four substituents on the furan ring was already clarified, the allylic methylene must be placed on an α'-position of the furan moiety for **1**. These observations led to a partial structure **A** (R=H), which could be extended, by means of biogenetic considerations, to two alternative structures, **B**(R=H) and **B'**(R=H), for **1**.

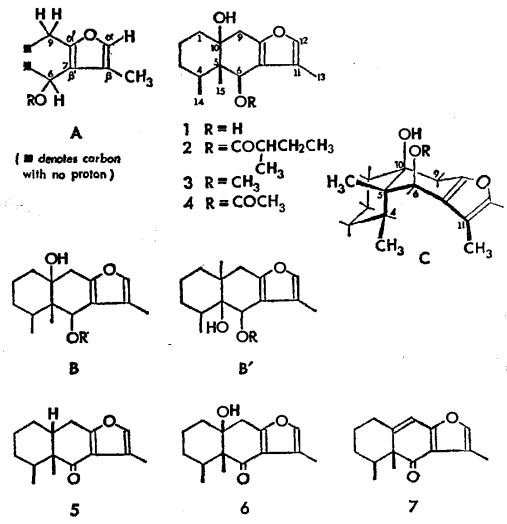

Table 1. Nuclear Overhauser effects

Compounds	Solvents	Observed protons	Saturated protons	NOE[a]
1	C_6D_6	9α-H	5-CH_3	nil
		9β-H	5-CH_3	nil
		12-H	11-CH_3	32
3	CCl_4	6-H	5-CH_3	13
4	C_6D_6	6-H	4-CH_3	21
		9α-H	5-CH_3	nil
		9β-H	5-CH_3	nil
		6-H	11-CH_3	4
		12-H	11-CH_3	20

a) The NOE's are expressed as increases in integrated signal intensities in %. The other indications are given in Experimental.

The IR spectrum of **2**, mp *ca.* 40 °C, showed a carbonyl absorption (ν_{max} 1725 cm^{-1}) due to an ester group. A molecular ion peak at *m/e* 334 ($C_{20}H_{30}O_4$) was observed in the mass spectrum of **2**, which was reduced with lithium aluminium hydride to give **1**. An acyl residue was therefore shown to be C_4H_9CO–. In the PMR spectrum of **2** in deuteriochloroform, a triplet at δ 0.88 (J=5.5 Hz) due to a primary methyl, a doublet at δ 1.14 (J=7 Hz) due to a secondary methyl, and a multiplet at δ 2.34 due to a methine proton of a –OCOCH(CH$_3$)– grouping appeared, besides signals due to protons of the structure moiety of

* Previously this value has been reported as +58° (EtOH).[1] The authors correct it to +33° for the same compound based on recent measurement data.

1. Thus, **2** must be an ester comprising from **1** and 2ξ-methylbutanoic acid.

Successive extraction of the roots with methanol and subsequent separation by column chromatography on silica gel gave a compound **3**, mp 82—84 °C, $[\alpha]_D$+ 5° (EtOH), whose molecular formula $C_{16}H_{24}O_3$ was given by elemental analysis and mass spectrometry (M^+ at *m/e* 264). The treatment of **1** with methanol in the presence of acetic acid, or with a mixture of methyl iodide, silver oxide, and dimethylformamide, afforded **3**. A secondary hydroxyl of **1** was thus methylated to give **3**. As the absence of **3** in the benzene extract was shown by thin layer chromatography, it was suggested that **3** might be an artifact produced by extraction with methanol.

A preference of the structure **B** (R=H) over **B'** (R=H) for **1** was shown as follows. The treatment of **1** with potassium periodate resulted in no consumption of the reagent. This showed the absence in **1** of an α-glycol (especially, of an α-*cis*-glycol) system. An NOE observed between a tertiary methyl (at C-5) and a proton (at C-6) on a methoxyl-bearing carbon for **3**, and the absence of NOE between a tertiary methyl (at C-5) and each of two allylic protons (at C-9) observed for **1** and **4**, suggested that the tertiary methyl was located on C-5 (Table 1). Finally, **1** was transformed to known ligularone (**5**).[4] Oxidation of **1** with chromium trioxide gave 10β-hydroxy-6-oxofuranoeremophilane (**6**), which was dehydrated with phosphorus oxychloride in pyridine to afford 6-oxofuranoeremophil-9-ene (**7**). Hydrogenation of **7** in the presence of palladium-charcoal in ethyl acetate proceeded stereoselectively to afford a ketone (yield: *ca.* 80%) as a main product, which was found to be identical with **5** in all respects. The structure **B** was thus derived for **1**.

The IR spectrum of **1** in carbon tetrachloride (0.005 M solution) showed the presence of an intramolecular hydrogen bond between the two hydroxyls. A tertiary hydroxyl at C-10 and a secondary hydroxyl at C-6 must therefore be in a 1,3-diaxial (that is, in *cis*) relationship to each other; this led to an equatorial conformation for a proton on C-6. These data along with the absence of NOE between the tertiary methyl at C-5 and each of methylene protons at C-9 (especially, an axial proton at C-9α) as described above, suggested an equatorial nature of this methyl (at C-5). This received support from a downfield shift by 0.23 ppm observed for a signal due to the tertiary methyl at C-5 of **1**, when the solvent was replaced from deuteriochloroform to pyridine-d_5.[6] In the PMR spectra of **3**, the corresponding downfield shift was relatively small (0.08 ppm) due to a strong intramolecular hydrogen bond (ν_{OH} 3488 cm^{-1}; in 0.005 M solution of carbon tetrachloride) which could inhibit competitively the solute-solvent association. The two hydroxyls and the tertiary methyl at C-5 are therefore in *cis* relationships to one another. The two methyls at C-4 and C-5 of **1** have been shown to be *cis* according to the conversion of **1** to **5** as mentioned above. The presence of NOE between a secondary methyl at C-4 and a proton at C-6 on an acetoxyl-bearing carbon was observed

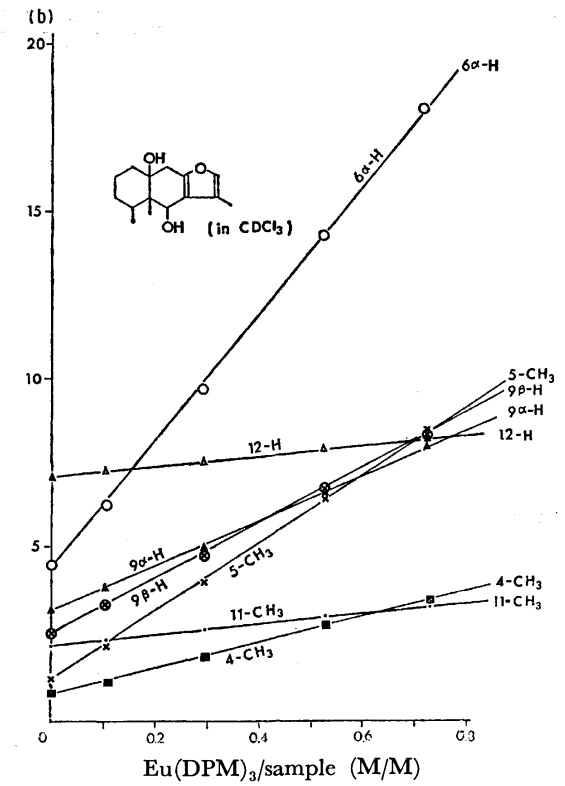

Fig. 1. Induced paramagnetic shifts for the diol(**1**)
[$Eu(DPM)_3$ was added to a 5% (w/v) soln of **1** in $CDCl_3$.]

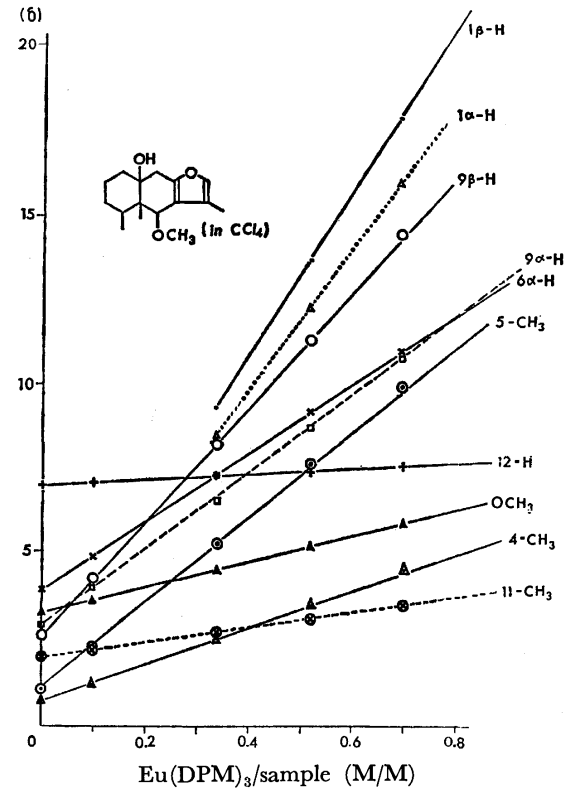

Fig. 2. Induced paramagnetic shifts for the monomethyl ether(**3**)
[$Eu(DPM)_3$ was added to a 5% (w/v) soln of **3** in CCl_4.]

for **4** (Table 1). These observations could only be explained based on a steroidal conformation of *cis*-decalin type depicted as in **C**.

The results of induced paramagnetic shift experiments[7] on the diol and the monomethyl ether were compatible with the structures **1** and **3**, respectively (Figs. 1 and 2). In the measurements for both of **1** and **3**, a large shift was observed for a signal due to a methyl at C-5. The signals due to a proton at C-9β and two protons at C-1 of **3**, as well as that due to a proton at C-6 of **1**, shifted very largely, while a smaller shift was observed for the corresponding signal due to a proton at C-6 of **3**. This could be interpreted by a preferencial association of the shift reagent, Eu(DPM)$_3$, with a hydroxyl rather than an ether group.[8]

As an absolute stereochemistry of **5** had been determined as in **5**,[4] the structure of the diol including absolute configuration should be represented by **1** with a conformation as shown in **C** (R=H). The structures **2**, **3**, and **4** followed for the ester, the monomethyl ether, and the monoacetate, respectively.

Experimental

IR spectra were measured using a Hitachi EPI-G2 spectrometer in Nujol mull, unless otherwise stated. UV spectra were determined on a Hitachi EPS-3 spectrophotometer. Measurements of optical rotation were carried out using a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV. PMR spectra were measured using a JEOL PS-100 (100 MHz) or a Hitachi R-20 (60 MHz) spectrometer. Chemical shifts were expressed in δ downfield from TMS as an internal standard, and coupling constants in Hz. For a measurement of NOE, PMR spectra were taken on a Varian HA-100 spectrometer operating at 100 MHz in the frequency-swept and internal TMS-locked mode, for *ca.* 5% (w/v) degassed solutions. NOE experiments were performed with sweep rates of 1 Hz per second for integrations and 0.2 Hz per second for signals on the spectrometer with a Hewlett-Packard HP-200ABR audio-oscillator and HP-5212A electronic counter. Accuracies are ±0.01 ppm for chemical shifts, ±0.2 Hz for coupling constants, and about ±2% for NOE values, for NOE experiments. Thin layer chromatography (tlc) was carried out on Kieselgel PF_{254} (E. Merck, Darmstadt). For column chromatography Wakogel C 200 (Wako Pure Chemical Co.) was used. All mps were determined on a hot block and reported uncorrected.

Isolation. Dried roots (1.6 kg) of *Ligularia japonica* LESS. were extracted with hot benzene (total 12 l). Evaporation of the solvent gave a residue (15 g) which was chromatographed on a column of silica gel (500 g). The eluted fractions were examined by tlc (silica gel). Fractions eluted with light petroleum–ether (10 : 1) gave, on evaporation of the solvents, a residue, which was crystallized from light petroleum to afford 10β-hydroxyfuranoeremophilan-6β-yl 2′ξ-methylbutanoate (**2**; 200 mg), mp *ca.* 40 °C; UV (EtOH) λ_{max} 218 nm (ε 9100); IR (CCl_4) 3570, 3500, 1725, 1640, 1565, 1245 cm^{-1}; PMR ($CDCl_3$) δ 0.83 (3H, d, J=7.5 Hz; methyl at C-4), 0.88 (3H, t, J=5.5 Hz; primary methyl in an acyl moiety), 1.14 (3H, d, J=7 Hz; secondary methyl in the acyl group), 1.25 (3H, s; methyl at C-5), 1.90 (3H, d, J=1.5 Hz; methyl at C-11), 2.34 (1H, m; –OCOCH(CH$_3$)– in the acyl residue), 2.65 and 3.20 (each, 1H, d, J=17.5 Hz; protons at C-9), 6.19 (1H, s; proton at C-6), 7.07 (1H, m; proton at C-12), ca. 3.3 (1H, broad signal; OH); mass spectrum *m/e* 334 (M$^+$; $C_{20}H_{30}O_4$), *m/e* 159 (base peak). Fractions eluted with light petroleum–ether (3 : 1) gave, on removal of the solvents, a solid, which was chromatographed on a column of silica gel (50 g). Elution with light petroleum–ether (3 : 1) and evaporation of the solvents gave a crude crystal, which was crystallized from a mixture of light petroleum and ether to afford furanoeremophilane-6β,10β-diol (**1**; 380 mg), mp 120—122 °C, $[\alpha]_D$ +33° (*c* 1.7, EtOH); UV(EtOH) λ_{max} 217 nm (ε 8000); IR (0.005 M solution of CCl_4) 3608, 3544, 3504, 1645, 1565, 1030 cm^{-1}; PMR (C_6D_6) δ 0.55 (3H, $\underline{A}_3B$, J=5.5 Hz; methyl at C-4), 1.11 (3H, s; methyl at C-5), 1.95 (3H, d, J=1.5 Hz; methyl at C-11), 2.42 (1H, d, J=17.8 Hz; proton at C-9β), 2.94 (1H, d, J=17.8 Hz; proton at C-9α), 7.00 (1H, m; proton at C-12); PMR (C_6H_6) (signals other than those described for C_6D_6) δ 2.72 (1H, d, J=7.5 Hz; OH at C-6), 2.93 (1H, s; OH at C-10), 4.41 (1H, d, J=7.5 Hz; proton at C-6); PMR ($CDCl_3$) δ 0.78 (3H, d, J=5.5 Hz; methyl at C-4), 1.22 (3H, s; methyl at C-5), 2.03 (3H, d, J=1.5 Hz; methyl at C-11), 2.53 (1H, d, J=17.8 Hz; proton at C-9β), 3.21 (1H, d, J=17.8 Hz; proton at C-9α), 4.52 (1H, s; proton at C-6), 7.08 (1H, m; proton at C-12); PMR (C_5D_5N) δ 0.75 (3H, d, J=5.5 Hz; methyl at C-4), 1.45 (3H, s; methyl at C-5), 2.11 (3H, d, J=1.5 Hz; methyl at C-11), 2.83 and 3.25 (each 1H, d, J=17.8 Hz; protons at C-9); mass spectrum *m/e* 250 (M$^+$), *m/e* 124 (base peak). Found: C, 72.23; H, 8.65%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%; mol wt 250.3.

Subsequent extraction of the roots with methanol and evaporation of the solvents gave a residue, which was passed through a column of silica gel (200 g). Fractions eluted with light petroleum–ether (5 : 1) gave, on removal of the solvents, a solid, which was sublimed at 60 °C (oil bath temperature) under 0.1 mmHg to afford 10β-hydroxy-6β-methoxyfuranoeremophilane (**3**: 60 mg), mp 82—84 °C; $[\alpha]_D$ +5° (*c* 2.0, EtOH); UV (EtOH) λ_{max} 220 nm (ε 9300); IR (0.005 M solution of CCl_4) 3488, 1634, 1560, 1084 cm^{-1}; PMR (CCl_4) δ 0.70 (3H, d, J=5.5 Hz; methyl at C-4), 1.12 (3H, s; methyl at C-5), 1.99 (3H, d, J=1.5 Hz; methyl at C-11), 2.59 (1H, d, J=17.8 Hz; proton at C-9β), 3.01 (1H, d, J=17.8 Hz; proton at C-9α), 3.28 (3H, s; methoxyl at C-6), 4.05 (1H, s; proton at C-6), 4.30 (1H, s; OH at C-10), 7.02 (1H, m; proton at C-12); PMR ($CDCl_3$) δ 0.73 (3H, d, J=5.5 Hz; methyl at C-4), 1.22 (3H, s; methyl at C-5), 2.07 (3H, d, J=1.5 Hz; methyl at C-11), 2.73 and 3.18, (each, 1H, d, J=17.8 Hz; protons at C-9), 3.39 (3H, s; methoxyl at C-6), 4.19 (1H, s; proton at C-6), 4.99 (1H, s; disappeared on addition of deuterium oxide; OH at C-10), 7.22 (1H, m; proton at C-12); PMR (C_5D_5N) δ 0.66 (3H, d, J=5.5 Hz; methyl at C-4), 1.30 (3H, s; methyl at C-5), 2.06 (3H, d, J=1.5 Hz; methyl at C-11), 2.87 and 3.20 (each, 1H, d, J=17.8 Hz; protons at C-9), 3.27 (3H, s; methoxyl at C-6), 4.25 (1H, s; proton at C-6); mass spectrum *m/e* 264 (M$^+$), *m/e* 138 (base peak). Found: C, 72.57; H, 9.27%. Calcd for $C_{16}H_{24}O_3$: C, 72.69; H, 9.15%; mol wt 264.4.

Acetylation of the Diol (1). A mixture of **1** (33 mg), acetic anhydride (1 ml), and pyridine (1 ml) was allowed to stand overnight at room temperature. After addition of methanol, the solvents were removed to give a residue, which was extracted with ether. The extract was treated as usual and the resulting residue was chromatographed on a column of silica gel (10 g). Elution with light petroleum–ether (10 : 1) gave, on removal of the solvents, 6β-acetoxy-10β-hydroxyfuranoeremophilane (**4**; 35 mg), an oil; IR (CCl_4) 3550, 1736, 1648, 1565, 1370, 1220, 1084, 1030 cm^{-1}; PMR (C_6D_6) δ 0.72 (3H, $\underline{A}_3B$, J=5.5 Hz; methyl at C-4), 1.04 (3H, s; methyl at C-5), 1.50 (3H, s; acetoxyl at C-6), 1.89 (3H, d, J=1.5 Hz;

methyl at C-11), 2.69 (1H, d, J=17.8 Hz; proton at C-9β), 2.99 (1H, d, J=17.8 Hz; proton at C-9α), 3.22 (1H, broad signal; OH at C-10), 6.34 (1H, s; proton at C-6), 6.94 (1H, m; proton at C-12); PMR ($CDCl_3$) δ 0.88 (3H, d, J=5.5 Hz; methyl at C-4), 1.05 (3H, s; methyl at C-5), 1.91 (3H, d, J=1.5 Hz; methyl at C-11), 2.05 (3H, s; acetoxyl at C-6), 2.65 and 3.20 (each, 1H, d, J=17.8 Hz; protons at C-9), 3.21 (1H, s; disappeared on addition of deuterium oxide; OH at C-10), 6.17 (1H, s; proton at C-6), 7.08 (1H, m; proton at C-12); PMR (C_5D_5N) δ 0.95 (3H, broad signal; methyl at C-4), 1.20 (3H, s; methyl at C-5), 1.96 (3H, d, J=1.5 Hz; methyl at C-11), 1.99 (3H, s; acetoxyl at C-6), 2.83 and 3.13 (each, 1H, d, J=17.8 Hz; protons at C-9), 6.46 (1H, proton at C-6); mass spectrum *m/e* 292 (M^+; $C_{17}H_{24}O_4$), *m/e* 124 (base peak).

*Methylation of the Diol (**1**).* (a) To a solution of **1** (30 mg) in methanol (4 ml) a drop of acetic acid was added and the resulting solution was allowed to stand at room temperature for 40 hr. After addition of water, the reaction mixture was extracted with ether. Usual work-up gave a residue which was chromatographed on a column of silica gel (10 g). Fractions eluted with light petroleum-ether (8 : 1) were collected and sublimed at 60 °C under 0.1 mmHg to afford the monomethyl ether (**3**; 20 mg), which was found to be identical (mp, mixed mp, IR, PMR, and $[\alpha]_D$) with an authentic sample of **3**. (b) A mixture of **1** (5 mg), methyl iodide (1 ml), silver oxide (20 mg), and dimethylformamide (2 drops) was heated under reflux for 6 hr. Extraction with ether and removal of the solvents gave a residue, which was purified as described above. A methylated product (2 mg) was found to be identical with the authentic specimen of **3**.

*Oxidation of the Diol (**1**).* To a solution of **1** (100 mg) in pyridine (1 ml), a solution of chromium trioxide (100 mg) in pyridine (5 ml) and water (2 drops) was added and stirred at room temperature for 40 hr. Extraction with ether and subsequent work-up as usual gave a crystal, which was crystallized from a mixture of light petroleum-ether to afford 10β-hydroxy-6-oxofuranoeremophilane (**6**; 50 mg), mp 147.5—148 °C, $[\alpha]_D$ +31° (*c* 1.3, EtOH); UV (EtOH) λ_{max} 268 nm (ε 3700); IR 3500, 1650, 1575, 1065 cm^{-1}; PMR ($CDCl_3$) δ 0.79 (3H, d, J=6 Hz; methyl at C-4), 1.18 (3H, s; methyl at C-5), 2.19 (3H, d, J=1.5 Hz; methyl at C-11), 2.72 and 3.50 (each, 1H, d, J=18 Hz; protons at C-9), 7.10 (1H, m; proton at C-12); mass spectrum *m/e* 248 (M^+; $C_{15}H_{20}O_3$), *m/e* 122 (base peak).

*Dehydration of the Hydroxyketone (**6**).* To a solution of **6** (50 mg) in pyridine (1 ml), phosphorus oxychloride (0.1 ml) was added dropwise with stirring. The reaction mixture was heated at 140 °C (oil bath temperature) for 35 min under an atmosphere of nitrogen. Extraction with ether and subsequent work-up as usual gave a residue, which was subjected to purification by preparative tlc to afford 6-oxofuranoeremophil-9-ene (**7**; 35 mg), mp 109—109.5 °C, $[\alpha]_D$ −410° (*c* 0.3, EtOH); UV (EtOH) λ_{max} 215 nm (ε 18000), 248 (7000), 334 (6700) (with shoulders at 242, 255, and 265 nm); IR 1640, 1610, 1595, 1550, 1080, 780 cm^{-1}; PMR ($CDCl_3$) δ 1.04 (3H, d, J=6 Hz; methyl at C-4), 1.22 (3H, s; methyl at C-5), 2.20 (3H, d, J=1.5 Hz; methyl at C-11), 6.37 (1H, broad s; proton at C-9), 7.01 (1H, m; proton at C-12); mass spectrum *m/e* 230 (M^+; $C_{15}H_{18}O_2$), *m/e* 175 (base peak).

*Hydrogenation of the Ketone (**7**).* The ketone (**7**; 13 mg) in ethyl acetate (5 ml) was hydrogenated in the presence of 10% palladium-charcoal (12 mg) with stirring for 1 hr. After filtration of the catalyst, the solvent was removed to give a residue (two spots on tlc). Separation by preparative tlc afforded ligularone (**5**) as a main product yield *ca.* 80%), mp 63 °C, $[\alpha]_D$ −58° (*c* 0.6, $CHCl_3$); UV (EtOH) λ_{max} 268 nm (ε 3300); IR 1670, 1610, 1565, 1070 cm^{-1}; PMR ($CDCl_3$) δ 0.86 (3H, d, J=7.5 Hz; methyl at C-4), 1.10 (3H, s; methyl at C-5), 2.17 (3H, d, J=1.5 Hz; methyl at C-11), 2.71 (1H, dd, J=17 and 6 Hz; proton at C-9), 2.89 (1H, dd, J=17 and 5.5 Hz; proton at C-9), 7.03 (1H, m; proton at C-12); mass spectrum *m/e* 232 (M^+; $C_{15}H_{20}O_2$), *m/e* 122 (base peak), which was found to be identical with an authentic sample of **5** in all respects. Compound corresponding to a minor spot on tlc was not further examined.

The authors wish to thank Dr. M. Fukuyama and Mr. K. Sato, Sagami Chemical Research Center, Sagamihara-shi, for the measurements of NOE's.

Codimerization of Butadiene and Ethylene Catalyzed by σ-Arylnickel(II) Compound in the Presence of Boron Trifluoride Etherate

Noboru KAWATA, Ken-ichi MARUYA, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received December 10, 1973)

The codimerization of butadiene with ethylene was studied with use of the catalyst system consisting of bis(triphenylphosphine)σ-arylnickel(II) halide and boron trifluoride etherate in methylene dichloride. The codimerization took place readily at 15 °C under 20 kg/cm² to give *trans*- and *cis*-1,4-hexadiene and 3-methyl-1,4-pentadiene. A catalytic amount of water significantly enhanced the catalytic activity. The reaction path to form the codimers is discussed in terms of the variation in product distribution with time and the reaction kinetics.

During the course of studies on the dimerization of ethylene catalyzed by nickel(II) compound, it was found that the bis(triphenylphosphine)σ-arylnickel(II) halide-boron trifluoride etherate system significantly enhances the rate of dimerization to give butene selectively.[1] This catalyst system was found to be less efficient for the dimerization of propylene or its codimerization with ethylene,[2] but highly active for the dimerization of styrene with ethylene.[3] This suggests that it is particularly efficient for the codimerization of ethylene with conjugated olefins. For confirmation the codimerization of ethylene with butadiene was examined, the reaction conditions to give a selective formation of the codimers with high yield being investigated.

A number of homogenous catalyst systems have been reported for the codimerization of butadiene with ethylene. They frequently consist of a transition metal compound and an alkylaluminium compound as a reducing agent.[4~7] The present catalyst system is characterized by the absence of such reducing agent, exhibiting a considerably high activity in the presence of boron trifluoride etherate. Hata and Miyake employed boron trifluoride etherate for the codimerization catalyzed by a zerovalent iron complex $Fe(\phi_2PCH_2CH_2P\phi_2)_2\cdot C_2H_4$,[7] although the catalytic activity was not very high.

Experimental

Materials. Bis(triphenylphosphine)σ-arylnickel(II) halide was prepared according to the methods in the literature.[8,9] The results of elemental analysis of the nickel complex were as follows:

Complex		Calcd.		Found		Ref.
		C(%)	H(%)	C(%)	H(%)

Butadiene was dried by passing through a molecular sieve column at room temperature. 1,4-Hexadiene was dried with anhydrous potassium carbonate and distilled under nitrogen. Cylinder ethylene was used without purification. Methylene dichloride was dried with a molecular sieve and distilled under nitrogen. Boron trifluoride etherate was also purified by distillation under nitrogen.

Procedure. All the operations were carried out under nitrogen atmosphere. Codimerization was performed in a Hasteloi autoclave(100 ml) equipped with a magnetic stirrer. The autoclave was first evacuated and flashed with ethylene, then cooled to −20 °C, at which temperature a methylene dichloride solution of a nickel complex and butadiene, separately prepared and kept at dry ice temperature, was introduced into the autoclave, followed by the addition of boron trifluoride etherate with or without water through a syringe. The autoclave was then warmed up to 15 °C, and ethylene was introduced to initiate codimerization. The pressure was kept constant during the course of reaction by supplying ethylene. Saturated aqueous solution of sodium hydroxide (*ca.* 15 ml) was added to terminate the reaction.

Analysis. The liquid product was separated by distillation at 110 °C into two parts, volatile(below C_8) and non-volatile (above C_{10}). The volatile part was analyzed by gas chromatography(PEG-6000 column), using benzene as an internal standard. The non-volatile part was well extracted with diethyl ether and the weight of extracted material was measured.

Identification. Most products were isolated by fractional distillation and identified by NMR, IR and/or Mass spectroscopy. 1,4-Hexadiene fraction(bp 65—67 °C) consisted of two components whose gas chromatographic retention times corresponded to those of authentic samples of *trans*- and *cis*-1,4-hexadiene. They were further confirmed by IR absorption (1653(C=C), 995 and 913 (vinyl), 967 (*trans* –CH=CH–), and 707 (*cis*–CH=CH–) cm^{-1}), and by NMR (an array of peaks from 6.10 to 4.80 ppm (CH_2=CH– and –CH=CH– 5H), and complex multiplets centered at 2.27 ppm (–CH_2– 2H) and 1.68 ppm (CH_3– 3H). 3-Methyl-1,4-pentadiene was estimated by means of the gas chromatographic retention time and mass spectroscopy, since its amount was too small to be isolated. 2,4-Hexadiene fraction (bp 81.5—82.5 °C) consisted of two components whose gas chromatographic retention times corresponded to those of authentic samples of *trans-trans* and *cis-trans* isomers. NMR spectra of the mixture showed an array of peaks from 6.50 to 4.8 ppm (–CH=CH–CH=CH– 4H) and a doublet centered at 1.65 ppm ($2CH_3$– 6H). IR absorption bands were observed at 1666(w), 1653(w), 987(s), 948(m), 926(m), 820(m), 735 (w), 707(m), and 675(m) cm^{-1}. The C_8-diene fraction (bp 108.6—110 °C) consisted of two major components, although they could not be isolated. Both components had the same molecular weight(110), which was determined by mass spectroscopy connected with gas chromatography. IR absorption bands of the fraction were observed at 1653, 991, and 917 cm^{-1} characterized by 1,4-diene. The NMR showed

that the peak area ratio of aliphatic to olefinic protons was 9/5, which was also in conformity with 1,4-C_8-dienes.

Results

Effect of Water. The codimerization of butadiene and ethylene takes place fairly rapidly at room temperature, but the reproducibility of yield and the selectivity of codimerization is poor. The purer the materials used in the reaction, the greater the decrease in yield. It was found that a catalytic amount of water present in the solution promotes catalytic activity. Such an effect was also found for the codimerization of styrene with ethylene by σ-phenylpalladium(II) complex catalyst.[10]

The effect of water added, when *o*-tolyl-bromo-nickel was used, is shown in Fig. 1. The products obtained were 1,4-hexadiene in *trans*/*cis* ratio 2.0—2.5 and 3-methyl-1,4-pentadiene in a 1/10—1/20 ratio to 1,4-hexadiene. The C_6+C_8 diene yield increases with the amount of water added and reaches a maximum at around 0.83 mmol (molar ratio, H_2O/BF_3OEt_2= 0.1), the higher oligomers monotonically increasing with the amount of water added. Although the C_6+C_8 diene yield depends on the amount of water, the selectivity of C_6-diene to C_6+C_8 dienes and that of 1,4-hexadiene to C_6-dienes is constant (Fig. 1-b). The effect of methanol and phenol instead of water were similarly tested. They also showed a promoting effect but less efficient than water. The effect of water was examined for ethylene dimerization and its codimerization with styrene, using the phenyl-bromo-nickel complex(B) at 0 °C under 1 atm. The results are summarized in Table 1. In both dimerization (Nos. 1 and 2) and codimerization (Nos. 3 and 4), the yield of butene or 3-phenyl-1-butene per min increases about 3 times with the addition of water (H_2O/BF_3OEt_2= 0.4). Formation of small amounts of styrene, phenylbutenes, and 3-methyl-3-phenyl-1-pentene was observed in the dimerization of ethylene, indicating that the ligand in the complex reacted with ethylene.

TABLE 1. DIMERIZATION OF ETHYLENE AND ITS CODIMERIZATION WITH STYRENE

No.	H_2O/BF_3OEt_2	Time (min)	Amounts (mmol) in product				
			Sty.[1]	3-p-1-b[2]	2-p-2-b[3]	3-m-3-p-1-p[4]	C_4'[5]
1	0	30	tr.	0.17	tr.	0.01	1.0
2	0.4	10	tr.	0.14	tr.	0.02	1.0
3	0	30	10.0	2.0	tr.	tr.	tr.
4	0.4	20	5.6	5.1	0.07	0.33	tr.

Phenyl-Ni($P\phi_3$)$_2$Br, 0.5 mmol; BF_3OEt_2, 0.5 mmol; Styrene (No. 3, 4), 17.4 mmol; CH_2Cl_2, 30 ml; 0 °C, 1 atm. 1) styrene, 2) 3-phenyl-1-butene, 3) 2-phenyl-2-butene, 4) 3-methyl-3-phenyl-1-pentene, and 5) butenes.

nickel complex(C) is illustrated in Fig. 2. The yield of C_6+C_8 diene increases linearly with ethylene pressure and reaches a maximum at around 20 kg/cm². The amount of butenes formed also increases, whereas the higher oligomers decrease with ethylene pressure. The higher oligomers obtained at 5 kg/cm² and above 10 kg/cm² were separately hydrogenated with Raney nickel catalyst. The amounts of absorbed hydrogen were 19.2 and 13.0 mmol/g respectively, suggesting that the oligomers formed under low pressure were more unsaturated and involved more butadiene than those under high pressure. The results are reasonable since the increase in ethylene concentration should be more favorable for cooligomerization than homooligomerization of butadiene.

Variation in Product Distribution with Time. In order to study the reaction path, variation in product distribution with time was examined using *o*-tolyl-bromo-nickel complex(C) as a catalyst component. The results are given in Fig. 3, where the amount of butadiene consumed for higher oligomers was estimated to be 40% at 100% conversion of butadiene. The rate of reaction, as given by the rate of increase in the amount of C_6+C_8 diene or 1,4-hexadiene, is rather insensitive to the decrease in butadiene concentration, suggesting a zero order reaction with respect to butadiene while 1,4-hexadiene rapidly disappears after butadiene is mostly consumed, being accompanied by an increase in C_8-dienes, higher oligomer and 2,4-hexadiene. Probably 1,4-hexadiene is first isomerized into its conjugated form 2,4-hexadiene, which, like butadiene, reacts readily with ethylene. The increase in higher oligomers in the later stage would be due to both homodimerization of hexadiene and codimerization of C_8-dienes with ethylene.

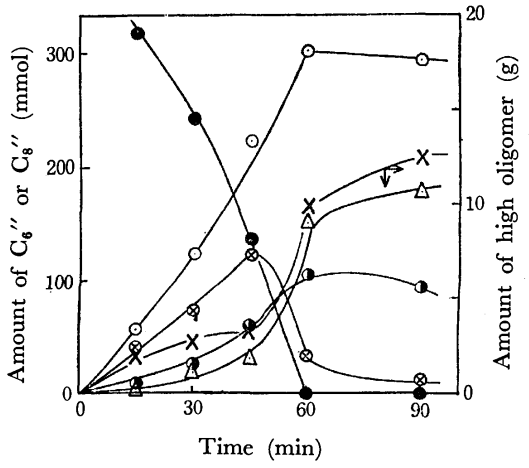

Fig. 3. Products distribution during the codimerization.
Ni-complex(C), 0.5 mmol; BF_3OEt_2, 8 mmol; H_2O, 0.83 mmol; Butadiene, 0.39 mol; C_2H_4, 20 kg/cm²; CH_2Cl_2, 20 ml; 15 °C.
○, $C_6''+C_8''$; ⊗, 1,4-hexadiene; ◑, 2,4-hexadiene; △, C_8''; ●, butadiene(calculated); ×, higher oligomer.

In order to confirm the above interpretation, the codimerization of 1,4-hexadiene with ethylene was examined using the same catalyst. The results are given in Fig. 4. 1,4-Hexadiene is rapidly isomerized

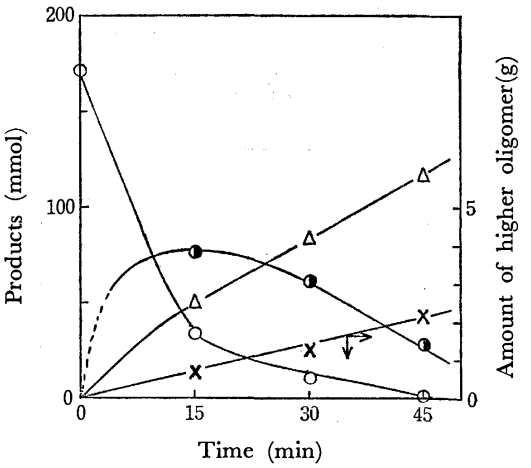

Fig. 4. Products distribution during the codimerization of ethylene with 1,4-hexadiene.
Ni-complex(C), 0.25 mmol; BF_3OEt_2, 4 mmol; H_2O, 0.41 mmol; 1,4-hexadiene(*trans*/*cis*=10), 0.172 mol; C_2H_4, 20 kg/cm²; 15 °C.
○, 1,4-hexadiene; ◑, 2,4-hexadiene; △, C_8''; ×, higher oligomer.

to 2,4-hexadiene, followed by the reaction with ethylene to give 1,4-C_8-dienes. Thus the reaction path might be deduced to be as follows:

$$C_4H_6 + C_2H_4 \longrightarrow CH_2{=}CH{-}CH_2{-}CH{=}CH{-}CH_3 \longrightarrow$$

$$CH_3{-}CH{=}CH{-}CH{=}CH{-}CH_3 \xrightarrow{C_2H_4}$$

$$CH_2{=}CH{-}\underset{\displaystyle CH_3}{\underset{|}{C}}H{-}CH{=}CH{-}CH_2{-}CH_3 \text{ and}$$

$$CH_2{=}CH{-}\underset{\displaystyle CH_2{-}CH_3}{\underset{|}{C}}H{-}CH{=}CH{-}CH_3$$

Effect of BF_3OEt_2 Concentration. The codimerization was carried out by varying the amount of BF_3OEt_2 using *o*-tolyl-bromo-nickel complex(C), the amount of the complex(0.5 mmol) and the molar ratio H_2O/BF_3OEt_2 being fixed. The rate of reaction can

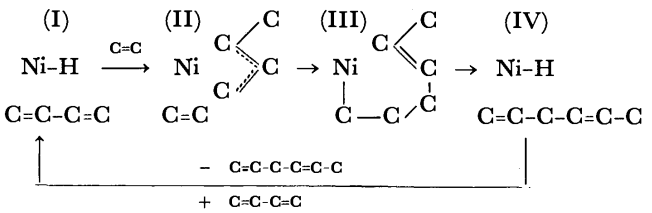
Ni-Complex, 0.5 mmol; BF_3OEt_2, 8 mmol; H_2O, 0.83 mmol; butadiene, 0.39 mol; CH_2Cl_2, 20 ml; C_2H_4, 20 kg/cm^2; 15 °C; 30 min. a) 3-methyl-1,4-pentadiene, b) 1,4-hexadiene, c) 2,4-hexadiene, d) C_8-diene, and e) higher oligomers.

be estimated from the amount of C_6+C_8 dienes or higher oligomers formed in 15 min. (Fig. 5). It appears that the reaction rate obeys approximately the second order kinetics with respect to BF_3OEt_2, as in the codimerization of styrene with ethylene by the same catalyst system.

Effect of Ligands. Seven complexes with different ligands were prepared and tested for the effect of ligand on the selectivity and activity in codimerization. The results are summarized in Table 2. The difference in the selectivity of C_6-dienes or 1,4-hexadiene seems too small to estimate a ligand effect. The catalytic activity, as given by the yield of C_6-dienes or C_6+C_8 dienes, is affected by the σ-aryl ligand (Nos. 1—4), but to a smaller extent by the halide or phosphine ligand (Nos. 2, 5, 6, and 7), *viz.* the activity decreases in the order, mesityl>*o*-tolyl>phenyl>naphthyl.

Discussion

Reaction Path for Butadiene and Ethylene Codimerization. It was postulated that the active species of the present catalyst system is a nickel hydride complex formed from dissociative addition of olefin to σ-arylnickel(II) compound, with the σ-aryl ligand remaining on the nickel atom during the course of catalytic reaction.[2] The formation of 1,4-hexadiene can also be understood in terms of the nickel hydride intermediate as follows. Butadiene reacts with the nickel hydride(I) to give 1-methyl-π-allyl nickel(II), followed by an insertion of ethylene to form 4-hexenyl nickel(III) and elimination of β-hydrogen to give 1,4-hexadiene.



In this scheme, 1,4-hexadiene should be readily replaced by butadiene, since the codimerization rate is of nearly zero order in butadiene concentration. This would be reasonable if the conjugated diene preferentially occupies the coordination site of the nickel. An abrupt change in the distribution of 1,4-hexadiene and C_8-dienes was observed when butadiene is mostly consumed (Fig. 3). Although the isomerization of 1,4-hexadiene to 2,4-hexadiene is very fast in the absence of butadiene (Fig. 4), the formation of 2,4-hexadiene during the butadiene and ethylene codimerization was not so high in spite of very high concentration of 1,4-hexadiene. This suggests that the isomerization of 1,4-hexadiene is greatly retarded by the presence of butadiene. The nickel hydride is likely to be utilized for the isomerization. Thus after the consumption of butadiene, the nickel hydride becomes available for isomerization, resulting in the rapid decrease in 1,4-hexadiene. Since 2,4-hexadiene thus formed is conjugated, it is readily attacked by ethylene to give the C_8-dienes, resulting in the rapid increase in their amounts. In this way the variation in product distribution with time is explained in terms of preferential occupation of coordination site by conjugated dienes.

Telomerization of Ethylene with Chloroform Initiated by *N*-Chloroalkylamines

Teruzo ASAHARA, Manabu SENŌ, and Noritaka OHTANI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received February 15, 1974)

N-Chloroalkylamines initiate the telomerization of ethylene with chloroform to give α,α,α-trichloroalkanes $CCl_3(C_2H_4)_nH$(I), which are the same products as those obtained by peroxide-initiated reactions. The *N*-chloroalkylamine-iron and *N*-chloroalkylamine-ferrous chloride systems also initiate the reaction of ethylene with chloroform to afford α,α,ω-trichloroalkanes $CHCl_2(C_2H_4)_nCl$ (II) as the main product, and a small amount of I along with other telomers. The rate of the reaction and the composition of the products vary widely with the kind of *N*-chloroalkylamine. The reaction mechanism was discussed, a "caged radical" mechanism being proposed for the *N*-chloroalkylamine-ferrous chloride system.

A number of reports have appeared on the radical telomerization of olefins with polyhaloalkanes. Various initiators have been examined in these reactions. Some redox systems such as copper chloride–amine[1] or iron chloride–triethyl phosphite[2] gave the 1 : 1 adduct as the main product. It was found that *N*-chloroalkylamine and *N*-chloroalkylamine–metallic salt also initiate the reactions of ethylene with carbon tetrachloride to afford the 1 : 1 adduct and telomers with low molecular weights. A coordinated radical or a caged radical reaction process was suggested in addition to the free radical reaction process.[3]

A "free" radical is considered to abstract the hydrogen atom of chloroform.[4] The reactions of ethylene with chloroform initiated by peroxides give α,α,α-trichloroalkanes instead of α,α,ω-trichloroalkanes. The results prompted us to examine the reaction of ethylene with chloroform using *N*-chloroalkylamines as initiators in order to clarify the reaction mechanism.

Experimental

Materials. Ethylene (purity 99.8%) was used without further purification. Commercial chloroform was purified through an activated alumina column, the purity being examined by gas chromatography. *N*-Chloroalkylamines were prepared and purified as described previously.[3]

Reactions of Ethylene with Chloroform. The reaction was carried out in a 200 ml stainless steel autoclave with a magnetic stirrer. Chloroform and initiators were placed in the autoclave and air was replaced several times by ethylene. After ethylene was charged to a definite pressure, the autoclave was heated up to a prescribed temperature. After the reaction, the autoclave was cooled to room temperature and the reaction mixture was washed by an aqueous potassium iodide solution and then an aqueous sodium thiosulfate solution.

Analyses of the Products. The reaction products were analysed by a temperature programmed gas chromatograph using a 2 m column of Silicone DC 550 at 40—200 °C. *n*-Hexane was used as an internal standard. The authentic samples were prepared by the following methods. α,α,α-Trichloroalkanes, $CCl_3(C_2H_4)_nH$ (I) (n=1,2,3), α,α,ω-trichloroalkanes, $CHCl_2(C_2H_4)_nCl$ (II) (n=1,2) and α,α,α,ω-tetrachloroalkanes, $CCl_3(C_2H_4)_nCl$ (IV) (n=1,2) were prepared by the telomerization of ethylene with chloroform initiated by di-*t*-butylperoxide (DTBP), by that of ethylene with chloroform initiated by the iron chloride–hexamethylphosphoric triamide (HMPA) system[5] and by that of ethylene with carbon tetrachloride initiated by DTBP, respectively. The products were fractionally distilled several times and the purity was confirmed by glc. α,α-Dichloroalkanes, $CHCl_2(C_2H_4)_nH$ (III) (n=1,2) and γ,γ-dichloroalkanes, $HC_2H_4CCl_2(C_2H_4)_nH$ (VII) (n=1,2) were prepared by the reaction of the corresponding aldehydes or ketones with phosphorus pentachloride and purified by distillation. For quantitative analyses of α,γ,γ-trichloroalkanes $ClC_2H_4CCl_2(C_2H_4)_nH$ (V) (n=1,2) and α,γ,γ,ω-tetrachloroalkanes $ClC_2H_4CCl_2(C_2H_4)_nCl$ (VI) (n=1), type I and IV telomers with the same molecular weight as that of V and VI, respectively, were used.

Results and Discussion

The reaction products can be classified according to their structures into the following seven telomers; $CCl_3(C_2H_4)_nH$ (I), $CHCl_2(C_2H_4)_nCl$ (II), $CHCl_2(C_2H_4)_nH$ (III), $CCl_3(C_2H_4)_nCl$ (IV), $ClC_2H_4CCl_2(C_2H_4)_nH$ (V), $ClC_2H_4CCl_2(C_2H_4)_nCl$ (VI), and $H(C_2H_4)_mCCl_2(C_2H_4)_nH$ (VII). Telomers I and IV, having a trichloromethyl group, can act again as a telogen, giving telomers V, VI, and VII.

In the telomerization of ethylene with chloroform, *N*-chloroalkylamines possibly play three roles:

(i) *N*-chloroalkylamines act as initiators, *viz.*, they decompose thermally[6] or under the action of metal[7] to yield amino radicals:

$$RNXCl \xrightarrow{\Delta} R\dot{N}X + Cl\cdot \quad (1)$$

$$2RNXCl + Fe \longrightarrow 2R\dot{N}X + FeCl_2 \quad (2)$$

X=H, Cl, or alkyl; R=alkyl

(ii) *N*-chloroalkylamines have a large chain transfer constant and can act as chain transfer reagents.

$$R\cdot + RNXCl \longrightarrow RCl + R\dot{N}X \quad (3)$$

(iii) Though the basicity of *N*-chloroalkylamines is not so large as that of amines, they can coordinate metal ions at nitrogen and/or chlorine atoms and affect the reactivity of metal ions with chloroform.

$$Fe^{2+} + kRNXCl \rightleftharpoons Fe(RNXCl)_k^{2+} \quad (4)$$

Iron–*N*-chloroalkylamine complex is likely a mixture of complexes with a different value of k, the value of k increasing with the concentration of *N*-chloroalkylamine.

In the absence of metal or metallic salt, the main products were telomers I (Table I), irrespective of the kind of *N*-chloroalkylamines. This suggests that *N*-chloroamine yields the free radical which initiates the reaction. The initiating radical is probably amino

radical in Eq. 1 and/or aminium radical in the following reaction.[3]

$$RNXCl \longrightarrow R'CH{=}NX + HCl \quad (5)$$

$$RNXCl + HCl \longrightarrow R\overset{+}{N}HXCl\ Cl^- \longrightarrow R\overset{+\cdot}{N}HX\ Cl^- + Cl\cdot \quad (6)$$

The order of reactivity of *N*-chloroalkylamines is the same as that in the reaction with carbon tetrachloride;[3] *N*-chlorodibutylamine (CDBA)> *N*-chloromonobutylamine (CMBA)> *N*,*N*-dichlorobutylamine (DCBA). Among the products, a small amount of IV and a smaller amount of III were found. It is likely that α,α,α-trichloroalkyl radical abstracts chlorine atom not from chloroform but from *N*-chloroamine (Eq. 3), since the amount of IV is larger than that of III. The products of the reactions initiated by DTBP under the same conditions contain scarcely any IV and only 1% of III. Two explanations can be given for the formation of III. The amino radical abstracts chlorine atom from chloroform at 130 °C; *N*-chloroamine dissolves iron out of the surface of the autoclave and the stainless steel stirrer, especially in the case of DCBA leading to the formation of metallic salts which take part in the reaction.

In the presence of ferrous chloride (Table 1), the yield and composition of the products varied widely depending on the amount of ferrous chloride and the kind of *N*-chloroalkylamine. Addition of ferrous chloride to CDBA lowered the yield of telomers when the relative concentration of $FeCl_2$ to CDBA was below 25%. Above 25%, however, the reactivity of this initiating system increases remarkably. A similar tendency was observed in the case of DCBA. This indicates that the decomposition of *N*-chloroalkylamines into free radicals (Eqs. 1 and 6) is suppressed by the addition of ferrous chloride and that another radical formation process exists. The suppression of free radical formation can be attributed to the consumption of the *N*-chloroamine to form the iron–*N*-chloroalkylamine complex (Eq. 4). The formation of the complex is confirmed by the following investigation. An equimolar mixture of CDBA and ferrous chloride in methanol has a new broad absorption band at 320 nm at room temperature. This band is different from that of CDBA (275 nm) and ferric chloride (360 nm) and resembles that of ferrous chloride–dibutylamine complex (about 315 nm). The intensity of absorption increases with an increase in the relative concentration of CDBA and decreases gradually with an increase in the absorption of ferric chloride. The complex reacts probably with chloroform to generate dichloromethyl radicals like the copper chloride–amine complexes.[1] If the dichloromethyl radicals thus formed are free radicals, the reaction products would not be II but I, as revealed in the system of ferrous chloride alone. Thus we might suppose that *N*-chloroalkylamine coordinates iron ion to form a cage around the ion and the dichloromethyl radical formed is trapped within the cage (Eq. 7). When dichloromethyl radicals leave the cage, they react with ethylene and then chloroform to yield III and free trichloromethyl radicals (Eq. 10), which afford I by a chain reaction (Eqs. 12 and 13). When dichloromethyl radicals react with ethylene in the cage, the chain transfer reaction with ferric chloride immediately occurs to afford $n=1$ telomers of II (Eq. 8).

$$\underset{X_0}{Fe(RNXCl)_k^{2+}} + CHCl_3 \rightleftharpoons \underset{X}{[Fe(RNXCl)_kCl^{2+}\cdot CHCl_2]_{cage}} \quad (7)$$

Table 1. Telomerization of ethylene with chloroform using ferrous chloride–*N*-chloroalkylamine system[a]

a) Telomerization conditions: initial ethylene pressure, 20 Kg/cm² at 30 °C; chloroform, 1 mol; reaction temperature, 130 °C. b) The telomers except for those contained in Experimental were ignored since their amounts were very small in all runs.

$$[X+C_2H_4]_{cage} \longrightarrow X_0 + CHCl_2C_2H_4Cl \quad (8)$$

$$X \longrightarrow \underset{X_1}{Fe(RNXCl)_kCl^{2+}} + \cdot CHCl_2 \quad (9)$$

$$\cdot CHCl_2 \xrightarrow[CHCl_3]{nC_2H_4} III + \cdot CCl_3 \quad (10)$$

$$\cdot CCl_3 \xrightarrow[CHCl_3]{nC_2H_4} I + \cdot CCl_3 \quad (11)$$

$$CCl_3(C_2H_4)_n\cdot + X_1 \longrightarrow IV + X_0 \quad (12)$$

$$CCl_3(C_2H_4)_n\cdot + RNXCl \longrightarrow IV + R\dot{N}X \quad (13)$$

Figure 1 shows the telomer distribution of I and II. Although a considerable amount of $n \geq 2$ telomers was formed for type I, the $n=1$ telomer was selectively formed for type II. This indicates that the formation of II proceeds by a different mechanism from the free radical mechanism (Eqs. 14—16) and supports the above consideration.[8] The kind of *N*-chloroalkylamines would have some effect on the activation of ferrous ion in Eq. 7, on the stability of the cage (Eqs. 8 and 9), and on the reactivity of X_1 in Eq. 12.

$$FeL_k^{2+} + CHCl_3 \longrightarrow FeL_kCl^{2+} + \cdot CHCl_2 \quad (14)$$

$$\cdot CHCl_2 + nC_2H_4 \longrightarrow CHCl_2(C_2H_4)_n\cdot \quad (15)$$

$$CHCl_2(C_2H_4)_n\cdot + FeL_kCl^{2+} \longrightarrow CHCl_2(C_2H_4)_nCl + FeL_k^{2+} \quad (16)$$

L = ligand

Figures 2 and 3 show the dependence of the telomer composition on the concentration of CDBA, when the molar ratio of [CDBA]/[$FeCl_2 \cdot 4H_2O$] is 1 and 2, respectively. In both cases, the telomer composition hardly changes at low concentrations but the ratio of II becomes high at high concentrations. The increase of II at higher concentrations seems to be due to the low solubility of the ferrous chloride–CDBA complex in chloroform. The reaction of Eq. 8 becomes dominant over the reaction of Eq. 9, since it appears on the solid complex.

The results of telomerization using the *N*-chloroalkylamine–iron system are given in Table 2. As the amounts of iron increase, the rate of telomerization reaction and the product ratio of II increase, irrespective of *N*-chloroalkylamines used. In these systems, it is expected that the reaction of *N*-chloroamine with iron takes place first (Eq. 2). The amino radical then initiates the telomerization according to Eqs. 17 and 11. The ferrous chloride produced by Eq. 2 forms the complex (X_0) with *N*-chloroamine and also induces the telomerization (Eqs. 7—13). In the case of CDBA, the ratio of II

$$R\dot{N}X \xrightarrow[CHCl_3]{nC_2H_4} RNX(C_2H_4)_nH + \cdot CCl_3 \quad (17)$$

was not so large as that in the binary system of CDBA and ferrous chloride. This suggests that the free radical processes are not so feasible and supports the above explanation. However, in the cases of CMBA and CDBA, the ratio of II was larger than that in the binary system of *N*-chloroamine and ferrous chloride. The results can not be explained on the assumption that amino radicals abstract chlorine atom from chloroform. Since these reaction systems are heterogeneous,

we can presume that the reaction proceeds mainly on the surface of solid complexes or the iron particles making the chlorine abstraction by generated radicals easier. The surface of iron particles activated by *N*-chloroamines reacts presumably with chloroform to generate dichloromethyl radicals.[9]

The authors express their appreciation to Mr. T. Suzuki and Mr. H. Nojiri for assistance in the experiments.

A Polarographic Study of the Rates of the Dissociation Reactions of Aminopolycarboxylato-zinc(II), -lead(II), and -cadmium(II) Complexes

Mutsuo KODAMA[1], Kyoko NAMEKAWA,* and Takashi HORIUCHI*

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036

**Department of Chemistry, Ibaraki University, Bunkyo, Mito 310*

(Received March 22, 1973)

The rates and the mechanisms of the dissociation reactions of aminopolycarboxylato zinc(II), lead(II), and cadmium(II) complexes were studied by analyzing their kinetic waves by conventional DC polarography. The dissociations of the zinc(II)–HIDA and –NTA complexes and the cadmium(II)– and lead(II)–HIDA complexes in an acetate buffer solution, and those of protonated lead(II)–EDTA and –EDTA–OH complexes were found to proceed through the following direct dissociation mechanisms:

i) HIDA and NTA systems

$MX_2^{2-2m} \rightleftharpoons MX^{2-m} + X^{m-}$ in a rapid equil.

$MX^{2-m} \rightleftharpoons M^{2+} + X^{m-}$ r.d.s.

ii) EDTA and EDTA-OH systems

$MHY^{3-n} \rightleftharpoons M^{2+} + HY^{1-n}$ r.d.s.

On the other hand, the dissociation of the zinc(II)–EDTA-OH and its protonated DTPA complexes gave this rate law: $-d[MH_iY^{2+i-m}]/dt$ $(i=0$ or $1)=k_d^H\cdot[H^+]\cdot[MH_iY^{2+i-m}]$. From a comparison of the observed rate constants, the zinc(II)–HIDA and –NTA, lead(II)– and cadmium(II)–HIDA and protonated lead(II)–EDTA and –EDTA-OH complexes are concluded to dissociate through a simple glycinate reaction intermediate, and the zinc(II)–EDTA-OH and its protonated DTPA complexes, through a glycinate reaction intermediate which includes polyfurcated hydrogen bonds.

The dissociation reactions of metal complexes have been studied by analyzing the kinetic waves by conventional polarography.[2~7] Previously,[8~10] we also studied the dissociation reactions of aminopolycarboxylato nickel(II) and cobalt(II) complexes in alkaline solutions by DC polarography. In this paper, the dissociation reactions of aminopolycarboxylato zinc(II), cadmium(II), and lead(II) complexes will be studied by DC polarography. The structure of the reaction intermediate and the reaction mechanism will be discussed in detail on the basis of a comparison of the observed rate constant with that calculated from the reaction intermediate proposed.

Experimental

Reagents. Our previous paper[11] explained the preparation of standard zinc(II) and cadmium(II) solutions. The standard lead(II) solution was prepared by dissolving a known amount of pure lead(II) nitrate in redistilled water. EDTA, NTA, *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid (EDTA-OH), 2,2′-ethylenedioxydi(ethylamine)-*N*,*N*,*N*′,*N*′-tetraacetic acid (GEDTA), and diethylenetriaminepentaacetic acid (DTPA) were recrystallized from their aqueous solutions. *N*-(2-hydroxyethyl)iminodiacetic acid (HIDA) was synthesized from ethanolamine and monochloroacetic acid and recrystallized from its aqueous solution three times by adding pure hydrochloric acid, ethanol, and acetone. All the other chemicals were of analytical-reagent grades and were used without further purification.

Apparatus and Experimental Procedures. All the DC current-voltage curves were measured with a manual polarograph similar to Kolthoff and Lingane's or with a Yanagimoto pen-recording polarograph PA-102. The characteristic features of the DME used were described in a previous paper.[8] All the other apparatuses and the experimental procedures were the same as those in that previous paper. In the HIDA, NTA, and GEDTA systems, an acetate buffer was used. For the EDTA, DTPA, and EDTA-OH systems, no buffer reagent was used, because the sample solutions contained a large excess of uncomplexed EDTA, EDTA-OH, or DTPA and had a sufficient buffer capacity in their pH ranges ($2.50<$ pH <3.50 in the EDTA-OH system, $2.00<$pH<3.00 in the EDTA system, and $2.40<$pH<3.00 in the DTPA system).

Results and Discussion

Reaction Rates and Mechanism. In an acetate buffer solution, zinc(II)–, cadmium(II)–, and lead(II)–HIDA complexes gave two step waves. The first waves were found to be kinetic waves due to the reduction of the aquo metal(II) ion and acetate complexes formed upon the slow dissociation of the metal(II) complexes, whereas the second waves, diffusion waves, were found to be the direct reduction of the metal(II) complexes. The zinc–(II)NTA complex also gave a kinetic wave due to its dissociation at the electrode surface. As was discussed in connection with the polarography of the aminopolycarboxylato cobalt (II) complexes,[10] the reaction mechanism and dissociation rates were determined from the i_k and i_d values using the treatment employed by Koryta.[4] Under the present experimental conditions, the Koryta equation for the kinetic waves of HIDA and NTA complexes could be formulated as:

$$\frac{i_k}{i_d-i_k}=0.886\cdot\sqrt{\frac{k_d\cdot t\cdot(\alpha_H)_X\cdot\beta_{Ac}}{K_{MX}\cdot[X]_f}}\,\frac{1}{1+\dfrac{K_2\cdot[X]_f}{(\alpha_H)_X}} \qquad (2)$$

corresponding to the (I) reaction mechanism:

(I)
- $MX_2^{2-2m} \rightleftharpoons MX^{2-m} + X^{m-}$ in a rapid equil.
- $MX^{2-m} \overset{k_d}{\rightleftharpoons} M^{2+} + X^{m-}$ (direct dissociation) (I_b) r.d.s.
- $M^{2+} + iAc^- \rightleftharpoons MAc_i^{2-i}$ (I_c) in a rapid equil.

$\underbrace{\qquad\qquad}_{Hg\downarrow 2e}$

M(Hg)

The β_{Ac} in Equation (1) is defined as $\beta_{Ac}=1+K_1^{Ac}\cdot[Ac^-]+K_1^{Ac}\cdot K_2^{Ac}\cdot[Ac^-]^2+\cdots$, and $(\alpha_H)_X$, $[X]_f$, $[Ac^-]$, K_{MX}, K_2, and K_1^{Ac} are, respectively, the (α_H) value of HIDA or NTA, the concentration of uncomplexed HIDA or NTA, the concentration of the free acetate ion, the second successive formation constant of the HIDA or NTA complex, and the i-th successive formation constant of the metal(II)-acetate complex.

From the slope of the linear relation between $i_k/(i_d-i_k)$ and $(\alpha_H)_X^{1/2}/(1+K_2'\cdot[X]_f)$ or $1/[X]_f^{1/2}\cdot(1+K_2'\cdot[X]_f)$, the k_d values were determined; they are listed in Tables 1, 2, and 3. The typical linear relations obtained are shown in Fig. 1. The lead(II)-EDTA-OH and -EDTA complexes in the pH range from 2.00 to 3.50 and the lead(II)-GEDTA complex in the pH range from 4.50 to 5.60 also gave kinetic waves due to their dissociations at the electrode surface. In the case of the EDTA-OH complex, we obtained a linear relation

with an intercept of a finite value by plotting $((i_d-i_k)/i_k)\cdot(\alpha_H)_Y^{1/2}/[H^+]^{1/2}$ against the reciprocal of the hydrogen-ion concentration, $[H^+]^{-1}$ (at a given uncomplexed EDTA-OH concentration) (Fig. 2). This means that, under the present experimental conditions, the Koryta equation for the kinetic wave of the lead(II)-EDTA-OH complex may be expressed as:

$$\frac{i_k}{i_d-i_k}=0.886\cdot\sqrt{\frac{k_d\cdot t\cdot(\alpha_H)_Y}{K_{PbY}\cdot K^H\cdot[H^+]\cdot[Y]_f}}\,\frac{K^H\cdot[H^+]}{1+K^H\cdot[H^+]} \quad (2)$$

corresponding to the (II) reaction mechanism:

Therefore, the ratio between the intercept and the slope of the above linear relation should correspond to the protonation constant of the lead(II)-EDTA-OH complex, K^H. From the above linear relation, the K^H value was determined to be 1.8×10^3. Although the formation of the protonated lead(II)-EDTA-OH complex has not yet been reported, if the pH dependence of the i_k value can be interpreted as due to the dissociation of the protonated lead(II)-EDTA-OH complex, the plot of the $i_k/(i_d-i_k)$ value against the $K^H\cdot[Y]_f^{-1/2}$ value (at a given $[Y]_f$) or the $[Y]_f^{-1/2}$ (at a given pH) should yield a straight line passing through the point of origin. These relations were examined successfully by using some typical experimental data (Fig. 3). The k_d value obtained from the slope of the above straight line is also listed in Table 3. In the GEDTA system, the straight line passing through the point of origin could be obtained by plotting $i_k/(i_d-i_k)$ against $K^H\cdot[H^+]\cdot(\alpha_H)_Y^{1/2}/(1+K^H\cdot[H^+])\cdot[H^+]^{1/2}$, $[Y]_f^{-1/2}$ or $\beta_{Ae}^{1/2}$, suggesting a reaction mechanism in which (II_b) is the slowest step. Therefore, the k_d value for the dissociation of the protonated lead(II)-GEDTA complex was determined from the slope of the above linear relation; it is listed in Table 3. In the case of the EDTA system, the plot of the $i_k^2\cdot[H^+]\cdot[(1+K^H\cdot[H^+])^2/(i_d-i_k)^2\cdot(\alpha_H)_Y\cdot(K^H\cdot[H^+])^2$ against $[H^+]$ gave a straight line with an intercept of a finite value. Furthermore, at a given pH, the plot of the $(i_k-(i_d-i_k))^2$ value against the $[Y]_f^{-1}$ value yielded a straight line passing through the point of origin. These facts evidently imply that the $i_k/(i_d-i_k)$ ratio is given by Eq. (3); hence, the dissociation of the protonated lead(II)-EDTA complex proceeds through (III_b) and (II_b):

$$\frac{i_k}{i_d-i_k}=0.886\cdot\sqrt{\frac{(k_d+k_d^H[H^+])\cdot t\cdot(\alpha_H)_Y}{K_{PbY}\cdot K^H\cdot[Y]_f\cdot[H^+]}}\;\frac{K^H\cdot[H^+]}{1+K^H\cdot[H^+]} \quad (3)$$

$$PbHY^{3-m}+H^+\overset{k_d^H}{\rightleftharpoons}Pb^{2+}+H_2Y^{2-m}$$ (proton-assisted dissociation) (III_b) r.d.s.

The k_d and k_d^H values were determined from the intercept and the slope of the linear relation between $i_k^2\cdot(1+K^H\cdot[H^+])^2/(i_d-i_k)^2\cdot(\alpha_H)_Y\cdot K^{H^2}\cdot[H^+]$ and $[H^+]$ (Table 3). Although the results are not shown here, the effects of the solution pH and the uncomplexed ligand concentration on the half-wave potential of kinetic waves of the lead(II) and cadmium(II) complexes were also examined. The shifts of the half-wave potential, as calculated on the basis of the proposed reaction mechanism, agreed well with those observed.

The zinc(II)-EDTA-OH and -DTPA complexes in an acid solution also produced kinetic waves due to their dissociations at the electrode surface. From the systematic examination of the nature of the kinetic waves, the $i_k/(i_d-i_k)$ ratios for the EDTA-OH and DTPA systems were found to be 0.886 $(k_d^H\cdot t\cdot[H^+]\cdot(\alpha_H)_Y/K_{ZnY}\cdot[Y]_f]^{1/2}$ and 0.886 $[k_d^H\cdot t\cdot(\alpha_H)_Y/K_{ZnY}\cdot[Y]_f]^{1/2}$ respectively. In considering the fact that all the zinc(II)-DTPA complex exists in the form of $ZnHY^{2-}$ under the present experimental conditions, the above fact suggests that the dissociation reactions of the zinc(II)-EDTA-OH and -DTPA complexes are given by (IVa) and (IVb) respectively:

$$ZnY^-+H^+\overset{k_d^H}{\rightleftharpoons}Zn^{2+}+HY^{2-}$$ (proton-assisted dissociation) (IV_a)

$$ZnHY^{2-}+H^+\overset{k_d^H}{\rightleftharpoons}Zn^{2+}+H_2Y^{3-}$$ (proton-assisted dissociation) (IV_b)

The k_d^H values for the zinc(II)-EDTA-OH and -DTPA systems were determined from the slope of the linear relation between $i_k/(i_d-i_k)$ and $[Y]_f^{-1/2}$ or that between $i_k/(i_d-i_k)$ and $(\alpha_H)_Y^{1/2}\cdot[H^+]^{1/2}$ (EDTA-OH system) or $(\alpha_H)_Y^{1/2}$ (DTPA system). They are listed in Table 4, together with the reported rate constants and EDTA and NTA systems.[12,13]

Direct Dissociation. As has been stated above, metal(II)-HIDA and -NTA and protonated lead(II)-EDTA, -EDTA-OH, and -GEDTA complexes dissociate through the direct dissociation mechanism. As was discussed in connection with the dissociation reactions of nickel(II)-glutamate and -IDA complexes,[8] it is hard to believe that, in the dissociation of the cadmium(II)-aminopolycarboxylate complexes, all the bond breakages are involved in the rate-determining step. Day and Reilley, in their NMR study of metal-aminopolycarboxylate complexes,[14] mentioned that the breakage process of the cadmium(II)-nitrogen bond is much more sluggish than that of the cadmium(II) to the oxygen bond. Therefore, the dissociations of the cadmium(II)-HIDA and -NTA[4] complexes should proceed through a reaction intermediate in which the leaving HIDA or NTA anion is bonded to the cadmium(II) ion through the glycinate or iminodiacetate chelate ring (glycinate or IDA mechanism). If both complexes dissociate through the glycinate reaction intermediate (Fig. 4), the rate constant ratio between HIDA and NTA systems, $(k_d)_{HIDA}/(k_d)_{NTA}$, must be given by $(K_{CdX})_{NTA}\times2\times3.16/(K_{CdX})_{HIDA}\times3\times10=10$,[1.96] because the dissociation rate constant, k_d, is given by the well-known relation: $k_d=k_{rds}\cdot k_{inter}\cdot K_{st}\cdot K_{elec}/K_{MX}$.[8] Here, the symbols used have their usual meanings, while $(K_{CdX})_{NTA}$ and $(K_{CdX})_{HIDA}$ are the formation constants of 1 : 1 ratio cadmium(II)-NTA and -HIDA complexes. On the other hand, if the IDA mechanism is operative here, the rate-constant ratio between the two systems should be 10.[2,11] The observed ratio of $10^{1.90}$ evidently excludes the IDA mechanism. The rate-constant ratio calculated on the basis of the other reaction intermediates showed no satisfactory agreement with the observed one. As is clear from the dissociation rate constants for the zinc(II)-acetate[15] and -ammine complexes,[16] the zinc(II)-nitrogen bond has a life span longer than that of the zinc(II)-oxygen bond. Therefore, the zinc(II)-aminopolycarboxylate complex seems to dissociate through a glycinate or IDA reaction intermediate produced by the partial dissociation of the original complex. Ogino[17] suggested a water-loss mechanism for the formation of the zinc(II)-aminopolycarboxylate complex from the aquo zinc(II) ion and the aminopolycarboxylate anion. If the formation reaction of the zinc(II)-glycinate complex also has a water-loss mechanism, the dissociation rate constant of the zinc(II)-glycinate complex with a 1 : 1 ratio can be calculated by using the formation rate constant: $k_f=k_{Zn}^{H_2O}\cdot K_{os}$ and the K_{ZnX} value for the zinc(II)-glycinate complex. By using the $k_{Zn}^{H_2O}$ value of 5×10^7,[13] the K_{os} value of 5, and the K_{ZnX} value of 7×10^4,[18] the k_d value for the zinc(II)-glycinate complex was calculated to be 3.6×10^3 s^{-1}. Here, the zinc(II)-*N*-methyl-glycinate complex was employed as a model. By using the k_d value thus estimated as k_{rds}, the dissociation rate constant of the zinc(II)-NTA complex was calculated to be 0.1 on the basis of the glycinate dissociation mechanism. This value showed a satisfactory agreement with the observed k_d value (Table 1). None of the rate constants calculated on the basis of other reaction intermediates showed a satisfactory agreement with the observed one. The relative rate constant of the zinc(II)-HIDA system, calculated on the basis of the glycinate mechanism, is listed in Table 1 and compared with the observed one. The agreement between the observed and calculated rate constants can be regarded as satisfactory, lending strong support to the glycinate-mechanism explanation.

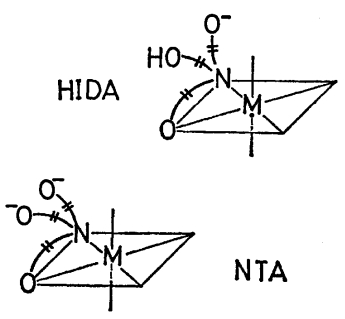

Fig. 4. Reaction intermediates for the direct dissociations of metal(II)-HIDA and -NTA complexes.

Rabenstein,[13] in his NMR study of the reaction of the lead(II)-NTA complex, reported several features

which support the conclusion that the lead(II)–NTA reaction also has a mechanism similar to those of the cadmium(II)- and zinc(II)–NTA reactions. Therefore it is natural to assume the glycinate mechanism for the dissociation of the lead(II)–aminopolycarboxylate complexes. As is shown by the data in Table 3, the relative dissociation rate constants evaluated on the basis of the glycinate mechanism agreed well with those observed. The dissociation rate constants of the protonated lead(II)–EDTA, –EDTA-OH, and –GEDTA complexes can also be understood in terms of the glycinate mechanism (Table 3). As is shown by the data in Table 3, the formation constant of the protonated complex evaluated from the K_{MY}, K^H, and pK_a values is always smaller than that of the corresponding normal complex, K_{MY}. This may mean that the formation of the protonated complex is always accompanied by the partial dissociation of the metal(II) ligand bonds in the original complex.[19] This would explain the dissociation of the protonated complex being more rapid than that of the normal complex. In exactly the same manner, the rapid dissociation of the protonated cadmium(II)–EDTA complex[2] can also be understood in terms of the glycinate mechanism.

Proton-Assisted Dissociation. As has been reported by several authors,[4,13] the proton-assisted dissociation of the metal(II)–aminopolycarboxylate complex proceeds much more rapidly than the corresponding direct dissociation. From a thermodynamic point of view, it can be said that when the metal complex of the polydentate ligand forms a binuclear complex with another metal ion through the free donor atom, its stability will increase appreciably. Therefore, it is reasonable to believe that, in the proton-assisted dissociation of the metal(II)–aminopolycarboxylate complex, the bond breakage in the course of the reaction intermediate formation always accompanied by the subsequent protonation at the freed donor atom, thus yielding a stable reaction intermediate. If the proton-assisted dissociations of zinc(II)–EDTA, –EDTA-OH, and –DTPA complexes proceed through the glycinate reaction intermediate, with the protonation occurring at the most basic free donor atom, one can estimate the relative rate constant by using the relation employed above. Here, the stability of the reaction intermediate, K_{inter}, should be the product of the stability constant of the zinc(II)-glycinate complex and the protonation constant of a free amino group, $K_h=1/K_a$. The relative rate constants calculated are listed in Table 4, together with the numerical values used in the calculation. The agreement between the calculated and observed values can be regarded as satisfactory. The rate constants for the proton-assisted dissociations of the lead(II)- and cadmium(II)–EDTA-OH, –EDTA, and –DTPA complexes also can be understood in terms of the glycinate reaction intermediate (Table 5). As is shown in Table 4 and 5, the rate constants for the proton-assisted dissociations of the zinc(II)–, lead(II)–, and cadmium(II)–NTA complex can also be understood by assuming a glycinate reaction intermediate where the carboxylate group is protonated (I in Fig. 5). If the reaction intermediates for the direct and proton-assisted dissociations of metal(II)–NTA complexes are given by the reaction intermediate in Fig. 4 and I in Fig. 5 respectively, the rate constant ratio between the two dissociation mechanisms should be 1 : 23.5. However, the observed ratios for the zinc(II)–,[13] lead(II)–,[13] and cadmium(II)–NTA[4,13,20] systems are $1:4\times10^4$, $1:5._5\times10^3$, and $1:1._3\times10^4$ respectively. As far as the $k_d=k_{rds}\cdot K_{inter}\cdot K_{st}\cdot K_{elec}/K_{MX}$ relation can be applied safely to the estimation of the relative dissociation rate constant, the above discrepancy would indicate that the protonation of the reaction intermediate results in not only an increase in the stability of the reaction intermediate, but also in an increase in the rate of the dissociation of the leaving ligand anion from the metal(II) ion. In order to describe the above effect, we propose an reaction intermediate with polyfurcated hydrogen bonds, shown by II in Fig. 5, in place of the simple binuclear complex, I. This structure can also explain why the zinc(II) system has a rate constant ratio different from those of the lead(II) and cadmium(II) systems. The rate constant for the proton-assisted dissociation of the nickel(II)–NTA complex[21] can also be understood by assuming the II reaction intermediate in Fig. 5. As is clear from the above discussion, it is not unreasonable to propose the III reaction intermediate in Fig. 5 for the proton-assisted dissociations of the metal(II) complexes of EDTA and its derivatives (Tables 4 and 5). The

rate constants for the direct and proton-assisted dissociations of the cobalt(II)–EDTA complex[22] can also be understood on the basis of the glycinate intermediate. However, in order to describe the precise role of the hydrogen ion in the dissociation of metal(II)–aminopolycarboxylate complexes, a further systematic investigation should be conducted.

Formation Reactions. The rate constants, k_f's, for the formation of the cadmium(II) complexes calculated with the aid of the $k_f=k_d \cdot K_{MX}$ relation were found to be slightly larger than the characteristic water-exchange rate constant of the cadmium(II) aquo ion[23] (Table 2). Since the equilibrium constant for the outer-sphere association of the cadmium(II) aquo ion with the aminopolycarboxylate anion, approximated by using the Fuoss exuation,[24] is expected to be larger than unity, the above fact can be taken as evidence for the usual water-loss mechanism. As in the case of cadmium(II) complex, the rate constants for the formation reactions of lead(II)- and zinc(II)-aminopolycarboxylate complexes, as calculated using the k_d values and the stability constants, can also be understood by assuming the usual water-loss mechanism (Tables 1 and 3).

Oxidation of Chromium(II) Complexes. I. Kinetics of the Oxidation of Tris(2,2′-bipyridine)- and of Tris(1,10-phenanthroline)chromium(II) Complexes with Hexaamminecobalt(III) Ion[1]

Yoshio NARUSAWA, Masao KIMURA, and Kunio NAKANO

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received April 11, 1973)

Kinetic studies have been carried out on the oxidation of $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ with $[Co(NH_3)_6]^{3+}$ (bipy and phen denote 2,2′-bipyridine and 1,10-phenanthroline, respectively). The rate law is found to be $-d[Cr(II)]/dt=k_1[Co(III)][Cr(II)]+k_2[Cr(II)]$. Simulation procedures with an analogue computer were applied for the analysis of these reactions. The rate constant k_1 (direct oxidation) and k_2 (dissociation) for $[Cr(bipy)_3]^{2+}$ were 180 M^{-1} s^{-1} and 0.120 s^{-1} ($\mu=0.11$ with NaCl, at 25 °C) and those for $[Cr(phen)_3]^{2+}$ were 310 M^{-1} s^{-1} and 0.630 s^{-1} ($\mu=0.20$ with NaCl, at 25 °C), respectively. The larger value of k_1 for $[Cr(phen)_3]^{2+}$ as compared with that of k_1 for $[Cr(bipy)_3]^{2+}$ was interpreted as being due to the good electron conductivity of the phenanthroline as a ligand in the activated state. The activation parameters were obtained as follows: in the case of $[Cr(bipy)_3]^{2+}$, $\Delta H^{\neq}=7.5$ kcal/mol and $\Delta S^{\neq}=-23$ e.u. for the k_1 path, and $\Delta H^{\neq}=17.2$ kcal/mol and $\Delta S^{\neq}=-5$ e.u. for the k_2 path; and in the case of $[Cr(phen)_3]^{2+}$, $\Delta H^{\neq}=8.2$ kcal/mol and $\Delta S^{\neq}=-20$ e.u. for the k_1 path, and $\Delta H^{\neq}=21.2$ kcal/mol and $\Delta S^{\neq}=+12$ e.u. for the k_2 path.

Many investigators[2-7] have pointed out that the oxidation reaction of $[Cr(bipy)_3]^{2+}$ with $[Co(NH_3)_6]^{3+}$ proceeds *via* an outer-sphere mechanism. Zwickel and Taube[6] reported on the rate constants under various conditions, and deduced from the ion-exchange of the product that there is no possibility of the formation of ligand-deficient species ($[Cr(H_2O)_2(bipy)_2]^{3+}$ or $[Cr(OH)_2(bipy)_2]^{+}$) in the course of the reaction. Murray and Waind[8] and Baker and Mehta[9] demonstrated, by spectrophotometric means in the case of the former and by polarographic means in the case of the latter, that $[Cr(H_2O)_2(bipy)_2]^{3+}$ is produced in the oxidation of $[Cr(bipy)_3]^{2+}$ with $[Co(NH_3)_6]^{3+}$. Endicott and Taube,[5] although their argument is not in line with that of Zwickel and Taube,[6] suggested that $[Cr(bipy)_3]^{2+}$ is very substitution-labile and the possibility exists that one of the coordination positions is exposed by opening one of the chelate rings in the activated state. The formation of $[Cr(H_2O)_2(bipy)_2]^{3+}$ and of $[Cr(OH)_2(bipy)_2]^{+}$ is not explained by the aquation of $[Cr(bipy)_3]^{3+}$ produced by oxidation, because Cr(III) complex is substitution-inert. This must be elucidated by a dissociative mechanism for $[Cr(bipy)_3]^{2+}$ into $[Cr(H_2O)_2(bipy)_2]^{2+}$, $[Cr(OH)(H_2O)(bipy_2)]^{+}$, or $[Cr(OH)_2(bipy)_2]$.

The present investigation was carried out following the kinetic work of Zwickel and Taube[6] by means of a stopped-flow technique, the rate equations being analyzed by simulation procedures with an analogue computer. The investigation also aims at a comparison of the kinetic parameters of $[Cr(bipy)_3]^{2+}$ with those of $[Cr(phen)_3]^{2+}$, which is similar to $[Cr(bipy)_3]^{2+}$ in structure.

Experimental

Reagents. Hexaamminecobalt(III) chloride monohydrate prepared by the usual method was purified several times. Hydrochloric acid was purified by distillation. The purity of 2,2′-bipyridine and 1,10-phenanthroline was examined by measuring the infrared spectra by KBr disk method. All other chemicals were of guaranteed grade and were not purified further.

Preparation of the Reactant Solutions. Solutions of $[Co(NH_3)_6]^{3+}$ were prepared by dissolving a weighed sample of $[Co(NH_3)_6]Cl_3\cdot H_2O$ in NaCl solution containing a given amount of 2,2′-bipyridine. Solutions of $[Cr(bipy)_3]^{2+}$ were prepared as follows: Cr metal (99.99%, Johnson Matthey) was dissolved in HCl which had been deaerated with a vacuum apparatus. After the excess HCl had been removed by distilling under reduced pressure, the residue was dissolved in NaCl solution containing a given amount of 2,2′-bipyridine. Solutions of $[Cr(phen)_3]^{2+}$ were prepared by the same procedure except that 1,10-phenanthroline was used instead of 2,2′-bipyridine. All the solutions were deaerated three times with a vacuum apparatus.

Measurements of Changes in the Absorbance. The stopped-flow apparatus used for following the reactions was a Yanaco SPS-1 spectrophotometer connected with an Iwasaki MS-5019A synchroscope with a memory device. The spectrophotometer used for measuring the absorption curves was a

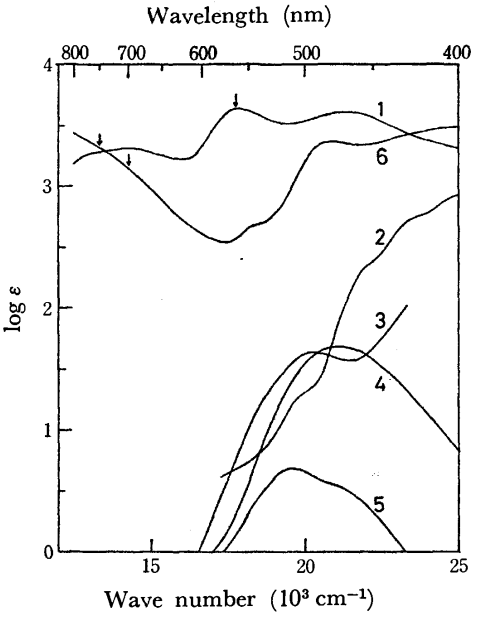

Fig. 1. Absorption spectra of various species.
1, $[Cr(bipy)_3]^{2+}$; 2, $[Cr(bipy)_3]^{3+}$; 3, $[Cr(H_2O)_2(bipy)_2]^{3+}$ [a]; 4, $[Co(NH_3)_6]^{3+}$; 5, Co^{2+}; 6, $[Cr(phen)_3]^{2+}$. a) From Ref. 11.

Hitachi 124 spectrophotometer. Introduction of the reactant solutions into the stopped-flow apparatus and the technique of the kinetic measurements followed the same procedures as the usual stopped-flow methods. Measurements of the absorption spectra of $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ complexes were made by sealing the solution in a 10-mm quartz cell in the absence of air. The spectra are shown in Fig. 1 along with those of the other complexes concerned. The absorption spectra of $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ complexes are in line with those reported,[10] except for slight differences in intensity.

Changes in the transmittance as a function of time were followed with the stopped-flow apparatus in an excess of $[Co(NH_3)_6]^{3+}$ at 562.5 nm ($\varepsilon=4340\,l\cdot mol^{-1}\,cm^{-1}$) for $[Cr(bipy)_3]^{2+}$ and at either 700 nm ($\varepsilon=1397$) or 750 nm ($\varepsilon=2046$) for $[Cr(phen)_3]^{2+}$. At each wavelength where the reaction was followed, the molar extinction coefficient of each reductant was *ca.* 500 times that of any other species present (Fig. 1). Oscilloscope trace of transmittance as a function of time is shown in Fig. 2. The gradual increase in transmittance with time (curve 2) corresponding to the disappearance of $[Cr(bipy)_3]^{2+}$ at a given wavelength was observed after the flow of the solution stopped (point A, curve 1). Curve 2 was converted into one showing the change in absorbance or concentration of Cr(II) complex *vs.* time using the molar extinction coefficient (ε), the value of % transmittance (T_∞) at 'infinite' time (curve 3), and the value of 5% calibration signal corresponding to $T_\infty\times0.05$ (curve 4). T_∞ was found to be 99.38% for the final solution in the kinetic run. The stopped-flow measurements were repeated several times for the same solution, and were repeated for $[Cr(phen)_3]^{2+}$ as well as for $[Cr(bipy)_3]^{2+}$ under various temperatures, oxidant concentrations and hydrogen ion concentrations.

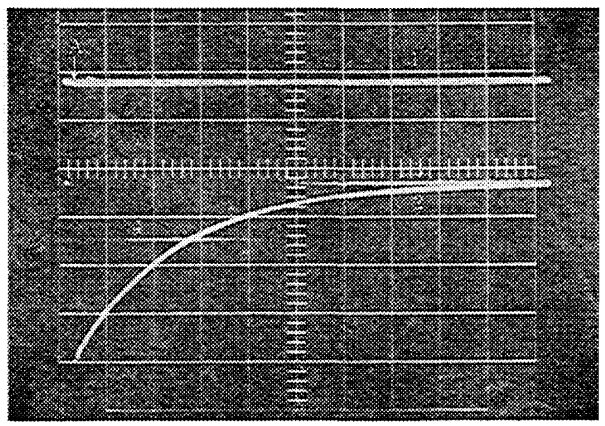

Fig. 2. Oscilloscope trace of transmittance (at 562.5 nm) of $[Cr(bipy)_3]^{2+}$ system as a function of time; $[Cr(bipy)_3^{2+}]=2.68\times10^{-4}$ M, $[Co(NH_3)_6^{3+}]=2.49\times10^{-3}$ M, $[bipy]=1.0\times10^{-2}$ M, pH=5.32, $\mu=0.10$ with NaCl, at 25.1 °C.
Curve 1, flow signal; 2, reaction signal; 3, transmittance (T_∞) at "infinite" time (99.38%); 4, 5% calibration signal. The abscissa scale is 1 sec per major division and the ordinate scale is in arbitrary unit of transmittance.

No attempt was made to identify the products of reaction or confirm directly the stoichiometry, which was assumed in each case to be $Cr(II)+Co(III)\rightarrow Cr(III)+Co(II)$ on the basis of the earlier observations of these and related reactions.

pH Measurements. The pH of the oxidant solution was measured with a pH meter. As it was impossible to measure directly the value of pH of the reductant solution, the value was estimated by measuring the pH of the solution in which Cr^{2+} ion was absent, because it was assumed that addition of Cr^{2+} ion to the solution does not affect the pH value under the experimental conditions of the present work, taking the acidity constants[12] of the bipyridinium and phenanthrolinium ions into consideration. The pH of the mixture of the reactant solutions was assumed to lie between the two pH's of the two reactant solutions, the values of which were within 0.1 pH unit of the average.

Analysis of Data

Analogue Computer Assembly. The analogue computer for analyzing the rate equations has circuits as shown in Figs. 3(a),[13] 3(b), and 4.

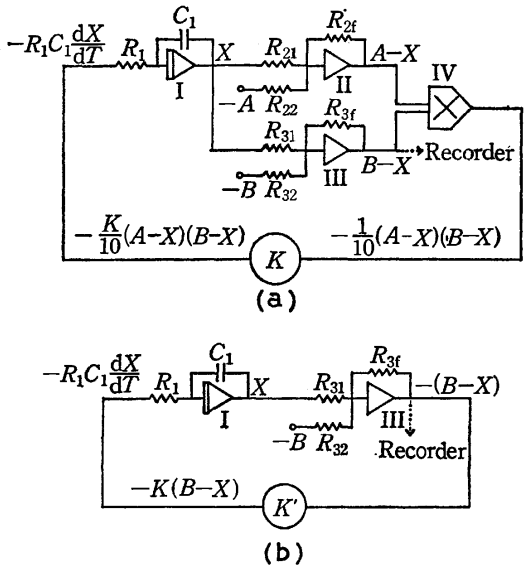

Fig. 3. Analogue computer circuit diagrams; (a) for the second-order reaction, and (b) for the first-order reaction, where inverter being omitted.
$C_1=10\,\mu F$; $R_1=100\,k\Omega$; $R_{21}=R_{22}=R_{2f}=R_{31}=R_{32}=10\,k\Omega$; $R_{3f}=10\,k\Omega$ or $100\,k\Omega$; $K=K'=1\,k\Omega$. I, SA-3a; II and III, SQ-10a; IV, Quarter-square multiplier, Model 4030/25.

$C_1=10\,\mu F$; $R_1=R_1'=100\,k\Omega$; $R_{21}=R_{22}=R_{2f}=R_{31}=R_{32}=R_{41}=R_{4f}=10\,k\Omega$; $R_{3f}=10\,k\Omega$ or $100\,k\Omega$; $K_1=K_2=1\,k\Omega$.
I, SA-3a; II and III, SQ-10a; IV, Quarter-square multiplier, Model 4030/25; V, SA-3a.

Operational amplifiers and a function multiplier were supplied by Philbrick–Nexus and Burr-Brown, respectively. A voltage regulator Type VK 15012W, Volgen, was used as the D.C. power stabilizer. In the figures, I, II, III, and V are operational amplifiers; I integrator, II and III adder, and V inverter. Function multiplier IV was used for multiplying two variables, and attenuators K, K', K_1, and K_2 were used for multiplying a constant value. For the resistor R_{3f}, a value of either 10 kΩ or 100 kΩ was used, depending on the magnitude of the input signal of III. The analogue computer with the circuit shown in Fig. 4 was used for the first time for simulating the composite first- and second-order reactions. The voltage change corresponding to the change in the concentration of the chromium(II) complex was followed by the output signal of III as a function of time and was recorded with an EPR-2TC Toa Electronics recorder. The exact values of the individual components were determined prior to use and applied as corrections in the final evaluation of the rate constants measured by the analogue computer simulations.

Simulation Procedures for Measuring Rate Constants. For determining the rate constants graphically by using the change in a concentration as a function of time, the initial concentration of each of the reactants and the concentration at each instantaneous time after the reaction starts should be known. In the present investigation, however, it is supposed that Cr(II) complex was oxidized partially before the reactant solutions were mixed, owing to its sensitiveness to oxidation, that the reactant solutions were not mixed instantaneously because of the so-called dead-time resulting from the mechanical restriction of the stopped-flow apparatus, and that both reactants are consumed during the time in which reactants go from the mixing point to the cell through which a light beam for the observation passes. For these reasons, the rate constants cannot be determined exactly by a graphical method. Thus the simulation method with an analogue computer was attempted for analyzing the reaction. The simulation for the second-order reaction, assumed to be Cr(II)+Co(III)→Cr(III)+Co(II), was carried out according to Nakanishi's method,[13] *viz.*, with an analogue computer (Fig. 3(a)); the voltage, $-B$, corresponding to the effective initial concentration (calculated from the absorbance at the starting point of the curve of the absorbance change and the molar extinction coefficient) of Cr(II) complex was applied to the adder III as the input signal, and the circuit was closed at the machine time $T=0$. The output voltage of III was then followed as a function of time T, and the voltage change with time was recorded on the recorder. Thus, if the curve obtained by the simulation procedure was fitted to the curve of the change in concentration with time by adjusting the input voltage ($-A$) of adder II and the dial reading of the helipot K, $-A$ could be considered to correspond to the effective initial concentration of Co(III) complex and the reading of K to a value proportional to the rate constant. Thus, by comparing the assumed rate equation (1) or (1') with machine equation (2), equation (3) is obtained as follows:

$$-\frac{d[Cr(II)]}{dt} = k_{obs}[Co(III)][Cr(II)] \quad (1)$$

$$\frac{dx}{dt} = k_{obs}(a-x)(b-x) \quad (1')$$

$$\frac{dX}{dT} = -\frac{K}{10R_1C_1}(A-X)(B-X) \quad (2)$$

$$k_{obs} = \frac{\alpha\beta K}{10R_1C_1} \quad (3)$$

where k_{obs} is an apparent rate constant obtained by analyzing the rate equation as a second-order reaction; a and b are effective initial concentrations of Co(III) and Cr(II) complexes, respectively; x is the amount of reactant consumed at an effective time t after the reaction signal became observable; X is the voltage on C_1 at time T after the circuit is switched on and is proportional to x; α is a factor in $V\cdot l\cdot mol^{-1}$ to convert the voltage $(B-X)$ into the concentration $(b-x)$; β is a dimensionless factor to convert the machine time T into the reaction time t; and $1/R_1C_1$ is a correction factor whose reciprocal is a time constant of the integrator I. Examples of the simulation actually performed are shown (Fig. 5(a) and (b), curve 1).

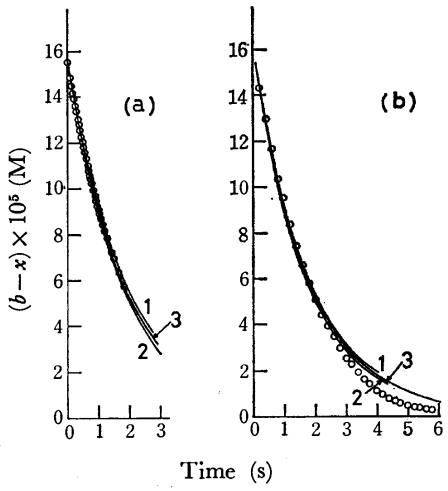

Fig. 5. Typical examples of analogue computer simulations for the oxidation of $[Cr(bipy)_3]^{2+}$ with $[Co(NH_3)_6]^{3+}$.
The open-circled points in (a) and (b) refer to No. 2—4 and No. 2—2 in Table 1, respectively. Solid curves 1, 2, and 3 are those obtained by the simulations for the second-order reaction (Eq. (1)) with the circuit of Fig. 3(a), the first-order reaction (Eq. (5)) with that of Fig. 3(b), and the composite first- and second-order reaction (Eq. (9)) with that of Fig. 4, respectively.

However, the values of k_{obs} thus obtained at the same temperature decrease as $[Co(NH_3)_6]^{3+}$ concentration increases (Tables 1 and 2). The results obtained by the graphical method are also shown.

It was assumed that k_{obs} is expressed by the sum of the term independent of [Co(III)] and the term reciprocally proportional to it:

$$k_{obs} = k_1 + \frac{k_2}{[Co(III)]} \quad (4)$$

a) pH=6.05±0.10, μ=0.20(NaCl), λ=750 nm except No. 27—14. b) Each reactant solution contains 0.012 M 1,10-phenanthroline. c) λ=700 nm.

The rate constants k_1 and k_2 should be obtained from the intercept and the slope, respectively, by plotting k_{obs} against $[Co(III)]^{-1}$ (Fig. 6, lines 1 and 2). The results for $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ complexes are given in Table 4.

The reaction was analyzed by assuming that it is of first-order:

$$-\frac{d[Cr(II)]}{dt} = k'_{obs}[Cr(II)] \tag{5}$$

For circuit diagram, see Fig. 3(b). The simulation procedure was almost the same as in the case of the second-order reaction. Examples are shown by curve 2 in Fig. 5(a) and (b). In this case, the machine equation is expressed as follows:

$$\frac{dX}{dT} = \frac{K'}{R_1C_1}(B-X) \tag{6}$$

If the dial of the helipot K' is properly adjusted, this turns out to correspond to Eq. (5), and we have

$$k'_{obs} = \frac{\beta K'}{R_1C_1} \tag{7}$$

The values of k'_{obs} thus obtained increase with the increase in concentration of $[Co(NH_3)_6]^{3+}$ at the same temperature (Table 3). Thus, it was assumed that k'_{obs} contains a term proportional to the concentration of Co(III):

$$k'_{obs} = k_1[Co(III)] + k_2 \tag{8}$$

The values of k_1 and k_2 obtained are given in Table 4.

Both equations obtained by substituting Eq. (4) into Eq. (1) and Eq. (8) into Eq. (5), respectively, become the same as the following equation:

$$-\frac{d[Cr(II)]}{dt} = k_1[Co(III)][Cr(II)] + k_2[Cr(II)] \tag{9}$$

However, the rate constants k_1 and k_2 obtained from

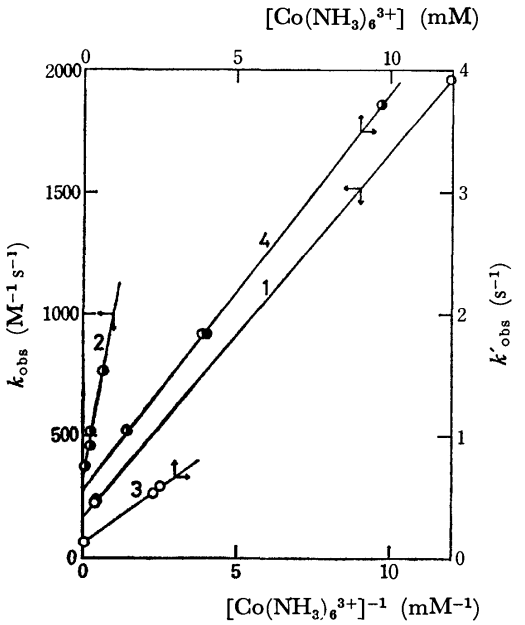

Fig. 6. Relationships of k_{obs} and k'_{obs} at 25 °C to $[Co(NH_3)_6^{3+}]^{-1}$ and $[Co(NH_3)_6^{3+}]$, respectively.[a] Data are taken from Tables 1, 2, and 3. ○, $[Cr(bipy)_3]^{2+}$; ◑, $[Cr(phen)_3]^{2+}$.
a) The concentration of $[Co(NH_3)_6]^{3+}$ ion was evaluated by using voltages $-A$ and $-B$ for $[Co(NH_3)_6]^{3+}$ ion and Cr(II) complex, respectively, and the concentration of Cr(II) complex at the starting poing of the simulation ($T=0$) according to the equation, $[Co(III)]_{T=0}=(A/B)[Cr(II)]_{T=0}$.

Table 3. Apparent first-order rate constants at 25 °C for $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ by simulation

Reductant	Run No.[a]	$[Co(NH_3)_6^{3+}]$ (mM)	k'_{obs} (s^{-1})

	2— 4	2.52	0.576±0.005
$[Cr(phen)_3]^{2+}$	28— 7	2.50	1.03
	27— 8[b]	4.98	1.84
	27—15	4.98	1.84
	29— 5	9.99	3.72

a) The numerals are the same as those given in the first columns of Tables 1 and 2. b) The conditions are the same as those of No. 27—15.

k_{obs} according to Eq. (4) do not agree with those obtained from k'_{obs} according to Eq. (8) (Table 4). This discrepancy is caused by the fact that concentrations of Co(III) (abscissa, Fig. 6) change during the course of the reaction. (The effective initial concentrations of Co(III) are plotted in Fig. 6). Thus, in order to obtain k_1 and k_2 accurately, it is necessary to simulate Eq. (9) directly. For this purpose, a simulator (Fig. 4) was constructed.

The machine equation for the simulator is expressed as follows:

Table 4. First- and second-order rate constants[a]

	Rate constant[b]	Reductant $[Cr(bipy)_3]^{2+}$	Reductant $[Cr(phen)_3]^{2+}$
From k_{obs} and Fig. 6 (lines 1 and 2)	k_1	165±8	300±10
	k_2	0.15±0.01	0.69±0.04
From k'_{obs} and Fig. 6 (lines 3 and 4)	k_1	200±10	321±10
	k_2	0.10±0.01	0.57±0.03
Averaged value	k_1	183±18	311±11
	k_2	0.12_5±0.02_5	0.63±0.06
From simulations for Eq. (9)[c]	k_1	180±3	310±6
	k_2	0.120±0.002	0.630±0.010

a) Data of k_{obs} and k'_{obs} at 25 °C for $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ were taken from Tables 1, 2, and 3. b) k_1 in $M^{-1}s^{-1}$ and k_2 in s^{-1}. c) Taken with the analogue computer whose circuit is shown in Fig. 4.

$$\frac{dX}{dT}=\frac{K_1}{10R_1C_1}(A-X)(B-X)+\frac{K_2}{R_1C_1}(B-X) \quad (10)$$

where K_1 and K_2 are proportional to k_1 and k_2, respectively, and given by

$$k_1=\frac{\alpha\beta K_1}{10R_1C_1} \quad (11)$$

$$k_2=\frac{\beta K_2}{R_1C_1} \quad (12)$$

The examples of the simulation carried out with this circuit are shown by curve 3 in Fig. 5(a) and (b). The values* of k_1 and k_2 thus obtained under the various conditions were constant irrespective of the concentration of Co(III) at a given temperature as shown in Table 5.

The accuracy of each rate constant obtained by the above procedures was within *ca.* 2% in relative error (Tables 1, 2, 3, and 5).

Therefore, k_1 and k_2 are considered to be the rate constants for the second-order and the first-order reactions, respectively, and it is concluded that Eq. (9) is adequate as the rate law for the present systems.

Results and Discussion

It was found that satisfactory values of rate constants in the oxidation reaction of $[Cr(bipy)_3]^{2+}$ and of $[Cr(phen)_3]^{2+}$ complexes with $[Co(NH_3)_6]^{3+}$ complex (Tables 1 and 2) cannot be obtained by the usual graphical method of analysis. However, by means of simulation procedures with an analogue computer (Fig. 3(a) and (b)), the apparent rate constants of appropriate values could be obtained for the second-order and the first-order reactions (Tables 1, 2, and 3). Both curves 1 and 2 obtained by these simulations deviate from the observed points in the later stage of the reaction (Fig.

* The values of k_{obs} and k'_{obs}, obtained with the circuits for simulations of the second-order and first-order reactions, respectively, do not correspond to those of k_1 and k_2 obtained by simulating as the composite reaction, and differ significantly. The values of k_{obs} and k'_{obs} are dependent on and those of k_1 and k_2 independent of the concentration of Co(III) complex.

TABLE 5. RATE CONSTANTS k_1 AND k_2 FOR $[Cr(bipy)_3]^{2+}$ AND $[Cr(phen)_3]^{2+}$ BY SIMULATION PROCEDURES[a]

a) Simulations were carried out by means of Eq. (9). b) The numerals are the same as those given in Tables 1, 2, and 3 unless otherwise stated. c) Conditions the same as those of No. 28—7. d) Conditions the same as those of No. 29—5. e) Solution compositions the same as those of No. 29—33.

5(b)). This discrepancy might be mainly due to the formation of $[Cr(OH)_2(bipy)_2]^+$, since the value of pH increased to *ca.* 8.5 in the final solution of the reaction. This is supported by the fact that the absorption spectrum of the reaction product[8] coincides with $[Cr(OH)_2(bipy)_2]^+$,[11] and it changes to $[Cr(H_2O)_2(bipy)_2]^{3+}$[11] on acidification.[8] The value of T_∞ is calculated to be 99.38%, which is just the same as the observed value (Fig. 2), if we assume that *ca.* 81% of the Cr(III) products is $[Cr(OH)_2(bipy)_2]^+$ ($\varepsilon_{562.5nm}$= 35 $l \cdot mol^{-1} cm^{-1}$)[11] and the rest is $[Cr(bipy)_3]^{3+}$, whereas the value is obtained to be 99.66% if we assume the formation of $[Cr(H_2O)_2(bipy)^2]^{3+}$ instead of $[Cr(OH)_2(bipy)_2]^+$. Thus, the product present as a ligand-deficient species is considered to be either $[Cr(H_2O)_2(bipy)_2]^{3+}$ or $[Cr(OH)_2(bipy)_2]^+$. The formation of the ligand-deficient species is explained by either an acid hydrolysis or a base hydrolysis. The dissociation of $[Cr(bipy)_3]^{2+}$ *via* the base hydrolysis becomes predominant with increase in pH of the solution in the later stage of the reaction, although the base hydrolysis does not occur in the earlier stage of the reaction because of the acidity. Since the dissociation rate for the base hydrolysis is considered to be greater than that for the acid hydrolysis,[14] the consumption of $[Cr(bipy)_3]^{2+}$ becomes more marked in the later stage than in the earlier stage of the reaction. The deviation of the simulation curve from the observed plot in the later stage of the reaction (Fig. 5(b)) can thus be explained. The curve-fitting procedures were applied during the time in which 65—70% of the effective initial concentration of each Cr(II) complex undergoes change by the reaction. The values of the rate constants thus obtained would not be affected by the base hydrolysis.

The results obtained for the rate constants for the oxidation and dissociation of $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ complexes are shown in Table 5. The excellent constancy of the rate constants obtained under a wide variety of $[Cr(NH_3)_6]^{3+}$ concentrations validates the assumed rate law (Eq. (9)). Since the reaction involves the processes of both second-order (k_1 path) and first-order (k_2 path), it seems that the reaction of $[Cr(bipy)_3]^{2+}$ with $[Co(NH_3)_6]^{3+}$ proceeds *via* the composite processes of the direct oxidation of the former with the latter (second-order) and the dissociation of the former into $[Cr(H_2O)_2(bipy)_2]^{2+}$ (first-order). Provided the oxidation of $[Cr(H_2O)_2(bipy)_2]^{2+}$ is more rapid than the dissociation of $[Cr(bipy)_3]^{2+}$ and the concentration of the former is very low, the dissociation process of $[Cr(bipy)_3]^{2+}$ becomes the rate-determining step for the oxidation of the dissociated species, and it follows that the rate of oxidation of $[Cr(H_2O)_2(bipy)_2]^{2+}$ with $[Co(NH_3)_6]^{3+}$ is first-order in $[Cr(bipy)_3]^{2+}$ and zero-order in $[Co(NH_3)_6]^{3+}$. Consequently, the most probable mechanisms of these reactions can be expressed as follows:

$$[Cr(bipy)_3]^{2+} + [Co(NH_3)_6]^{3+} \xrightarrow{k_1} [Cr(bipy)_3]^{3+} + Co^{2+} + 6NH_3 \quad (13)$$

$$[Cr(bipy)_3]^{2+} + 2H_2O \underset{k_3}{\overset{k_2}{\rightleftharpoons}} [Cr(H_2O)_2(bipy)_2]^{2+} + bipy \quad (14)$$

$$[Cr(H_2O)_2(bipy)_2]^{2+} + [Co(NH_3)_6]^{3+} \xrightarrow{k_4} [Cr(H_2O)_2(bipy)_2]^{3+} + Co^{2+} + 6NH_3 \quad (15)$$

Baker and Mehta[9] assumed the rate constant k_5 of the equation

$$[Cr(H_2O)_2(bipy)_2]^{2+} + [Cr(bipy)_3]^{3+} \underset{k_6}{\overset{k_5}{\rightleftharpoons}} [Cr(H_2O)_2(bipy)_2]^{3+} + [Cr(bipy)_3]^{2+} \quad (16)$$

to be of the order of 10^5 M^{-1} s^{-1}. Since both oxidants in the reactions of Eqs. (15) and (16) are the 'outer-sphere' type of complex and the reductant $[Cr(H_2O)_2(bipy)_2]^{2+}$ is the low-spin[8] type of complex, it is assumed that k_4 and k_5 are at least of the same order of magnitude. Further, the rate constant k_3 is assumed to be *ca.* 10^3 M^{-1} s^{-1} from equilibrium[15] and kinetic[7,9] data. Thus it is estimated that the rates of Eqs. (14) and (15) satisfy the relations

$$k_3[bipy] < k_4[Co(NH_3)_6{}^{3+}] \quad (17)$$

$$k_2[Cr(bipy)_3{}^{2+}] < k_4[Cr(H_2O)_2(bipy)_2{}^{2+}][Co(NH_3)_6{}^{3+}] \quad (18)$$

under the present experimental conditions. Thus the forward reaction of Eq. (14) is concluded to be the rate-determining step for the oxidation of the dissociated complex with $[Co(NH_3)_6]^{3+}$. The following should be taken into account in Eqs. (13), (14), and

(15): the effect of $[Cr(bipy)_3]^{3+}$ formed by the reaction of Eq. (13) on the oxidation of $[Cr(H_2O)_2(bipy)_2]^{2+}$ (k_5 path), and the effect of $[Cr(H_2O)_2(bipy)_2]^{3+}$ formed by the reaction of Eq. (15) on the oxidation of $[Cr(bipy)_3]^{2+}$ (k_6 path).

If the reaction of the k_5 path affects reaction (15), these reactions are regarded as competition reactions for the oxidation of $[Cr(H_2O)_2(bipy)_2]^{2+}$. Since $[Cr(bipy)_3]^{2+}$ is produced by the reaction of the k_5 path, the value of the rate constant k_2 becomes smaller with the decrease in the concentration of $[Co(NH_3)_6]^{3+}$. However, the results in Table 5 show a constancy of the rate constant k_2 in a wide range of $[Co(NH_3)_6]^{3+}$ concentrations, indicating that the effect of $[Cr(bipy)_3]^{3+}$ (k_5 path) on the dissociation (k_2 path) is negligible. This is explained by the relation

$$k_5[Cr(bipy)_3{}^{3+}] \ll k_4[Co(NH_3)_6{}^{3+}] \quad (19)$$

This holds in a large excess of $[Co(NH_3)_6]^{3+}$ as compared with $[Cr(bipy)_3]^{2+}$, since the relation $[Cr(bipy_3)^{3+}] \ll [Co(NH_3)_6{}^{3+}]$ also holds if we consider the formation of $[Cr(bipy)_3]^{3+}$ by the direct oxidation of $[Cr(bipy)_3]^{2+}$ (*cf.* Eq. (13)).

The effect of the oxidant $[Cr(H_2O)_2(bipy)_2]^{3+}$ on the reaction of Eq. (13) will be ruled out if the relation

$$k_6[Cr(H_2O)_2(bipy)_2{}^{3+}] \ll k_1[Co(NH_3)_6{}^{3+}] \quad (20)$$

holds under the present experimental conditions. The value of k_6 in Eq. (16) is estimated to be *ca.* 10 M^{-1} s^{-1} from the assumed value of k_5 and the values of the reversible half-wave potentials of $[Cr(bipy)_3]^{3+}$ and $[Cr(H_2O)_2(bipy)_2]^{3+}$ obtained polarographically by Baker and Mehta,[9] and the concentration of $[Cr(H_2O)_2(bipy)_2]^{3+}$ is estimated to be *ca.* 10^{-4} M since its formation predominantly takes place *via* the reaction of Eq. (15). Since the concentration of $[Co(NH_3)_6]^{3+}$ is at least *ca.* 10^{-3} M under the large excess of the oxidant and the value of k_1 is assumed to be at least of the order of 10^2 M^{-1} s^{-1},[6] the magnitude of the right-hand side of Eq. (20) amounts to at least *ca.* 100 times that of the left-hand side of the equation. Thus it seems that the backward reaction of Eq. (16) does not affect the reaction of Eq. (13).

The effect of the backward reaction of Eq. (16) (k_6 path) on the dissociation (k_2 path) can also be neglected for the reason that the relation

$$k_6[Cr(H_2O)_2(bipy)_2{}^{3+}] \ll k_2 \quad (21)$$

holds, because the value of k_2 is estimated to be of the order of 10^{-1} s^{-1}.[7,9] Thus the rate constant k_2 is not affected by the backward reaction of Eq. (16).

Equations (20) and (21) seem to hold similarly in the slight excess of $[Co(NH_3)_6]^{3+}$, since k_1 and k_2 remain constant in a wide concentration range (Table 5). It is concluded that the reaction of $[Cr(bipy)_3]^{2+}$ with $[Co(NH_3)_6]^{3+}$ proceeds *via* the processes of both the direct oxidation of the former with the latter (second-order k_1 path) and the dissociation of the former to $[Cr(H_2O)_2(bipy)_2]^{2+}$ (first-order k_2 path) followed by the rapid oxidation with $[Co(NH_3)_6]^{3+}$; and that Eq. (9) assumed experimentally is adequate for expressing the rate law of the present system. These relationships and the rate law might hold also for the system $[Cr(phen)_3]^{2+}$–$[Co(NH_3)_6]^{3+}$.

A comparison of the rate constants is shown in Table 6. The rate constants for the dissociation of $[Cr(bipy)_3]^{2+}$ have been reported[7,9] (k_2 in Table 6). The values coincide with each other, in spite of the different medium and different ionic strength, and both are greater than ours. Although the value reported by Candlin, Halpern, and Trimm[7] was obtained by a preliminary experiment and thus a detailed discussion is not possible, the greater value in perchlorate medium as compared with that in chloride medium may be interpreted as being due to a salt effect. Both k_{obs}[6] and k_2[7] in the perchlorate medium are about three times those in the chloride medium. These rate constants (k_{obs} and k_2) might be subjected to the salt effect to the same extent. A detailed discussion cannot be presented, since k_{obs} involves k_1. On the other hand, the result for k_2 obtained by Baker and Mehta[9] can be discussed somewhat in detail. They measured the rate of dissociation of $[Cr(bipy)_3]^{2+}$ by following polarographically the decrease in the diffusion current of $[Cr(bipy)_3]^{3+}$ coexisting in solution. They dealt with the reaction on the assumption that the forward re-

a) This work. Oxidation with $[Co(NH)_3)_6]^{3+}$. b) Oxidation with $[Co(PO_4)(NH_3)_5]$. c) Reduction of $[Cr(bipy)_3]^{3+}$ with $[Cr(bipy)_3]^{2+}$ followed polarographically. d) Rate data reported are not of the rate constants k_1's but of the apparent rate constants k_{obs}'s defined in the present paper, since the dissociation path in Ref. 6 was not taken into consideration.

action of Eq. (16) proceeds faster than both its backward reaction and the reaction in either direction in Eq. (14), in which the dissociation is the rate-determining step. The assumption should be valid for the reaction in the bulk of the solution. However, the rate constant for the dissociation (k_2) cannot be obtained polarographically unless the rate of diffusion of the depolarizer, $[Cr(bipy)_3]^{3+}$, to the surface of the dropping mercury electrode is greater than that of the reduction of $[Cr(bipy)_3]^{3+}$ with $[Cr(H_2O)_2(bipy)_2]^{2+}$ (Eq. (16)). Otherwise, the consumption of $[Cr(bipy)_3]^{3+}$ during the course of diffusion causes a depression in the concentration of the depolarizer on the electrode surface, leading to the overestimation of the decrease in the bulk concentration. In fact the rate of diffusion does not seem to be so great as that of the reduction of $[Cr(bipy)_3]^{3+}$ with $[Cr(H_2O)_2(bipy)_2]^{2+}$.[16] However, Baker and Mehta ignored the diffusion term leaving the kinetic term, making their treatment inconsistent. Thus, the value 0.38 s^{-1} they obtained must have been overestimated. The greater value, as compared with the present value, cannot be explained either by considering the difference in the ionic strength.

The increasing rates with increase in ionic radii for anions ($Cl^- < Br^- < ClO_4^-$) of the media are considered to be largely due to the salt effect (*cf.* k_{obs} in Table 6). However, the apparent rate constants (k_{obs}) involving the dissociation rate constant k_2 are not necessarily well suited for comparing with each other. A detailed discussion should be based on the rate constant k_1 obtained under various conditions of ionic strengths and media.

The second-order rate constant for $[Cr(phen)_3]^{2+}$ is *ca.* 1.7 times greater than that for $[Cr(bipy)_3]^{2+}$, although there is a difference in ionic strength (*cf.* k_1 in Table 6). The greater rate for $[Cr(phen)_3]^{2+}$ cannot be explained by the tunneling effect as in the case of the reaction of $[Co(NH_3)_6]^{3+}$ or $[Co(en)_3]^{3+}$ (en denotes ethylenediamine) with $[Cr(bipy)_3]^{2+}$,[6] because of the greater size of the phenanthroline complex as compared with the bipyridine complex. The greater reactivity is in accord with the results obtained by Ford-Smith and Sutin[17] and Sutin and Gordon,[18] who reported the rate constants for the systems Fe^{2+}–$[Fe(bipy)_3]^{3+}$ and Fe^{2+}–$[Fe(phen)_3]^{3+}$ in 0.5 M $HClO_4$ at 25.0 °C to be 2.7×10^4 M^{-1} s^{-1} [17,18] and 3.7×10^4 M^{-1} s^{-1},[17] respectively. The ratio of the rate constant reported for the phenanthroline complex to that for the bipyridine complex is *ca.* 1.4, which agrees with ours, if the difference in ionic strength for Cr(II) complexes is taken into consideration. The greater reactivity for $[Cr(phen)_3]^{2+}$ is ascribed to the effect of an electron on the metal t_{2g} orbital spreading itself around on the ligand π orbital through the π interaction. The reaction is facilitated in spite of the larger size of the complex. The reactivity for these systems is caused by the electron conductivity of the ligand in the π-conjugate complex. For a complex without π-conjugation, such as Cr^{2+}, the slow rate for the oxidation with $[Co(NH_3)_6]^{3+}$ *via* the outer-sphere mechanism (8.8×10^{-4} M^{-1} s^{-1}, μ=0.40, at 25.0 °C)[2] can be explained by the poor electron conductivity of the water molecule attached.

From the temperature dependence of the rate constants k_1 and k_2 and of the apparent rate constant k_{obs}, the activation parameters for $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ systems were evaluated by transition-state theory according to:

$$k = \frac{kT}{h} e^{-\Delta H^{\neq}/RT} e^{\Delta S^{\neq}/R}$$

The results are shown in Table 7, together with those of other investigators. The activation parameters for k_{obs} are in excellent agreement with those obtained by Zwickel and Taube,[6] considering the difference in ionic strengths. It is concluded that the rate constants they obtanied correspond to the apparent rate constant (k_{obs}) defined in the present paper. Since the reaction proceeds in two paths as expressed by Eq. (9), the parameters for both paths should be obtained (Table 7).

a) This work. b) For k_2 paths, the rate constant is in s^{-1}. c) Value for the activation energy, E_a. d) The value was not reported by Baker and Mehta,[9] so it is cited from Ref. 14a. e) *Cf.* footnote c), Table 6.

It is reasonable to consider that a similar mechanism is operative for the oxidation of $[Cr(bipy)_3]^{2+}$ and of $[Cr(phen)_3]^{2+}$ (k_1 in Table 7), because activation enthalpies (7.5 kcal/mol and 8.2 kcal/mol) and activation entropies (−23 e.u. and −20 e.u.) obtained for respective complexes are of similar magnitude. However, as the activation entropies, $\Delta S^{\neq}$'s, for outer-sphere reactions are sensitive to the medium, the values obtained at different ionic strengths cannot be compared directly with each other. Nevertheless, the values of the activation entropies obtained for $[Cr(bipy)_3]^{2+}$ and $[Cr(phen)_3]^{2+}$ indicate that the total charges on the transition complexes are between +4 and +5.[19] Discussions should be carried out with the use of the thermodynamic activation parameters.

The greater activation enthalpy for the k_1 path of $[Cr(phen)_3]^{2+}$ as compared with that of $[Cr(bipy)_3]^{2+}$ (Table 7) is interpreted as being due to the greater stability in the ground state of the former.

It should be noted that the coincidence of the $\Delta G^{\neq}$ value calculated from the results by Baker and Mehta[9] with ours for the k_2 path occurs as a result of the cancellation of the overestimated $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values. Although the overestimation of the activation parameters cannot be easily interpreted, it might be caused by a greater overestimation of the rate constant for the dissociation at a higher temperature, since the temperature dependence of the diffusion rate is not as significant as that of the reduction rate of $[Cr(bipy)_3]^{3+}$.

Conclusion

The oxidation reaction of $[Cr(bipy)_3]^{2+}$ and of $[Cr(phen)_3]^{2+}$ complexes with $[Co(NH_3)_6]^{3+}$ ion proceeds in two paths through the outer-sphere mechanism: direct oxidation of $[Cr(bipy)_3]^{2+}$ or $[Cr(phen)_3]^{2+}$ (second-order reaction); oxidation of $[Cr(H_2O)_2(bipy)_2]^{2+}$ or $[Cr(H_2O)_2(phen)_2]^{2+}$ formed by the dissociation of $[Cr(bipy)_3]^{2+}$ or $[Cr(phen)_3]^{2+}$, the dissociation (first-order reaction) being rate-determining for the oxidation of the dissociated complex. The rate constants of the paths for these complexes were obtained by means of analogue computer simulation procedures. The activation parameters for the direct oxidation and dissociation processes of each of these complexes were also obtained.

The authors wish to express their thanks to Professor Masaki Nakanishi of Ochanomizu University for his advice on the analogue computer. The investigation was supported in part by a grant from the Ministry of Education.

Effects of Additives on Solid State Reaction. I. A Kinetic Study of the Effects of Halides of the Formation of $MgAl_2O_4$

Shiro SHIMADA, Ryusaburo FURUICHI, and Tadao ISHII
Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received July 9, 1973)

The mechanism for the promoting effects of additives on the formation of $MgAl_2O_4$ has been systematically discussed from the results of kinetic measurements. A mixture of MgO and α-Al_2O_3 powder containing 10 mol% additives (LiF, NaF, MgF_2, CaF_2, BaF_2, NaCl or $CaCl_2$) and that without additives were isothermally heated in N_2 atmosphere in the temperature ranges 670—1142 °C and 1190—1360 °C. The diffusion-controlled Jander's equation was applied to all kinetic data obtained. In the case of fluoride additives, it has been found that the promoting actions are in the order $LiF \geq NaF > BaF_2 > MgF_2 > CaF_2$ and that the cations of fluorides play an important role in accelerating diffusion. The same promoting mechanism seems to be applicable in the case of chloride additives.

Solid state reactions are affected by various factors such as impurities or additives, preparation history of reacting material and atmosphere.[1,2] The effect of additives on the solid state reaction in MgO–Al_2O_3 system has been investigated by several authors.[3-5] Little attention, however, has been paid to the effect of additives on the solid state reaction, no explanation being given on their actions from a kinetic viewpoint.

In this paper, the promoting actions of alkali and alkaline earth halides on the formation of $MgAl_2O_4$ were discussed on the basis of the kinetic data. It was examined whether a mechanism similar to that for $MgCl_2$[6] additive could be applied to other chlorides.

Experimental

Sample. α-Al_2O_3 samples were prepared by calcining active alumina (Merck Co., 99.9% pure) at 1300 °C for 2 hr in the air. MgO samples were prepared from $Mg(OH)_2$ (Kanto Chemical Co., G.R. grade) under the same conditions. The particle size of α-Al_2O_3 was microscopically estimated to be in the range 58—90 μ, with an average of 70 μ. The MgO was found to have an average particle size of 0.1 μ by electron-microscopic observation. Powders of MgO, α-Al_2O_3 and additive were well mixed in the molar ratio 1 : 1 : 0.1. The additives used were LiF, NaF, MgF_2, CaF_2, BaF_2, NaCl and $CaCl_2 \cdot H_2O$ and were stored in a desiccator with silica gel before experiments. The additives (Kanto, Wako or Morita Companies) were of G.R. grade. The mixtures were pressed into pellets at 150 kg/cm^2 except for $CaCl_2 \cdot H_2O$ additive. The powders of MgO, α-Al_2O_3 and $CaCl_2 \cdot H_2O$ were mixed in a dry box because of the hygroscopic nature of $CaCl_2 \cdot H_2O$. These powder mixtures were heated at 400 °C to dehydrate $CaCl_2 \cdot H_2O$ prior to the kinetic experiment.

Kinetic Measurements. Two furnaces, Pt- and SiC-electric furnaces, were used for the measurements. The Pt-furnace was used for MgO–Al_2O_3–additive (LiF, NaF, MgF_2, BaF_2, NaCl or $CaCl_2$) systems in the temperature range 670—1100 °C). The furnace was equipped with a fused-silica tube connected to the vacuum system in which static nitrogen pressure was kept at 300 mmHg. The SiC-furnace was used for MgO–Al_2O_3 and MgO–Al_2O_3–CaF_2 systems in the temperature range 1100—1360 °C. This was equipped with a mullite tube through which nitrogen was allowed to flow at a rate of 30 ml/min. Compact pellets were placed on a Pt-boat in the tube and then heated isothermally. The temperature was measured with a Pt-Pt13Rh thermocouple.

Conversion of $MgAl_2O_4$ was determined by measuring the amount of the remaining MgO or α-Al_2O_3 after the reaction. The MgO unreacted was dissolved in 1.0 M nitric acid. The procedure was applied to the samples in the experiments of MgO–Al_2O_3 system and MgO–Al_2O_3–additive (LiF, NaF, NaCl or $CaCl_2$) system. Before titration, $CaCl_2$ was removed by washing the sample with alcohol. The amount of unreacted α-Al_2O_3 was estimated from the quantitative X-ray analysis by using CaF_2 as an external standard. This method was applied to the samples obtained from the MgO–Al_2O_3–additive (MgF_2, CaF_2 or BaF_2) systems. The results are shown in Table 1, and a satisfactory agreement can be seen between the chemical analysis and X-ray method.

a) results for 10 mol % additive of NaF

Reaction in MgO–Al_2O_3–additive System by the use of Pellets of MgO and α-Al_2O_3 (Model experiments). MgO and α-Al_2O_3 pellets, *ca.* 1 mm thick, were obtained by heating the compressed powders of MgO and α-Al_2O_3 at 1300 °C for 3 hr in the air. The experiment was carried out in the temperature range 900—950 °C for 5 hr in a vacuum (10^{-1} mmHg). The samples were prepared by sandwiching the powders of additives *ca.* 0.1 mm thick (LiF, NaF, BaF_2, LiCl, NaCl or $CaCl_2$) between MgO and α-Al_2O_3 pellets. After the reaction, the chlorides adhering to the pellets were removed by washing with alcohol in order to observe the surfaces and to measure the weight change of the pellets.

DTA Experiments. DTA experiments on the MgO–Al_2O_3–NaF system were carried out in nitrogen atmosphere at a heating rate of 10 °C/min. The sample was a mixture of MgO, α-Al_2O_3 and NaF with mol ratio 1 : 1 : 0.1, its weight being 300 mg.

Results and Discussion

Formation Rate of $MgAl_2O_4$. The rate of reaction between reactant particles is generally governed by either phase-boundary process or diffusion process.[7] The equations for the diffusion-controlled reaction have

been given by Jander,[8] Serin-Ellickson,[9] Ginstling-Brounshtein,[10] and Carter.[11] Jander's equation is

$$[1-(1-\alpha)^{1/3}]^2 = kt \quad (1)$$

$$k = 2DC_0/R^2 \quad (2)$$

where α=fractional conversion, k=rate constant, t=reaction time, D=diffusion coefficient, C_0=concentration of reactant at the interface, and R=particle radius.

The formation rates of $MgAl_2O_4$ in MgO–Al_2O_3 system and MgO–Al_2O_3–additive systems are shown in Figs. 1 and 2. All the data were obtained from the pellet except for the $CaCl_2$ additive (Fig. 2-D). The ⊗ marks in Fig. 1-A indicate the α values for loosely packed powder mixtures of MgO and α-Al_2O_3 heated at 1190 °C. Little difference was observed in the α values between the loosely packed powders and the compacted pellets under these experimental conditions.

A part of the data given in Figs. 1 and 2 plotted according to Eq. (1) is shown in Fig. 3. It can be seen that the data can fit Jander's equation up to about α=70%. For MgO-Al_2O_3 mixtures (Fig. 3-B, ○ and

●) and those containing the fluoride additives (Fig. 3-A), the straight lines intersect the ordinate at kt values corresponding to α=20—30%. The fluoride additives seem to show larger intersecting values than those for non-additives systems. The straight lines of the chloride additives, however, fall approximately on the original point (Fig. 3-B). It seems that in the case of the fluoride additives, the initial formation of $MgAl_2O_4$ results from the reaction at the surface between the particles, and the subsequent reaction proceeds by the diffusion of the reactants through the $MgAl_2O_4$ layer formed. Abrupt change in slope was observed only for LiF additive system (Fig. 3—A, ○ and ●).

The rate constant k can be estimated from the slope of line in Fig. 3. The activation thermodynamic functions, ΔG^*, ΔH^*, ΔS^*, are calculated by

$$k = RT/Nh \exp(\Delta S^*/R) \exp(-\Delta H^*/RT) \quad (3)$$

where R=gas constant, T=absolute temperature, N=Avogadro's number, and h=Planck's constant. The transmission coefficient is assumed to be unity. The

B: ○: 1190 °C, ●: 1240 °C } non-additive; △: 1006 °C } NaCl; ⊙: 900 °C, ◐: 953 °C } $CaCl_2$

values listed in Table 2 illustrate how greatly the formation reaction of $MgAl_2O_4$ is promoted by the presence of the additives. From the values for ΔG^*, the promoting actions of the additives can be represented by the sequences, LiF ≥ NaF > BaF_2 > $CaCl_2$ > NaCl > MgF_2 > CaF_2.

A comparison of the activation thermodynamic functions for the various additive systems with those for the non-additive system also shows that the additive systems give the values of ΔH^* and ΔS^* differing from those for non-additive system. This suggests that the diffusion mechanism in the additive systems differs from that in the non-additive system.

Halvac[12] studied the reaction of the powder compacts of α-Al_2O_3 and MgO in the air, in the temperature range 1000—1290 °C, and suggested that the formation rate of $MgAl_2O_4$ was controlled by either grain-boundary or volume diffusion step. The values of D in this temperature range have been calculated to be $D=10^{-12}$ 10^{-10} cm^2/s in the temperature range 1190—1360 °C, by assuming that $R=0.007$ cm, $C_0=1.0$[13] in Eq. (2). The value closely agrees with Halvac's. For LiF, NaF, BaF_2 and $CaCl_2$ additives, the values of D were also found to be $D=10^{-10}-10^{-8}$ cm^2/s in the temperature range 800—1000 °C, which was larger than the value of D for the non-additive system by a factor of 10^3—10^5, when D's at 800—1000 °C were corrected for 1190—1360 °C. The comparable values of D for the non-additive system therefore show that the grain-boundary or volume diffusion should be operative in the formation of $MgAl_2O_4$. On the other hand, the significant increase in the value of D in the case of LiF, NaF, BaF_2 and $CaCl_2$ additives indicates that these additives exert an enhancing action on the diffusion along grain-boundary or within bulk.

Model Experiment. The formation of $MgAl_2O_4$ in the systems with fluoride additives seems to consist of two stages; rapid reaction at the surface between the particles in the initial stage and diffusion in the later stage. In order to examine the rapid reaction at the surface, model experiments were carried out by using α-Al_2O_3 and MgO pellets between which the fluorides were placed.

Although the chloride additions showed no such rapid reaction at the surface, the interactions of chlorides with MgO or α-Al_2O_3 were examined by model experiments.

Fluoride: The model reaction on MgO–Al_2O_3–fluoride (LiF, NaF or BaF_2) systems was carried out at 950 °C for 5 hr in a vacuum.

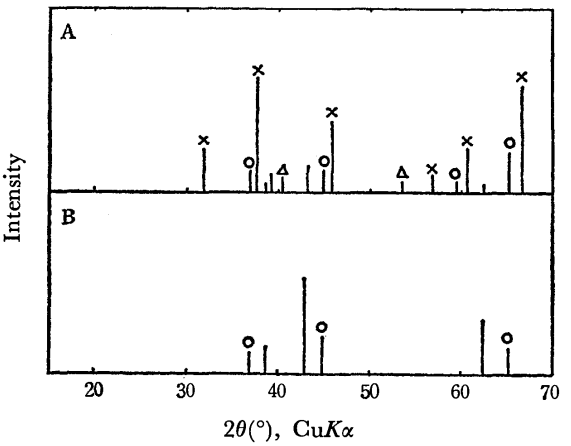

Fig. 4. X-ray diffraction patterns of the reaction surface of α-Al_2O_3 and MgO pellets in the MgO–Al_2O_3–LiF system.
Reaction temperature: 950 °C, time: 5 hr, in vacuum (10^{-1} mmHg).
A: α-Al_2O_3 pellet, B: MgO pellet
○: $MgAl_2O_4$, ×: $LiAl_5O_8$, △: MgF_2

Figure 4 shows the X-ray diffraction patterns of the surface of α-Al_2O_3 and MgO pellets obtained by the reaction in MgO–Al_2O_3–LiF system. We see that $LiAl_5O_8$ is formed on the surface of α-Al_2O_3 pellet (Fig. 4-A). Another two experiments showed that $NaAl_{11}O_{17}$ and $BaAl_2O_4$ were formed on the surface of α-Al_2O_3 pellet in the reaction of MgO–Al_2O_3–NaF system and MgO–Al_2O_3–BaF_2 system, respectively. $NaAl_{11}O_{17}$ was assumed to result from unreacted α-Al_2O_3 and $Na_2Al_2O_4$ formed from α-Al_2O_3 and NaF.[14] Thus, it can be concluded that the reaction of α-Al_2O_3 with fluoride results in the formation of aluminate.

Chloride: The model reactions of MgO–Al_2O_3–chloride ($CaCl_2$, LiCl or NaCl) systems were performed at 900—950 °C for 5 hr in a vacuum.

Table 3. Weight change of pellets of MgO and α-Al_2O_3 for the model reactions in the MgO-Al_2O_3-chloride systems

Additives	React. temp. (°C)	React. time (hr)	Melting point of additives[a] (°C)	Weight changes (mg) MgO[b]	Weight changes (mg) α-Al_2O_3[c]
$CaCl_2$	900	5.0	782	− 2	+ 5
$CaCl_2$	950	5.0	782	−21	+10
LiCl	940	5.0	610	− 4	+14
NaCl[d]	950	5.0	808	—	—
non-additive	960	5.0	—	0	0

a) From Ref. 15. b) weight loss of MgO pellets. c) Weight increase of α-Al_2O_3 pellets. Two pellets of MgO and α-Al_2O_3 could not be separated. The reacted surface of α-Al_2O_3 pellet obtained was exposed by polishing.

The weight changes of MgO and α-Al_2O_3 pellets and the melting point of additives are given in Table 3. The weight of MgO pellets is seen to decrease and that of α-Al_2O_3 pellets to increase. The X-ray diffraction patterns of the reacted surface of the pellets indicate that $MgAl_2O_4$ is formed only on the α-Al_2O_3 surface. These results suggest that molten chloride behaves as a vehicle, in which MgO is dissolved to disperse uniformly, and the molten phase containing MgO is transported into the α-Al_2O_3 particle which is an agglomerate of the crystallites.

Promoting Actions of Additives. *Fluoride*: From the results it seems that a large part of the cations of fluoride exists in the form of aluminate which is incorporated into $MgAl_2O_4$ layer. Thus, it is necessary to examine whether such cations exert an influence on the diffusion process.

The plots of log ($k_{additive}/k_{pure}$) for 1173 K against the electronegativity of cations[16] are shown in Fig. 5. The logarithmic ratios corrected for $T=1174$ K were calculated by means of Eq. (3) and the value of the thermodynamic functions in Table 2. The figure shows an exponential increase in the formation rate with the decrease in the electronegativity of cations. The activation enthalpy, ΔH^*, can be correlated with the electronegativity as shown in Fig. 6; the value of ΔH^* decreases linearly with the decrease in the electronegativity except for the NaF additive. It can be concluded

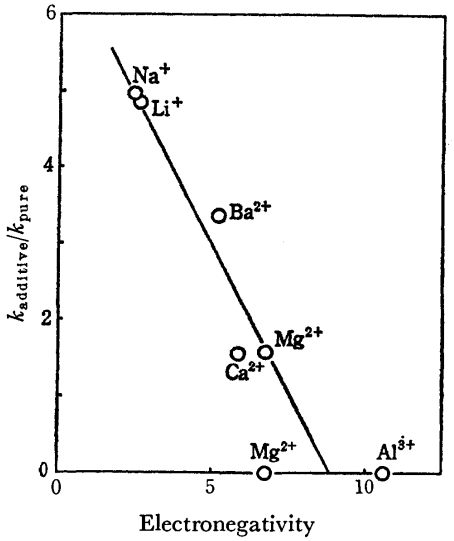

Fig. 5. Relationship between log ($k_{additive}/k_{pure}$) and the electronegativity of cations of fluorides.

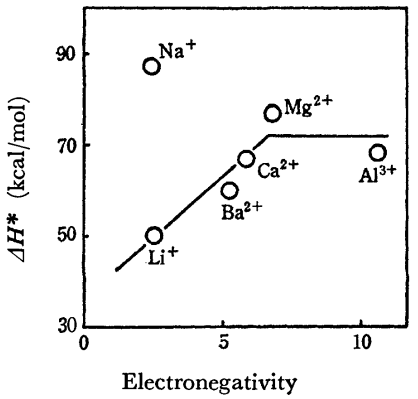

Fig. 6. Relationship between ΔH^* and the electronegativity of cations of fluorides.

that the cation of additives plays an important role in increasing the mobility of the Mg^{2+} or Al^{3+} ions and in lowering the energy required for diffusion.

The exceptional ΔH^* value of the NaF additive seems to be associated with the presence of liquid phase, since the DTA curves for MgO-Al_2O_3-NaF system showed an endothermic peak due to formation of liquid phase at near 800 °C. A similar relation between the large ΔH^* and the presence of liquid phase holds for the cases of $CaCl_2$ (ΔH^*=113 kcal/mol) and NaCl (ΔH^*= 104 kcal/mol) additives which are in liquid state at the reaction temperatures. The presence of liquid phase in the course of the reaction might be associated with the possitive value of ΔS^* of these additives (Table 2) which shows an activated state disordered more than the reactants.

Chloride: The same mechanism as that for the molten $MgCl_2$ may be applied to the other chloride additives since they are in liquid state at reaction temperatures. MgO particles may dissolve in the molten chloride, then they spread uniformly over the surface of α-Al_2O_3 particles and are transported to the inner part of α-Al_2O_3 particles consisting of the crystallites. In such cases, the value of C_0 in Eq. (2) is expected to be large and the diffusion distance reduced from the radius (R=70 μ) of α-Al_2O_3 particle to that (R=1—2 μ) of α-Al_2O_3 crystallites. However, such a reduction of distance would not occur in the non-additive system because of the absence of molten phase.

Effect of Additive on Solid State Reaction. II. A Thermoanalytical Study of the Effect of Fluorides on the Formation of $MgAl_2O_4$ in Initial Stage

Shiro SHIMADA, Ryusaburo FURUICHI, and Tadao ISHII

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received July 9, 1973)

The promoting actions of fluoride on the formation of $MgAl_2O_4$ in the initial stage have been studied by means of DTA and high-temperature X-ray diffraction techniques. LiF, NaF, MgF_2, CaF_2 and BaF_2 were used as additives. The three MgO-Al_2O_3-fluoride (LiF, NaF or BaF_2) systems showed similar DTA curves; an endothermic peak (peak-1) in the temperature range 660—800 °C, followed by an exothermic peak (peak-2) at 700—900 °C. The DTA curves for MgO-Al_2O_3-fluoride (MgF_2 or CaF_2) systems showed no thermal change. It was found that peak 1 corresponds to Reaction (2), $3MF+2Al_2O_3=3MAlO_2+AlF_3$, and peak 2 to Reaction (1), $3MgO+2AlF_3=3MgF_2+Al_2O_3$, and the formation of $MgAl_2O_4$. It was concluded that Reaction (2) takes place before the formation of $MgAl_2O_4$ and that AlF_3 resulting from Reaction (2) initiates the formation of $MgAl_2O_4$.

In the preceding paper[1] the promoting actions of fluorides and chlorides on the formation of $MgAl_2O_4$ were discussed from a kinetic viewpoint. Rate constants were obtained from isothermal experiments for determining the extent of promoting action. Some clues for the reaction mechanism such as a linear relation between the rate constant and electronegativity of cations of the halides were also obtained. However, it was not possible to see what kind of chemical reaction between the halide additives and reactants MgO and Al_2O_3 promotes the formation. DTA and high-temperature X-ray diffraction, both being non-isothermal techniques, are useful for clarifying the reaction over a wide temperature range and for finding the initiation temperature of the reaction. We have studied MgO–Al_2O_3–fluoride systems by the non-isothermal technique in order to find the chemical reaction between additive and reactant.

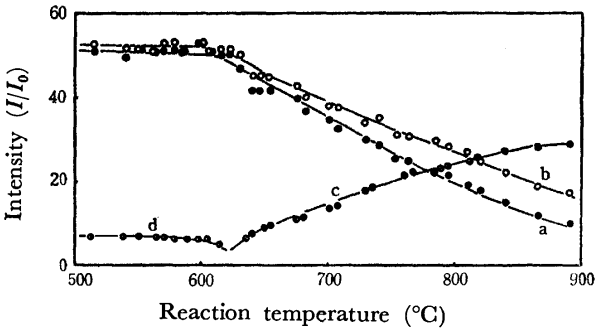

Fig. 1. High-temperature X-ray diffraction patterns of the reaction in MgO-Al_2O_3-LiF system. Molar mixing ratio: 1 : 1 : 0.2, Heating rate: 2—4 °C/min, in N_2 (300 mmHg).
a: α-Al_2O_3 (113), b: MgO (200), c: $MgAl_2O_4$ (400), d: LiF (200)

Experimental

Sample. α-Al_2O_3 and MgO samples were prepared by a method similar to that described.[1] The particle size of sample was smaller than 44 μ for α-Al_2O_3 and *ca.* 0.1 μ for MgO. The fluorides used as additive were LiF, NaF, MgF_2, CaF_2 and BaF_2.

DTA Experiments. DTA experiments were carried out with a Thermoflex 8001 type apparatus (Rigaku-Denki). Before heating the sample, the apparatus was evacuated to approximately 10^{-1} mmHg and then filled with N_2 of 300 mmHg to avoid the effect of water vapor in the air. Pt-Pt13Rh thermocouples were used for measuring the temperature, a heating rate of 10 °C/min being employed in all experiments. The sample weight was about 300 mg. α-Al_2O_3 of the same weight was taken as the standard material.

X-Ray Diffraction. A Geigerflex 2141 type diffractometer (Rigaku-Denki) was used for X-ray analysis of the samples obtained during DTA runs, the analysis being carried out with Ni-filtered Cu$K\alpha$, operation voltage 25 kV and current 10 mA. The fractional conversion of $MgAl_2O_4$ was determined by the quantitative X-ray analysis.[1]

High-temperature X-Ray Diffraction. A high-temperature A-4 type attachment (Rigaku-Denki) was used. The experiments were carried out in static N_2 of 300 mmHg at heating rate of 2—4 °C/min, operation voltage and current respectively 40 kV and 20 mA.

Results and Discussion

MgO-Al_2O_3-LiF System. The change of high-temperature X-ray diffraction intensities with the reaction temperature is shown in Fig. 1. Curve a: (113) line of α-Al_2O_3, Curve b: (200) of MgO, Curve c: (400) of $MgAl_2O_4$, Curve d: (200) of LiF. We see that $MgAl_2O_4$ begins to form simultaneously with the decrease of the reactants of MgO, α-Al_2O_3 and LiF near 630 °C, and that in the initial stage of the $MgAl_2O_4$ formation, the extent of the decrease in the X-ray intensity with temperature is larger for α-Al_2O_3 than for MgO. The shift of (200) diffraction line of LiF to the lower angle starts at a temperature near 400 °C. At 630 °C, the shift became 1°, and the diffraction line of $MgAl_2O_4$ appears. This shift indicates that LiF is strongly thermally expanded at the temperature of beginning of the formation of $MgAl_2O_4$.[2]

Figure 2 shows DTA curves (A: 1 : 1 : 0.2 mixture of MgO, Al_2O_3 and LiF in molar ratio) and X-ray diffraction patterns of the samples heated up to temperatures corresponding to points a and b on Curve A. The curve shows one endothermic peak 1 in the range 660—690 °C and one exothermic peak 2 in 690—750 °C. The cycles of heating and cooling of the sample for Curve A give endothermic and exothermic changes at 780—790 °C, respectively (Curve B). The samples containing LiF (0.5 molar ratio) showed DTA curves similar to Curves A and B. The DTA curves of MgO–LiF, Al_2O_3–LiF and MgO-Al_2O_3 systems, however, showed no thermal changes in the range 20—1000 °C except for the endothermic peak due to melting of LiF. It thus seems that only the ternary system of MgO,

a) From Ref. 7.

Al_2O_3 and LiF shows peaks 1 and 2 (Curve A, Fig. 2). Peak 2 is probably related to the formation of $MgAl_2O_4$, since $MgAl_2O_4$ is formed at point a after peak 2 and $\Delta H°$ of this spinel formation is −9.1 kcal/mol (Table 1). At point b, a large amount of $MgAl_2O_4$ is also found to be formed. The reversible thermal changes of Curve B may be due to the formation of the liquid phase by the reaction in MgO–Al_2O_3–LiF system.

MgO–Al_2O_3–NaF System. Figure 3 shows the results of high-temperature X-ray analysis for the reaction of MgO–Al_2O_3–NaF system. The initiation of formation of $MgAl_2O_4$ is seen at 720 °C, a rapid increase in its amount with the rapid decrease in that of MgO and Al_2O_3 being observed. The temperature dependency leads to a large activation energy for the ΔH^* value formation of $MgAl_2O_4$. This is consistent with a ΔH^* value large (activation enthalpy).[1)] The thermal expansion of NaF is considered to be significant at 720 °C, since the large shift of diffraction line (200) to the

lower angle with temperature, similar to the case of LiF, was also observed for NaF.[3]

Figur 4 shows DTA curves and X-ray diffraction patterns of samples heated up to temperatures corresponding to points a, b and c on Curves C and D. The molar mixing ratios of MgO, Al_2O_3 and NaF for Curves A, B and C are: A, 1 : 1 : 0.1; B, 1 : 1 : 0.2; C, 1 : 1 : 0.8. Curve D was obtained from the 1 : 1 binary mixture (weight ratio) of MgF_2 and NaF, and Curve E from the sample used for Curve C after it had been heated up to 960 °C. Each curve of MgO–Al_2O_3–NaF systems shows an endothermic peak 1 in the range 760—795 °C and the overlap of an exothermic peak 2[4] with an endothermic peak 3. The DTA curves of binary systems such as MgO–NaF and Al_2O_3–NaF showed no thermal change except for the melting of NaF.

The fractional conversions of $MgAl_2O_4$ for the samples heated up to 852 °C (point m) on Curve A and up to 842 °C (point n) on Curve B were estimated to be α=60% and 55%, respectively. Comparable α values imply that the amount of $MgAl_2O_4$ produced does not necessarily depend on the amount of NaF added. The area of peak 2 seems to increase with the amount of NaF, suggesting peak 2 to contain another exothermic reaction in addition to $MgAl_2O_4$ formation. From X-ray diffraction patterns (Fig. 4), the presence of $NaMgF_3$, a complex compound formed from NaF and MgF_2,[5] is observed in addition to $MgAl_2O_4$ at point b on Curve C. Thus, it can be assumed that the exothermic peak 2 is due to the formation of $MgAl_2O_4$ and MgF_2. Peak 3 is considered to be due to the formation of liquid phase, since the cycles of heating and cooling of the sample for Curve C give endothermic and exothermic changes (Curve E). The two peak temperatures in Curve E are in agreement with those in Curve D obtained from MgF_2–NaF mixture, the temperatures being near the eutectic temperature of $NaMgF_3$ and NaF.[6] Thus, peak 3 might correspond to the melting of the mixture of $NaMgF_3$ and NaF. The results show that MgF_2 is formed in the MgO–Al_2O_3–NaF system, but not in the MgO–NaF system.

MgO–Al_2O_3–BaF_2 System. The results of high-temperature X-ray diffraction of this system are shown in Fig. 5. BaF_2 begins to decrease at *ca.* 680 °C (Curve d), and subsequently $MgAl_2O_4$ and $BaAl_2O_4$ begin to form near 700 °C (Curves c and e) with the simultaneous decrease of MgO and α–Al_2O_3 (Curves b and a). $BaAl_2O_4$ could be formed from the reaction of BaF_2 with α–Al_2O_3.

Figure 6 shows DTA curve (A: 1 : 1 : 0.5 mixture of MgO, Al_2O_3 and BaF_3 in molar ratio) and X-ray diffraction patterns of sample heated up to 870 °C (point a). Curve A shows similar thermal behaviors; a small endothermic peak 1, followed by an exothermic peak 2. DTA curves for the binary system of MgO–BaF_2 and Al_2O_3–BaF_2, however, showed no thermal change in the range 20—1100 °C. The cycles of heating and cooling of the sample for Curve A show no thermal change either. $MgAl_2O_4$ and $BaAl_2O_4$ were found to form at point a and the fractional conversion of $MgAl_2O_4$ was 63%. Thus peak 2 is related to the formation of $MgAl_2O_4$.

MgO–Al_2O_3–MgF_2 System. The high-temperature X-ray diffraction data are shown in Fig. 7. $MgAl_2O_4$ begins to form near 835 °C (Curve c) accompanied by the decrease of MgO, α-Al_2O_3 and MgF_2 (Curves b, a and d). The DTA curves in the MgO–Al_2O_3–MgF_2 and MgO–Al_2O_3–CaF_2 systems showed no thermal change in the range 20—1100 °C.

The Reaction of Fluorides with MgO and α-Al_2O_3. Peak 2 in Fig. 4 (MgO–Al_2O_3–NaF system) was found to correspond to the reaction, $MgO+Al_2O_3=MgAl_2O_4$ with $\Delta H°=-9.1$ kcal/mol, and to another extra exothermic reaction which seems to be MgF_2 formation from MgO and fluoride from the results of X-ray and DTA experiments. It was also found that the systems containing LiF (Fig. 2) and BaF_2 (Fig. 6) showed two peaks on the DTA curves similar to those of MgO–Al_2O_3–NaF system. Thus, peak 2 on the DTA curves of the systems containing LiF and BaF_2 is also assumed

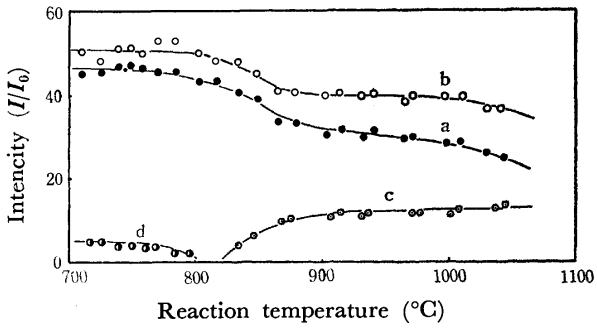

Fig. 7. High-temperature X-ray diffraction patterns of the reaction in $MgO-Al_2O_3-MgF_2$ system. Molar mixing ratio: 1 : 1 : 0.2, heating rate: 2—4 °C/min, in N_2 (300 mmHg).
a: α-Al_2O_3 (113), b: MgO (200), c: $MgAl_2O_4$ (400), d: MgF_2 (111)

to be due to the formation of MgF_2 and $MgAl_2O_4$, the latter being confirmed by X-ray analysis.

Three possible reactions, those of MgO with MF, AlOF or AlF_3, can be considered for MgF_2 formation (Table 1). However, the reactions of MgO with MF and AlOF can be excluded, since $\Delta H°$, the heat of the reaction of MgO with MF is positive, *viz.*, endothermic and experimental evidence for AlOF formation at temperatures below 1700 °C has not been reported.[8] Thus, it is reasonable to assume that MgF_2 is formed by the reaction

$$3MgO + 2AlF_3 = 3MgF_2 + Al_2O_3 \quad (1)$$

where AlF_3 is endothermally formed from Al_2O_3 and fluoride (Table 1). Thus the endothermic peak 1, which precedes peak 2, would be due to the reaction of α-Al_2O_3 with fluoride. On the other hand, the binary systems, Al_2O_3–fluoride, showed neither thermal changes in DTA curves nor X-ray diffraction lines of AlF_3. The results lead to an assumption that AlF_3 is formed from Al_2O_3 and fluoride in the presence of MgO in the temperature range 20—1000 °C. The reactions considered possible for peak 1 are as follows.

$$2Al_2O_3 + 3M^{I}F \xrightarrow{MgO} 3M^{I}AlO_2 + AlF_3 \quad (2)$$

$$4Al_2O_3 + 6M^{I}F \xrightarrow{MgO} 3M^{I}_2Al_2O_4 + 2AlF_3 \quad (2')$$

$$4Al_2O_3 + 3M^{II}F_2 \xrightarrow{MgO} 3M^{II}Al_2O_4 + 2AlF_3 \quad (3)$$

Formation of $M^{II}Al_2O_4$ was observed in the BaF_2–Al_2O_3–MgO system ($BaAl_2O_4$), and $NaAl_{11}O_{17}$, assumed to result from $M^{I}_2Al_2O_4$ ($Na_2Al_2O_4$) and Al_2O_3, was found in NaF–Al_2O_3–MgO system when NaF was sandwiched between MgO was Al_2O_3 pellets.[1]

AlF_3 was not found in any system examined directly by X-ray. This might be due to the small amount of fluoride additives and the easily occurring sublimation of AlF_3.[9] In order to examine the effects of AlF_3 resulting from Reaction (2)—(3), experiments were carried out for MgO–Al_2O_3–AlF_3 and MgO–AlF_3 system. Figure 8 shows DTA curves (A: MgO–Al_2O_3–AlF_3 system; B: MgO–AlF_3 system) and X-ray diffraction patterns. $AlF_3 \cdot H_2O$ used as starting material was subjected to dehydration in order to obtain anhydride AlF_3

at 200—300 °C. MgO–AlF_3 system (Curve B) shows an exothermic peak due to Reaction (1) at 790—850 °C, since X-ray analysis indicated the formation of MgF_2 after this peak (point c). Curve A shows two exothermic peaks in the ranges 750—800 °C and 800—870 °C; the first corresponds to the exothermic peak on Curve B since only MgF_2 is formed at point a on Curve A; the second peak might be due to the formation of $MgAl_2O_4$, since $MgAl_2O_4$ was found to form at point b. It is thought that two exothermic peaks on Curve A can be associated with reaction of the exothermic peak 2 (Figs. 2, 4 and 6). The conversion of $MgAl_2O_4$ at point b (890 °C) was estimated to be α=32%. This

a: LiF, b: BaF_2, c: NaF, d: MgF_2

is comparable with $\alpha=20$—30%, the values corresponding to the rapid $MgAl_2O_4$ formation observed in the initial stage of isothermal experiments.[1] It seems from the data of MgO–Al_2O_3–AlF_3 (Fig. 9) that the presence of AlF_3 promotes the formation of $MgAl_2O_4$ as much as alkali and alkaline earth fluorides.

The formation of $MgAl_2O_4$ might be initiated by the presence of fluorides which form AlF_3 (Eqs. (2) and (3)), although each fluoride gives different initiation temperatures (Fig. 10). We see that the lower the value of $\Delta H°$ for Eqs. (2) and (3), the lower the initiation temperature of $MgAl_2O_4$ formation which can be determined by the high-temperature X-ray diffraction. We also see that the lower the melting point of the fluoride[10] except for point d (BaF_2), the lower the initiation temperature. This seems to be correlated to the strong thermal expansion of the crystalline lattices of LiF and NaF: the thermal vibration of these fluorides lattices is enhanced by the rise in temperature, and the exchange reaction between F^- and O^{-2} on the surface of α-Al_2O_3 and/or MgO particles occurs to form AlF_3. This might influence the surface of α-Al_2O_3 and MgO particles and causes the reaction between MgO and α-Al_2O_3 leading to the formation of $MgAl_2O_4$. The deviation of point d from the straight line (Fig. 10) cannot be explained at present.

The cations of fluoride play an important role in the enhancement of diffusion rate.[1] If the activation enthalpy (Table 2, Ref. 1) can be taken as a relative measure of the ease of the occurrence of reaction, it is expected that the smaller the activation enthalpy, the lower the initiation temperature of the formation of $MgAl_2O_4$. This is satisfied in Fig. 11 except for point c. Accordingly, it can be assumed that the initiation temperature of $MgAl_2O_4$ formation is lowered by the incorporation of Reactions (1), (2) and (3) with the reaction between MgO and α-Al_2O_3.

The Thermal Deaquation-Anation Reactions of Aquopentamminechromium(III) Complexes in the Solid State

Kenzo NAGASE and Hiroko YOKOBAYASHI

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received September 28, 1973)

The thermal deaquation-anation reactions of aquopentamminechromium(III) nitrate, chloride, bromide, and iodide in the solid state were investigated by the techniques of TG, DSC, X-ray powder diffraction analysis, and manometry. The first-order rate constants were obtained by isothermal kinetics. The activation enthalpies calculated from the first-order rate constants increased in the order: the nitrate(24.3) <the chloride(26.4) <the bromide(29.7) <the iodide(30.7 kcal/mol). The enthalpy changes by DSC were 12.3, 6.5, 6.3, and 7.0 kcal/mol for the nitrate, chloride, bromide, and iodide respectively. The slight deviation from the first-order kinetics was observed in cases of the nitrate and the chloride.

Although the deaquation-anation reactions of aquopentamminechromium(III) complexes in the solid state have been widely investigated by several workers, some problems still remain. The deaquation-anation reactions of aquopentamminechromium(III) complexes are, in general, represented by this equation:

$$[Cr(H_2O)(NH_3)_5]X_3 \longrightarrow [CrX(NH_3)_5]X_2 + H_2O$$

where X contains of nitrate, chloride, bromide, and iodide anions. The temperature of the initial weight-loss, which is taken as a measure of the thermal stability of the complex, was given by Wendlandt and Bear[1] as increasing in this order: the chloride <the nitrate <the bromide <the iodide. According to Tsuchiya and his co-workers,[2] though, the order is as follows:

the nitrate <the chloride <the bromide <the iodide

(40°) (60°) (68°) (70°C)

The thermal stabilities of the complexes depend on the variety of outer-sphere anions, and the order given by Tsuchiya *et al.* differs, of course, from that by Wendlandt and Bear.

Wendlandt and Bear[1] were the first to obtain the kinetic data of the deaquation-anation reactions of the aquopentamminechromium(III) complexes. They obtained the first-order rate constants by following the increase in the water vapor-pressure as a function of time at given temperature; the activation energies were thereby calculated to be 16, 18, 31, and 18 kcal/mol for the nitrate, chloride, bromide, and iodide respectively. Tsuchiya and his co-workers[2] also obtained the activation energies of the sulfate and sulfate in addition to those of the four complexes by non-isothermal methods, DTA or DTG curve analyses. The activation energies obtained by two groups of workers are in good agreement with one another except for those of the chloride.

Tsuchiya and his co-workers[2] discussed the mechanisms of the deaquation-anation reactions on the basis of the activation energies obtained and suggested that the bromide, sulfate, and sulfite, which have the larger activation energies, include, to some extent, the tendency of S_N1; this is attributed to the larger ionic radii of the bromide, sulfate, and sulfite anions. Their discussion seems reasonable, but the question remains of why the iodide, which contains the larger iodide anion has the smaller activation energy.

In the present paper, the deaquation-anation reactions of some aquopentamminechromium(III) complexes will be re-examined in order to explain the problems mentioned above.

Experimental

Materials. Aquopentamminechromium(III) nitrate[3] was prepared by the method in the literature and was recrystallized by adding a small amount of concentrated nitric acid to an aqueous solution of $[Cr(H_2O)(NH_3)_5](NO_3)_3$ below 20 °C. The chloride, bromide, and iodide were obtained by adding concentrated hydrochloric, hydrobromic, and hydriodic acid respectively to an aqueous solution of pure $[Cr(H_2O)(NH_3)_5](NO_3)_3$ below 20 °C. In each case, this process was repeated two times. The elemental analyses for N and H agreed with the calculated values within ±0.3%.

Measurements. The TG and DSC curves were simultaneously recorded with a Rigaku 8002 CS apparatus at a heating rate of 3 °C/min in a flowing-nitrogen atmosphere of 50 ml/min. Twenty milligrams of the powdered sample were placed in a crucible made from an aluminum sheet 0.1 mm thick. A lid of the same material rested inside the crucible. α-Alumina was used as the reference material. The heats of the deaquation-anation reactions were measured from the areas of the DSC curves. The instrument was calibrated in the sensitivity range of 2 millical/full-scale deflections, from the heat of transition of potassium nitrate, which appears at 128 °C with ΔH(transition) = 12.28 kcal/mol.

The X-ray diffraction patterns were measured with a Toshiba diffractometer ADG 101 equipped with a standard high-temperature sample holder in a vacuum. Copper-$K\alpha$ radiation with a nickel filter was used.

Pressure-time curves were obtained at a constant temperature with the apparatus reported in a previous paper.[4] The temperature of the furnace was kept within ±0.2 °C. The pressure was measured with a mercury manometer and cathetometer reading to 0.01 mm. About twenty milligrams of the sample in a Pyrex crucible were used in each measurement. The final water vapor-pressure became about 4 mmHg for $[Cr(H_2O)(NH_3)_5](NO_3)_3$. The procedure was as follows. A system about 300 ml in volume was previously evacuated for 1 hr by means of a rotary pump in order to remove any adsorbed gases. After the system was purged with N_2 gas, the reaction tube was taken out of a furnace

held at the required temperature. The sample was placed in the reaction tube, and then the reaction tube was again inserted in the furnace, which was immediately evacuated for 3 min. The system was closed by operating two stopcocks, and the change in the pressure with the time was measured.

Results

TG and DSC Studies. The DSC curves of the aquopentamminechromium(III) complexes gave a single endothermic peak in the 60—100 °C temperature region. It was found that a crystalline sample and a less crystalline sample of the nitrate gave different thermal stabilities, while the stability of the bromide and iodide were almost independent of their crystalline states, and that the chloride depended, to some extent, on its crystalline state. The corresponding weight-losses from the TG curves were 5.42(5.27), 5.48(5.27), 6.78(6.88), 4.55 (4.56), and 3.52(3.36%) for the nitrate[I], nitrate[II], chloride, bromide, and iodide respectively. Each calculated value of weight-losses is described in parentheses. The nitrate[I] is a crystalline sample which was prepared by the method described in the Experimental section, while [II] is a less crystalline sample which was prepared by adding a large amount of ethanol, all at once, to a saturated aqueous solution of $[Cr(H_2O)(NH_3)_5](NO_3)_3$. The X-ray diffraction patterns of both nitrates are given in Fig. 1, along with those of the nitrate[I] subjected to heat treatment. The temperatures of the initial weight-loss(t_i) and the enthalpy changes (ΔH) corresponding to the deaquation-anation reactions are summarized in Table 1, along with the data described previously.

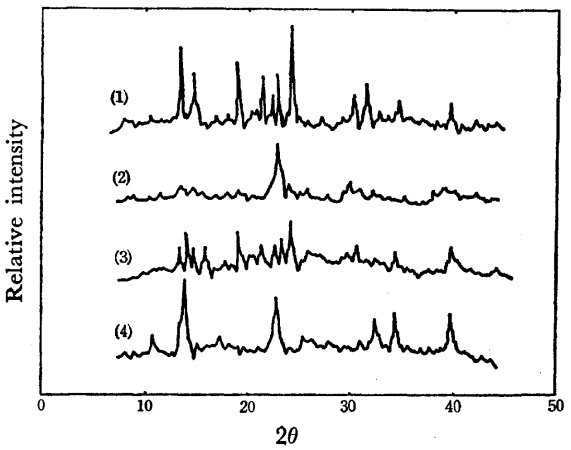

Fig. 1. X-ray diffraction patterns of $[Cr(H_2O)(NH_3)_5](NO_3)_3$ [I](line 1) and [II](2), and of the products after heating the nitrate[I] in a vacuum at 77 °C for 1 hr(3) and 3 hr(4).

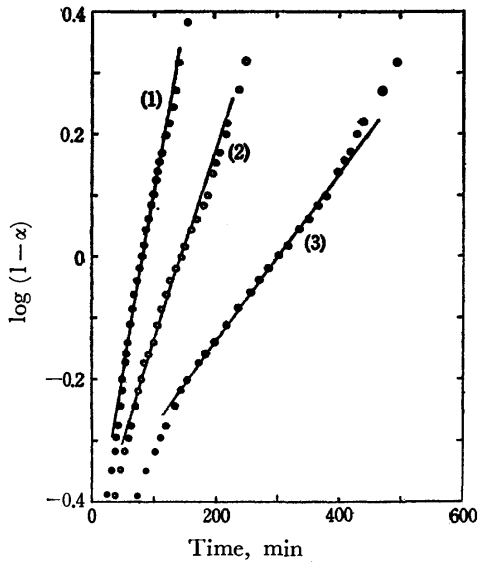

Fig. 4. Plots of log $(1-\alpha)$ *versus* time of $[Cr(H_2O)(NH_3)_5]Br_3$ at (1) 81, (2) 76, and (3) 70.8 °C. The rate constants obtained are a first-order.

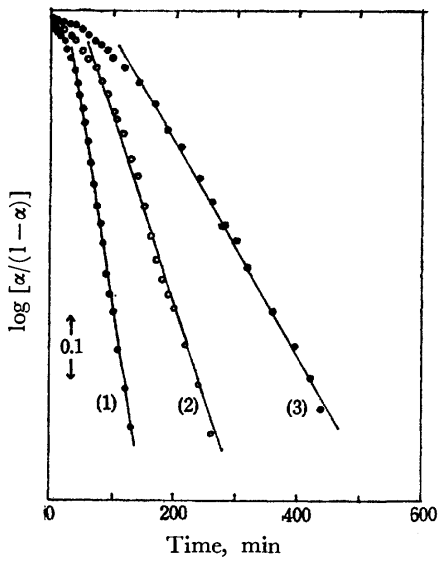

Fig. 5. Plots of log $[\alpha/(1-\alpha)]$ *versus* time of $[Cr(H_2O)(NH_3)_5](NO_3)_3$[I] at 86.5, (2) 81, and (3) 76 °C. The rate constants obtained are a second-order.

All the curves, except for those of the nitrate[I], were analyzed by means of the first-order rate equation: $\ln(1-\alpha)=-kt$. The first-order plots of $[Cr(H_2O)(NH_3)_5]Br_3$ are given in Fig. 4 as examples. The linear relations of $\ln(1-\alpha)$ *versus* the time were maintained in the rang of $0.1<\alpha<0.7$, $0.1<\alpha<0.7$, $0.2<\alpha<0.9$, and $0.2<\alpha<0.9$ for the nitrate[II], chloride, bromide and iodide, respectively. The curves of the nitrate[I] were analyzed by means of the Prout-Tompkins equation.[5] The plots of $\ln[\alpha/(1-\alpha)]$ *versus* the time for the nitrate[I] gave linear relations in the range of $0.1<\alpha<0.8$, as is shown in Fig. 5.

From the rate constants at various temperatures, the activation parameters were calculated. The rate constants(k), activation enthalpies ($\Delta H^{\ddagger}$), and activation entropies ($\Delta S^{\ddagger}$) obtained are presented in Table 2, along with those of the previous works.[1,2]

Discussion

The investigated deaquation-anation reactions of the aquopentamminechromium(III) complexes are essentially initiated by the substitution of an outer-sphere anion for a coordinated water molecule. The nitrate gives different thermal stabilities and shapes of kinetic runs between the crystalline sample and the less crystalline one. The former was dehydrated at temperatures higher than 24 °C, and the shape of the kinetic runs was sigmoidal. Since the reaction of the former gave an induction period and could be described by the $d\alpha/dt=k\alpha(1-\alpha)$ equation in the acceleration and decay periods, the reaction may be supposed to proceed through a nucleation and growth mechanism.[5,6] Therefore, the disagreement with the nitrate results reported in the previous works[1,2] may be due to the difference in the crystalline states of the samples used.

The activation enthalpies obtained from the first-order rate constants at various temperatures increased parallel to the increase in the temperatures of the initial weight-loss. The results differ from those of the previous works, as may be seen in Tables 1 and 2. Since the complexes containing larger anions have larger activation enthalpies, the reactions of the complexes investigated may proceed through the displacement mechanism(S_N2).[7] Although the reactions of the nitrate[II] and chloride have negative activation

a) The second-order rate constant, obtained from $kt=\ln[\alpha/(1-\alpha)]$. b) This value was obtained from the change of weight at constant temperature in a nitrogen atmosphere.

entropies, those of the bromide and iodide have positive values. The latter complexes may not form rigid activated complexes because of the larger ionic sizes of the entering outer-sphere anions.

The activation enthalpies obtained for the deaquation-anation reactions of the aquopentamminechromium(III) complexes are smaller than those for the deammonation-anation reactions of hexamminechromium(III) complexes:[7] $[Cr(NH_3)_6]Cl_3$, 30; $[Cr(NH_3)_6]Br_3$, 43; $[Cr(NH_3)_6]I_3$, 49 kcal/mol. This may be due to the smaller bond strength in $Cr-OH_2$ in the former complexes than those in $Cr-NH_3$ in the latter complexes.

It may be noted that, when the enthalpy changes obtained in this work are compared with the previous data, as in Table 1, there is an approximate agreement among them, only with a few exceptions. The data in the previous works were obtained by DTA. The values chloride, bromide, and iodide are similar to each other, while that of the nitrate is larger. This tendency has also been observed for the deaquation-anation reactions of aquopentamminecobalt(III) complexes.[8]

The authors wish to thank Nobuyuki Tanaka, Professor of Tohoku University, for his advice.

Studies on the Metal Complexes of Quinoxaline Derivatives. III.[1] Metal Chelates of 2-Quinoxalinecarboxylic Acid and Its *N*-Oxides

Yoshinori KIDANI, Kazuo OHIRA, and Hisashi KOIKE

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received December 24, 1973)

Spectrophotometric measurements were carried out for the stability constants of the divalent metal chelates of 2-quinoxalinecarboxylic acid and copper, nickel, cobalt and zinc in a 5% aqueous ethanol solution. Successive stability constants, log K_1, of the copper, nickel, cobalt and zinc chelates were 3.30, 2.87, 2.83 and 2.80, respectively. The metal complexes were difficult to dissolve in water. Copper and cadmium afforded both 1 : 1 and 2 : 1 complexes, while other divalent metals such as nickel, cobalt, manganese, zinc and lead resulted in the 2 : 1 complex formation. From the results of IR and Far-IR spectral analyses it was found that the carboxyl group and the ring nitrogen group appear simultaneously in the chelate formation. Copper complexes of 2-quinoxalinecarboxylic acid 1- and 4-oxides, as well as its 1,4-dioxide were also studied.

Dutt *et al.*[2] attempted the use of 2-quinoxalinecarboxylic acid (2-QxCOOH) as a coprecipitant, since it forms water insoluble metal complexes with various divalent metals, as in the case of quinaldic acid. We reported[3] on the polarographic behavior of quinoxaline derivatives including 2-QxCOOH, and gave hypothesis that among the quinoxaline derivatives studied, the 2-QxCOOH is merged to form structural metal chelate compounds. Syntheses of copper, nickel, cobalt and zinc chelates with 2-QxCOOH were attempted and the stability constants of the metal chelates were determined in a 5% aqueous ethanol solution spectrophotometrically. In order to find the binding site of the metals, cadmium, manganese and lead chelates were also synthesized. Copper complexes of 2-QxCOOH 1- and 4-oxides, and 1,4-dioxide were prepared and examined by IR and Far-IR spectral analyses.

Experimental

Apparatus. Measurements were carried out with a Hitachi EPS-3T spectrophotometer, a Hitachi Model 139 spectrophotometer, a Nihon Bunko IRA-2 infrared spectrophotometer, a Nihon Bunko DS-701G infrared spectrophotometer, a Shimadzu IR 450 infrared spectrophotometer and a Hitachi-Horiba M-5 pH meter.

Reagents. 2-Quinoxalinecarboxylic acid was synthesized according to the method of Maurer and Boettger[4] and its *N*-oxides were prepared by Elina's method.[5] The ligand were recrystallized from EtOH and identified by melting point and elemental analyses. The other reagents used were of reagent grade.

Syntheses of Metal Complexes. Two parts of 0.1 M 2-QxCOOH EtOH solution and one part of a 0.1 M metal acetate aqueous solution were mixed in a 2 : 1 ratio and then heated on a water bath. On being cooled, precipitates were separated and removed and washed first in water and then in hot EtOH. The complexes obtained were dried at 90 °C under reduced pressure, chelates in the ratio 2 : 1 being prepared.

Aqueous solution of metal chloride and 2-QxCOOH EtOH solution were mixed in a 10 : 1 molar ratio, the precipitates deposited were washed with water and dried at 70 °C under reduced pressure. The 1 : 1 chelates of Cu and Cd were thus prepared.

Similarly, a EtOH solution of copper chloride was added to the EtOH solution each of 2-QxCOOH 1-oxide, 4-oxide and 1,4-dioxide in a 2 : 1 molar ratio and then heated. The mixture on being cooled, gave Cu complexes with the ratio 2 : 1. Elemental analyses of the complexes are shown in Table 1.

Measurements of Stability Constants. One ml of the 2.0×10^{-3} M 2-QxCOOH EtOH solution, and 5 ml of aqueous $(2.4-8.0)\times10^{-2}$ M metal chloride solution of Cu, Ni, Co and Zn were mixed together. To this mixture was added a

2 M KCl-HCl buffer of pH 1.40 to make the volume of the sample 20 ml. The absorptions were measured at each wavelength, and the ionic strength of the sample was kept at 0.1 with KCl. The measurements were carried out at 25 °C.

Results and Discussion

Stability Constants of Metal Chelates. A 5% aqueous ethanol solution of 2-QxCOOH shows a maximum absorption at 250 and 319.5 nm. However, the metal chelates have a maximum absorption at about 325 nm. The acid dissociation constant of the carboxylic acid group as measured by potentiometric method reported by Gum and Joullie[6] is 2.875. A spectrophotometric determination of the stability constants of the metal chelates was made according to the method of McConnell and Davidson.[7] When the divalent metal, M^{2+}, reacted with the ligand LH to give complex $L_nM_m^{2m-n}$, the stability constant $K_{m.n}$ is given as follows;

$$mM^{2+} + nLH \rightleftharpoons L_nM_m^{2m-n} + nH^+$$

$$K_{m.n} = \frac{[L_nM_m^{2m-n}][H^+]^n}{[M^{2+}]^m[LH]^n}$$

If the pH is maintained constant, the conditional stability constant, $K'_{m.n}$ is given by

$$K'_{m.n} = \frac{[L_nM_m^{2m-n}]}{[M^{2+}]^m[LH]^n}$$

When the total ligand concentration b remains constant and a total metal concentration a is added in very large excess of b, only one species, namely, the metal complex of $n=1$, can be taken into account, the linear relation falls between $b/(A-A_L)$ and $1/a^m$, where A and A_L are the total and ligand absorbances, respectively.

As an example, a 1 : 1 complex at pH 1.48 shows a straight line when $m=1$, and a curve when $m=2$. (Fig. 1).

Under these conditions, a 1 : 1 complex is usually the dominant form. The conditional stability constant, K', was calculated from the intercept and slope of the straight line, $b/(A-A_L)$ and $1/a$. From the $[H^+]$ and the dissociation constant, the successive stability constants log K_1 were obtained.

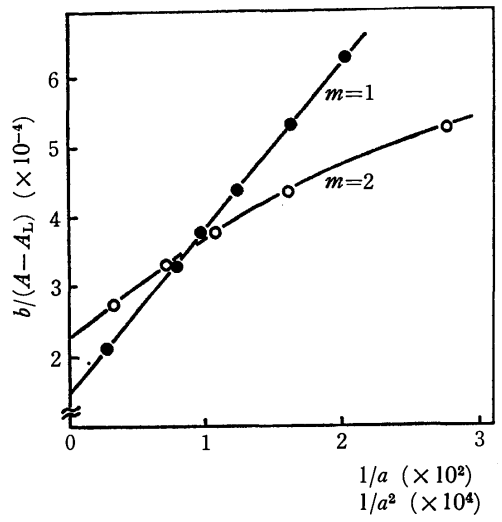

Fig. 1. Relationship between $b/(A-A_L)$ and $1/a^m$ of 2-QxCOOH-Cu complex at pH 1.48 in 5% aqueous EtOH.

The copper complex shows λ_{max} around 750 nm. Stability constants were determined using the method of Suzuki *et al.*[8] Table 2 gives a summary of the results obtained. In the case of the copper complex, the values measured in the ultraviolet region were recorded satisfactorily.

Table 2. Stability constants of 2-QxCOOH-metal chelates

Metal	λ_{max}(nm)	Analytical wavelength (nm)	pH	log K_1
Cu	326	341	1.48	3.29
Cu		748	1.48	3.31
Ni	325.5	342	1.45	2.87
Co	325	342	1.48	2.83
Zn	325	340	1.41	2.80

The values found for the stability constants of nickel, cobalt and zinc were about the same, but the stability constant log K_2 could not be measured, since precipitation takes place when a ligand is added in excess.

IR Spectral Analyses. Measurements of IR spectra (4000—600 cm^{-1}) were made by means of the KBr disk method. The 2-QxCOOH shows two broad bands, one at 2423 and the other at 1875 cm^{-1}. These bands are also observed in a heterocyclic carboxylic acid, such as picolinic acid and pyrazinecarboxylic acid at the same reading. Yoshida and Asai[9] explain that the bands result from the hydrogen bond formation between the ring nitrogen and the carboxyl groups. The two bands of 2-QxCOOH could be explained in the same way, since 2-QxCOOH potassium salt is not found in these hydrogen bonds.

On the other hand, the absorption bands due to the stretching of the carbonyl group appearing at 1740 and 1705 cm^{-1} in dioxane solution shift to 1750 and 1721 cm^{-1}, respectively. The band at a higher frequency is considered to be due to monomeric form without any hydrogen bond, while the other can be attributed to the intramolecular hydrogen bond formation.

Potassium salt of 2-QxCOOH shows asymmetric and symmetric stretching frequencies at 1618 and 1387 cm^{-1}, respectively.

IR Spectra of Metal Complexes. By a detailed examination of IR spectra of metal chelates of the various amino acids Condrate and Nakamoto[10] concluded that the increment of coordination character between the carboxyl group and metals shifts the asymmetric stretching vibration of the carboxyl group toward higher and the symmetric stretching vibration toward lower frequencies, resulting in a wider separation between the two absorption bands. By a similar argument of the metal chelates of picolinic and nicotinic acids, the following order was given among the metals for the increment of coordination charac-

TABLE 3. ASYMMETRIC AND SYMMETRIC ν_{COO} AND ΔE OF 2-QxCOOH METAL COMPLEXES (cm^{-1})

Compounds	$\nu_{asym COO}$	$\nu_{sym COO}$	ΔE

ters.[11]

$$Cu > Co > Ni > Zn$$

Table 3 shows the asymmetric and symmetric stretching frequencies of the carboxyl group together with the degree of separation (ΔE) between the two bands for the metal complexes of 2-QxCOOH.

As in the case of metal chelates of picolinic acid, ΔE obtained shows the same tendency of coordination character among the metals examined. The copper complex has a stronger coordination bond.

For the sake of comparison, the separation between the asymmetric and symmetric frequencies of the carboxyl group for sodium or potassium salts and copper complexes of acetic,[12] benzoic[13] and picolinic acids[14] is shown together with the dissociation constants of the carboxylic acid and stability constants (log K_1) of the copper chelates in Table 4.

The amount of separation found for copper complexes of picolinic acid and 2-QxCOOH is much greater than that of copper acetate and benzoate, the same tendency being observed for the potassium carboxylates.

The ΔE values obtained increase in the order picolinic, 2-quinoxalinecarboxylic, acetic and benzoic acids, corresponding to the stability constants of these carboxylates. From these ΔE values, we see that copper complex of 2-QxCOOH is more stabilized by the additional bond formation between the ring nitrogen and copper than copper benzoate and acetate, where bond formation is expected only between the carboxyl group and copper.

In spite of the fact that the dissociation constant of 2-QxCOOH is smaller than that of benzoic acid, the stability constants of the former with copper is larger, showing the chelate formation compensate for the gap in the dissociation constants.

The fact that asymmetric stretching of manganese and lead complexes of 2-QxCOOH appears in a lower frequency than that of the corresponding potassium salt leads to the conclusion that in these metal complexes the bond between the metal and carboxyl groups is ionic and the interaction between the metal and ring nitrogen is negligible.

Figure 2 illustrates the spectra of 1 : 1 and 2 : 1 copper complexes.

With regard to the two bands located at 1380 cm^{-1}, the 2 : 1 chelate shows a band of stronger intensity in the higher frequency region, while the 1 : 1 complex shows the reverse tendency. A similar phenomenon was observed for the cadmium chelate.

Far-IR of Metal Chelates. Measurements of Far-IR spectra (600—200 cm^{-1}) were made by means of the nujol mulls method. The metal complexes expected to form a chelate ring cause shortening of the bond

distance between metal–oxygen and metal–nitrogen to shift the stretching vibration of M–O and M–N toward higher frequencies.

The main peaks of 2-QxCOOH metal chelates are listed in Table 5. Absorption spectra of copper and nickel chelates of 2-QxCOOH are shown in Fig. 3.

According to the work of Taylor *et al.*[17] on lanthanide benzoate, out of and in plane rocking frequencies of carboxylate appear at 516—560 cm^{-1} and 390—425 cm^{-1}, respectively.

2-QxCOOH shows two bands at 546 and 392 cm^{-1} which, on chelation with metals, shift to around 550—580 cm^{-1} and 347—453 cm^{-1}, respectively, which is attributable to the stretching frequencies of metal-oxygen with combination of carboxyl rocking modes. These M–O stretchings take place at higher frequencies in the order Cu>Co>Ni>Zn. This correspond to the coordination character of the carboxyl group, namely, M–O bond in the copper chelate has stronger coordination character than the other metals examined. Billing *et al.*[18] investigated the copper metals of substituted quinoxaline derivatives and concluded that the band at 208—246 cm^{-1} is assigned to the stretching frequencies of M—N. From these values the bands around 326—257 cm^{-1} and 228—200 cm^{-1} are assigned to the M—N stretching. The first bands in particular show marked metal dependence on both absorbance and their shifts.

The 1 : 1 chelate shows a similar pattern of bands to that of the 2 : 1 chelate, indicating that the 1 : 1 chelate can assume a dimeric form including chlorine bridge.

Metal Chelates of 2-QxCOOH N-Oxides. The IR and Far-IR data of 2-QxCOOH *N*-oxides and their metal chelates are summarized in Table 6.

2-QxCOOH 4-oxide shows two broad bands around 2400 and 1900 cm^{-1} indicating hydrogen bond formation between the ring nitrogen and the carboxyl group, while in 2-QxCOOH 1-oxide and its 1,4-dioxide no such bands are observed. The stretching vibration of the carbonyl group shifts to higher frequencies in the order 2-QxCOOH 4-oxide, 1-oxide and 1,4-dioxide (Table 6). The band at 1702 cm^{-1} of 2-QxCOOH 4-oxide splits into two bands at 1722 and 1753 cm^{-1} in dioxane solutions, indicating non-existence of the hydrogen bond formation in 1-oxide and 1,4-dioxide.

The absorption bands of the *N*-oxide groups appeared at 1348—1378 cm^{-1} and those of the 2-QxCOOH 1,4-dioxide appeared in the higher frequency region, as in the case $\nu_{C=O}$.

The copper chelates of these ligands show $\nu_{asymCOO}$ at 1646—1667 cm^{-1}, ν_{symCOO} at 1368—1388 cm^{-1}

Table 5. Characteristic frequencies of 2-QxCOOH-metal complexes (cm^{-1})

2 : 1 Complexes							1 : 1 Complexes		Assignments

Table 6. Characteristic frequencies of 2-QxCOOH *N*-oxides and its copper complexes (cm^{-1})

2-QxCOOH 1-oxide		2-QxCOOH 4-oxide		2-QxCOOH 1,4-dioxide		Assignments
Ligand	Complex	Ligand	Complex	Ligand	Complex	
1710	1654	1702	1667	1721	1646	$\nu_{asymCOO}$
	1383		1388		1368	ν_{symCOO}
1372	1357	1348	1364	1378	1353	ν_{N-O}
	531		567		542	
	405		417		403	ν_{Cu-O}
	395				350	ν_{Cu-O}
			240			ν_{Cu-N}

and ν_{N-O} at 1353—1364 cm^{-1}. The lower frequency shift of $\nu_{asym COO}$ apparently indicates the bond formation between the carboxyl group and the copper atom. On the other hand, ν_{N-O} of 2-QxCOOH 4-oxide–copper complex shifts to higher frequency and those of 1-oxide and 1,4-dioxide–copper complexes shift to lower frequency.

We previously reported[1] that in Qx 1-oxide–cupric chloride complex the bond formation between copper and the ring nitrogen caused a ν_{N-O} higher frequency shift, and in Qx 1,4-dioxide–cupric chloride complex coordination of copper to the oxygen atom of *N*-oxide group a ν_{N-O} lower frequency shift. The coordination of copper to the ring nitrogen of 2-QxCOOH 4-oxide increases the double bond character of N–O bond to shift ν_{N-O} to a higher frequency. The other copper *N*-oxide complexes, namely, 1-oxide and 1,4-dioxide-copper coordination site of the ligands is the oxygen atom of *N*-oxide group, which causes lower frequency shifts of ν_{N-O}.

The fact that Qx 1,4-dioxide–cupric chloride complex dissociates into its components in aqueous solution[1] but not the 2-QxCOOH *N*-oxide-copper complexes can be explained by the increase in stabilization energy caused by the chelate ring formation in the latter.

Studies on the Far-IR spectra of these complexes were also made. The absorption peaks observed at 531—542 cm^{-1} and 403—407 cm^{-1} are assigned to the ν_{Cu-O} from the behavior of 2-QxCOOH–copper complex. The absorption peaks at 395 and 350 cm^{-1} of 2-QxCOOH 1-oxide and 1,4-dioxide are close to that of Qx 1,4-dioxide–cupric chloride complex at 397 cm^{-1},[1] and assigned to the Cu–O band between copper and the oxygen atom of the *N*-oxide group. The band due to Cu-O with the carboxyl oxygen of 2-QxCOOH 4-oxide copper complex is observed at a higher frequency than that of 1-oxide and 1,4-dioxide copper complexes.

This can be explained to be due to the fact that formation of the five-membered ring nitrogen, carboxyl oxygen and copper is more stable than that of the six-membered ring including oxygen atom of the *N*-oxide group. The same conclusion was also reported by Gupta *et al.*[19] concerning oxine and its *N*-oxide metal complexes.

2-QxCOOH 4-oxide–copper complex gives an absorption peak at 240 cm^{-1}, which is attributed to ν_{Cu-N} from the data of 2-QxCOOH–copper complex. IR and Far-IR analytical data indicate that 2-QxCOOH *N*-oxide–copper complexes forms the chelate ring as in the case of 2-QxCOOH complexes.

Crystal Structure of Chloro-1-(2-thiazolylazo)-2-naphtholatopalladium(II) Dioxane Solvate

Masayasu KURAHASHI

Chemistry Division, National Research Institute for Metals, Meguro-ku, Tokyo 153

(Received Junuary 29, 1974)

The crystals of chloro-1-(2-thiazolylazo)-2-naphtholatopalladium(II) dioxane solvate, [PdCl(TAN)]·$C_4H_8O_2$, are orthorhombic and of space group Pbcm, with unit cell dimensions: $a=8.44(2)$, $b=30.97(4)$ and $c=6.82(2)$ Å and $Z=4$. The structure was determined by the heavy-atom method and refined by the least-squares procedure to give an R value of 0.097 for 1392 observed reflections. The crystallographic mirror plane normal to the c-axis coincides with the molecular plane of [PdCl(TAN)]. The 1-(2-thiazolylazo)-2-naphtholato group, *i.e.*, TAN, is a terdentate ligand; the phenolic oxygen atom, azo nitrogen atom and thiazole nitrogen atom are coordinated to the palladium atom to form two five-membered chelate rinsgs. The fourth coordination position is occupied by a chlorine atom.

Since Cheng and Bray used 1-(2-pyridylazo)-2-naphthol, "H-PAN", as an analytical reagent for metals in 1955,[1] a number of heterocyclic azo dyes have been prepared, their application to chemical analysis being studied by many researchers. 1-(2-Thiazolylazo)-2-naphthol (abbr. H-TAN) was found to be a useful and frequently used reagent for the spectrophotometric and titrimetric determination of metal ions as well as for their separation by solvent extraction techniques. In view of the lack of information on the structures of the metal chelate of H-TAN, a systematic X-ray investigation has been undertaken. This paper describes the structure of chloro-1-(2-thiazolylazo)-2-naphtholatopalladium(II) dioxane solvate.[2] This complex has been selected because its coordination configuration might be planar and it would differ from the configuration of iron(II)-, cobalt(II)- and nickel(II)-complexes. It is also of interest to see whether or not the thiazole sulfur atom takes part in the chelate ring formation.

Experimental

Green-colored and needle-like crystals were obtained by slow diffusion of aqueous palladium(II) chloride into dioxane solution of H-TAN. The crystal data are given in Table 1. The unit-cell dimensions were determined by oscillation and Weissenberg photographs.

From systematic absences, the space group was found to be Pbc2 or Pbcm, the latter being more probable from the positive result of intensity statistics for centrosymmetry.

TABLE 1. CRYSTAL DATA

$\mu = 111$ cm^{-1} (for Cu$K\alpha$)
Space group: Pbcm

The three dimensional data of hk(0—5) were collected from the equi-inclination Weissenberg photographs taken with Cu$K\alpha$ radiation. The intensities of reflections were measured visually by comparison with a standard scale, and corrected for the usual Lorentz and polarization factors. No absorption and extinction corrections were applied. The absolute scale of each layer were obtained at a later stage of refinement by correlation with the calculated values.

Structure Determination and Refinement

The positions of the palladium, sulfur, and chlorine atoms were readily deduced from three-dimensional Patterson maps. The Fourier synthesis of electron density phased on the positions of these heavy atoms revealed the location of the remaining atoms of the complex molecule. A difference synthesis was then carried out and 1,4-dioxane molecule was found to be trapped in the lattice. The structure thus obtained was refined by the block-diagonal least-squares method with the use of individual isotropic thermal factors. Unit weight was given to all the observed reflections. At the final stage of refinement, anisotropic temperature factors were introduced for all the non-hydrogen atoms and the R factor was reduced to 0.097 for 1392 non-zero reflections. The atomic scattering factors were taken from International Tables for X-ray Crystallography. The atomic coordinates and anisotropic thermal parameters along with their estimated standard deviations are given in Table 2, and the observed and calculated structure factors in Table 3*.

Description of the Structure and Discussion

The crystal consists of palladium(II)-complex and dioxane molecule. The bond lengths and angles are given in Table 4 together with their standard deviations. The thermal ellipsoids are shown in Fig. 1 with numbering of atoms.

The palladium(II)-complex is exactly planar, having a mirror symmetry fulfilling the requirement of the space group. The configuration around the palladium atom is square-planar. The 1-(2-thiazolylazo)-2-naphtholato group TAN is present as a terdentate

ligand; the phenolic oxygen atom, the azo nitrogen atom and the thiazole nitrogen atom are coordinated jointly to the palladium atom to form two five-membered chelate rings. The fourth coordination position is occupied by a chlorine atom. The feature of coordination of TAN to the palladium atom is quite common to those found in iron(II)-,[3] nickel(II)-[2] and copper(II)-TAN[2] chelates, although it is not the case with the configuration around the metal.

The structure of the palladium(II)-TAN chelate bears a close resemblance to that of the 1 : 1 copper(II)-PAN chelate observed in the crystals of $[Cu(PAN)\text{-}H_2O]\cdot ClO_4$.[4] Distances of Pd–Cl(2.31 Å), Pd–O(1) (2.03 Å) and Pd–N(2.01 Å) are all normal, but the central bond in the chelate, Pd–N(1)(1.93 Å), is slightly shorter than the normal Pd–N distance(2.02 Å). Bond angles around the palladium atom, O(1)–Pd–N(1) and N(1)–Pd–N(3), are compressed to 80° and 82°, respectively.

The crystal structure of H-TAN recently has been determined by the present author.[5] There are two crystallographically independent molecules in an asymmetric unit. Both molecules are in concordance with the chemical formula presented in Fig. 2a, although the details of their molecular structures differ from each other. A comparison of the structure of H-TAN with that of TAN in the form of [PdCl(TAN)] (Fig. 2) shows that both of the two ring systems of H-TAN attached to the central azo group are rotated by 180° around the two N–C single bonds in the case of chelate ring formation.

The crystal structure, as projected along the c-axis, is shown in Fig. 3 together with intermolecular distances less than 3.75 Å. Successive [PdCl(TAN)] molecules lie above one another along the c-axis to form columns. The interplanar distance is 3.41 Å. The molecular columns are held together by the van der Waals forces, constructing layers parallel to the (010) plane. Diox-

The Mechanism of the Hydrolysis of Condensed Phosphates. I. The Solvent Effect on the Hydrolysis of Pyro- and Tripolyphosphates

Makoto WATANABE

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi 487

(Received March 28, 1974)

The hydrolysis of pyro- and tripolyphosphates was run in formic acid–water, acetic acid–water, dioxane–water, and water solvents with an initial concentration of 0.025 mol/l. The hydrolysis of both the phosphates followed first-order kinetics with respect to the concentration of the phosphate under all the conditions studied. The rate of the hydrolysis of both the phosphates in the formic acid–water and acetic acid–water solvents is slower, and that in dioxane–water solvent is faster, than in water. From the results, it has been concluded that, in the formic acid–water and acetic acid–water solvents, the nucleophilicity of the water molecule may decrease on account of the hydrogen bond of the water molecule with these acids, while, in the dioxane–water solvent, since the scission of the hydrogen bond between water molecules may occur by the interaction of the dioxane and the water molecules, the nucleophilicity of the water molecule may increase. The activation energy of the hydrolysis of the phosphates was 19—28 kcal/mol and increased with an increase in the pH value of a solution. The hydrolysis of pyro- and tripolyphosphates has been concluded to be a S_N2 reaction; the rate-determining step may be the nucleophilic attack of a water molecule on the phosphorus atom of the phosphates.

Many papers concerning the hydrolysis of condensed phosphates have been published during the last hundred years. The previous works on the hydrolysis of condensed phosphates have, however, been done chiefly for the purpose of determining the rate constant at a constant pH and of examing the effect of cations on the hydrolysis, rather than for studying the exact interaction of phosphates with the water molecule. It is well known that the hydrolysis of condensed phosphate in a several percent aqueous solution exhibits first-order kinetics with respect to the concentration of phosphate. The effect of the pyrophosphate concentration on the linearity of the rate plot was examined by Campbell and Kilpatrick.[1] In the present paper, the kinetics of the hydrolysis of pyro- and tripolyphosphates will be studied from the viewpoint of the nucleophilicity of a water molecule.

Experimental

Materials and Procedure. All the materials used other than the sodium tripolyphosphate were of a commercial grade. The sodium tripolyphosphate, I, was made by the method described in Reference[2] and was purified by recrystallization. The solvents employed in this experiment are listed in Table 1. When the solvent was water or aqueous dioxane, the pH of the solution was controlled with nitric acid and aqueous tetramethyl ammonium hydroxide by using a Hitachi-Horiba pH meter, F-5. The initial concentration of sodium pyro- and tripolyphosphate was 0.025 mol/l. About 25 ml of the solution was transferred to a test tube, and the tube was stoppered to prevent evaporation of the solvent. The test tube was then placed in water in a thermostat and the temperature was maintained at 30, 50, or 70±0.05 °C. A measured sample of the solution was withdrawn after the temperature of the solution in the test tube had reached the required temperature by using a microsyringe and spotted on to chromatograms. At measured intervals of time, further samples were similarly taken for quantitative chromatographic analysis. The pH of the solution was periodically measured. In the case of the formic acid–water and acetic acid–water solvents, the pH of the solution of the phosphates was not changed at any time, while in the case of the water and dioxane–water solvents, the pH of the solution was changed. Therefore, if they were in need of adjustment, enough tetramethyl ammonium hydroxide or nitric acid was added to bring them back to the proper pH. The pH adjustment was made within ±0.05 pH unit of the required value.

Table 1. Solvents used for the hydrolysis of pyro- and tripolyphosphates

Solvent	Symbol
35 vol% aqueous dioxane	S_1
25 vol% aqueous dioxane	S_2
15 vol% aqueous dioxane	S_3
Water	S_4
Formic acid–water	S_5
Acetic acid–water	S_6

Chromatography. One-dimensional paper-chromatographic separations were carried out by using filter paper of Toyo No. 51A of 2×50 cm. Samples of the phosphate solution (10 μl) were placed at the starting point of the filter paper and developed at 5 °C for 50 hr by using an acidic solvent; then the chromatograms were dried in an oven at 75 °C for more than 30 min. The acidic solvent was made by mixing 70 ml of isopropyl alcohol, 20 ml of 25% aqueous trichloroacetic acid, 10 ml of water, and 0.3 ml of 28% aqueous ammonia. The papers were then sprayed with a perchloric acid–molybdate solution, which had been made by mixing 200 ml of 5% aqueous ammonium molybdate, 10 ml of conc. hydrochloric acid, and 50 ml of 70% aqueous perchloric acid, and by then diluting the solution to 1000 ml with water. The paper was subsequently dried for about 10 min at 50 °C and exposed to ultraviolet rays until blue zones appeared.

Quantitative Analysis of Phosphates on Chromatograms. Every individual spot on the chromatogram was cut at the demarcation line and transferred to a 100-ml beaker. Ten milliliters of a 0.1 M-ammonium hydroxide solution were then added to the beaker. After one hr, the solution was transferred to a 25-ml volumetric flask together with 10 ml of wash water, and a 2-ml portion of Lucena-Conde and Prat's reagent[3] was added to the flask. The flask was heated in a boiling-water bath for one hr, subsequently cooled by placing it in a bath of cold water, and diluted to the mark with water. The absorbance of the blue solution was measured with a Hitachi 101 spectrophotometer at 830 nm. The absorbance of a reagent blank was deducted from each of the readings to give a net absorbance for each

phosphate fraction. The phosphorus content of each spot was expressed as a portion of the total phosphorus present as follows:

$$P(\%) = \frac{\text{Net absorbance for each fraction}}{\text{Sum of the net absorbances for each fraction}} \times 100$$

Results and Discussion

Order of Reaction and the pH Dependence of the Reaction Rate. The rate of the hydrolysis of pyro- and tripolyphosphates followed first-order kinetics with respect to the concentration of the phosphate under all the conditions studied. The pH dependences of the rate constant of pyro- and tripolyphosphates are shown in Figs. 1 and 2 respectively. In any solvent, the rate constant of the hydrolysis of pyro- and tripolyphosphates increases with a decrease in the pH of the solution. Therefore, the hydrolysis of the phosphates is an acid-catalyzed reaction, as has already been reported by many investigators.[1,4-9] There is a difference between the rate constants of the hydrolysis of pyro- or tripolyphosphate in different solvents at the same pH value. In a dioxane-water solvent, as the content of dioxane increases the rate constant of pyro- and tripolyphosphates increases at any pH value. On the other hand, in the formic acid- and acetic acid-water solvents the reaction rate is slow in comparison with that in the other solvents at the same pH and the difference in the rate constant between the acid solvent and dioxane–water or water solvent is larger at larger pH values (the concentrations of the formic acid at the pH values of 1.1, 1.9, and 2.5 are about 30, 10, and 3.2% respectively, while those of acetic acid at the pH values of 1.3, 1.9, and 2.5 are about 76, 61, and 30% respectively). This can reasonably be explained in terms of the difference in the nucleophilicity of the water molecule in each solution as follows: since formic acid or acetic acid combines with the water molecule by means of a hydrogen bond, the nucleophilicity of the water molecule for the phosphorus atom of phosphates may decrease, and since dioxane forms a hydrogen bond with the water molecule and since, consequently, the hydrogen bond between water molecules may be broken, the nucleophilicity of the water molecule for the phosphorus atom of phosphates may increase in the dioxane–water solvent. When the nucleophilicity of the water molecule decreases through the hydrogen bond with the acids, the hydrolysis of phosphate may become energetically disadvantageous because of the hydrogen-bond energy, and the approach of the water molecule to the phosphorus atom of phosphate may also be prevented. Accordingly, the activation energy and log A (A; frequency factor) were calculated by means of the Arrhenius plot, and the relation between these values and the reaction process of the hydrolysis of pyro- and tripolyphosphates was considered.

Activation Energy and log *A.* The activation energy and log A of the hydrolysis of pyro- and tripolyphosphates are listed in Tables 2 and 3 respectively. In any solvent, the activation energy of both the phosphates increases with an increase in the pH value. This tendency is in accordance with the results obtained by Van Wazer and his co-workers,[6] and the values of activation energy are similar to their results. The activation energy of both the phosphates is smaller in the dioxane–water solvent and larger in the formic

a) Solvents refer to Table 1.

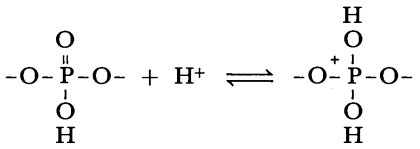
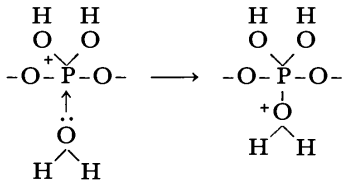
acid–water solvent than in water. In addition, the difference in the activation energy between water and the other solvents increases as the content of formic acid or dioxane increases. The results could be reduced to the formation or scission of the hydrogen bond of the water molecule with formic acid or dioxane respectively. In the acetic acid–water solvent, the hydrolysis of tripolyphosphate has the same solvent effect as that in the formic acid–water solvent, while the hydrolysis of pyrophosphate differs. The activation energy of the hydrolysis of pyrophosphate in the acetic acid–water solvent is smaller than that in water. Therefore, it can be concluded that the effect of entropy term is larger than that of the energy term for the rate of the hydrolysis of pyrophosphate in the acetic acid–water solvent. The compensation effect is valid between the activation energy and the entropy term under all the conditions studied.

Mechanism of Hydrolysis. According to the above results, the hydrolysis of pyro- and tripolyphosphates may be a dipole-dipole-type S_N2 reaction of the classification of Ingold and Hughes.[10] Since the hydrolysis of pyro- and tripolyphosphates is an acid-catalyzed reaction, the following reaction mechanism can be considered. In an acidic solution, a rapid equilibrium may be set up between the phosphate and hydrogen ion;



The phosphate ion on the right-hand side of the above equation may more readily accept the nucleophilic attack of the water molecule than the phosphate on the left-hand side. The rate-determining step of this reaction may be this next reaction;



Thus, in an acidic solution, a rapider rate process of the hydrolysis of the phosphate may be given. The first-order kinetics of the hydrolysis of pyro- and tripolyphosphates with respect to the concentration of the phosphates can be reduced to the constancy of the activity of the water molecule because of the dilute nature of the concentration of the phosphates.

(Received September 22, 1973)

The liquid phase autoxidation of isobutyraldehyde to peroxyisobutyric acid was investigated with ozone as an initiator. The selectivity of the peroxyacid increases with decrease in the amount of aldehyde converted per unit volume of reacting fluid, increase in the ozone feed rate, and decrease in temperature. A few percent of water in solvents increases the selectivity, although too much water brings about a reverse effect. Isopropyl alcohol, acetone, isopropyl formate, propane, propylene, carbon dioxide, and carbon monoxide are observed as by-products besides isobutyric acid. Purified peroxyisobutyric acid (97.2 wt%) was obtained by fractionally distilling the autoxidation product and some of its physical properties were determined. The utility of the peroxyacid as an epoxidizing agent is described.

Isobutyraldehyde is available as a by-product of the *n*-butyraldehyde production by the hydroformylation of propylene. However, little is known about its autoxidation to peroxyisobutyric acid.[1] This paper reports on the autoxidation of isobutyraldehyde in the liquid phase with ozone as an initiator.

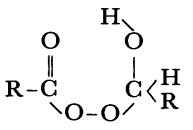
Results and Discussion

Variations of the Selectivity of Peroxyisobutyric Acid (II) with Reaction Conditions. The influence of reaction conditions was investigated with a stirred flow reactor using ethyl acetate saturated with water at room temperature as a solvent. The autoxidation of isobutyraldehyde (I) involves the following two stages:

$$\underset{\text{I}}{{}^{i}\text{PrCHO}} + O_2 \rightarrow \underset{\text{II}}{{}^{i}\text{PrCO}_3\text{H}} \text{ (Rate, } R\text{)} \quad (1)$$

$${}^{i}\text{PrCHO} + {}^{i}\text{PrCO}_3\text{H} \rightarrow \underset{\text{IV}}{2\,{}^{i}\text{PrCO}_2\text{H}} \quad (2)$$

Formation of intermediate addition product (III) is known in the reactions of aliphatic saturated aldehydes with peroxyacids.[2-5]



III

The amount of intermediate peroxide III (R=^{i}Pr) was estimated by NMR to be less than 0.05 mol/l. Thus, peroxyisobutyric acid (II) could be approximately estimated by iodometric titration, III being neglected. Isobutyric acid (IV) and unchanged I were determined by glpc after II had been reduced with dimethyl sulfide. The results are shown in Table 1, where

$$\text{Conversion of I} = \frac{\text{I converted (mol)}}{\text{I fed (mol)}} \times 100,$$

$$\text{Selectivity of II} = \frac{\text{II produced (mol)}}{\text{I converted (mol)}} \times 100$$

The variations of the selectivity of II with reaction conditions (conversion, feed concentration of I, ozone feed rate, and temperature) are summarized as follows: the selectivity increases with decreasing conversion of I (Runs 3, 2; 6, 5, 4; 14, 13), decreasing feed concentration of I (Runs 5, 2, 1), increasing ozone feed rate (Runs 9, 12, 3), and decreasing reaction temperature (Runs 14, 1).

White and Bailey[6] suggested that ozone attacks an aromatic aldehyde to form a transient intermediate peroxide, which decomposes to give radicals and initiates autoxidation.

$$\text{RCHO} + O_3 \rightarrow \text{X} \quad (3)$$

$$\text{X} \rightarrow n\text{R}'\cdot \quad (4)$$

Assuming that the initiation of the autoxidation of I occurs according to the above mechanism and the rate of reaction (3) is rapid enough to be represented by the feed rate of ozone (r),[7] we obtain

$$r_i = nr \quad (5)$$

where r_i is the rate of initiation. The general mechanism for autoxidation is

$$\text{R}'\cdot + \text{RCHO} \rightarrow \text{R}'\text{H} + \text{R}\dot{\text{C}}{=}\text{O} \quad (6)$$

$$\text{R}\dot{\text{C}}{=}\text{O} + O_2 \rightarrow \text{R-C}(=\text{O})\text{-O-O}\cdot \quad (7)$$

$$\text{R-C}(=\text{O})\text{-O-O}\cdot + \text{RCHO} \xrightarrow{k_p} \text{R-C}(=\text{O})\text{-OOH} + \text{R}\dot{\text{C}}{=}\text{O} \quad (8)$$

$$2\,\text{R-C}(=\text{O})\text{-O-O}\cdot \xrightarrow{k_t} \text{Non-radical products} \quad (9)$$

and the steady-state approximation leads to

$$\left[\text{R-C}(=\text{O})\text{-O-O}\cdot\right] = \left(\frac{nr}{k_t}\right)^{1/2} \quad (10)$$

Thus, the rate of the formation of II would be

$$\text{d[II]/d}t = R - k_2[\text{I}][\text{II}], \quad (11)$$

$$R = k_p\left[\text{R-C}(=\text{O})\text{-O-O}\cdot\right][\text{I}]$$

$$= k_p\left(\frac{nr}{k_t}\right)^{1/2}[\text{I}] = k_1 r^{1/2}[\text{I}] \quad (12)$$

where the rate of reaction (2) is assumed to obey second-order kinetics (rate constant, k_2).

a) Autoxidation with a stirred flow reactor. b) Moles per unit volume of reacting fluid per unit time.

In the stirred flow reactor, the material balance for I or II at steady-state affords

$$F[\mathrm{I}]_0 = \{R+k_2[\mathrm{I}][\mathrm{II}]\}V + F[\mathrm{I}],$$
$$[\mathrm{I}]_0 - [\mathrm{I}] = \tau\{R+k_2[\mathrm{I}][\mathrm{II}]\} \quad (13)$$
$$0 = \{-R+k_2[\mathrm{I}][\mathrm{II}]\}V + F[\mathrm{II}],$$
$$[\mathrm{II}] = \tau\{R-k_2[\mathrm{I}][\mathrm{II}]\} \quad (14)$$

where $[\mathrm{I}]_0$ is the feed concentration of I, [I] and [II] are the concentrations of I and II in the product, respectively, F is the volumetric flow rate, and τ is the residence time. From Eqs. (13) and (14), we obtain

$$R = \frac{1}{2\tau}\{[\mathrm{I}]_0-[\mathrm{I}]+[\mathrm{II}]\} \quad (15)$$

$$k_2 = \frac{1}{2\tau[\mathrm{I}][\mathrm{II}]}\{[\mathrm{I}]_0-[\mathrm{I}]-[\mathrm{II}]\} \quad (16)$$

R values were estimated from Eq. (15) using the data listed in Table 1. Figures 1 and 2 show the $\log R$ *vs.* log[I]

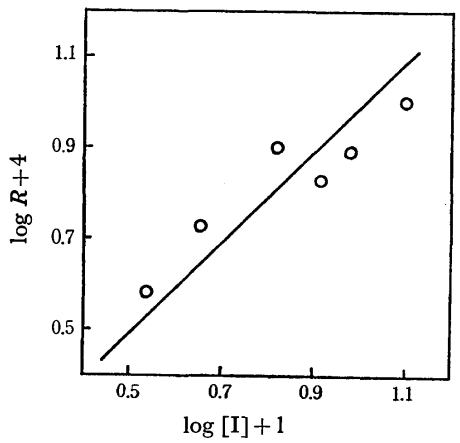

Fig. 1. Plot of $\log R$ *vs.* log [I]. r, $(4-6)\times10^{-5}$ mol/l·s; 10 °C.

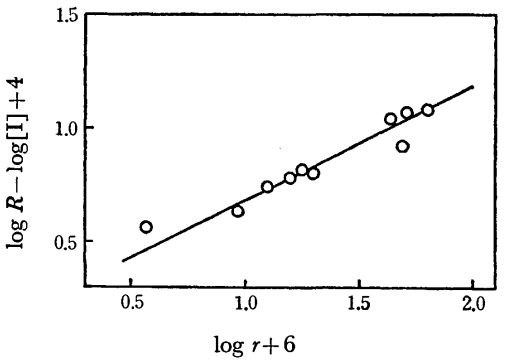

Fig. 2. Plot of $\log R-\log$ [I] *vs.* $\log r$. 10 °C.

Table 2. Rate data of the autoxidation of I in ethyl acetate saturated with water

(at approximately equal r) and the $\{\log R - \log[I]\}$ *vs.* $\log r$ relationships, respectively. Our data approximately satisfy Eq. (12). Constants k_1 and k_2 were evaluated from Eqs. (12) and (16), respectively, and are listed in Table 2.

Division of Eq. (14) by Eq. (13) and introduction of Eq. (12) give

$$\frac{[II]}{[I]_0-[I]} = \frac{\kappa-[II]}{\kappa+[II]} \tag{17}$$

where

$$\kappa = k_1 r^{1/2}/k_2 \tag{18}$$

Equation (17) expresses the dependence of the amount of II formed on that of I converted at various κ values. Figure 3 illustrates the [II] *vs.* $\{[I]_0-[I]\}$ curves calculated from Eq. (17) using κ values of 12 and 3. At the ozone feed rate of $(4—6)\times10^{-5}$ mol/l·s, the observed values of [II] and $\{[I]_0-[I]\}$ are also plotted in Fig. 3, in which the κ values are approximately 12 and 3 at 10° and 40 °C, respectively. The selectivity of II, defined as $[II]/\{[I]_0-[I]\}$, increases with decreasing $\{[I]_0-[I]\}$ at a constant κ, and with increasing κ at a constant $\{[I]_0-[I]\}$. Since a decrease in the conversion or the feed concentration of I leads to a decrease in $\{[I]_0-[I]\}$ and a lower reaction temperature or a higher feed rate of ozone leads to a larger κ value, all these effects result in an increase in the selectivity of II.

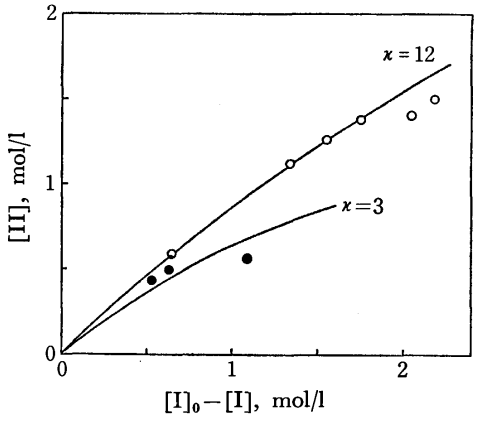

Fig. 3. [II] as a function of $[I]_0-[I]$.
Solid line, calculated from Eq. (17); ○, observed at 10 °C (r, $(4-6)\times10^{-5}$ mol/l·s); ●, observed at 40 °C (r, $(4-6)\times10^{-5}$ mol/l·s).

The values of k_1 and k_2 lack somewhat in constancy. This might be due to the difficulty of analysis and/or an over-simplification of the reaction kinetics. However, the above semi-quantitative treatment explains the results in spite of the complexity of the reaction.

Effect of Water. The effect of water was investigated by batchwise autoxidation. Figure 4 shows the yield of II as a function of water content in the solvent. A few percent of water in acetone increases the yield, although too much water brings about a reverse effect. The autoxidation in ethyl acetate saturated with water at room temperature[8] under similar reaction conditions as above gives II in about a 10% higher yield than that in anhydrous ethyl acetate.

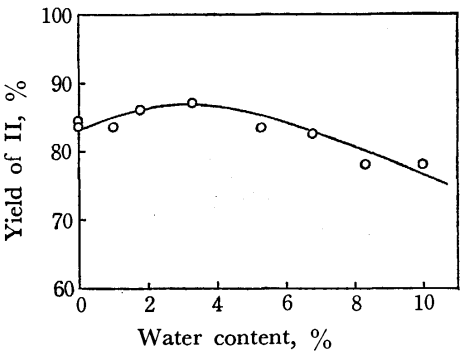

Fig. 4. Effect of water content in solvent on the yield of II.
Batch reactions at 40 °C; solvent, acetone; $[I]_0$, 1.00 mol/l; volume of reacting fluid, 200 ml; O_2, 0.52 l/min; O_3/O_2, 0.22 mmol/l; reaction time, 1.5 hr.

By-products. Besides IV, isopropyl alcohol and acetone were observed in 1—3% yields as by-products. They were identified through appropriate crystalline derivatives. When the autoxidation product was left to stand at 80—90 °C, their amounts of (particularly isopropyl alcohol) increased markedly. A possible pathway for the formation of these by-products is as follows:

$$II \rightarrow {}^{i}Pr\text{-}C(=O)(O\cdot) + \cdot OH \tag{19}$$

$${}^{i}Pr\text{-}C(=O)(O\cdot) \rightarrow {}^{i}Pr\cdot + CO_2 \tag{20}$$

$${}^{i}Pr\cdot + II \rightarrow {}^{i}Pr\text{-}OH + {}^{i}Pr\text{-}C(=O)(O\cdot) \tag{21}$$

$${}^{i}Pr\cdot + O_2 \rightarrow {}^{i}Pr\text{-}O\text{-}O\cdot \tag{22}$$

$${}^{i}Pr\text{-}O\text{-}O\cdot \rightarrow Me_2C{=}O + \cdot OH \tag{23}$$

A peak, the retention time of which agreed with that of isopropyl formate, was detected by glpc. This peak appeared in a comparable amount with that of isopropyl alcohol or acetone in the autoxidation in anhydrous ethyl acetate, but only in a trace amount in ethyl acetate saturated with water. On adding I to the autoxidation product, the intensity of this peak increased. Apparently, this was derived from the Baeyer-Villiger reaction of II with I.[9]

$$I + II \begin{cases} \xrightarrow{2\,IV} \\ \rightarrow IV + H\text{-}C(=O)\text{-}O\text{-}{}^{i}Pr \end{cases} \tag{24}$$

Isopropyl alcohol observed in the autoxidation in ethyl acetate saturated with water may have been partly derived from the hydrolysis of the formate. Carbon dioxide, carbon monoxide, propane, and propylene were detected by glpc in the exit gas. The formation of these by-products could be explained by Eqs. (20), (25), and (26).

$${}^{i}Pr\text{-}\dot{C}{=}O \rightarrow {}^{i}Pr\cdot + CO \tag{25}$$

$$2\,{}^{i}Pr\cdot \rightarrow CH_3CH_2CH_3 + CH_3CH{=}CH_2 \tag{26}$$

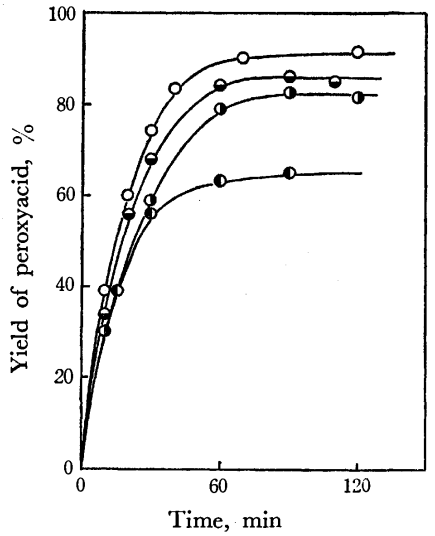

Fig. 5. Autoxidation of aldehydes.
Batch reactions at 40 °C; $[RCHO]_0$, 1.00 mol/l; solvent, ethyl acetate saturated with water (anhydrous ethyl acetate in the case of acetaldehyde); volume of reacting fluid, 200 ml; O_2, 0.52 l/min; O_3/O_2, 0.22 mmol/l; ○, isobutyraldehyde; ◒, *n*-butyraldehyde; ◑, propionaldehyde; ◐, acetaldehyde.

Comparison with Other Aldehydes. The autoxidation of I was compared with that of acetaldehyde,[10] propionaldehyde, and *n*-butyraldehyde. I gives peroxyacid in the highest yield (Fig. 5). This might be a reflection of the electron-donating nature of ^{i}Pr group, which would facilitate reaction (8), in view of preference for the attack of peroxy radicals on carbon-hydrogen bonds with the highest electron density.[11]

The solution of II, thus obtained, can be stored satisfactorily by addition of a small amount of stabilizer such as the sodium salt of a partially esterified polyphosphate.[12]

Epoxidation. The solution of II obtained by batchwise autoxidation was used for the epoxidation of cyclohexene. The rate constants are shown in Table 3 together with those by Frostick *et al.*,[13] who used peroxyacetic acid solution obtained by pyrolyzing α-hydroxyethyl peroxyacetate. Peroxyacid II can be used effectively as an epoxidizing agent.

Physical Properties of Peroxyisobutyric Acid (II). By fractional distillation under reduced pressure II was isolated from the autoxidation product. The purity was determined to be 97.2 wt% by iodometric titration. Some of the physical properties are listed in Table 4.

Table 3. Epoxidation of cyclohexene

a) 97.2 wt%. b) By extrapolation.

Experimental

All boiling points and melting points are uncorrected. NMR spectra were taken with a Varian A-60A spectrometer. Ozone was generated with a Nihon-Ozone 0-3-2 generator. Gas-liquid partition chromatographic data were obtained with a Hitachi K-23 gas chromatograph using helium as a carrier gas. Aldehydes were distilled under nitrogen just before use.

Autoxidation. Batch reactions were carried out in an all-glass cylindrical reactor having an external jacket as well as an internal coil for heat exchange. Oxygen containing ozone entered the reactor through a glass frit in the bottom and was vented through a Dry Ice condenser.

Continuous reactions were carried out in a glass vessel thermostatically controlled at a specified temperature. Under stirring, a solution of isobutyraldehyde was fed to the reactor into which oxygen containing ozone was dispersed through a glass frit in the bottom. The gas stream was vented through a Dry Ice condenser. Samples of the product stream, which overflowed, were chilled at once in a Dry Ice–acetone mixture and immediately subjected to analysis.

Analysis. α-Hydroxyisobutyl Peroxyisobutyrate (III, R=^{i}Pr): NMR spectrum was taken at −46 °C. Peroxide III (R=^{i}Pr) was estimated by comparing the peak area of $-O\diagdown\!\!\diagup O-C\!\!<^{H}$ proton (δ, 4.94) with that of the aromatic protons of mesitylene (δ, 6.75) as an internal standard.

Peroxyisobutyric Acid (II): A 1 ml sample was introduced into a flask containing 2 g of potassium iodide, 45 ml of water, 5 ml of acetic acid, 10 ml of chloroform, and a few pieces of Dry Ice. The liberated iodine was titrated with 0.1 M aqueous sodium thiosulfate solution to a colorless end-point.

Isobutyraldehyde (I) and Isobutyric Acid (IV): Dimethyl sulfide, 1 ml, was added dropwise to a 5 ml sample in a Dry Ice–acetone bath. The mixture was allowed to stand in an ice box for 15 min and analyzed by glpc on a Porapack Q column at 170 °C using benzene as an internal standard. Free IV in the reaction mixture was determined by subtracting II from the total IV found by glpc. Preliminary experiments showed that the reaction of dimethyl sulfide with II to yield dimethyl sulfoxide and IV was quantitative under the above conditions.

Identification of By-products. Glpc analysis (PEG 6000 column, 60 °C) of the autoxidation product, obtained by the ozone-initiated batchwise reaction in anhydrous ethyl acetate ($[I]_0$, 1.0 mol/l; 40 °C), showed three by-product peaks, x_1, x_2, and x_3. The retention times of x_1 and x_3 agreed with those of acetone and isopropyl alcohol, respectively. On decomposing the peroxyacid by heating the autoxidation product at 80—90 °C for 29 hr or by adding a small amount of cobaltic acetylacetonate and heating the mixture at 80—

90 °C for 30 min, the amounts of x_1 and x_3 (particularly x_3) increased markedly, while that of x_2 remained almost unaltered.

The retention time of x_2 agreed with that of isopropyl formate. When 80 ml of the autoxidation product was left to stand for 6.3 hr at 40 °C with 10 ml of I, the amount of x_2 increased by a factor of 4.5.

The autoxidation product, obtained with cobaltic acetylacetonate as an initiator ($[I]_0$, 1.0 mol/l; $[Co(acac)_3]$, 1.0×10^{-5} mol/l; 40 °C), decomposed spontaneously on being left to stand at room temperature. This was fractionally distilled with a 30 cm packed column (271 g).

Fraction	Head temp., °C	Wt., g
1	69.0—70.4	10.6
2	70.4—76.0	45.9
3	76.0—78.0	197.0

Acetone 2,4-dinitrophenylhydrazone (mp 122.5—123.5 °C) and isopropyl 3,5-dinitrobenzoate (mp 110—114 °C) were obtained from fractions 1 and 2, respectively. Mixture melting points with the authentic samples showed no depression.

Kinetic Measurements. To a solution of cyclohexene (210 ml), thermostated at a specified temperature, was added a solution of II (40 ml) stabilized by addition of a small amount of the sodium salt of a partially esterified polyphosphate. Ethyl acetate saturated with water at room temperature was used as a solvent. The initial concentrations of cyclohexene and II were $(2.93—5.85)\times10^{-1}$ and 1.31×10^{-1} mol/l, respectively. The reaction mixture was constantly agitated and the progress of the reaction was determined by analysis of II. The solution of II used in these measurements was prepared by the ozone-initiated batchwise autoxidation of I ($[I]_0$, 1.0 mol/l; 40 °C).

Isolation of Peroxyisobutyric Acid (II). A solution of I in anhydrous ethyl acetate (250 ml, 3.0 mol/l) was autoxidized at 5—16 °C (batchwise; O_2, 72 l/hr; O_3/O_2, 0.29 mmol/l). 2.3 molar solution of II was obtained after 70 min. A portion of this solution was distilled at 150 mmHg to remove most of the solvent, then at 30 mmHg to obtain crude II. This was purified by fractional distillation with a 30 cm packed column; bp 41 °C/30 mmHg. An all-glass apparatus was used, and a small amount of the sodium salt of a partially esterified polyphosphate was added before each distillation. Purified II, the purity of which was determined to be 97.2 wt% by iodometric titration, was stored in a Dry Ice box.

The authors thank Mr. Y. Ooe, Mr. I. Koga, Mr. T. Kakuhashi, and Mr. S. Kanno for their cooperation throughout this work.

Application of Chemical Reactions on Thin-layer Chromatoplates. IV. Triterpenes

A. M. Osman, M. El-Garby Younes,* and Mrs. F. M. Ata
Department of Chemistry, Faculty of Science, University of Assiut, Assiut, Egypt, A.R.E.
(Received November 21, 1973)

Some specific reactions of triterpenoids had been performed on thin-layer chromatoplates. The reactions conducted were: oxidation with oxygen in K-*t*-butoxide, benzilic acid rearrangement, decarboxylation with lead tetraacetate, Wolff-Kischner reduction, reduction with sodium borohydride, reduction with lithium aluminium hydride, oxidation with chromium trioxide in pyridine and in acetic acid, oxidation with manganese dioxide in chloroform, methylene chloride and isopropyl alcohol, insertion of an oxygen atom in ring A of triterpenoids by the formation of acid anhydride and reduction by a modified Clemmensen method.

Previously,[1] we had carried out some chemical reactions characteristic of triterpenoids on thin-layer chromatoplates. Since we are working mainly on compounds belonging to this group, we decided to do more specific chemical reactions of triterpenes on thin-layer chromatoplates in order to serve in widenning the aspects of the technique and to overcome some difficulties encountered in our work on natural products. Besides the reactions carried out with amino-acids[2] on chromatoplates, also we had perfomed reactions characteristic of the monoterpenes.[3] Really, we found that the application of chemical reactions on chromatoplates solved several problems, particularly in the field of natural products.

Generally speaking, the reaction is carried out by mixing the substance under examination mostly in solution form, with the reactants within the area of a small spot at the starting line of a plate of an inert adsorbent. The mixture of reactants is then subjected to the favourable conditions and suitable length of time to simulate, as far as possible, the normal reaction conditions in the flask. The adsorbed layer is then treated in the normal manner as a chromatographic medium for the resolution of the components of the reaction mixture. Thus, development with a suitable solvent system enables the detection of the formed derivative or comparison with the expected material, spotted at the starting line immediately prior to development. Differentiation of the derivative from the starting material, if any remains, is always possible if the appropriate conditions are used.

Results and Discussion

Reactions involving oxidation of the triterpene ketones with oxygen in potassium *t*-butoxide at room temperature[4] to give the corresponding diosphenol, proceeded with difficulty, and most of the starting material was obtained unreacted (compound **1**, **2**, *cf.* Table 1), while the resulting diosphenol was obtained in a poor yield.

Benzilic acid rearrangement[5] of the diosphenol, was performed on the chromatoplate successfully for all the compounds tried, and the resulting α-hydroxy acids were obtained in a reasonable yield (**3**—**4** *cf.* Table 1).

Reactions of the α-hydroxy acids with lead tetraacetate in acetic acid[6] at room temperature was almost complete and smooth and the A-nor triterpenes were obtained in good yields.

Wolff-Kischner reduction of the triterpene ketones, proceeded under severe conditions and with difficulty, and the reacted materials were obtained in very poor yields, while most of the starting ketone remained unchanged.

Reduction of compounds (**8**—**10**, *cf.* Table 1) with sodium borohydride was performed easily with a good yield, while reduction with a suspension of lithium aluminium hydride in dry ether proceeded with difficulty and was incomplete, even by changing the experimental conditions,[3] for instance prolonging the time of exposure period.

Oxidation of compounds (**13**—**15** in Table 1) with chromium trioxide–pyridine at room temperature overnight was difficult, while oxidation with chromium trioxide–acetic acid at 50 °C for a few minutes proceeded smoothly with a good yield.

Oxidation of the hydroxy triterpenes (**13**—**18**; *cf.* Table 1) with manganese dioxide in different solvents[7] gave interesting reuslts and the yield changes according to the nature of the solvent. Using chloroform as a solvent the yield was poor, while by using methylene dichloride and isopropyl alcohol the oxidation reaction gave a better yield.

The formation of the triterpene anhydride[8] from the secodiacid (**19**; *cf.* Table 1) by heating at 100 °C for 2 hr with acetic anhydride proceeded with difficulty and a poor yield of the desired anhydride was formed, while most of the starting material was obtained unchanged.

Reduction of the keto-groups to methylene groups by a modified Clemmensen procedure[9] was proceeded smoothly under mild conditions using active zinc dust and acetic anhydride saturated with hydrogen chloride gas at 0 °C. The resulting methylene compounds were obtained in good yields (See experimental for compounds **8** and **20** in Table 1).

Conclusion: The results obtained in this study show that the application of chemical reactions of the triterpenoids on chromatoplates can afford reliable informations regarding the "preparation" of known derivatives and determining whether a given reaction can take place, all with the use of only negligible amounts of material.

a) Solvent system: I:benzene–ether (9: 1), II: benzene, III: light petroleum–benzene (1: 1), IV: light petroleum–benzene (4: 1), V: benzene–ether (4: 1), VI: light petroleum–benzene (1: 4), VII: benzene–ether (1: 1), VIII: light petroleum–benzene (3: 2), IX: light petroleum–benzene (3: 1).

Experimental

Chromatoplates. These were prepared by slurring Kiesel gel G. (Merck) in water (1: 2 by weight) and applying manually onto plates (5×15 cm), followed by heating at 120 °C for 2 hr, then placed in a drying desiccator containing calcium chloride for drying. The development of the plates was done by placing them for 15 min in a tank containing iodine.

Oxidation with Oxygen in K-t-Butoxide. This reaction was performed by treating the ketonic triterpene spot in *t*-butyl-alcohol at the starting line of the chromatoplate with a saturated solution of potassium *t*-butoxide. The plate was then placed in a vacuum desiccator having a saturated atmosphere of *t*-butyl alcohol, the plate was evacuated from air and a stream of oxygen was then passed through for 2 hr. At the end of the reaction, the plate was dried in air prior to development.

Benzilic Acid Rearrangement. This reaction of the diospenols **3** and **4** (*cf.* Table 1) was achieved by treating the diosphenol spot in ethanol at the starting line of a chromatoplate with ethanolic KOH (10%). The plate was placed in a desiccator containing a saturated solution of the reagents and then heated at 70 °C for 5 hr after which the plate was cooled in air before chromatographic development.

Decarboxylation with Lead Tetraacetate. This reaction was performed by treating the α-hydroxy acid spot with a suspension of lead tetraacetate in acetic acid, the spotting of the reagent was continued for 10 min. The plate was placed in a desiccator containing acetic acid and the whole was maintained at 45 °C for 1 hr. After this period the spot was treated with ethylene glycol to destroy the excess of lead tetraacetate. The plate was dried and ready for chromatographic development.

Wolff-Kischner Reduction. This reaction was conducted on thin-layer chromatoplates by treating the triterpene ketonic spot under examination in ethanol with hydrazine hydrate (95%) and ethylene glycol. The plate was placed in a desiccator containing ethyl alcohol and ethyleneglycol, then the whole were heated at 150 °C in an oven for 2 hr, after this period the plate was cooled in air and a concentrated solution of ethanolic potassium hydroxide was applied on the reacting spot and heated again for extra 4 hr. At the end of this period the spot was cooled and acidified with sulfuric acid (1 M) prior to development.

Reduction with Sodium Borohydride. The ketone spot in methanol was treated with a suspension of sodium borohydride in water: methanol (5: 1) and the plate was heated as usual in the desiccator at 55 °C for 2 hr to give mainly the resultant alcohol after development.

Reduction with Lithium Aluminium Hydride. The reduction was performed by treating the ketone spot with a suspension of lithium aluminium hydride in dry ether at room temperature overnight prior to development.

Oxidation with Chromium Trioxide. (A) In Pyridine: The triterpene alcohol spot in pyridine was treated with chromium trioxide in pyridine and the plate was left in a desiccator containing pyridine for overnight. It showed that most of the starting alcohol remained unchanged.

(B) In Acetic Acid: The alcohol spot in acetic acid was treated with a solution of chromium trioxide in acetic acid and the chromatoplate in an atmosphere of acetic acid was heated at 50 °C for 15 min after which it was dried prior to development.

Oxidation with Manganese Dioxide. (A) In Chloroform: This reaction was performed by treating the triterpene alcohol spot n chloroform with manganese dioxide in chloroform and the plate was placed in a desiccator saturated with an atmosphere of chloroform and the whole was left at room temperature overnight after which the plate was dried in air prior to development.

(B) In Methylene Dichloride: The procedure is the same as that mentioned under method (A), except chloroform was replaced by methylene dichloride.

(C) In Isopropyl Alcohol: The reaction was performed as that under method (A), by replacing isopropyl alcohol instead of chloroform.

Formation of Acid Anhydride. The seco-diacid spot was treated with acetic anhydride and the plate was put in a desiccator containing acetic anhydride and the whole was heated at 100 °C for 2 hr, after which the plate was cooled prior to chromatographic development.

A Modified Clemmensen Reduction. This reaction was conducted on a tlc plate by treating the ketonic compound under examination at the starting line with a suspension of active zinc dust[9] in acetic anhydride. The plate was then placed in a vacuum desiccator containing a saturated atmosphere of acetic anhydride and the whole was cooled at 0 °C. Hydrogen chloride was passed into the desiccator until the space inside it became saturated with hydrogen chloride, then the whole system was left for 2 hr at 0 °C. The spot was treated with a solution of sodium carbonate and the plate was dried in air prior to development.

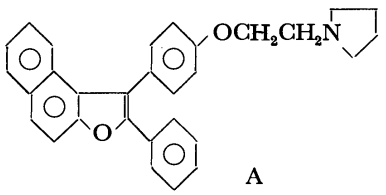
Furano Compounds. XXII

M. Kanakalingeswara Rao and S. Rajagopal
Department of Chemistry, Regional Engineering College, Warangal, 506004 India
(Received November 21, 1973)

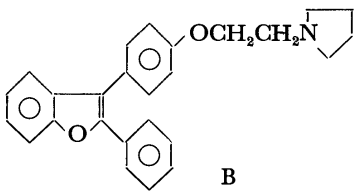
The synthesis of 2′,3′-diphenylfuranobenzoxanthones with the condensed benzene ring at the 5,6; 6,7; and 7,8 positions and with possible antifertility activity is recorded.

The first report on the use of polyphosphoric acid as an effective reagent for the condensation of phenols with benzoin to give 2′,3′-diphenylbenzofurans was made by us earlier.[1] Subsequently employing this method and various 1,3-dihydroxyxanthones in the place of phenols a number of 1-hydroxy-2′,3′-diphenylfurano[4′,5′: 3,4]xanthones carrying alkyl (methyl) substituents in various positions of the free benzenoid ring were synthesised and the results recorded.[2] The synthesis of these compounds was warranted on the basis that they may serve as potential antifertility agents due to the presence of 2,3-diphenylfuran moiety.

The beneficial influence of a naphthaleno nucleus on the antifertility activity is established by the observations of Carney *et al.*[4] on the enhanced activity of 2,3-diphenylnaphthofurans over 2,3-diphenylbenzofurans. This is further corroborated by Chawla *et al.*[3] who have shown that the antifertility activity of 3-(1-pyrrolidinoethoxyphenyl-2-phenyl)naptho[2,1-*b*]furan (A) (as hydrochloride) is ten times that of 2-phenyl-3-pyrrolidinoethoxyphenylbenzofuran (B).



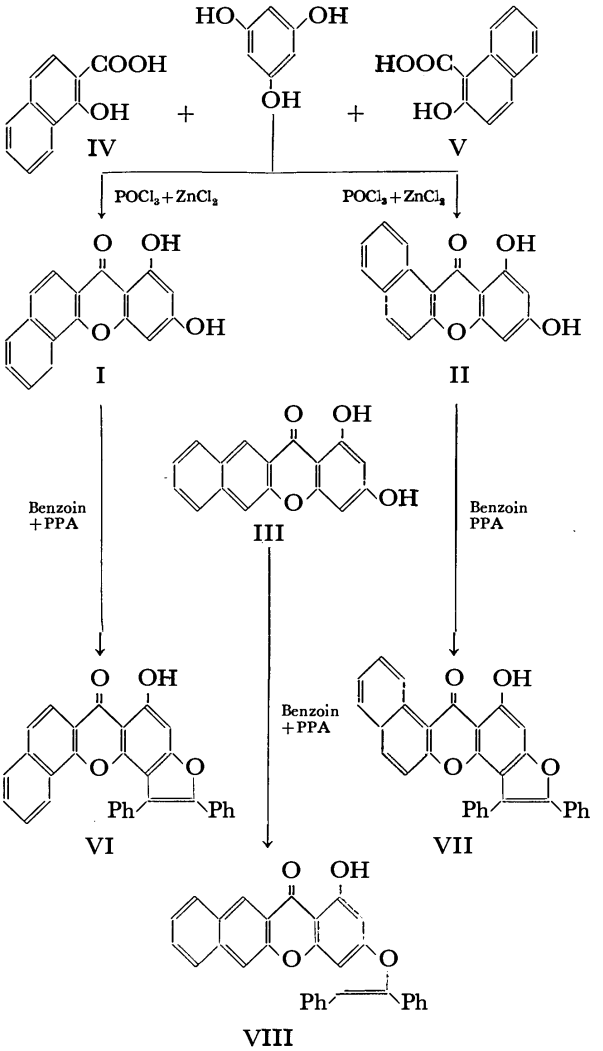
A



B

Hence the synthesis of various 2′,3′-diphenylfurano-[4′,5′: 3,4]benzoxanthones has been undertaken and the results recorded. Two angular and one linear benzoxanthones *viz.* 1,3-dihydroxy-5,6-benzoxanthone (I), 1,3-dihydroxy-7,8-benzoxanthone (II) as also 2,3-dihydroxy-6,7-benzoxanthone (III) have been used as the starting material. The xanthones (I) and (II) whose syntheses are recorded for the first time have been obtained by condensing phloroglucinol with 1-hydroxy-2-naphthoic acid (IV) in the case of I and 2-hydroxy-1-naphthoic acid (V) in the case of II in the presence of phosphorus oxychloride and zinc chloride (Grover, Shah, and Shah[5]). It may be added that in view of the easy decarboxylation of 2-hydroxy-1-naphthoic acid under the conditions employed for the preparation of xanthone, the reaction had to be carried out at room temperature for a longer period.

The hydroxyxanthones (I, II, and III) are then condensed with benzoin in the presence of polyphosphoric acid at 100—110 °C to yield the desired 2′,3′-diphenylfuranobenzoxanthones (VI—VIII). These compounds will be screened for their antifertility activity in due course.



Experimental

IR Spectra were determined on a perkin-Elmer Model 221 spectrophotometer with sodium chloride prisim—in KBr disc.

1,3-Dihydroxy-5,6-Benzoxanthone (I). 1-Hydroxy-2-naphthoic acid (10 g), phloroglucinol (10 g), freshly fused zinc chloride (30 g) and phosphorus oxychloride (70 ml) were heated at 60—70 °C for 2 hr. The separated product was filtered, washed with dilute sodium bicarbonate solution

and with water. The xanthone crystallised from aqueous alcohol as yellow needles, mp 299—300 °C. Yield: 2.8 g. Found: C, 73.8; H, 4.2%. Calcd for $C_{17}H_{10}O_4$: C, 73.3; H, 3.6%. νCO: 1650 cm^{-1}, νOH: 3200 (broad) cm^{-1}.

1-Hydroxy-2',3'-diphenyl-5,6-benzo[4',5':3,4]furanoxanthone (VI). 1,3-Dihydroxy-5,6-benzoxanthone (2 g), benozin (2 g) were mixed and added in small portions to polyphosphoric acid (25 g of P_2O_5 and 12 ml of orthophosphoric acid) at 110 °C for 1 hr. The mixture was heated at 100—110 °C, with constant stirring for 4 hr. It was then cooled and poured into ice-water. The solid that separated was filtered, macerated with 5% aqueous sodium bicarbonate and again filtered. Purification of the crude product by chromatography over silica gel employing petroleum ether as the eluent gave compound (VI) which crystallised from benzene as shining needles, mp 212—213 °C. Yield: 0.06 g. Found: C, 81.5; H, 4.5%. Calcd for $C_{31}H_{18}O_4$: C, 81.9; H, 4.0%. νCO: 1645 cm^{-1}, No free OH absorption.

1,3-Dihydroxy-7,8-benzoxanthone (II). 2-Hydroxy-1-naphthoic acid (8 g), phloroglucinol (8 g) freshly fused zinc chloride (24 g) and phosphorus oxychloride (56 ml) were mixed together and kept at room temperature for 48 hr. The reaction mixture was poured into crushed ice and worked up as usual. The xanthone crystallised from aqueous alcohol as yellow needles, mp 271—272 °C. Yield: 2.5 g. Found: C, 69.6; H, 4.6%. Calcd for $C_{17}H_{10}O_4 \cdot H_2O$: C, 69.2; H, 4.7%. $\nu_{C=O}$: 1650 cm^{-1}. ν_{OH}: 3000, 3100 cm^{-1} (broad).

1-Hydroxy-7,8-benzo-2',3'-diphenyl[4',5':3,4]furanoxanthone (VII). A mixture of 1,3-dihydroxy-7,8-benzoxanthone (3 g), benzoin (3 g) were added to PPA (25 g of P_2O_5 and 14 ml of orthophosphoric acid) at 120 °C during 1 hr with stirring. The reaction mixture was heated for a further period of 5 hr at 100 °C and then poured into crushed ice. The crude substance was purified by chromatography over silicagel. Petroleum ether elution gave (VII) which crystallised from benzene as yellow shining needles, mp 245 °C. Yield: 0.1 g. Found: C, 81.7; H, 4.3%. Calcd for $C_{31}H_{18}O_4$: C, 81.9; H, 4.0%. $\nu_{C=O}$: 1645 cm^{-1}. No free OH absorption.

Substitution Effect in the Hydrogenation of Monoalkylbenzenes with Ruthenium Catalyst

Toshihisa YOSHIDA

Department of Natural Science, Faculty of Education, Saitama University, Shimo-Okubo, Urawa, Saitama 338

(Received November 5, 1973)

Synopsis. The influence of substituents on adsorption coefficients as well as rate constants can be understood from the rules of Horiuti-Polanyi and Taft. It is suggested that a nucleophilic adsorption of alkylbenzene and a nucleophilic surface reaction of the adsorbed alkylbenzene with the metal-hydride occur successively.

Various kinds of linear free energy relationship (LFER), such as the Hammett[1] and the Taft[2] equation, have been given in homogeneous reactions, but only the Horiuti-Polanyi rule[3] has been given in heterogeneous reactions. Recently, Kraus[4] pointed out that the equations of Hammett or Taft could be applied to some heterogeneous reactions over metals. The velocity constants k he used were obtained from experimental rate equations of Langmuir-Hinshelwood type, such as $k\prod_i K_i[A_i]/(1+\sum_j K_j[A_j])$.[5]

The object of the present work is to examine the influence of the substituents on the adsorption coefficients, K_i, as well as on the rate constants, k, in the hydrogenation of monoalkylbenzenes over ruthenium black catalyst.

Experimental

Materials. Alkylbenzenes (purity above 99%, Tokyo Kagaku Seiki Co. Ltd.); Ethanol and other reagents (G.R., Wako Pure Chem. Ind. Ltd.). Ruthenium black was prepared by the reduction of $RuCl_3 \cdot 3H_2O$ (Engelhard Ind. Inc.) with formaldehyde. It was washed 10 times with distilled water and stored in ethanol.

Apparatus and Procedure. The reaction vessel: 50 ml flask with cooler and sampling stopcock. After 4.85 mg of ruthenium black had been admitted into the reaction vessel, a given amount of substrate and solvent (ethanol) was added to make the total volume 20 ml under hydrogen atomosphere. Hydrogenation was carried out under a constant (atomospheric) pressure of hydrogen at 10—30 °C. The rate of hydrogenation was determined by measuring either amounts of absorbed hydrogen by a gas-buret or concentrations of the products by gas-liquid chromatography.

Results and Discussion

The initial rates of the benzene hydrogenation with the same catalyst can be expressed by the following rate equation.[6]

$$-\left(\frac{d[X]}{dt}\right)_0 = \frac{k_X K_X [X] P_H}{1+K_X[X]} \quad (1)$$

where [X] is the concentration of benzene and P_H is the pressure of hydrogen. It has been confirmed that the equation can also be applied to the hydrogenation of monoalkylbenzenes (–CH_3, –C_2H_5, –n-C_3H_7 and –i-C_3H_7). We can obtain respective values of k and K from the equation. For the competitive hydrogenation of monoalkylbenzenes A and B, we get

$$\frac{d[B]}{d[A]} = \frac{k_B K_B [B]}{k_A K_A [A]} \quad (2)$$

or

$$\frac{\log(1-X_B)}{\log(1-X_A)} = \frac{k_B K_B}{k_A K_A} \quad (3)$$

where X_A and X_B are conversions of substrates A and B, respectively. We can obtain respective values of k and K from the hydrogenation of single substrate,

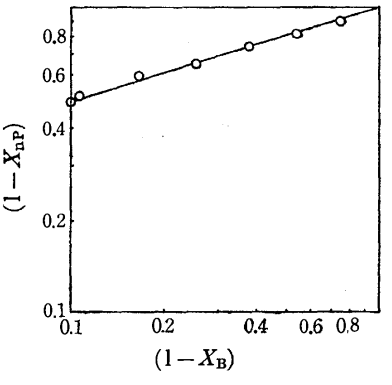

Fig. 1. Competitive hydrogenation between benzene (B) and n-propylbenzene (nP) at 30 °C in ethanol solvent.

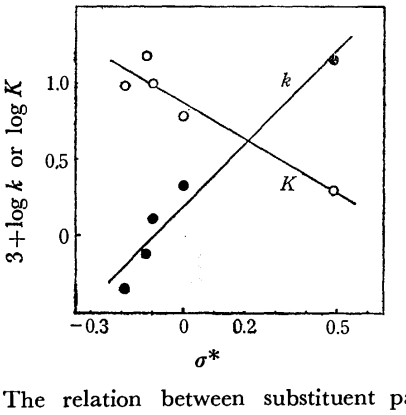

Fig. 2. The relation between substituent parameters (σ^*) and rate constants or adsorption constants at 20 °C in ethanol solvent.

taking the experimental ratios of kK from competitive hydrogenation of two substrates into consideration. The applicability of Eq. (3) in the case of the competitive hydrogenation of benzene and *n*-propylbenzene is shown in Fig. 1 and that of the Taft equation to rate constants k and the adsorption coefficients K in the hydrogenation of alkylbenzenes over ruthenium black in Fig. 2. It should be noted that the slopes of the two lines are opposite each other. That is, the reaction parameter k is positive ($\rho^*=2.05$), while adsorption parameter K is negative ($\rho^*=-1.17$). This can be understood on the basis of the Horiuti-Polanyi rule,[3] provided that the initial state of hydrogenation is the adsorption step of monoalkylbenzenes and that the attack of adsorbed hydrogen as a rate-determining step occurs in succession. The lower the value of σ^*, the higher the electron density in benzene nucleus. Thus, adsorbed alkylbenzene exists stably and surface reaction is retarded.

The negative reaction parameter thus obtained from the Taft plot of adsorption coefficients suggests that a nucleophilic adsorption occurs on the surface of ruthenium, as follows.

$$\text{Adsorption} \quad R + \overset{\delta+}{|}_{M} \longrightarrow R^{\delta+}|_{M} \qquad (4)$$

The positive reaction parameter between k and σ^* obtained suggests that a nucleophilic reaction of the adsorbed alkylbenzene complex with a metal-hydride occurs on the surface:

$$\text{Surface reaction} \quad R^{\delta+}|_{M} + H^{\delta-}|_{M} \rightarrow RH^{\delta-}|_{M} + {}^{\delta+}|_{M} \qquad (5)$$

The mechanism is similar to the nucleophilic type mechanisms proposed for other reactions; the hydrogenation of alkylbenzene over PtO_2[4,7] ($\rho^*=0.842$), the hydrogenolysis of chlorobenzenes over Pd-carbon[5] ($\rho^*=1.77$) and the homogeneous hydrogenolysis of organic halides with sodium bis(2-methoxyethoxy)aluminium hydride[5,8] ($\rho^*=4.0$).

In this experiment, the Taft plot is more favorable than the Hammett one, as was also pointed out by Kraus[4] who did not deal with adsorption coefficients. Recently, Simonikova *et al.*[9] have reported that the adsorption coefficients showed an opposite trend to the rate constants in heterogeneous hydrogenation of aliphatic ketones, in good agreement with out findings.

The author wishes to express his cordial thanks to Prof. Tominaga Keii, Tokyo Institute of Technology, for his advice and discussions.

Molten-State Spectra of Anisyl-*p*-Benzoquinones[1)]

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 7, 1974)

Synopsis. The absorption spectra of three anisyl-*p*-benzoquinones were observed in the molten state. Interestingly, only the *p*-anisyl isomer was found to form a self-complex in the molten state as in the solid state. Possible explanation was presented for this effect.

In the previous paper, we reported on dimorphism of anisyl-*p*-benzoquinones.[2)] These compounds are typical intramolecular charge-transfer compounds, in which the electron-donating anisyl moiety is directly bonded to *p*-benzoquinone with an electron affinity of 1.34 eV.[3)] Among them, *o*- and *p*-anisyl-*p*-benzoquinones were found to crystallize in two forms. Of these two isomers, one form is spectroscopically monomeric and another form exhibits an additional electronic transition on the low-energy side, which is missing in the solution spectrum. Such a transition was considered as due to intermolecular charge-transfer interactions. That is, there is supposedly a finite overlap between the donor orbital of one molecule and the acceptor orbital of the adjacent molecule in the crystal. Only one crystalline form of the *m*-anisyl isomer was monomeric.

In order to extend our understanding of the organic self-complex, we attempted to observe the absorption spectra of these compounds in the molten state. To the best of our knowledge, there have been no investigations of this kind except some visual observation of molten charge-transfer complexes.[4)]

Experimental

The experimental technique concerning spectrophotometry was described earlier.[5)] Instead of the powdered sample, a melt was sandwiched between two quartz plates. The apparent reflectance obtained by this method was quite similar to the transmittance of the sample. The reflectance from the interface between the sample and the quartz plate is negligible. Accordingly, the absorbance of the melt can be derived by applying Beer's law to the apparent reflectance. The relative absorbance was checked by comparing the ordinary solution spectra taken by this method and the transmission spectroscopy. The spectrum thus obtained is excellently reproducible unless the absorbance varies by two or more orders of magnitude within the energy range concerned.

The measurements were made at temperatures about 15 °C above the melting points. Fortunately, the present compounds have relatively low melting points; 64—65, 121 and 126—127 °C for *o*-, *m*- and *p*-anisyl-*p*-benzoquinones, respectively, in the stable form.[2)]

Results and Discussion

Figures 1—3 show the absorption spectra of *o*-, *m*- and *p*-anisyl-*p*-benzoquinones, respectively, in two fluid phases. Every solution spectrum displays an intramolecular charge-transfer band in the visible region. The absorption peaks are located at 25800, 27500 and 23800 cm^{-1} for *o*-, *m*- and *p*-anisyl isomers, respectively, in ethanol. On the other hand, the melts are yellowish, yellowish and red, respectively. The red melt of *p*-anisyl-*p*-benzoquinone is suggestive of the presence of the dimeric species. Actually, such visual observation is supported by the molten-state spectra of these compounds.

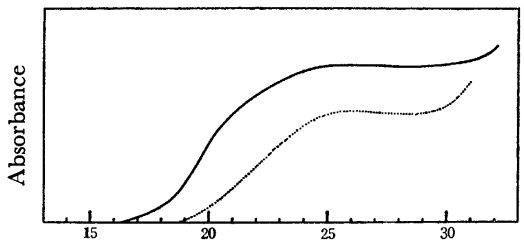

Fig. 1. Absorption spectra of *o*-anisyl-*p*-benzoquinone in ethanol (·····) and in the molten state (——).

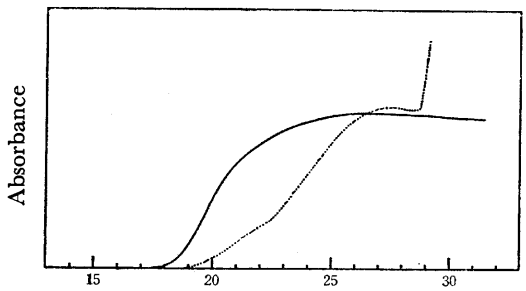

Fig. 2. Absorption spectra of *m*-anisyl-*p*-benzoquinone in ethanol (·····) and in the molten state (——).

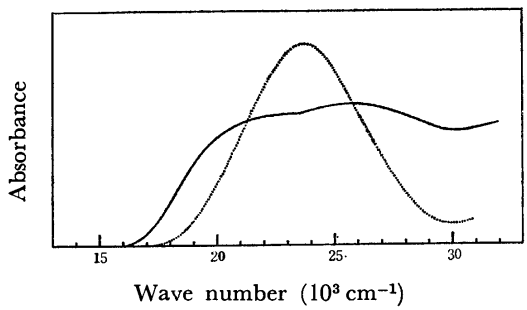

Fig. 3. Absorption spectra of *p*-anisyl-*p*-benzoquinone in ethanol (·····) and in the molten state (——).

The molten-state spectrum of the *o*-anisyl isomer closely resembles that of the *m*-anisyl isomer. The intermolecular interactions in the solid *o*-anisyl-*p*-benzo-

quinone are found to be effectively blocked by the fluidity of the melt. The molten-state spectrum of the *m*-anisyl isomer is a reproduction of the solid-state spectrum. Though these spectra are undoubtedly monomeric, they are somewhat different from the solution spectra in that the low-energy portions are considerably intensified.

In each spectrum, there is a round hump around 21000 cm^{-1}, which is energetically assignable to the n-π^* transition characteristic of the *p*-benzoquinones.[2,6] In the solution spectra of the *o*- and *p*-anisyl isomers, such an n-π^* transition overlaps totally with a more intense intramolecular charge-transfer band. However, the n-π^* transition is partially disclosed in an appropriate region of the solution spectrum of *m*-anisyl-*p*-benzoquinone, since the intramolecular band is much shifted to the higher-energy side for this isomer. The assignment of the hump to the n-π^* transition seems to be thus rationalized.

On the other hand, the absorption spectrum of the molten *p*-anisyl-*p*-benzoquinone is in marked contrast to the solution spectrum. From the viewpoint of the spectral shape, the presence of two different absorption bands is fairly obvious besides the missing n-π^* transition. The absorption peak around 25700 cm^{-1} corresponds well to the intramolecular transition in the solution spectrum. Since each band appears very smooth in the molten state, the break, *i.e.*, the inflection point, near 23500 cm^{-1} difinitely suggests that another absorption band is present on the low-energy side. In analogy with the solid-state spectrum, this band is assigned to the intermolecular charge-transfer transition.[2]

For *p*-anisyl-*p*-benzoquinone, the relative intensities of the intra- and inter-molecular charge-transfer bands are comparable to each other in the molten state as in the dimeric solid. Considering that, if the crystal is dimeric at all, the self-complex formation is attained to 100 percent in it, we might safely say that such a situation is almost preserved in the molten *p*-anisyl-*p*-benzoquinone. The association constant of this self-complex is extimated to be very large in the melt.

As was suggested in the previous paper,[2] the steric effect of the methoxy group might determine the optical behavior of the three anisyl-*p*-benzoquinones in condensed phases. This effect makes the dimer of the *p*-anisyl isomer the most stable of all. However, it is not sufficient to elucidate the monomeric aggregation of the *m*-anisyl isomer which is free from the steric hindrance. As was described above, the absorption peak of the intramolecular charge-transfer transition of the *m*-anisyl isomer is located at the highest energy in solution. This fact may reflect the weak donor ability of the *m*-anisyl isomer.

In summary, the intermolecular interactions of this kind are considered to be very weak, and are not always primary factors in determining the structure of the condensed phase.

The Absorption Spectra of the Electrochemically-generated Unstable Species of Tris(2,2′-bipyridine)cobalt(II) by Reflectivity Measurements at the Silver Electrode in Propylene Carbonate

Yuichi SATO

Toshiba Research and Development Center, Tokyo Shibaura Electric Co., Ltd., Komukai Toshiba-cho, Kawasaki 210

(Received September 3, 1973)

Synopsis. Tris(2,2′-bipyridine)cobalt(II) perchlorate gave a two-step reduction wave ascribed to $[Co(bipy)_3]^{2+} \xrightarrow{e} [Co(bipy)_3]^{+} \xrightarrow{2e} [Co(bipy)_3]^{-}$ at the Ag electrode in a propylene carbonate solution. The simultaneously-recorded reflectivity-potential curve showed a reflectivity decrease corresponding to each wave on the *i-E* curve. The absorption spectra due to the unstable reduction products, $[Co(bipy)_3]^{+}$ and $[Co(bipy)_3]^{-}$, were obtained by plotting the reflectivity change *vs.* the wavelengths.

In a previous paper,[1] we showed that the reflectivity measurement enabled one to obtain the spectra of unstable species generated during electrolysis, and that the method has successfully been used to detect the reduction products of the tris(2,2′-bipyridine)chromium(III) complex.

The present communication will extend the method to support the previous conclusion[2] that lower-valence complexes can be generated by the reduction of tris(2,2′-bipyridine)cobalt(II).

Experimental

The current-potential (*i-E*) and reflectivity-potential (R/R_0-*E*) curves were obtained in propylene carbonate (PC) by the same apparatus and method as were reported in the previous paper.[1] Tris(2,2′-bipyridine)cobalt(II) perchlorate, $[Co(bipy)_3](ClO_4)_2$, was prepared according to the literature.[3]

Results and Discussion

Figure 1 shows the *i-E* and R/R_0-*E* curves simultaneously obtained in a solution containing $[Co(bipy)_3](ClO_4)_2$. This complex gave a two-step reduction wave in the potential range between 0 and −2.0 V and the corresponding anodic wave. Upon the addition of free 2,2′-bipyridine to a solution containing the complex, the peak heights of the first and the second step were not affected; this shows that two steps may be concluded to be due to the reduction of the cobalt(II) complex itself and not to the reduction of the free bipyridine liberated from the complex. The peak potential of the first step is not affected, whereas that of the second one is shifted to more negative potentials with an increase in the concentrations of free bipyridine. This seems to be attributable to the substitution labile nature of the product—*viz.*, a dissociation of the ligand from the reduction product.[2] Such an instability could be avoided by the addition of a large excess of free ligands to the solution.

With the aid of the results obtained in an acetonitrile solution,[2] the first step in the cathodic scan seems to be ascribable to the one-electron reduction of;

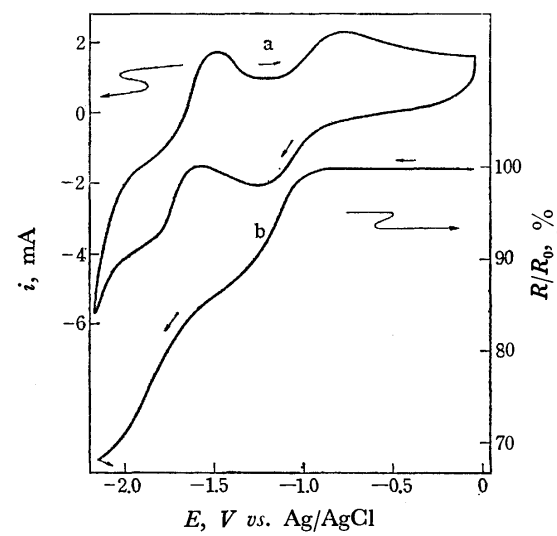

Fig. 1. The *i-E* (a) and R/R_0-*E* (b) curves of 0.5 mM $[Co(bipy)_3](ClO_4)_2$ at silver electrode in the presence of 20 mM 2,2′-bipyridine in 0.05 M $(C_2H_5)_4NClO_4$ of PC solution. Potential sweep rate was 440 mV/s and R/R_0 was measured at 630 nm.

$$[Co(bipy)_3]^{2+} + e \longrightarrow [Co(bipy)_3]^{+} \quad (1)$$

The peak potential difference between the first and the second cathodic peaks in a PC solution is about 0.65 V, nearly equal to the difference between the half-wave potentials of the first and the second reduction waves (0.66 V) obtained in an acetonitrile solution.[2] This fact suggests that the same electrode process as that in an acetonitrile solution occurs in the PC solution in the second process; namely:

$$[Co(bipy)_3]^{+} + 2e \longrightarrow [Co(bipy)_3]^{-} \quad (2)$$

Tanaka and Ogata[4] also pointed out that $[Fe(bipy)_3]^{2+}$ and $[Ni(bipy)_3]^{2+}$ in the PC solution showed almost the same polarographic waves due to the reduction into the low-valence states as those observed in the acetonitrile solution.

The simultaneously-recorded R/R_0-*E* curve is shown in Fig. 1 as Curve (b); only the cathodic process is shown. The correspondence between the *i-E* and R/R_0-*E* curves is very good; *i.e.*, the starting potentials of all the steps on the *i-E* and R/R_0-*E* curves are almost the same, and the first (−1.25 V) and the second peak potentials (−1.90 V) on the *i-E* curve correspond to the potentials where the reflectivity changes most dramatically, implying the formation of the reduced states at these potentials.

The reflectivity decrease is associated with the successive formation of two different types of reduction

products formed at each corresponding potential. The reflectivity decrease at the first wave is considered to be due to the formation of $[Co(bipy)_3]^+$. If this is true, and if Reaction (1) is reversible, the recovery of the reflectivity will be observed upon the oxidation of the reduction product. This was confirmed by measuring the R/R_0-t curve shown in Fig. 2. At first the potential was set at -1.35 V to produce $[Co(bipy)_3]^+$; then the potential was stepped to -0.70 V to oxidize the reduction product. During these operations, the recovery of the reflectivity at -0.70 V was clearly seen on the R/R_0-t curve, seeming to indicate the re-formation of $[Co(bipy)_3]^{2+}$ by the electro-oxidation.

The formation of $[Co(bipy)_3]^+$ is further supported by the absorption spectrum obtained. The reflectivity decrease observed at -1.35 V was plotted *vs.* the wavelength; it is shown in Fig. 3 as Curve (a). The observed reflectivity change is mainly due to the entities formed in the solution and not to the change in the optical properties of the silver electrode*; accordingly, plotting gives the absorption spectrum.

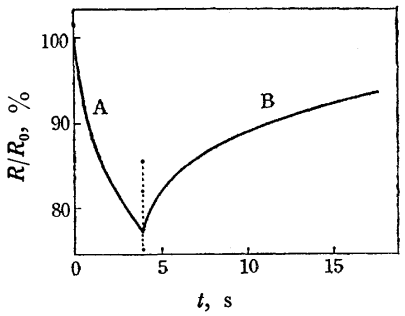

Fig. 2. The R/R_c-t curve of 0.5 mM $[Co(bipy)_3](ClO_4)_2$ in the presence of 20 mM 2,2′-bipyridine and 0.05 M $(C_2H_5)_4NClO_4$ in PC obtained at 630 nm.
Electrode potential was set at -1.35 V in region A and then stepped to -0.70 V in region B.

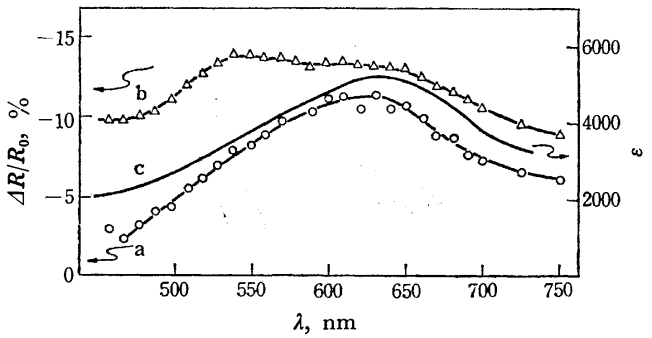

Fig. 3. Wavelength dependence of reflectivity decreases due to electrochemically generated species (a, b) and the absorption spectrum of $[Co(bipy)_3]^+$ in aqueous solution (c).[5] $\Delta R/R_0$ was obtained at varied wavelengths from R/R_0-E curve of the same solution as Fig. 1. $\Delta R/R_0$ of curve (a) was read at -1.35 V and curve (b), at -1.90 V.

* Even during the electrolysis, the decreased reflectivity was eliminated when the solution was stirred vigorously to remove the reduction product from the optical path.

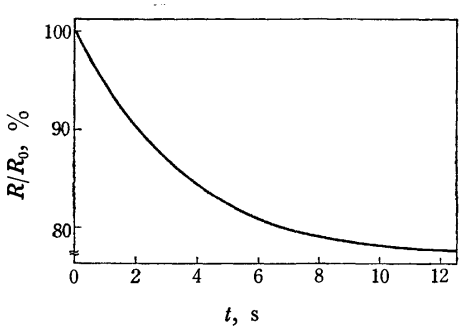

Fig. 4. The $\Delta R/R_0$-t curve measured at 630 nm at open circuit after electrolysis was carried out for 5 s at -1.90 V. Electrolytic solution contained 0.5 mM $[Co(bipy)_3](ClO_4)_2$, 20 mM 2,2′-bipyridine and 0.05 M $(C_2H_5)_4NClO_4$ in PC.

Curve (c) in Fig. 3 is the absorption spectrum of $[Co(bipy)_3]^+$ in an aqueous solution.[5] The curve obtained from the reflectivity measurement fairly well coincides with the reported curve.[5] The small difference in the position of the absorption maximum may be due to the difference in the medium used. Therefore, the reduction product at the first wave on the i-E curve may be concluded to be $[Co(bipy)_3]^+$, and the reflectivity measurement is proved to be a useful method for obtaining the absorption spectrum of the unstable species generated by the electrochemical method.

The absorption spectrum of the species formed at the potential of the second wave, which may be $[Co(bipy)_3]^-$, is given in Fig. 3 as Curve (b), where the difference in R/R_0 between the first and second steps in Fig. 1, (b) is plotted against the wavelength.[1] The bipyridine complex of Co(-I) has not yet been prepared, according to the author's knowledge, so this may be the first spectrum due to $[Co(bipy)_3]^-$.

The $\Delta R/R_0$-t curve was recorded at 630 nm at an open circuit after the electrolysis had been carried out at second wave for 5 s to produce $[Co(bipy)_3]^-$; then the electrolysis was turned off. The curve thus obtained is shown in Fig. 4. The $\Delta R/R_0$ at 630 nm decreased with the lapse of time. This means that $[Co(bipy)_3]^-$ was changed to a substance with an absorption at 630 nm; it may be $[Co(bipy)_3]^+$. That is, a proportionation reaction such as:

$$[Co(bipy)_3]^- + 2[Co(bipy)_3]^{2+} \longrightarrow 3[Co(bipy)_3]^+ \quad (3)$$

seems to occur, where $[Co(bipy)_3]^-$ is formed at -1.90 V and $[Co(bipy)_3]^{2+}$ is supplied from the bulk solution. For the confirmation of such a reaction, however, further detailed study will be required.

The Crystal Structure of Bis(1-(2-thiazolylazo)-2-naphtholato)nickel(II)

Masayasu KURAHASHI

Metal Chemistry Division, National Research Institute for Metals, Meguro-ku, Tokyo 153

(Received Junuary 29, 1974)

Synopsis. The crystals of bis(1-(2-thiazolylazo)-2-naphtholato)nickel(II), [Ni(TAN)$_2$], are triclinic with unit-cell dimensions: $a=12.38(6)$, $b=12.72(6)$, $c=8.41(4)$ Å, $\alpha=78.9(5)$, $\beta=95.0(5)$ and $\gamma=115.1(5)°$, $Z=2$, space group $P\bar{1}$. The TAN is terdentate, one nickel atom being surrounded octahedrally by two ligand anions in the *mer* configuration.

As part of studies on the structures of metal chelates of 1-(2-thiazolylazo)-2-naphthol (abbr. as H-TAN), the X-ray determination of bis(1-(2-thiazolylazo)-2-naphtholato)nickel(II), [Ni(TAN)$_2$], has been carried out.[1] The aim of the present investigation is to establish the configuration around the nickel atom. Two terdentate ligands in the complex were expected to be coordinated to the central metal atom as in the case of iron(II)-chelate, [Fe(TAN)$_2$];[2] however, the crystal of [Ni(TAN)$_2$] is not isomorphous with that of [Fe(TAN)$_2$] even though they are recrystallized from the same solvent (chloroform), the former giving diffuse diffraction spots. It was thus desirable to establish the structure of [Ni(TAN)$_2$]. It is of interest to compare the structure of this compound with that of the palladium(II)-TAN complex, [PdCl(TAN)],[3] since the electronic configuration is of d^8 for both metal ions.

Experimental

The crystals of [Ni(TAN)$_2$] were obtained by slow evaporation of a chloroform solution. Unit-cell dimensions were determined by the oscillation and Weissenberg photographs around the *a*-, *b*-, and *c*-axes. The density was measured by the flotation method in an aqueous NaI solution. The crystal data are shown in Table 1. Owing to the poor crystallinity of the specimens, the diffraction spots were markedly diffuse. With the use of Cu$K\alpha$ radiation, intensities of 795 independent non-zero reflections were determined visually from multiple film Weissenberg photographs of the layers (0—6)*kl*, *h0l*, and *hk*0. The usual Lorents and polarization factors were applied to the observed intensities, no correction being made as regards absorption effect. All the intensities were then placed on a common scale. Since there are two complex molecules in a unit cell, the space group $P\bar{1}$ was assumed. This was justified by the subsequent smooth refinement.

TABLE 1. CRYSTAL DATA FOR [Ni($C_{13}H_8N_3OS)_2$] (F.W.=567.3)

Triclinic, Space group $P\bar{1}$	
$a=12.38\pm0.06$ Å	$V=1177$ Å^3
$b=12.72\pm0.06$ Å	$Z=2$
$c=8.41\pm0.04$ Å	$D_m=1.55$ g·cm^{-3}
$\alpha=78.9\pm0.5°$	$D_x=1.60$ g·cm^{-3}
$\beta=95.0\pm0.5°$	$\mu=32.7$ cm^{-1} (for Cu$K\alpha$)
$\gamma=115.1\pm0.5°$	

Structure Determination and Refinement

The structure was determined by the heavy-atom method. The coordinates of the nickel and two sulfur atoms were deduced from the three dimensional Patterson maps. The remaining atomic positions were obtained by successive Fourier syntheses. The least-squares calculations were carried out with the use of isotropic temperature factors for all non-hydrogen atoms the *R* factor converging to 0.19. The anisotropic temperature factors were then applied to the nickel and two sulfur atoms, and the *R* index was improved to 0.16 after three cycles of refinement. The weighting scheme used was $w=1.0$ for $|F_o|\geqq11.0$, and $w=0.0$ for $|F_o|<11.0$. The diffraction data were so poor that no attempt was made to locate the hydrogen atoms. The structure thus obtained is chemically acceptable with satisfactory bond lengths and angles. The final atomic coordinates and thermal parameters of non-hydrogen atoms are shown in Table 2. The observed and calculated structure factors are listed in Table 3.*

Description of the Structure and Discussion

A perspective view of the molecule is shown in Fig. 1 along with the numbering of the atoms. The bond distances and angles are listed in Table 4 with their standard deviations. The TAN is present as a terdentate ligand; the thiazole nitrogen atom, the azo nitrogen atom adjacent to the naphthol ring and the phenolic oxygen atom are involved in chelate ring formation. The nickel atom is surrounded octahedrally by two ligand anions in the *mer* configuration. The features of the coordination of TAN to Ni(II)-, Fe(II)-, Pd(II)- and Cu(II)-atoms are common in their TAN-complexes. The configuration of [Ni(TAN)$_2$] coincides with that found in the crystals of [Fe(TAN)$_2$],[2] but differs from that of palladium(II)-chelate, [PdCl(TAN)],[3] or copper(II)-chelate, [Cu(TAN)($H_2O)_2$]$^+$,[3] in which the coordination configuration is square-planar or square-pyramidal, respectively. Both TAN anions are planar within the deviation ±0.2 Å. The bond angles of O–Ni–N(1), N(1)–Ni–N(3), O′–Ni–N′(1) and N′(1)–Ni–N′(3) are 80, 79, 80 and 76°, respectively, being fairly deviated from 90°. This is the characteristic feature which can be always seen in the TAN-complexes.

The crystal of Zn(II)–TAN chelate [Zn(TAN)$_2$] was found to be isostructural with that of [Ni(TAN)$_2$]. Both crystals have similar cell dimensions showing a

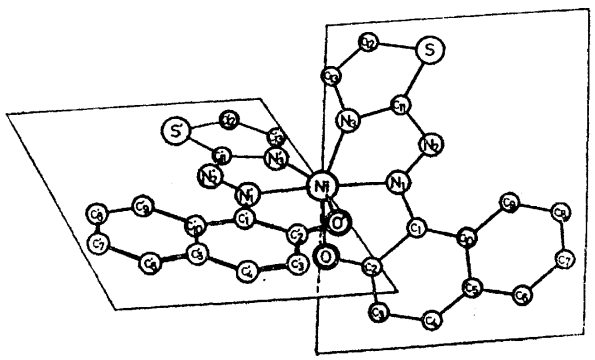

Fig. 1. Molecular structure of $[Ni(TAN)_2]$ and numbering of atoms.

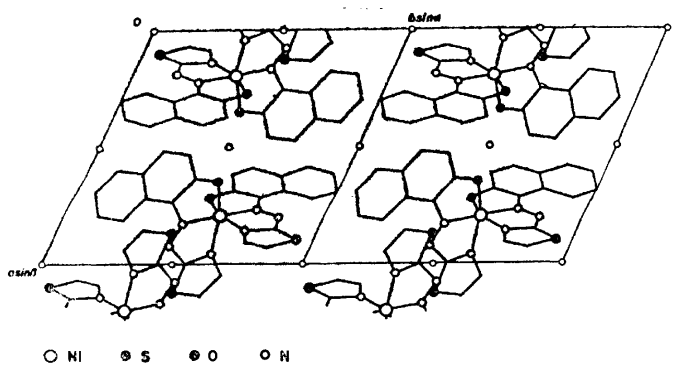

Fig. 2. The crystal structure of $[Ni(TAN)_2]$ as projected along the *c*-axis.

striking resemblance to each other in intensity distribution. It can thus be presumed that the molecular configuration of $[Zn(TAN)_2]$ is congruent with that of $[Ni(TAN)_2]$.

The crystal structure projected along the *c*-axis is shown in Fig. 2. No strong intermolecular interactions such as hydrogen bonding are observed in the structure. Since the positive charge of nickel(II) ion is neutralized by the coordination of the two bulky TAN ligands, the dominant force in the crystal should be essentially of the van der Waals type. Analogous packing of the chelate molecules can be observed in the crystals of $[Fe(TAN)_2]$ and $[Ni(TAN)_2]$, though vacant spaces are filled with solvent molecules in the former. Poor crystallinity of $[Ni(TAN)_2]$ might be related to the fact that some vacant spaces are retained in the crystal structure.

The Preparation of Mixed Cobalt(III) Complexes of *N,N*-Bis(2-aminoethyl)-glycine with the Carbonate or Oxalate Ion[1]

Syoji NAKASHIMA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received February 20, 1974)

Synopsis. *mer*(N)- and *fac*(N)-[$CoCO_3$(*i*-dtma)] complexes have been prepared by the reaction of the tetradentate ligand with the $[Co(CO_3)_3]^{3-}$ complex. The corresponding [Coox(*i*-dtma)] complexes have been derived from the *mer*(N)-carbonato complex.

As to the cobalt(III) complex containing the tetradentate ligand *N,N*-bis(2-aminoethyl)glycine (abbreviated as *i*-DTMA) and the bidentate carbonate ion, two geometric isomers, *mer*(N) and *fac*(N), can possibly exist (Fig. 1). Of these, the *fac*(N) isomer has already been prepared by Schneider and Collman by means of a reaction between the [$CoCl_2$(*i*-dtma)] complex and lithium carbonate.[2] We have now succeeded in obtaining the second isomer, *mer*(N), by means of a reaction of the *i*-DTMA on the tricarbonatocobaltate(III) complex.

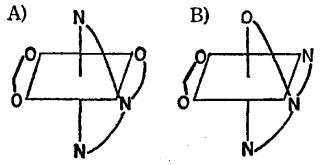

Fig. 1. Geometrical isomers of [$CoCO_3$(*i*-dtma)]
A: *mer*(N), B: *fac*(N).

The *i*-DTMA ligand was prepared from diethylenetriamine as a stock solution according to "Method B" described in the literature.[2] A proper quantity (0.1 mol) of the *i*-DTMA stock solution was added to a fresly prepared solution of potassium tricarbonatocobaltate (III) (0.1 mol),[3] and the mixture was stirred at room temperature for an hour. The resulting solution was charged on a column of a cation-exchange resin (Dowex 50WX8, Na-form). With careful washing with water, two bands, colored pink-violet and red-violet, descended the column, and the effluent was collected in two fractions. For convenience, these fractions were labeled "E-1" and "E-2". Each fraction was concentrated, and a small amount of a mixture of ethanol and ether was added to the concentrate; then the mixture was kept in a refrigerator. Very fine crystals were obtained from each concentrate. The complexes obtained from E-1 and E-2 were tentatively identified as *mer*(N) and *fac*(N) respectively, based on the order of elution.[4,5] The yields were about 6 g for *mer*(N) and about 9 g for *fac*(N). Found for *mer*(N): C, 29.40; H, 5.40; N, 14.56%. Calcd for [$CoCO_3$-($C_6H_{14}N_3O_2$)]·0.5H_2O: C, 29.18; H, 5.25; N, 14.58%. Found for *fac*(N): C, 30.05; H, 5.29; N, 15.07%. Calcd for [$CoCO_3$($C_6H_{14}N_3O_2$)]: C, 30.12; H, 5.06; N, 15.05%.

Two related complexes, *mer*(N), and *fac*(N)-[Coox(*i*-dtma)], were derived from the *mer*(N)-[$CoCO_3$(*i*-dtma)] complex. After the hydrolysis of the carbonato complex (10 g) by 60% $HClO_4$, a proper amount of potassium oxalate was added to the acid solution; then it was neutrallized with an aqueous solution of potassium hydroxide. After the removal of the precipitated material, the resulting solution was chromatographed in the same manner as the carbonato complexes. The two bands corresponding to the *mer*(N)- and *fac*(N)-isomers descended. The crystals of these isomers were obtained in the same manner as before. The yields were 3 g for *mer*(N) and 2 g for *fac*(N). Found for *mer*(N): C, 30.50; H, 4.71; N, 13.20%. Calcd for [Coox-($C_6H_{14}N_3O_2$)]·0.5H_2O: C, 30.39; H, 4.78; N, 13.29%. Found for *fac*(N): C, 31.12; H, 4.72; N, 13.73%. Calcd for [Coox($C_6H_{14}N_3O_2$)]: C, 31.28; H, 4.59; N, 13.68%.

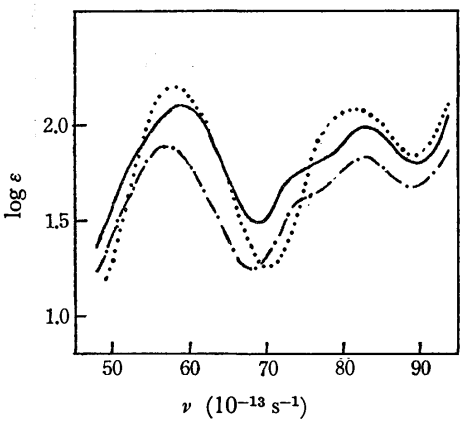

Fig. 2. Absorption spectra of *mer*(N)-[$CoCO_3$(*i*-dtma)] (——), *fac*(N)-[$CoCO_3$(*i*-dtma)] (·····) and *mer*-(*trans*)-[$CoCO_3$(gly)(NH_3)$_2$] (—·—).

The absorption spectra of the two carbonato complexes are shown in Fig. 2. The spectrum of the complex obtained from E-2 shows the first absorption band (ν_I) at 58.0×10^{13} s^{-1} (log ε=2.21) and the second band (ν_{II}) at 81.5×10^{13} s^{-1} (log ε=2.11). These values agree fairly with those for the known *fac*(N) complex (ν_I=58.5, ν_{II}=81.5).[2] From this it can be judged that this complex is the *fac*(N)-isomer. On the other hand, the spectrum of the complex obtained from E-1 shows the ν_I at 58.1×10^{13} s^{-1} (log ε=2.12) and the ν_{II} at 82.3×10^{13} s^{-1} (log ε=1.98). In addition, this spectrum exhibits a shoulder at *ca.* 74.5×10^{13} s^{-1} (log ε=1.7). A similar spectrum shape has been reported with the *mer*(*trans*)-[$Co(CO_3)$($gly(NH_3)_2$)] complex (*trans* refers to the two NH_3 groups).[6] The spectrum is included in Fig. 2. Although some hypso-

chromic shifts in the ν_I and ν_{II} bands can be seen in the present complex, the position of the shoulder scarcely shifts at all. From this similarity in spectrum, the present complex can be assigned to the *mer*(N)-isomer.

The PMR spectra of the same complexes are shown in Fig. 3. The E-1 or *mer*(N) complex shows a singlet at 3.75 ppm which has its origin in the methylene protons of the acetate group in the chelated *i*-DTMA, while the E-2 or *fac*(N) complex shows a quartet with the AB pattern at 3.80—4.25 ppm. These results confirm the assignments based on the absorption spectra.

As to the corresponding oxalato complex, the isomer obtained from the second fraction in chromatographic separation showed an absorption spectrum similar to that of the *fac*(N)-isomer of the carbonato complex except for hypsochromic shifts due to a higher ligand field: $\nu_I=57.9\times10^{13}\,s^{-1}$ (log $\varepsilon=2.19$), $\nu_{II}=82.6\times10^{13}\,s^{-1}$ (log $\varepsilon=2.25$). This fact indicates that this isomer has the *fac*(N) geometry. As to the isomer obtained from the first fraction, the gross features of the spectrum correspond well to those of the *mer*(N)-isomer of the carbonato complex except for the disappearance of a shoulder at *ca.* $74.5\times10^{13}\,s^{-1}$. Thus, this complex can be identified as the *mer*(N)-isomer.

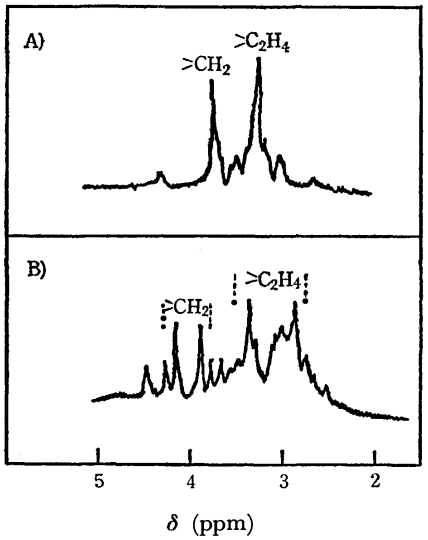

Fig. 3. PMR spectra of $[CoCO_3(i\text{-dtma})]$ (in D_2O, δ *vs.* DSS).
A: *mer*(N), B: *fac*(N).

In a previous paper,[7] it has been said that a cobalt (III) complex consisting of a five-membered α-aminoacidate ring, two NH_3 groups in the *trans* position, and a four-membered carbonate ring reveals a shoulder which may be considered to be one component of the split second absorption band. This remark can now be modified as follows: such a shoulder appears even though the two NH_3 groups and a NH_2 group of an α-aminoacidate ion are replaced by a diethylenetriamine backbone (NNN).

This work was supported in part by a grant from the Ministry of Education, to which the authors' grateful acknowledgements are made.

Miscibility of Lithium with Lithium Chloride and Lithium Chloride–Potassium Chloride Eutectic Mixture

Tsuyoshi NAKAJIMA, Ryohei MINAMI, Koichiro NAKANISHI, and Nobuatsu WATANABE

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received May 11, 1974)

Synopsis. The mutual solubilities of Li-LiCl and Li-LiCl-KCl systems were determined both in liquid-liquid and solid-liquid equilibrium regions. No critical solution temperature was observed for Li-LiCl system. The enthalpy of solution of LiCl in Li was estimated and compared with those for other alkali metal-alkali halides.

The phase diagrams and electric conductivity data for metal-salt systems are important information for the elucidation of the metal fog in molten salt electrolysis or the development of molten salt battery. Bredig *et al.*[1] have reported a number of phase diagrams for alkali metal–alkali halides systems and Pitzer[2] has given a theoretical analysis primarily based on the regular solution theory and the electronic nature of metal bonding. However, only a few data were obtained with lithium–lithium halides systems. In this work, the mutual solubilities of lithium–lithium chloride and lithium–lithium chloride–potassium chloride eutectic mixture systems were determined and a thermodynamic interpretation was given.

Experimental

The determination of solubilities between 294 and 850 °C were made by a static equilibration (saturation)-and-sampling method. The apparatus for the measurement of solubility of lithium in molten salt and the analytical methods were the same as those described previously.[3] An apparatus of the same type was used for the solubility measurement of salts in molten lithium. The amounts of chloride ion in the sample were determined with the Mohr method.

Furthermore, in order to determine the solubilities at temperature above 850 °C, differential thermal analysis was carried out using the molybdenum cell in which lithium and salts were sealed by means of electron beam welding. A Shimadzu Model DT-20B micro DTA apparatus was used.

Results and Discussion

Solubility Data. All the solubility data obtained in this work are shown in Table 1, and the phase diagram based on the data for lithium–lithium chloride system is given in Fig. 1. In the same figure, the data obtained by Bredig[1] and by Smirnov[4] for the solubility of Li in LiCl are also included. It is seen that our values are in good agreement with theirs. From the present measurement, the monotectic points for Li–LiCl system can be determined with reasonable accuracy. The monotectic temperature is estimated to be 608 °C which is about two degrees lower than the

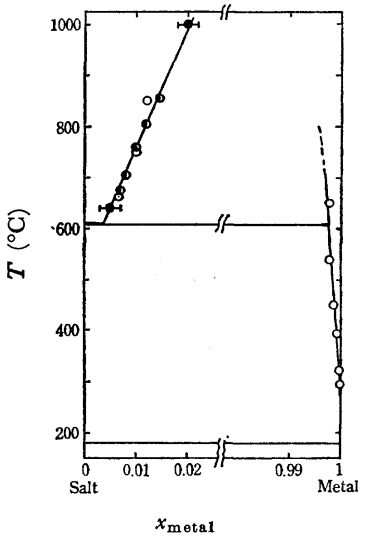

Fig. 1. Phase diagram of Li-LiCl system.

662	0.66±0.10[3]			
750	1.00±0.02		0.53±0.02	
850	1.22±0.01		0.65±0.03	

melting points of LiCl. The monotectic compositions are $X_{Li}=0.0045$ for salt-rich phase and $X_{LiCl}=0.0022$ for metal-rich phase (X: mole fraction). It is found that the mutual solubilities for Li–LiCl system are considerably smaller than those for Na–NaX or K–KX (X: halides) systems,[1] and accordingly their temperature coefficients are also very small. On the other hand, the mutual solubilities of Li–LiCl-KCl(eut. mixture) is still smaller than those for Li–LiCl system. This may be attributed to the fact that the equilibrium constant of the following equation, $Li+KCl \rightleftharpoons LiCl+K$, is 0.052.[5]

Critical Solution Temperature. Most of alkali (or alkali earth) metal-salt solutions are confirmed to exhibit an upper critical solution point at elevated temperatures.[1] One of the purposes of this work was to determine the critical point for Li–LiCl system. However, the upper critical solution temperature for this system could not be detected in spite of raising temperature of the system up to 1350 °C. This is higher than the boiling point of lithium metal. It may therefore be concluded that the present system has no upper critical point, though decisive observation could not be made.

Enthalpy of Solution of LiCl in Li. The plot of the logarithm of the solubility of solid LiCl in molten Li against the reciprocal of the absolute temperature are found to be linear within the experimental error, and the enthalpy of solution ΔH_{sol} of solid LiCl in molten Li was estimated to be about 14 kcal/mol. This is fairly small value when one compare this with those for NaCl in Na (20 kcal/mol)[6,7] or KCl in K (20 kcal/mol).[6,7] Since the enthalpy of solution ΔH_{sol} is the sum of the heat of fusion ΔH_f and the partial molar heat of mixture $\Delta \overline{H}_{mix}$, the ΔH_f values for these three salts are of comparable magnitude, this means that $\Delta \overline{H}_{mix}$ of LiCl in Li-LiCl solution is relatively smaller than those for Na-NaCl or K–KCl solution. This is rather unexpected result, because the cohesive energy of lithium metal is larger than those for Na or K metal and lithium is believed to be energitically unfavorable for the mixing with salt.

Excess Entropy. It is interesting to examine the sign and magnitude of the excess entropy of the present system. Since the mutual solubilities of, say, Na–NaCl system is larger than those of Li–LiCl, the excess free energy ΔG^E for Na–NaCl system should be positive and smaller in magnitude than that for Li–LiCl system. But they will be of comparable magnitude if comparison is made at the same lower temperature by extrapolation of the data for Na–NaCl system. Now ΔH^E for Na–NaCl is larger than that for Li–LiCl, then ΔS^E for Li–LiCl system will become smaller than that for Na–NaCl system. Possible contributions to the ΔS^E of metal-salt solutions were discussed by Pitzer[2] and the above result coincides with his analysis.

The authors thank to Toho Kinzoku Inc. for the manufacture of the molybdenum cells for DTA and to Kawasaki Jukogyo Inc. for the electron beam welding of them.

The Mass Spectra of Heteroaromatics. II.[1] Mass-spectral Fragmentation of 5-Nitro-2-furohydrazide Imide and Its N^2-Acyl Compounds[2]

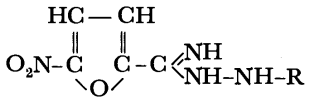
Yasuhiko KATO

Department of Industrial Chemistry, Kyushu Institute of Technology, Tobata-ku, Kita-Kyushu 804

(Received May 17, 1973)

Synopsis. The high-resolution mass spectra of 5-nitro-2-furohydrazide imide and its N^2-acetyl, N^2-propionyl, and N^2-butyryl compounds have been examined. The major fragmentation pathways of the compounds were thus deduced.

It has been reported that the N^2-acyl derivatives of 5-nitro-2-furohydrazide imide (I) are cyclized to 5-alkyl-3-(5-nitro-2-furyl)-1,2,4-triazoles, with the release of a molecule of water, when heated at their melting points in a nitrogen stream.[3] In a continuation of a previous paper[1] concerning the mass-spectral fragmentation of the 1,2,4-triazoles, the mass spectra of I (R=H) and its N^2-acetyl (II, R=$COCH_3$), N^2-propionyl (III, R=COC_2H_5), and N^2-butyryl (IV, R=COC_3H_7) compounds have been examined in order to obtain information on the electron-impact reaction and in order to deduce the fragmentation pathways of the compounds.



(I—IV)

Experimental

Measurement of the Mass Spectra. The high-resolution mass spectra were obtained with a Japan Electron Optics Laboratory Co., Ltd., JMS-OlSG-2 mass spectrometer, using the direct-inlet system. The operating conditions were as follows: ionizing energy, 75 eV; total emission current, 250 μA; accelerating voltage, 8 kV; ion multi., 1.5 kV (I and III) and 1.7 kV (II and IV); ion-source temperature, 200 °C; sample-vaporizing temperature, 100—120 °C (selected for each sample).

Samples. The samples used in this experiment were prepared by methods previously described.[4,5] IV; orange-yellow needles (recrystallized from methanol); mp 197—199 °C (decomp.).

Results and Discussion

The mass-spectral data of the compounds are shown in Table 1, while the major fragmentation paths are postulated in Schema 1 and 2.

5-Nitro-2-furohydrazide Imide (I). Compound I gave the most prominent molecular ion (M^+) (the base peak), with an *m/e* value of 170, reflecting its stability, caused by the resonance between the furan ring and its side chain at the 2 position. The distinct M–17 ion at *m/e* 153 is formed by the elimination of the ·OH radical from the M^+. This ion shows two modes of cleavage and may give ions at *m/e* 123 (Rel. int. 5%)[6] and *m/e* 96 (Ion composition, $C_4H_2NO_2$) by respectively, the loss of ·NO and HN=C=N-NH_2 fragments. The subsequent loss of HN, HCN, N_2, or ·N_2H from the *m/e* 123 ion would lead to the $(C_5H_4N_2O)^+$, $(C_4H_4N_2O)^+$, $(C_5H_5NO)^+$, and $(C_5H_4NO)^+$ ions at *m/e* 108, 96, 95, and 94. It may also be possible that the *m/e* 95 ion gives the *m/e* 94 ion by the loss of a ·H radical. On the other hand, the elmination of the

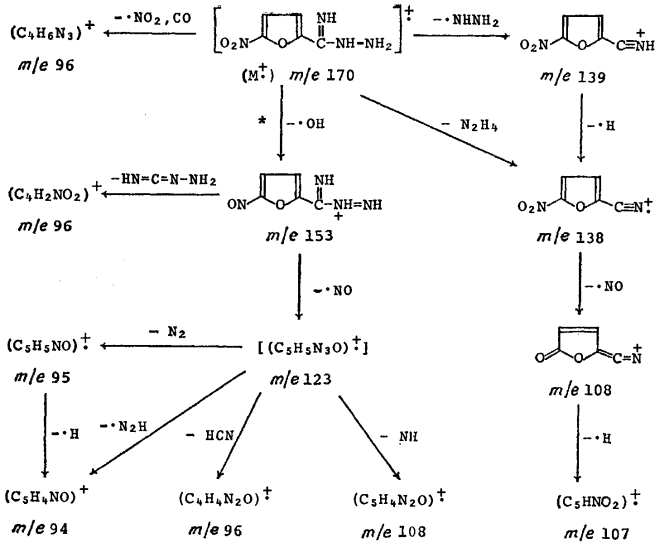
a) The high-resolution mass spectra of the compounds gave correct composition of all ions mentioned in the table, within the error of ±5 millimass units.



*; meta-stable ion observed

Scheme 1. Fragmentation of the compound, I.

$\cdot N_2H_3$ radical or N_2H_4 molecule from the M^+ gives distinct ions at *m/e* 139 and 138; the latter can be formed from the former by the loss of a ·H radical. The *m/e* 138 ion undergoes the elimination of an ·NO radical, followed by the loss of a ·H radical, thus giving the *m/e* 107 ion, which is consistent with the composition of C_5HNO_2.

Much as in the case of 3-(5-nitro-2-furyl)-1,2,4-triazoles,[1] the M^+ loses NO_2 and CO fragments by a one-step process to give an ion with the composition of $C_4H_6N_3$ at *m/e* 96.

N²-*Acyl Compounds (II, III, and IV).* In the spectra of II-IV, M^+ were also observed as intense peaks. In the first step of the fission of the M^+, as is shown in Scheme 2, there are four principal modes of elimination of the acyl groups:

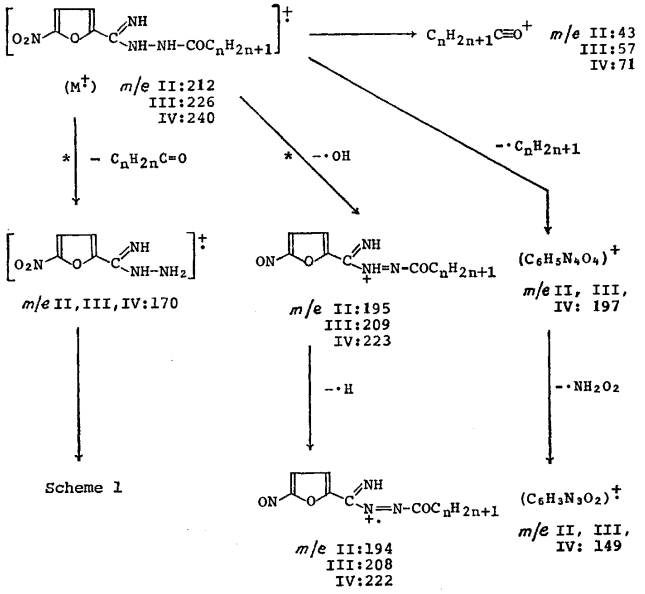
(1) With the rearrangement of a hydrogen atom, the base peaks at *m/e* 170, which are consistent with the mass of the M^+ in I, result from the elimination of C_nH_{2n}-C=O (n=1, 2, and 3 respectively);

(2) the loss of an alkyl radical leads to the ion with *m/e* 197;

(3) the loss of an ·OH radical gives *m/e* 195 (II), *m/e* 209 (III), and *m/e* 223 (IV) ions respectively, and

(4) the elimination of an acyl group with the charge-transfer brings about *m/e* 43, 57, and 71 ions with 99, 50, and 43% intensities respectively, although the ion compositions have not been determined.

The ion at *m/e* 170 may be expected to show the same fragmentation as that of I, as is indicated in Scheme 1.



*; meta-stable ions observed

Scheme 2. Fragmentation of the compounds, II, III, and IV.

In addition to the four principal modes of fragmentation discussed above, there may exist some other fragmentation paths. Only in the case of Compound II, the ion at *m/e* 153 with the composition of $C_5H_3N_3O_3$ can be formed by the expulsion of the CH_3CONH_2 molecule from the M^+. In III, the NO_2 fragment is eliminated from the M^+, thus affording an ion at *m/e* 180, while in IV, the butyryl group of the M^+ is cleaved in the course of the McLafferty rearrangement to give the *m/e* 212 ion.

The author wishes to thank Dr. Y. Itagaki, the chief of the AID Application Laboratory of the Japan Electron Optics Lab. Co., Ltd., for the measurement of the mass spectra and for his useful suggestions.

Derivatives of Cyclic Disulfides. III.[1] A New Method of Deoxygenation of Thiolsulfinates and Thiolsulfonates with Inorganic Cyanide

Seizo TAMAGAKI, Hiroo HIROTA, and Shigeru OAE[2]

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received November 21, 1973)

Synopsis. The reaction of rigid cyclic thiolsulfinates and thiolsulfonates such as 1,2-dithiaacenaphthene *S*-oxide and *S,S*-dioxide with inorganic cyanide afforded the corresponding reduced 1,2-dithiaacenaphthene, but not the open-chain *p*-tolyl benzenethiolsulfonate. This was explained by the proximity effect due to the rigidly confined S–S bond at peri-position of the naphthalene ring.

In the nucleophilic substitution reactions of atomic centers such as carbon, sulfur, and transition metal atoms, cyanide is known to show peculiar behavior as an excellent nucleophile.[3] It sometimes acts as a reducing agent and picks up oxygen, being oxidized to isocyanate despite its poor deoxygenative ability.[4] This was found to be the case in the reaction of 1,2-dithiaacenaphthene *S*-mono and *S,S*-dioxides.

The present investigation was undertaken to clarify the reaction of these disulfide derivatives, *i.e.*, thiolsulfinates, thiolsulfonates, and the related open-chain analogues with cyanide ion.

Results and Discussion

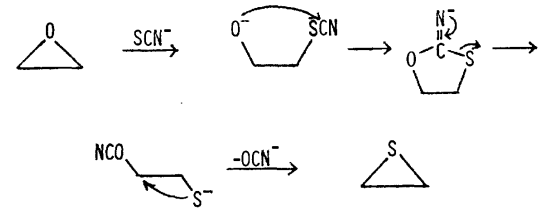
Many studies have been made on the heterolytic S-S bond cleavages of disulfides and their oxygenated derivatives by various types of nucleophiles. The S-S bond in disulfide undergoes facile scission by the action of CN^- to give the thiocyanate and the thiolate, while the thiolsulfonate gives the sulfinate and the thiocyanate.[5]

The reaction of *p*-tolyl benzenethiolsulfonate with sodium cyanide gives the products, which are identical with those reported[6] (Table 1). Cyanide ion simply attacks the S-S bond to afford sodium benzenesulfinate and *p*-tolylthiocyanate with no detectable amount of reduction product. On the other hand, a similar treatment of phenyl benzenethiolsulfinate with NaCN in MeOH at room temperature readily affords the transient sulfenate which subsequently reacts with the other partner, *i.e.*, thiocyanate, eventually giving the corresponding disulfide and NaOCN.

$$\mathrm{PhSO\text{-}SPh + CN^- \rightarrow PhSO^- + PhSCN \rightarrow}$$

$$\mathrm{PhSO\text{-}C(=N^-)\text{-}SPh \rightarrow PhSOCN + {}^-SPh \rightarrow PhS\text{-}SPh + OCN^-}$$

In contrast to the reaction of the open-chain *p*-tolyl benzenethiolsulfonate, 1,2-dithiaacenaphthene *S,S*-dioxide yields the reduced 1,2-dithiaacenaphthene when treated with NaCN in MeOH. This finding demonstrates that in the reduction of 1,2-dithiaacenaphthene *S,S*-dioxide the proximity effect due to the rigidly confined two sulfur atoms at peri-position is effectively in operation at the reduction stage where the oxygen atom of the sulfinate moiety and the carbon atom of the thiocyanate group are forced to approach each other sufficiently to react intramolecularly to form the intermediate(I) which upon the elimination of OCN^- gives the reduced disulfide. With regard to the elimination of OCN^- the above deoxygenation resembles the pathway for the formation of thiirane from the corresponding epoxide and SCN^-.[7]



The fact that in the course of the reaction a spot due to 1,2-dithiaacenaphthene *S*-monoxide(M) was observed in thin layer chromatography supports the mechanism in which the reaction proceeds through the monoxide as a stable intermediate which in turn can be readily reduced to the corresponding disulfide in a good yield (Table I). The overall reaction pathway is outlined below.

Srivastava and Field reported that the alicyclic thiolsulfonate reacts with Na_2S to afford the trisulfide without giving any reduction product.[8]

However, with the rigidly confined thiolsulfonate even a reduction *via* the initial displacement reaction takes place smoothly, eventually producing the corresponding

TABLE 1. REACTION OF THIOLSULFINATES AND THIOLSULFONATES WITH NaCN[a] IN MeOH AT ROOM TEMPERATURE

Substrate	Reaction time	Reduced product	(%)	Other product (%)
	2 days		(48) (72)[c]	NaOCN[b]
	2 days		(83)	NaOCN

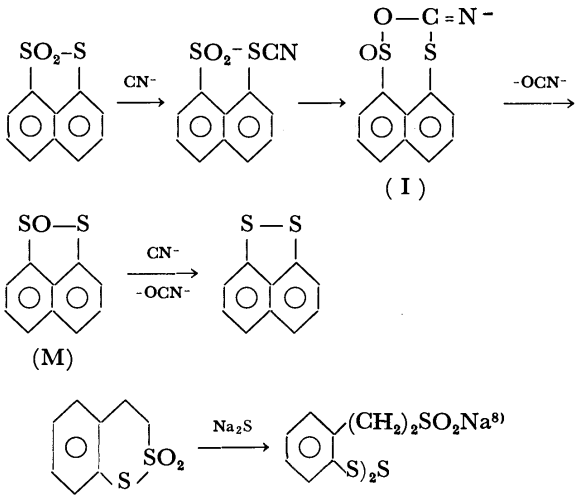
a) 1 equiv. of NaCN. b) Yields were not determined. c) 2 equiv. of NaCN.



disulfide in an 86% yield. This would also show the characteristic aspect of this rigidly confined thiolsulfonate.

Comparing the reaction time for the open-chain compounds with that for the rigid cyclic analogues, we see that the latter is less reactive. This implies that the S-S bond rigidly confined at peri-positions of naphthalene nucleus should be less reactive toward an attack of nucleophile as compared with the open-chain compound. In fact the deoxygenation of 1,2-dithiaacenaphthene oxides by trimethyl phosphite is 100 times slower than that of phenyl benzenethiolsulfinate and the thiolsulfonate.[9]

Experimental

Materials. 1,2-Dithiaacenaphthene *S,S*-dioxide was prepared according to the reported procedure.[10] The monoxide was obtained in good yield either by the sodium metaperiodate oxidation of 1,2-dithiaacenaphthene or the deoxygenation of 1,2-dithiaacenaphthene *S,S*-dioxide with trimethyl phosphite; mp 82.5—83.5 °C.

Deoxygenation of Thiosulfinates and Thiosulfonates. Deoxygenation of 1,2-dithiaacenaphthene *S,S*-dioxide and *S*-monoxide by NaCN was carried out in MeOH at room temperature for 2 days. After the solvent was removed on a rotary evaporator, the preparative tlc using benzene afforded 1,2-dithiaacenaphthene. Identification of NaOCN was made by a comparison of its IR spectrum with that of the authentic sample(2240 cm^{-1}: C N).

The Hydrolysis of Several Purine Nucleosides with Strong Hydrochloric Acid or Cation Exchange Resin

Yoshihisa SUZUKI

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received November, 24, 1973)

Synopsis. The rates of hydrolysis were determined for several purine nucleosides with aq. HCl(0.1—4 M) or cation exchange resins(H-form) at 30 °C. The hydrolysis of adenosine with Diaion SK-1B is slower than guanosine while that with HCl is faster. This discrepancy was discussed.

Purine nucleosides are known to be susceptible to acid, giving nucleic bases and D-ribose. This property is based on the hydrolysis of the glycosidic bond. However, the treatment with cation exchange resin in the H-form has been found to be useful for the industrial isolation or purification of purine nucleosides.[1] This paper will describe their rates of hydrolysis with strong acids including cation exchange resins at room temperature.

Experimental

Materials. The guanosine, inosine, and adenosine used were commercial products of the Ajinomoto Co., Inc. Diaion SK-1B (Mitsubishi Chem. Ind. Ltd.), Duolite C-3 and Duolite ES-63 (Diamond Alkali Co.) were of 20—50 mesh and were conditioned to the H-form.

Paper Chromatography (PC). One-dimensional ascending PC was carried out on Toyo-Roshi No. 51A, the following two solvent systems being used: Solvent A, *n*-butanol-acetic acid-water(4 : 1 : 1); Solvent B, *n*-propanol-28% ammonia-water (20 : 15 : 3). Solvent A was used for the analysis of experimental runs involving inosine and adenosine (R_f, inosine 0.25, hypoxanthine 0.42, adenosine 0.46, adenine 0.58), and Solvent B, for guanosine (R_f, guanosine 0.50, guanine 0.41). The UV-absorbing spots of the samples and authentic standard references were cut off, together with their appropriate blanks, and eluted in 0.1 M HCl. The optical densities of the eluents at the wavelength of the maximum absorption of each component were measured. The percentages of the remaining original nucleosides and the nucleic bases thus produced were calculated from the optical densities.

Hydrolysis with HCl. Guanosine(0.1 g), inosine(0.25 g) or adenosine(0.25 g) was added to an Erlenmeyer flask which contained 50 ml of an HCl solution with a definite concentration (0.1—4.0 M) and kept at 30 °C. Each nucleoside was dissolved with vigorous stirring as soon as it was added. After the solution had been allowed to stand for a definite period (30 min-216 hr), it was cooled on an ice bath and neutralized with a cold NH_3 aqueous solution in order to stop the reaction. The resultant solution was analyzed with PC.

Hydrolysis with Cation Exchange Resins. Each nucleoside (0.3 g) was dissolved in a 0.15 M acetic acid solution(300 ml). Then, each wet resin(10 ml) was put into a stoppered Erlenmyer flask which contained the acetic acid solution described above. The resultant mixture was shaken for a definite period (20 min—48 hr) at 30 °C. The resin was filtered, washed with 20 ml of water, and then put into another Erlenmeyer flask which contained 50 ml of a 2 M NH_3 aqueous solution. After the mixture had been shaken for 30 min in order to elute the nucleoside and the base formed on the resin, the resin was put in a column and eluted with 350 ml of the 2 M NH_3 aqueous solution for complete elution. The eluates were then mixed and analyzed with PC. In the case of the experimental run using Duolite ES-63, 2M NaOH was used for the elution in place of the NH_3 aqueous solution because resin is not a strong cation-exchange resin.

Results and Discussion

Guanosine, inosine, and adenosine were hydrolyzed to give guanine, hypoxanthine, and adenine respectively. The decrease in the mole amount of nucleoside was equal to the amount of the nucleic base produced within the range of experimental error, and no side reaction was observed. In all the cases in the present study, first-order linear plots were obtained for the logarithm of the concentration of nucleoside with the reaction time. The observed first-order rate constants, k, were determined by the linear plots given by Eq. (1) or Eq. (2);

$$\ln([N_0]/[N]) = kt \quad (1)$$

$$\ln\{([N]+[B])/[N]\} = kt \quad (2)$$

where $[N_0]$ is the initial concentration of nucleoside, $[N]$ is the concentration of it at time t, and $[B]$ is that of the nucleic base.

On Diaion SK-1B, 93% of the guanosine or adenosine was adsorbed within 1 hr. It increased up to 97% within 6 hr. However, 50% and 47% of the inosine remained in the solution unadsorbed on the resin after the contact times of 6 hr and 16 hr respectively. This was because of the small pK_a value[2] of inosine(1.2) compared with that of guanosine(2.2) or adenosine(3.5). On Duolite ES-63, only 50% of the guanosine was adsorbed during the contact time of 48 hr, while the figure was above 95% within 1 hr on Duolite C-3. This was because of the small dissociation of the cation exchange group, phosphonic acid, in the former resin compared with that of methylenesulfonic acid in the latter.

More than 95% of the adsorbed substances were eluted in all the cases. There were some nucleic bases produced on the resin. The amount of the bases increased with the increase in the contact time, and the rate constants of hydrolysis were determined by Eq. (2).

Figure 1 shows the observed rate constants summarized with the acidity function, H_0. The acidity function represents, in short, the strength of the acidity of the solvent. The H_0 values of HCl solutions were determined from the literature.[3] Linear plots were obtained for the logarithm of the rate constant, log k,

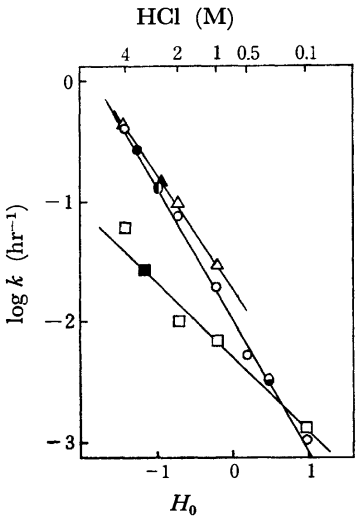

Fig. 1. Rate constants of acid hydrolysis for some purine nuclesides at 30 °C. The scale of the upper abscissa is given for convenience to compare the strength of cation exchange resins with that of HCl solutions. Adenosine with HCl (△) and with Diaion SK-1B (▲); guanosine with HCl (○), with Diaion SK-1B (●), with Duolite C-3 (◐) and with Duolite ES-63 (◒); inosine with HCl (□) and with Diaion SK-1B (■).

with the acidity function of H_0 from the experimental results for hydrolysis with an HCl solution. The results for hydrolysis with cation-exchange resins were placed on the lines corresponding with the individual nucleoside.

The rate constant with Diaion SK-1B for guanosine is equal to that with 3.2 M HCl. Hydrolysis with Duolite C-3 was equivalent to that with 2.5 M HCl. It is known that the hydrogen-ion concentration in cation-exchange regins is a few mol per liter. The above results are consistent with this knowledge, and the difference in the acid strength between Diaion SK-1B (sulfonic acid group, R–SO_3H) and Duolite C-3 (methylenesulfonic acid group, R–CH_2SO_3H) was quantitatively determined. The hydrogen-ion concentration in Duolite ES-63(phosphonic acid group, R–$P(O)(OH)_2$) was estimated to be equivalent to 0.3 M HCl from the rate of hydrolysis for guanosine, as above.

The hydrogen-ion concentration in Diaion SK-1B, as estimated from the rate constant for the acid hydrolysis of inosine, is in good agreement with that estimated from guanosine, while that estimated from adenosine is somewhat different from them. In relation to this estimation, a contradiction has been observed in this study in that hydrolysis with Diaion SK-1B for adenosine is slower than for guanosine, whereas hydrolysis with HCl is slightly faster. These facts strongly suggest that there is some difference between the position of the protonation in the acidic forms of adenosine (N-1)[4] and of guanosine (N-7).[5] This difference must affect the stereospecific binding of the nucleosides with the fixed cation-exchange group, the sulfonic acid in the resin, and the susceptibility of cleavage at the glycosyl bond. Therefore, the apparent values of the hydrogen-ion concentration were different between them. Jones and Robins[6] suspected that the position of the protonation in the acidic form of inosine was probably N-7, the same as that of guanosine.

In strong acid, the rate constant of hydrolysis for inosine is smaller than for guanosine, while the reversal is observed in 0.1 M HCl (Fig. 1). It is presumed that inosine will be hydrolyzed faster than guanosine in the weaker-acid or in the acidic pH region.

Preparation and Structures of Unsubstituted and Monofluorinated 2*H*(or 4*H*)-1,3,4-Benzoxadiazines

Peng Wai CHOW and Nobuo ISHIKAWA

Chemistry Department, University of Singapore, Singapore 10.

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received December 14, 1973)

Synopsis. Azo-coupling of diazomethane with benzenediazonium-2-oxide yielded 2*H*-1,3,4-benzoxadiazine while coupling of the same reagent with the monofluoro-substituted benzenediazonium-2-oxide derivatives gave the corresponding 4*H*-1,3,4-benzoxadiazines.

The preparation of 6,7,8-trifluoro-5-methoxycarbonyl-4*H*-1,3,4-benzoxadiazine by the reaction of 3,4,5-trifluoro-6-methoxycarbonylbenzenediazonium-2-oxide with diazomethane was previously reported.[1] An analogous reaction between a diazo-oxide and a substituted diazomethane was studied by Huisgen and Fleischman,[2] who observed the formation of 5,6,7,8-tetrachloro-2-phenyl-4*H*-1,3,4-benzoxadiazine from 3,4,5,6-tetrachlorobenzenediazonium-2-oxide and phenyldiazomethane.

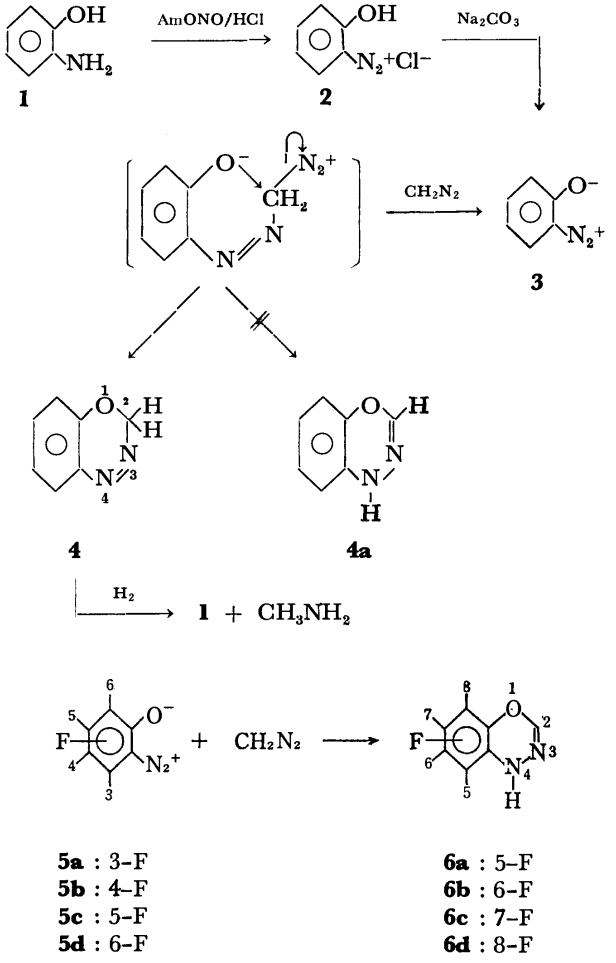
No other report seems to have appeared on the heterocyclic system. We undertook to prepare unsubstituted 2*H*(or 4*H*)-1,3,4-benzoxadiazine and to confirm the effect of the electronegative halogen atoms of the benzene ring upon the stability of this heterocyclic compound.

For the purpose of preparing unsubstituted 2*H*(or 4*H*)-1,3,4-benzoxadiazine (**4** or **4a**), *o*-aminophenol (**1**) was reacted with *iso*-amyl nitrite to give 2-hydroxybenzenediazonium chloride (**2**),[3] from which elimination of a molecule of hydrochloric acid was effected with sodium carbonate.[4] On reaction with diazomethane, benzenediazonium-2-oxide (**3**) then afforded an oxadiazine compound, the result of diazo coupling followed by loss of nitrogen prior to ring cyclization.

The product, a fairly unstable yellow liquid, was assigned the structure 2*H*-1,3,4-benzoxadiazine (**4**), from infrared and nuclear magnetic resonance spectra. Thus, the IR absorptions at 2890 cm^{-1} and 2885 cm^{-1} were assigned to the methylene group, and those at 1360 cm^{-1} and 1250 cm^{-1} to C–N stretching vibrations and an ether linkage, respectively. The NMR spectrum, besides showing a complex multiplet at τ 2.27—3.35 due to the four aromatic protons, also revealed a singlet at τ 4.74, assigned to the methylene protons.[5]

On reacting with hydrogen over palladium catalyst, **4** afforded *o*-aminophenol (**1**) and methylamine, supporting the assignment of structure **4** for 2*H*-1,3,4-benzoxadiazine but not for 4*H*-compound (**4a**), since formation of these products is a consequence of hydrogenolysis during the course of reaction.

Introduction of a negative group such as fluorine atom in the benzene ring seemed to stabilize the 4*H*-1,3,4-benzoxadiazine compound rather than the 2*H*-compound, and we therefore attempted to prepare



5a : 3-F

6b : 6-F
6c : 7-F
6d : 8-F

all species of hydro-1,3,4-benzoxadiazines which carry fluorine substituent in their benzene rings.

Coupling of the various monofluoro-substituted diazo-oxides (**5a**—**5d**) obtained from their respective fluoro-aminophenols by diazotization with aqueous sodium nitrite, gave fluorinated 4*H*-benzoxadiazines.

The compounds were obtained as stable crystals. The evidence for structures **6a**—**6d** for the fluorinated 4*H*-1,3,4-benzoxadiazines was readily deduced from their IR and NMR spectra. In line with the proposed structures, all the IR spectra showed absorptions which could be assigned to NH and C–N (Table 1). The NMR spectrum of **6d**, for example, also supported the structure, since the signal at τ 3.80, which was exchanged for deuterium oxide, could be assigned to a secondary amine, while the methine proton resonated as a singlet at τ 3.65.

In the azo-coupling of the fluoro-substituted diazo-oxide derivatives, preferable formation of the

4*H*-benzoxadiazines is expected, since the negative inductive effect of the fluorine atom is expected to make the oxadiazole ring somewhat acidic. The resulting intermolecular hydrogen bonding which combines N–H···N or N–H···O seems to stabilize the 4*H*-form and make the substances rather stable crystals.

Experimental

2H-1,3,4-Benzoxadiazine (4). Benzenediazonium-2-oxide (**3**) (3.90 g), prepared from *o*-aminophenol (**1**) by the reaction with isoamyl nitrite in hydrogen chloride saturated methanol and subsequent treatment of the resulting 2-hydroxybenzenediazonium chloride (**2**) with anhydrous sodium carbonate, was reacted with an excess of ethereal diazomethane at room temperature for 4 hr. The solvent was then evaporated. The crude product (4.23 g) was filtered through silica gel (20 g) in hexane. Evaporation of the solvent and subsequent distillation of the partially purified product gave pure benzoxadiazine **4** (3.80 g, 86%), bp 58—59 °C/2 mmHg. The yellow liquid, which turned reddish-brown when exposed to light, gradually decomposed at room temperature. Found: C, 60.8; H, 4.3; N, 20.3%. Calcd for $C_7H_6N_2O$: C, 62.7; H, 4.5; N, 20.9%. Mass spectrum: M^+ 134 (Calcd: 134).

Hydrogenolysis of 4. Benzoxadiazine **4** (1.32 g, 9.85 mmol) and 5% Pd/C catalyst (0.30 g) in ethanol (50 ml) were shaken in an atmosphere of hydrogen at room temperature and pressure. When the uptake of hydrogen had ceased (29.6 mmol), the catalyst was removed by filtration. The filtrate was heated to boiling in a water bath and the methylamine evolved was absorbed in ethanol (5 ml) maintained at about −5 °C. The filtrate was then evaporated and the resulting solid (0.86 g) was purified by sublimation *in vacuo* to give colorless crystals, mp 170—174 °C, which was undepressed on admixture with authentic *o*-aminophenol (**1**).

To the methylamine solution was added saturated ethanolic picric acid (5 ml), and the mixture was left at room temperature for 30 min, then heated in a water bath (5 min) and left to cool. The orange crystals deposited were purified by recrystallization from ethanol and confirmed to be methylamine picrate by IR and mixed mp.

Fluoro-4H-1,3,4-benzoxadiazine (6a—6d). The fluorobenzene diazonium oxides **5a—5d** were synthesized from the respective fluoro aminophenols, which in turn were prepared[6] from their corresponding nitro-derivatives by reduction with hydrogen gas over palladium catalyst. The diazo-oxides **5a—5d** thus obtained were then reacted with ethereal diazomethane in a similar manner.

As an example, 3-fluoro-2-aminophenol (1.50 g, 11.8 mmol), dissolved in water (32 ml) containing concentrated hydrochloric acid (5.5 ml), was converted into 6-fluorobenzenediazonium-2-oxide (1.51 g, 93%) with 5% aqueous sodium nitrite solution (18 ml, 13.0 mmol). This crude gummy product was treated with an excess of ethereal diazomethane and left at room temperature for 16 hr. The reaction mixture was filtered and the solvent evaporated to give a gum (1.5 g). This was extracted with boiling hexane, which was then evaporated leaving the benzoxadiazine **6a** (1.32 g, 79%) as yellow plates, mp 72.5—73.5 °C after crystallization from hexane followed by sublimation *in vacuo*. Found: C, 54.5; H, 3.4; N, 18.4; F, 12.4%. Calcd for $C_7H_5FN_2O$: C, 55.3; H, 3.3; N, 18.4; F, 12.5%. Mass spectrum: M^+ 152 (Calcd: 152).

The Reductive Amination of *d*-Camphor with the Methylamine and Carbon-13 NMR of the Reaction Products

Syun'ichi KIYOOKA and Kojiro SUZUKI

Department of Chemistry, Faculty of Literature and Science, Kochi University, Asakura, Kochi 780

(Received January 7, 1974)

Synopsis. The effects of catalysts (Raney Ni, 5% Pd-C, and PtO_2) in the title reactions have been discussed. The PtO_2 catalyst is excellent in reductive power and in selectivity. The CMR spectra of the reaction products (I, II, and III) are assigned, and the *N*-protonation shifts are further measured.

The reductive amination reactions using *d*-camphor and methylamine have not been investigated. The present paper reveals the reductive power and selectivity of some catalysts in the reactions. Generally, the reductive amination reactions of ketone with a primary amine are carried out in the presence of the Raney Ni catalyst and hydrogen, while the yields of the reactions are decreased by the sterically-enhanced bulkiness about the carbonyl groups and amino groups.[1] Raney Ni, 5% Pd–C, and PtO_2 were employed as catalysts. The reaction mixtures of methylamine and *d*-camphor, together with one of the three catalysts in an autoclave, were stirred at 120 °C for 24 hr. The basic oil obtained after the reaction was quantitatively analyzed by gas-chromatography. Three peaks appeared on the chromatogram. The structures of the three components (I, II, and III) were comfirmed by a comparison with the retention times of authentic samples (*N*-methylcamphorimine, *N*-methylbornylamine, and *N*-methylisobornylamine) prepared by known methods.[2-4]

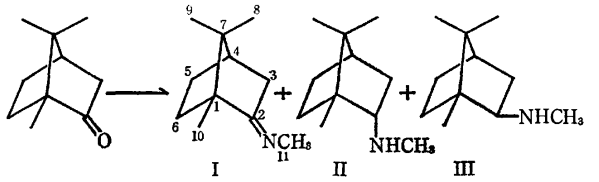

TABLE 1. THE CATALYTIC EFFECTS OF THE REDUCTIVE AMINATION

	Mixture yields (%)	Ratio of products (%)		
		I	II	III
Raney Ni	65	82.8	1.3	15.9
5% Pd-C	61	30.4	3.9	65.7
PtO_2	70	3.7	4.6	91.7
No catalyst	70	100.0		

Table 1 shows the yields and ratios of the products resulting from the effects of each catalyst. The remarkable differences in the reductive power of the catalysts were clarified. The reaction using the W-1 Raney Ni catalyst gave scarcely any Compounds II, and III, while the reaction using the PtO_2 catalyst gave mostly Compound III. Consequently, the PtO_2 catalyst is superior to the other catalysts in reductive powder and in selectivity, as shown by the ratios of the products of Compounds II and III, in the reductive amination reaction using ketones with sterically bulky groups, such as *d*-camphor. Similar results regarding the reductive power of the catalyst have been previously obtained by Goldberg and Lam.[5] As the reaction using no catalysts gave only Schiff base I, it may be assumed that the Schiff base was reduced to give Compounds II, and III in the reactions using catalysts. Moreover, the fact that Compound III was afforded as the main product means that the Schiff base was reduced by the *cis* addition of hydrogen from the endo side. Next, the ^{13}C NMR spectra of the three products in $CDCl_3$ and TFA (trifluoroacetic acid) were measured. Table 2 shows the observed chemical shifts, the multi-

a) ^{13}C chemical shifts are given in ppm from TMS and considered accurate to ±0.1 ppm. b) The plus and minus signs mean the upfield and downfield protonation shifts. * The asterisks designate pairs of shifts which have been assigned for consistency with other shift data, although there is a possibility that the assignments should be interchanged.

plicities observed in the off-resonance proton decoupled spectra, and the *N*-protonation shifts. The assignments of the ^{13}C signals of Compounds I, II, and III were decided with the aid of the CMR studies of norbornyl derivatives by Grutzner *et al*,[6] of camphor by Wenkert *et al*,[7] and of general substituent effects, the so-called α and β effects.[8]

Assignment of the ^{13}C NMR Spectra of N-*methylbornylamine II.* The 69.2 ppm resonance peak in the lowest field are immediately identified as C-2 attached to the methylamino group. The 45.2 ppm absorption appearing as a doublet in the off-resonance decoupled spectrum must be C-1 and C-7. Further, it is assumed, on the basis of the β effect of the substituent, that the line of C-1 is in a lower field than C-7. The lowest field peak at 38.3 ppm in the three triplet peaks when partially decoupled must belong to C-3, caused by a substantial downfield shift at positions β to the amino group. There are two absorptions, at 27.4 and 37.0 ppm, which appear as triplets', they must be C-5 and C-6. The C-6 is situated at positions β to the C-10 methyl group. The 35.3 ppm absorption appears as a quartet in the off-resonance decoupled spectrum and thus must be methyl carbon. The resonance line of methyl carbon agrees with the assignment given to the *N*-methyl groups.[9] The peak at 12.0 ppm was identified as C-10 according to Wenkert's work.[7] The remaining absorptions, at 20.5 and 20.6 ppm, must belong to C-8 and C-9. The assignment of C-8 and C-9 can not be decided on the basis of our present information. According to the general procedure described above, the ^{13}C chemical shifts of I and III have been assigned. The protonation-induced shifts are also shown in Table 2. It has been observed by Morishima *et al.*[10] that almost all the ^{13}C signals move to a higher field upon the *N*-protonation of some saturated amines. They concluded that, by the protonation of saturated amines, the C–H bond is polarized to produce the C^-–H^+ structure and that the electron on the hydrogen atom is transmitted through the carbon skeleton onto the positively-charged nitrogen atom. However, the observed protonation shifts of I, II, and III were downfield shifts at C-1, C-2, C-4, C-6, and C-7. It is especially notable that the protonation shift at C-2 of (I) was −25.9 ppm.

Experimental

General Procedure of Reductive Amination. To a 200-ml autoclave containing 20 g of *d*-camphor in 80 ml of a 30% methylamine-methanol solution, a catalyst (W-1 Raney Ni (5 g), 5% Pd-C (20 g), or PtO_2 (1.5 g)) was added. The autoclave was then filled with hydrogen at 60 kg/cm^2 (room temperature) and stirred magnetically at 120 °C for 24 hr. After cooling, 60 ml of 10% hydrochloric acid was added to the reaction mixture. The catalyst and the unreacted camphor were then filtered off. The filtrate was made strongly basic with 30% sodium hydroxide and extracted with ether, and the ethereal solution was dried over sodium hydroxide pellets. The evaporation of ether afforded a basic oil. The mixture oil was subsequently analyzed by gas chromatography. Four grams of the oil were chromatographed on 120 g of alumina. Elution with benzene afforded (I) (bp_{757} 203 °C), which was identified as *N*-methylcamphorimine (by means of infrared and PMR spectra). Further elution with a 10% ethanol-benzene solution yielded a mixture (bp 83—97 °C 10 mmHg), the identity of which were confirmed by comparing the retention times of the oily mixture on the gas chromatogram with those of *N*-methylbornylamine (II) (bp 89—96 °C/10 mmHg) and *N*-methylisobornylamine (III) (bp 82—83 °C 10 mmHg), both prepared by known methods.[3,4]

Gas-chromatographic Analysis. The gas chromatography was carried out with a Shimadzu GC-3AF Model apparatus. A $3\phi \times 2000$-mm stainless steel column was packed with THEED (15%) on Shimalite F (20—80 mesh). Nitrogen was used as the carrier gas. The column temperature was 100 °C. The percentages of the constituents of the oil were calculated from the areas of the peaks of the gas chromatogram.

CMR Spectral Measurement. All the ^{13}C spectra were obtained at natural abundance in 8-mmϕ tubes by means of a JNM-PS-100/PFT-100 spectrometer operating at 25.15 MHz (28 °C). The chemical shifts were determined with reference to the internal TMS from spectra taken with noise decoupling, which removed all the ^{13}C–H coupling. The repetition time of the pulse was 1—4 s. The numbers of scans were 1000—2000. Further, the off-resonance proton decoupling technique was applied to all samples. $CDCl_3$ and TFA were employed as the solvents. The concentrations of the samples were approximately 100 mg/ml.

^{13}C Nuclear Magnetic Resonance Spectra of Unsymmetrical Naphthyridines

Minoru HIROTA, Hideyuki MASUDA, Yoshiki HAMADA* and Isao TAKEUCHI*

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 233

**Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468*

(Received May, 21, 1974)

Synopsis. ^{13}C Nuclear magnetic resonance spectra of some naphthyridines were measured and the chemical shifts were compared with those theoretically calculated by an SCF-MO method of π-electron system. Fairly good linear relationship is observed between these values.

In the course of the investigations on the syntheses of naphthyridines and related compounds by modified Skraup reactions,[1] some naphthyridines were obtained and their ^{13}C NMR spectra were measured. The ^{13}C chemical shifts of the naphthyridines are shown in Table 1, together with the electron densities obtained by simple-LCAO and SCF(Pariser-Parr-Pople approximation) MO calculations.[2] The unambiguous assignment of the chemical shifts were obtained by the selective heteronuclear decoupling.

^{13}C Chemical shifts of aromatic hydrocarbons have been correlated approximately with the π-electron density by the following equation:[3]

$$\Delta\sigma_r = \alpha(q_r - 1)$$

where $\Delta\sigma_r$ is the chemical shift from benzene and α is a constant which is estimated to be 160 ppm by Lauterbur.[4] In order to examine the applicability of the equatoin to six-membered nitrogen heterocycles, the ^{13}C chemical shifts were plotted against the π-electron densities calculated by the SCF-MO method, and shown in Fig. 1. The full line in this figure illustrates the correlation line for $\alpha = 160$ ppm. The best fit value for this series of compounds was estimated to be about 140 ppm by the least-square calculation of the most appropriate slope of the correlation line as illustrated by the dotted line in the figure, and this value is close to the α value for aromatic hydrocarbons.

The observed and the theoretical spectra of 1,6- and 1,7-naphthyridines were given in Fig. 2. The theoretical spectra were calculated by the equation with the best fit parameters (See Fig. 1). Thus, the less elaborate π-electron calculation is proven to be

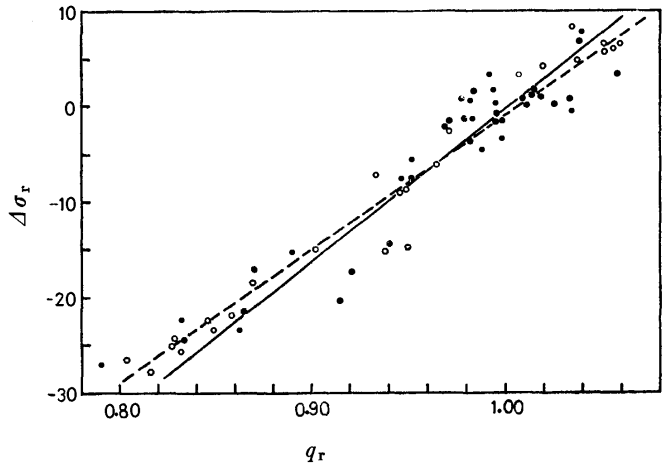

Fig. 1. ^{13}C Chemical shift *vs.* electron density plot. The full line in this figure corresponds to the equation $\Delta\sigma_r = 160\ (q_r - 1)$, and the broken line to the best fit equation $\Delta\sigma_r = 139.8\, q_r - 140.7$. The chemical shifts of naphthyridines investigated are illustrated by ○, and those of other six-membered aromatic nitrogen heterocycles by ●.

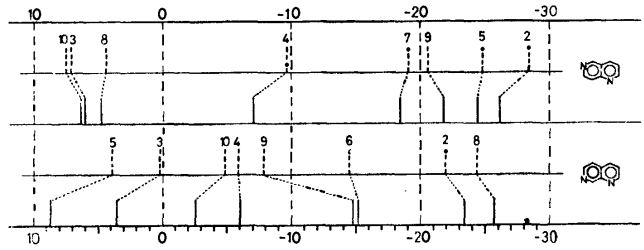

Fig. 2. Observed and calculated ^{13}C chemical shifts of 1,6- and 1,7-naphthyridines.

nearly as well useful as those including all valence shell electrons[5] to predict the ^{13}C chemical shifts of these heterocycles. The simple LCAO-MO calculation also predicts the ^{13}C chemical shifts of nitrogen heterocycles qualitatively. However, the correlation between the observed and the theoretical chemical shifts is poorer.

The authors are grateful to Dr. M. Imanari of the Japan Electron Optics Laboratories Co. for the measurement of ^{13}C NMR spectra.

Thermal Decay of the Colored Form in Photochromism of 2-Hydroxy-4-methoxytriphenylmethanol in *n*-Hexane

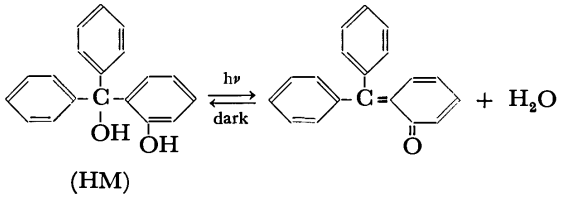
Sanyo HAMAI and Hiroshi KOKUBUN

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received September 25, 1973)

It was found that, like 2-hydroxytriphenylmethanol (HM), 2-hydroxy-4-methoxytriphenylmethanol (HMM) shows photochromism as well as thermochromism. Photo- and thermochromism of HMM occur even in *n*-hexane, in which a photochemical irreversible reaction occurs for HM. In *n*-hexane solution of HMM, a three-stage thermal fading pattern was observed at room temperature and at lower temperatures, the pattern becoming a one-stage type at a higher temperature. Mechanical stirring of a sample solution caused a decrease in the concentration of the colored form in *n*-hexane at room and lower temperatures but not at a higher temperature. These phenomena are caused by the backward reaction on the wall of a sample cell including diffusion as the rate-determining step. In *n*-hexane–dimethoxyethane (or acetonitrile) mixed solvents, the first-order rate constant becomes smaller with increase in the dimethoxyethane (or acetonitrile) concentration. From a certain concentration, shaking of a cell causes no decrease in the concentration of the colored form.

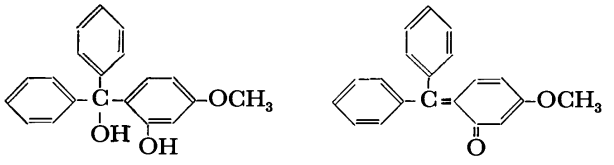
2-Hydroxytriphenylmethanol (HM) is known to show thermochromism.[1] It also shows photochromism, its reaction being shown by the following scheme.[2]



(HM)

Scheme 1.

At room temperature, HM shows photochromism in acetonitrile, ethyl ether, dimethoxyethane, benzene and 1,2-dichloroethane but only an irreversible reaction occurs in saturated hydrocarbon. Like HM, 2-hydroxy-4-methoxytriphenylmethanol (HMM) shows photochromism and thermochromism in these solvents. Photochromism occurs even in *n*-hexane, cyclohexane and methylcyclohexane, thermochromism being also observed in these solvents.



(HMM) (MF)

The behavior of the thermal decay of the colored form, *p*-methoxy-*o*-fuchsone (MF) in these hydrocarbon solvents is very curious differing from that in other solvents such as acetonitrile, ethyl ether. In order to make clear this curious behavior the thermal decay was followed under different conditions.

Experimental

Materials. 2-Hydroxy-4-methoxytriphenylmethanol was synthesized by the Grignard reaction of 2-hydroxy-4-methoxybenzophenone and phenylmagnesium bromide and purified by repeated recrystallization from an ether–*n*-hexane mixture and a methanol-water mixture after being treated with activated charcoal. *n*-Hexane, cyclohexane and methylcyclohexane were treated with fuming sulfuric acid diluted with concentrated sulfuric acid for a long time, washed with water, neutralized with an aqueous alkaline solution, treated with alkaline potassium permanganate, washed again with water, and then dried over calcium chloride. They were finally distilled over sodium wire. Acetonitrile was distilled over phosphorus pentoxide. Dimethoxyethane was dehydrated for several months over sodium-potassium alloy after evacuation.

The concentration of HMM was *ca.* 2×10^{-4} M in all the experiments.

Apparatus. A 6 W germicidal mercury lamp was used as a light source. The absorption spectrum was measured with a Hitachi EPS-3T spectrophotometer. The thermal decay was followed at 340 nm on the same instrument. Haake-FJ was used for temperature control.

Results

General Aspect of the Thermal Decay. MF appeared when the *n*-hexane solution of HMM was irradiated at 253.7 nm. The absorption spectrum of MF in *n*-hexane is shown in Fig. 1. The absorption maxima in *n*-hexane shift to shorter wavelength than those in acetonitrile or ethyl ether. In acetonitrile or ethyl ether an irreversible photo-product was formed in a small amount, but in saturated hydrocarbon the absorption spectrum after the termination of the thermal decay agreed almost completely with that of unirradiated HMM. The concentration of MF produced

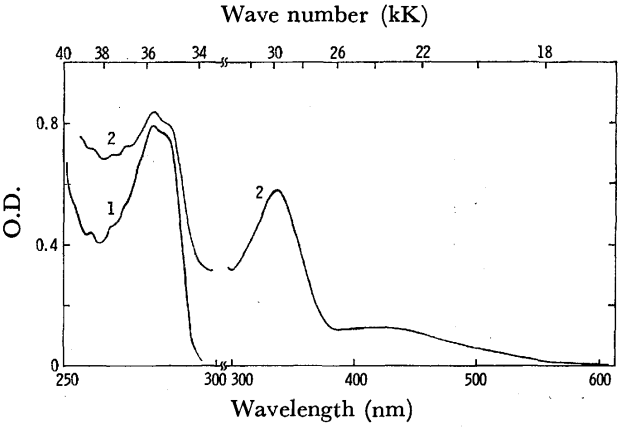


Fig. 1. Absorption spectrum of HMM in *n*-hexane.
1: Before irradiation, 2: After irradiation

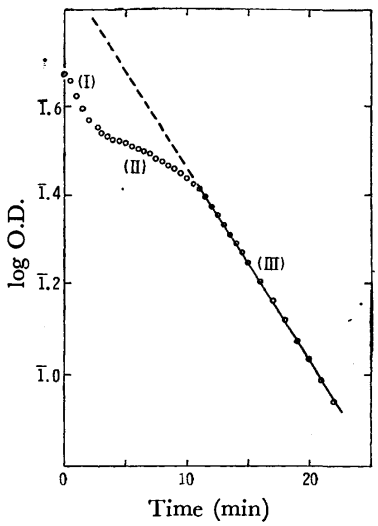

Fig. 2. Three-stage thermal decay of the colored form, MF, in *n*-hexane at 22 °C.

is the order of 10^{-5} M, water being also produced in the same concentration as in the case of HM (Scheme 1).

Mechanical stirring of a sample solution markedly decreases MF concentration. The thermal decay of MF was followed after the sample cell had been shaken. The decay rate decreased gradually after several minutes and became greater again approaching a constant value. The same phenomenon occurred each time the cell was shaken. The three-stage thermal decay after shaking is shown in Fig. 2. The decay pattern was identical within the optical density range of MF *ca.* 1.5—*ca.* 0.3 at 340 nm. The rate of decay of stage I is almost the same as that of III, the rate of stage II being smaller than that of I and III. A satisfactory first-order decay is seen at stage III. When a cell was shaken at stage III, a change was observed in which the rate constants at stages III and III′ agreed with each other fairly well (Fig. 3). The absorption spectrum is identical at any stage of the thermal decay. Consequently, no stable intermediate other than MF is involved in the thermal fading reaction in *n*-hexane. Oxygen would not be involved in it since the decay pattern was the same as that of the air saturated solution when the decay was followed after deoxygenation of the solution by bubbling nitrogen.

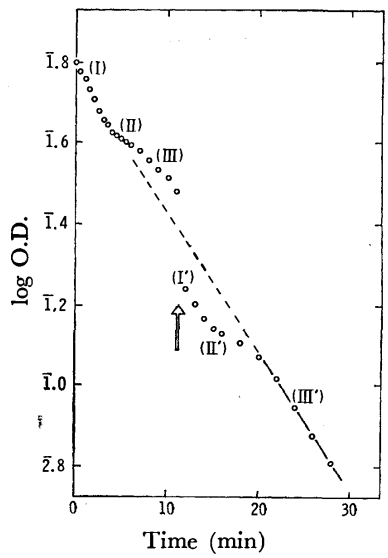

Fig. 3. Thermal decay of the colored form, MF, in *n*-hexane at 12 °C.
An arrow shows the point at which a sample cell was shaken.

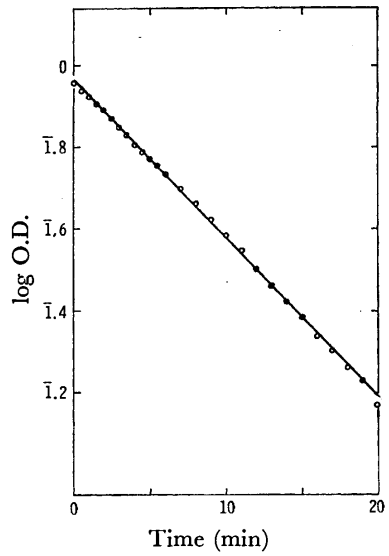

Fig. 4. One-stage thermal decay of the colored form, MF, in *n*-hexane at 36 °C.

Temperature Effect. The three-stage thermal fading pattern was observed at room temperature and lower temperatures, but at a higher temperature, *e.g.* at 36 °C, the pattern changed and an ordinary first-order decay was observed from the beginning (Fig. 4). Mechanical stirring of a cell in the course of decay does not accelerate the decrease of the concentration of MF. From the temperature dependence of the rate constant at III, the activation energy for the reaction was evaluated to be 1.7 kcal/mol, which agrees with the activation energy for the viscosity of *n*-hexane. Although the first-order decay was observed from the beginning at 28 °C, the decay pattern is a mixed type of the three-stage pattern and the ordinary first-order decay pattern (one-stage decay pattern), since shaking of a cell in the course of the decay slightly decreases the optical density of MF.

Addition Effect of Dimethoxyethane and Acetonitrile. The decay pattern of MF changes gradually from a three-stage to a one-stage type in the mixed solvent *n*-hexane–dimethoxyethane (or acetonitrile) with the increase of the dimethoxyethane (or acetonitrile) concentration. The decay rate constant also decreases at the same time. The relationship between the rate constant and the concentrations of dimethoxyethane and acetonitrile is shown in Fig. 5.

Thermal Decay in Water Saturated n-Hexane Solution. In acetonitrile or ethyl ether, the thermal decay rate constant of the colored form of HM or HMM is proportional to the concentration of the water added. However, in *n*-hexane saturated with water the decay pattern is the same as that in ordinary *n*-hexane, *i.e.*,

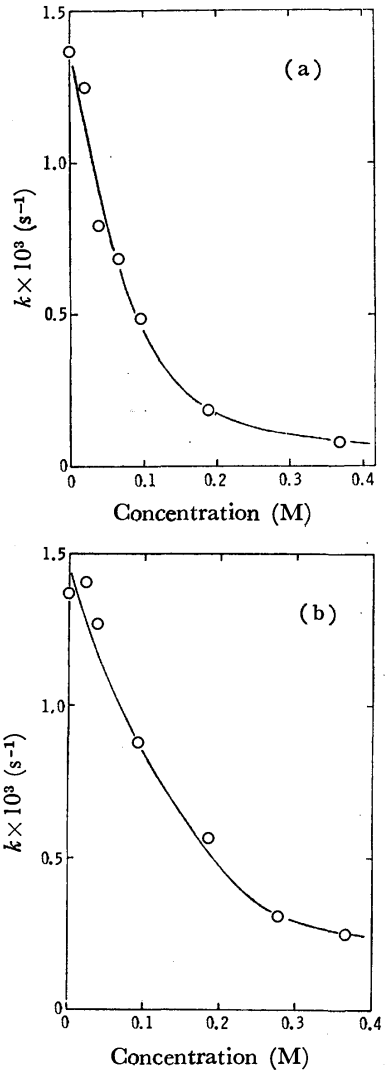

Fig. 5. (a) Dependence of the decay rate constant on the concentration of dimethoxyethane at 22 °C.
(b) Dependence of the decay rate constant on the concentration of acetonitrile at 22 °C.

the three-stage decay pattern changes to one-stage decay type with the rise of temperature. The rate constant 1.48×10^{-3} s^{-1} was nearly the same as that in ordinary *n*-hexane, 1.37×10^{-3} s^{-1}.

In the case of *n*-hexane solution saturated with water in a cell whose surface was damped with water, the decay pattern was the one-stage type and a shaking did not decrease the concentration of MF. This rate constant was about 1/20 as compared with a no-damped experiment.

Discussion

In *n*-hexane, the reaction mechanism of the thermal decay is quite different from that in acetonitrile and ethyl ether. The reaction system is never homogeneous. Dissolved water in cyclohexane or benzene does not exist as the associated forms such as dimer or trimer, but as a monomer.[3] It is highly probable that dissolved water in *n*-hexane exists as a monomer. Since the same decay pattern was observed in cyclohexane as well as *n*-hexane, the associated form of water would not be involved in the thermal fading reaction.

Adsorbed water on the surface of a quartz cell is considered to react with MF, but it is not clear whether MF is adsorbed or not. This is the diffusion-controlled reaction since the rate hardly changes with the concentration of dissolved water in *n*-hexane and a shaking of a cell accelerates the fading of MF. The concentration gradient on the surface of the cell is given by

$$\left(\frac{\partial c}{\partial x}\right)_{x=0} = \frac{{}^*c - {}^0c}{\sqrt{\pi Dt}}$$

where $\sqrt{\pi Dt}$ represents the thickness of the diffusion layer. The thickness of the diffusion layer depends on time in the system in which only diffusion occurs. Usually natural convection occurs because of the density gradient by the reaction on the surface, and then the thickness of the diffusion layer is constant after a certain period.[4] If we denote the thickness of the diffusion layer by δ, the concentration gradient is given by

$$\left(\frac{\partial c}{\partial x}\right)_{x=0} = \frac{{}^*c - {}^0c}{\delta}$$

Since the reaction on the surface is fast in comparison with diffusion, ${}^0c=0$. Thus the concentration gradient on the surface of the cell is expressed simply as follows.

$$\left(\frac{\partial c}{\partial x}\right)_{x=0} = \frac{{}^*c}{\delta}$$

Consequently, the rate formula for the thermal decay is

$$-\frac{dc}{dt} = D\frac{A}{V}\frac{c}{\delta} = kc$$

where A is the surface area in contact with solution and V is the volume of solution. A/V is equal to 4.25 cm^{-1} when 4 ml of solution is placed in a cell of 1 cm$\times$ 1 cm. For diffusion coefficient D, 10^{-5}—10^{-6} cm^2/s is taken, δ being *ca.* 10^{-3} cm, and for rate constant k, 10^{-2}—10^{-3} s^{-1} is taken. The reaction should be of first order. This satisfactorily elucidates the third stage of the three-stage decay. The diffusion coefficient for a molecule larger than a solvent molecule is given by Einstein's equation

$$D = \frac{kT}{6\pi r\eta}$$

where r is the radius of the diffusing molecule and η is the viscosity of the solvent. The activation energy for the thermal decay rate constant is, then, expected to agree with the activation energy for the viscosity of *n*-hexane. The former is 1.7 kcal/mol and the latter 1.76 kcal/mol, an excellent agreement being seen. Almost the same rate constants in water-saturated *n*-hexane and ordinary *n*-hexane are also understood in view of the diffusion-controlled reaction.

The forced convection by shaking of a cell remains at stage I of the three-stage decay. The convection decreases the thickness of the diffusion layer of MF. The decay is fast at this stage. At stage II, the forced convection gradually subsides and the thickness of the diffusion layer increases, the decay rate becoming small and finally the reaction is governed only by the dif-

fusion of MF. The change from stage II to stage III would be caused by the development of natural convection, which occurs by the accumulation of HMM in the vicinity of the cell surface with the progress of reaction. Natural convection reaches a steady state after a certain period, the thickness of the diffusion layer thus becoming constant and the first-order decay being observed. When compared with stage II the thickness of the diffusion layer decreases at stage III and the decay rate becomes great.

The decrease in diffusion coefficient due to the solvation by dimethoxyethane (or acetonitrile) molecules might make the rate decrease when dimethoxyethane (or acetonitrile) is added. The thermal decay rate decreases rapidly with the increase of the concentration of polar component and approaches a constant value. The switching of the reaction mechanism occurs at about 0.2 M for dimethoxyethane and about 0.3 M for acetonitrile. Above these concentrations, the thermal decay is governed by the one-stage type not controlled by diffusion. The reaction on the surface of a cell is inhibited and the reaction in solution may become the rate-determining step. The result of damped experiment shows that the reactivity of physically adsorbed water is of the same order as that of water in solution.

The Catalytic Activity of AgX-type Zeolite for the Isomerization of 1-Butene

Hiroshi SUGIHARA, Ling Yuan CHEN,* and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 5, 1974)

The catalytic activity of X-type zeolite exchanged by Ag^+ was studied for the isomerization of 1-butene. The activity gradually increased with the degree of exchange up to *ca.* 60%, whereafter it rose steeply. A good correlation was found between the activity and the number of acid sites of H_0 less than 3.3. Both preferences, that for the formation of *cis*-2-butene from 1-butene and that for the geometrical isomerization rather than the double-bond shift, indicated that the reaction proceeds *via* a carbonium-ion intermediate formed on an acidic site. In the region of exchange around 40%, however, the *cis*/*trans* ratio in the 2-butenes produced was less than unity and a change in the reaction mechanism was suggested. Treatment with H_2 enhanced the activity of exchanged zeolite by a factor of 10^2—10^3 without any change in the character of the reaction. These results were attributed to the formation of proton-X-zeolite by the replacement of Ag^+ with a proton. This conclusion was confirmed by the analysis of deuterium exchange during the isomerization on D_2-treated AgX.

Zeolites have been chosen as the subjects of many studies because of their well-defined structures and distinguished properties in adsorption and catalysis. Catalytic activities enhanced by the replacement of Na^+ by rare earth or alkaline earth cations have often been correlated to the protonic acidity.[1,2]

Transition-metal zeolites have also been studied recently.[3] The lack of a simple relationship between activity and acidity on them, however, necessitates precise studies of the state of the exchanged cation and its role in the reaction mechanism for each zeolite.

As for the exchange effect of the silver ion, Ward found, using the IR technique, that AgX-type zeolite differs from other zeolites with monovalent cations in having acid sites of mainly the Brönsted type.[4] Yates observed X-ray diffraction due to the (111) and (200) planes of metallic silver after the reduction of AgX by H_2.[5] Recently Tsutsumi and Takahashi found that silver particles were formed during the course of cumene cracking on AgY and concluded that the zeolite becomes decationated-form in which metallic silver was dispersed.[6]

This paper will report the results of our study on the nature of active sites on AgX, using the isomerization of 1-butene as a test reaction. The degree of ion-exchange by Ag^+ was extended to the range of 11—100%. The effect of treatment with H_2 on the catalytic activity was examined; the deuterium distribution in butenes was also determined for the reaction on the catalyst treated with D_2.

Experimental

Materials. AgX-type zeolites were prepared by immersing Linde Na 13X-zeolite, free of clay binder, in an aqueous solution of silver nitrate at room temperature for 12 hr. The amount of Na^+ exchanged by Ag^+ was determined by means of EDTA analysis.[7] Throughout this paper, the catalysts will be denoted by AgX, with the percentage of ion-exchange by Ag^+ in parentheses. The surface area of zeolite was evaluated from a Langmuir plot for nitrogen adsorption at 77 K. The X-ray diffraction pattern was recorded before and after the isomerization reaction; AgX-type zeolites were thus found to retain the original structures, irrespective of the degree of ion-exchange. The acidity of the catalysts was estimated from the adsorption of *n*-butylamine.[8] Methyl red ($pK_a=4.8$) and methyl yellow ($pK_a=3.3$) were used as indicators. Decationated X-zeolite, HX, was prepared by exchanging the Na^+ in the zeolite with NH_4^+ and by then heating to 350 °C under a vacuum.[9] The hydrogen (nominal purity, 99.9 mol%), deuterium (99.5 mol%), and 1-butene (containing less than 0.2 mol% of 2-butene) in a glass ampoule were obtained from the Takachiho Shoji Co. and were used without further purification.

Procedure. The reaction was studied using an apparatus which consisted of a reaction system of 440 ml combined with a circulation pump and a high-vacuum line. Samples were taken periodically from the reaction system and were analyzed by means of a reduced-pressure-type gas chromatograph[10] with a 16 m DMS-alumina column at room temperature. For kinetic measurements, 0.1 g of the catalyst was placed in the reaction vessel and the vessel was evacuated at 350 °C for 12 hr. After the subsequent degassing at the reaction temperature for 1 hr, 1-butene was admitted to the vessel to start the reaction. The pressure of 1-butene was maintained at 18 Torr in all the kinetic runs. In the treatment with H_2, 2.4×10^{-4} mol of hydrogen was introduced into the system and was circulated over the AgX catalyst at 150 °C for 1 hr. The amount of hydrogen consumed corresponded to a *ca.* 45% reduction of the Ag^+ to Ag^0, regardless of the degree of ion-exchange in zeolites. AgX treated similarly with D_2 was also used for the reaction. The distribution of deuterium in butene was determined by using a mass spectrometer, Hitachi RMU-5B. The isomerization of *cis*-2-butene and *trans*-2-butene was also examined on H_2-treated AgX (93.2%) and AgX (32.9%).

Results

The surface areas per unit of weight of dried catalysts are shown in Table 1. By taking into account the formular weight (NaX=13418, AgX(100%)=20719 and so on), the area per unit of weight of the zeolite framework was found to be almost independent of the degree of exchange and was estimated as 893 ± 35 m^2/g_{fr}. The surface area decreased when zeolite was exposed to 1-butene (2), but was recovered partly by a sub-

* Present address: Department of Technical Engineering, Cheng Kung University, Tainan, Taiwan, Republic of China.

TABLE 1. SURFACE AREAS OF ZEOLITES

Catalyst (% Na^+ exchanged)	Surface area (m^2/g_{dry}) (1)[a] Evacuation at 350 °C	(2) Reaction at 150 °C	(3) Contact with hydrogen at 150 °C	(4) Reaction at 150 °C
NaX	792	790	—	—
AgX (11.3%)	745	621	695	694
AgX (32.9%)	612	444	562	536
AgX (42.6%)	600	445	516	484
AgX (72.3%)	529	305	401	377
AgX (93.2%)	507	220	338	323
AgX (100%)	505	205	327	315

a) Number in parentheses shows the order of treatments.

sequent H_2-treatment (3). These changes may be attributed to the irreversible adsorption of 1-butene through the formation of the Ag^+–olefin complex,[11] thus blocking up the micropores of zeolite and its partial removal by hydrogen. This conclusion is supported by the finding that the decrease in the surface area becomes smaller when the zeolites are pretreated with hydrogen (4), since hydrogen reduces Ag^+ to Ag^0.[6]

Figure 1(a) illustrates the time course of 1-butene isomerization on AgX (93.2%) at 120 °C. The reaction did not have an induction period, and no product was detected other than 2-butenes. The reproducibility was satisfactory when the reaction temperature was kept below 150 °C. The rate of the disappearance of 1-butene was well expressed by the reversible first-order equation:

$$\log x_e/(x_e - x) = kt$$

were k represents the rate constant ($min^{-1}\,g^{-1}$), and where x and x_e denote the fraction of 2-butenes at time t and at equilibrium, respectively. The equilibrium compositions of three isomers were estimated from the literature.[12] The plots of this relation are shown in

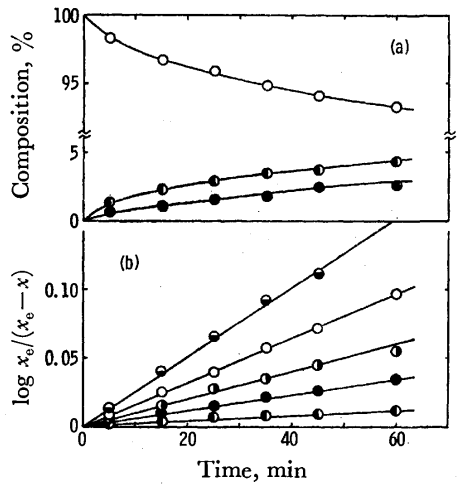

Fig. 1(a). Isomerization of 1-butene over AgX (93.2%) at 120 °C. ○, 1-butene; ●, *trans*-2-butene; ◐, *cis*-2-butene. 1(b). First-order plots for 1-butene isomerization. Reaction temperatures are 150, 140, 130, 120, and 100 °C in downward order.

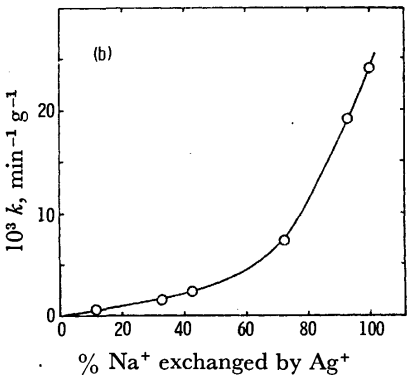

Fig. 2(b). Dependence of rate constants at 130 °C on the degree of ion-exchange.

Fig. 1(b) on AgX (93.2%) at temperatures ranging from 100 to 150 °C.

Effect of Ion-exchange. The dependence of the catalytic activity on the reaction temperature is given in Fig. 2(a). The broken lines indicate that the activity increases with repeated reactions above 150 °C. Figure 2(b) shows the first-order rate constants at 130 °C derived from these results. The activity increases gradually until the degree of exchange approaches 60% and rises steeply beyond that percentage. The energy of activation, as may be seen in Table 2, also changes abruptly at this degree of exchange. The initial ratio of the produced *cis*-2-butene to the *trans*-2-butene was larger than unity except in the case of AgX (42.6%) and increased with the temperature.

The results of acidity measurements are illustrated in Fig. 3. The total number of acid sites is linear with the degree of exchange, while strong acid sites of H_0 less than 3.3 increase drastically in number when the degree exceeds *ca.* 60%.

Effect of H_2-treatment. It was found that the silver particle was formed after the reaction at 200 °C, whereas this formation was not observed in the reaction below 100 °C. This fact suggests that olefins such as 1-butene can reduce AgX at high temperatures. Therefore, the effect of treatment with hydrogen as a reductant was examined.

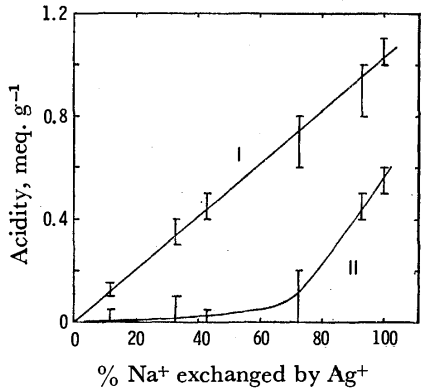

Fig. 3. Dependence of acidity on the degree of ion-exchange.
I, $H_0 \leqq +4.8$; II, $H_0 \leqq +3.3$ (H_0 is acidity function).

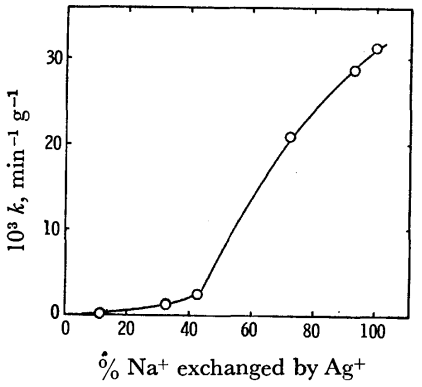

Fig. 4. Dependence of rate constants at 40 °C on the degree of ion-exchange over AgX pretreated with H_2.

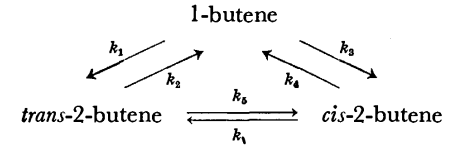
Figure 4 shows the relationship between the rate constant and the degree of exchange for H_2-treated AgX. The abrupt increase in the activity begins at the degree of *ca.* 40%. The rate constants at 130 °C are greater than those for AgX without H_2-treatment by a factor of 10^2—10^3. The contribution of the formed silver particle to the activity may be negligible; a separate study of the silver powder catalyst has shown that the reaction became appreciable only above 350 °C. The energies of activation and the *cis*/*trans* ratios in the products are listed, together with the degrees of exchange, in Table 2. The ratio is less than unity for AgX (32.9%) as well as for AgX (42.6%).

Experiments with three butene isomers as the starting material provided the relative rate constants shown in the scheme below:[13]



In the case of H_2-treated AgX (93.2%) at 72 °C, $k_1=12.8$, $k_3=17.3$, $k_4=3.5$, $k_5=2.1$, and $k_6=5.3$ were obtained by putting k_2 at unity, while $k_1=7.3$, $k_3=5.5$, $k_4=1.6$, $k_5=0.5$, and $k_6=1.1$ were obtained for H_2-treated AgX (32.9%) at 125 °C in a similar manner. On the reaction of 2-butenes, the treated AgX (93.2%) was evidently more active for the geometrical isomerization than for the double-bond shift. The preferential formation of *cis*-2-butene from 1-butene was also indicated. The treated AgX (32.9%) showed, on the contrary, a preference for the double-bond shift rather than for the geometrical isomerization and was active for the formation of *trans*-2-butene from 1-butene.

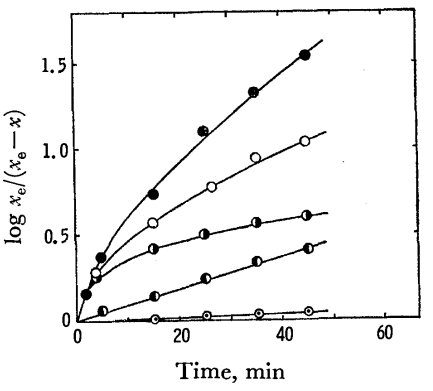


Fig. 5. First-order plots for 1-butene isomerization at 54 °C over AgX(100%) pretreated with H_2. Treatment temperature (⊙, 100 °C; ◐, 150 °C; ●, 250 °C; ○, 350 °C; ◑, 450 °C)

In Fig. 5, the effect of the treatment temperature on the activity is illustrated in terms of the first-order plot for the isomerization. The activity was raised slightly with H_2-treatment at 100 °C and became moderate and reproducible after treatment at 150 °C. When the treatment and the reaction were done alternately, the activity increased step by step and exceeded that of the decationated X-type zeolite, HX. When the temperature of treatment was higher than 250 °C, the initial rate became larger, but the degradation of activity occurred rapidly.

Parallel to this study of the activity, the X-ray diffraction of H_2-treated catalysts was examined. As the temperature of treatment was raised above 150 °C, a rapid growth of silver particles was recognized from the increase in the (111) and (200) diffraction intensities. The zeolite structure began to collapse above 250 °C and vanished completely after treatment at 450 °C.

Isotope Effect and Deuterium Distribution. In the case of treatment with D_2, the formation of HD as the result of exchange with surface hydrogen was negligible and the amount of deuterium atoms adsorbed on AgX (100%) was 9.30×10^{20} atom/g. This value was coincident with that of hydrogen atoms adsorbed when treated with H_2 under the same conditions. The initial rate constant for the isomerization of 1-butene at 56 °C was estimated to be 1.12×10^{-1} min^{-1} g^{-1}, compared with 1.67×10^{-1} min^{-1} g^{-1} over the H_2-treated catalyst; hence, the isotope effect was straightforward. The observed deuterium distribution is shown in Table 3. *trans*-2-butene, not quoted, had a distribution similar to that in *cis*-2-butene.

H_2- and D_2-treatment on AgX (32.9%) produced the rate constants of 1.10×10^{-1} min^{-1} g^{-1} and 1.00×10^{-1} min^{-1} g^{-1} respectively at 125 °C. The isotope effect appears to be small. The initial product by the isomerization of 1-butene on D_2-treated AgX (32.9%) consisted of 39% 2-butene-d_0 and 61% 2-butene-d_1.

Discussion

The preliminary experiment showed that the starting material, NaX, was inactive for the isomerization of 1-butene below 200 °C. As is evident from Fig. 2(b), the partial replacement of Na^+ by Ag^+ increases the activity, particularly when the degree of exchange exceeds 60%. There are several kinds of sites available to nonframework cations in zeolite: SI is at the center of the hexagonal prism; SII and SIII are in the sodalite cage; SIV faces the supercage, and SV is at the entrance into the supercage.[14] Shoemaker *et al.* determined the positions of the cation in AgY-type zeolite by means of X-ray diffraction and showed that all of the SI sites were occupied with silver ions.[15] Although the X-type zeolite differs from the Y-type in its Si/Al ratio and, consequently, in the number of cations, a similar site preference of Ag^+ is feasible. The preferential occupation of the interior sites, SI and SII and/or SIII, by Ag^+ is responsible for the slight increase in activity up to an exchange of *ca.* 60%. The cations which occupy the surface sites are expected to bring about a profound effect on the activity.

Table 2. Kinetic results of 1-butene isomerization on AgX-type zeolites

(a) Without H_2-treatment

Catalyst	Temperature range (°C)	*cis*/*trans* ratio	Energy of activation (kcal/mol)
AgX(11.3%)	127—141	1.4—1.6	34.2
AgX(32.9%)	120—144	1.8—2.1	31.9
AgX(42.6%)	135—150	0.7—0.9	29.2
AgX(72.3%)	100—150	1.3—1.7	16.4
AgX(93.2%)	100—150	1.8—2.1	16.4
AgX(100%)	120—140	1.9—2.1	16.4

(b) With H_2-treatment

Catalyst	Temperature range (°C)	*cis*/*trans* ratio	Energy of activation (kcal/mol)
AgX(11.3%)	125—183	1.3—1.7	15.4
AgX(32.9%)	77—125	0.3—0.8	13.4
AgX(42.6%)	71—144	0.4—0.7	13.4
AgX(72.3%)	27—86	1.3	11.2
AgX(93.2%)	40—83	1.2—1.5	11.0
AgX(100%)	40—83	1.5	11.1

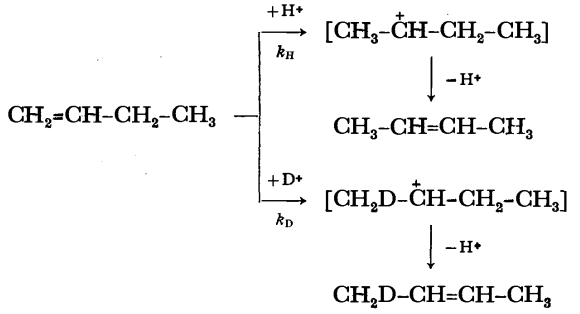
The variation in the number of acid sites with the degree of exchange also reflects this location of cations. Exchanged zeolites with Ag^+ in the interior sites have only weak acid sites of H_0 between 3.3 and 4.8. Strong acid sites of H_0 less than 3.3 are observed on zeolites in which Ag^+ occupies the surface site. The correlation between the number of strong acid sites and the activity is remarkable when we combine Fig. 3 with Fig. 2(b). This result suggests that the isomerization on AgX proceeds on acidic sites.

cis-2-Butene was produced preferentially on all the AgX-type zeolites except AgX (42.6%). In the case of 2-butene, the geometrical isomerization was more rapid than the double-bond shift. These features are characteristic of the isomerization by a carbonium-ion mechanism on acidic sites. On the other hand, studies of basic catalysts have shown that, if the reaction proceeds *via* an allyl carbanion, much larger *cis*/*trans* ratios and higher selectivities toward the double-bond shift may be expected because of the restricted rotation of the intermediate.[16] The repetition of reactions above 150 °C or H_2-treatment on AgX enhanced the activity, accompanied by the formation of silver particles. However, the effect of H_2-treatment on the activity increase is larger than that of repeated reactions by a factor of 10^1—10^2. The H_2-treatment lowers the energy of activation (Table 2) and also shifts the threshold of the increase in the activity to a 40% exchange (Fig. 4); nevertheless, the features of the reaction are similar to those of the reaction on AgX without the treatment. The region of the degree of ion exchange, where the *cis*/*trans* ratio becomes anomalous and less than untiy, shifts to around 35% upon H_2-treatment. In this region, an alternative mechanism such as a hydrogen-switch seems to hold, where the double-bond shift is favored on the isomerization of 2-butene.[17]

Table 3. Deuterium distribution in products for 1-butene isomerization over D_2-treated AgX (100%) at 56 °C

Conversion (%)	1-butene				*cis*-2-butene			
	d_0	d_1	d_2	d_3	d_0	d_1	d_2	d_3
1	99.5	0.5	—	—	52.0	47.4	0.6	—
6	98.9	1.0	0.1	—	51.2	43.1	4.7	0.4
20	97.5	2.3	0.2	—	66.0	30.0	3.7	0.3
25	97.3	2.5	0.2	—	69.2	27.3	3.2	0.3
94	80.1	17.9	1.9	0.1	80.0	17.4	2.4	0.2

The deuterium distribution obtained by the use of D_2-treated AgX (100%) gives the following information (Table 3): the deuterium content in both 1-butene and *cis*-2-butene is 23% at 94% conversion, and the total number of deuterium atoms entering the butenes during the isomerization is estimated to be 7.80×10^{20} atom/g. Therefore, the finding that the number of deuterium atoms adsorbed upon D_2-treatment is 9.30×10^{20} atom/g predicts that the majority of deuterium atoms participate in the reaction. The result that the fraction of 2-butene-d_0 produced attained 50% even at 1% conversion requires some source of hydrogen. If the AgX (100%) treated with D_2 or H_2 is used for the isomerization of 1-butene and if a carbonium-ion mechanism is operative, the initial step in the formation of 2-butene may be supposed to be:



The ratio of rates on H_2- and D_2-treated catalysts can be given by:

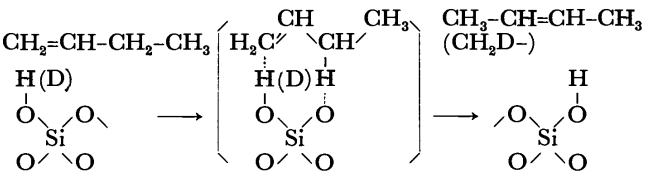
$$V_H/V_D = k_H(n_H^0+n_H)/(k_Hn_H^0+k_Dn_D) \quad (1)$$

where n_H and n_D correspond to the numbers of hydrogen and deuterium atoms produced by the treatments, where n_H^0 is the number of hydrogen atoms existing in AgX before the treatment, and where k_H and k_D are rate constants. In a similar manner, the ratio of 2-butene-d_1/2-butene-d_0 produced in the reaction on D_2-treated AgX can be expressed by:

$$d_1/d_0 = k_Dn_D/k_Hn_H^0 \quad (2)$$

when the reaction is extrapolated to zero conversion. By substituting the observed values for V_H/V_D, d_1/d_0, n_H, and n_D in Eqs. (1) and (2), one can evaluate k_H/k_D to be 2.03 and n_H^0 to be 5.0×10^{20} atom/g. The latter value is comparable with the estimated total number of acid sites, 6.02×10^{20} site/g. This result strongly indicates that the acid sites in AgX are mainly of the Brönsted type and conforms to the finding of the IR study that AgX zeolite lacks Lewis acid sites.[4]

A similar analysis of the reaction on AgX (32.9%) gave a k_H/k_D ratio of 1.16 and an n_H^0 value of 2.3×10^{20} atom/g. The observed small isotope effect suggests that an alternative path is merged in the carbonium-ion mechanism. In the consideration of the tetrahedral geometry of SiOH on the surface, a hydrogen-switch mechanism[17] may be applicable to the reaction on AgX, with the degree of exchange around 35% expressed as follows:



Since the surface hydrogen is protonic, the O–H bond may be thought to be weaker than the C–H bond. The rupture of the C–H bond is rate-determining, and there appears to be no direct isotope effect associated with the surface hydrogen. Accordingly, it is probable that the reaction proceeds by means of a simultaneous mechanism involving a hydrogen-switch and a carbonium-ion respectively, because 2-butene undergoes a *cis-trans* isomerization on this catalyst. This change in mechanism occurs in the limited range of ion exchange where Ag^+ would probably be located in the sodalite cage. This correlation between mechanism and structure requires further investigation.

The treatment with H_2 reduces silver ions into atoms, and an equivalent number of protons is produced. Since the number of acidic sites after treatment is, at most, three times as large as that before treatment, the remarkable increase in activity by a factor of 10^2—10^3 cannot be explained unless we introduce the increase in acid strength. Unfortunately, the acidity measurement is not possible because of the darkening of the treated AgX, but it seems reasonable to say that the distribution of acidic sites on the treated AgX became similar to that on the HX, spreading over a region of lower H_0 values. The H_2-treated AgX in the present study retains its crystal structure even though many of the Ag^+ ions are replaced with protons. As long as the H_2-treatment of AgX was performed at the relevant temperature, no water molecule was evolved and the Ag^+ ions remained as nonframework cations to maintain the zeolite structure. Protons with a strong acid strength are possibly stabilized in the structure.

Formation and Collapse of Mixed Monolayers of Trilaurin with Cholesterol and with Tristearin[1]

Masayuki NAKAGAKI and Noriaki FUNASAKI*

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received January 24, 1974)

The surface pressure-area curves of mixed monolayers and the equilibrium spreading pressure of solid mixtures were measured at 25 °C for cholesterol and trilaurin as well as tristearin and trilaurin. The phase diagrams of these mixtures were obtained by the measurement of the melting point. From two curves, one representing the relation between the collapse pressure (if the mixed monolayer was not overcompressed) and the composition of mixed monolayer, and the other representing the relation between the equilibrium spreading pressure and the composition of solid mixture, it was shown that the compositions of the mixed monolayer and the solid mixture coexisting in equilibrium were obtained. It was found that when the mixed monolayer of cholesterol and trilaurin was compressed, pure trilaurin began to collapse and deposit, and that the mixed monolayer of tristearin and trilaurin was apt to be overcompressed. It was concluded on the basis of phase rule and thermodynamics for plane interfaces that the equilibrium spreading pressure is constant regardless of the composition of solid mixture if the solid mixture consists of two phases of mixed crystals, and that cholesterol and trilaurin form a regular solution in mixed monolayer.

The miscibility in a mixed monolayer can be discussed on the basis of the composition dependence of collapse pressure of the mixed monolayer.[2-4] A theoretical study has recently been reported on the equilibrium spreading pressure of mixed crystals.[5] In both processes, *i.e.*, when a lipid mixture forms a monolayer and when a mixed monolayer collapses and deposits a lipid mixture, a mixed monolayer and a lipid mixture coexist on the air-water interface. In order to clarify the coexisting state of a mixed monolayer and a bulk mixture, the phase rule[6] and thermodynamics of plane interface seem to be useful. However, a thorough study has not been reported yet.

In the present investigation, the collapse pressure of mixed monolayers of cholesterol and trilaurin as well as tristearin and trilaurin and also the equilibrium spreading pressure of these solid mixtures were measured and these results were discussed on the basis of the phase rule and thermodynamics of plane interface.

Experimental

Materials. Trilaurin and tristearin used in this work were the same as those used previously.[7] They were synthesized directly from the corresponding fatty acid chloride and glycerol and then purified by repeated recrystallization. Cholesterol (guaranteed grade, Wako Pure Chemicals, Ltd.) was recrystallized from ethanol.[8]

Measurement of Surface Pressure. The surface pressure-area curve of mixed monolayers of cholesterol and trilaurin as well as tristearin and trilaurin were drawn by measuring the surface pressure of the monolayer which was compressed at nearly constant speed.

Solid mixtures of cholesterol and trilaurin as well as tristearin and trilaurin were prepared by mixing the chloroform solutions of both components and evaporating the solvent gradually at room temperature. When this crystalline mixture was sprinkled gently onto a clean aqueous surface, the surface pressure increased and reached a constant value. When this was compressed to some extent and then kept at that area, the surface pressure once increased and then decreased to a value nearly equal to the original value. By averaging these two equilibrium values of surface pressure, the equilibrium spreading pressure, F_e, was determined. Although a part of the solid mixture spreads as a monolayer, the composition of the solid mixture does not vary, since the amount of mixture sprinkled was more than, at least, a hundred times as much as required to form the monolayer. The surface pressure was measured at 25±0.1 °C. Details of the measurement of surface pressure have been reported.[7]

Measurement of Melting Point. The solid was mixed in the same way as described above. The initial and final melting points of the solid mixture were measured with a Yanagimoto micro-melting point apparatus, SR-50, equipped with a polarization microscope.

Results

Surface Pressure-Area Curve. The relations between surface pressure F and mean area A of mixed monolayers of trilaurin with cholesterol and with tristearin are shown in Figs. 1 and 2, respectively. The kink-points (indicated by arrows) are the points at which the monolayers begin to collapse. The pressure and area

of these points are collapse pressure F_c and collapse area A_c, respectively. The deposit formed by the collapse of a monolayer is expected to contain a component with lower collapse pressure in larger amount than one with a higher collapse pressure. In an extreme case, it is possible that only the former comes into the deposit, the latter remaining entirely in the monolayer. This might be clarified by dividing the area by the number of molecules of the component whose collapse pressure is higher, instead of the total number of initially spread molecules in the mixed monolayer, and by comparing the area thus obtained with the area per molecule in the pure monolayer of the component of higher collapse pressure. We see from Figs. 1 and 2 that the component with lower collapse pressure is trilaurin in both mixed monolayers. Instead of the mean area A, the area occupied by one molecule of cholesterol A_{ch}, and that occupied by one molecule of tristearin A_{st}, are plotted in Figs. 3 and 4, respectively. All the experimental values lies on one and the same curve (dotted line) at a pressure higher than collapse pressure regardless of the composition initially spread (Fig. 3). On the other hand, the collapse pressure is the same and equal to that of a trilaurin monolayer (dotted line) but the area at higher pressure varies with initial composition (Fig. 4).

Relation between Mean Area and Mole Fraction in the Mixed Monolayers. The relations between the mean area A at a given pressure and the mole fraction of trilaurin in the mixed monolayers x_1^s are given in Figs. 5 and 6, respectively. In these figures, the dotted line is calculated by the equation

$$A = x_1^s A_1 + x_2^s A_2 \qquad (1)$$

where x^s is the mole fraction in a monolayer, A the mean area per molecule, and subscripts 1 and 2 indicate the components. The experimental values of the area of mixed monolayer of tristearin and trilaurin agree with the values from Eq. (1) (Fig. 6), while the experimental values are smaller than the calculated values for the monolayer of cholesterol and trilaurin (Fig. 5).

Equilibrium Spreading Pressure and Collapse Pressure. Equilibrium spreading pressure was measured by gently sprinkling a large quantity of the crystalline mixture on the water surface. In the case of the mixture of tri-

gradually to the original value. Equilibrium spreading pressure was determined as the mean value. It was thus confirmed that the crystal and the monolayer were in equilibrium. It took about one minute for trilaurin, about 30 min for cholesterol and more than 10 day for tristearin to return nearly to the original value after the monolayer had been compressed and kept at that area, while in mixed monolayer, it took about 30 min for the cholesterol–trilaurin system.

The relation between the equilibrium spreading pressure and mole fraction of trilaurin in solid mixture is shown by closed circles for cholesterol and trilaurin in Fig. 8 and for tristearin and trilaurin in Fig. 9. The composition of point B was uncertain, and the equilibrium spreading pressure near this point (shown by dotted lines) was not measured. The relation between the collapse pressure F_c, obtained from Figs. 1 and 2, and the mole fraction of trilaurin in the mixed monolayers x_1^s is also shown by open circles in Figs. 8

and 9, respectively.

Melting Point of Solid Mixture. The melting points of solid mixtures for cholesterol and trilaurin and for tristearin and trilaurin are shown in Figs. 10 and11, respectively. Closed circles indicate the initial melting points and open circles the final melting points.

Discussion

Pressure-Area Curve. A_{ch} of mixed monolayer is larger than the area occupied by one molecule of cholesterol in its own monolayer (Fig. 3). The pressure-area curves of mixed monolayers at higher pressure than collapse pressure are on a single line regardless of the composition of initially spread monolayer. These two facts indicate that when the mixed monolayer collapses, only trilaurin deposits to solid and all the initially spread molecules of cholesterol remain in the monolayer, containing a part of trilaurin, and that the molar ratio of trilaurin to cholesterol in the monolayer depends only on the surface pressure regardless of the composition of the initially spread monolayer.

The mixed monolayer begins to collapse at the pressure equal to the collapse pressure of the trilaurin monolayer and after all the trilaurin molecules have deposited, *viz.*, the area A_{st} has reached the occupied area of the tristearin monolayer, the monolayer collapses again at the collapse pressure of the pure tristearin monolayer (Fig. 4). At a pressure lower than the collapse pressure, the mean area of the mixed monolayer agrees with the additivity of the area given by Eq. (1) (Fig. 6). Thus, it might be concluded that tristearin and trilaurin are completely immiscible in monolayer. However, the fact that the F-A_{st} curve varies with the composition of initially spread monolayer in the range from the first collapse pressure (equal to that of trilaurin monolayer) to the second collapse pressure (equal to that of tristearin monolayer), cannot be explained without taking the interaction between both components into account.

Equilibrium Spreading Pressure and Collapse Pressure. A phase diagram of cholesterol–trilaurin system is given in Fig. 8. The mixed monolayer exists at a surface pressure lower than the curve of collapse pressure (open circles), but mixed monolayer and solid coexist in the range between this curve and the curve of equilibrium spreading pressure (closed circles). If a horizontal line is drawn at a given surface pressure, its intersection with the curves of equilibrium spreading pressure and collapse pressure give mole fractions of trilaurin in the solid and in the monolayer, respectively, coexisting on the water surface. In this meaning, the curve of collapse pressure and that of equilibrium spreading pressure might be called monolayer and solidus lines, respectively, the latter being more generally called bulk phase line. It is seen that cholesterol, whose equilibrium spreading pressure is higher, is richer in the monolayer and trilaurin, whose equilibrium spreading pressure is lower, is richer in the solid phase. The mixed monolayers (Fig. 3) were those whose mole fraction of trilaurin was greater than x_1^G (Fig. 8), *viz.*, the mole fraction 0.06 of trilaurin at point G. In this range of composition, nearly pure trilaurin is expected to deposit, when the mixed monolayer is compressed. This agrees with the result given in Fig. 3. As expected, when the mixed monolayer was further compressed, the surface pressure increased and remained constant at about 34.2 dyn/cm, not increasing with further compression (Fig. 3). Further compression was not carried out, since the mixed monolayer had spread over the top of the trough.

The equilibrium spreading pressure is constant over the range of composition between A and B in Fig. 8. For interpretation, the phase rule for plane interface might be used. The number of freedom, ω, is given by[6]

$$\omega = c - \varphi - (\psi - s) + 2 \qquad (2)$$

where c is the number of components, φ is the number of the bulk phase, ψ is the number of interface phases and s is the number of types of interface. If the solid deposits over the range of composition between x^A and x^B is a mixture of two mixed crystals S^A, and S^B, whose compositions are x^A and x^B, respectively, and if A and W denote air and water, respectively, then c=4 (A, W, cholesterol and trilaurin), φ=4 (A, W, S^A and S^B) s=6 (A/W, A/S^A, A/S^B, W/S^A, W/S^B and S^A/S^B), and ψ=6 (one phase at each interface). Thus we get ω=2. Since temperature and pressure are kept constant, the surface pressure and composition of mixed monolayer should be constant irrespective of the composition of the solid mixture. The equilibrium spreading pressure is thus found to be constant in the range of composition between A and B in Fig. 8. Comparing this with the phase diagram of the bulk phase, it is found from Fig. 10 that the solids of the compositions of x^A and x^B coexist at 44.5 °C. If these compositions are considered nearly unvaried at temperatures below 44.5 °C, they correspond to compositions A and B (25 °C).

In the case of the tristearin–trilaurin system, the components were suspected of being immiscible in the

mixed monolayer (Figs. 4 and 6). However, it is not certain whether the monolayer is in equilibrium with the solid formed when the monolayer collapses, or not. The collapse pressure of tristearin monolayer is 38 dyn/cm, while the equilibrium spreading pressure is 0 dyn/cm (Fig. 9). This discrepancy may be due to the fact that the rate of collapse of the tristearin monolayer is low, so that its monolayer is apt to be overcompressed. Actually, the surface pressure decreased gradually with time and reached 1 dyn/cm after ten days, when the area of the tristearin monolayer was kept constant as soon as the monolayer began to collapse. Thus, the mixed monolayer of tristearin and trilaurin, also, has the possibility of being overcompressed. If the area of the mixed monolayer of tristearin and trilaurin at $x_1=0.406$ was kept constant as soon as the monolayer began to collapse, the surface pressure decreased (Fig. 9) down to the value ① after two days and did not decreased any more. The collapse pressure obtained from the pressure-area curves of the mixed monolayer of tristearin and trilaurin (Figs. 2 and 4) is too great to be in an equilibrium state. It cannot be concluded from the results (Figs. 4 and 6) that tristearin and trilaurin are immiscible in the mixed monolayer.

Since tristearin and trilaurin are completely miscible in the liquid state and partially miscible in the solid state (Fig. 11), it is unlikely that they are completely immiscible in the monolayer state. Therefore, the result showing the establishment of the additivity of the area (Fig. 6) should be interpreted as the ideal mixing in the monolayer.

The equilibrium spreading pressure is constant over the range from x_1^A to x_1^B (Fig. 9). This is interpreted to be due to the coexistence of the mixed crystals of the compositions x_1^A and x_1^B, corresponding to points A and B (Fig. 8) for the mixture of cholesterol and trilaurin. It is found that the compositions of points A and B (Fig. 9) are equal to those of points A and B (Fig. 11).

Thermodyndmic Treatment of the Equilibrium between Monolayer and Solid. Only trilaurin is deposited as a solid and the mixed monolayer is in equilibrium with the pure solid of trilaurin when the mixed monolayer of cholesterol and trilaurin collapses. Since the chemical potential of trilaurin in the mixed monolayer is equal to that in the solid, the following equation can be written according to Joos.[9]

$$\mu_1^{ob} = \mu_1^{os} + kT \ln \gamma_1^s x_1^s + F\bar{A}_1 \qquad (3)$$

where μ^0 is the standard chemical potential, γ the activity coefficient, x the mole fraction and $\bar{A}$ the partial molecular area. Superscripts b and s indicate a solid and a monolayer, respectively. For one-component system of trilaurin, we have

$$\mu_1^{ob} = \mu_1^{os} + F_{1c}A_{1c} \qquad (4)$$

with $x_1^s=1$, $\bar{A}_1=A_{1c}$ and $\gamma_1^s=1$. Substituting this equation into Eq. (3), we obtain the following equation for the surface activity coefficient of trilaurin γ_1^s.

$$\gamma_1^s = \frac{1}{x_1^s} \exp\left(\frac{F_{1c}A_{1c} - F\bar{A}_1}{kT}\right) \qquad (5)$$

From Fig. 1 we have $F_{1c}=19.4$ dyn/cm, and $A_{1c}=80.5$ Å^2/molec. The mole fraction of trilaurin in the mixed monolayer x_1^s at a given surface pressure is obtained from the curve of collapse pressure (Fig. 8). The value of $\bar{A}_1$ is obtained from the intercept of the tangent at the composition of x_1^s on the curve representing the relation between the mean area A and the mole fraction of the monolayer x_1^s under the given pressure. The right hand of Eq. (5) can be calculated at a given surface pressure. Proportionality holds between the logarithm of the surface activity coefficient of trilaurin γ_1^s and the square of the mole fraction of

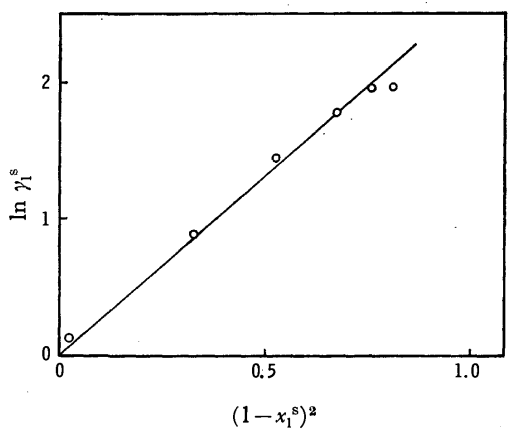

Fig. 12. The relation between the logarithm of surface activity coefficient of trilaurin and the square of mole fraction of cholesterol in mixed monolayer of cholesterol and trilaurin.

cholesterol in the monolayer $(1-x_1^s)^2$ (Fig. 12). If we denote proportionality constant by B/kT, we have

$$\ln \gamma_1^s = \frac{B}{kT}(1-x_1^s)^2. \qquad (6)$$

$B=1.58$ kcal/mol is obtained from Fig. 12. Equation (6) is the relationship expected from the theory of regular solution. Thus, it is concluded that cholesterol and trilaurin form a regular solution in the monolayer.

(Received March 4, 1974)

The formation of transient *N*-vinylcarbazole cation-radical and pyromellitic dianhydride anion-radical was demonstrated for the *N*-vinylcarbazole-pyromellitic dianhydride-solvent system by means of flash spectroscopy. The transient decay process was found to be solvent-dependent. In 1,2-dichloroethane the decay of the anion-radical was of the first-order at initial stage ($t<100$ μs), and the second-order kinetics ($t>100$ μs) then followed. In acetonitrile the transient decay followed the second-order kinetics in the whole time region.

The photochemical reaction of *N*-vinylcarbazole (VCZ) in the presence of an electron acceptor is currently receiving great attention. The reaction involves cationic polymerization, radical polymerization or radical copolymerization with an electron-accepting monomer and cyclodimerization to give the *trans*-head-to-head cyclodimer, the reaction course being strongly solvent-dependent.[1] It has been postulated that these reactions are initiated by VCZ cation-radical formed by the photochemical electron transfer from VCZ to the electron acceptor, and the multi-reaction courses are explained in terms of the dual cationic and radical reactivity of the VCZ cation-radical.[1]

Recently, efforts have been made to elucidate the primary process of the above photochemical reactions. We demonstrated for the first time the formation of VCZ cation-radical and the anion-radical of the electron acceptor by means of flash spectroscopy for the VCZ–chloranil system in acetone, acetonitrile and methanol.[2] The formation of ion-radical species has since been confirmed successively for the VCZ–tetracyanobenzene[3] and VCZ–dimethyl terephthalate[4] systems by means of laser photolysis or conventional flash photolysis. However, only a few systems were studied as regards the photochemical primary process of the VCZ-electron acceptor system, not many studies being carried out on the effect of solvent on the transient decay.

As an extension of our studies on the photosensitized charge-transfer reaction of VCZ, we have investigated the flash photolysis for the VCZ–pyromellitic dianhydride (PMDA)–solvent system. 1,2-Dichloroethane and acetonitrile were selected as solvents: cationic polymerization of VCZ takes place in the former solvent, while the cyclodimerization of VCZ occurs in the latter solvent.[1] The transient absorption spectra and the transient decay process are described and discussed.

Experimental

Materials. *N*-Vinylcarbazole (VCZ) was purified and dried as described before.[2] Pyromellitic dianhydride (PMDA) (Wako Pure Chemical Ind., Ltd.) was recrystallized from anhydrous ethyl acetate and then sublimed twice *in vacuo*. 1,2-Dichloroethane was shaken with dilute aqueous sodium hydroxide, washed with water, dried over calcium chloride, refluxed with calcium hydride, and distilled immediately before use. Acetonitrile was refluxed over phosphorus pentoxide for more than 24 hr, distilled and then refluxed over anhydrous potassium carbonate and again distilled immediately before use.

Flash Spectroscopy. The concentrations of VCZ and PMDA for flash spectroscopy were mostly 3×10^{-4} M and 4×10^{-4} M, respectively. Freshly prepared solutions were degassed at 10^{-5} mmHg by means of several freeze-pump-thaw cycles and flashed at room temperature in a cylindrical silica cell with 20 cm path length and 1.5 cm diameter. The flash apparatus, a conventional one, was almost the same as that described by Yamamoto *et al.*[5] A stored electrical energy available for the flash was approximately 250 J, the half-duraction time of the flash being about 7 μs. The transient absorption spectra were photographed with a Narumi RM-23-I grating spectrograph with a Kodak high speed infrared film. A photoelectric recording system consisting of a R446 photomultiplier and a National type 501 oscilloscope was used. A filter solution composed of a glass plate and an aqueous solution of $NaNO_3$ (86 g in 500 ml solution) was inserted between the flash lamp and the reaction cell in order to ensure selective excitation of VCZ by the flash illumination (Fig. 1). In the case of the photoelectric recording of a transient decay, an aqueous solution of $CuSO_4\cdot5H_2O$ (80 g) and $NaNO_3$ (30 g) in 500 ml solution was used as a filter to obtain light of wavelength 330—620 nm. The electronic absorption spectra of the ground state molecule were taken with a Hitachi 124 spectrophotometer.

Results and Discussion

The VCZ–PMDA system forms a charge-transfer complex in the ground state, showing a charge-transfer absorption band (CT band) with a maximum at 490 nm (for the 1st CT band) in 1,2-dichloroethane. In the present flash photolysis, however, the donor-acceptor interaction in the ground state was negligible because of the low concentration of the solution (*ca.* 10^{-4} M order). Selective excitation of VCZ was possible as shown in Fig. 1.

Transient Spectra Obtained for the VCZ-PMDA–Acetonitrile System. The cyclodimerization of VCZ takes place to give *trans*-1,2-(9-dicarbazolyl)cyclobutane. The reaction mechanism is explained in terms of the intermediacy of VCZ cation radical formed by

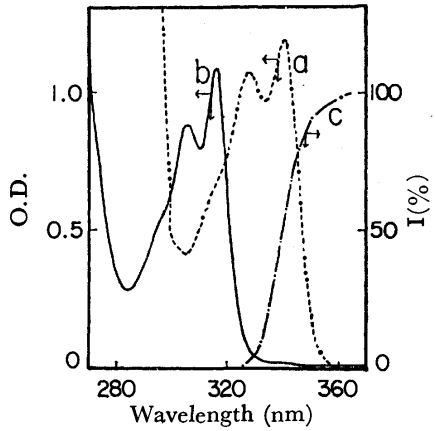

Fig. 1. The electronic absorption spectra of VCZ and PMDA in 1,2-dichloroethane and the transmittance of the filter solution used for the flash photolysis. (a) VCZ(3×10^{-4} M) (b) PMDA(4×10^{-4} M) (c) filter solution ($NaNO_3$ 86 g in 500 ml aqueous solution)

the photochemical electron transfer from VCZ to PMDA.[1] Flash excitation of VCZ in this system gave rise to a transient absorption spectrum consisting of two band systems, one in the wavelength region 550—700 nm with maxima at 665 and 615 nm, and the other in the wavelength region 700—850 nm with a maximum at 780 nm (Fig. 2). The former was identified as the PMDA anion-radical by comparison with the spectrum of the chemically prepared PMDA anion-radical.[6] The latter was assigned to the VCZ cation-radical by comparison with the spectrum of the authentic VCZ cation-radical generated by γ-ray irradiation in *sec*-butyl chloride glass at 77 K.[2] The absorption band of the VCZ cation-radical seems to more or less overlap with the absorption band of the PMDA anion-radical especially in the wavelength region around 615 nm. The transient absorption weakened more rapidly at around 615 nm than at 665 nm (Figs. 2 and 3). No transient absorption was obtained by the flash excitation of VCZ alone in acetonitrile. This indicates that the electron transfer occurred from the excited VCZ to PMDA to produce the VCZ cation-radical and the PMDA anion-radical.

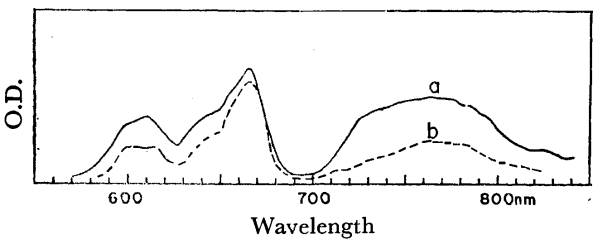

Fig. 2. The transient absorption spectra obtained by the flash photolysis for the VCZ(3×10^{-4} M)-PMDA (4×10^{-4} M)-acetonitrile system at room temperature. Delay time after flash excitation: (a) 4 μs (b) 59 μsec.

Transient Spectra Obtained for the VCZ-PMDA-1,2-Dichloroethane System. The cationic polymerization of VCZ occurs in preparatory scale reactions of this system. It has been proposed to be initiated by the VCZ cation-radical.[1] The formation of the transient VCZ cation-radical and PMDA anion-radical was likewise demonstrated by flash photolysis. The transient absorption spectra obtained by flash illumination are similar to those obtained in acetonitrile (Fig. 3). Confirmation of the occurrence of the electron transfer from VCZ to PMDA to produce the VCZ cation-radical and the PMDA anion-radical in acetonitrile and in 1,2-dichloroethane by means of flash spectroscopy provided direct evidence for the intermediacy of the VCZ cation-radical proposed for the photocyclodimerization and cationic photopolymerization of VCZ.

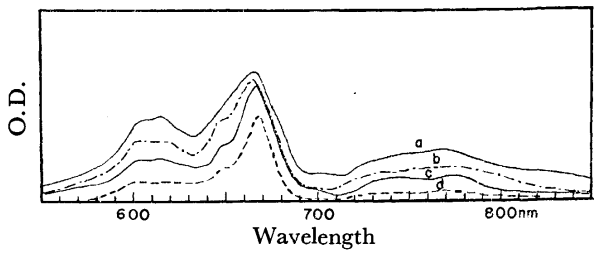

Fig. 3. The transient absorption spectra obtained by the flash photolysis for the VCZ(3×10^{-4} M)-PMDA (4×10^{-4} M)-1,2-dichloroethane system at room temperature. Delay time after flash excitation: (a) 3 μs (b) 23 μs (c) 53 μs (d) 105 μs.

Transient Spectra Obtained for the VCZ-1,2-Dichloroethane System. *N*-Vinylcarbazole generally undergoes radical polymerization by direct irradiation in the UV light in a high vacuum system in various solvents such as tetrahydrofuran, acetone, acetonitrile, *N*,*N*-dimethylformamide or dimethyl sulfoxide, the polymerization being suggested to be initiated by the excited triplet state of VCZ.[7,8] However, cationic photopolymerization of VCZ takes place in dichloromethane or in 1,2-dichloroethane even in the absence of an electron acceptor.[8] It has been suggested that the solvent, dichloromethane or 1,2-dichloroethane acts as an electron acceptor to the excited VCZ, the electron transfer occurring in these solvents from the excited VCZ to the solvent to produce the transient VCZ cation-radical which initiates the cationic polymerization of VCZ.[9] When VCZ alone was flash illuminated in 1,2-dichloroethane at room temperature, a transient absorption spectrum assignable to the VCZ cation-radical was obtained (Fig. 4), whereas no transient absorption was obtained in tetrahydrofuran, acetonitrile or *N*,*N*-dimethylformamide.[10] The results of flash photolysis support the mechanism of the VCZ cation-

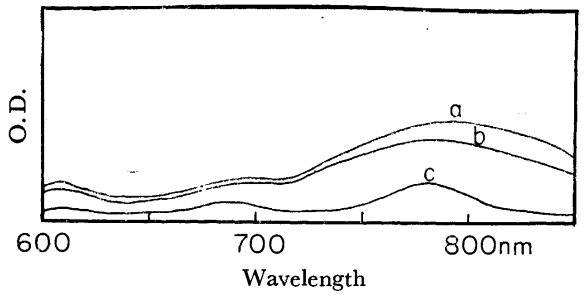

Fig. 4. The transient absorption spectra obtained by the flash photolysis for the VCZ(3×10^{-4} M)-1,2-dichloroethane system at room temperature. Delay time after flash excitation: (a) 5 μs (b) 28 μs (c) 60 μs.

radical initiation for the cationic photopolymerization of VCZ in 1,2-dichloroethane or in dichloromethane in the absence of an added electron acceptor.

Decay of the Transient Species. The transient decay followed by the photoelectric recording method was found to be solvent-dependent. In 1,2-dichloroethane, the decay of the PMDA anion-radical was of first-order at an initial stage ($t<100$ μs), followed by the second-order kinetics ($t>100$ μs). In contrast, the transient decay in acetonitrile followed the second-order kinetics for all the time intervals ($t>20$ μs). The oscilloscope traces for the decay of the PMDA anion-radical measured at the wavelength of the absorption maximum, 668 nm in 1,2-dichloroethane and 665 nm in acetonitrile, are shown in Figs. 5(a) and (b), and 6(a) and (b), respectively. The first-order and second-

Fig. 6 (a) and (b). The oscilloscope traces for the decay of the transient PMDA anion-radical measured at 665 nm in acetonitrile at around 20 °C. [VCZ] $=3\times10^{-4}$ M, [PMDA] $=4\times10^{-4}$ M. The vertical scale is 0.02 V/div.

Table 1. Rate constants for the decay of the transient PMDA anion-radical produced in the VCZ–PMDA–solvent system at around 20 °C

Solvent	Wavelength (nm) measured	Rate constant
1,2-Dichloroethane	668	1.3×10^{4} s^{-1} ($t<100$ μs) $7.8\times\varepsilon_A-\times10^{5}$ M^{-1} s^{-1} ($t>100$μs)
Acetonitrile	665	$1.4\sim3.1\times\varepsilon_A-\times10^{5}$ M^{-1} s^{-1} (in all the time region measured, $t>20$ μs)

ε_A- represents the molar extinction coefficient of the PMDA anion-radiacl at each wavelength.

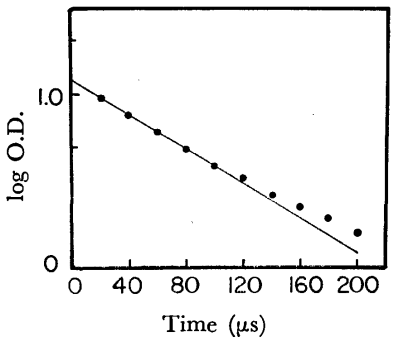

Fig. 7. The first-order plots for the decay of the transient PMDA anion-radical shown in Fig. 5(a) (in 1,2-dichloroethane).

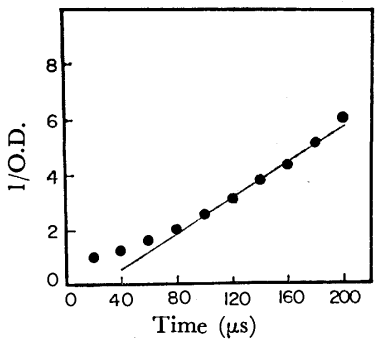

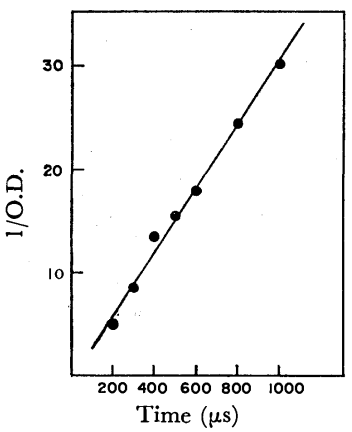

Fig. 8 (a) and (b). The second-order plots for the decay of the transient PMDA anion-radical shown in Figs. 5 (a) and (b), respectively (in 1,2-dichloroethane).

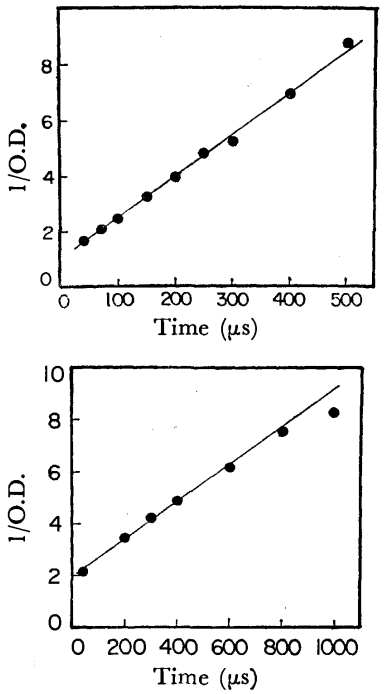

Fig. 9 (a) and (b). The second-order plots for the decay of the transient PMDA anion-radical shown in Figs. 6 (a) and (b), respectively (in acetonitrile).

order plots for the transient decay in 1,2-dichloroethane are shown in Figs. 7, and 8(a) and (b), respectively. The second-order plots for the transient decay in acetonitrile are shown in Fig. 9(a) and (b). Rate constants for the decay of the PMDA anion-radical obtained in each solvent are summarized in Table 1. Since the molar extinction coefficient of the absorption of the PMDA anion-radical is estimated to be at least 10000 at the wavelength of its absorption maximum,[6] it is indicated that the second-order decay occurred at a diffusion-controlled rate in each solvent. A similar transient decay has been observed for the triphenylene-PMDA system.[6]

The transient decay behaviors observed in the present systems can be explained by essentially the same kinetic treatment as described for the triphenylene-PMDA system. It is suggested that in acetonitrile possessing a high dielectric constant (37 at 20 °C) formation of the free ions are predominant by flash excitation, while in less polar 1,2-dichloroethane (dielectric constant: 10.37 at 25 °C) the ion pair is produced predominantly. The initial first-order decay followed by the final second-order decay process of the PMDA anion-radical in 1,2-dichloroethane is rationalized in terms of the initial very fast decay of the ion-pair, followed by the slower decay of the free ions. The photochemical primary process is given as in the following scheme of reactions.

$$D \xrightarrow{h\nu} D^*$$

$$D^* + A \xrightarrow{k_1} D^+A^- \text{ or } D^+ + A^-$$

$$D^+A^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} D^+ + A^-$$

$$D^+A^- \xrightarrow{k_3} D + A$$

$$(D^+ + D \rightsquigarrow \text{Cyclodimer or Polymer})$$

The optical density of the absorption of the PMDA anion-radical is given by $\Delta D=\varepsilon_{A^-}[A^-]+\varepsilon_{D^+A^-}[D^+A^-]$, where ε_{A^-} and $\varepsilon_{D^+A^-}$ represent the molar extinction coefficients of the free ion and the ion-pair, respectively. In 1,2-dichloroethane the ion-pair D^+A^- is the predominant species, thus $\Delta D\simeq\varepsilon_{D^+A^-}[D^+A^-]$. Since the decay of D^+A^- is very fast, $k_3\gg k_2$ holds and the k_2 and k_{-2} terms can be neglected in the above scheme of reactions, and time-dependent behavior of the change in the optical density of the PMDA anion-radical in the initial decay stage would be given by $-d\Delta D/dt=k_3\Delta D$. When the ion-pair concentration rapidly decreases, essentially only ions are present (although in low concentrations) and the optical density of the PMDA anion-radical is given by $\Delta D\simeq\varepsilon_{A^-}[A^-]$. In the final decay stage the ion-pair is formed from D^+ and A^-, assuming the role of an unstable intermediate. The steady-state concentration $[D^+A^-]=k_{-2}/(k_2+k_3)\cdot[A^-]^2$ is obtained from the condition $d[D^+A^-]/dt=0$. Since $k_3\gg k_2$, the decay equation becomes $-d\Delta D/dt=(k_{-2}/\varepsilon_{A^-})(\Delta D)^2$. On the other hand, free ions are the predominant species in acetonitrile. Thus $\Delta D\simeq\varepsilon_{A^-}\cdot[A^-]$. The ion-pair equilibrium seems to be established very rapidly (within 20 μs) in acetonitrile. It is reasonable to assume that $k_2\gg k_3$, *viz.*, the ion-pair equilibrium is maintained during the decay process. In this case the concentration of D^+A^- would also be negligibly small. The second-order decay equation $-d\Delta D/dt=k_3(k_{-2}/k_2)(\Delta D)^2/\varepsilon_{A^-}$ is then obtained in acetonitrile. The first-order and the second-order rate constants for the decay of PMDA anion-radical in 1,2-dichloroethane and in acetonitrile (Table 1) represent k_3, k_{-2}, and $k_3(k_{-2}/k_2)$, respectively, in the above scheme of reactions (the absolute values of k_2, k_{-2}, and k_3 may differ with solvent).

(Received March 25, 1974)

The reaction of *o*-phenylenediamine with chloranil in ether was studied by measuring visible and ultraviolet absorption spectra at various temperatures between −78 °C and room temperature. Dehydrogenation of *o*-phenylenediamine by chloranil occurred, *o,o'*-diaminoazobenzene, 2,3-diaminophenazine and tetrachlorohydroquinone being produced as main reaction products. It was suggested that the reaction involves *o*-benzoquinone di-imine as an intermediate. For the sake of confirmation, *o*-benzoquinone di-imine was prepared by an independent method, and its reaction with *o*-phenylenediamine was examined. The difference in reactivity of isomeric phenylenediamines toward chloranil is discussed.

The reactions of chloranil (CA) with such aromatic amines as aniline, *s*-triaminobenzene, *m*-phenylenediamine, *p*-phenylenediamine, and *N,N*-dimethyl-*p*-phenylenediamine have been studied, special attention being paid to charge-transfer interaction.[1a-d] Spectrophotometric studies show that substitution reaction occurs for the *meta*-substituted derivatives of aniline in ether or acetone *via* inner complex (σ-complex) formed through outer complexes, while the reaction proceeds for the *para*-substituted derivatives in the mixed solvent, ether–isopropyl alcohol (3: 1), through ionic species produced from the outer complex. The difference in the reaction mechanism between the *m*- and *p*-substituted derivatives of aniline was explained in terms of the nonbonding electron density on the amino group.

The reaction of *ortho*-substituted derivatives of aniline with CA remains to be solved. We have studied spectrophotometrically the reaction between *o*-phenylenediamine (*o*-PD) and CA in ethyl ether. The results are given in this paper.

Experimental

Materials. Chloranil was purified by column chromatography (benzene–calcium carbonate) in order to eliminate acidic impurities,[2] and then recrystallized twice from acetone. *o*-Phenylenediamine was purified by repeated sublimation *in vacuo*.

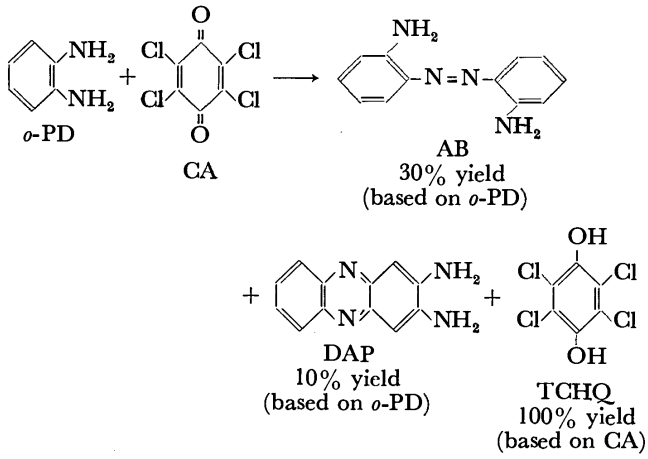
Measurements. The ultraviolet and visible absorption spectra were measured with a Hitachi two-wavelength double beam spectrophotometer model 356 and also with a Hitachi 124 spectrophotometer. Donor and acceptor solutions were prepared separately and mixed together just before each measurement. For measurements at low temperatures, the sample was cooled with a dry-ice methanol mixture in a quartz Dewar vessel designed for spectroscopic measurements. The temperature was measured by a copper-Constantan thermocouple.

Isolation and Identification of the Reaction Products. *o*-Phenylenediamine (0.616 g) in 60 ml ether and chloranil (0.702 g) in 500 ml ether (the mole ratio, [*o*-PD]: [CA]= 2: 1) were mixed together at room temperature and kept for five days.[3] Precipitate (I) produced was collected by filtration, yield 0.175 g. The filtrate was evaporated to dryness under reduced pressure, 0.892 g of powder (II) being obtained. No component molecules were detected in I and II judging from their thin layer chromatograms. I and II were independently chromatographed on alumina (benzene–acetone mixed solvent as an elute). Three main fractions were collected, *i.e.*, a yellow eluent in I, a red one in II, and a colorless one in II. They were further purified by thin layer chromatography and identified as 2,3-diaminophenazine (DAP) (yellow eluent in I), *o,o'*-diaminoazobenzene (AB) (red eluent in II), and tetrachlorohydroquinone (TCHQ) (colorless eluent in II). The yields of DAP, AB, and TCHQ were respectively 10, 30, and 100% of theoretical values. In addition to the three main products, seven or more other minor products were formed. However, they were not identified because of small quantities and difficulty in purification. Identification of DAP and TCHQ was made by comparing their mass, IR and electronic absorption spectra with those of authentic samples. Electronic absorption spectra (in ethyl ether); DAP: λ_{max} 450 nm (ε=17000), 425 nm (ε=21000). TCHQ: λ_{max} 310 nm (ε=6600). Identification of AB was made by mass, IR and electronic absorption spectra and elemental analysis. Mass spectra; *m/e* 212 (M^+), 92 ($M^+-C_6H_4(NH_2)N_2$). IR spectra; 3430, 3350 cm^{-1} (NH stretching), 1560 cm^{-1} (N=N stretching). Electronic absorption spectra; λ_{max} 470 nm (ε=1580), 312 nm (ε=1580), 265 nm (ε=2170). Found: C, 67.39; H, 6.24; N, 26.37%. Calcd for $C_{12}H_{12}N_4$: C, 67.92; H, 5.66; N, 26.42%.

Synthesis of o-*Benzoquinone Di-imine.*[4] Freshly prepared lead dioxide[5] (350 mg) and anhydrous sodium sulfate (100 mg) baked beforehand for 30 min were added to an ether solution (30 ml) of *o*-PD (1.7 mg) under cooling with ice-salt and then vigorously stirred for five min. The solution was filtered, and the yellow filtrate was used directly. All the procedures were performed under anhydrous conditions. The yellow compound in the solution thus obtained seems to be spectroscopically of high purity, and is assigned to *o*-benzoquinone di-imine (*o*-BQDI), since the absorption spectrum of the yellow solution (λ_{max} 352 nm, ε=1300[6]) is similar to that of the corresponding isoelectronic *o*-benzoquinone.[7] *o*-BQDI obtained in ether solution was fairly stable only when kept below 0 °C in a dilute solution, but it was unstable in a concentrated solution because of its gradual conversion into AB. This prevented us from carrying out its isolation.

Results and Discussion

The reaction of *o*-PD with CA in ether at room temperature yielded AB, DAP, and TCHQ as main products.



CA was quantitatively converted into TCHQ. This indicates that the dehydrogenation reaction of *o*-PD by CA occurs at first and the oxidized *o*-PD undergoes further reactions to yield AB and DAP.[8] The reaction course was followed by electronic absorption measurements under controlled temperature.

Spectroscopic Course of the Reaction in o-PD–CA System. After mixing an ether solution of *o*-PD (3.0×10^{-3} M) with one of CA (1.5×10^{-3} M) at −78 °C, the change of absorption spectra was measured at various temperatures. Figure 1 shows the spectral change measured below −50 °C. The 708 and 460 nm bands which appear immediately after mixing were assigned to the outer complex for the following reasons. (a) The 708 nm band is interpretated to be a charge-transfer (CT) band of the *o*-PD–CA complex from a comparison of its position with the CT band positions observed for the CA and trinitrobenzene complexes with several aromatic amines. (b) The intensities of both bands change parallel with temperature. Their intensities decrease monotonically with increasing temperature between −78 and −50 °C because of the decrease in the equilibrium constant of the outer complex.

Figure 2 shows the spectral change of the reaction system measured above −50 °C. The spectra measured at higher temperatures have new bands at 470 nm and around 360 nm[9] and show an isosbestic point at 590 nm. The bands are assigned to AB and *o*-BQDI, respectively. Figure 3 shows the time dependence of the absorption spectrum measured at room temperature ([*o*-PD]$=2.0\times10^{-3}$ M, [CA]$=1.0\times10^{-3}$ M). The intensity of the AB band at 470 nm increases slowly with time. The 430 nm band due to DAP appears about 13 hr after mixing. The 360 nm band was observed clearly only 6 hr after mixing. The increase of TCHQ band peaking at 310 nm could not be followed because of an overlap with the absorption of component molecules and reaction products.

Role of Outer Complex in the Reaction. It is of interest to see whether the outer complex takes part in the main reaction as a reaction intermediate or exists only in a side reaction. In this connection, Garbutt and Gerrard and Farrell and Ngo demonstrated by kinetic study that the outer complex directly takes part in the main reaction in the tricyanovinylation reaction of aniline and *N,N*-dimethylaniline with tetracyanoethylene.[10] We could not clarify the role of the outer complex in the present system, but it is probable that the reaction proceeds through the outer complex in view of the correspondence of the decrease of the outer complex band and the increase of AB band (Fig. 2).

o-Benzoquinone Di-imine as a Reaction Intermediate. The present result indicates that *o*-benzoquinone diimine (*o*-BQDI) can take part in the formations of AB and DAP as a reaction intermediate. For the sake of clarification, we attempted to prepare *o*-BQDI by another route and succeeded in obtaining *o*-BQDI fairly stably in an ether solution.[11] The absorption maximum of *o*-BQDI at 352 nm was found to be in good agreement with the shoulder around 360 nm appearing in the reaction of *o*-PD with CA.

o-BQDI alone produced AB, though very slowly. It was found that the addition of *o*-PD greatly accelerated the AB formation reaction. This indicates that AB is produced by the interaction between the

intermediate o-BQDI and o-PD in the reaction of o-PD with CA. The time dependence of the absorption spectrum in o-BQDI–o-PD system in ethyl ether measured at room temperature is shown in Fig. 4. This figure shows that with the decreasing intensity

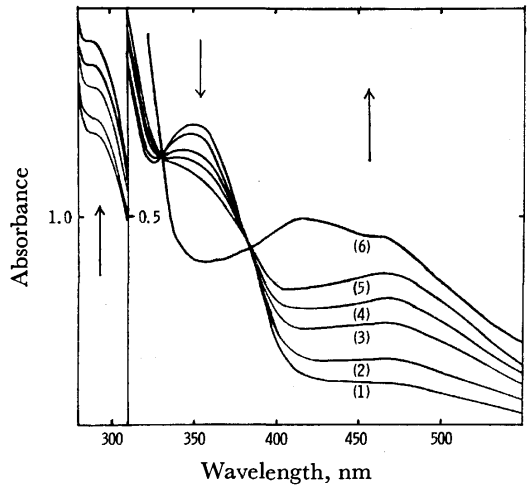

Fig. 4. Spectroscopic course of the reaction in o-BQDI–o-PD system in ethyl ether measured at room temperature. [o-BQDI]=3.8×10^{-3} M, estimated from the initial concentration of o-PD in the synthesis of o-BQDI, [o-PD]=9.5×10^{-4} M.
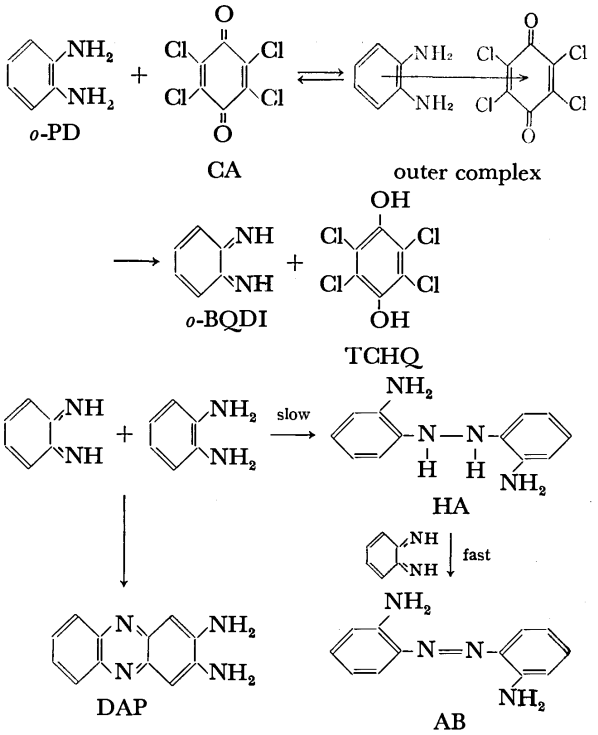
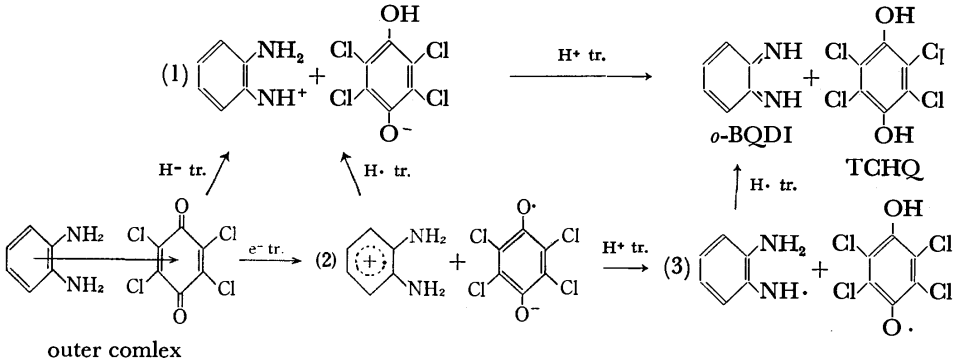
(1) 1 min, (2) 8 min, (3) 41 min, (4) 85 min, (5) 164 min, (6) 24 hr after mixing.

of the o-BQDI band at 352 nm, the intensity of AB band at 470 nm increases with the isosbestic point at 380 nm. It was found that DAP was produced when the solution of o-BQDI–o-PD system was left to stand for 24 hr. Thus, we can conclude that o-BQDI takes part in the reaction of o-PD with CA as an intermediate.

Reaction Scheme. The reaction scheme for the formation of AB, DAP, and TCHQ in the reaction of o-PD with CA might be shown as follows. The formation of AB through o,o'-diaminohydrazobenzene (HA) was suggested from its similarity with the reactions of p-benzoquinone di-imine with several aromatic amines.[12]



Details of the dehydrogenation process of o-PD by CA have not been clarified in the present study. The following two mechanisms have currently been accepted for the dehydrogenation mechanism by benzoquinone and its derivatives.[13] (1) Initial hydride ion abstraction from the donor compound D by CA to produce intermediate $D(-H)^+$ and CA semiquinone anion. (2) Initial electron transfer from D to CA to produce D cation radical and CA anion radical. In addition to these mechanisms, we considered a third one which involves semiquinone radical.[14] The possible reaction mechanisms can be described as follows:



Spectrophotometrically, we could detect no transient species in the above scheme[15] probably due to the following reasons. (1) The reaction consists of the initial rate-determining formation of these intermediate species, followed by the rapid formations of *o*-BQDI and TCHQ. (2) The absorption bands of these intermediate species are covered with those of the reaction products and component molecules. (3) These species are too unstable in the presence of air to be detected by electronic absorption spectra.

Differences of Reactivity of Isomeric Phenylenediamines toward Chloranil. A series of studies on the reactions of CA with *o*-, *m*-, and *p*-phenylenediamines in ethyl ether[1a-d] lead to the conclusion that their reaction mechanisms differ from one another, although in all cases the outer complexes are involved as intermediates. Dehydrogenation reaction occurs for the *o*-PD–CA system, substitution reaction through inner complex for the *m*-PD–CA system, and formation of stable ion-pair salts *p*-PD^+CA^- and $(p\text{-PD})_2{}^+CA^-$ for the *p*-PD–CA system. The differences in the reactions can be explained by considering the following three competitive factors, (1) the electron-donating ability of the nonbonding electron on the amino group, (2) the facility of dehydrogenation of amino hydrogen, (3) the stability of the ion-pair salts. The nonbonding electron density on the amino nitrogen is larger in *m*-PD than in *o*-PD and *p*-PD.[1c] Thus, *m*-PD forms the inner complex with CA much easier, leading to the subsequent substitution reaction. In addition to the higher electron density on the amino nitrogen of *m*-PD, its dehydrogenation is less probable since the *m*-isomeric benzoquinone di-imine structure is impossible. The dehydrogenation reaction by CA is conceivable both in *o*-PD–CA and *p*-PD–CA systems. However, because of the stability of the ion-pair salts formed between *p*-PD and CA, salts formation reactions occur preferentially in the *p*-PD–CA system. We could not obtain the ion-pair salts in *o*-PD–CA and *m*-PD–CA systems using several solvents, showing the instability of the salts. Thus, the ion-pair salt is unstable and dehydrogenation occurs relatively easily for the *o*-PD–CA systems.[13] Reactivity factors are summarized in the Table 1. It should be noted that these discussions hold when one uses ethyl ether as a solvent.

TABLE 1. FACTORS REGULATING THE REACTIVITIES OF *o*-, *m*- AND *p*-PHENYLENEDIAMINES IN ETHYL ETHER

	Nonbonding electron density on amino nitrogen	Facility of dehydrogenation	Stability of ion-pair salt
o-PD	relatively small	large[a]	unstable
m-PD	relatively large[b]	small	unstable
p-PD	relatively small	large	stable[c]

a) This leads to the dehydrogenation reaction in the *o*-PD –CA system. b) This leads to the substitution reaction in the *m*-PD –CA system. c) This leads to the ion-pair salts formation in the *p*-PD –CA system.

Porous Structure Formed by the Decomposition of the Surface Product on ZnO Preserved in the Atmosphere

Mahiko NAGAO, Kunimitsu MORISHIGE, Toshie TAKESHITA, and Tetsuo MORIMOTO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received March 29, 1974)

The slow reaction of ZnO with CO_2 and water in the atmosphere is investigated by following the changes in both the surface area of the structure formed and the amounts of CO_2 and water evolved, by heating the product *in vacuo* at increasingly elevated temperatures. The results obtained show that ZnO reacts extremely gradually with CO_2 and water cooperatively in the atmosphere to produce an amorphous surface product with a composition approximate to $Zn_5(OH)_6(CO_3)_2$, and that this product is decomposed by heating *in vacuo* to release the CO_2 and water, leaving a porous structure on the ZnO. The surface area of the product was found to change upon heating: first it increases, passes a prominent maximum value at 200 °C, recovers the original value at 500 °C, and further decreases at higher temperatures; this reflects the initial growth and subsequent destruction of the porous structure. Furthermore, it was confirmed that the destruction of such a honeycomb-like structure is promoted by the adsorption of water.

Recently, it has become clear that ZnO chemisorbs water molecules to produce surface hydroxyl groups, on which a further physisorption of water occurs, and that the adsorption isotherm of water on ZnO reveals a sudden jump around the relative pressure of 0.2—0.3.[1-4] On the other hand, the chemisorption of CO_2 occurs on the dehydroxylated surface of ZnO, but not on the surface hydroxyl groups.[5] The chemisorption force of CO_2 is weaker than that of water, so the substitutional chemisorption of water for prechemisorbed CO_2 takes place on ZnO in contact with water vapor of 4.6 mmHg at 25 °C.[6] All these results are those obtained after equilibrating the system for several hours at most.

The present investigation is intended to examine the naturally-occurring reaction of ZnO with CO_2 and water present in the atmosphere for a much longer time. Another purpose of this work is to investigate the porous structure formed by heating the product *in vacuo* through the measurement of the surface area.

Experimental

Material. The original sample of ZnO used in this study was made by the Sakai Chemical Co. by burning Zn metal in air. The sample was stored in a bottle with a usual ground-glass stopper. The bottle was opened from time to time in order to use the sample for the measurements of the surface properties. The humidity in the laboratory varied within the range from 50 to 85%, the content of CO_2 in the atmosphere, from 0.030 to 0.041%, and the room temperature, from 5 to 32 °C.

Measurement of Surface Area. The specific surface area of ZnO was determined by applying the BET method to the N_2 adsorption data at −196 °C, in which the molecular area of N_2 was assumed to be 16.2 Å^2.

Determination of the Amounts of Water and CO_2 which Reacted with the ZnO Surface. The amounts of water and CO_2 which reacted with the ZnO surface were determined by analysing the gases evolved when the product was decomposed by heating at increasingly elevated temperatures. The sample from the stock bottle was first evacuated at room temperature for 10 hr in a vacuum of 10^{-5} Torr in order to remove the physisorbed molecules; then it was heated at 100 °C for 4 hr to permit the evolution of gases, which were introduced into a trap kept at −196 °C. The total gas volume of water and CO_2 condensed was determined volumetrically after evaporating at room temperature. The gas was recondensed at −78 °C and evacuated at the same temperature, which left water in the solid state; the volume of water was determined after reevaporation at room temperature as before. By subtracting the amount of water from the total gas volume, the amount of CO_2 could be obtained. Then the sample, was subjected to the next gas-evolution at 150 °C, and the determination of the CO_2 and water present was carried out in the same way. A similar set of procedures was repeated successively after each gas evolution at increasingly elevated temperatures up to 1100 °C. Mass-spectroscopic analysis showed that the gas evolved by heating the ZnO samples contained both CO_2 and water, and that the separation of them was accomplished by the above procedure. Thus, the amounts of CO_2 and water absorbed in ZnO during preservation in the atmosphere can be obtained by the summation of the gas volumes evolved at all the stages of heat treatment.

Differential Thermal Analysis. The apparatus used for the simultaneous measurements of the weight loss (TGA) and differential thermal analysis (DTA) was of the YGHD type made by the Rigaku Electric Co. The apparatus was operated in air, and the temperature was raised at the rate of 10 °C/min.

Results and Discussion

On the ZnO samples preserved for different periods of time in the atmosphere, the surface area was measured after degassing for 4 hr; they are plotted against the degassing temperature in Fig. 1. It can be seen from Fig. 1 that the surface area of the sample changes remarkably with the degassing temperature: it remains almost unchanged up to 150 °C, increases steeply to reach a maximum value at 200 °C, and decreases to recover the original value at 500 °C. A further decrease in surface area was observed upon heating at temperatures higher than 600 °C, suggesting the occurrence of sintering. Here, it should be noted that the longer the preservation period of the sample, the larger the maximum value of the surface area observed; the highest value obtained is about 2.3 times greater than the initial value, although the initial values are almost equal to one another irrespective of the preservation period of the sample.

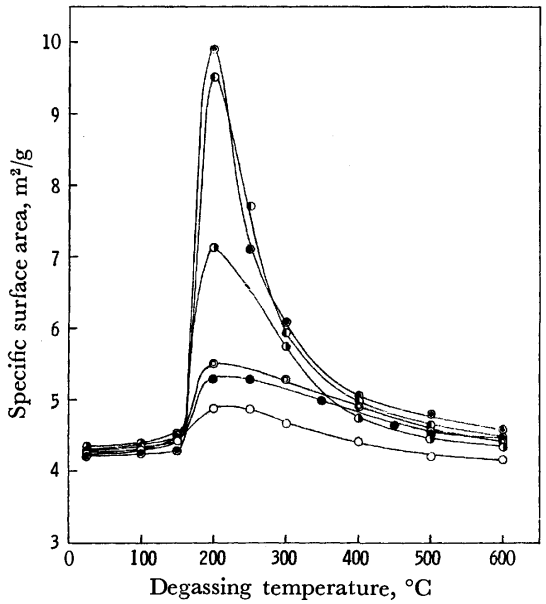

Fig. 1. Relation between specific surface area and degassing temperature on ZnO samples preserved for different periods: ○ 2, ● 30, ◎ 54, ◑ 60, ◐ 84, ◉ 90 months.

The amounts of water and CO_2 evolved are represented as functions of the heating temperature in Figs. 2 and 3 respectively, both expressed in the number of molecules expelled per 100 Å² of the initial surface of ZnO. It may be found from Figs. 2 and 3 that the evolution of CO_2 from ZnO reaches a maximum on heating at 200 °C, and is mostly finished by 300 °C, whereas the evolution of water occurs in two stages, corresponding to the two maxima at 200 and 300 °C,

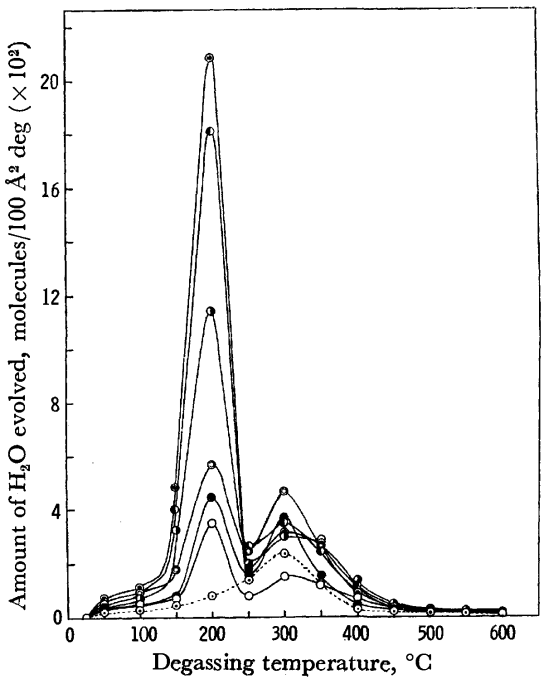

Fig. 2. Differential amount of water evolved against degassing temperature. Samples preserved for 2 (○), 30 (●), 54 (◎), 60 (◑), 84 (◐), 90 (◉) months. Dotted line means the desorption curve of chemisorbed water.

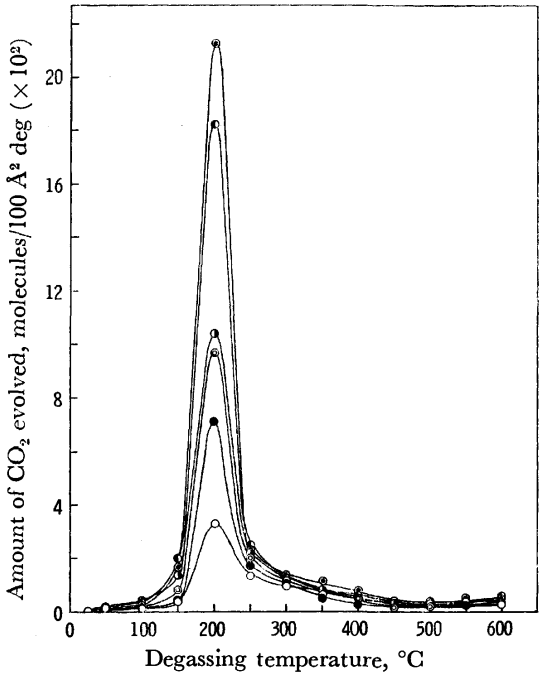

Fig. 3. Differential amount of CO_2 evolved against degassing temperature. Samples preserved for 2 (○), 30 (●), 54 (◎), 60 (◑), 84 (◐), 90 (◉) months.

and that the gas evolution increases gradually with the time of preservation.

A comparison of the results in Fig. 1 with those in Figs. 2 and 3 makes it possible to infer that the increase in the surface area of ZnO originates from the formation of pores after the evolution of gases. During the preservation of ZnO in the atmosphere, the surface layer will react with water and CO_2 cooperatively to produce a complicated compound; on subsequent heating *in vacuo*, the compound decomposes to recover the ZnO, accompanied by the evolution of water and CO_2, thus resulting in the formation of a porous structure, *i.e.*, presumably of a honeycomb-like structure, in the surface layer. The reaction of the surface layer will proceed more deeply with the time of preservation, so the depth of the honeycomb structure resulting from the decomposition will be increased. The increment of the surface area obtained can thus be considered to correspond to that of the inner wall in the honeycomb structure. The decrease in the surface area at temperatures higher than 200 °C will be due to the destruction of the honeycomb structure or the recrystallization of the wall in the structure upon heating.

TABLE 1. INTEGRATED VALUES OF CO_2 AND H_2O EVOLVED

Preservation period, month	CO_2 amount, molecules/100 Å²	H_2O amount, molecules/100 Å²	CO_2/H_2O	Number of ZnO layers
2	4.02	5.94	0.68	1.17
30	4.98	6.14	0.81	1.31
54	7.70	10.68	0.72	2.16
60	9.68	14.42	0.67	2.84
84	13.19	16.70	0.79	3.52
90	14.94	21.35	0.70	4.27

Table 1 gives the integrated values of water and CO_2 which are obtained from the data in Figs. 2 and 3. Though the numerical values of the ratio of CO_2 to water are widely dispersed, as is shown in Table 1, they approximate the 2: 3 ratio, suggesting the formation of $Zn_5(OH)_6(CO_3)_2$.[7] In order to ascertain more definitely the composition of the compound formed on the surface of ZnO in the atmosphere, an experiment was attempted: a few grams of ZnO, which had been newly prepared in our laboratory by burning metallic Zn in the atmosphere,[5] was allowed to react in a mixed gas of 760 mmHg CO_2 and 23 mmHg H_2O at room temperature. Though the reaction, when the ZnO sample was kept in a vessel containing one component of the mixed gas, did not proceed even after 3 months, all the ZnO sample was consumed in the mixed gas within 2 months to produce an amorphous product. This product was then subjected to differential thermal analysis; the results obtained are shown in Fig. 4. It may be found from Fig. 4 that the product decomposes in the temperature range from 230 to 260 °C, accompanied by heat absorption; the weight decrease amounts to 25.6%, which corresponds to the composition of $Zn_5(OH)_6(CO_3)_2$ (theoretical, 25.98%).[7]

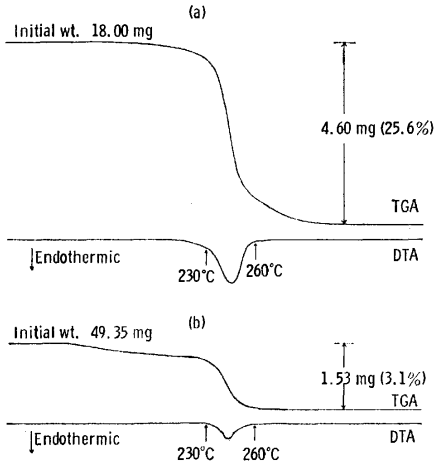

Fig. 4. DTA and TGA curves of ZnO samples. (a) completely converted sample, (b) partially modified sample in the atmosphere for 7 years.

In Fig. 4, the data on a sample preserved in the atmosphere are also added; the decomposition temperature of the sample is found to be the same as that of the completely-converted compound, which testifies that the two substances are the same, though the weight of the former is considerably smaller than that of the latter because of the smaller portion of the modified part in the former sample. These results indicate that the composition of the basic carbonate prepared from the reaction of ZnO in a gaseous atmosphere is $Zn_5(OH)_6(CO_3)_2$, though the product in this investigation was found to be amorphous by X-ray diffraction measurement.

It is interesting to consider why the second peak of water appears at 300 °C, as is shown in Fig. 2, contrary to the absence of the second peak in the case of CO_2. Undoubtedly, this peak area is included in the integration of the value of water in Table 1. In order to clarify this phenomenon, another test was made as follows. The ZnO sample, which had been treated at 450 °C *in vacuo* to remove most of the water and CO_2 absorbed, was exposed to saturated water vapor for 24 hr, degassed at room temperature for 12 hr, and then subjected to the analysis of water by means of the method described above. The results obtained are illustrated by the dotted line in Fig. 2. It shows that the position of the peak agrees well with that of the second peak of the other samples, and that the integrated value of water on this sample amounts to 8.2 OH's/100 Å^2. This indicates that the second peak of water originates from the chemisorbed water on ZnO. It may thus be reasonable to conclude that part of the water evolved by the decomposition of the complicated product is chemisorbed instantly on the ZnO surface newly developed.

Influence of Adsorbed Water on the Destruction of the Porous Structure. Figure 1 demonstrates that the porous structure formed on ZnO is destroyed by heating at temperatures higher than 200 °C. As has just been stated, part of the water evolved by the decomposition is presumably chemisorbed on the newly-formed surface. Here, it appears that the temperature at which the surface area sharply decreases, as is shown in Fig. 1, coincides with that corresponding to the second peak in Fig. 2; this suggests that the decrease in surface area is largely influenced by the adsorption of water. Figure 5 shows the data concerning the influence of adsorbed water upon the change in surface area. In this experiment, part of the 5-year sample was evacuated for 4 hr at 200 or 300 °C, subjected to the measurement of the surface area (Point 1 in Fig. 5), allowed to adsorb water at 25 °C in a vapor of 23 mmHg for 12 hr, and degassed at the same temperature for 4 hr in a vacuum of 10^{-5} Torr to remove the physisorbed water; then the second measurement of the surface area was carried out (Point 2). After the subsequent exposure of the sample to water vapor in the same way as before,

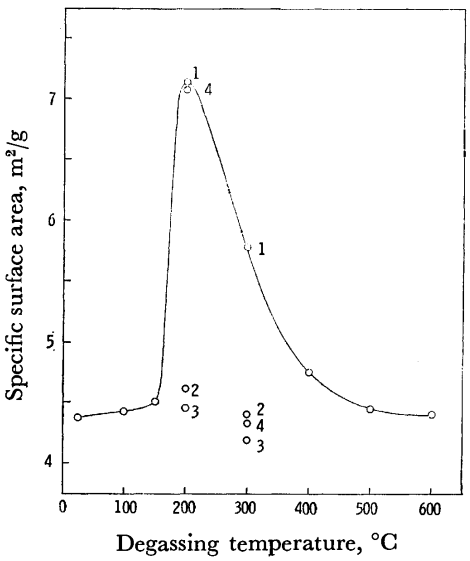

Fig. 5. Influence of adsorbed water upon the change in surface area of ZnO sample preserved for 5 years.

the third value of the surface area was obtained (Point 3). The final measurement of surface area was performed after the reevacuation of the sample at 200 or 300 °C for 4 hr (Point 4). In this series of measurements, the adsorption isotherms of N_2 were found to have no hysteresis, thus indicating the absence of pores with radii larger than about 15 Å.[8]

Figure 5 shows that the surface area of the 200 °C-treated sample drops after the chemisorption of water, but it recovers its original value after the subsequent desorption of the chemisorbed water. On the contrary, in the case of the 300 °C-treated sample, the surface area does not return to the original value even after the evacuation at 300 °C. Furthermore, it should be pointed out that, in both cases, the surface area of the samples covered with chemisorbed water is almost the same as that of the undecomposed sample. The nature of such an apparently similar result, however, is probably different depending on the treatment of the sample. The result obtained for the 200 °C-treated sample suggests that the pore radius in the honeycomb structure is so small as to lock out the adsorption of N_2 after the chemisorption of water on the inner surface of the structure. On the other hand, the walls of the honeycomb structure of the 300 °C-treated sample may be so delicate that they are ruptured and incorporated into the substrate crystals as a result of the adsorption of water, though they cannot be destroyed by the adsorption of N_2. This postulation seems feasible, since water has a large influence on the sintering of metal oxides.[9] However, it is not clear whether the destruction of the honeycomb structure occurs in the stage of water adsorption or in that of the subsequent heating to 300 °C. The reversibility of the surface area of the 200 °C-treated sample may reasonably be thought to be caused by the reinforcement of the pore wall due to the incomplete decomposition of the product.

In conclusion, we can roughly estimate the thickness of the surface layer of ZnO which reacted in the atmosphere. Assuming that, on the actual surface of ZnO, the (0001) and (10$\bar{1}$0) planes, both excellent in cleavage, appear in equal amounts, the average number of Zn atoms on the ZnO surfaces can be calculated to be 8.5/100 Å^2.[2] Since each molecule of water or CO_2 will react with each atomic pair of Zn and O on the crystal surface, as is expressed in the formula stated above, an average of 3.5 layers of Zn atoms on the ZnO crystal changes during a preservation of about 7 years. Thus, if half the atomic pairs of Zn and O in the surface layer is pulled out to form small pores, the depth of the pores will correspond to about 7 layers of the crystal planes.

Resonace Raman Spectra of Acid-Base Indicators. II. Hydroxyarylazobenzene Derivatives

Yutaka SAITO, Bak-Kwang KIM, Katsunosuke MACHIDA, and Toyozo UNO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received April 13, 1974)

The effects of pH on resonance Raman spectra of several hydroxyarylazobenzene-type acid-base indicators have been investigated. All the compounds examined show the azo-type spectra in basic solutions, while the neutral solution spectra are the azo-type for *p*-hydroxyphenyl compounds and the quinoid-type for α- and β-hydroxynaphthyl compounds. The spectrum of Tropaeoline O changes complicatedly along with the protonation and deprotonation on the pH change.

The acid-base indicators containing azo group can be classified into two categories, the amino and the hydroxy derivatives. Recently, we have investigated the resonance Raman spectra of some important amino-azo-type acid-base indicators, and have shown that the spectral pattern reflects clearly the structure change accompanying the color change.[1] When the neutral solution of an aminoazo-type indicator is acidified to pH below the color change interval, the azo-type base form is protonated at the azo group and is transformed into the quinoid-type acid form. This transformation gives rise to the replacement of azo bands by quinoid bands in resonance Raman spectra along with the red shift of λ_{max} in visible absorption spectra. On the contrary, the color change of hydroxyazo-type acid-base indicators occurs mostly in the basic pH region, in such a way that λ_{max} shifts to red on addition of alkali to the neutral solution. The tautomerism between the azo and the quinoid forms is conceivable for the acid form. Extensive studies on visible and ultraviolet spectra of hydroxyarylazo compounds have shown that the tautomeric ratio varies widely depending on the nature of aromatic rings and substituents.[2-7] Accordingly, the color change of hydroxyazo-type indicators cannot be elucidated from such a simple correlation between λ_{max} and the structure as seen for amino-azo-type indicators for which the reddish color in acidic solutions is due to the quinoid form.[1] In this respect, it is of importance to clarify how the molecular vibrations of hydroxyazo derivatives are affected by the structure change underlying the color change.

In this paper, we report the resonance Raman spectra of several representative hydroxyphenyl- and hydroxynaphthylazobenzene derivatives, and discuss the structures of these compounds at various pH by referring to spectra of related compounds and deuteration effects.

Experimental

The hydroxyarylazobenzene derivatives taken up in this work were obtained from commercial sources, and were recrystallized several times from water or ethanol. In Table 1, the λ_{max} in the visible and ultraviolet absorption spectra and the color change intervals of these compounds are listed together with the abbreviations to be used in the text. The Raman spectra between 1800 and 1000 cm^{-1} were recorded on a JEOL S-1 laser Raman spectrophotometer by using the 488 nm excitation line of a coherent Ar^+ laser.

Each sample was sealed in a 1 mm capillary tube. The pH of aqueous solutions was adjusted by using 1 M HCl, 1 M NaOH and the phosphate and borate buffers. For the deuteration of active hydrogen atoms, the stock solutions of 1 M DCl and 1 M NaOD in heavy water were prepared and used as described in the previous paper.[1] Reagent grade ethanol and *n*-hexane were used as the solvents for SuI. The concentration dependence of Raman intensities was roughly surveyed for each compound, and the optimum concentration was found to fall between 10^{-2} and 10^{-4} M. The decomposition of samples due to the irradiation of the excitation beam was not detected except for the cases of AY in the neutral solution and SuI in 50% ethanol. The absorption spectra between 330 and 600 nm were recorded on a Shimadzu W-40 spectrophotometer.

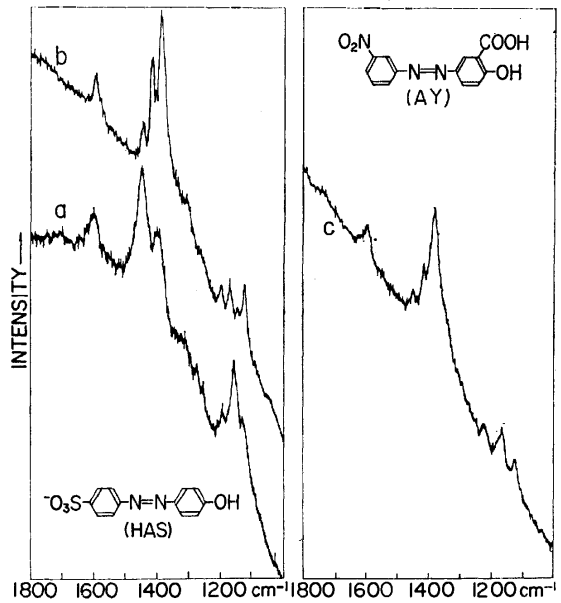

Fig. 1. Resonance Raman spectra of HAS and AY: (a) 1×10^{-2} M HAS in H_2O, slit width 27 cm^{-1}; (b) 1×10^{-3} M HAS in 0.5 M NaOH, slit width 14 cm^{-1}; (c) 1×10^{-3} M AY in 0.5 M NaOH, slit width 14 cm^{-1}.

of HAS and AY in 0.5 M NaOH are shown in Fig. 1. In all these spectra, several bands appear commonly in the region between 1600 and 1000 cm^{-1}, the strongest being near 1400 cm^{-1}. This spectral pattern is similar to those of *p*-phenylazophenol in methanol[8] and methyl-orange in water.[1,9] The strong band at 1445 cm^{-1} in Fig. 1a arises clearly from the stretching vibration of the *trans* N=N group, indicating that the monovalent anion of HAS exists dominantly as the azo form. This result is in agreement with the previous conclusions based on visible and ultraviolet spectra.[3,4] The assignment of the remaining bands was easily made as

Table 2. Observed frequencies and assignments for HAS and AY

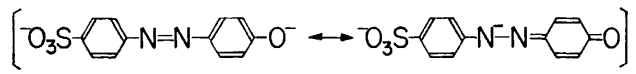
shown in Table 2 from analogy with the base form of methyl orange and related compounds.[1] The good correspondence of weak bands between HAS and AY in basic solutions shows that vibrations of the $-SO_3^-$, $-NO_2$, and $-CO_2^-$ groups do not participate in the resonance Raman effects of the hydroxyazo compounds treated in this work. The shift of the N=N stretching frequency from 1445 to 1386 cm^{-1} on going from the acid form to the base form of HAS indicates that the N=N bond order decreases on the deprotonation of the phenolic OH group. Accordingly, the divalent HAS anion can be described as a resonance hybrid



in which the contribution of the azo structure is predominant but that of the quinoid structure is not negligible. The red shift in the visible absorption on the deprotonation of azophenol derivatives may be related to this contribution of the quinoid structure.

Resonance Raman spectra of 1×10^{-3} M OrI and OrII: (a) OrI in H_2O, slit width 14 cm^{-1}; (a') OrI in D_2O, slit width, 14 cm^{-1}; (b) OrI in 0.5 M NaOH, slit width 27 cm^{-1}; (c) OrII in H_2O, slit width 14 cm^{-1}; (c') OrII in D_2O, slit width 14 cm^{-1}; (d) OrII in 0.5 M NaOH, slit width 27 cm^{-1}.

Hydroxynaphthylazo Derivatives. Figure 2 shows the resonance Raman spectra of hydroxynaphthylazobenzenesulfonic acids in neutral and basic solutions. In contrast to the case of HAS, the spectra of these naphthylazo derivatives undergo significant changes on the increase of pH from the neutral region to the basic region above the color change interval. In the resonance Raman spectrum of OrI in the neutral solution, there is no strong band around 1400 cm^{-1} assignable to the N=N stretching vibration. Instead, this spectrum shows medium to strong bands at 1629, 1508, and 1292 cm^{-1} in analogy with the previously reported spectra of *p*-aminoazobenzene derivatives in acidic solutions.[1] By referring to the latter case and also to the infrared spectra in the solid state,[10,11] most of the resonance Raman bands presently observed for OrI are assigned reasonably to vibrations of the quinoid form as shown in Table 3. Although OrI has a naphthalene ring in place of the benzene ring of *p*-aminoazobenzene derivatives, the spectral change on deuteration between 1400 and 1000 cm^{-1} of the former is quite analogous to that observed for the latter.[1] This result indicates that only the bands related to the structure C=N–NH–C are deuteration sensitive in both cases.

a) Contributed also by the C=C stretching vibration.

The absence of the resonance Raman bands due to the azo form of OrI in the neutral solution seems at first sight to indicate that OrI exists exclusively as the quinoid form. There have been evidences from visible and ultraviolet spectra, however, for the existence of the azo form as the minor component in solutions of various 4-phenylazo-1-naphthol derivatives in polar solvents.[5)] The present result does not conflict with the visible and ultraviolet data since the quinoid form showing the λ_{max} near 480 nm should be much more sensitive to the resonance Raman effect by the 488 nm excitation than the azo form showing the λ_{max} near 420 nm.

The resonance Raman spectrum of OrII in the neutral solution resembles that of OrI in positions and relative intensities of several bands (see Table 3), suggesting that OrII takes the quinoid form predominantly in the neutral solution. OrII shows, however, a number of medium to weak bands which are not observed for OrI. The presence of these bands may be taken to reflect the structural difference between the *o*-quinoid and the *p*-quinoid rings, but it is also possible to attribute these bands of OrII, especially the medium band at 1390 cm^{-1}, to the azo form which may exist as the minor component. In order to clarify this point, we have recorded the resonance Raman spectra of SuI, for which the solvent effect on the visible and ultraviolet spectra has been studied in detail to discuss the tautomeric equilibrium between the azo and the quinoid forms.[5)] The result seems to support the assignment of the 1390 cm^{-1} band to the *o*-quinoid structure. If this band is due to the azo form, an appreciable increase of its relative intensity should occur on the change of solvent from ethanol to *n*-hexane, since the azo form is the major component in *n*-hexane but is not in ethanol according to the visible and ultraviolet spectra.[5)] As shown in Fig. 3, however, we observed no appreciable difference in the relative intensity of the 1396 cm^{-1} band between the ethanol and the *n*-hexane solutions of SuI.

In basic solutions, the hydroxynaphthyl derivatives show the same pattern of resonance Raman spectra as HAS, giving rise to the strong N=N stretching band around 1380 cm^{-1}; see Table 4. Accordingly, the base form of hydroxynaphthyl derivatives is the divalent anion existing as the resonance hybrid in which the contribution of the azo structure is predominant. The difference between OrI and OrII in the spectra of basic solutions is far less conspicuous than that in case of neutral solutions. This result reflects well the selective enhancement of the band intensities for vibrations of the chromophore group in the resonance Raman effect. It is expected that the vibrations of the C–N=N–C group are not practically affected by the position of the substituent on the aromatic ring, whereas the structure difference between the *o*-quinoid and the *p*-quinoid rings should give rise to appreciable differences in vibrational modes and frequencies.

change of the solution from 1 M NaOH to 1 M HCl (see footnote,[c] Table 1). The resonance Raman spectra corresponding to these steps are different from one another as shown in Fig. 4. These spectral changes are thought to represent the stepwise protonation of TrO taking place according to Chart 1. The band assignments for the four spectra of TrO are summarized in Table 5. When dissolved in 1 M NaOH, TrO exists as the completely deprotonated trivalent anion and shows an azo-type resonance Raman spectrum in which the strongest band is observed at 1341 cm^{-1}. In analogy with the case of so far discussed monohydroxy compounds, the trivalent anion of TrO can be described as a resonance hybrid contributed mainly by the azo structure. The pattern of the resonance Raman spectrum of TrO in the pH 9.2 buffer solution is different from any of those already mentioned. This spectrum involves a number of bands attributable to the quinoid form of the divalent anion, *e.g.*, the strong

band at 1500 cm^{-1} and the weak band at 1278 cm^{-1}, of which the latter disappears on deuteration. The appearance of a very strong band at 1387 cm^{-1} in this spectrum suggests also that the azo form exists in an appreciable amount at pH 9. The resonance Raman spectrum of TrO in the pH 4 buffer solution is similar to those of the hydroxynaphthyl derivatives in neutral solutions, and is therefore due clearly to the quinoid form. It is not probable, however, that the monovalent anion of TrO takes the quinoid form exclusively in the pH 4 buffer solution, since the λ_{max} at pH 4 lies near 380 nm, where many azobenzene derivatives in the azo form show an absorption band.[2,3] The weakness of all the Raman bands in this spectrum indicates that the quinoid form is the less dominant tautomer at pH 4. In the solution in 1 M HCl, TrO shows strong resonance Raman bands at 1628, 1500, and 1290 cm^{-1} all attributable to the quinoid structure. On deuteration, the first two bands remain unchanged while the last disappears completely just as in case of the acid form of *p*-aminoazobenzene derivatives.[1] TrO in 1 M HCl is therefore described best as the zwitterionic resonance hybrid contributed mainly by the quinoid structure.

We wish to thank Professor Hisashi Tanaka for the use of the W-40 spectrophotometer in his laboratory, and Miss Kyoko Igarashi for her technical assistance.

Interaction between Electron Donor and Acceptor: MINDO/2 Calculations on the Ammonia-I_2, Benzene-I_2 and Benzene-TCNE Systems

Toshiaki OHTA, Takashi FUJIKAWA, and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received April 17, 1974)

The MINDO/2 method was applied to typical molecular complexes such as ammonia-I_2, benzene-I_2, and benzene-TCNE, these bimolecular systems being treated as single molecules. The intermolecular interaction energy was calculated as a function of intermolecular distance. Stable complex formation with a reasonable stabilization energy was predicted in the ammonia-I_2 system. It was predicted in the benzene-I_2 system for the axial model, but not for the resting model. However, the stabilization energy for the former was found to be too large. No stable conformation was found in the case of the benzene-TCNE system.

The concept of charge-transfer interaction between donor and acceptor in a molecular complex has been well established, but several problems concerning molecular complexes remain unclarified. The charge-transfer force has been considered to be of primary importance in stabilizing molecular complexes, and the conformations of complexes have often been discussed on the basis of the charge-transfer theory. However, several authors have pointed out the possibility that Coulomb and polarization forces play an important role in the complex formation.[1-4]

The intermolecular interaction has been treated most frequently by means of perturbation theory. However, in order to give quantitative prediction, an approach based on the molecular orbital method seems to have several advantages for carrying out numerical calculations. On the π-π complexes which involve polycyclic aromatic hydrocarbons as donor and tetracyanoethylene (TCNE) as acceptor, we have shown that their electronic spectra can be predicted by semi-empirical SCF-MO-CI calculations within the framework of the π-electron approximation by treating the bimolecular system as a single molecule.[5] However, in order to discuss the stabilization energy of a complex, this method seems inadequate since the contribution of σ- and/or n-electrons might not be negligible even in a typical π-π complex.

Wold[6] carried out an extended Hückel calculation on the benzene-TCNE complex, but failed to find any stable conformation. In the CNDO/2 calculation of the same complex, Chesnut and Wormer[7] predicted an extraordinarily deep potential minimum at an unreasonably short intermolecular distance.

As compared with the CNDO/2 method, the MINDO/2 method proposed by Bodor *et al.*[8] often gives better predictions as regards the heat of formations and ionization energies, at least, for relatively small organic molecules. The present paper reports on the results of MINDO/2 calculations of the ammonia-I_2, benzene-I_2, and benzene-TCNE systems. The purpose of this study is to elucidate the applicability and limitation of this type of calculation for studying the interaction between donor and acceptor molecules.

Method of Calculation

The MINDO/2 calculation was performed on a bimolecular system by the treatment as a single molecule. All empirical parameters except those related to the iodine atom were taken as proposed by Dewar and his collaborators.[8,9] For the iodine atom, we took only the 5s and 5p orbitals into account and determined the empirical parameters. For the CNDO/2 calculation, Whitehead[10] gave the core energies of 5s and 5p orbitals, U_{ss} and U_{pp}, and the one center Coulomb integral, F^0 for the iodine atom. We adopted these values with a slight modification. The one center exchange integral and electron repulsion integral can be expressed in terms of the Slater-Condon parameters, F^2 and G^1. The values of the Slater-Condon parameters have been given by Pople *et al.*[11] for the fluorine atom, but not for the iodine atom. The empirical values of F^2 and G^1 are usually estimated by means of spectroscopic data, but no such data were available for iodine. We therefore determined the empirical values of F^2 and G^1 of iodine in the following manner. F^2 and G^1 were first calculated non-empirically for the iodine and fluorine atoms by use of the Slater orbitals with the orbital exponents 1.90 and 2.60 for iodine and fluorine, respectively. The empirical values for iodine were then estimated so that their ratios to the non-empirical values are the same as the corresponding ratios in the fluorine atom. The ionization energy of the iodine 5s orbital was estimated by means of the equation given by Dewar *et al.*,[9] while the observed first ionization energy of the iodine atom was taken to be the 5p ionization energy. The iodine parameters thus obtained are listed in Table 1.

Table 1. Atomic parameters of iodine

U_{ss}	−76.905(eV),	U_{pp}	−67.202(eV)
F^0	9.448(eV),	F^2	4.077(eV)
G^1	6.526(eV),		
I_s	−26.743(eV),	I_p	−10.454(eV)
neutral atom energy			−305.010(eV)
ΔH_f for free atom			33.412(kcal)
Slater exponent			1.90

In MINDO/2 calculations, the following relation is assumed for the resonance integral:

$$\beta_{ij} = B_{ij} \times (I_i + I_j) \times S_{ij}, \quad (1)$$

where I_i and I_j are the ionization energies of the orbitals concerned, S_{ij} is the overlap integral, and B_{ij} is an empirical parameter. Ohno's approximation[12] is used

for the electron repulsion integral γ_{mn}, and the core-core repulsion integral CR_{mn} is estimated by means of the following equation,

$$CR_{mn} = \gamma_{mn} + (Z_m Z_n e^2/r_{mn} - \gamma_{mn})e^{-\alpha r_{mn}}, \quad (2)$$

where Z_m and Z_n are the core charges, r_{mn} is the distance between atoms m and n, and α is an empirical parameter.[13] Parameters B_{ij} and α are both characteristic of the kinds of atoms concerned. Their values had to be estimated for cases which involve iodine. We determined them by using I_2, HI, CH_3I, and ICN as the reference molecules so that the calculated heat of formations, equilibrium bond lengths and dipole moments of these molecules are in good agreement with the experimental values. The values of B_{ij} and α thus determined are listed in Table 2.

Table 2. Parameters α and B_{ij} for iodine

	I-H	I-C	I-N	I-I
α	0.78	1.403	1.22	0.40
B	0.60	0.52	0.58	0.88

The calculations were carried out for the bimolecular systems and for each constituent molecule. The intermolecular interaction energy ΔE was estimated by taking the difference between the total energy of the bimolecular system and the sum of the total energies of the isolated molecules.

The calculations were performed with a HITAC 5020E computer at the Computer Centre, the University of Tokyo, with our program.

Results and Discussion

Ammonia–I_2 Complex (n-σ type). As a typical example of n-σ complexes, we examined in detail the ammonia-I_2 system. We assumed a model (Fig. 1) in which the iodine molecule lies on the three-fold axis of the ammonia molecule, taking only the I–I distance, l, and N···I distance, z, as the variables specifying the conformation of the system. The bond distances and bond angles within the NH_3 moiety were fixed to be the same as those in the free ammonia molecule.[14]

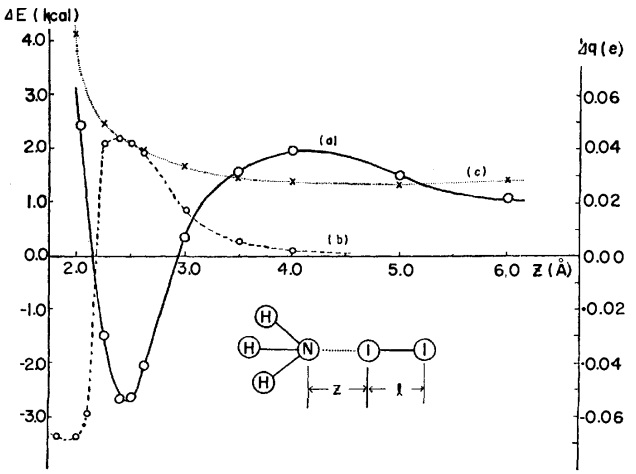

Fig. 1. Intermolecular interaction energy ΔE (a), net amount of charge transfer from NH_3 to I_2 Δq (b), and the decrease of the charge at N atom of ammonia, $-\Delta q_N$, (c) of the ammonia-iodine system as a function of the intermolecular separation, z(Å).

Although the actual structure of the ammonia–I_2 complex is not known, it should resemble the structure of the triethylamine–I_2 complex, where the I-I and N···I distances have been determined to be 2.83 and 2.27 Å respectively, from crystal structure data.[15] Thus we first carried out calculations for various z values assuming that l=2.8 Å. The results are shown in Fig. 1. On decreasing z from infinite, ΔE gradually increases and reaches a very broad maximum around 4 Å, and shows a well-defined minimum at z=2.5 Å with ΔE=−2.75 kcal/mol. Although the general shape of this energy curve is reasonable, the appearance of the repulsive region at $z>3$ Å is unexpected. A similar phenomenon appears also in other complexes. This seems to be a problem inherent to the present method of calculation.

Figure 1 also shows the net amount of charge transfer Δq, from ammonia to the iodine molecule, together with the decrease of the charge at N atom, $-\Delta q_N$, caused by the intermolecular interaction. While $-\Delta q_N$ is always positive and increases with decreasing N···I distance, the net amount of charge transfer shows a maximum at the distance corresponding to the minimum of the ΔE curve, and becomes negative in the region $z<2.2$ Å. This means that, at a short intermolecular distance, electron is transferred from iodine to ammonia, which results in the increase of the electron density at H atoms.

We next looked for the ΔE minimum by varying both l and z values. A minimum was found at z= 2.45 Å and l=2.67 Å, where ΔE was −7.5 kcal/mol. This seems to correspond to the stable conformation of the ammonia–I_2 complex. Figure 2 shows the dependence of ΔE and Δq on the I-I distance, for z= 2.45 Å. Since the lowest vacant orbital of the iodine molecule is an anitibonding σ-orbital, we can expect the I–I distance to increase with the amount of charge transfer. The relation between Δq and l shown in Fig. 2 is consistent with this expectation. The I–I distance in the free iodine molecule is 2.667 Å, while it is 2.83 Å in the triethylamin-I_2 complex, indicating

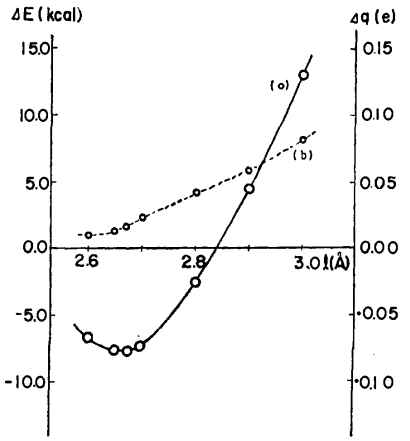

Fig. 2. Intermolecular interaction energy ΔE (a), and net amount of charge transfer Δq (b) of ammonia-iodine system as a function of the bond length of the iodine molecule, l(Å).

a relatively large charge transfer. As compared with the observed I–I distance in the triethylamine-I_2 complex, the l value 2.67 Å at the predicted ΔE minimum seems to be a little too small.

The heat of formation, dipole moment and other properties calculated for the predicted conformation of the ammonia-I_2 complex are summarized in Table 3 together with the corresponding experimental values. The calculated dipole moment is in reasonable agreement with the observed one. However, the amount of charge transfer, 1.8×10^{-2} electron, is quite small as compared with the ionic character of the complex estimated from the dipole moment by the conventional procedure without giving any allowance for the polarization effect.[16]

Table 3. Comparison of the calculated and experimental values of NH_3-I_2 complex

	Calcd	Exptl
μ(Debye)	4.5	6.1∼6.7[a]
$-\Delta E$(kcal/mol)	7.5	4.84[b]
Δq(e)	0.018	
z(Å)	2.45	
l(Å)	2.67	

a) Ref. 16. b) Ref. 25.

The calculated charge density for the stable conformation of the complex as well as for the ammonia molecule is shown in Fig. 3. As compared with the results of the calculation on the free molecule, the electron density in the complex is smaller by 0.039 at N atom, but larger by 0.007 at each H atom. A significant change is found in the I_2 part, where the density at the I atom directly contacting the N atom of ammonia decreases by 0.115, on the other hand, the density at the other I atom increases by 0.132. This means that a considerably large dipole moment has been induced in the I_2 molecule, making a significant contribution to the dipole moment of the complex.

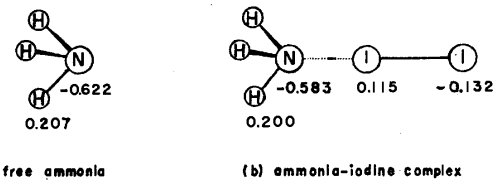

Fig. 3. Net charges of free ammonia (a) and the ammonia–iodine complex at the most stable configuration (b).

Several authors have recently pointed out the importance of the induced polarization in the observed dipole moments of molecular complexes.[1-3,17] The results of our calculation support the view.

Since the amount of charge transfer was calculated to be quite small, it seems of interest to examine the contribution of charge transfer in the stabilization energy of the complex. We estimated the contributions of different types of interaction by means of the approximations described in the Appendix, and found that the attraction energy due to the charge-transfer force is of primary importance for stabilizing the complex. The orbital energies of the molecular orbitals of the ammonia and iodine molecules are given in Table 4, and the contributions of different charge-transfer configurations to the intermolecular attraction energy in Table 5. The charge transfer from the highest occupied orbital of ammonia to the lowest vacant orbital of iodine makes the largest contribution, but there is an almost comparable contribution of a charge transfer from a deeper occupied orbital of ammonia. It should be noted that the contributions of back charge transfer are also quite significant.

Table 4. Energies of molecular orbitals

orbital	energy(eV)	orbital	energy(eV)
NH_3		C_6H_6[a]	
2e	4.91	$5e_2$	4.08
$3a_1$	3.21	$4e_1$	2.88
		4b(π)	2.66

			$2a(\pi)$→	2e	0.010
			$2s(\pi)$ →	2e	0.006

a) Only the important components are listed in this table.

From the results of energy analysis described above, we can conclude that the prime effect in the ammonia–I_2 complex, *viz.*, stabilization of the system, is the charge-transfer force, but the net amount of charge transfer is small because of the significant contribution of the charge transfer from occupied orbitals of iodine to vacant orbitals of ammonia.

Benzene-I_2 Complex (π-σ type). For the benzene-I_2 complex, Mulliken[18] first proposed the resting model where the iodine molecule lies parallel to the benzene molecule. The model was considered doubtful from the analysis of infrared spectrum of the complex, which seemed to support the axial or oblique model.[19] How-

ever, it was realized later that the infrared spectrum does not provide any definite conclusion as regards the conformation of the benzene-I_2 complex.[20-22] In the crystals of the benzene-halogen complexes, the halogen molecules are oriented perpendicular to the molecular plane of benzene,[23] but the conformation of an isolated complex is not necessarily the same as the one found in the crystal of the molecular complex. Thus the actual conformation of the benzene-I_2 complex still remains unclarified.

We examined two models, axial and resting, in the present calculation (Fig. 4). Assuming the geometries of the benzene and iodine molecules to be the same as those of the free molecules, we varied the intermolecular distance z which is defined in Fig. 4.

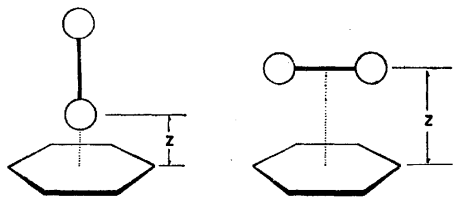

Fig. 4. Two models for the benzene–iodine complex: (a) axial model, (b) resting model.

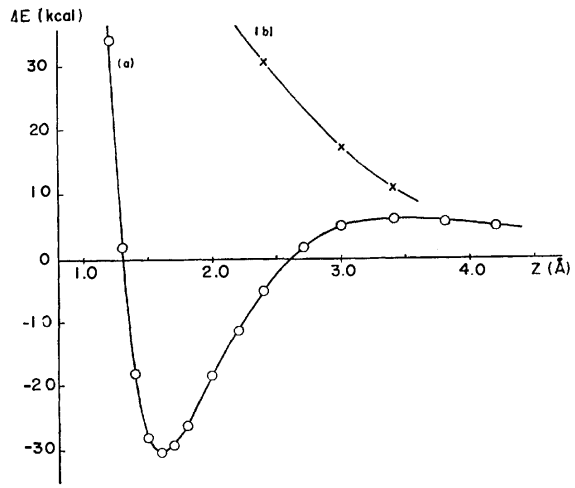

Fig. 5. Intermolecular interaction energy ΔE of the benzene-iodine system as a function of the intermolecular separation, z(Å).

The calculated ΔE is plotted against z in Fig. 5. The results indicate that the axial model is more stable than the resting model. It is also to be noted that a well-defined energy minimum is predicted in the former but not in the latter. The axial model is plausible for the benzene-I_2 complex. Quantitatively, however, our results confront serious problems. The z value at the energy minimum, 1.7 Å, is unreasonably short for the intermolecular separation between benzene and iodine, and the stabilization energy of the complex is predicted to be too large. The net amount of charge transfer from benzene to iodine is calculated to be -3.21×10^{-1} electron for the conformation corresponding to the energy minimum. This means that a considerable amount of charge is transferred from iodine to benzene and not from benzene to iodine, which is unreasonable. Thus it is hard to take the conformation at the ΔE minimum as the real structure of the benzene-I_2 complex.

The z-value dependence of the amount of charge transfer and dipole moment of the system is shown in Fig. 6. Δq is positive in the region $z>2.1$ Å, which first increases on decreasing z, reaches a maximum value, 3.72×10^{-2} electron, at $z=2.5$ Å, then steeply decreases to change its sign. The actual value of z for the axial model would be about 3.4 Å. Although the intermolecular interaction at this value is predicted to be repulsive, it seems worthwhile to examine the properties predicted for the conformation. The calculated dipole moment is 0.34 Debye, which is approximately one fifth of the observed value.[24] Even so, the ionic character of the complex corresponding to this calculated value of the dipole moment will be estimated as about 1.5%, if this dipole moment is attributed entirely to the charge transfer, but the amount of charge transfer actually obtained from the predicted electron densities is only 5.77×10^{-3} electron. The electron density is 6.994 at the iodine atom which is in direct contact with benzene, and 7.009 at the other iodine atom. This implies that a considerable polarization has been induced in the iodine molecule, which is of primary importance in the predicted dipole moment. The situation is more or less similar for other intermolecular distances.

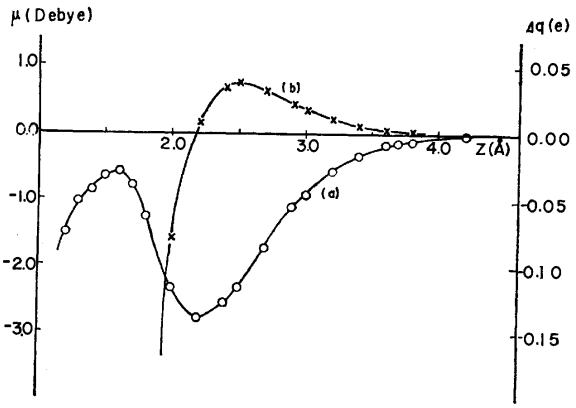

Fig. 6. Dipole moment μ (a) and net amount of charge transfer Δq from benzene to iodine (b) of the benzene-iodine complex as a function of z(Å).

The orbital energies of benzene and iodine are listed in Table 4. We estimated the contributions of various charge transfers for ΔE in the case of the conformation with $z=3.4$ Å. The results are shown in Table 6. One can see that the charge transfer from a lower π-orbital, $3a(\pi)$, of benzene to the lowest vacant orbital, $3a$, of iodine is of primary importance.

Benzene-TCNE Complex (π-π type). As an example of π-π complex we chosed the benzene-TCNE system. We assumed that the molecular planes of benzene and TCNE are parallel to each other, the center of the TCNE molecule being on the six-fold axis of benzene. The calculated interaction energy ΔE is plotted against the intermolecular distance z in Fig. 7.

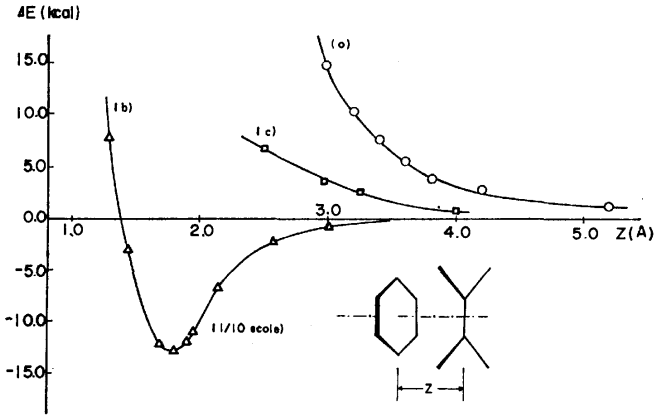

Fig. 7. Intermolecular interaction energy ΔE of the benzene–TCNE system from various methods. (a) MINDO/2 method in this work, (b) CNDO/2 method from Ref. 7, (c) extended Hückel method from Ref. 6.

The interaction between benzene and TCNE was predicted to be always repulsive. This result is quite different from that of the CNDO/2 calculation by Chesnut and Wormer,[7] and resembles the result of the extended Hückel calculation by Wold.[6]

We performed calculations on some other π-π complexes, but again failed to predict any stable conformation. Seemingly, the MINDO/2 calculation cannot give satisfactory results for a system consisting of weakly interacting π-donor and π-acceptor.

Conclusion

In the present study, we carried out MINDO/2 calculations on bimolecular systems composed of an electron donor and an electron acceptor. The calculation gave satisfactory results in the case of the ammonia–I_2 system, and succeeded in predicting the formation of a stable ammonia–I_2 complex. The dipole moment and other properties calculated for the predicted conformation of the complex were in reasonable agreement with the experimental results. The calculation was less successful for the benzene–I_2 system, where an unreasonably small intermolecular distance was predicted as the most stable conformation of the system. In the case of the benzene-TCNE system, the calculation completely failed to predict the formation of a stable complex.

Parametrization of MINDO/2 has been carried out for application on relatively small molecules. It gives good prediction as regards the heat of formation and ionization energy of various organic molecules, but it is not always suitable for calculations on a bimolecular system.

In MINDO/2 as well as in CNDO/2, the Slater atomic orbitals are used as the basis set with the Slater-Zener orbital exponents. This may be sufficient in calculations of small molecules, but not in those of bimolecular systems where the integrals between atoms with relatively large interatomic distance have significant contributions. This situation might not be so important for the ammonia–I_2 system, but seems to be of prime importance for the benzene-TCNE system.

While the MINDO/2 calculation fails to predict the stabilization of the benzene–TCNE complex, the CNDO/2 calculation gives an unreasonably large stabilization energy for the same complex. When we compare the two methods, the resonance integrals between the 2p orbitals of two carbon atoms are estimated to be more than twice as large in the CNDO/2 method as in the MINDO/2 method. As is known, the resonance integral between atoms with a large interatomic distance is usually markedly underestimated when the Slater AO's are used as the basis set. This can be improved by the use of the SCF–AO's. A possible way for the improvement of calculations on bimolecular systems, is to perform parametrization by use of the SCF–AO's as the basis set.

Appendix

In a molecular orbital approach on a bimolecular system, the physical nature of the intermolecular interaction cannot be understood straightfowardly. We will show an approximate way to separate the contributions of different types of interaction.

Let us express the Fock matrix of a bimolecular system composed of molecules A and B as follows.

$$\mathbf{F} = \begin{vmatrix} \mathbf{A}+\mathbf{A}' & \mathbf{C} \\ {}^t\mathbf{C} & \mathbf{B}+\mathbf{B}' \end{vmatrix} \tag{1}$$

where $\mathbf{A}$ and $\mathbf{B}$ are the SCF Fock matrices of the isolated molecules, $\mathbf{A}'$ and $\mathbf{B}'$ the perturbation matrices, $\mathbf{C}$ is the interaction matrix and ${}^t\mathbf{C}$ the transposed matrix of $\mathbf{C}$. The molecular orbital approach on the bimolecular system is to solve

$$\mathbf{FX} = \varepsilon\mathbf{X} \tag{2}$$

Any eigenvector $\mathbf{X}$ can be expressed in terms of the eigenvectors of $\mathbf{A}$ and $\mathbf{B}$ matrices as follows.

$$\mathbf{X} = \sum_{i=1}^{n} a_i \begin{bmatrix} \mathbf{a}_i \\ \mathbf{O} \end{bmatrix} + \sum_{j=1}^{m} b_j \begin{bmatrix} \mathbf{O} \\ \mathbf{b}_j \end{bmatrix} \tag{3}$$

where $\mathbf{a}_i$ ($i=1, 2, \cdots, n$) and $\mathbf{b}_j$ ($j=1, 2, \cdots, m$) are the eigenvectors of $\mathbf{A}$ and $\mathbf{B}$ matrices, respectively, and $\mathbf{O}$ and $\mathbf{O}'$ zero vectors of m and n rows, respectively.

Substituting Eqs. (1) and (3) into Eq. (2), we obtain

$$\begin{bmatrix} (\mathbf{A}+\mathbf{A})\sum_i a_i\mathbf{a}_i + \mathbf{C}\sum_j b_j\mathbf{b}_j \\ {}^t\mathbf{C}\sum_i a_i\mathbf{a}_i + (\mathbf{B}+\mathbf{B}')\sum_j b_j\mathbf{b}_j \end{bmatrix} = \varepsilon \begin{bmatrix} \sum_i a_i\mathbf{a}_i \\ \sum_j b_j\mathbf{b}_j \end{bmatrix} \tag{4}$$

from which the following equation can be derived.

$$\sum_i(\alpha_i-\varepsilon+\mathbf{A}')a_i\mathbf{a}_i + \mathbf{C}\sum_j b_j\mathbf{b}_j = 0 \quad (5)$$

and

$$^t\mathbf{C}\sum_i a_i\mathbf{a}_i + \sum_j(\beta_j-\varepsilon+\mathbf{B}')b_j\mathbf{b}_j = 0 \quad (6)$$

where α_i's are the eigenvalues of **A** matrix, and β_i's those of **B** matrix. Premultiplying Eq. (5) by $\mathbf{a}_k$ and Eq. (6) by $\mathbf{b}_l$, we get the following equations.

$$(\alpha_k-\varepsilon)a_k + \sum_i a_i\langle\mathbf{a}_k|\mathbf{A}'|\mathbf{a}_i\rangle + \sum_j b_j\langle\mathbf{a}_k|\mathbf{C}|\mathbf{b}_j\rangle = 0 \quad (7)$$

and

$$\sum_i a_i\langle\mathbf{b}_l|\mathbf{C}|\mathbf{a}_i\rangle + (\beta_l-\varepsilon)b_l + \sum_j b_j\langle\mathbf{b}_l|\mathbf{B}'|\mathbf{b}_j\rangle = 0 \quad (8)$$

These equations are reduced to the secular equation given below.

$$\begin{vmatrix} \alpha_1-\varepsilon+A'_{11} & A'_{12} \cdots\cdots & A'_{1n} & C_{11} & C_{12} \cdots\cdots & C_{1m} \\ A'_{21} & \alpha_2-\varepsilon+A'_{22} & & & C_{22} & \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ A_{n1} & \cdots\cdots\cdots & \alpha_n-\varepsilon+A'_{nn} & C_{n1} & \cdots\cdots\cdots & C_{nm} \\ C_{11} & C_{12} \cdots\cdots & C_{1n} & \beta_1-\varepsilon+B'_{11} & \cdots\cdots & B'_{1m} \\ & C_{22} & & B'_{21} & & \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ C_{m1} & \cdots\cdots\cdots & C_{mn} & B'_{m1} & \cdots\cdots & \beta_m-\varepsilon+B'_{mm} \end{vmatrix} = 0 \quad (9)$$

where $A'_{ik}=\langle\mathbf{a}_i|\mathbf{A}'|\mathbf{a}_k\rangle$, $B'_{il}=\langle\mathbf{b}_i|\mathbf{B}'|\mathbf{b}_l\rangle$, and $C_{ij}=\langle\mathbf{a}_j|\mathbf{C}|\mathbf{b}_j\rangle$. This is exactly the same as the secular equation which we have to solve in the molecular orbital calculation on the bimolecular system. When the interaction matrix **C** and the perturbation matrices **A'** and **B'** are sufficiently small, the solutions of Eq. (9) can be approximately given by the perturbation method as follows.

$$\varepsilon_i = \alpha_i + A'_{ii} + \sum_{k\neq i}\frac{A'^2_{ik}}{\alpha_i-\alpha_k} + \sum_j\frac{C_{ij}^2}{\alpha_i-\beta_j} + \cdots \quad (10)$$

and

$$\varepsilon_j = \beta_j + B'_{jj} + \sum_k\frac{C_{jk}^2}{\beta_j-\alpha_k} + \sum_{l\neq j}\frac{B'^2_{jl}}{\beta_j-\beta_l} + \cdots \quad (11)$$

where we have neglected higher order terms. The total energy of a closed-shell molecule is

$$E = 2\sum_i^{occ}\varepsilon_i - \sum_{i,j}^{occ}(2J_{ij}-K_{ij}) + \sum_{n,m}CR_{nm} \quad (12)$$

where J_{ij} is the Coulomb integral, K_{ij} the exchange integral, and $\sum_{n,m}CR_{nm}$ the sum of the core repulsion energy. Thus the intermolecular interaction energy ΔE, defined as the difference between the total energy of the bimolecular system and the sum of the total energies of the constituent molecules, can be expressed as follows.

$$\begin{aligned}\Delta E = {} & [2\sum_{i(A)}^{occ}A'_{ii} + 2\sum_{j(B)}^{occ}B'_{jj} - \sum_{i,j(A-B)}^{occ}(2J_{ij}-K_{ij}) \\ & + \sum_{i,i'(A)}^{occ}(2J_{ii'}-K_{ii'}) + \sum_{l,l'(B)}^{occ}(2J_{ll'}-K_{ll'}) + \sum_{n(A)}\sum_{m(B)}CR_{nm}] \\ & + 2\left[\sum_{i(A)}^{occ}\sum_{k(A)}^{vac}\frac{A'^2_{ik}}{\alpha_i-\alpha_k} + \sum_{j(B)}^{occ}\sum_{l(B)}^{vac}\frac{B'^2_{jl}}{\beta_j-\beta_l}\right] \\ & + 2\left[\sum_{i(A)}^{occ}\sum_{l(B)}^{vac}\frac{C_{il}^2}{\alpha_i-\beta_l} + \sum_{j(B)}^{occ}\sum_{k(A)}^{vac}\frac{C_{jk}^2}{\beta_j-\beta_k}\right] \end{aligned} \quad (13)$$

where $\sum_{i(A)}^{occ}$ stands for the summation over all occupied orbitals of the molecule A, and $\sum_{j(B)}^{occ}$ the corresponding summation for the molecule B. Roughly speaking, the terms in the first brackets give the contribution of the Coulomb and core repulsion energies, those in the second brackets give that of the induction energy and dispersion force, and those in the last brackets correspond to the charge transfer force. All of the integrals in Eq. (13) can be easily evaluated. As an example, C_{il} can be expressed as follows.

$$C_{il} = \sum_{r,s}a_{ir}b_{ls}F_{rs} \quad (14)$$

where a_{ir} is the coefficient of the atomic orbital r in the i-th molecular orbital of molecule A, b_{ls} the coefficient of the atomic orbital s in the l-th molecular orbital of molecule B, and F_{rs} is the element of the Fock matrix, which is given as follows in the MINDO/2 method.

$$F_{rs} = \beta_{rs} - \frac{1}{2}P_{rs}\gamma_{nm}$$

Thus, we can estimate the contribution of a charge-transfer configuration, CT($i\rightarrow l$),

$$\Delta E_{CT(i\rightarrow l)} = \frac{C_{il}^2}{\alpha_i-\beta_l}$$

by using the results of the molecular orbital calculations of the bimolecular system and those of the isolated molecules.

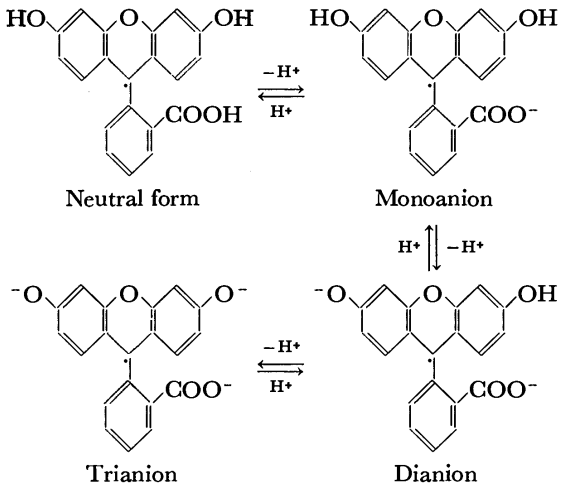
ESR Study on Fluorescein Semiquinone Radical

Shigeya NIIZUMA, Yoshiharu SATO, Shiro KONISHI, and Hiroshi KOKUBUN
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980
(Received April 19, 1974)

The ESR spectrum of the fluorescein semiquinone radical (dianion form) produced by illumination of an alkaline aqueous solution of uranine and leuco-uranine at pH between 11 and 14 was observed and its hfs constants were determined by comparing the spectrum with those of the mono- and trianion forms of fluorescein semiquinone and those of eosin semiquinone reported by Leaver. Six protons in the xanthene ring were found to be comprised of three pairs of magnetically equivalent protons, which suggests a certain dynamic mechanism to average the coupling constants. From a temperature dependence of the line width, protonation to the -O⁻ group followed by deprotonation from the -OH group was proposed as a plausible mechanism.

When alkaline water-ethanol and water-2-propanol solutions of uranine (disodium salt of fluorescein) are illuminated with visible light, uranine is reduced to leuco-uranine *via* a half-reduced form (semiquinone radical).[1] The semiquinone, which is relatively stable in the alkaline solution, is also produced by uranine-sensitized photo-oxidation of leuco-uranine.[2] According to the investigations using the steady light as well as the flash illuminations, it was established that the radical is in ionic equilibrium as shown in scheme (I). The pK_a values of the mono- and dianions are reported to be 9.5 and >13,[3] respectively.



Scheme (I)

Therefore at the pH between 11 and 13, the semiquinone exists as the dianion form. From the kinetic study of the ESR signal of this radical, it was clarified that the signal intensity change after making the illumination off shows a typical second-order decay and the activation energy of disproportionation or recombination for this radical was found to be 10 to 12 kcal/mol.[4] Though a highly resolved ESR spectrum has ever been observed,[5,6] the analysis of hfs has not yet been performed sufficiently.

As to radicals containing one or more phenyl rings, for example benzophenone ketyl[7] and α-phenylbenzilidene malononitrile,[8] a steric and an electronic effect on rotation of the phenyl rings are recently treated as interesting problems. From this point of view, it will be interesting to analyse the hfs of the fluorescein semiquinone radical in detail in order to obtain the information about the rotation of the phenyl ring in this molecule.

By using the improved light source system, the more resolved spectrum than that in the previous report[4] has been detected. The results of the analysis of hfs and the signal behavior give the following information; (1) The radical species obtained at pH between 11 and 14 was the only one and was identified as a dianion. At the pH range from 9.5 to 10.5, the asymmetric spectra were obtained, which means in general that signals of two kinds of radicals superpose each other. No further analysis of these spectra was made. (2) The ESR spectrum of the radical identified as a dianion revealed that six protons in the xanthene frame consist of three pairs of magnetically equivalent protons. Therefore it is suggested that this molecule has a certain mechanism to make some pairs of protons equivalent magnetically. (3) Line broadening and narrowing occur reversibly with the temperature decrease and increase. The interpretation of these results was attempted. Two conceivable mechanisms are (a) the hindered rotation of the phenyl ring and (b) protonation to the -O⁻ group followed by deprotonation from the -OH group. The latter is more plausible.

Experimental

Materials. Uranine was prepared by treating fluorescein (Hikotaro Shudzui & Co., G. R. grade) with sodium carbonate in water and was recrystallized three times from ethanol. Leuco-uranine was obtained by reducing the above uranine with sodium amalgam in water and was used without further purification.

Procedures. The radical dianion was produced mainly by illuminating the aqueous solution of uranine (10^{-5}—10^{-4} mol/l) and leuco-uranine (10^{-3}—10^{-2} mol/l) mixture in an

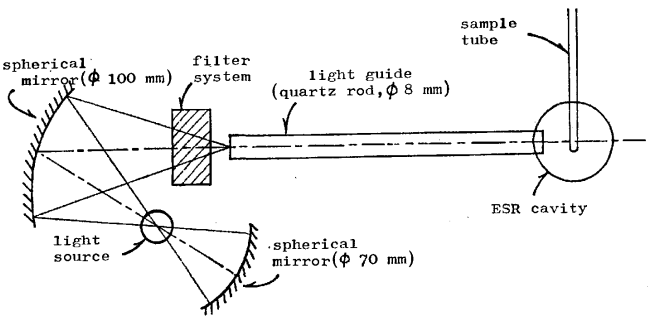


Fig. 1. The apparatus for the illumination system.

ESR sample tube placed in a cavity. pH of the solution was controlled with sodium hydroxide concentration. An Ushio super high-pressure mercury lamp (USH 500D) was used as a light source. The illuminating apparatus is shown in Fig. 1. Light was collected by two spherical mirrors, larger one (10 cm in diameter) being set to have a correct angle between the axis of incident light and that of reflected light and to focus the light on the front surface of a quartz light-guide. A filter system which consists of 1 cm water, a 1 cm cupric sulfate aqueous solution and a Toshiba VY-43 glass filter was placed between the mirror and the light-guide. This filter system transmits the visible light in the range from 430 to 600 nm. The wavelength of absorption maximum of uranine in alkaline aqueous solutions is 495 nm.

The temperature of the sample was controlled by inserting the doubly sealed quartz tube into a cavity and introducing cold nitrogen gas or hot air through the tube. A thermocouple was used to monitor the temperature in the tube.

Hyperfine splittings were determined using the signal of seven lines of Mn^{2+} in MgO as a standard. The separation between the third and fourth lines is 87.5 G.

A JEOL P-10 type ESR spectrometer (X band, 100 kHz modulation) was used. A NEAC 2200 MODEL 700 Electronic Computer in the Calculation Center of Tohoku University was used for the calculation of unpaired spin densities. For a simulation of ESR spectra, a JEOL JEC-6 Spectrum Computer was used.

Results and Discussion

ESR Spectra Obtained in the Solutions of Different pH Values. The ESR spectra obtained during photolysis of solutions of various pH values higher than 9.5 are shown in Fig. 2. The signals observed at pH values lower than 10.5 have a small S/N ratio because of a short lifetime of the radical and have an asymmetric line shape, which may be due to the superposition of signals from the mono- and dianions. At the pH range from 11 to 13, rather highly resolved spectra were detected. The di- and trianions might coexist at pH values greater than 14, but in fact similar spectra to those at pH range from 11 to 13 were observed with smaller intensity.

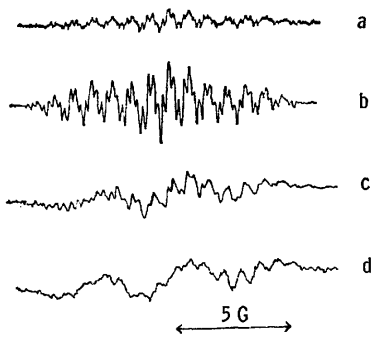

Fig. 2. ESR spectra of fluorescein semiquinone at pH> 14 (a), 12.3 (b), 10.5 (c), and 9.5 (d).

Simulation of ESR Spectrum and Determination of Coupling-Constants and Unpaired Spin Densities on Carbons. Figure 3(1) shows a typical spectrum of the dianion which is approximately the same as that obtained by Kimura *et al.*[5] in the γ-irradiated methanol solution of uranine. The arrow marked a indicates the center of the spectrum. When the modulation width is wide, the signal is a 1 : 2 : 1 triplet. As the modulation width becomes narrow, it splits into fifteen lines as a whole. Each component of the fifteen lines comprises seven or eight lines which are not well-resolved. The line shape of components marked a and b in Fig. 3(1) resembles each other: moreover both sides of marks a and b have a similar shape over a few gauss. The same relation hold between marks a and b'. (b' is the point at lower field half and not given in the figure.) Therefore the largest coupling exhibiting the triplet is taken as 3.287 G from the distance between a and b (or a and b'). The spectrum of a (or b) component (Fig. 4(1)) can be simulated satisfactorily by using four coupling constants of 0.220, 0.190, 0.170, and 0.090 G (Fig. 4(2)). This pattern is similar to the component of the triplet signal which has been obtained by photolysis of eosin in methanol-d_1[6] by Leaver (Fig. 4(3)). He reconstructed this pattern by using three protons of

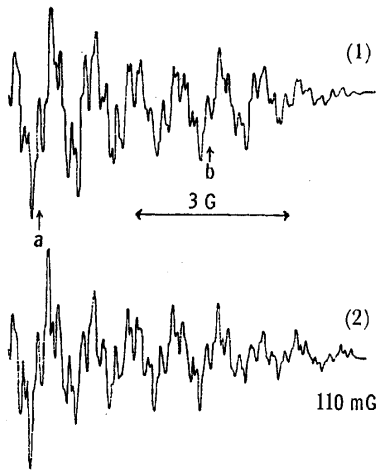

Fig. 3. ESR spectrum of the dianion in ethanol–aqueous solution (20 volume percent ethanol) at 44 °C (1) and its simulation (2).

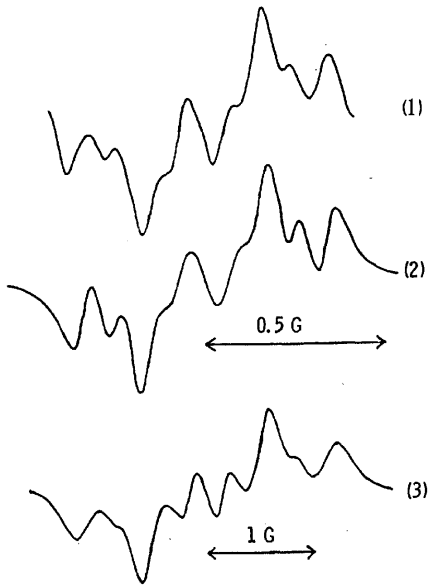

Fig. 4. a (or b) component of the fifteen lines (1), its simulation (2) and one component of the triplet spectrum of eosin semiquinone (3).

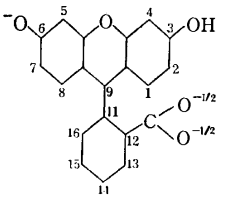
0.61 G and one proton of 0.29 G. The shape in Fig. 4(3) was assigned to that constructed with the coupling of four protons in the phenyl ring of eosin semiquinone.

The whole spectrum consisting of fifteen lines in Fig. 3(1) can be simulated by combining the four coupling constants, which produce the line shape in Fig. 4(1) with those of six protons in the xanthene ring, two of which are already estimated to be 3.287 G. As for the rest of the couplings, two of them are estimated to be 1.510 G and the other two 0.889 G. The coupling constants determined in this way are given in Table 1. The spectrum simulated with the aid of parameters in Table 1 is shown in Fig. 3(2).

Table 1. Coupling constants and unpaired spin densities

Position	Coupling const. Obsd(G)	Unpaired spin density Obsd[a)]	Calcd	Average
1	3.287	0.1133	0.1124	0.1120
8			0.1116	
2	1.510	0.0521	−0.0332	−0.0326
7			−0.0322	
4	0.889	0.0307	−0.0304	−0.0290
5			−0.0276	
13	0.220	0.0076	0.0098	
14	0.190	0.0066	0.0078	
15	0.170	0.0059	0.0028	
16	0.090	0.0031	0.0010	

a) $Q=29$ G was used.



The unpaired spin densities calculated by McLachlan's method based on simple LCAO MO method are listed in the fourth column of Table 1. The following parameters were used in the calculation:

$$\alpha_{-O-} = \alpha + 2.0\beta \qquad \beta_{C-O-} = 0.6\beta$$
$$\alpha_{-OH} = \alpha + 2.5\beta \qquad \beta_{C-OH} = 0.7\beta$$
$$\alpha_{-O^{-1/2}} = \alpha + 2.25\beta \qquad \beta_{C-O^{-1/2}} = 0.8\beta$$
$$\alpha_{-O^{-}} = \alpha + 2.0\beta \qquad \beta_{C-O^{-}} = 0.8\beta$$

where α_i and β_{C-R} are respectively the Coulomb integral of C–i atom and exchange integral of C–R bond. As for McLachlan's parameter, $\lambda=1.0$ was used. Because of steric hindrance, the xanthene and phenyl rings cannot be in the same plane but incline to a considerable to extent each other. $\beta_{C_9-C_{11}}=\beta\cos^2\theta$ was added to the parameter for calculation, where θ is the angle between the axis of the p-orbital of C_9 and that of C_{11}. The calculated values listed in Table 1 are for $\theta\approx55°$. The agreement between the observed and the calculated values is rather good.

It is obvious from the pK values of the mono- and dianions determined by Lindqvist that the radical in question has the dianion form. This is also supported by the fact that the observed coupling value of the protons at the 1- and 8-positions (3.287 G) lies between those of the monoanion (3.39 G) and the trianion (2.89 G) reported by Leaver for methanol solutions. The tendency of decreasing coupling constants of the 1- and 8-positions with increasing negative charge of the radical implies that the unpaired electron migrates from the xanthene into the phenyl ring as the -OH groups at the 3- and 6-positions are replaced by the $-O^-$ groups.

If only the asymmetry of the molecule is taken into consideration, the coupling constant of the proton at the 1-position should differ slightly from that at the 8-position. A pair of protons at the 2- and 7-positions as well as a pair of those at the 4- and 5-positions should also have the different coupling constants due to the same reason. The differences in the calculated coupling constants of these pairs of protons are obviously beyond the simulation error. Therefore, a certain dynamic mechanism should be considered to explain the observed spectrum which shows the existence of three pairs of equivalent proton coupling constants.

Temperature Dependence of ESR Spectrum. The dynamic mechanisms conceivable are (a) the rapid hindered internal rotation of the phenyl ring about the C_9–C_{11} bond and (b) the isomerization reaction by protonation to the $-O^-$ group followed by deprotonation from the -OH group. The former is based on the assumption that the difference between the influences of $-O^-$ and -OH on the unpaired electron distribution in the xanthene ring is negligible and that although the substituted phenyl ring lowers symmetry of the spin distribution in the xanthene ring, the C_{2v} symmetry may be restored by a rapid rotation of the phenyl ring. At any rate, as the ESR spectrum of this radical suggests the existence of dynamic mechanism, the temperature effect on the ESR spectrum was investigated.

The low-field half of the ESR spectra measured at various temperatures using the mixture of ethanol and water (volume percent of water is 20) are given in Fig. 5(1). The line broadening is seen with the decrease of temperature and this change is reversible. Figure 5(2) shows the simulation of the above spectra obtained

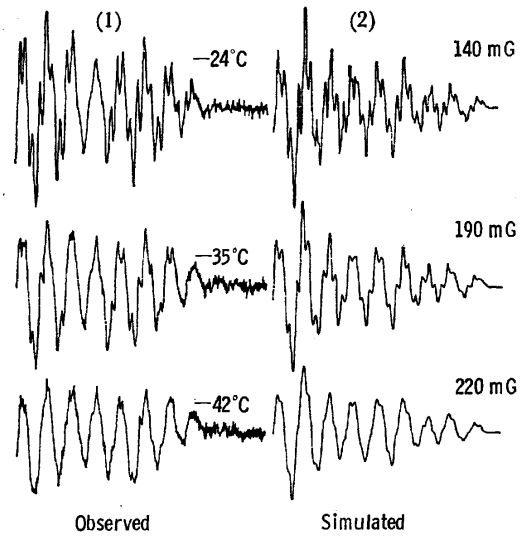


Fig. 5. ESR spectra of the dianion in an ethanol–aqueous solution (80 volume percent ethanol) at three different temperatures. Numbers in mG units are the line widths used for simulation.

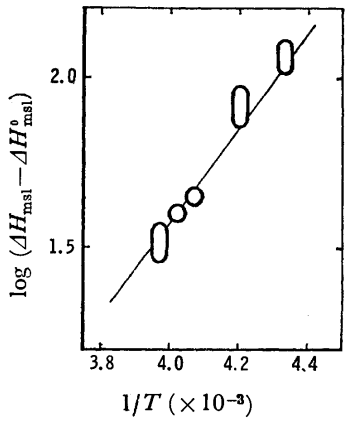

Fig. 6. Arrhenius plots for the increased portion of the line width used for simulation of the ESR spectra of the dianions in an ethanol-aqueous solution (80 volume percent ethanol).

from the same coupling constants as those used in simulating the spectrum of Fig. 3(1) and from the various line widths corresponding to various temperatures. Further, since the areas under the integrated curves of the ESR spectra at various temperatures are nearly constant, the change of the radical concentration is negligible.

Strictly speaking, the line width alternation ought to be detected, if the mechanism (a) or (b) is involved. But practically the line width broadening might be seen as a whole, because the semiquinone has three pairs of protons to commute their coupling constants each other and the differences in coupling constants of each pair are not so large. At the temperatures higher than room temperature, the line width converges to a constant value (100—110 mG; this is the half-width of Lorentzian line shape used for simulation). Therefore, as the observed line width, $1/T_{2,obsd}$ is given by Eq. (1),[9] the reciprocal of the increased portion of the line width associated with the temperature decrease was plotted against the reciprocal of the absolute temperature,

$$\frac{1}{T_{2,obsd}} = \frac{1}{T_2} + \frac{1}{\tau} \qquad (1)$$

where τ is the life time of one of the isomers in the mechanism (a) or (b) and T_2 is the transverse relaxation time when neither (a) nor (b) is involved. A straight line was obtained as shown in Fig. 6, which means Eq. (2) holds. From the slope of the line in

$$\frac{1}{\tau} = \frac{1}{\tau_0} \exp\left[-E/kT\right] \qquad (2)$$

Fig. 6, 6.3 kcal/mol is obtained as the activation energy E of the mechanism that brings the line broadening. The E values obtained for the various mixtures are listed in Table 2.

TABLE 2. ACTIVATION ENERGY OF THE ISOMERIZATION REACTION

Solvent (volume ratio)	Activation energy (kcal/mol)
EtOH: H_2O (4: 1)	6.3
EtOH: H_2O (1: 4)	6.5
EtOH: D_2O (4: 1)	6.2
EtOH: D_2O (1: 4)	7.2

Discussion on Coupling Constant Averaging Mechanism. If the hindered rotation of the $-COO^-$ substituted phenyl ring has any effect on the unpaired electron distribution in the xanthene ring, the interaction must be the steric hindrance between the $-COO^-$ group and the xanthene ring plane. As fluorescein and eosine molecules can change their structure from normal to lactone form under a suitable condition, the $-COO^-$ group might have a large influence on the distribution of the odd electron in the xanthene ring.

Next, considered was the line broadening by the isomerization reaction of protonation to the $-O^-$ group followed by deprotonation from the –OH group. The linewidth alternation due to a similar mechanism was found, for instance, in the ESR spectra of *p*-benzosemiquinone radical[9] and *trans*-biacetyl semidione radical.[10] If that is the case in our system, the life time required to average a pair of coupling constants can be estimated from the values in Table 1 and from the relation $\tau \ll 1/\gamma|a_i - a_j|$, where γ is a gyromagnetic ratio and a_i and a_j are a pair of coupling constants to be exchanged. The estimated life times are *ca.* 2.5×10^{-6} s, 2.0×10^{-6} s, and 6.7×10^{-6} s for the coupling constants of protons at the 1- and 8-positions, those at the 2- and 7-positions and those at the 4- and 5-positions, respectively. Therefore, the averaging may occur in order of 4- and 5-positions, 1- and 8-positions and 2- and 7-positions with the decrease of temperature. But the differences in the critical life time are not so large that the temperature range where the line broadening begins to appear may superpose each other.

According to Leaver, the proton coupling of the –OH groups was observed in the monoanion form while in our case the same ESR signal as that in H_2O was detected in D_2O. This fact means that the signal does not contain the coupling of the proton (or deuteron) in the –OH (or –OD) group. Moreover, taking the fact into account that the activation energy is too large for the rotational barrier of the phenyl ring, it seems reasonable to consider the protonation and deprotonation as a mechanism of averaging the proton coupling constants in the xanthene ring.

The proton concentration in the high pH solution where the fluorescein semiquinone radical has the stable form is extremely small. Therefore, the isomerization (protonation and deprotonation) of semiquinone must be altered as follows; at first semiquinone reacts with water molecule and then a proton transfers from water to the $-O^-$ group of the xanthene ring and immediately after that the –OH group on another side of the xanthene ring releases a proton. The activation energy of 6—7 kcal/mol may be responsible for the transfer of a proton from water to the radical.

A New Condensed Gas Calorimeter. Thermodynamic Properties of Solid and Liquid Dinitrogen Oxide

Tooru ATAKE and Hideaki CHIHARA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received June 3, 1974)

A new adiabatic calorimeter for use with condensed gases from 1.8 K to room temperature has been constructed. The heat capacity of solid and liquid dinitrogen oxide was measured between 1.9 and 184 K together with the vapor pressure above 146 K. The residual entropy was re-evaluated as 6.0 J K^{-1} mol^{-1}, which is now closer to R ln2, suggesting that the disorder of molecular end-for-end orientation is perfectly frozen in the solid state. The moments of lattice frequency spectrum were derived from low-temperature heat capacities and high-temperature vapor pressures. The anomalous increase of heat capacity below the triple point was interpreted as arising from thermal creation of orientational defects with the enthalpy of formation 10.8 kJ mol^{-1}. Other thermodynamic quantities determined are as follows: triple point of pure N_2O 182.407±0.002 K, heat of fusion 6 516±20 J mol^{-1}, entropy of fusion 35.7±0.1 J K^{-1} mol^{-1}, heat of vaporization at 184.81 K and 101.7 kPa 16 544± 20 J mol^{-1}, normal boiling point 184.74 K, translational zero-point energy 1.6±0.3 kJ mol^{-1}, Debye temperature corresponding to $3N$ degrees of freedom 141.0±1.0 K.

Dynamical properties of molecules in the solid state has attracted attention from experimental as well as theoretical points of view. Crystals of monatomic molecules have been studied by a variety of methods and their properties are rather well understood. The crystals of linear molecules have librational degrees of freedom which add some complexity to what has been known for monatomic crystals. In particular, α-CO and N_2O crystallize in a modified fcc lattice in which a molecular axis is oriented along one of the body diagonals in such a way that molecular quadrupole interaction determines the arrangement. Furthermore, there is a possibility of head-to-tail disorder, which has been considered to be at least partially frozen-in at low temperatures, as inferred from the existence of the residual entropy ($\approx R \ln 2$) determined by Giauque *et al.*[1,2] In 1964, however, Melhuish and Scott[3] calculated the Curie temperatures for the order-disorder transitions associated with molecular reorientation in solid CO and N_2O from evaluation of electrostatic energies, and they suggested that the transitions were to be expected at 5 and 11 K, respectively. Because these transition points were lower than the lowest temperature (about 15 K) from which Giauque *et al.*[1,2] started measurements of the heat capacities, attempts were made to locate the transition by extending the measurements on carbon monoxide to lower temperatures (down to 2.5 K) by the authors and J. A. Morrison and their coworkers in 1966.[4,5] Although no additional phase transition was found, the residual entropy of carbon monoxide was re-evaluated as 3.3±0.8 J K^{-1} mol^{-1}, which was significantly different from the value of $R \ln 2 = 5.76$ J K^{-1} mol^{-1}. In 1968, Pitzer *et al.*[6] examined kinetics of the order-disorder transition by tunneling mechanism and found the rate of transition to be unobservably slow. In 1969, Burford and Graham[7] further extended the heat capacity measurements on carbon monoxide down to about 0.8 K but failed to find an anomaly. For decisive explanation of the residual entropy of solid carbon monoxide, therefore, more investigation is still required. In the case of dinitrogen oxide, which is analogous to carbon monoxide in many respects, the calculated Curie temperature for the order-disorder transition is higher by a factor of 2. Therefore, more precise calorimetry below 15 K seemed to be in order. This paper reports the measurements of heat capacity and related thermodynamic properties of dinitrogen oxide and the results are analyzed in detail. In the course of this investigation, we found unusually large 'premelting' tail of the heat capacity below the triple point, which will be interpreted in terms of defect formation in the solid.

Descriptions will be presented of the new adiabatic calorimeter for use with condensed gases which works between 1.8 K and room temperature. Some modifications and improvements of the measuring system over the earlier model[4,8] will also be described.

Experimental

Calorimeter and Cryostat. A cryostat and an adiabatic calorimeter for condensed gases have been newly designed and constructed. The sectional plan of the apparatus is shown in Fig. 1. A feature of the cryostat is that it has two refrigerant containers of cascade type E, (inside volume of 430 cm^3) and I (1 770 cm^3), above the calorimeter vessel A, the adiabatic mantle B and the thermal sink C. The two containers are made of heavy brass and may be loaded with different refrigerants depending on the temperature region to work with. For the measurements from 2.6 to 13 K, the container E is filled with liquid helium which, by a single charging, lasts about twenty hours, as long as there is solid hydrogen in the container I. For the measurements in the lowest temperature region down to 1.8 K, both containers are filled with liquid helium in which case the refrigerant lasts about ten hours. The inner jacket H is soldered vacuum-tight to the hydrogen container I with Wood's alloy but the radiation shield D is only thermally anchored to the container E because the space inside H is a common vacuum. Both H and D are made of copper whereas the outer jacket J is made of brass. All the tubes a—f are made of SUS-27 stainless steel and have outside diameters of 10—16 mm and wall thickenss of 0.15 mm. The entire cryostat can be evacuated through the tubes c and f and maintained in a vacuum better than 1×10^{-4} Pa during measurements. The calorimeter is cooled by breaking the vacuum with small amount of helium exchange gas down to about 15 K. Below

about 15 K, the calorimeter is cooled only by heat conduction through the electrical leads. The sample filling tube F (German silver, 1 mm in outside diameter, 0.1 mm in wall thickness, 163 cm in length) connects the calorimeter vessel A to the external gas handling system (see Fig. 3). The filling tube is thermally anchored to the bottom of the container I by way of a short insert of copper wire (G in Fig. 1), over the length of which a Manganin heater is wound to prevent the gas from condensing at the cold spot. This thermal shunt is used when measurements are made in the lowest temperature region, where the sample has negligible vapor pressures, to keep minimum the heat leak into the calorimeter through the tube. Manganin heaters (B.S. # 36) are also closely wound non-inductively over the entire length of the filling tube except the portions inside the mantle B and above the top of the cryostat, and the heater wires are varnished to the tube with glyptal lacquer (G.E. adhesive No. 7031). The heaters are wound in seven separate parts and the temperature of each part is monitored and measured with a Constantan *vs.* Chromel-P thermocouple. Four lower parts of the filling tube may be at so low a temperature that a thermocopule would not have a sufficient sensitivity and therefore the parts are also equipped with carbon resistors (nominal value of 10 Ω, Allen-Bradley Co.) to use in the

low temperature region. The electrical leads are double silk-insulated B.S. # 36 copper and are in good thermal contact with the refrigerant containers I and E at their bottoms.

Figure 2 shows the lower part of the cryostat. The copper thermal sink N is of three year-ring shaped construction for securing good thermal contact between the wires and the rings. The calorimeter vessel (gold, 44 cm^3 in volume, 75 g in net weight) has eight vanes for the inside thermal uniformity. A platinum resistance thermometer G is cast into the reentrant well with Wood's alloy and a germanium resistance thermometer F is fitted into a copper sheath which is soldered to the bottom of the vessel. The calorimeter heater E (150 Ω, B.S. # 36 KARMA wire, Driver-Harris Co.) is wound around the lower part of the vessel and also around the lower part of the platinum thermometer. The copper adiabatic mantle consists of three parts whose temperatures are monitored and controlled separately as described in the earlier paper.[8] The filling tube from the calorimeter vessel is soldered to the top L to ensure good control of its temperature. All the electrical leads between the calorimeter vessel and the terminal box outside the cryostat have soldered connections only at the bottom of the side of the mantle I.

External Equipments for Gas Handling. The gas handling apparatus external to the cryostat is schematically shown in Fig. 3. It consists of three manometers, a calibrated flask of about 5 dm^3 capacity, and traps for sample distillation. The sample gas from a cylinder or a sealed flask is desiccated

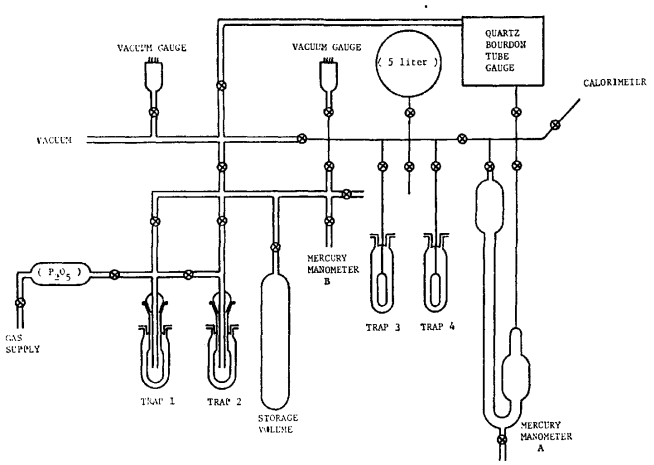

Fig. 3. The gas handling apparatus.

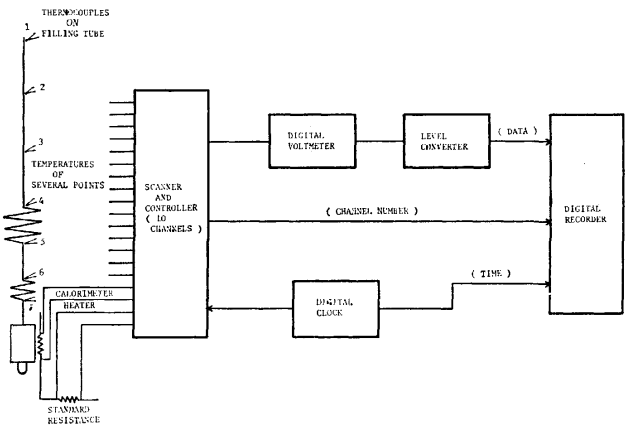

Fig. 4. The data acquisition system.

over P_2O_5 or other desiccants before condensing in trap 1 or 2. The traps 1 and 2 are used for purification by distilling the gas back and forth between the two. The pressure during the distillation is monitored with the mercury manometer B. The gas is then transferred to either trap 3 or 4 depending on the amount of the sample gas. The traps are of special design with a buffer space surrounding the sample container. This space is useful for a fine control of the temperature: a low-melting liquid may be put into this space while the entire trap is immersed in liquid nitrogen or in a cooled empty Dewar vessel (not shown). The condensed gas in trap 3 or 4 is then slowly evaporated into the 5 dm^3 flask (thermostated) and after standing for a sufficient length of time the pressure of the gas is carefully determined with the manometer A or with the quartz Bourdon gage (Texas Instruments Inc., Model 144-01). The dead space volume was determined by using helium as the working gas in advance. The amount of the specimen used for calorimetry is derived from two determinations of the gas before and after the filling into the calorimeter vessel. A small amount of the gas can be taken out into an appendix tube (not shown) for analysis.

In the earlier stage of the present study, the pressure was read on the mercury manometer A and in the later stage, it was determined with the Bourdon gage. The mercury manometer is so designed that it requires no corrections for the capillary depression and causes only small change in the dead space volume. The precision of the manometer is limited to ± 7 Pa, determined by the precision of the standard scale (stainless steel) and of the verniers of the travelling telescopes. The Bourdon gage, on the other hand, has an advantage that the measured volume can be kept constant. This is particularly helpful when measuring the vapor pressures and the heat capacities at the same time.

When measuring heat of vaporization, the calibrated flask is also used as a storage volume of the gas evaporated from the calorimeter vessel. During heat input, the pressure is controlled manually to within ± 150 Pa by adjusting a stopcock, being monitored with the Bourdon gage.

Electrical Measurements. The outputs from the seven thermocouples for measuring the temperature gradient along the length of the filling tube and also the potential and the current across the calorimeter heater are recorded on the automatic data acquisition system, the block diagram of which is shown in Fig. 4. The system consists of a scanner (TR-7216-20S and TR-7513, Takeda Riken Industry Co., Ltd.), a digital integrated voltmeter (3450A, Hewlett-Packard), a digital clock (TR-7414), and a digital printer (TR-6196) which records the time, the channel number, and the outputs of the digital voltmeter. The nominal sensitivity is better than ± 1 μV on the 100 mV range. The method of temperature measurements with platinum and germanium resistance thermometers is the same as that described in the earlier papers.[4,8,9]

Temperature Scales. The platinum resistance thermometer for the present calorimeter (Model 8164, Leeds & Northrup Co.) is the one calibrated on the IPTS-48 and the NBS-55 temperature scales at the U.S. National Bureau of Standards. Therefore, the temperature scale has been converted to the IPTS-68 by using the NEAC-2200-500 computer system at Computer Center of Osaka University.

The germanium scale (used below 13.81 K) was fixed by using a different method for each of the three temperature regions: (a) the 1958 ^{4}He vapor pressure temperature scale below 4.2 K, (b) the ^{4}He gas thermometric temperature scale between 4.2 and 13.81 K (for this purpose the calorimeter was used as a gas thermometer), (c) the IPTS-68 above 13.81 K (the germanium thermometer was compared with the platinum thermometer). The germanium resistance thermometer used in the early stage of this investigation bears the laboratory designation, the germanium thermometer α, and the one used in the later stage the germanium thermometer γ. The germanium thermometer γ (CR-1000, Cryocal Inc.) is of better quality (smaller size and higher sensitivity) than the α (MHSP-2401, Minneapolis-Honeywell Regulator Co.). The following two functions were examined for computer fitting by the method of least squares,

$$\log_{10} R = \sum_{i=1}^{b} A_i T^{i-a}, \tag{1}$$

$$\log_{10} R = \sum_{i=1}^{b} A_i (\log_{10} T)^{i-a}, \tag{2}$$

where R is the resistance in ohm and A_i's are constants. The best fit for germanium thermometer α was obtained by employing the formula:

$$\log_{10} R = \sum_{i=1}^{10} A_i T^{i-2}. \tag{3}$$

The ten coefficients are listed in Table 1, together with the sum of deviations, and the deviation plot is given in Fig. 5. In the second series of the heat capacity measurements of dinitrogen oxide, the α has been replaced by the germanium thermometer γ, which was calibrated by comparison with the resistance of the α. However, below 4.2 K the γ was recalibrated on the 1958 ^{4}He vapor pressure temperature scale, and for this purpose this condensed gas calorimeter was used as a vapor pressure thermometer. In this case, the formula

Table 1. The ten coefficients for the germanium resistance thermometer α.[a,b]

i	A_i	i	A_i
1	−0.072 215 608 7	6	0.028 195 779 8

a) Calibration formula:
$\log_{10} R=\sum_{i=1}^{10} A_i\ T^{i-2}$

b) Sum of deviations of the 27 calibration points:
$\sum_{i=1}^{27}(\log_{10} R_i(\text{calcd})-\log_{10} R_i(\text{obsd}))^2=0.000\ 428\ 87$

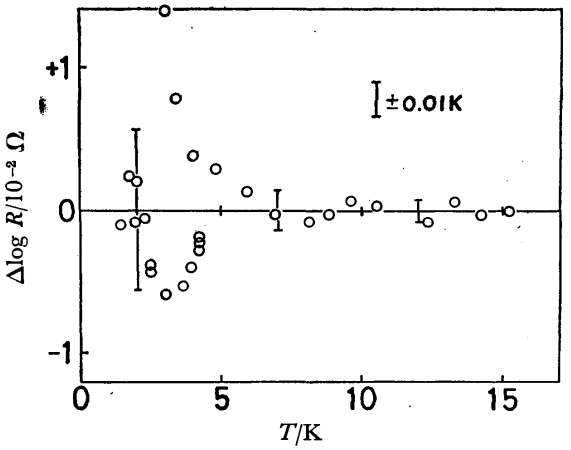

Fig. 5. The deviation plot for the germanium thermometer α fitted to the formula: $\log_{10} R=\sum_{i=1}^{10} A_i \cdot T^{i-2}$.

best fit between 1.7 and 15 K was determined as

$$\log_{10} R = \sum_{i=1}^{10} A_i T^{i-4}. \quad (4)$$

The ten coeffiecients and the sum of deviations are given in Table 2, and the deviation plot is shown in Fig. 6. Apparently, the γ scale is much closer to the measured calibration points than the α scale. Below 4.2 K, especially, the γ scale is more accurate than the α scale.

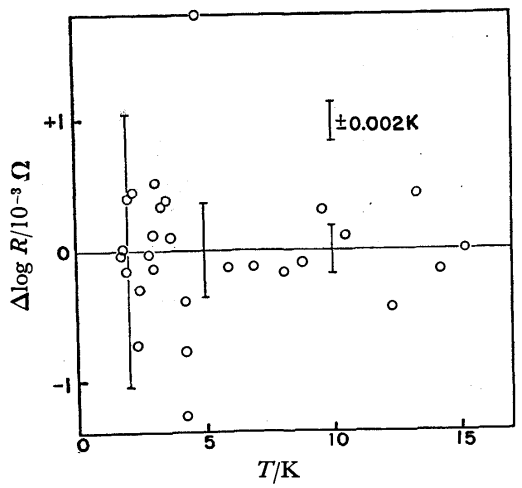

Fig. 6. The deviation plot for the germanium thermometer γ fitted to the formula: $\log_{10} R=\sum_{i=1}^{10} A_i\ T^{i-4}$.

Table 2. The ten coefficients for the germanium resistance thermometer γ.[a,b]

$\log_{10} R=\sum_{i=1}^{10} A_i\ T^{i-4}$

b) Sum of deviations of the 28 calibration points:
$\sum_{i=1}^{28}(\log_{10} R_i(\text{calcd})-\log_{10} R_i(\text{obsd}))^2=0.000\ 007\ 91$

Material. The sample of dinitrogen oxide in 1 liter flasks at 101 kPa was purchased from Takachiho Kagaku Kogyo Co., Ltd., and its stated purity was 99.9 mol%. Dried over P_2O_5, the dinitrogen oxide was distilled twice by means of the traps 1—4 in Fig. 3. The final purity was 99.999 mol% as determined by the fractional melting method during the calorimetry. Gas-chromatographic and mass-spectrographic analyses showed no detectable impurities. The quantities of the purified dinitrogen oxide used for the calorimetry were determined by the *P-V-T* measurements, corrected for non-ideality of the gas by using published values of the second virial coefficients:[10] 0.426 5±0.001 6 mol in the first series and 0.180 0±0.003 0 mol in the second series. In the second series, however, the runs 1 and 2 were carried out on the sample of the amount of 0.200 7±0.000 5 mol.

Calorimetry. In the first series of the calorimetry on dinitrogen oxide, the germanium thermometer α was used and the pressure was measured with the mercury manometer, which caused the rather large uncertainties of the present results. In the second series, the germanium thermometer γ was used and the pressure was measured with the quartz Bourdon gage.

At high temperatures, the filling tube temperatures were so adjusted that the calorimeter may be the coldest in order to prevent distillation of the specimen out of the calorimeter.

No helium gas was introduced into the calorimeter vessel for heat exchange. The time for thermal equilibrium within the calorimeter vessel was a few seconds in the lowest temperature region, one minute at about 20 K, and a few minutes at about 50 K, increasing to ten or more minutes above 100 K.

In the region below about 10 K, the adiabatic condition between the calorimeter and the mantle was controlled manually because the sensitivity of the thermocopules was not sufficient to energize the automatic control device.[8]

Results

Heat Capacity. The heat capacity of dinitrogen oxide was measured between 1.9 and 184 K. The temperature rise by a single heat input was 0.3—0.5 K below 10 K, about 1 K below 30 K, and about 2 K above 30 K. Because the liquid phase exists over only 2.4 K temperature interval, a single temperature rise was chosen as about 1 K in this region. Corrections to the heat capacity were necessary above 140 K for vaporization of the solid or the liquid and other accompanying effects. Other quantities relevant for heat capacity computation were evaluated in the following

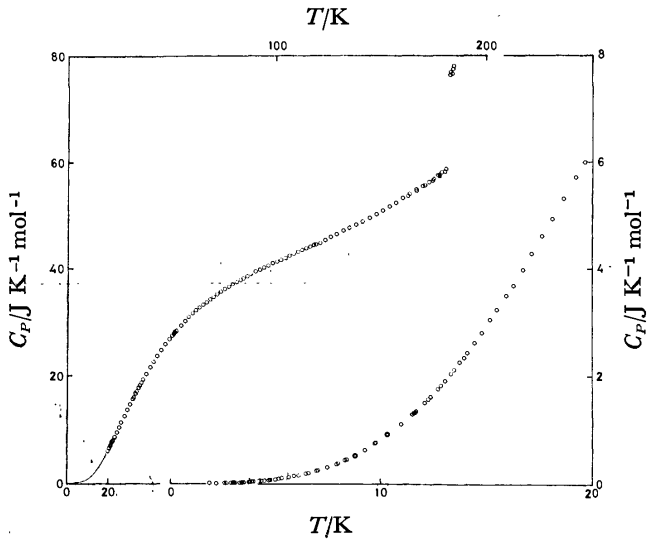

Fig. 7. Molar heat capacity of dinitrogen oxide.

way. The density of solid N_2O has been reported only at two temperatures (molar volume 27.0 cm^3 at 20 K and lattice constant a_0=0.566 nm at −190 °C);[11,12] therefore the densities at other temperatures were estimated by linear extrapolation to higher temperatures. The liquid densities were obtained by smoothing the published data.[13] The heat capacity of the gas of dinitrogen oxide was calculated from the spectroscopic data: fundamental frequencies of 1 277 cm^{-1}, 589 cm^{-1} (doubly degenerate) and 2 224 cm^{-1}. The values of the second virial coefficient were taken from literature;[10] however, they had to be extrapolated to below 197 K. The overall correction amounted to at most about 5% of the total input energy. In the first series of measurements, the calorimeter vessel contributed about 40% of the total heat capacity at all temperatures measured. The heat capacity values thus obtained are C_s under the saturated vapor pressures but the difference between C_s and C_P is negligibly small because the pressures are low and the C_s data are presented as C_P.

a) Deviation=[C_P(Blue and Giauque)−C_P(This)] ×100/C_P(This)

The heat capacity values of dinitrogen oxide without curvature corrections are given in Table 3 and plotted in Fig. 7. The smoothed values at rounded temperatures are given in Table 4, where comparisons are shown with the results by Blue and Giauque[2] in terms of deviations. Blue and Giauque's results are systematically larger than the present results but the differences are probably within the combined limits of errors. A more sensitive comparison can be made by use of equivalent Debye temperature Θ_D, whose temperature dependence for $5N$ degrees of freedom is shown in Fig. 8. We shall discuss the shape of the

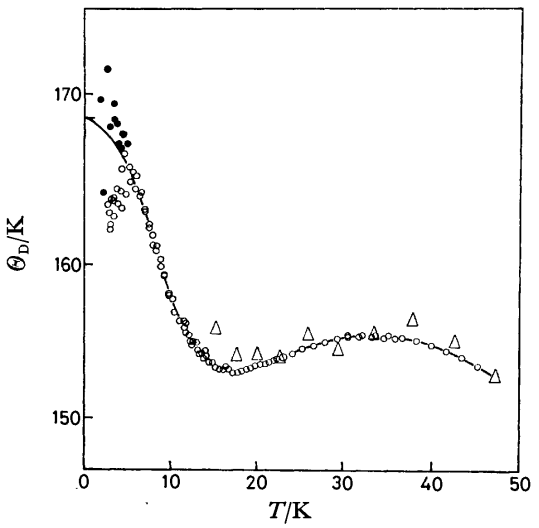

Fig. 8. The Debye characteristic temperatures of dinitrogen oxide derived from the measured heat capacities, assuming $5N$ degrees of freedom. ○, This research (measured with the germanium thermometer α and the platinum thermometer); ●, This research (measured with the germanium thermometer γ); △, R.W. Blue and W.F. Giauque (1935).

Θ_D curve in a later section but here focus our attention on the low temperature end of the curve. Apparently, there is a systematic difference between the results using the germanium thermometer α and those using γ. Since the γ scale is much closer to the measured calibration points than the α scale as is evident from a comparison of Tables 1 and 2, and Figs. 5 and 6, we would place more weight upon the results using the γ thermometer. The results of the two series agree with each other above 3.7 K. The scatter of the present results is much smaller than that of the results by Blue and Giauque: at most ±3% at 4 K, ±1% at 10 K, ±0.1% above 20 K, and ±0.5% above 170 K where the vapor pressure of dinitrogen oxide becomes

significantly high.

Fusion. The curve of the heat capacity of solid dinitrogen oxide shows an upward trend near the triple point (see Fig. 7). However, fusion itself occurs over a narrow range of 0.002 5 K (see Table 6) and therefore the latent heat of fusion was determined in the ususal manner, excluding the premelting portion of the heat capacity. The two series of measurements of heat of fusion are summarized in Table 5 together with the value of Blue and Giauque.[2] The mean value of the heat of fusion of dinitrogen oxide obtained was 6 516±20 J mol^{-1}, which is considerably smaller than the value of Blue and Giauque.[2] The rather large uncertainty in the present value comes from an error in determination of the amount of specimen used in the calorimetry. The triple point temperatures and the amount of impurities were evaluated from fractional melting experiment (see Table 6). The triple point of pure dinitrogen oxide thus determined was 182.407±0.002 K, and the amount of liquid-soluble, solid-insoluble impurities was estimated as 0.001 mol%. The triple point of the dinitrogen oxide used in this calorimetry was 182.406±0.002 K.

Heat of Vaporization. The heat of vaporization of dinitrogen oxide was measured during the second series of calorimetry in the manner as described in the preceding section. The results are summarized in Table 7, showing higher precision than for the heat of fusion because of more precise determination of the amount of the specimen evaporated. The heat of vaporization of dinitrogen oxide was obtained as 16 544±20 J mol^{-1} at 184.81 K and 101.7 kPa, which is again smaller than the value of Blue and Giauque[2] but agrees within the combined limits of error.

Vapor Pressures. The vapor pressures of solid and liquid dinitrogen oxide were measured concurrently with the heat capacity measurements. The results given in Table 8 were fitted to the Antoine equation as follows by the method of least squares;

a) 146 K—182.4 K (triple point): solid

$$\log_{10}(P/\text{Pa}) = -1\,270.42/T + 8.955\,644 - 0.000\,941\,21\,T, \quad (5)$$

b) 182.4 K (triple point)—185 K: liquid

$$\log_{10}(P/\text{Pa}) = -886.293/T + 9.803\,215. \quad (6)$$

Deviations from Eqs. (5) and (6) are also included in Table 8. The normal boiling point of dinitrogen oxide was evaluated as 184.74 K from Eq. (6). From the temperature dependences of vapor pressure described above, the heat of vaporization can be obtained by Clapeyron-Clausius equation: $dP/dT=\Delta H_v/T\Delta V_m$. The results calculated by use of this formula agree with the heat of vaporization determined by calorimetry to within ±0.5%. The molar volume of the gas was evaluated by applying the correction for non-ideality using the second virial data.[10]

Thermodynamic Functions. The thermodynamic functions of dinitrogen oxide were calculated from the smoothed heat capacity values and other data described above and are given in Table 9. The contribution of the heat capacities below the lowest temperature 1.9 K was estimated by a smooth extrapolation, which however was negligibly small.

Analysis and Discussion

Orientational Disorder. The residual entropy is defined as the difference between the calorimetric and the statistical entropies and represents apparent failure of the third law of thermodynamics. The current interpretation of the residual entropy is based on one of three possibilities; (1) anomaly in the heat capacity exists below the lowest measured temperature, (2) degeneracies of the spin-rotation interaction are partially removed in the crystal lattice, and (3) the solid is in non-equilibrium state which is frozen-in at the lowest temperature attained.

Since Giauque *et al.*[1,2] reported the existence of residual entropy in carbon monoxide and dinitrogen oxide and presented an interpretation that the entropy arose from head-to-tail disorder of molecular arrangement, a number of papers were published to identify its origin with either (1) or (3). Thus, Melhuish and Scott[3] calculated electrostatic energies of some molecular crystals and suggested that the Curie temperatures for dipole orientation in CO and N_2O would be 5 and 11 K, respectively. Because these temperatures were lower than 15 K from which Giauque *et al.*[1,2] started heat capacity measurements, attempts were made to extend the measurements on CO to lower temperatures.[4,5] The results were, however, inconclusive; no additional phase transition was observed down to 2.5 K. Later experiments by Burford and Graham[7] went as far down as 0.8 K without detecting any anomalies either. Although there still remains a

possibility that the experimental temperatures were not low enough to see the removal of the residual entropy, odds are in favor of the 'freezing-in' interpretation. In the mean time, Pitzer *et al.*[6] considered the kinetics of the order-disorder transition in solid carbon monoxide by a tunneling mechanism and showed that the rate of transition was too small to produce a heat capacity anomaly.

The situation is quite analogous in the case of dinitrogen oxide which has a very small dipole moment of 0.55×10^{-30} Cm and the same crystal structure as the low-temperature form of carbon monoxide. Because the calculated Curie temperature of dinitrogen oxide was higher by a factor of 2, a greater chance was to be expected to observe a heat capacity anomaly. However, the experimental heat capacity curve is quite normal down to 1.9 K as shown in Fig. 7 and in the following section. We consider that this is due to 'freezing-in' of the end-for-end reorientational motion below the triple point partly because the potential barrier hindering such motion may be as high as 4000 K, as estimated from the libration frequency of 70 cm^{-1}, and partly because it would be hardly conceivable to be unable to find a rotational transition down to 1.9 K if we were dealing with the perfect equilibrium state.

The residual entropy	6.0 ±1.0
Blue and Giauque (1935)	$S_0°=4.8$

The residual entropy of dinitrogen oxide was re-evaluated by using the present calorimetric results and recent molecular constants. The details of calculation is given in Table 10 which gives $S_0=6.0\pm1.0$ J K^{-1} mol^{-1}, very close to $R\ln2=5.76$ J K^{-1} mol^{-1}. Therefore, it appears that molecular reorientation has become frozen somewhere between the triple point and 1.9 K but exactly where it occurs is not known. The measurements of heat capacity were carried out quite normally: Nowhere slow equilibration phenomenon was observed as was in the case of ice.[14]

Lattice Frequency Spectrum. Very little is known about the lattice frequency spectrum of molecular crystals having internal degrees of freedom. Simple ionic crystals (*e.g.* NaCl), covalent crystals (*e.g.* Ge), metals and other monatomic crystals (*e.g.* Ar) have been studied and the shape of their frequency spectra is rather well known. Molecular crystals may be characterized by small force constants for intermolecular interaction, compared with other types of solids. Such characteristics should manifest themselves in the vibrational spectrum of the solids. We shall examine this by an analysis of the low-temperature heat capacities through Debye temperature cruve and moments of lattice frequency spectrum of N_2O.

The Debye temperature curve converted from the measured heat capacity values for $5N$ degrees of freedom is given in Fig. 8. Very shallow, broad minimum is a feature of molecular crystals in contrast to the cases of ionic and covalent crystals. The feature should more clearly be seen by deriving the even moments $\mu_n(\nu)$ of the lattice vibration spectrum. To do this, contributions from translational modes of vibration were extracted from measured heat capacity values by subtracting intramolecular and libration contributions. Here we used frequency values 1 293, 590, and 2 240 cm^{-1} for intramolecular vibrations and 70 (E), 83 (T), and 126 cm^{-1} (T) for librations. The C_p–C_v corrections were negligibly small below 25 K. The procedure for calculating the moments were the same as in the previous paper.[8] Moments of different order n may be compared by deriving $\nu_D(n)$,

$$\nu_D(n)=\left[\frac{1}{3}(n+3)\mu_n\right]^{1/n} \quad (n>-3). \tag{7}$$

This is plotted as a function of n in Fig. 9. Points have also been included in Fig. 9 that correspond to $\nu_D(-3)$ (from $\Theta_0=141.0\pm1.0$ K), $\nu_D(0)$ (from $\Theta_\infty{}^S=141$ K), and $\nu_D(1)$ (from E_z; see following subsection). The ν_D functions for other values of n were not obtained because of poor convergence of expansion formulae. Figure 9 shows that there is a flat region for low n where there is a deep minimum in the case of NaCl or other strongly ionic crystals. This is the portion where contributions from low-frequency end of the spectrum are the largest. A difference in vibrational properties between ionic (covalent) and molecular crystals lies, therefore, in the fact that vibrational modes are more condensed into the low-frequency portion of the spectrum in molecular crystals.

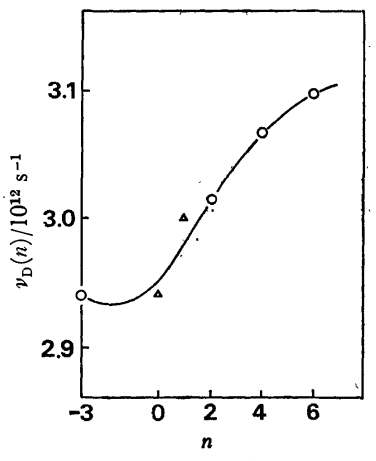

Fig. 9. Plot of $\nu_D(n)$ against n for solid dinitrogen oxide. △, from approximate calculation (see in text).

Zero-point Properties. Some of the properties of solid N_2O at 0 K will be summarized here.

Θ_0 was obtained from a plot of C/T^3 *vs.* T^2 as 141.0 ± 1.0 K for $3N$ degrees of freedom. If one uses 'translational' heat capacity curve for $5N$ degrees of freedom, Θ_0 becomes 167.4 ± 1.0 K.

Static lattice energy was derived by analysis of the vapor pressure data which were fitted to the formula[15]

$$\ln(PT^{3/2}) = (a/T) + b. \quad (8)$$

The static lattice energy E_0 is related to a through

$$aNk \doteq E_0' = E_0 - E_{z,\mathrm{lib}}, \quad (9)$$

where $E_{z,\mathrm{lib}}$ is the zero-point librational energy. The slope of a graph of $\ln(PT^{3/2})$ against T^{-1} gives E_0' a value of 25.91 kJ mol^{-1}. A small correction to this value must be made for the effect of defect formation in the neighborhood of the triple point,[15] which leads to a revised value of 26.0 kJ mol^{-1}. $E_{z,\mathrm{lib}}$ can be evaluated approximately from the librational frequencies as 1.15 kJ mol^{-1}; therefore $E_0=27.2$ kJ mol^{-1}.

The total zero-point energy E_z may be obtained as the difference between the static lattice energy E_0 and the heat of sublimation at 0 K which is 24.21 kJ mol^{-1}. Thus, $E_z=3.0$ kJ mol^{-1} of which 1.85 kJ mol^{-1} is the translational zero-point energy $E_{z,\mathrm{trans}}$. $E_{z,\mathrm{trans}}$ can also be obtained from $\nu_D(1)$. By smooth interpolation of Fig. 10, one obtains $E_{z,\mathrm{trans}}=1.34$ kJ mol^{-1} which is some 0.5 kJ mol^{-1} smaller but is in reasonable agreement with the value derived from E_0 and $\Delta H_v°$. The discrepancy probably comes from the uncertainty in the value of E_0.

Premelting Phenomenon. As is evident from Fig. 7, the heat capacity of solid N_2O tends to increase with a positive curvature from about 120 K to the triple point. We may call this phenomenon 'premelting' although it does not actually correspond to liquid formation. Similar tendency has been noted in a number of low-melting metals and some molecular crystals. It has been customary to account for the effect in terms of formation of vacancies in the crystalline lattice.

Other possibilities such as anharmonicity of the lattice vibration cannot be ruled out in general; but this is rather unlikely for the following reasons. Taking solid argon as an example, the anharmonicity, if any, appears in such a way that the heat capacity increases to a smaller extent than expected for a Debye solid, *i.e.*, the Debye temperature becomes gradually higher as the temperature is increased from about 40 K.[16] This means that the resultant heat capacity curve should never show a positive curvature after it has passed the Θ_D minimum. Moreover, the volume expansivity of argon shows the same trend as the heat capacity below the triple point. In the case of dinitrogen oxide, contributions from librational freedom of motion makes a similar analysis of the Θ_D curve much less meaningful but nevertheless it is quite reasonable to assume that some kind of defect formation is progressively excited as the triple point is approached.

Now by assuming that separated lattice imperfections are thermally created and their equilibrium concentration is determined by the Boltzmann factor, one obtains an excess ΔC_p of the heat capacity

$$\Delta C_p = \frac{\Delta H_s^2}{RT^2} \exp(\Delta S_s/R) \exp(-\Delta H_s/RT), \quad (10)$$

and the enthalpy of defect formation ΔH_s derived from a plot of $\log(T^2\Delta C_p)$ *vs.* $1/T$. The excess heat capacity was estimated by taking differences between the observed and the 'normal' heat capacity; the latter was obtained by smooth extrapolation from about 50 K upwards. The value of ΔH_s thus obtained is 10.8 ± 0.6 kJ mol^{-1}, corresponding to 45% of the heat of sublimation 24.2 kJ mol^{-1} at 0 K.

There is no direct experimental evidence that enables us to fix the type of imperfections. The equilibrium concentration of the imperfection at the triple point is only 2%; therefore very precise diffraction methods would only help to elucidate the nature of imperfections. The only clue we have at present is the magnitude of ΔH_s and its comparison with other relevant properties.

It is interesting to compare N_2O with iso-structural α-N_2 and α-CO. The low-temperature α-phase of nitrogen has an approximate space group Pa3 ($P2_13$ to be exact) and the α-phase of CO is also of Pa3. In this structure, the molecular centers are arranged at the lattice points of the fcc unit cell and the molecules are directed toward one of four equivalent body diagonals of the cell. By X-ray and nuclear quadrupole resonance studies of the high-temperature β-phase of N_2 (hexagonal), the molecules were shown to precess about the c-axis with an angle of precession 55°. This precession angle is exactly equal to the angle which a molecule makes with the c-axis in the α-phase. To visualize the mechanism of the phase transition at 35.61 K in N_2, the molecules undergo a precessional oscillation about the crystallographic axes and, as the temperature is increased, some molecules reorient themselves into another body-diagonal direction. In connection with such a phase transition, the heat capacity of nitrogen also shows an upward curvature below the transition point besides the similar phenomenon observed below the triple point.[17] An interpretation of the low-temperature tail of the transition is one by what might be called 'orientational defect', *i.e.*, some molecules are disoriented from their normal direction or some undergo reorientational motion. Application of Eq. (10) to the excess heat capacity of N_2 below its transition point leads to a value of 2 kJ mol^{-1} for the enthalpy of formation of an orientational defect. This value is not accurate because the heat capacity measurements were not closely spaced. However analogous treatment for the case of CO, for which more appropriate data are available,[4,5] gives $\Delta H_s=3$ kJ mol^{-1} or 38% of the heat of sublimation at 0 K.

We would thus like to propose that the pre-melting excess of heat capacity in N_2O mainly arises from thermal creation of orientational defects with the enthalpy of formation 10.8 kJ mol^{-1}. It is very likely that 'positional' defects or vacancies are also present at the same time, which probably accompany a heat effect of some 16 kJ mol^{-1} or more and are not seen in the present analysis.

For diatomic and pseudo-diatomic molecules, N_2, CO, and C_2H_2, the transition temperature T_c is determined by quadrupole interaction as inferred from close correla-

tion between T_c and Θ^2/R^5 where Θ is the molecular quadrupole moment and R is the nearest neighbor distance. In the case of triatomic molecules, N_2O and CO_2, repulsive interaction is so large as to push T_c to above the triple point but not too far above, because orientational disorder is in fact a pre-transition effect.

Magnetic Property and Electronic Structure of Tris(2,2′-bipyridine) Complexes of Manganese in Low Oxidation States

Motomichi INOUE, Ken-ichi HARA, Tatsuo HORIBA, and Masaji KUBO
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received June 7, 1974)

The magnetic susceptibilities of tris(2,2′-bipyridine)manganese complexes, $[Mn(bpy)_3]\cdot 2THF$ and $Li[Mn(bpy)_3]\cdot 4THF$ (THF: tetrahydrofuran), have been determined over a temperature range of 1.6—320 K. The susceptibility of $Li[Mn(bpy)_3]\cdot 4THF$ can be explained with a radical ion model, in which three 2,2′-bipyridine radical ions are coordinated to a manganese(II) ion. A similar model is applicable to $[Mn(bpy)_3]\cdot 2THF$ as well. The presence of antiferromagnetic interaction indicates the formation of a weak covalent bond between manganese and bipyridine. This can be elucidated consistently by the molecular orbital theory.

A number of the so-called zerovalent transition metal complexes of 2,2′-bipyridine, $[M(bpy)_3]$, have been prepared.[1] Varieties of experimental studies including those of magnetic moment,[1] ESR,[2] optical spectra,[3,4] and IR spectra[5] have been carried out on the complexes at room temperature in an attempt to obtain information about the valency of central metals. However, no definite conclusions have been obtained as yet. The temperature dependence of magnetic susceptibility is expected to give a valuable information about the oxidation state of central metals in these complexes. In our previous paper,[6] we have briefly reported that the magnetic susceptibility of $[Mn(bpy)_3]\cdot 2THF$ and $Li[Mn(bpy)_3]\cdot 4THF$ suggests the presence of a divalent manganese ion coordinated by 2,2′-bipyridine radical ions. In this paper, we present a more detailed discussion on the magnetic property and the electronic structure of the manganese complexes.

Experimental

The materials were prepared by methods reported by Herzog and Schmidt.[7,8] $[Mn(bpy)_3]\cdot 2THF$ was obtained from a tetrahydrofuran solution as deep brown needle crystals. Calcd: Mn, 8.2%; THF, 21.6%. Found: Mn, 8.0%; THF, 22.4%. The observed effective magnetic moment, $\mu_{eff}=4.1_3$ B.M. (290 K), of $[Mn(bpy)_3]\cdot 2THF$ agrees with the value, 4.1_0 B.M., reported for the crystals of $[Mn(bpy)_3]$.[7] Deep red crystals of $Li[Mn(bpy)_3]\cdot 4THF$ were separated from a tetrahydrofuran solution. Calcd: Mn, 6.7%; THF, 35.2%. Found: Mn, 6.3%; THF, 33.2%. The effective magnetic moment, $\mu_{eff}=3.6_3$ B.M., at 290 K agrees with the value, 3.7_1 B.M., described in the literature.[8]

The susceptibility was determined in the temperature range of 1.6—20 K by means of a Hartshorn bridge operating at 90 Hz with a field strength equal to about 10 Oe. Iron(III) alum was employed as a standard. Between 4.2 and 320 K, the susceptibility was determined by use of a magnetic balance already described.[9] The two different methods yielded data agreeing with each other within about ±2%. Each sample was sealed in a quartz cell with ambient helium because the compounds were very sensitive to atmospheric oxygen and moisture.

The molar susceptibilities were corrected for diamagnetic contributions (10^{-6} emu/mol) from 2,2′-bipyridine (−93) and THF (−55).[10] The contributions from manganese and lithium ions are negligible. The temperature-independent paramagnetism of manganese ions was disregarded because it is expected to be negligibly small in comparison with the observed susceptibility.

Results

Figures 1—4 show the observed susceptibility. The magnetic susceptibility of $Li[Mn(bpy)_3]\cdot 4THF$ does not obey the Curie-Weiss law in the temperature range investigated (see Fig. 1). On the other hand, that of $[Mn(bpy)_3]\cdot 2THF$ conforms to the Curie-Weiss law

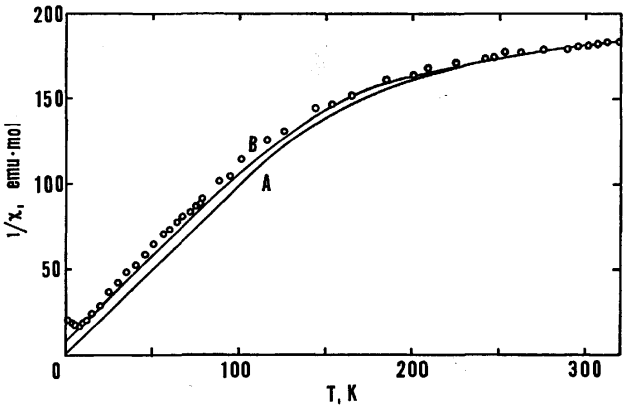

Fig. 1. Reciprocal magnetic susceptibility of $Li[Mn(bpy)_3]\cdot 4THF$. Curve A shows theoretical susceptibility calculated by Eq. (2) with $g=2.00$, $J/k=-180$ K, and $a=1.0$. Curve B represents susceptibility based on Eq. (6) with $g=2.00$, $J/k=-175$ K, $a=1.0$, and $\theta=-8$ K.

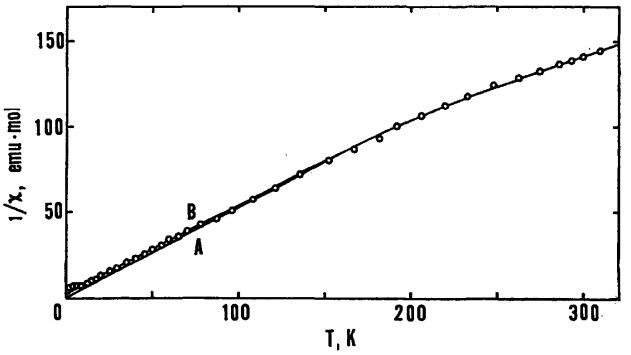

Fig. 2. Reciprocal magnetic susceptibility of $[Mn(bpy)_3]\cdot 2THF$. Curve A shows theoretical susceptibility calculated by Eq. (7) with $g=2.00$, $J/k=-200$ K, and $a=1.0$. Curve B represents modified susceptibility which takes into account magnetic interaction between complex molecules ($g=2.00$, $J/k=-200$ K, $a=1.0$, and $\theta=-4$ K).

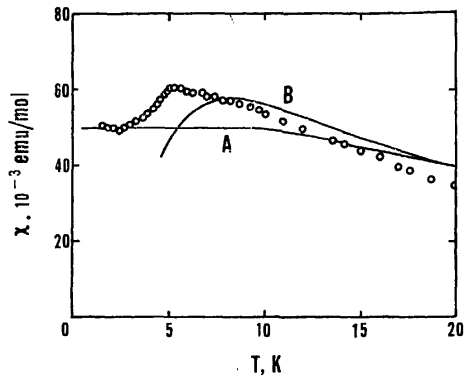

Fig. 3. Magnetic susceptibility of Li[Mn(bpy)$_3$]·4THF in a low temperature range and the theoretical susceptibility for the zero-field splitting. Curves A and B show the average susceptibility and the parallel susceptibility, respectively.

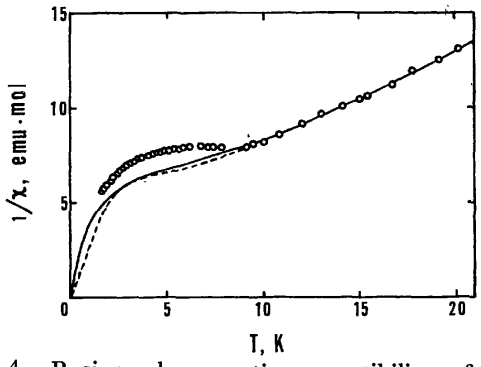

Fig. 4. Reciprocal magnetic susceptibility of [Mn(bpy)$_3$]·2THF in a low temperature range and the theoretical susceptibility for the zero-field splitting. The solid and broken curves show the average susceptibility and the parallel susceptibility, respectively.

fairly well between 20 and 160 K as is shown in Fig. 2. From the Curie constant, the magnetic moment was evaluated as $\mu=3.9$ B.M. It is noticeable that the susceptibility deviates from the Curie-Weiss law above about 160 K.

Discussion

The results of X-ray crystal analyses carried out on [Ti(bpy)$_3$], [V(bpy)$_3$], and [Cr(bpy)$_3$] have shown that each metal atom has a distorted octahedral coordination of six nitrogen atoms from three bipyridine molecules.[11] Therefore, the crystals of the manganese complexes are presumed to consist of discrete distorted octahedral units.

If the formula [Mn^{-1}(bpy^0)$_3$]$^-$ is assumed for Li[Mn(bpy)$_3$]·4THF, *i.e.*, if "excess electrons" are localized only on manganese, the central metal has a $3d^8$ configuration, in which a $^3A_2$ term lies lowest in an octahedral crystal field. The deviation from the Curie-Weiss law in the high temperature range cannot be explained theoretically on the basis of the crystal field, because the *g*-value of the $^3A_2$ term is independent of temperature. Interpretation is infeasible also by contribution from the temperature-independent paramagnetism given by $8N\beta^2/10Dq$.[12] Assuming that

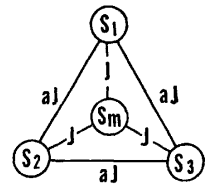

Fig. 5. Radical ion model. S_m and S_i ($i=1, 2, 3$) represent the spin quantum numbers of manganese and bipyridines, respectively. J and aJ denote exchange integrals.

$10Dq\sim7000$ cm^{-1}, the paramagnetism is roughly estimated to be 3×10^{-4} emu/mol. This value is too small to interpret the deviation from the Curie-Weiss law. For these reasons, we have proposed a radical ion model,[6] in which three bipyridine ions are coordinated to a divalent manganese ion instead of neutral ligands coordinating to a monovalent negative manganese (see Fig. 5). This model represents an extreme case of excess electrons distributed only on the ligands. For this model, the susceptibility can be derived from the following Hamiltonian,

$$\mathcal{H} = -2J\sum_{i=1}^{3}\mathbf{S}_m\cdot\mathbf{S}_i - 2aJ\sum_{\langle1,2,3\rangle}\mathbf{S}_i\cdot\mathbf{S}_j + g\beta\mathbf{H}(\mathbf{S}_m+\sum_{i=1}^{3}\mathbf{S}_i) \quad (1)$$

where apart from obvious notations, J and aJ represent exchange integrals and $\langle1,2,3\rangle$ denotes all pairs among $\mathbf{S}_1$, $\mathbf{S}_2$, and $\mathbf{S}_3$. Because $S_m=5/2$ in high spin manganese(II) complexes and $S_1=S_2=S_3=1/2$, the zero-field magnetic susceptibility is given by

$$\chi = \frac{2Ng^2\beta^2}{kT}\left[\frac{1+5x^4+10x^{7-3a}+14x^{10}+28x^{13-3a}+30x^{18}}{3+5x^4+10x^{7-3a}+7x^{10}+14x^{13-3a}+9x^{18}}\right] \quad (2)$$

where $x=\exp(J/kT)$. If the *g*-value is assumed to be equal to 2.00, the observed susceptibility can be reproduced by the theoretical equation with $a=1.0$ rather than with $a=0$ or 0.5 as reported in our previous paper.[6] Curve A in Fig. 1 represents the theoretical curve with $a=1.0$ and $J/k=-180$ K, showing a fairly good agreement with the observed data except for a low temperature range. Evidently, the disagreement is related to the anomaly at about 6 K. A broad maximum of susceptibility at the temperature (see Fig. 3) is attributable to a slight splitting of the degenerate ground level (triplet state) in a distorted coordination octahedron. The susceptibilities due to this zero-field splitting have been formulated as[13]

$$\chi_{\parallel} = \frac{2Ng_{\parallel}^2\beta^2}{kT}\left[\frac{\exp(-D/kT)}{1+2\exp(-D/kT)}\right] \quad (3)$$

$$\chi_{\perp} = \frac{2Ng_{\perp}^2\beta^2}{kT}\left[\frac{1-\exp(-D/kT)}{1+2\exp(-D/kT)}\right] \quad (4)$$

$$\chi_{av} = \frac{1}{3}(\chi_{\parallel}+2\chi_{\perp}) \quad (5)$$

where $\chi_{\parallel}$ and $\chi_{\perp}$ are the parallel and perpendicular susceptibilities, respectively, χ_{av} is the average susceptibility, and D denotes the zero-field splitting constant. Curve A in Fig. 3 shows χ_{av} calculated with $g=2.00$ and $D/k=40$ K. The curve exhibits no maximum and consequently does not explain the observed data. If only the parallel susceptibility is taken into account, the observed curve can be reproduced fairly

well by Eq. (3) with $g=2.00$ and $D/k=12$ K (see Fig. 3). An alternative explanation is conceivable for the behavior at about 6 K. The magnetic behavior might involve magnetic interaction between complex ions at very low temperature. If interaction between complex ions is much weaker than that within an ion, Eq. (2) can be modified as

$$\chi = \frac{2Ng^2\beta^2}{k(T-\theta)}[F(x)] \qquad (6)$$

where θ denotes the Weiss constant that takes into account the interaction between complex ions,[14] and $F(x)$ stands for the expression bracketed in Eq. (2). As shown in Fig. 1, curve B calculated by Eq. (6) with $g=2.00$, $J/k=-175$ K, and $\theta=-8$ K reproduces very well the observed curve at temperatures above about 6 K.

The magnetic moment, $\mu=3.9$ B.M., of $[Mn(bpy)_3]\cdot 2THF$ indicates that the ground state is a quartet ($\mu=3.87$ B.M.). When three bipyridine anions are coordinated to a manganese(III) ion ($S_m=2$ and $S_1=S_2=S_3=1/2$), a doublet state (1.73 B.M.) lies lowest in contradiction to the experimental result. If two bipyridine anions and a neutral bipyridine molecule are coordinated to a divalent manganese ion, *i.e.*; $S_m=5/2$, $S_1=S_2=1/2$, and $S_3=0$, the ground state is a quartet. In this case, the theoretical susceptibility is formulated as

$$\chi = \frac{Ng^2\beta^2}{4kT}\left[\frac{10+35x^5+35x^{7-2a}+84x^{12}}{2+3x^5+3x^{7-2a}+4x^{12}}\right] \qquad (7)$$

This formula reproduces the observed curve excellently with $g=2.00$, $J/k=-200$ K, and $a=1.0$ as shown in Fig. 2, except for a very low temperature range. If excess electrons are localized only on manganese, the metal has a $3d^7$ configuration, in which a $^4T_1$ level lies lowest in a weak octahedral field, whereas a ^2E level represents the gound state in a strong field. As the theoretical magnetic moment of the $^4T_1$ term shows temperature dependence owing to spin-orbit coupling,[15] it is possible to explain the observed curve qualitatively. However, the absolute value of the spin-orbit coupling constant, $\zeta=4170$ cm^{-1} ($\lambda=-1390$ cm^{-1}), for the best fit[6] is much greater than 239—402 cm^{-1} normally observed for manganese.[12] These suggest that the radical ion model is applicable to the so-called zero-valent manganese complexes as well. A magnetic anomaly appearing below about 10 K is due probably to the zero-field splitting of the ground level ($S=3/2$), which yields theoretical susceptibilities given by[13]

$$\chi_{\parallel} = \frac{Ng_{\parallel}^2\beta^2}{4kT}\left[\frac{1+9\exp(-2D/kT)}{1+\exp(-2D/kT)}\right] \qquad (8)$$

$$\chi_{\perp} = \frac{5Ng_{\perp}^2\beta^2}{4D}\left[\frac{1-\exp(-2D/kT)}{1+\exp(-2D/kT)}\right] \qquad (9)$$

The solid and broken curves in Fig. 4 represent the average susceptibility ($g=2.00$ and $D/k=10$ K) and the parallel susceptibility ($g=2.00$ and $D/k=4.8$ K), respectively; they show a good agreement with the observed curve. Magnetic interaction between complex molecules also may contribute to the aforementioned anomaly at low temperature. Equation 7 can be modified by introducing the Weiss constant in the same manner as for Eq. (6). Curve B in Fig. 2 shows modified susceptibility calculated with $g=2.00$, $J/k=-200$ K, and $\theta=-4$ K. It reproduces the observed curve excellently.

The radical ion model can explain the magnetic susceptibilities of the manganese complexes consistently, indicating that the excess electrons are localized for the most part on the ligands rather than on the central metal in agreement with the results of optical spectra.[3] However, the presence of antiferromagnetic interaction ($J<0$) suggests also the formation of weak covalent bonds between bipyridine anions and a manganese(II) ion. Therefore, the radical ion model has been treated by the molecular orbital theory for coordination compounds. The molecular orbital scheme has been proposed for tris(2,2'-bipyridine) complexes.[16,17] Figure 6 shows an energy diagram associated with 3d orbitals in a D_3 field. The bonding σ levels of the complex are completely filled with electrons from the σ orbitals of the ligands. When manganese in $[Mn(bpy)_3]^0$ is in a divalent high-spin state, the degenerate σ^* levels are occupied by two electrons from the $d\gamma$ orbitals of a manganese ion. The π level is filled with three electrons from $d\varepsilon$ orbitals of manganese and two electrons from the antibonding π orbitals of bipyridine ions, leading to a $\sigma^{12}\pi^5\pi^{*0}\sigma^{*2}$ configuration as shown in

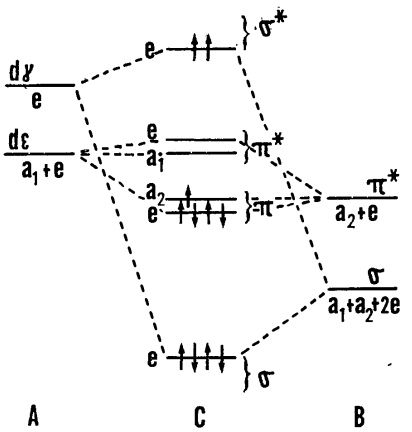

Fig. 6. Energy diagram of $[Mn(bpy)_3]^0$. A: 3d orbitals of a manganese ion. B: Combined orbitals of bipyridines. C: Molecular orbitals of the complex. The σ levels associated with the s and p orbitals of the metal are not shown.

Fig. 6. Because the π, π^*, and σ^* orbitals are orthogonal to one another, the ground state is a quartet ($\mu=3.87$ B.M.) in conformity with the observed magnetic moment. If the central metal has a valence of 3, the ground state has a $\sigma^{12}\pi^6\pi^{*0}\sigma^{*1}$ configuration ($\mu=1.73$ B.M.) in contradiction to the experimental result. A $\sigma^{12}\pi^6\pi^{*1}\sigma^{*0}$ configuration corresponding to a low-spin manganese(II) complex also conflicts with the observed moment. For the ground state having the configuration $\sigma^{12}\pi^5\pi^{*0}\sigma^{*2}$, the first excited state has a $\sigma^{12}\pi^4\pi^{*1}\sigma^{*2}$ configuration, which yields a total spin quantum number and degeneracy consistent with those derived from Eq. (1) for the radical ion model. The spin multiplicity of higher excited states also is in conformity with that for the radical ion model. In the molecular orbital

system of $[Mn(bpy)_3]^-$, the σ^* level is occupied by two electrons from the $d\gamma$ orbitals of a manganese(II) ion while the π level is filled with six electrons from the $d\varepsilon$ orbitals of manganese and the π^* orbitals of bipyridine ions, leading to a $\sigma^{12}\pi^6\pi^{*0}\sigma^{*2}$ configuration (μ=2.83 B.M.). Excited states, *i.e.*, $\sigma^{12}\pi^5\pi^{*1}\sigma^{*2}$ (S=2), $\sigma^{12}\pi^4\pi^{*2}\sigma^{*2}$ (S=3), and $\sigma^{12}\pi^3\pi^{*3}\sigma^{*2}$ (S=4), have magnetic moments and degeneracies consistent with those based on the radical ion model. Strictly speaking, energy separation between *a* and *e* levels should be taken into account. However, this does not affect essentially the foregoing discussion, especially when the energy separation is very small in comparison with the π-π^* separation.

As discussed above, the magnetic properties of the manganese complexes can be interpreted consistently by the molecular orbital theory as well as by the radical ion model involving antiferromagnetic interaction. This indicates that weak $d\pi$-π^* bonds are formed between manganese and bipyridine but that excess electrons are mostly localized in the antibonding π orbitals of bipyridine rather than in the orbitals of manganese. The π-π^* energy separation can be approximated with the value of $4|J|$ or $5|J|$ expressing an energy separation between the ground state and the first excited state in the radical ion model (see Eqs. (2) and (7)). The value may be nearly equal to an energy difference between the π^* of bipyridine anions and the $d\varepsilon$ of a manganese ion, because the π^* and $d\varepsilon$ orbitals are suspected to interact with each other only to a small extent.

The Estimation of Rate Constants in Systems of Linear and Nonlinear Differential Equations Using the Polynomial-approximated Least Squares-error and Iterative Search Technique

Katsutoshi OHKUBO, Hiroyuki SAKAMOTO, and Kohji TSUCHIHASHI

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received October 1, 1973)

A new technique is proposed for estimating the rate constants in systems of linear or nonlinear differential equations, using a polynomial approximation of the observed concentrations of species participating in the reaction and an iterative search technique. The method is implemented by minimizing the errors of the concentrations (of species), as computed by the theoretical equations derived from the linear differential equations or by the trapezoidal averaging simulation, relative to those calculated by the polynomial approximation. The present technique requires the concentrations (at the initial reaction stage) of s-2 species (the s species takes part in the reaction). Two kinetic example, A⇄B⇄C and S+E⇄ES→E+P, have been used to illustrate and develop the present technique.

The estimates of the rate constants in systems of linear or nonlinear differential equations have hitherto been performed by means of such numerical methods as the Runge-Kutta integration,[1] the Marquardt method,[2] and Taylor's series expansions.[3] These methods require, however, precision fits to very dense data and much computation time.

The new technique proposed in this paper is based on a polynomial-approximated least squares-error method and an iterative search technique. This technique for estimating the rate constants requires the time-dependence of the concentrations of species participating in the reaction. In order to illustrate and develop the present technique, the following two kinetic examples are used:

Example I

$$\mathrm{A} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{B} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \mathrm{C} \qquad (1)$$

The example depicted by Eq. (1) represents a reaction like the Cannizzaro reaction, which can be described by linear differential equations:

$$\mathrm{RCHO} \overset{\mathrm{OH^-}}{\rightleftharpoons} \mathrm{R\text{-}\underset{\underset{\mathrm{O^-}}{|}}{\overset{\overset{\mathrm{H}}{|}}{C}}\text{-}OH} \rightleftharpoons \mathrm{R\text{-}\overset{\overset{\mathrm{O}}{\|}}{C}\text{-}OH} + \mathrm{H^-} \qquad (1')$$

(R=alkyl group; OH^-=base catalyst)

Example II

$$\mathrm{S} + \mathrm{E} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES} \xrightarrow{k_3} \mathrm{E} + \mathrm{P} \qquad (2)$$

where S=substrate; E=enzyme; ES=enzyme-substrate complex, and P=product. The classical enzyme model depicted by Eq. (2) is used for a representative reaction described by nonlinear differential equations.

Method of Computation

First Example. The three-variable, four-rate constant isothermal model illustrated by Eq. (1) can be described by the following differential equations on the basis of the law of mass action:

$$\mathrm{d(A)}/dt = -k_1(\mathrm{A}) + k_2(\mathrm{B}) \qquad (\mathrm{A})_0 \neq 0 \qquad (3a)$$

$$\mathrm{d(B)}/dt = k_1(\mathrm{A}) - (k_2+k_3)(\mathrm{B}) + k_4(\mathrm{C}) \qquad (\mathrm{B})_0 = 0 \qquad (3b)$$

$$\mathrm{d(C)}/dt = k_3(\mathrm{B}) - k_4(\mathrm{C}) \qquad (\mathrm{C})_0 = 0 \qquad (3c)$$

where the parentheses denote the concentrations, typically in M units, and where the subscript zeros stand for the initial concentrations of the species.

The time dependence of (A), (B), or (C) is obtained from Eqs. (3a—c) as:

$$(\mathrm{A})_{t,\mathrm{calcd}} = k_2k_4(\mathrm{A})_0/b + C_1e^{\delta_1 t} + C_2e^{\delta_2 t} \qquad (4a)$$

$$(\mathrm{B})_{t,\mathrm{calcd}} = k_1k_4(\mathrm{A})_0/b - (C_1+C_2)e^{\delta_1 t} - (C_2+C_4)e^{\delta_2 t} \qquad (4b)$$

$$(\mathrm{C})_{t,\mathrm{calcd}} = k_1k_3(\mathrm{A})_0/b + C_3e^{\delta_1 t} + C_4e^{\delta_2 t} \qquad (4c)$$

where $\delta_1 = -a+\sqrt{a^2-b}$; $\delta_2 = -a-\sqrt{a^2-b}$; $a=(k_1+k_2+k_3+k_4)/2$; $b=k_1k_3+k_2k_4+k_1k_4$; $C_1=((k_2k_4-b)\delta_2-bk_1)(\mathrm{A})_0/b(\delta_1-\delta_2)$; $C_2=((b-k_2k_4)\delta_1+bk_1)(\mathrm{A})_0/b(\delta_1-\delta_2)$; $C_3=\delta_2k_1k_3(\mathrm{A})_0/b(\delta_1-\delta_2)$, and $C_4=\delta_1k_1k_3(\mathrm{A})_0/b(\delta_2-\delta_1)$.

Second Example. The classical enzyme model represented by Eq. (2) can be described by means of the following nonlinear differential equations:

$$\mathrm{d(S)}/dt = -k_1(\mathrm{S})(\mathrm{E}) + k_2(\mathrm{ES}) \qquad (\mathrm{S})_0 \neq 0 \qquad (5a)$$

$$\mathrm{d(E)}/dt = -k_1(\mathrm{S})(\mathrm{E}) + (k_2+k_3)(\mathrm{ES}) \qquad (\mathrm{E})_0 \neq 0 \qquad (5b)$$

$$\mathrm{d(ES)}/dt = k_1(\mathrm{S})(\mathrm{E}) - (k_2+k_3)(\mathrm{ES}) \qquad (\mathrm{ES})_0 = 0 \qquad (5c)$$

$$\mathrm{d(P)}/dt = k_3(\mathrm{ES}) \qquad (\mathrm{P})_0 = 0 \qquad (5d)$$

The trapezoidal averaging technique will no be adopted for solving Eqs. (5a—d). Three increments, $D(i)$ (i=1—3), are first defined as:

$$D(1) = k_1(\mathrm{S})(\mathrm{E})\Delta t; \quad D(2) = k_2(\mathrm{ES})\Delta t; \quad D(3) = k_3(\mathrm{ES})\Delta t \qquad (6)$$

The increments at the reaction time t, $D(i)_t$, are, then, defined by the use of those at $t-\Delta t$ and $t+\Delta t$, $D(i)_{t-\Delta t}$ and $D(i)_{t-\Delta t}$ respectively:

$$D(i)_t = (D(i)_{t-\Delta t}+D(i)_{t+\Delta t})/2 \quad (D(i)_{-\Delta t}=D(i)_0=0) \qquad (7)$$

where Δt indicates a very small time-interval. The average $D(i)$ values, $D(i)_{\mathrm{av}}$, are represented by:

$$\begin{aligned} D(i)_{\mathrm{av}} &= (D(i)_t+D(i)_{t+\Delta t})/2 \\ &= (D(i)_t+(2D(i)_t-D(i)_{t-\Delta t}))/2 \\ &= 1.5D(i)_t - 0.5D(i)_{t-\Delta t} \end{aligned} \qquad (8)$$

From Eqs. (5a—d), (6), and (8), the average increments of components (C_s) (s=number given for the component), $D(C_s)_{\mathrm{av}}$, are written by:

$$D(\mathrm{S})_{\mathrm{av}} = -D(1)_{\mathrm{av}} + D(2)_{\mathrm{av}};$$
$$D(\mathrm{E})_{\mathrm{av}} = -D(1)_{\mathrm{av}} + D(2)_{\mathrm{av}} + D(3)_{\mathrm{av}};$$
$$D(\mathrm{ES})_{\mathrm{av}} = D(1)_{\mathrm{av}} - D(2)_{\mathrm{av}} - D(3)_{\mathrm{av}};$$
$$D(\mathrm{P})_{\mathrm{av}} = D(3)_{\mathrm{av}} \quad (9)$$

The concentration of C_s at t, $(C_s)_{t,\mathrm{calcd}}$, is evaluated by means of:

$$(C_s)_{t,\mathrm{calcd}} = (C_s)_0 + \sum^{v} D(C_s)_{\mathrm{av}} \Delta t \quad (v\Delta t = t) \quad (10)$$

In the evaluation of the concentrations of the components participating in Reaction (1) or (2), the rate constants, k_i (i=1—4 in Reaction (1) and i=1—3 in Reaction (2)), are supplied by:

$$k_i = \min k_i + \sum^{m} 10^{(\gamma-\beta)} \min k_i, \quad \gamma = \mathrm{gauss}\left[\frac{m-1}{9\alpha}\right]$$
$$(m = 1, 2, 3, \cdots, \beta = 0, 1, 2, \cdots, \alpha = 10^{\beta}) \quad (11)$$

where min k_i=lower limit of k_i ($1.0\times10^{\delta}$; δ=integral constant); γ=integral number; β=integral constant; α=parameter determining the significant figures for k_i (*viz.*, k_i=(β+1) significant figures at $\alpha=10^{\beta}$). If the rate constant, k_i, is to be supplied in the range of 1.0×10^{-5}—1.0×10^{2} under the conditions of k_i=2 significant figures (β=1 and α=10), m=5400 is required, because $m=9\alpha$ can change the k_i value from $1.0\times10^{\delta}$ to $1.0\times10^{\delta+1}$. As a matter of course, the range of the value for each rate constant (k_i) can be controlled separately in compliance with the desired conditions.

On the other hand, the observed concentration of the s-th component at t, $(C_s)_{t,\mathrm{given}}$, is expressed by the following algebraic polynomial:

$$(C_s)_{t,\mathrm{given}} = a_n t^n + a_{n-1} t^{n-1} + \cdots + a_1 t + a_0 \quad (12)$$

where a_n (n=0, 1, 2, ···) denotes a coefficient. This polynomial approximation can be performed by the least squares-error analysis of the observed concentrations of C_n at t=0, 1, 2, 3, —, n (n corresponds to the n subscript of a_n in the highest order term of Eq. (12)).

The best set of rate constants is, then, selected from the set satisfying the following F function by means of the iterative search technique (see below):

$$\varepsilon_{p,s} = |(C_s)_{t,\mathrm{calcd}} - (C_s)_{t,\mathrm{given}}|/(C_s)_{t,\mathrm{given}} \quad (13a)$$

$$F = \text{minimize} \sum_{s=1}^{s-1} \sum_{p=1}^{p} \varepsilon_{p,s} \quad (13b)$$

where p is the number of the check points used for the calculation of the F function. In order to cancel the orders of the $(C_s)_{t,\mathrm{calcd}}$ and $(C_s)_{t,\mathrm{given}}$ values, the relative error defined by Eq. (13a) is more useful than the squares error under $(C_s)_{t,\mathrm{given}} \neq 0$. In the reaction system involving s components (s=1—3 in Reaction (1) or s=1—4 in Reaction (2)), the concentrations of the two components can be evaluated from the material balance.

The iterative search technique is carried out by the following procedure: one of the rate constants, k_j (j=1, 2, 3, ···, or j), is repetitively changed in turn with fixed $k_{i(i\neq j)}$ values (k_i=originally estimated or those assumed for the first run), until the set of k_i (i=1, 2, 3, —, and i) values which satisfy the condition described by Eq. (13b) is made identical. This technique requires about 20 s (by FACOM 230-60 computer) for the first example as the computation time for one iteration run under the conditions of p=1, i=4, m=5400, and α=100 (β=2).

In order to obtain reliable k_i values using the above iteration technique, the following factors should be taken into consideration:

(a) During each run of the iteration, the selected k_i group satisfying the F function should not include the lower or upper limit value of k_i. In order to avoid this problem, the k_i values should be supplied over a fairly wide range, or an automatic widening procedure for the range of k_i values should be included in the computation.

(b) If the preliminary estimate of k_i differs by 10^2 or more from the true values, the present technique requires two or three more iterations to obtain reliable values as compared with the case in which the orders of the k_i values are very close to the true ones. It is desirable, therefore, to estimate the order of k_i originally under the condition of the k_i=1 significant figure.

It should also be stressed here that check points ($p \geqq i$ are desirable) should be given at the initial early stage of the reaction, because the polynomials of Eq. (12) become more precise at $t\rightarrow0$:

$$\lim_{t\to0} \varepsilon_{p,s} = \lim_{\substack{n\to\infty \\ t\to0}} |(C_s)_{t,\mathrm{calcd}} - (C_s)_{t,\mathrm{given}}|/(C_s)_{t,\mathrm{given}} \approx 0 \quad (14)$$

However, the check point should not always be selected at an initial short time of the reaction, since the polynomials defined by Eq. (12), in which n is sufficiently large, can reproduce the time-conversion curve of $(C_s)_{t,\mathrm{given}}$ obtained from the experiments within the limits of experimental error. The accuracy of the rate constants estimated by the present technique is directly dependent on that of the polynomials and is almost independent of the check point number, so long as the check points ($p \geqq i$) are reasonably selected at suitable reaction times.

Computation Results and Discussion

First Example. Table 1 shows the given kinetic data obtained from Eqs. (4a—c) with the following specifications: k_1=0.3, k_2=0.1, k_3=0.6, k_4=0.2, $(\mathrm{A})_0$=10.0, and $(\mathrm{B})_0=(\mathrm{C})_0=0$. We will thus use the simulated concentrations as the given kinetic data, because we can easily compare the estimated rate constants ($k_{i,\mathrm{estimated}}$) with the originally known ones ($k_{i,\mathrm{given}}$) in order to check the accuracy of computations. Using the concentrations of C at t=0, 1, 2, 3, ···, n, the coefficients of a_n (n=0, 1, 2, ···, n) in Eq. (12) were evaluated by the least squares-error analysis. The time dependence of the $(C_s)_{t,\mathrm{given}}$ (s=3) values under n=2, 3, 4, 5, 6, and 10 is shown in Fig. 1. As Fig. 1 indicates, the higher the order (n) of the polynomial, the more precise the approximation becomes. Moreover, the check points should be taken from those near t=1.0, because the $(C_s)_{t,\mathrm{given}}$ (s=3) values are evaluated more accurately at $t\approx1.0$ (for instance, see Table 3). Therefore, we will use the $(C_s)_{t,\mathrm{given}}$ (s=3 and $0\lesssim t\lesssim1.0$) values evaluated by the following polynomial (n=10) approximation:

Table 1. Given kinetic data for first example

t[a)]	(A) $s=1$	(B) $s=2$	(C) $s=3$

29	0.77153	2.30807	6.92040
30	0.77096	2.30797	6.92106

a) Arbitrary time unit.

$$(C_s)_{t,\text{given}}(s=3) = 4.1951\times10^{-9}t^{10} - 2.7882\times10^{-7}t^{9} + 8.2055\times10^{-6}t^{8} - 1.4329\times10^{-4}t^{7} + 1.6659\times10^{-3}t^{6} - 1.3737\times10^{-2}t^{5} + 8.2424\times10^{-2}t^{4} - 3.5191\times10^{-1}t^{3} + 8.9409\times10^{1}t^{2} + 1.7822\times10^{-3}t + 3.6863\times10^{-8} \quad (15)$$

The $(C_s)_{t,\text{given}}$ values required in Eq. (13a) are supplied from those (at $t=0.7$, 0.8, 0.9, and 1.0) calculated by Eq. (15), and the check points, (p,t), are taken to be: $(p, t)=(1, 0.7)$, (2, 0.8), (3, 0.9), and (4, 1.0). Table 2 lists the $k_{i,\text{estimated}}$ values obtained from Eq. (15) and the following polynomial form of Eq. (4c):

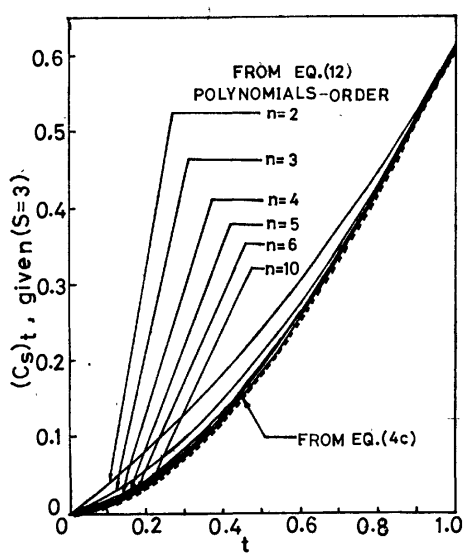

Fig. 1. Plots of $(C_s)_{t,\text{given}}$ $(s=3)$ *vs.* t.

$$(C_s)_{t,\text{calcd}}(s=3) = k_1k_3(\text{A})_0/b + C_3(1+\delta_1t+\delta_1^2t^2/2+\cdots+\delta_1^nt^n/n!+\cdots) + C_4(1+\delta_2t+\delta_2^2t^2/2+\cdots+\delta_2^nt^n/n!+\cdots) \quad (16)$$
$$(n=2, 3, 4, 5, \text{and } 6)$$

where the notations, b, C_3, C_4, δ_1, and δ_2, are the same as in Eq. (4c). We will here define the following series of errors, ε_k and $\varepsilon_{\max}$, in order to check the accuracy of estimated rate constants; they are also shown in Table 2:

$$\varepsilon_k = \sum_i\varepsilon_i = \sum_i|k_{i,\text{estimated}}-k_{i,\text{given}}|/k_{i,\text{given}} \quad (17)$$
$$(i=1, 2, 3, 4)$$

$$\varepsilon_{\max} = \sum_p\varepsilon_{p,3} + \sum_i\varepsilon_i \quad (18)$$
$$(p=1, 2, 3, 4;\ i=1, 2, 3, 4)$$

As can be seen from Table 2, the polynomials containing the high-order terms give reliable rate constants.

Let us compare the $k_{i,\text{estimated}}$ values given by Eq. (4c) with those given by Eq. (16) $(n=6)$ under the conditions of $(\text{A})_0=10.05$, and $(\text{B})_0=(\text{C})_0=0$ (the check points of (p,t) are the same as those mentioned above). The computation results are: $k_1=0.28$ (0.28); $k_2=0.046$ (0.050); $k_3=0.60$ (0.60); $k_4=0.20$ (0.20), and $\sum_p\varepsilon_{p,3}(\%)=0.844$ (0.922), where the values in parentheses are those evaluated by means of the polynomial $(n=6)$ of Eq. (16). Thus, both method give almost

a) $\Delta t=0.10$

the same estimates for the rate constants.

Second Example. The given kinetic data, such as the $(C_s)_{t,\text{given}}$, for the classical enzyme model were also simulated with the specifications of $(S)_0=1.00$, $(E)_0=0.10$, $k_1=k_2=k_3=1.0$, and $\Delta t=0.10$ (shown in part in Table 3). In this section, we will try to estimate the best set of rate constants using only the concentrations of the product (P). The coefficients (a_n) of Eq. (12) were estimated similarly by means of least squares-error analysis of the (P) values at $t=0$, 1, 2, 3, —, and n. Table 3 lists the $(C_s)_{t,\text{given}}$ $(s=4)$ values $(0\leqq t\leqq 1.0)$ as evaluated by the polynomial functions $(n=1$, 2, 3, 4, 5, 6, and 10). As can be seen from Table 3, the lower the order (n) of the polynomial term, the more markedly the $(C_4)_{t,\text{given}}$ values differ from those of the simulation. It is also noticeable that the $(C_4)_{t,\text{given}}$ values become inaccurate as $t\to 0$, because the rate of the formation of P, $(d(P)/dt)_t$ does not increase monotonously during the initial short stage (*i.e.*, $(d(P)/dt)_{t\ 0}\simeq 0$). Therefore, we will use the $(C_4)_{t,\text{given}}$ values at $t=0.8$, 0.9, and 1.0 for computing the $\varepsilon_{p,s}$ $(s=4)$ values: that is, the check points, (p,t), are taken to be $(p,t)=(1, 0.8)$, $(2, 0.9)$, $(3, 1.0)$. Then, we will estimate the best sets of the k_i group using the $(C_4)_{t,\text{given}}$ values as evaluated by means of the polynomials $(n=1$—$10)$ and the $(C_4)_{t,\text{calcd}}$ values given by the trapezoidal simulation. Thus, the method of the k_i estimation in the Second Example is different from that in the First Example.

The iterative search technique gives the $k_{i,\text{estimated}}$ values for Second Example shown in Table 4. It may be seen from Table 4 that the higher the order of the polynomials used for the $(C_4)_{t,\text{given}}$ evaluation, the lower the errors of $\sum_p \varepsilon_{p,4}$ and ε_k. It may be deduced, therefore, that the accuracy of the $(C_4)_{t,\text{given}}$ values presented in Table 3 directly influences the estimation of the best k_i values.

The present technique used for Second Example can now be shown to be useful for estimating the rate constants in more detail.

In order to check the variation in the k_i estimation with the change in the initial specifications, such as, the concentrations of species and the Δt value,[4] the estimates of the rate constants were performed again with the specifications of $(S)_0=1.01$, $(E)_0=0.1$, and $\Delta t=0.10$, using the $(C_4)_{t,\text{given}}$ values $(t=0.8$, 0.9, and 1.0) obtained from the polynomial $(n=10)$ in Table 3. The computed results are: $k_1=1.0$, $k_2=1.0$, $k_3=$

The Crystal Structure of the 2:1 Complex of Pyromellitic Dianhydride with *trans*-4-Methylstilbene

Toshiko KODAMA and Shigekazu KUMAKURA*

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received December 26, 1973)

The 2:1 complex of pyromellitic dianhydride with *trans*-4-methylstilbene crystallizes in the Cc space group with four pyromellitic dianhydride molecules and two *trans*-4-methylstilbene molecules in a unit cell with dimensions of $a=12.780$, $b=7.446$, $c=15.050$ Å, and $\beta=91.09°$. In addition to the clearly-defined Laue spots, diffuse streaks elongated perpendicular to the molecular layers were observed with a half period of the b^* axis of the reciprocal lattice. The structure was solved from a three-dimensional $|E|^2$ Patterson synthesis and was refined by a block-diagonal least-squares method to the final R value of 0.13 for the visually-estimated 703 reflections. Refinement was difficult, however, because of the large correlation between parameters caused by the disorder. The crystal is built up of molecular layers stacked parallel to the $(10\bar{2})$ plane and is disordered in the stacking arrangement of the molecular layers. The pyromellitic dianhydride molecule and one of the benzene rings of the *trans*-4-methylstilbene molecule are alternately stacked plane-to-plane in infinite columns along $[10\bar{2}]$. The ethylene group of the *trans*-4-methylstilbene molecule joins the two columns. The molecular arrangement of the component molecules resembles those observed in the anthracene, pyrene, and perylene complexes with pyromellitic dianhydride and presents a striking contrast to that of the *trans*-stilbene complex. The interplanar distances range from 3.25 to 3.56 Å, smaller than that of the *trans*-stilbene complex.

The crystal structure of the equimolar charge transfer (CT) complex between pyromellitic dianhydride (PMDA) and *trans*-stilbene (STB) has been determined.[1] The crystal-structure analysis of the 2:1 pyromellitic dianhydride-*trans*-4-methylstilbene (ME-STB) complex was undertaken in order to study the CT interaction by comparing the molecular arrangement of the donor and acceptor molecules with those of a series of complexes of PMDA.[1-3]

Experimental

Red crystals of the complex grown from an ethyl acetate solution were kindly supplied by Professor Taku Matsuo of Kyushu University. The crystals cleave easily into thin plates and are sensitive to atmospheric moisture. The crystals are monoclinic, and the systematic absences, hkl (when $h+k$ is odd) and $h0l$ (when l is odd), are consistent with the C2/c or Cc space group (Cc was proved to be the true space group at a stage of the refinement). The lattice parameters were determined from zero-layer back-reflection Weissenberg photographs around the b and c axes. The crystal density was determined by flotation in trichloroethylene-chloroform mixture. The crystal data are:

$C_{15}H_{14}\cdot 2C_{10}H_2O_6$ F.W.=630.5

Monoclinic

$a = 12.780 \pm 0.008$ Å

$b = 7.446 \pm 0.005$ Å

$c = 15.050 \pm 0.004$ Å

$\beta = 91.09 \pm 0.04°$

$U = 1432$ Å^3

$D_m = 1.48$ g·cm^{-3}

$z = 2$

$D_x = 1.48$ g·cm^{-3}

Space group: Cc

On oscillation photographs around the b axis, well-defined sharp spots appeared in the k th layer lines ($k=0, 1, 2, \cdots$), whereas diffuse spots drawn out into streaks perpendicular to the b^* axis appeared in the $k+1/2$th layer lines, as is shown in Fig. 1. From Weissenberg photographs around the b axis (Fig. 2), the streaks were found to be elongated along $[10\bar{2}]$ in the reciprocal space.

The specimens with dimensions of $0.15\times0.23\times0.11$ mm and $0.17\times0.21\times0.13$ mm were used for the intensity measurements around the b and c axes respectively. The intensity data were recorded on multiple-film equi-inclination Weissenberg photographs around the b axis up to the 5th layer and around the c axis up to the 10th layer using Cu$K\alpha$ radiation. The intensities were estimated visually by a comparison with a time-calibrated intensity strip prepared from a well-defined sharp spot. 703 independent reflections were collected. The usual Lorentz, polarization, and spot shape correc-

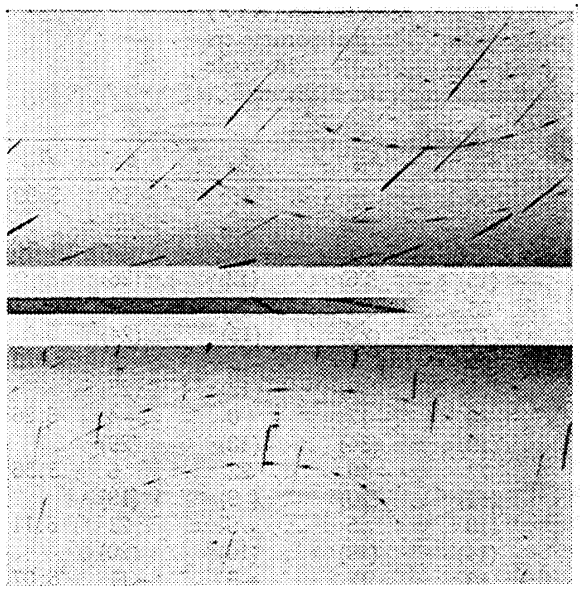

Fig. 2. Weissenberg photograph of the 3/2th layer around the *b* axis taken by the equi-inclination method using Cu$K\alpha$ radiation

tions were applied, but the absorption correction was neglected in view of the small size of the specimens.

Structure Determination

The layer structure of molecules parallel to $(10\bar{2})$ was indicated by the characteristic features that the cleavage plane is $(10\bar{2})$ and that the $20\bar{4}$ reflection and its higher-order reflections give strong X-ray intensities with thermal diffuse scattering and fall off uniformly in intensity. An $N(z)$ test based on the $h0l$ reflections indicated the crystal structure to be hypercentric. Therefore, the C2/c space group was assumed. Since only four PMDA molecules and two ME–STB molecules exist in a unit cell, they must be located at some kind of special positions.

A three-dimensional Patterson synthesis using $|E|^2$ as the coefficient was calculated using the complete set of observed data. The structure of the PMDA molecule was found to have a center of symmetry, thus accounting for the predominant peaks. The atomic coordinates of the PMDA molecule thus determined, combined with appropriate individual isotropic temperature factors, gave an R value of 0.45 for all the reflections.

A Fourier synthesis showed the ME–STB molecule to be located along the two-fold axis parallel to the *b* axis and to extend over a range of twice the *b* length-that is, over the twice repetition unit $b'=2b$ along the *b* axis; in other words, the two benzene rings of the ME-STB molecule were found to be overlapped at the same area in a scale of *b* units. It is necessary to measure the intensities of the diffuse reflections in order to determine the structure of the true unit cell of the crystal, but we did not undertake to do so because of the many atomic parameters in comparison with the small number of diffuse reflections and because of the poor quality of the crystals. Therefore, the average structure in the scale of *b* units along the *b* axis was determined in the present work. Assigning the C2/c space group to the crystal, the asymmetric unit of the structure consists of one-half of a PMDA molecule and a quarter of a ME–STB molecule. In the ME–STB molecule there is only one methyl group attached to the C(4) or the C(4′) position, so a quarter of a ME–STB molecule is a quasi-asymmetric unit.

After another Fourier synthesis, the atomic coordinates were refined by means of the block-diagonal least-squares procedure using a program written by Dr. Ashida. The structure data based on the C2/c space group gave an R value of 0.23. The difference synthesis showed several extra peaks around the benzene ring of the ME–STB molecule. Therefore, refinement based on the Cc space group, starting from a model with two independent benzene rings, was carried out; an R value of 0.15 was thus obtained. Since the R value was significantly lower, and since only simple patterns with low peak heights appeared on the difference synthesis, Cc was found to be the correct space group. Because of the parameter interaction, the positional and thermal parameters of one benzene ring of the ME–STB molecule were fixed, while those of the other were refined at each stage of the refinement. After three cycles of refinement using anisotropic temperature factors, the R value was lowered to 0.118, but there were several absurd bond lengths, from 1.1 to 1.6 Å, in the benzene rings of the ME–STB molecule. At each stage of the refinement, the R value shifted up and down. Therefore, refinement was done again by adjusting the positional parameters so as to give plausible bond lengths before each cycle of refinement. The R value gradually fell to 0.13. The weighting scheme for the least-squares procedure was: 0.5 for $|F_o|<5.0$ and 1.0 for $|F_o|\geq 5.0$. The topography of the final difference synthesis is flat within the range of ± 0.7 eÅ^{-3}. The final atomic and thermal parameters are listed in Table 1. A complete list of the observed and calculated structure factors is deposited at the Chemical Society of Japan.[4] The atomic scattering curves were taken from the International Tables for X-ray Crystallography.

Description and Discussion of the Structure

Crystal Structure. The projection of the structure viewed along the *a* axis is shown in Fig. 3. One of the possible positions of the methyl carbon atom is indicated by dotted lines. In view of the stacking disorder to be described later, it seemed that the position is on either the C(7) or the C(7′) position. The crystal is built up of molecular layers stacked parallel to $(10\bar{2})$. The component molecules are alternately stacked plane to plane in infinite columns along $[10\bar{2}]$. Each unit of the structure, namely, a PMDA molecule or one half of a ME–STB molecule, is surrounded by six others in a quasi-hexagonally close-packed array.

The molecular arrangement and intermolecular contacts of the component molecules in the column are shown in Figs. 4 and 5. The arrangement is quite

TABLE 1. FINAL ATOMIC COORDINATES ($\times 10^4$) AND THERMAL PARAMETERS ($\times 10^4$) (Estimated standard deviations are shown in parentheses. Thermal parameters are in the form of $\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+hk\beta_{12}+hl\beta_{13}+kl\beta_{23})]$. Isotropic temperature factors equivalent to the given anisotropic temperature factors, B_{eq}, are also shown in the last column.)

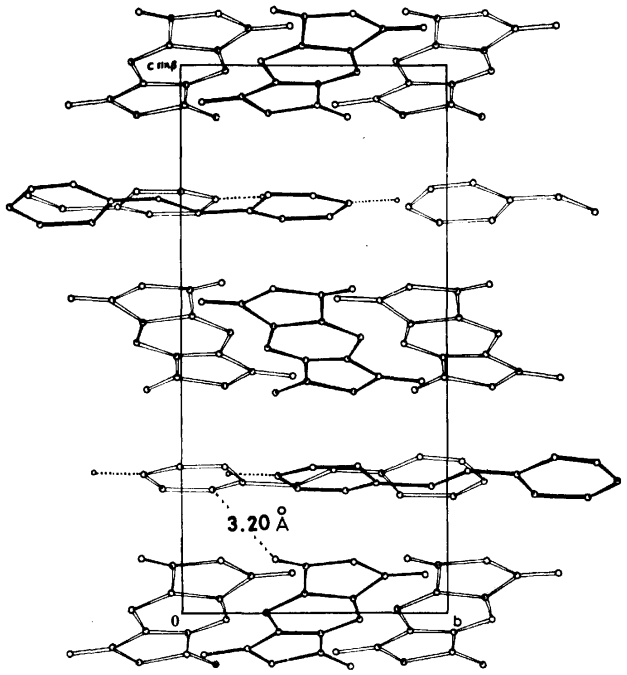

Fig. 3. The projection of the crystal structure viewed along the *a* axis. The molecules in thick lines are related to those in thin lines by the symmetry operation of C-face center.

different from that of the STB complex,[1] which is shown in Fig. 6. The long axes of the component molecules are perpendicular to each other in the ME–STB complex, whereas they are parallel in the STB complex. Thus, the molecular arrangement of the component molecules was shown to be easily

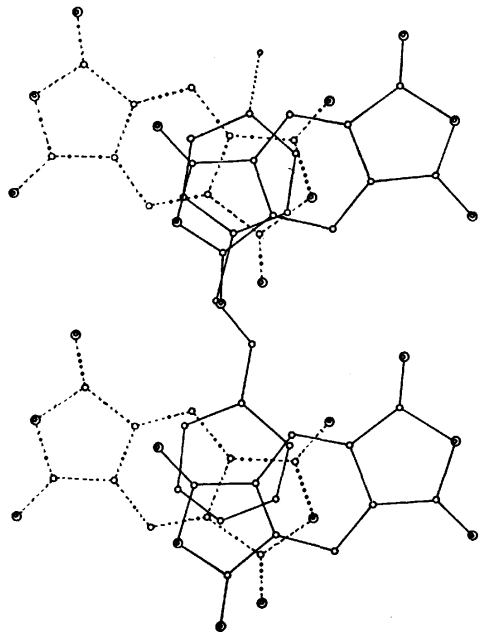

Fig. 4. The molecular arrangement of the component molecules of the PMDA-ME-STB complex projected perpendicular to the plane ($10\bar{2}$). The benzene ring planes of the ME-STB molecule contact the PMDA molecules in solid and dotted lines on both sides.

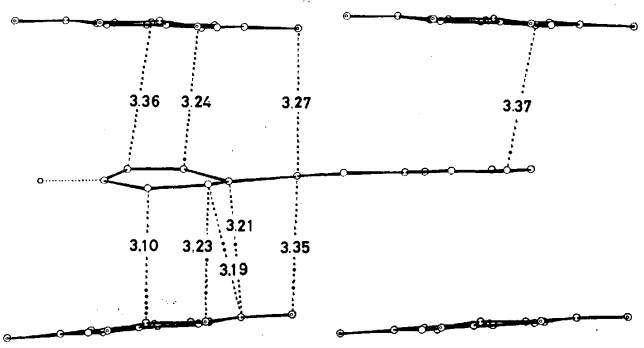

Fig. 5. Intermolecular contacts between PMDA and ME-STB with intermolecular distances shorter than 3.40 Å in Å units.

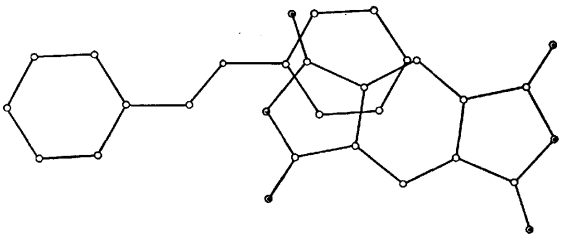

Fig. 6. The molecular arrangement of the component molecules of the PMDA-STB complex.

changed in the crystalline state by the slight geometrical difference between the ME–STB and the STB molecules. The difference in the molecular ratio of the component molecules between the 2:1 PMDA–ME–STB complex and the equimolar PMDA-STB complex corresponds to the difference in the molecular stacking; in the ME–STB complex both sides of the benzene ring planes of the ME-STB molecule are in contact with PMDA molecules, whereas in the STB complex only one side of the ring is in contact with a PMDA molecule. Because of the distinct difference in the overlapping geometry, the stacking axis of the component molecules is approximately perpendicular to the PMDA plane in the ME–STB complex, but is inclined about 39° against the PMDA plane in the STB complex. The ethylene group of the ME-STB molecule

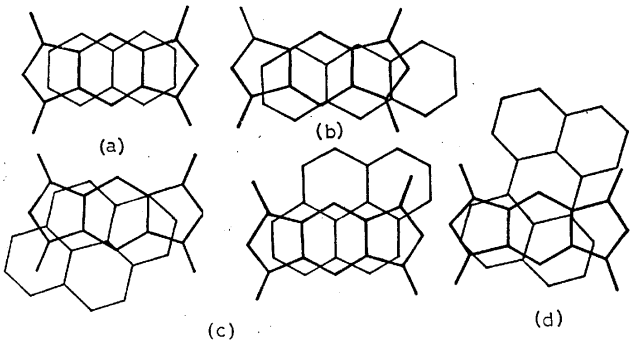

Fig. 7. The molecular arrangements of the component molecules of the complexes of PMDA with (a) naphthalene,[6] (b) anthracene,[2] (c) pyrene,[3] and (d) perylene.[2] Two independent molecular arrangements exist in PMDA-pyrene complex as shown in the figure.

of the ME-STB complex lies halfway between two columns and joins them, but that of the STB molecule of the STB complex lies within a column.

No theoretical consideration of the molecular arrangement of the component molecules of a series of CT complexes containing PMDA as an acceptor has hitherto been reported, but considerations of complexes containing maleic anhydride as an acceptor have been reported by Kobayashi *et al.*[5] The most stable molecular arrangements predicted in view of the CT interaction are consistent with those experimentally found in complexes of PMDA with perylene[2] and pyrene[3] (as is shown in Fig. 7). In view of the CT interaction, the molecular arrangement of the ME-STB complex seems to be more stable than that of the STB complex.

The PMDA molecule is planar within the maximum deviation of 0.007 Å of the atoms from the mean molecular plane. Moreover the benzene ring plane formed by C(1),···C(6) and that formed by C(1'),··· C(6') of the ME-STB molecule are planar within the maximum deviations of 0.01 and 0.06 Å respectively. The three molecular planes are expressed by the following equations, in the order mentioned above:

$$0.416x - 0.071y + 0.907z = 0.024 \quad (1)$$

$$0.41x - 0.01y + 0.91z = 3.39 \quad (2)$$

$$0.27x + 0.03y + 0.96z = -3.56 \quad (3)$$

where x, y, and z are coordinates (in Å) with respect to the a, b, and c crystal axes respectively. The (2) plane makes angles of 4.1 and 4.4° with the planes of the PMDA molecules within a column, with the average interplanar distances of 3.42 and 3.41 Å. The (3) plane makes angles of 10.7 and 9.7° with the planes of the PMDA molecules within a column, with the average interplanar distances of 3.52 and 3.56 Å.

The average intermolecular distances, the angles between the overlapping planes, and the C=O bond lengths of the CT complexes containing PMDA as an acceptor are shown in Table 2. The average intermolecular distance between the component molecules of the STB complex is the longest. The C=O bond lengths of a series of the complexes containing PMDA as an acceptor seem to tend to be shorter as the average intermolecular distances between the component molecules become longer.

The bond lengths and angles of the component molecules are shown in Figs. 8 and 9; they are also listed, along with the standard deviations, in Table 3. The ME-STB molecule is not planar, and the two benzene rings of the ME-STB molecule are twisted

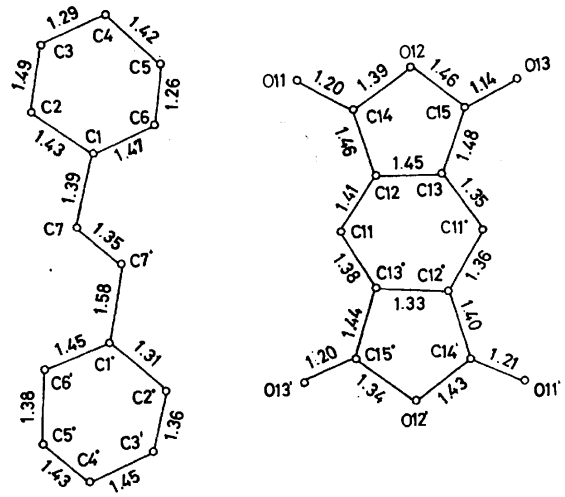

Fig. 8. Bond lengths (Å).

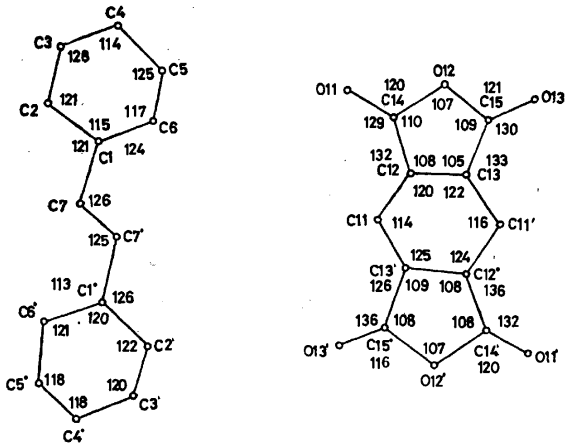

Fig. 9. Bond angles (degrees).

with an angle of 9°. A detailed structural discussion of the component molecules cannot be done because of the large standard deviations.

Description of the Disordered Crystal Structure. The observed diffuse reflections with indices of $k+1/2$ are elongated along [10$\bar{2}$]; that is, they are perpendicular to the molecular layers. Therefore, they can be explained if we assume that the stacking sequence of the molecular layers contains such mistaken layers that are shifted from the normal positions by half the $b'(b'=2b)$ axis. One of the models of the disordered crystal structure of this complex is shown schematically in Fig. 10. Although the inter-layer arrangement of the component molecules remains practically unchanged,

and although, moreover, the PMDA molecules are stacked regularly, the ethylene groups of the ME–STB molecules are randomly exchanged by the methyl groups and the hydrogens attached to C(4) of the neighboring ME–STB molecules. Since approximately equal electron densities were observed at the C(7) and C(7′) positions, the –CH=CH– ethylene groups are probably exchanged not only by the $-CH_3\cdots H-$ atomic groups, but also by the $-H\cdots CH_3-$ atomic groups which correspond to the upside-down arrangement of the ME–STB molecules. Such a random arrangement is probable because the forces between the layers are weaker than the forces within each layer and because the sizes of the –CH=CH– and $-CH_3\cdots H-$ atomic groups are similar. Such a geometric resemblance is considered to play an important role in the present type of disorder. No similar type of disorder was observed in the crystal of the PMDA–STB complex, which possesses no methyl group.

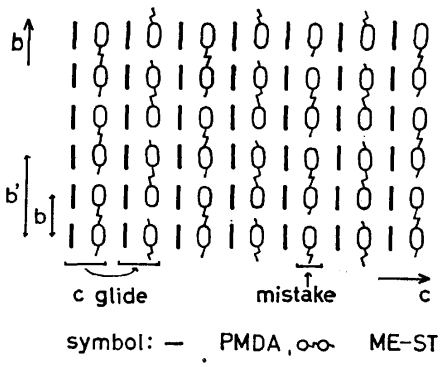

Fig. 10. Diagram showing the arrangement of molecules parallel to (100) described one of the models of the disordered structure.

The calculations were carried out on the HITAC 5020E computer at the Computer Centre of the University of Tokyo. The authors wish to express their thanks to Professor Yoshihiko Saito, the University of Tokyo, and Professor Fumiyuki Marumo, Tokyo Institute of Technology, for their helpful discussions.

The Protonation of the TCNQ Anion Radical by Hydrogen Chloride

Akihiko YAMAGISHI and Masahiro SAKAMOTO*

Department of Chemisty, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 5, 1974)

The kinetics of the protonation of sodium salt of 7,7,8,8-tetracyanoquinodimethane (Na^+TCNQ^-) by hydrogen chloride in alcohols and acetonitrile was investigated, using a stopped-flow apparatus. In methanol, the protonation rate is first-order in HCl and second-order in Na^+TCNQ^-, while in ethanol, the rate is one-half-order in HCl and second-order in Na^+TCNQ^-. The protonation rate in acetonitrile is first-order in HCl, but it deviates from second-order in Na^+TCNQ^-. These results are interpreted in terms of the rapid formation of a protonated intermediate in the initial stage of the reaction, according to $TCNQ^- + H^+ \rightleftharpoons HTCNQ\cdot$. The reversibility of this reaction is well demonstrated by the second-order dependence of the rate on Na^+TCNQ^-. The rate is also compared with the protonation rate of semiquinones, such as sodium salts of *p*-chloranil and 2,3-dicyano-1,4-benzoquinone, from the view point of the difference in reactivity between carbon and oxygen acids.

The kinetics of the protonation of aromatic radical anions by alcohols or water has been studied by several research groups.[1-5] Radical anions are protonated according to this stoichiometry:

$$2Ar^- + 2ROH = ArH_2 + Ar + 2RO^- \quad (1)$$

in which ArH_2 is the dihydroproduct of the parent hydrocarbon. On the basis of this stoichiometry, this mechanism of the protonation reaction was proposed by Paul, Lipkin, and Weissman:[6]

$$Ar^- + ROH \longrightarrow ArH\cdot + RO^- \quad (2)$$

$$ArH\cdot + Ar^- \longrightarrow ArH^- + Ar \quad (3)$$

$$ArH^- + ROH \longrightarrow ArH_2 + RO^- \quad (4)$$

The protonation of sodium naphthalenide (Na^+N^-) by water in tetrahydrofuran (THF) was found to proceed through this mechanism.[1] It implies that the proton-transfer reaction (2) is followed by the rapid electron-transfer reaction (3) due to the electron-accepting property of NH· being higher than N^-. There are, however, many aromatic radical anions whose protonations do not follow the above mechanism. Studies of the protonation of sodium perylenide (Na^+Pe^-) in THF by alcohols have revealed that the species to be protonated is a dianion, $2Na^+Pe^{2-}$, instead of Na^+Pe^-, although the dianion is present in a small amount. In the protonation of sodium and potassium anthracenides (Na^+A^- and K^+A^-) by alcohols in THF and dimethoxyethane (DME), the nature of the ion pairs profoundly affects their reactivity of protonation.[4,5] Protonation by methanol and ethanol proceeds through the protonation of Na^+A^- and K^+A^-. On the other hand, the participation of dianion of anthracene, $2Na^+A^{2-}$, is observed in the protonations by *t*-BuOH. In a word, the solvation and reduction states drastically affect the reactivity of the anion radicals and determine the main reaction paths.

Our work, described in this paper, is concerned with the protonation reaction of the 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical by hydrogen chloride in alcohols and acetonitrile. $TCNQ^-$ is a weaker base than the ion radicals as has been mentioned above, it is stable in protonic solvents like alcohols and water. The first point we focus our attention on is the reversibility of Reaction (2). We expect that $TCNQ^-$ accepts a proton reversibly because of its weak basicity. The reversibility of Reaction (2) enables us to estimate the thermodynamically-defined basicity strength of $TCNQ^-$. The second point is to obtain the rate constant of Reaction (2) in order to compare it with the rate constants of the protonation of semiquinones. $TCNQ^-$ seems to accept a proton on a carbon atom,[7] while semiquinones are protonated on oxygen atoms, leading to hydroquinones. As far as diamagnetic molecules are concerned, it has been reported in several examples that the limiting rate of proton transfer to carbon acids is generally below the diffusion-controlled limit characteristic of oxygen and nitrogen acids.[8-10] We attempted to examine the validity of this rule in the scope of radical anions.

Experimental

Na^+TCNQ^- was prepared by reducing TCNQ with NaI in acetonitrile. The salt was dried *in vacuo*. Sodium salts of *p*-chloranil (QCl_4) and 2,3-dicyano-1,4-benzoquinone ($Q(CN)_2$) were prepared in a similar way. *p*-Phenylenedimalononitrile (H_2TCNQ) was prepared from Na^+TCNQ^- according to Method C as described by Acker and Hertler.[7] Tetraethylammonium chloride of a C.P. grade was used without purification. The methanol (MeOH) and ethanol (EtOH) were purified by distillation in the presence of CaO, using about a 30 cm distillation column. The acetonitrile (MeCN) was distilled after refluxing in the presence of P_2O_5 and K_2CO_3 successively. The water contents were determined by the Karl Fischer method; 0.5 mg/ml (MeOH), 4.3 mg/ml (EtOH) and 0.3 mg/ml (MeCN). Dried hydrogen chloride gas evolved by the reaction between concentrated sulfuric acid and concentrated hydrochloride acid was absorbed into these solvents. Stock solutions of these acid solutions (about 0.1 M) were kept in a refrigerator. The concentration of HCl was determined by titration with an 0.1 M NaOH aqueous solution.

The reaction was studied at 25 °C, utilizing a rapid-scan stopped-flow spectrophotometer, Union Giken Model 1300. The reaction was investigated under air dried by $CaCl_2$ and P_2O_5 successively. The progress of protonation was usually monitored by the absorbance at 840 nm (λ_{max} of Na^+TCNQ^-).

Results

Stoichiometry of the Protonation Reaction. Throughout this work, we assume that Na^+TCNQ^- dissociates completely into free ions in the solvents used. This assumption has not been verified experimentally, but it seems to be reasonable considering that the dielectric constants of these solvents are high and that these are all known as strong ion-solvating solvents. Figure 1

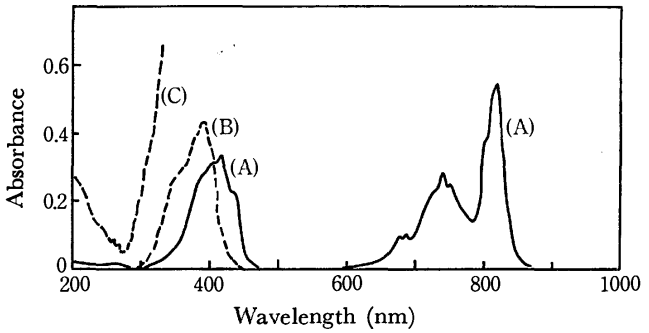

Fig. 1. Spectral change of Na^+TCNQ^- in MeCN when mixed with HCl solution.
(A) $[Na^+TCNQ^-]_0 = 1.32 \times 10^{-5}$ M, (B) $[Na^+TCNQ^-]_0 = 1.32 \times 10^{-5}$ M, [HCl] = 8.0×10^{-4} M. (C) $[Na^+TCNQ^-]_0 = 4.32 \times 10^{-4}$ M, [HCl] = 8.0×10^{-3} M (25 °C). ——: Na^+TCNQ^-, ------: $Na^+TCNQ^- + HCl$

shows the spectral change in Na^+TCNQ^- in MeCN when the Na^+TCNQ^- solution is mixed with the HCl solution. With the disappearance of the absorption due to $TCNQ^-$, the new peaks in 340—450 nm appear, they coincide with the spectra of TCNQ.[7] When a more concentrated solution of Na^+TCNQ^- is acidified, additional peaks are observed at 258, 264, and 270 nm. Comparing the spectra of H_2TCNQ in MeCN, these peaks are assigned to H_2TCNQ. Using the extinction coefficients of ε_{840} ($TCNQ^-$) 43300, ε_{395} (TCNQ) 63600,[7] and ε_{270} (H_2TCNQ) 300, which is approximately determined in this work, the initial concentration of Na^+TCNQ^-, and the final concentrations of TCNQ and H_2TCNQ were calculated

Table 1. Stoichiometry of reaction in MeCN at 25 °C

Run A)	Na^+TCNQ^-	initial	1.32×10^{-5}M
	TCNQ	final	6.60×10^{-6}M
Run B)	Na^+TCNQ^-	initial	4.20×10^{-4}M
	TCNQ	final	2.10×10^{-4}M
	H_2TCNQ	final	*ca.* 2×10^{-4}M

(Table 1). In EtOH and MeOH similar results were obtained except that the UV absorption due to H_2TCNQ was not observed. In the experiment where H_2TCNQ is dissolved in EtOH *in vacuo*, H_2TCNQ is found to have a broad peak at 309 nm in addition to several small peaks in the 250—270 nm region. At the present stage, it is uncertain why the H_2TCNQ product is not observed in alcoholic solvents. The reason may lie in the interaction of H_2TCNQ with alcohols in an acidic medium. The number of protons consumed in the reaction was determined in MeOH, using thymol blue as the proton indicator. We obtained 1.1 ± 0.2 as the ratio of protons consumed per $TCNQ^-$. Thus, the over-all stoichiometry of the reaction may be written as follows:

$$2Na^+TCNQ^- + 2HCl = TCNQ + H_2TCNQ + 2NaCl \quad (5)$$

which is identical with Eq. (1).

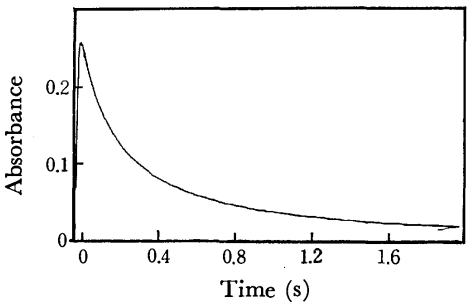

Fig. 2a. The decay of absorbance at 840 nm due to Na^+TCNQ^- during the reaction with HCl in MeOH.

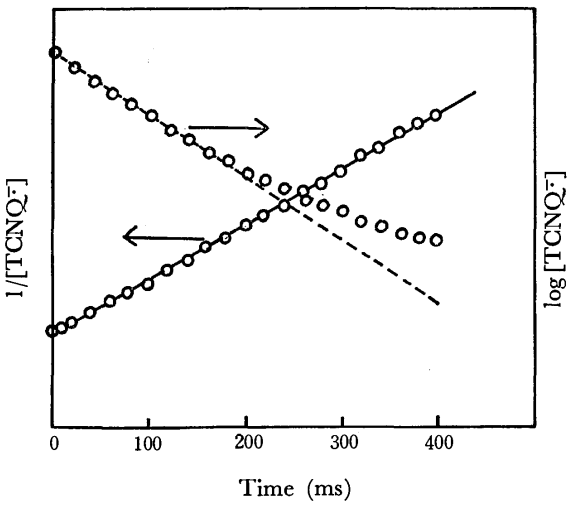

Fig. 2b. Plots of $1/[TCNQ^-]$ *vs.* time and $\log[TCNQ^-]$ *vs.* time in MeOH at 25 °C.
$[Na^+TCNQ^-]_0 = 7.60 \times 10^{-6}$ M, $[HCl] = 4.30 \times 10^{-4}$ M

Reaction in MeOH. The decay of $TCNQ^-$ was followed by mixing the MeOH solution of Na^+TCNQ^- with the MeOH solution of HCl. Even under the $[Na^+TCNQ^-] \gg [HCl]$ condition (Fig. 2a), the reaction is not first-order. As is shown in Fig. 2b, the decay of $TCNQ^-$ is second-order with respect to $TCNQ^-$. The apparent second-order rate constant increases linearly with the concentration of HCl (Table 2). The rate of protonation may, therefore, be written as:

$$\frac{d[TCNQ^-]}{dt} = -k_{obs}[TCNQ^-]^2[H^+] \quad (6)$$

The change in the spectra in 330—530 nm with the time (Fig. 3) shows the existence of the isosbestic point at 394 nm. This implies that the amount of intermediates accumulated in the course of the reaction, if any, is too small to give any disturbance to the condition:

TABLE 2. k_{obs} VALUES AT VARIOUS HCl CONCENTRATIONS IN MeOH AT 25 °C

Na^+TCNQ^-/M	HCl/M	$k_{obs}/M^{-2}s^{-1}$
7.60×10^{-6}	1.08×10^{-4}	1.73×10^{8}
7.60	2.15	1.66
7.60	4.30	1.64
7.60	8.60	1.40
7.60	21.5	1.48

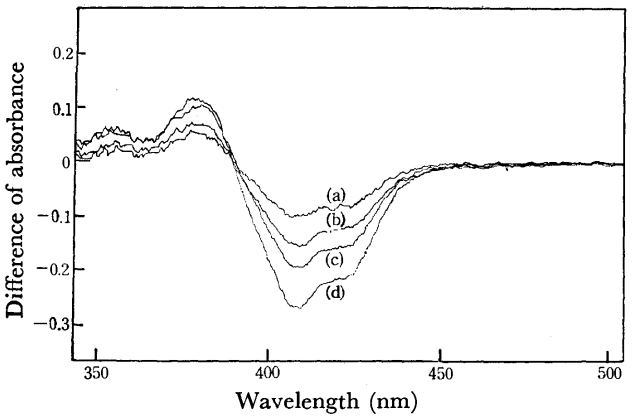

Fig. 3. Rapidly-scanned difference spectra for the system of Na^+TCNQ^- and HCl in MeOH.
(a) is the difference between the initial absorbance and the one 25 ms after mixing; (b) 50 ms after mixing; (c) 100 ms after mixing; (d) 500 ms after mixing. Scan speed 5 ms/300 nm. $[Na^+TCNQ^-]_0$ 8.23×10^{-6} M. [HCl] 1.50×10^{-3} M.

$$[TCNQ^-] + 2[TCNQ] = [TCNQ^-]_0$$

in which $[TCNQ^-]_0$ is the initial concentration of $TCNQ^-$. There are three possibilities conceivable for the origin of the second-order dependence of the rate on $TCNQ^-$. The species to be protonated is (i) a dianion, $TCNQ^{2-}$, which is produced by this reaction:

$$2TCNQ^- \rightleftharpoons TCNQ + TCNQ^{2-} \quad (7)$$

(ii) a dimer anion, $(TCNQ^-)_2$, which is produced by this reaction:

$$2TCNQ^- \rightleftharpoons (TCNQ^-)_2;\ K \quad (8)$$

or (iii) a $TCNQ^-$, and there exists a reversible reaction to form a protonated intermediate:

$$TCNQ^- + H^+ \underset{k_2}{\overset{k_1}{\rightleftharpoons}} HTCNQ^\cdot \quad (9)$$

$$HTCNQ^\cdot + TCNQ^- \xrightarrow{k_3} HTCNQ^- + TCNQ \quad (10)$$

The (i) possibility can be discarded because the addition of TCNQ has no effect on the protonation rate (Table 3). If Reaction (7) worked, TCNQ would retard the reaction rate, decreasing the concentration of $TCNQ^{2-}$.

TABLE 3. EFFECT OF TCNQ ON THE RATE OF PROTONATION REACTION IN MeOH AT 25 °C

Na^+TCNQ^-/M	HCl/M	TCNQ/M	$k_{obs}/M^{-2}s^{-1}$
8.23×10^{-6}	1.50×10^{-3}	0.00×10^{-5}	1.76×10^{8}
8.23	1.50	2.27	1.83
8.23	1.50	4.54	1.76

If the (ii) assumption is correct, the k_{obs} in Eq. (6) is equal to $k\cdot K$, where k is the protonation rate of $(TCNQ^-)_2$ by the proton and where K is an equilibrium constant of (8). Using $k_{obs}=1.5\times10^8\ M^{-2}\ s^{-1}$ and $k=10^{10}\ M^{-1}\ s^{-1}$, the lower limit of K is estimated to be $10^{-2}\ M^{-1}$. On the other hand, assuming that the extinction coefficient of $(TCNQ^-)_2$ at 643 nm is 33600,[11] the upper limit of K may be estimated to be $10\ M^{-1}$ from the electronic spectra. Therefore, the (ii) possibility can not be denied on the basis of only the kinetic results. However, in the case of sodium anthracenide, it is indicated that the $(A^-, Na^+)_2$ dimer is relatively unreactive.[4] The result in MeCN also supports the (9) and (10) mechanisms, as will be mentioned later. Thus, it seems that the (iii) possibility is most plausible at the present stage. From the first-order dependence of the rate on HCl, the reaction which follows Reaction (10) to produce a stable product may be concluded to be very fast. Applying the stationary state condition to $HTCNQ^\cdot$ in (9) and (10), we obtain the following rate equation:

$$\frac{d[TCNQ^-]}{dt} = -\frac{2k_1k_3[TCNQ^-]^2[H^+]}{k_2+k_3[TCNQ^-]} \quad (11)$$

in which H^+ is introduced as a proton source instead of HCl based on the results for the EtOH system.[12] Under this condition:

$$k_2 \gg k_3[TCNQ^-] \quad (12)$$

Eq. (11) becomes identical to the observed rate expression (6), leading to $k_{obs}=2k_1k_3/k_2$. Equation (11) predicts that the rate will deviate from the second-order dependence on $TCNQ^-$ at a sufficiently high concentration of $TCNQ^-$. This actually happens in the MeCN system. However, no deviation from Eq. (6) was observed up to $[Na^+TCNQ^-]=1.22\times10^{-4}$ M in MeOH, making it possible to conclude that $k_2/k_3 > 1.22\times10^{-4}$ M.

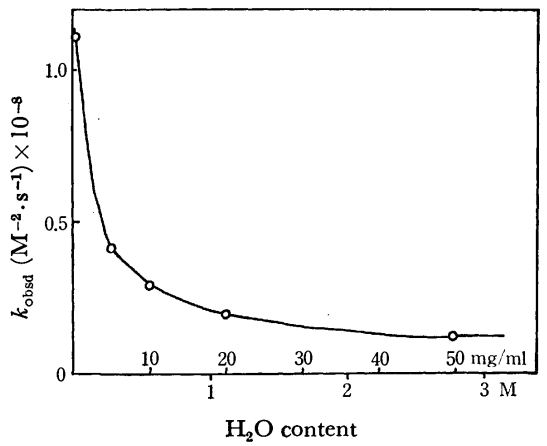

Fig. 4. Effect of H_2O on k_{obs} in MeOH at 25 °C. $[Na^+TCNQ^-]_0$ 2.8×10^{-6} M, [HCl] 1.07×10^{-2} M.

The small amount of water was found to reduce the k_{obs} value to a remarkable extent, although the mechanism is not altered (Fig. 4). We may ascribe this water effect to the solvation of the proton by water molecules:

$$H^+(MeOH)_n + mH_2O \rightleftharpoons nMeOH + H^+(H_2O)_m \quad (13)$$

which results in the leftward shift of the (9) equilibrium. The solvation of H^+ by water is reported to occur even in a small amount of water.[13] Since the electron-transfer reaction (10) is thought to be diffusion-controlled and little affected by the water content, the change in the k_{obs} value with water reflects the change in the equilibrium constant of Reaction (9) with the water content.

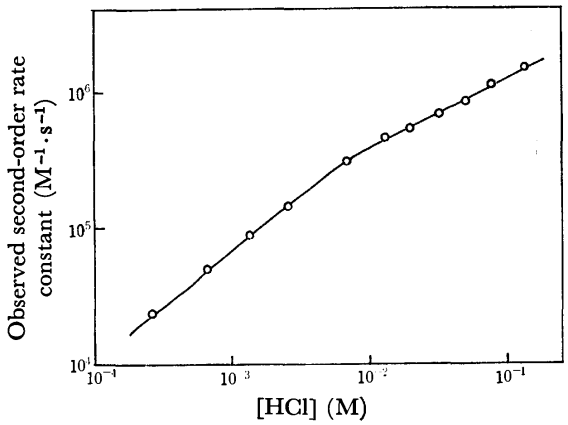

Fig. 5. Dependence of the second-order rate constant on HCl concentration in EtOH at 25 °C.
$[Na^+TCNQ^-]_0$ 6.81×10^{-6} M.

Reaction in EtOH. The decay of $TCNQ^-$, mixed with HCl in ethanol, is found to be second-order with respect to the $TCNQ^-$ concentration. However, the second-order rate constant is not always linearly dependent on the HCl concentration (Fig. 5). In the range of [HCl] larger than 10^{-2} M, the rate equation is written as:

$$\frac{d[TCNQ^-]}{dt} = -k_{obs}[TCNQ^-]^2[HCl]^{1/2} \qquad (6')$$

rather than as Eq. (6). The one-half-order dependence of the rate on the HCl concentration can best be interpreted by assuming a rapid equilibrium in EtOH:

$$HCl \rightleftharpoons H^+ + Cl^-;\ K \qquad (14)$$

and by assuming, in addition, that the dissociated proton H^+, but not HCl, is a protonating reagent. The free proton concentration is $[H^+]=K^{1/2}[HCl]^{1/2}$, supposing that the degree of dissociation is very small. From the plot in Fig. 5, the k_{obs} corresponding to $2k_1k_3/k_2$ in Eq. (6) and the equilibrium constant of (14), K, are estimated to be $1\pm0.2\times10^8$ $M^{-1}s^{-1}$ and $2.4\pm0.8\times10^{-3}$ M respectively.[14] This conclusion is confirmed by the fact that tetraethylammonium chloride is found to suppress the protonation rate, as is shown in Table 4.[15]

Table 4. The effect of tetraethylammonium chloride on the rate of protonation reaction in EtOH

Na^+TCNQ^-	HCl	Tetraethyl-ammonium chloride	k_{obs}[a]
1.28×10^{-5}M	1.8×10^{-2}M	0 M	$1.86\times10^5M^{-1}s^{-1}$
1.28	1.8	0.031	1.63
1.28	1.8	0.15	0.709
1.28	1.8	0.30	0.446

a) Temperature 15 °C, water content 8 mg/ml.

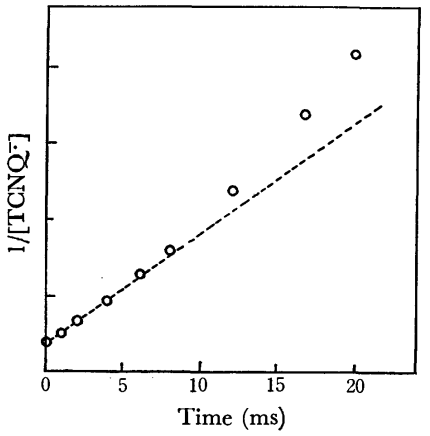

Fig. 6. Plot of $1/[TCNQ^-]$ *vs.* time for the reaction of $TCNQ^-$ with HCl in MeCN.
$[Na^+TCNQ^-]_0$ 4.12×10^{-5} M, [HCl] 1.08×10^{-3} M at 25 °C.

Reaction in MeCN. We studied the protonation reaction in MeCN with the purpose of obtaining the forward rate constant, k_1, in Reaction (9) directly. Since MeCN seems to solvate H^+ less effectively than alcohols, the backward rate constant, k_2, in (9) is expected to become smaller in MeCN than in alcohols. Consequently, the observed rate expression may approach:

$$\frac{d[TCNQ^-]}{dt} = -2k_1[TCNQ^-][H^+]$$

This rate law has been obtained in the case of the protonation of sodium naphalenide in THF.[1] As Fig. 6 shows, the decay of $TCNQ^-$ during the reaction with HCl is found to deviate from the second-order dependence on $TCNQ^-$. We consider that, at least in the initial stage, $TCNQ^-$ is protonated according to the (9) and (10) mechanism, keeping the condition of $k_2\approx k_3$ [$TCNQ^-$]. By integrating Eq. (11) under the condition of $[H^+]\gg[TCNQ^-]$, we obtain:

$$\frac{1}{2k_1[H^+]}\ln\frac{[TCNQ^-]_0}{[TCNQ^-]} + \frac{k_2}{2k_1k_3[H^+]}\left(\frac{1}{[TCNQ^-]} - \frac{1}{[TCNQ^-]_0}\right) = t$$

In order to obtain k_1 and k_2/k_1k_3 from the observed decay curve, we draw a group of straight lines on the (x, y) plane as expressed by:

$$\frac{2.3}{t}\log\frac{[TCNQ^-]_0}{[TCNQ^-]}\cdot x + \frac{1}{t}\left(\frac{1}{[TCNQ^-]} - \frac{1}{[TCNQ^-]_0}\right)\cdot y = 1$$

using a pair of $\frac{2.3}{t}\log\frac{[TCNQ^-]_0}{[TCNQ^-]}$ and $\frac{1}{t}\left(\frac{1}{[TCNQ^-]} - \frac{1}{[TCNQ^-]_0}\right)$ at various values of t for a constant $[H^+]$.

The common point (x_0, y_0), through which a group of straight lines pass gives the desired values of $1/2k_1$ and $k_2/2k_1k_3$. An example is shown in Fig. 7, leading to the results tabulated in Table 5. It should be noted that, if the dimer anion mechanism (possibility (ii) in MeOH) worked, the deviation from a second-order dependence on $TCNQ^-$ would be interpreted as the

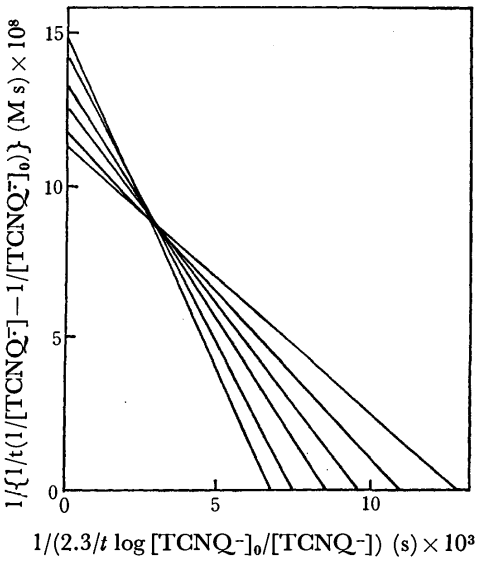

Fig. 7. Plots of a group of straight lines according to $\frac{2.3}{t}\log\frac{[TCNQ^-]_0}{[TCNQ^-]}\cdot x+\frac{1}{t}\left(\frac{1}{[TCNQ^-]}-\frac{1}{[TCNQ^-]_0}\right)\cdot y=1$ for various values of t.

TABLE 5. k_1 AND k_1k_3/k_2 VALUES IN MeCN AT 25 °C

Na^+TCNQ^-/M	HCl/M	$k_1/M^{-1}s^{-1}$	$k_1k_3/k_2/M^{-2}s^{-1}$

4.12	21.6	1.9	2.3
4.12	36.0	2.0	2.3

result of the participation of the direct protonation of $TCNQ^-$ (Reaction (9)). If this were the case, the deviation from second-order would appear at lower concentrations of $TCNQ^-$, since Reaction (8) would be predominant at higher concentrations of $TCNQ^-$. However, the fact is that the deviation was observed at higher concentrations of $TCNQ^-$, but not at lower concentrations. In this way, the possibility of a dimer mechanism could be dismissed. The magnitude of k_1 is about four orders below the diffusion-controlled rate constant.

In order to compare the k_1 value with the protonation rate of semiquinones, in which protonation occurs on oxygen atoms, we tried to obtain the reaction rates of protonation, $Na^+QCl_4^-$ and $Na^+Q(CN)_2^-$. Unfortunately, the decay of these semiquinones is too fast for us to analyse the kinetics of the protonation reaction. Therefore, the lower limits of k_1 and k_1k_2/k_3 were roughly estimated from the half-life of the decay curves of semiquinones, assuming that the decay curves are completely first-order or completely second-order respectively. The results are shown in Table 6. These values indicate that the protonation rates of semiquinones by free protons are more than one order larger than that of $TCNQ^-$.

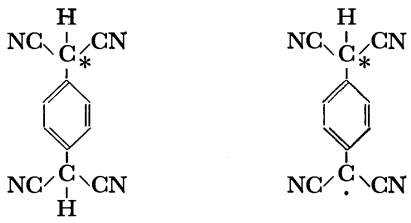
Discussion

The reversibility of the initial step of the protonation:

$$TCNQ^- + H^+ \underset{k_2}{\overset{k_1}{\rightleftharpoons}} HTCNQ\cdot;\quad K_b \qquad (9)$$

is well demonstrated by the second-order dependence of the rate on the concentration of $TCNQ^-$. If the backward rate of the above reaction were forbidden, the rate would be first-order in $TCNQ^-$ as far as the decay of $TCNQ^-$ is monitored. As the final product of the protonation of $TCNQ^-$ is H_2TCNQ (I), $HTCNQ\cdot$ seems to have the (II) structure.



Therefore, the reversible protonation reaction (9) takes place on the carbon atom, C*. The magnitude of the equilibrium constant, K_b, can be estimated by assuming that the electron-transfer reaction (10) is diffusion-controlled. This assumption is reasonable, since Reaction (10) is more favoured from the energetic point of view than the exchange reaction:

$$TCNQ^- + TCNQ^* \rightleftharpoons TCNQ + TCNQ^{*-}$$

whose rate constant is known to be about $10^9\ M^{-1}s^{-1}$.[7] Table 7 gives the estimated values of K_b, assuming that $k_3=10^{10}\ M^{-1}\ s^{-1}$. The variation in K_b for various kinds of solvents is interpreted consistently in terms of the proton-solvating capacity of these solvents. Alcoholic solvents give K_b values of the same order. The

TABLE 7. THE ESTIMATED VALUE OF THE EQUILIBRIUM CONSTANT K_b FOR $TCNQ^- + H^+ \rightleftharpoons HTCNQ\cdot$ AT 25 °C

Solvent	H_2O/mg/ml	K_b/M^{-1} a)
MeOH	0.46	7.9×10^{-3}
MeOH	5.0	2.0
MeOH	10.0	1.5
MeOH	20.0	0.97
MeOH	50.0	0.62
EtOH	4.3	5±1
MeCN	0.3	1700±600

a) estimated from the observed k_1k_3/k_2 values, assuming $k_3=10^{10}M^{-1}s^{-1}$.

large value of the K_b in MeCN is due to the poor solvating capacity of MeCN. The water effect in MeOH implies that H_2O is the strongest solvating solvent for the proton.

A comparison of the k_1 value for the protonation of $TCNQ^-$ in MeCN with the lower limit of k_1 for QCl_4^- and $Q(CN)_2^-$ indicates that the k_1 for $TCNQ^-$ is more than one order smaller than that for semiquinones. We can not conclude that the smaller k_1 value for $TCNQ^-$ is characteristic of the protonation on a carbon atom in ion radicals, since a comparison between carbon and oxygen acids should be made for the limiting rate of protonation, which is obtained by extrapolating the rate to the limit of an infinite K_b. However, at the present stage of investigation it is meaningful to consider what factor of $TCNQ^-$ makes the protonation rate smaller than for semiquinones. At least three factors must be taken into consideration as determining the rate of protonation: (i) electron density of the atom on which protonation takes place, (ii) the localization energy caused by the protonation, and (iii) the steric hindrance in the vicinity of the proton-accepting atoms. In addition, another assumption (iv) may be introduced—that, in a transition state of protonation, a proton-accepting atom has an anionic character.

Table 8. Electron and spin densities of C* of $TCNQ^-$ and oxygen atom of QCl_4^-.

	Electron density	Spin density	Ref.
$TCNQ^-$	1.17−1.24	0.29−0.24	a)
QCl_4^-		0.213±0.010	b)

a) D. A. Lowitz, *J. Chem. Phys.*, **46**, 4698 (1967).
b) Y. Iida, This Bulletin, **44**, 1271 (1971).

At the initial stage of the reaction, where H^+ approaches anion radicals from an infinite distance, electostatic interaction may be predominant. The electron and spin densities of C* in $TCNQ^-$ are thus compared in Table 8 with those of the oxygen atom in QCl_4^-. There seems to be no remarkable difference in these quantities between $TCNQ^-$ and QCl_4^-. As H^+ comes closer to anion radicals, a localization of the odd π-electron takes place, together with a change in the electronic state of the C* atom into C^-. We regard the instability of the C^- state is the main factor for the protonation of $TCNQ^-$ being slower than that of semiquinones. In order to make this point clear, we roughly estimated the energy produced by the changes in electronic state (i) $=C<+e$ to $-C^-<$ and (ii) $=O+e$ to $-O^-$. Using the values given by Hinze and Jaffe,[16] the energies produced for (i) and (ii) are calculated to be 1.57 and 2.01 eV respectively. Thus, the C^- state is less stable by 0.44 eV than the O^- state. Assuming a small difference in π-localization energy between $TCNQ^-$ and semiquinones, the slower rate for the protonation of $TCNQ^-$ is attributable to the unstable character of the carbon anion. This circumstance is expected to hold similarly in diamagnetic molecules.

The authors wish to thank Professor Masatoshi Fujimoto for his continuous encouragement and Dr. Hiroshi Kashiwagi for his profitable suggestions.

The Mechanism for the Sulfonation of Olefins with a Sulfur Trioxide-Dioxane Complex[1)]

Masuzo NAGAYAMA, Osamu OKUMURA, Seiji NODA, Hiroshi MANDAI, and Akira MORI

Central Research Laboratories, Lion Fat & Oil Co., Ltd., Hirai, Edogawa-ku, Tokyo 132

(Received January 10, 1974)

The rates for the sulfonation of 1-dodecene with the sulfur trioxide-dioxane complex were measured spectrophotometrically. A bimolecular process occurred in this reaction, the rate being proportional to [1-dodecene] [SO_3-dioxane]. Furthermore, the stereochemistry of the initial products of the sulfonation reaction between *cis* or *trans*-2-butene and the sulfur trioxide-dioxane complex was studied. An equimolar amount of sulfur trioxide-dioxane (1 : 1) was added to *cis*- or *trans*-2-butene in chloroform to give the sultone, (I) or (II); (I) 1.5(q), 4.7—5.1(m), J_{AB} 7.9, J_{BC} 8.0, J_{CD} 6.0 Hz; (II) 1.5(q), 4.2—4.6(m), J_{AB} 6.8, J_{BC} 5.4, J_{CD} 6.8 Hz. These results indicate that the 2,3-butanesultones were produced stereospecifically from the corresponding 2-butene isomers. Similarly, the sulfonation of *cis*- or *trans*-2-pentene with sulfur trioxide-dioxane gave the corresponding 2,3-pentanesultones.

The sulfonation reaction of olefins, in particular long chain aliphatic α-olefins, with sulfur trioxide is utilized widely, even on a commercial scale, today. The reaction mechanism for the sulfonation of aliphatics, however, is scarcely known, although that of aromatic hydrocarbons has been extensively investigated.[2)] Some reports have been published on the mechanisms for the sulfonation of aliphatic olefins, these reports suggest that a four-membered ring sultone is formed *via* a zwitter-ion intermediate.[3-5)] However, no experimental proof for such an intermediate has been described, nor has any kinetic study about the sulfonation of aliphatic compounds been done.

In this paper, we wish to report on kinetic studies of the reaction between 1-dodecene and the sulfur trioxide-dioxane complex and a stereochemical studies of the sulfonation products of *cis*- and *trans*-2-butenes and *cis*- and *trans*-2-pentenes with the sulfur trioxide–dioxane complex.

Experimental

Experimental Procedure. *Kinetic Studies of the Sulfonation*: Kinetic experiments were carried out by the stopped-flow method* using a rapid scanning-type spectrophotometer (Hitachi Model RSP-2). In order to determine the rate of sulfonation, 1-dodecene and the SO_3-dioxane (1 : 1) complex were mixed in a mixing cell (path length, 1 cm); the decay curve in the absorbance appearing on an oscilloscope at 240 nm was used.

Three different molar ratios of 1-dodecene to SO_3-dioxane were taken: 1.05 : 1; 1 : 1; 1 : 1.5. A 0.2 M solution of 1-dodecene in ethylene dichloride and a 0.2 M solution of SO_3-dioxane in the same solvent were mixed at 25 °C, and then the absorbance was measured up to 500 ms after mixing. For the identification of the reaction products, the NMR spectra were measured.

Stereochemical Studies of the Sulfonation: Each of the *cis* and *trans* isomers of 2-butene and 2-pentene was allowed to react with a SO_3-dioxane (1 : 1) complex in chloroform at 0 °C for one hr, after which the 220 MHz or 100 MHz NMR spectra of the reaction mixture were measured at −5 °C. One half of the reaction mixture was then hydrolyzed with water and neutralized wih an excess of sodium hydroxide to give white crystals. To the other half of the reaction mixture were added two equivalents of aniline, and the mixture was allowed to stand for 24 hr and then neutralized to give crystals, which were recrystallyzed from aqueous ethanol (50 : 50). These crystals were subjected to NMR spectral analysis.

Reagents. The 1-dodecene——99.5% in purity by glc, prepared by the polymerization of ethylene——was dried over metallic sodium and distilled before use. The dioxane——a commercial product of a reagent grade——was dried over metallic sodium and distilled before use. The ethylene dichloride and chloroform——commercial materials of a reagent grade——were dried over P_2O_5 and distilled. The *cis*-2pentene (95.5%), *trans*-2-pentene (99.8%), *cis*-2-butene (98.3%) and *trans*-2-butene (98.0%)——all commercial materials——were used as received. The purity in parentheses were determined by glc.

Results and Discussion

Kinetic of the Reaction between 1-Dodecene and the SO_3-Dioxane Complex. The reaction product between 1-dodecene and the SO_3-dioxane complex in the initial stage was identified[6)] as a β-sultone** by 100 MHz NMR analysis.

The molar extinction coefficients (ε) at 240 nm were measured for SO_3-dioxane, 1-dodecene and β-sultone. Lambert-Beer's law held in each case and the values of ε were found to be as follows.

	$\varepsilon_{240\,nm}$ (l/mol·cm)
SO_3-dioxane	6.63
1-dodecene	1.37
C_{12}-β-sultone	2.72
ethylene dichloride	0.00272

The $\varepsilon_{240\,nm}$ value of ethylene dichloride is so much smaller than those of SO_3-dioxane, *etc.* that the total absorbances *versus* x is given by:

$$Abs_{240\,nm} = 6.63(a-x) - 1.37(b-x) + 2.72x$$

The reaction rate equation can be expressed as follows.

* Immediately after the 1-dodecene and SO_3-dioxane complex were mixed, measurement of the UV absorbance (at 240 nm) was started *versus* time.

** β-Sultone was stable to heat (no change in the NMR spectrum in 10 min at 65 °C) but was decomposed in a short time in the presence of a relatively weak base, for example, upon addition of a small amount of CD_3OD.

$$dx/dt = k_{n+m}(a-x)^n(b-x)^m$$

where

k_{n+m}: rate constant of the $(n+m)$th-order reaction
n,m: integer
a: initial concentration of the SO_3-dioxane complex
b: initial concentration of 1-dodecene
x: concentration of the reacted SO_3-dioxane (=that of the formed β-sultone)

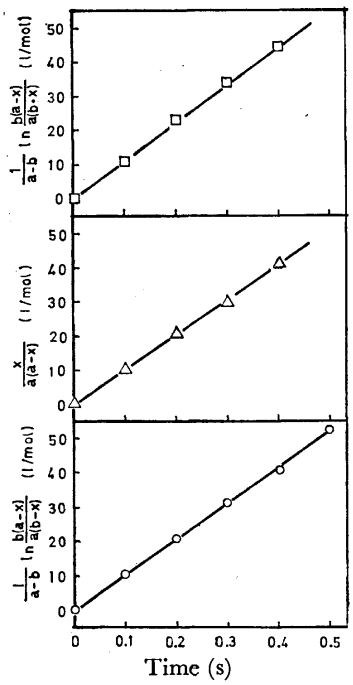

Fig. 1. The second-order type plots for different molar ratios of 1-dodecene to SO_3-dioxane at 25 °C.

An electrophilic addition reaction by SO_3 seems applicable in the first stage of this reaction; much as in the sulfonation of aromatic hydrocarbons.[7,8] The formation of sulfonic acid anhydride was not found here unlike the case of aromatic hydrocarbons; hence, the reaction is likely to become simpler thus, $m=1$. Besides, a straight line was obtained in the case of the second-order plot; $1/(a-b)\cdot\ln b(a-x)/a(b-x)$ *versus* time (Fig. 1). Therefore, in the molar ratios of 1-dodecene to the SO_3-dioxane complex from 1.05: 1 to 1: 1.5, the reaction is first-order with respect to both [α-olefin] and [SO_3] and second order as a whole. The second-order rate constant (k_2) was determined as follows from the figure.

$$k_2 = (1.1\pm0.1)\times10^2\ \mathrm{l\,mol^{-1}\,s^{-1}}\ (\text{at } 25°C)$$

This value is smaller by a factor of 10^3 than the rate constant of the sulfonation of an α-olefin in a thin-film reactor with gaseous SO_3.[9]

Stereochemical Studies. The kinetic studies showed that (1) the reaction between an α-olefin and SO_3 yields a β-sultone in the initial stage, and (2) the reaction is second-order and first order with respect to α-olefin and SO_3 respectively. Now, to see whether SO_3 undergoes a step-by-step addition to the α-olefin *via* a zwitter-ion or a concerted reaction, stereochemical studies of the reaction of SO_3 with *cis* and *trans* isomers of 2-butene and 2-pentene were undertaken.

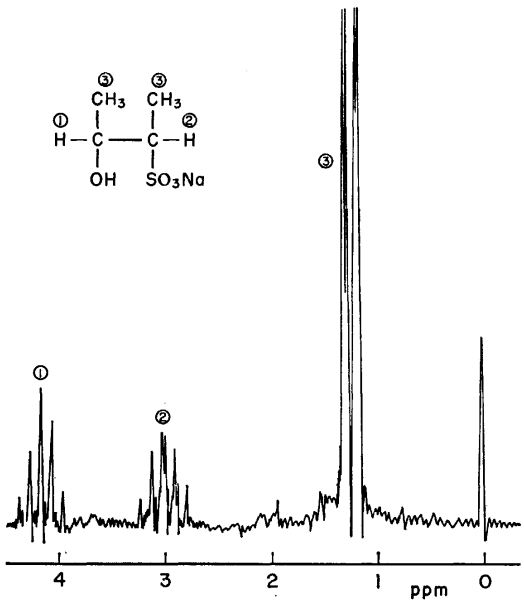

Fig. 2. The NMR spectrum of 3-hydroxybutane-2-sulfonate derived from *cis*-2-butene in D_2O at 25 °C, internal standard DSS.

The NMR spectra of the hydrolyzed products from *cis*- and *trans*-2-butene were exactly the same, as is shown in Fig. 2, demonstrating them to be 3-hydroxybutane-2-sulfonate. Found: S, 18.0 (*cis*); 18.3 (*trans*)%; Calcd for $C_4H_9O_4SNa$: 18.2%. Furthermore, from either *cis*- or *trans*-2-butene, we could isolate sodium 3-anilinobutane-2-sulfonate as white crystals (Table 1). Found: S, 12.7 (*cis*); 13.0 (*trans*)%; Calcd for $C_{10}H_{14}O_3SNa$: 12.7%. Therefore, the initial sulfonation products from both *cis*- and *trans*-2-butene must be the four-membered ring 2,3-sultone and not the six-membered ring 4,5-dimethyl-1, 3-dioxa-2,6-dithiacyclohexane-2,2,6,6-tetraoxide ("carbyl sulfate").[6,10]

Table 1. Chemical shifts (ppm) from the internal standard DSS and assignment of aniline derivatives of 2,3-sultones

Assignment		Chemical shift (ppm) *cis*	Chemical shift (ppm) *trans*
H-C-SO_3Na		3.20	3.20
H-C-NH-C_6H_5		4.16	3.88
CH_3		1.25	1.38
C_6H_5	*o*-, *p*-	6.86	6.86
	m-	7.30	7.30

It is noteworthy that the IR spectrum of the anilinobutane sulfonate obtained from *cis*-2-butene was superimposable upon that from the *trans* isomer, whereas the NMR spectra of these two samples exihibited different chemical shifts due to the H-C-NHC_6H_5 methine group, as is shown in Table 1. This difference will be discussed in some detail later in this paper.

We next studied the stereochemistry of the reaction products of *cis*- and *trans*-2-butene with the SO_3-dioxane complex by means of 220 MHz NMR analysis (Fig. 3). The NMR spectra of the products from the

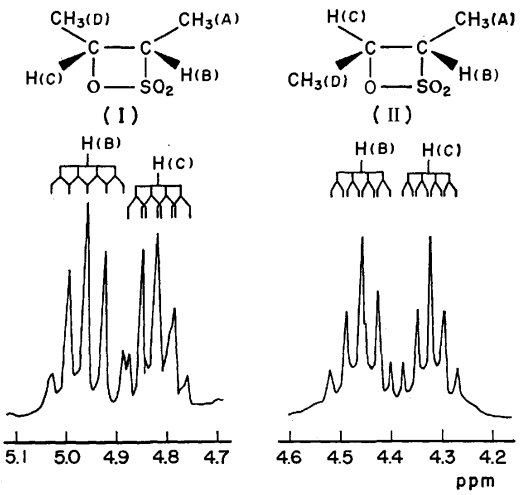

Fig. 3. The methine region of the 220 MHz NMR spectra of *cis*-butane sultone and *trans*-butane sultone derived from *cis*- and *trans*-2-butene in $CHCl_3$ at −5 °C, internal standard TMS.

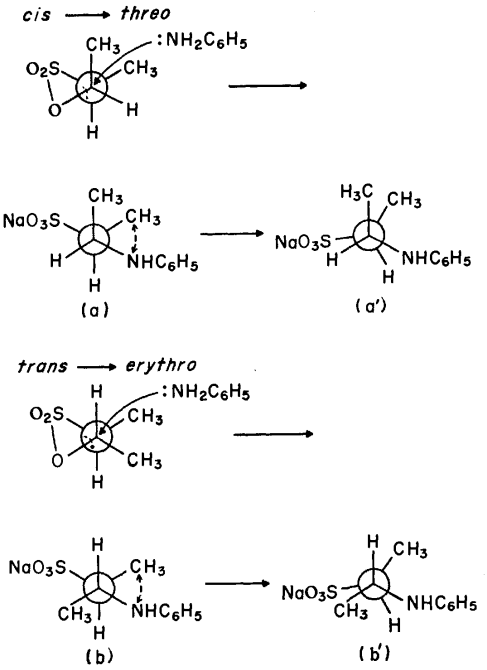
isomeric olefins both showed an ABM system with a quartet at 1.5 ppm and a multiplet at 4.7—5.1 ppm for the *cis*, while it showed a quartet at 1.5 ppm and a multiplet at 4.2—4.6 ppm for the *trans*, and no other peak was found. It follows that the 2,3-sultones were produced stereospecifically from the corresponding 2-butene isomers.

Similarly, the sulfonation of *cis*- and *trans*-2-pentene with the SO_3–dioxane complex gave the corresponding 2,3-sultones.

Even in a non-complex system (an equimolar amount of SO_3 was added to *cis*- or *trans*-2-butene in chloroform at 0 °C), the stereospecific formation of *cis*- and *trans*-2,3-butanesultone was observed and a minor amount of products as yet unidentified was obtained.

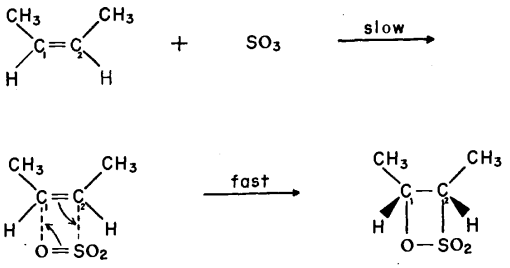
The chemical shifts for two methines of the 2,3-sultone derived from *cis*-2-butene appeared at a lower field than those of the 2,3-sultone derived from *trans*-2-butene. It is almost certain that the former sultone has a *cis* configuration, while the latter has a *trans*, because, in the *cis*-sultone, the two methine hydrogen atoms are likely to be pushed toward the O–SO_2 side as a result of the repulsion by two methyl groups; as a result, the resonance signal would appear at a lower field, as was indeed observed.

The above-mentioned differences between the NMR spectra of the aniline adducts can be ascribed to the *threo* and *erythro* configuration. Aniline attacks the carbon atom bonded to oxygen by the S_N2 mechanism, and the *threo* configuration is formed from the *cis*-sultone, whereas the *erythro* is formed from the *trans*, as is shown in Scheme 1. An examination of the molecular models indicates that the sulfonate and anilino groups are so large that the rotation about the C–C axis bearing these groups is restricted. Also, the *gauche*-disposed NH-C_6H_5 and CH_3 groups undergo mutual repulsion to take such a conformation as (a') and (b') and no isomerization was observed. These findings also suggest that the 2,3-sultones were produced stereospecifically.



Scheme 1.

These results contain two possible mechanisms; one is that SO_3 forms a ring perfectly in a concerted reaction, while the other is that a zwitter-ion is once formed. However, the sultone ring is formed much faster than the rotation of C_1–C_2, which is minimized by the dipolar attractive force (Scheme 2). In this case, dioxane merely weakens the reactivity of SO_3; rather, it behaves as a polar solvent to make the zwitter-ion stable. Consequently, it seems more difficult to consider a zwitter-ion intermediate in the case of the non-complex system.



Scheme 2.

The authors wish to thank Dr. Morishima of Kyoto University for his cooperation in taking 220 MHz NMR spectra. Thanks are due to Professor Dr. Kumada of Kyoto University for his valuable advice throughout our experiment.

A Study of the Recoil Labeling of Fluothane with ^{82}Br during Neutron Irradiation

Hiroshi KUDO, Terutomi MOGI, and Kiyoshi HOIZUMI

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken 319-11

(Received January 14, 1974)

1,1,1-Trifluoro-2-chloro-2-bromoethane labeled with ^{82}Br (fluothane-^{82}Br) was purely separated from neutron-irradiated fluothane by means of a gas-chromatographic technique. The maximum radiochemical yield of fluothane-^{82}Br was 38.3% when the target material was irradiated with neutrons to nvt of 3.4×10^{16} n·cm^{-2}. Of the many organic species produced by the recoil events following the radiative neutron capture and subsequent (I.T.) processes, $CF_3{}^{82}Br$ and $CF_3CHBr{}^{82}Br$ were also identified. In order to elucidate the mechanism of recoil labeling, the scavenger effects were examined in the $CF_3CHClBr$–Br_2 system, Br_2 being used as a radical scavenger. The "high-energy" yields of $CF_3CHCl{}^{82}Br$ thus estimated were approximately 3.6 to 4.8%. It was suggested that most of the ^{82}Br-labeled species were formed through the "thermal" processes including the reaction of ^{82}Br with the organic radicals produced by the radiolysis of the parent fluothane.

Fluothane (1,1,1-trifluoro-2-chloro-2-bromoethane) is a volatile anesthetic, and its metabolism has attracted much interest in biological research.[1] Fluothane labeled with radioisotopes has been used for the investigation of the behavior of anesthetics *in vivo*. Carbon-14 labeled fluothane has been synthesized starting with chloroacetic-1-^{14}C acid and used for the studies of metabolism.[2,3]

The aim of the present work is to investigate the feasibility of the recoil labeling of fluothane with ^{82}Br during neutron irradiation. The method is expected to be convenient for preparing labeled compounds with short-lived radioisotopes. Several factors leading to the preparation of fluothane-^{82}Br, determined by means of a gas chromatographic analysis, will be described in this article.

Fluothane is, on the other hand, an interesting substance in the fields of recoil and radiation chemistry, because C–H, C–F, C–Cl, C–Br, and C–C bonds coexist in a molecule. To compare the reactivity to a recoil atom among different kinds of chemical bonds may give important information for elucidating the mechanism of recoil labeling. The fundamental chemical behavior of ^{82}Br recoil atoms produced in neutron-irradiated fluothane will be discussed, with emphasis laid on the radiation and scavenger effects as well as on the reactivity of recoil atoms.

Experimental

1,1,1-Trifluoro-2-chloro-2-bromoethane (fluothane) from Takeda Chemical Industries, containing 0.01% of thymol, was purified at room temperature by means of a vacuum line with an approximate pressure of 10^{-3} mmHg. The vaporized portion of the material, the vapor pressure of which was 242 mmHg at 20 °C, was condensed in a cold trap. No impurity was observed in the gas chromatogram for the material thus trapped, although trace amounts of signals considered to be due to impurities[4] were observed in the mass spectrum even after the purification. The target material, 5 or 10 μl of liquid fluothane, or a mixture of it with bromine (0.5—70% Br_2 by molar ratio), was sealed in a 0.3—0.5 ml quartz ampoule *in vacuo* (0.9×10^{-3} mmHg) and then irradiated in the T-pipe of the JRR-4 reactor of the Japan Atomic Energy Research Institute, operated at 2.5 MW, at an ambient reactor temperature ~50 °C. The thermal neutron flux at the irradiation position was 2.8×10^{13} n·cm^{-2} s^{-1}, with an approximate γ-ray dose rate of 0.8×10^{8} rad·hr^{-1}. The neutron-irradiated samples were left in the cooling water of the reactor for more than 24 hr. A γ-ray irradiation facility with 45 kCi of ^{60}Co sources was utilized when the target materials were exposed to γ rays for the study of radiolysis. Ten microliters of liquid fluothane sealed in the same way as in the neutron irradiation were exposed to ^{60}Co γ-rays at room temperature (dose, 2.1×10^{21} and 1.0×10^{22} eV·g^{-1}).

The irradiated sample was directly introduced into a radio-gas chromatograph by means of a specially-designed ampoule breaker,[5] so that both the gaseous and the liquid substances were injected successfully into the column. Organic species labeled with ^{82}Br were separated by a gas-chromatographic set-up consisting of a thermal conductivity detector (TCD) and a glass column 2.5 m in length and with an inner diameter of 5 mm, packed with dioctyl phthalate (20% on chromosorb W, 60—80 mesh). Helium was used as the carrier gas at the flow rate of 120 ml·min^{-1}. The temperature at the TCD was 115 °C, while that of the glass column was kept at 60 °C. The latter was gradually raised to 110 °C after the signal of fluothane was observed.

The radioactivity of ^{82}Br of the gases leaving the TCD was detected using a single-channel pulse-height analyzer with a NaI(Tl) detector (well-type, 1.75″$\phi\times$2″). The radioactivity signals were registered both on a ratemeter, feeding a signal to a two-channel recorder, and on a digital printer. In the determination of the product yields, the radioactivities adsorbed both on potassium ferrocyanides (for inorganic products) and on activated carbons (for organic products), placed before and after the gas-chromatographic column, were measured.

In identifying the chromatographically-separated species, a gas chromatograph and mass spectrometer (GC-MS) from the Japan Electron Optics Laboratory, at Miyagi University of Education, was used. When the neutron-irradiated sample was analyzed by means of the GC-MS, the sample was stored in a vessel filled with ice for more than 3 months before analysis.

Results and Discussion

In neutron-irradiated fluothane, more than 20 organic products labeled with ^{82}Br, including fluothane-^{82}Br ($CF_3CHCl{}^{82}Br$), $CF_3{}^{82}Br$, and $CF_3CHBr{}^{82}Br$, were found. The gas chromatogram, of both the radioactivity and the mass signals, of fluothane irradiated

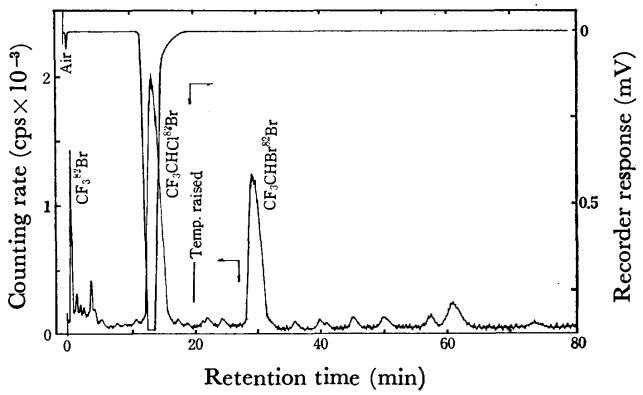

Fig. 1. Gas chromatograms of fluothane irradiated for 30 s in the JRR-4 reactor. The temperature of the gas chromatographic column was kept at 60 °C, although it was raised gradually up to 110 °C after the signal of $CF_3CHClBr$ was observed.

for 30 s in the JRR-4 reactor is illustrated in Fig. 1, where a 10 μl portion of the neutron-irradiated sample was subjected to analysis. Of the many radioactivity peaks, $CF_3CHCl^{82}Br$ showed the highest emergence. None of the mass peaks except for fluothane was found in the chromatogram, within the limits of detection.

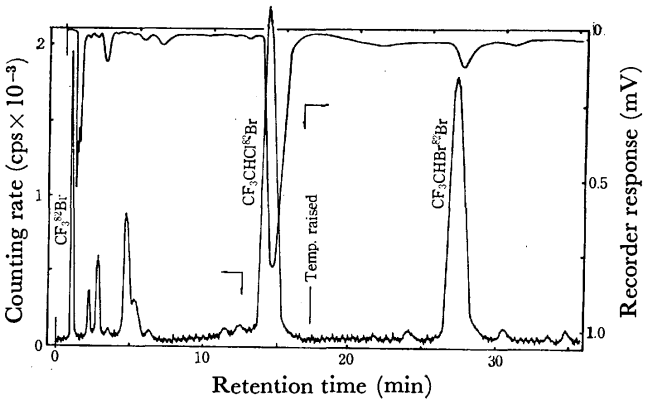

Fig. 2. Gas chromatograms of fluothane irradiated for 20 min in the JRR-4 reactor. The separation condition was identical with that of Fig. 1.

Figure 2 shows the gas chromatogram of fluothane irradiated with neutrons for 20 min. In this case, a 5 μl portion of the sample was subjected to analysis. The pattern of the radioactivity signal was identical with that in Fig. 1, while a few additional peaks were seen in the mass signal. Separation was performed by means of the gas chromatograph under the same conditions as in the previous case. Additional mass peaks were observed in the sample irradiated for more than 2 min, and the intensity increased with an increase in the irradiation time. The results suggest the occurrence of the radiolysis of the parent fluothane.

In order to examine the radiation effect, fluothane was exposed to ^{60}Co γ-rays at doses of 2.1×10^{21} and 1.0×10^{22} eV·g^{-1}. These γ-ray doses corresponded to the doses given the target material irradiated in the reactor for 25 min and 2 hr respectively. Various peaks of the radiolytic products from fluothane appeared in the gas chromatograms for both cases of

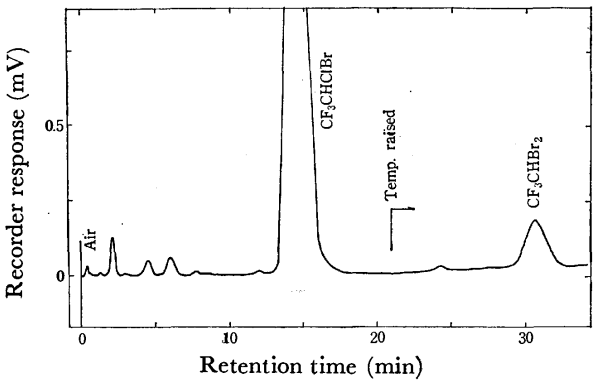

Fig. 3. Gas chromatogram of fluothane irradiated with ^{60}Co γ-rays to dose of 1.0×10^{22} eV/g. Only the liquid portion of the sample was subjected to the analysis.

γ-irradiation, although the intensities of all the peaks except for that of the parent fluothane were rather small in the former case. The pattern of the gas chromatogram for the latter case, illustrated in Fig. 3, was comparable enough with that of Fig. 2. The separation conditions of the gas chromatograph were identical with those of neutron-irradiated samples. It is noticeable that the radiolysis of fluothane is more sensitive to the irradiation in the reactor than to exposure to ^{60}Co γ-rays. This may be explained in terms of the internal radiation effect due to the recoil particles, such as ^{38}Cl, ^{80m}Br, ^{80}Br, ^{82m}Br, and ^{82}Br itself, produced in the neutron-irradiated sample. Details of the study of the radiolysis will be discussed elsewhere.[6]

The chemical distribution of ^{82}Br-labeled species resulting from the recoil processes in fluothane was investigated as a function of the irradiation time in the reactor. The radiochemical yields of the inorganic and organic products, including $CF_3CHCl^{82}Br$, are plotted against the irradiation time in Fig. 4. The overall organic yield increased abruptly around the irradiation time of 2 min and then reached a plateau at 95%, while the inorganic yield decreased from 32.6 to 5.5% in the same range of irradiation times. The yield of

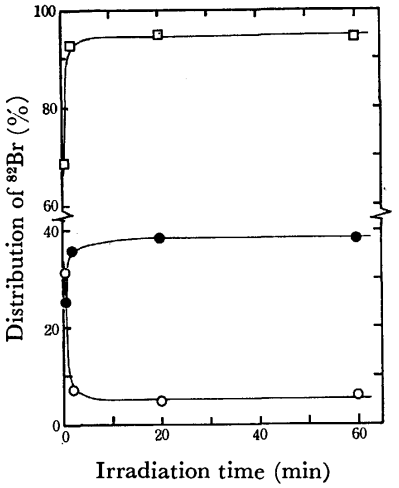

Fig. 4. Radioactivity yields of ^{82}Br-labeled products as a function of the irradiation time in the reactor. □, Overall organic products; ○, inorganic products; ●, $CF_3CHCl^{82}Br$.

$CF_3CHCl^{82}Br$ was about 26% for the target irradiated for less than 30 s; it increased to 38% at irradiation times above 2 min. Table 1 is a list of the detailed yields of the ^{82}Br-labeled products in neutron-irradiated fluothane. It is noteworthy that the yield of $CF_3CHBr^{82}Br$ was as high as 25% in the target irradiated for more than 2 min. The change in the chemical distribution of ^{82}Br-labeled species was investigated as a function of the elapsed time between 25 and 170 hr after the neutron-irradiation, but little change was observed when the irradiated samples were stored below room temperature. The results shown in Fig. 4 and Table 1 are the mean values of the experimental data, without any particular correction.

Table 1. Chemical distribution of ^{82}Br-labeled species in neutron-irradiated $CF_3CHClBr$ as a function of the irradiation time

Irradiation time	Fractional yield, %				
	Inorganic species	Organic species			
		$CF_3{}^{82}Br$	$CF_3CHCl{}^{82}Br$	$CF_3CHBr{}^{82}Br$	Others
10 s	32.6	1.1	27.4	17.9	21.0
30 s	31.4	1.2	25.6	18.5	23.3

Bromine-82 is produced by both the radiative neutron capture of Br and the isomeric transition (I.T.) of the resulting ^{82m}Br. By the time the ^{82m}Br nuclei with a half-life of 6.1 min have decayed, 90% of the surviving ^{82}Br (35.34 hr half-life[7]) will have come from the isomeric transition and 10% directly from the (n, γ) activation.[8] The primary recoil event of the ^{82}Br recoil atom is almost always followed by the Auger effect, since the 0.06 MeV transition of ^{82m}Br to its ground state has an internal conversion coefficient of 382.[8,9] Several studies have shown that, in the liquid phase, the organic yields from the converted isomeric transition process occurring in bromine nuclides are higher than the organic yields from the (n, γ) recoil processes.[10-13] The relatively high yield of $CF_3CHCl^{82}Br$ obtained in this experiment may be attributed to the contribution of the (I.T.) process. In this article, however, the problems involving the difference in the primary recoil events are not discussed in detail.

Two chemical processes are, on the whole, involved in the mechanism of recoil labeling: a high-energy (or "hot") process and a thermal process including radical reactions. In order to estimate the ratio of a high-energy process to the thermal processes, the scavenger effect was examined in connection with the chemical distribution of ^{82}Br-labeled products in neutron-irradiated fluothane, in which Br_2 was used as the radical scavenger. As is shown in Fig. 5, typical scavenger curves were obtained for the $CF_3CHClBr$–Br_2 system irradiated for 30 s in the reactor. By extrapolating the almost linear portion of the curves to the zero bromine concentration, 4.8±0.5% of $CF_3CHCl^{82}Br$ was estimated to be produced through the "high-energy" process. As is listed in Table 2, the "high-energy" yield of $CF_3CHCl^{82}Br$ estimated for the 20 min-irradiated target was 3.6±0.5%. A small difference in the "high-energy" yield was observed between the 30 s- and 20 min-irradiated targets. This difference was also found in the "high-energy" yields of $CF_3CHBr^{82}Br$: 4.0±0.5 and 2.4±0.5% for the targets irradiated for 30 s and 20 min respectively. If the "high-energy" yield estimated from the scavenger curve represents the yield due to a hot-atom reaction, it should be rather constant, independent of the irradiation time. The difference in the "high-energy" yield thus obtained may be correlated with the caging effect which is expected in the reaction of bromine atoms in the condensed phase. Because of this effect, the radical scavenger is considered to be inhibited in some portion from reacting with the thermalized ^{82}Br atoms. The decrease in the "high-energy" yield in a longer irradia-

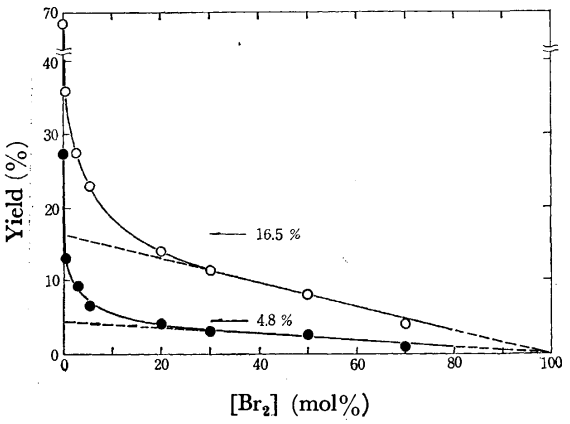

Fig. 5. Radioactivity yields of ^{82}Br-labeled product in the $CF_3CHClBr$–Br_2 system irradiated for 30 s in the JRR-4 reactor. ○, Overall organic products; ●, $CF_3CHCl^{82}Br$.

Table 2. Contribution of "thermal" and "high-energy" processes to the radiochemical yield of ^{82}Br-labeled species produced in neutron-irradiated $CF_3CHClBr$

30 s	53.1±2.5	16.5±1.0	20.8±1.5	4.8±0.5	14.5±1.0	4.0±0.5
20 min	83.0±2.5	12.0±1.0	34.7±1.5	3.6±0.5	22.3±1.5	2.4±0.5

a) The Y_t and Y_h denote the "thermal" and "high-energy" yields, which were estimated from the scavenger curves obtained for the $CF_3CHClBr$–Br_2 system.

tion may be attributed to the contribution of the radiolytic organic radicals produced in the reaction zone.

At least, it can be pointed out that the high-energy yield of $CF_3CHCl^{82}Br$ is larger than that of $CF_3CHBr^{82}Br$. The high-energy yield of $CF_3{}^{82}Br$ is undoubtedly smaller than 1.1%, judging from the data listed in Table 1. Hardly any of the labeled product caused by ^{82}Br-for-F substitution was observed in this experiment. As a result, the order of the high-energy yields may be described as: $CF_3CHCl^{82}Br > CF_3CHBr^{82}Br > CF_3{}^{82}Br$ (>^{82}Br-for-F substituted species). This suggests that the high-energy reaction of ^{82}Br recoil atoms with $CF_3CHClBr$ has a close relation with the bond strength in the molecule, because the bond dissociation energies of the individual bond in $CF_3CHClBr$ should be in the order of: C–Br<C–Cl<C-C<C–H<C–F.[14]

The abrupt increase in the overall organic yield at the irradiation time of around 2 min may be explained in terms of the thermal reactions of ^{82}Br with organic radicals. When the target material was irradiated for less than 30 s, the bulk concentration of the radiolytic organic radicals should be quite low, judging from the fact that hardly any mass signals of organic species except for fluothane were observed in the gas chromatogram in Fig. 1. In this case, the thermalized ^{82}Br atom should give rise to an inorganic compound, probably forming $H^{82}Br$, $Cl^{82}Br$, or $Br^{82}Br$, although we have not yet identified them. On the other hand, in the case of the irradiation for more than 2 min, the concentration of the organic radicals produced by the radiolysis of the parent molecules might be sufficiently high in the vicinity of the ^{82}Br recoil atoms, so that the thermalized ^{82}Br atom could react with those radicals to form organic compounds *via* shorter diffusion paths. In fact, the increase in the thermal yield of the overall organic products between 30 s- and 20 min-irradiation, 29.9%, is comparable with decrease in the inorganic yield of 26.4%, within the limits of experimental error.

Through the present study of the chemical behavior of ^{82}Br recoil atoms produced in neutron-irradiated fluothane, several factors which determine the chemical distribution of the ^{82}Br-labeled species were elucidated. Recoil labeling was revealed to be a feasible method for the preparation of fluothane-^{82}Br; some technical information related to the practical preparation will be reported in a forthcoming journal.[5]

The authors wish to express their thanks to Professor Shinich Sasaki and Dr. Hidetsugu Abe of Miyagi University of Education for permitting the use of the gas chromatograph and mass spectrometer (GC-MS). The authors would also like to thank Dr. Hiroshi Amano and Mr. Takashi Moriya of the Japan Atomic Energy Research Institute for their useful suggestions and discussions.

Although the particular bond dissociation energies for the individual chemical bond in the CF_3-CHClBr molecule have not been reported in the literstures, it is not grossly in error to consider that the bond strength is in the order of C–Br<C-Cl<C-C<C–H<C–F.

A Shock-tube Investigation of Ignition in Ethylene-Oxygen-Argon Mixtures

Yoshiaki HIDAKA, Tsuyoshi KATAOKA, and Masao SUGA

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received January 21, 1974)

The ignition of ethylene-oxygen mixtures highly diluted with argon was studied in a shock tube by monitoring the emission from CH* and C_2* or OH*. The measurements covered the temperature range of 1400—2100 K at the C_2H_4/O_2 ratios of 0.33—1.00. From the observation of the CH*, C_2*, and OH* emissions, a mechanism for the production of chemiluminescent species upon ethylene oxidation was briefly discussed, and from the observation of the induction period of the CH* emission, the following equation was found:

$$\log \tau_{CH}[O_2] = -11.45 + 27.5 \times 10^3/4.58T$$

in units of s mol l^{-1}, the rate-determining step being $C_2H_3+O_2 \rightarrow C_2H_3O+O$.

About fifteen years ago, one of the present authors studied the oxidation of ethylene in the temperature range from 700 to 1000 K by the "admission method" and found an apparent activation energy of about 30 kcal/mol.[1]

Since that time, the shock tube has been adopted as a very important tool for studying ignition processes and the shock-tube oxidation of ethylene has been studied by several investigators, for it allows gases to be heated rapidly and homogeneously so that wall effects and diffusion may be neglected. White[2] has reported that the induction period of the oxidation depends on both the ethylene and oxygen concentrations at small ratios (0.0025—0.01) of ethylene to oxygen in the temperature range from 1100 to 2200 K, using the interferometrical method. In this case, the total order was about one and the estimated activation energy was 17.3 kcal/mol. Gay *et al.*[3] have also observed the induction period at higher ratios (0.1—1.5) of C_2H_4/O_2 in the temperature range from 1500 to 2300 K; they found 24 kcal/mol to be the apparent activation energy. On the other hand, by monitoring both the infrared emission from CO and CO_2 and the CH* visible emission, Homer and Kistiakowsky[4] have obtained the activation energy of 17.1 kcal/mol at C_2H_4/O_2 ratios of 0.17—0.5 in the temperature range from 1500 to 2300 K.

In the present paper, we wish to report the results of simultaneous observations of CH* and C_2* or OH* emissions and wish to interpret the observed emission profiles. Another purpose of this paper is to determine the apparent activation energy of ethylene oxidation by means of measurements with the induction period of the CH* emission in a shock tube.

Experimental

Apparatus and Procedure. The shock tube used in these experiments was composed of a stainless steel tube 4.3 cm in inner diameter. The tube was divided into two sections, that is, the driver section, B (129 cm in length), and the test section, A (250 cm in length), separated by a diaphragm, D_i of polycarbonate or polyester film 25—70 μ thick punctured by a spring-located needle, N. The outline of the apparatus is shown in Fig. 1.

The velocity of the shock waves was measured by using two barium titanate gauges, G_2 and G_3. The G_1 gauge,

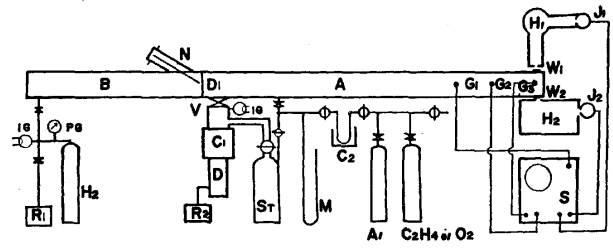

Fig. 1. Schematic diagram of apparatus.

located at a distance of 210 cm from the diaphragm, D_i, was used for starting the sweep of the synchroscope, S. Both distances, G_1—G_2 and G_2—G_3, were 15 cm. The incident shock speeds were recorded in order to evaluate the reflected shock temperatures.

The quartz windows, W_1 and W_2, located 1 cm from the reflecting plate, could be used to monitor the CH* emission and the C_2* or OH* emission simultaneously during the reaction. At one window, W_1, the measurement of the CH* emission was made using a Hilger prism monochromator, H_1 (with a half-width of 20 Å) equipped with a Hamamatsu R-300 photomultiplier, J_1. At the other window, W_2, the measurement of the OH* or C_2* emission was made using a Rico-MC-20 grating monochromator, H_2 (with a half-width of 25 Å), equipped with a Hamamatsu R-300 photomultiplier, J_2.

The out-put voltages from the gauges (G_2 and G_3) and the photomultipliers (J_1 and J_2) were recorded simultaneously on an Iwatsu DS-5158 A dual-beam synchroscope, S. The time response was better than 1 μs.

The driver section, B, was evacuated until the pressure was about 10^{-3} Torr by means of a rotary pump, R_1, before admitting the driver gas. On the other hand, the test section, A, and the gas sampling system could be evacuated until 1×10^{-5} Torr by the pumping system which included a 2 inch oil-diffusion pump, D, with a liquid nitrogen trap, C_1; the evacuation was checked by means of a cold cathode ionization gauge, IG. The test section, A, of the shock tube was always checked to a pressure of 1×10^{-4} Torr before filling it with a reaction mixture, and the shock was fired within 2 min after isolation from the pumping system, because it has a residual leak at the rate of 2×10^{-4} Torr per minute.

The inner wall of the test section, A, and especially the inner surfaces of the windows (W_1 and W_2) were cleaned after each run with a dry cloth in order to remove any unvolatile products. Also, the reaction mixtures were prepared manometorically and stored in a stainless steel storage vessel, ST (volume, *ca.* 30 l). The line and storage were flushed with argon before the preparation of the mixtures.

The other accessories of this apparatus and the method of operation were similar to those reported in an earlier publication.[5]

Materials. The ethylene, oxygen, and argon used were obtained from commercial cylinders; the purities were 99.99%, 99.9%, and 99.99% respectively. The driver gas was 99.9% pure-grade hydrogen. All the gases were used without further purification except for passing them through a dry ice trap, C_2.

Samples. The compositions of the reaction mixtures were (1% C_2H_4, 1% O_2, 98% Ar), (1% C_2H_4, 2% O_2, 97% Ar), and (1% C_2H_4, 3% O_2, 96% Ar), and the initial pressures of the reaction mixtures used were about 50 Torr and 100 Torr. Each shock-run was denoted a or b for the initial pressures of 50 Torr and 100 Torr, and 1, 2, and 3 for the oxygen concentrations of 1%, 2%, and 3% respectively. For example, 3a corresponds to the initial pressure of 50 Torr and the oxygen concentration of 3%.

Results and Discussion

The reflected shock temperatures were calculated from the measured incident shock velocities, using the three conservation equations and the ideal equation of a state assuming a thermal equilibrium.

Interpretation of Observed Emission Profiles. In the present experiments, we observed the C_2* emission at 5165 Å, the CH* emission at 4515 Å, and the OH* emission at 3067 Å. The CH* emission intensity observed using a Rico-MC-20 grating monochromator was about 1.4 times that observed using a Hilger prism monochromator at 4315 Å. In addition, the Hamamatsu R-300 photomultiplier has a different response of intensity according to the wavelength, that is, it is 100 at 3067 Å, 85 at 4315 Å, and 52 at 5165 Å. These values were applied in order to correct the emission intensities which were directly obtained from the observed emission profiles, as is shown in Fig. 2.

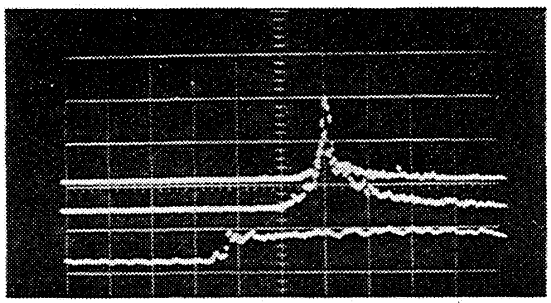

Fig. 2. Comparison of time history of CH* emission using the prism monochromator and OH* emission using the grating monochromator,
T_5=1506 K, P_5=1495 Torr, sweep=50 μs/div..
Upper trace: OH* emission at 3067 Å using grating monochromator, gain=0.05 V/div.
Middle trace: CH* emission at 4315 Å using the prism monochromator, gain=0.1 V/div.
Lower trace: G_3 signal.

The following characteristics were obtained from the emission profiles of each run:

1. The maximum emission intensity of OH* was considerably smaller than those of CH* and C_2*, showing a ratio of emission intensity of about 10 (CH*): 10 (C_2*): 1 (OH*); it was not distinguishable from noises, especially in the range of lean oxygen.

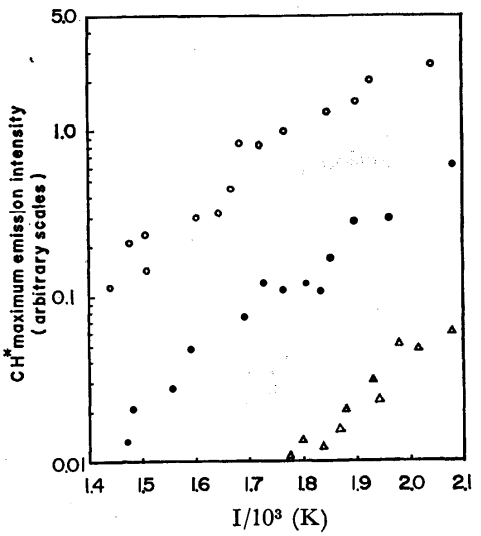

Fig. 3. Comparison of CH* maximum emission intensity of series a at various temperatures.

2. The maximum intensity of the CH* emission decreased extremely at both a lowering of the temperature and a decrease in the O_2 concentration, as is shown in Fig. 3; the OH* emission showed similar behavior.

3. The maximum intensity of the C_2* emission shows no clear dependence on the O_2 concentration, unlike the CH* and OH* emissions.

4. The onset of emission was qualitatively observed to be in the order of: CH*, C_2*, and OH*.

Several reaction mechanisms have been proposed by Gaydon[6] and Hand and Kistiakowsky[7] for the formation of CH* in hydrocarbon flames, *e.g.*;

$$C_2 + OH \longrightarrow CH^* + CO \quad (1\text{-}1)$$
$$C_2H + O_2 \longrightarrow CH^* + CO_2 \quad (1\text{-}2)$$
$$C_2H + O \longrightarrow CH^* + CO \quad (1\text{-}2')$$

The present experimental results indicate that the CH* emission arises mainly from Reactions (1-2) and (1-2′) rather than from (1-1), because of the great dependence of the O_2 concentration on the CH* emission; the onset of emission was observed in the order of: CH*, C_2*, and OH*.

Secondly, as to the production of C_2* in hydrocarbon flames, several reactions have been considered by Ferguson,[8] Miller and Palmer,[9] and Gaydon and Wolfhord,[10] *e.g.*;

$$CH + CH \longrightarrow C_2^* + H_2 \quad (1\text{-}3)$$
$$C + CH \longrightarrow C_2^* + H \quad (1\text{-}4)$$
$$CH_2 + C \longrightarrow C_2^* + H_2 \quad (1\text{-}5)$$
$$C_2O + C \longrightarrow C_2^* + CO \quad (1\text{-}6)$$

As CH_2 and C_2O may not be produced during C_2H_4 oxidation, the C_2* emission may arise from (1-3) and (1-4).

The production of OH* in hydrocarbon flames has been explained by this reaction:

$$CH + O_2 \longrightarrow CO + OH^* \quad (1\text{-}7)$$

for which evidence has been reported.[6,11]

The intensity of OH* emission was greatly dependent on the O_2 concentration, just like the CH* emission, and the intensity of the OH* emission was weak as compared with the intensities of CH* and C_2*. This implied that OH* emission may arise from Reaction (1-7); thus, Reaction (1-3) or (1-4) and Reaction (1-7) should be competitive reactions which consume the ground-state CH, while Reaction (1-2) or (1-2′) and Reaction (1-7) are also competitive reactions which consume oxygen.

It seemed that it would be very interesting to know exactly the process of the onset of emission in order to discuss the reaction mechanism. The order of the onset of emission was, qualitatively, the CH*, C_2*, and OH* emissions, as has been described above. However, we cannot discuss the reaction mechanism in detail on the basis of the CH*, C_2*, and OH* order of emission onset because of the complexity of the phenomena of the CH*, C_2*, and OH* emissions.

Induction Period. Table 1 summarizes the experimental conditions of the four groups of runs and the results of the measurement of the induction period, τ_{CH}, which is defined as the time lag between the reflected shock arrival and the onset of the CH*-emission signal. Figure 4 shows the plot of log τ_{CH} *versus* 1/T for three experimental groups, 3a, 2a, and 1a. It can readily be seen that the values of log τ_{CH} in Groups 3a, 2a, and 1a fall on a single linear line, indicating the effect of oxygen on the induction period. Figure 5 shows the plotting of log $\tau_{CH}[O_2]$ *versus* 1/T for four groups of experiments, 3a, 2a, and 1a, and 1b; all the points fit a single line. The temperature coefficient of the induction period can be obtained from the slope of the line drawn in Fig. 5. Consequently, over the temperature and concentration ranges covered by the present experiments, the induction period for the

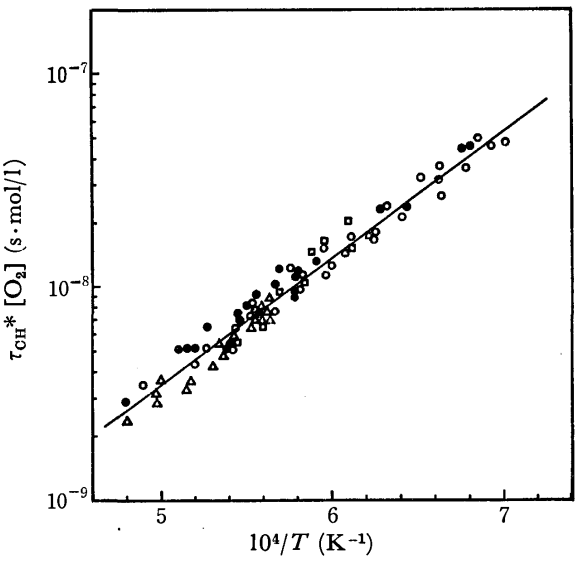

Fig. 5. A plot of log τ_{CH}*[O_2] *versus* $1/T$ for three reaction mixtures.
Initial pressure of about 50 Torr,
○: 3% O_2+1% C_2H_4, ●: 2% O_2+1% C_2H_4,
△: 1% O_2+1% C_2H_4.
Initial pressure of about 100 Torr,
□: 1% O_2+1% C_2H_4.

CH* emission can be represented as:

$$\log \tau_{CH}[O_2] = -11.45 + 27.5 \times 10^3/4.58T$$

in units of s mol l^{-1}.

White,[2] examining very lean mixtures (fuel/oxygen—0.1), observed that the induction periods before any detectable heat release from the C_2H_4–O_2 and C_2H_2–O_2 reactions were similar to each other in the temperature range from 1100 to 2200 K and led to an essentially common activation energy of 17.3 kcal/mol. Gay *et al.*,[3] using C_2H_4/O_2 ratios of 0.1—1.5, reported that the induction period and the intensity of chemiluminescence from CH* were similar in magnitude to those found in the C_2H_2–O_2 reaction, especially at the higher temperatures of 1800—2100 K. At lower temperatures, towards 1500 K, the induction periods were significantly greater than in the case of C_2H_2; the results gave an activation energy 24 kcal/mol larger than the 17 kcal/mol found for C_2H_2–O_2. They detected quite large concentrations of acetylene during the course of the C_2H_4–O_2 reaction and proposed the following tentative schemes:

	ΔH (kcal/mol)	
$C_2H_3 + O_2 \longrightarrow C_2H_3O + O$	+27	(2-1)
$O + C_2H_4 \longrightarrow C_2H_3 + OH$	+3	(2-2)
$OH + C_2H_4 \longrightarrow C_2H_3 + H_2O$	−14	(2-3)
$C_2H_3 + O_2 \longrightarrow 2CO + H_2 + H$	−67	(2-4)
$C_2H_3 + O_2 \longrightarrow C_2H_2 + HO_2$	+5	(2-5)
$C_2H_3O + M \longrightarrow C_2H_2 + OH + M$	+30	(2-6)
$C_2H_3O + O_2 \longrightarrow 2CO + H_2O + H$	−100	(2-7)
$C_2H_3 + M \longrightarrow C_2H_2 + H + M$	+41	(2-8)
$H + C_2H_4 \longrightarrow C_2H_3 + H_2$	+1	(2-9)

To satisfy the higher activation energy, they suggested that the rate-determining step was (2-1), the endothermicity being 27 kcal/mol.

On the other hand, Homer and Kistiakowsky[4] reported an activation energy of 17 kcal/mol and the rate-determining step of:

$$H + O_2 \longrightarrow OH + O \qquad (2\text{-}10)$$

at lower ratios of C_2H_4/O_2. They then proposed that the C_2H_4–O_2 reaction, in its early stages, consists mainly of the pyrolysis to the C_2H_2 and H_2 above 1800 K. They have also suggested the existence of some value larger than 24 kcal/mol controlling the ethylene-oxidation mechanism involving such intermediates as have been postulated by Gay *et al.*

The measurement of the induction period in the shock tube has been undertaken in the hope that it would offer a convenient method elucidating an activation energy and would be able to suggest a rate-determining step. The value of the apparent activation energy obtained from the present experiment is 27.5 kcal/mol at 1400—2100 K, the value of Gay *et al.* is 24 kcal/mol at 1500—2300 K, and our previous work[1] has shown the value of 30 kcal/mol in the range of 700—1000 K in spite of the difference in method. The variation in the apparent activation energy with the temperature has also been considered.[12] Since a rate-determining step in an elementary reaction will vary with the temperature and the composition, the difference in these values can be understood. As has been mentioned above, White and Homer *et al.* have reported an activation energy of about 17 kcal/mol at lower ratios of C_2H_4/O_2, and Gay *et al.* have reported an activation energy of 24 kcal/mol at higher ratios of C_2H_4/O_2. The value of activation obtained from the present experiment at higher ratios of C_2H_4/O_2 is 27.5 kcal/mol. Hence, it seems that, in the C_2H_4 oxidation, Reaction (2-10) is predominant at lower ratios of C_2H_4/O_2 and

Reaction (2-1) is predominant at higher ratios of C_2H_4/O_2. Considering the schemes proposed by Gay *et al.*, it may be supposed that the reaction:

$$C_2H_3 + O_2 \longrightarrow C_2H_3O + O \qquad (2\text{-}1)$$

is the rate-determining step for ethylene oxidation under our experimental conditions. Since Reaction (2-1) is endothermic, the activation energy of Reaction (2-1) should be larger than its endothermicity (27 kcal/mol).[13] The apparent activation energy obtained, 27.5 kcal/mol, satisfies the above relation. Therefore, the apparent activation energy, 27.5 kcal/mol, obtained from our measurements seems reasonable.

The authors would like to thank Professor H. Yamamura of Hiroshima University for his interest and helpful discussions, and be also grateful to Mr. H. Fujimoto and Mr. S. Doi for the assistance of observations done partly in the present experiment.

The Temperature Dependence of the *G*-Values of Nitrogen from the Gas-phase γ-Radiolysis of C_3-Hydrocarbons in the Presence of Nitrous Oxide

Kiyoshi OKAZAKI, Rei YUGETA, Ken-ichi KOWARI, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 6, 1974)

The *G*-values of nitrogen from the gas-phase γ-radiolysis of the C_3-hydrocarbons (propane, propylene, and cyclopropane) in the presence of nitrous oxide have been measured at the temperatures from −35 to 150 °C. The *G*-values increased with an increase in the pressure of N_2O and were saturated at about 4 mol% of N_2O. The saturated values, $G(N_2)_{max}$'s showed characteristic temperature dependences. In propane, they scarcely changed with the temperature and stayed at around 2 G_e. Here G_e is the *G*-value of electrons estimated from the *W*-value of the hydrocarbon. In propylene, the $G(N_2)_{max}$ changed from G_e at −35 °C to about 2 G_e at 150 °C, while in cyclopropane it changed from G_e at −35 °C to 4.5 G_e at 100 °C. Possible reaction mechanisms to explain these results have been discussed.

Nitrous oxide is a well-known electron scavenger.[1,2] When a hydrocarbon is γ-irradiated in the presence of a small amount of nitrous oxide, nitrogen is one of the main products and its formation can be explained by the mechanism initiated by the electron capture of nitrous oxide. The quantitative measurement, however, shows that the *G*-value of nitrogen is always larger than the *G*-value of scavenged electrons. This fact is now one of the most persistent problems in the study of hydrocarbon-radiolysis.[3-7]

In a previous paper,[7] we showed that the *G*-value of nitrogen from the N_2O-1-butene system is strongly dependent upon the temperature as well as on the total dose and the dose rate, and that these effects make the problem more complex. The present paper will report the results obtained with the C_3-hydrocarbons (propane, propylene, and cyclopropane), with which we can make experiments at lower temperatures at the same pressures.

Experimental

The experimental procedure was the same as that reported previously.[7] The temperature of −35 °C was obtained by mixing ice and $CaCl_2$ in a Dewar flask. The temperature lasted (within ±5 °C) long enough for the γ-irradiation, usually three hours.

Results

Figure 1 shows the temperature dependence of the $G(N_2)$'s from the three C_3-hydrocarbons-N_2O systems. Figure 2 shows the $G(H_2)$'s obtained simultaneously with the $G(N_2)$'s. The pressure of hydrocarbons is always around 600 Torr, and the dose rate is 1.3×10^{13} eV ml^{-1} s^{-1}. In order to elucidate the reaction mechanisms, the effects of several additives were also studied. The results are summarized in Table 1.

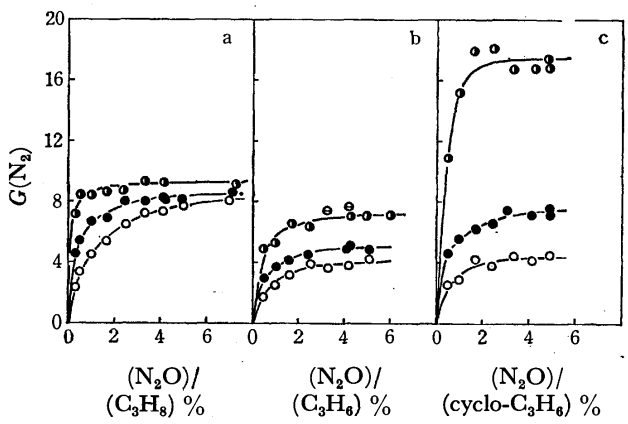

Fig. 1. The temperature dependence of the $G(N_2)$'s from C_3-hydrocarbons in the presence of nitrous oxide. a: propane, b: propylene, c: cyclopropane; ○: −35 °C, ●: 0 °C, ◑: 100 °C, ⊖: 150 °C.

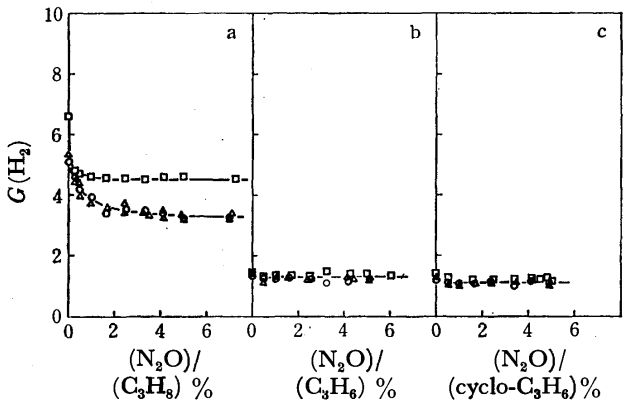

Fig. 2. The temperature dependence of the $G(H_2)$'s from C_3-hydrocarbons in the presence of nitrous oxide. a: propane, b: propylene, c: cyclopropane; ○: −35 °C, △: 0 °C, □: 100 °C.

Table 1. The effects of the additives on the $G(N_2)$'s from the 4 mol% N_2O-C_3 hydrocarbon systems at 0 °C

	$G(N_2)$				
	N_2O only	SF_6 0.03 mol %	CO_2 4 mol %	NH_3 4 mol %	CH_3OH 4 mol %
Propane	8.2	0.2	4.4	4.4	20.6
Propylene	5.0	0.3	3 8	4.4	11.1
Cyclopropane	5.9	0.2	3.8	4.4	27.1

Discussion

The electrons generated by γ-rays in a high-pressure hydrocarbon will be thermalized very quickly. According to the measurement of Warman and Sauer[8] using a microwave technique, 0.2 Torr of *n*-hexane is high enough to thermalize electrons in a few microseconds. In the present experiment, all the samples contain 600 Torr of C_3-hydrocarbons. The precursor of the nitrogen measured above must be thermalized electrons.[9]

Warman and Fessenden suggested that the electron capture by N_2O occurs through the third-body reaction:[10]

$$e^- + N_2O + M \longrightarrow N_2O^- + M \qquad (1)$$

However, the formation of N_2O^- ions is doubted by many researchers. One of the reasons is that N_2O^- ions have not been observed in the mass-spectrometric study at low pressures of N_2O.[11] The reaction might be:

$$e^- + N_2O \xrightarrow{(+M)} N_2 + O^- \qquad (2)$$

The present experiment cannot specify the reaction.

In a previous paper,[7] we proposed this reaction:

$$N_2O^- + SF_6 \longrightarrow N_2O + SF_6^- \qquad (3)$$

to explain the fact that a very small amount of SF_6 can inhibit the formation of nitrogen from the N_2O-hydrocarbon systems. However, according to the recent paper of Bansal and Fessenden,[12] the electron capture of SF_6 is extremely fast (2×10^{-7} cm^3 mol^{-1} s^{-1}). If this is true, the inhibition effect can be explained simply by the competition of N_2O and SF_6 for thermalized electrons.

In the following discussion, we will assume that N_2O^- ions, even if produced, react much as do O^- ions. When O^- (or N_2O^-) ions are produced in propane, the following reaction will occur very readily:

$$O^- + C_3H_8 \longrightarrow OH^- + C_3H_7 \qquad (4)$$

The rate of Reaction (4) has been reported to be 9.3×10^{-10} cm^3 mol^{-1} s^{-1}.[13] Since the OH^- ions thus formed are stable ions as far as they are not neutralized (the neutralization time at the dose rate used here is estimated to be 10^{-3} s), the following addition reaction may occur:

$$OH^- + N_2O \longrightarrow OHN_2O^- \qquad (5)$$

This reaction has been proposed by Parkes[14] on the basis of the mass-spectrometric observation that the principal product in the N_2O-C_2H_6 system is the mass 61, OHN_2O^-.

In our propane case, therefore, the main neutralization reaction may be:

$$OHN_2O^- + C_3H_8^+ \longrightarrow N_2 + C_3H_7 + 2OH \qquad (6)$$

If this mechanism is correct, we can understand the $G(N_2)\simeq 2G_e$ relation, which should be independent of the temperature examined. If NH_3, the dipole moment of which is larger than that of N_2O, is present, Reaction (5) will be interrupted by the clustering of NH_3 on the OH^- ion. This is in accord with the observation that the addition of NH_3 to the N_2O-hydrocarbon system decreased the $G(N_2)_{max}$'s to G_e, as shown in Table 1.

When propylene is the substrate, there are two possible processes in the reaction of O^- ions, because they are mono-radicals:

$$CH_3CH{=}CH_2 + O^- \longrightarrow \dot{C}H_2CH{=}CH_2 + OH^- \qquad (7)$$

$$\searrow\ CH_3\dot{C}H\text{-}CH_2\text{-}O^- \qquad (8)$$

Process (8) may be a third-body reaction, and the product ions may not contribute to the formation of nitrogen. By analogy to the reactions of monoradicals with olefins, Process (7) will have a certain amount of activation energy, while the activation energy of Process (8) may be nearly zero. Taking these reactions into account, the temperature dependence of the $G(N_2)_{max}$ in propylene may be expressed as follows:

$$\frac{G(N_2)_{max}}{G_e} = 1 + \frac{A\exp(-E_7/RT)}{1+A\exp(-E_7/RT)}$$

Here, E_7 represents the activation energy of Process (7). A is the ratio of the pre-exponential factors of Processes (7) and (8). The curve shown in Fig. 3 is drawn by assuming that $E_7=4.7$ kcal mol^{-1} and $A=2.8\times10^2$. These values are not unreasonable for a radical reaction.[15]

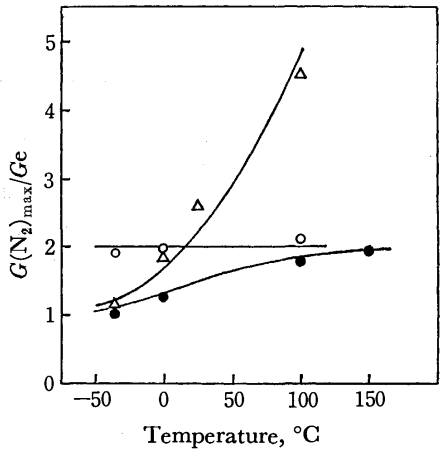

Fig. 3. The temperature dependence of the $G(N_2)_{max}$'s
○: propane, ●: propylene, △: cyclopropane.

In the case of cyclopropane, much more speculation has to be undertaken, because very few reports have been published on the reactions of cyclopropane. The results described above obviously show the chain decomposition of N_2O. One possible chain reaction is as follows:

$$O^- + \text{cyclo-}C_3H_6 \longrightarrow CH_2O^- + C_2H_4 \qquad (9)$$

$$CH_2O^- + N_2O \longrightarrow CH_2O + N_2 + O^- \qquad (10)$$

The apparent activation energy for the formation of nitrogen was calculated to be 3.6 kcal mol^{-1} by using this equation:

$$G(N_2)_{max}/G_e = 1 + A_9\exp(-E_9/RT)$$

Here, A_9 and E_9 are the pre-exponential factor and the activation energy of Process (9) respectively.

The addition of CO_2 to the 4 mol% N_2O-C_3-hydrocarbon systems reduced the $G(N_2)$'s to around G_e, irrespective of the C_3-hydrocarbons. Such an effect

has already been reported by Warman;[5] it may be interpreted in terms of this reaction:

$$O^- \text{ (or } N_2O^-) + CO_2 \longrightarrow CO_3^- (+N_2) \qquad (11)$$

The effect of CH_3OH on the $G(N_2)$'s is obviously different from those of other additives. In the radiolysis of pure methanol, it has already been recognized that, when N_2O is added to the system, nitrogen is produced in a chain reaction.[16] Although CH_3OH has been used as a positive ion-interceptor in the liquid-phase radiolysis, its effect is obviously not so simple in the gas-phase.

The Estimation of the *G*-Values for the Ionization and Excitation of Noble Gases Irradiated by 100 keV Electrons

Shin SATO, Kiyoshi OKAZAKI, and Shin-ichi OHNO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

**Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11*

(Received March 7, 1974)

The binary-encounter collision theory has been applied to the calculation of the *G*-values for the ionization and excitation of noble gases irradiated by 100 keV electrons. The *G*-values obtained were as follows in the order of He, Ne, Ar, Kr, and Xe: 2.27, 2.19, 2.81, 3.20, 3.45 for *G*(electrons), 0.85, 1.55, 1.92, 1.64, 1.51 for *G*(singlet states), and 0.17, 0.07, 0.13, 0.23, 0.39 for *G*(triplet states). The method of the calculation and the significance of the results were discussed.

One of the most attractive and challenging problems for radiation chemists is the non-empirical calculation or prediction of the *G*-values of products from the compounds they are concerned with. Such a calculation, however, has not been carried out except for helium gas, because there are too many unknown factors and not-established procedures. Even if the factors and the procedures are properly approximated, laborious calculations have to be performed. The calculation for helium was carried out by Erskine,[1] Miller,[2] and Platzman.[3] Since then, several calculations for the degradation spectra in a number of media were carried out, and some of the results were compared with the experimental data obtained largely in metallic media.[4] Recently, Alkhazov has recalculated the degradation spectrum of non-relativistic electrons in helium and discussed the yields of ionization and excitations.[5] This calculation may be the most detailed one for helium at present. His method, however, cannot be applied to other compounds, because several experimental values, which are known only for a limited number of gases, are used. From the point of view of radiation chemists, a more general method which is applicable to a variety of compounds is desirable even though the results are less accurate.

One of the present authors has recently shown[6] that, if the binary-encounter collision theory and the procedure for calculating the degradation spectrum of electrons are combined, the *G*-values of ionization and excitations can be calculated for practically all of the molecules. As an example, he showed the calculation for helium and the hydrogen molecule,[7] the results of which were in reasonable agreement with those estimated from the experimental work. This calculation was so laborious when it is applied to more complex atoms that we wrote a program for an electronic computer and carried out the calculations for the noble gases from He to Xe. The present paper will report the details of the calculation and will attempt to ascertain the limitations of this method.

Method of Calculation

Cross Sections for Ionization and Excitations. The most difficult problem in the calculation of the degradation spectrum of a high-energy electron is the accurate formulation of the cross sections for various energy-loss processes, especially when the energy of electrons is lower than 100 eV. However, if the binary-encounter collision theory is assumed to be applicable to any incident electron, the formulation is rather straightforward. Such a formulation has already been summarized by Vriens and reported in detail.[8] For the present purpose, the final expressions will be satisfactory.

According to the symmetrical model for the collision of a high-energy electron with an atomic electron, the energy loss of the incident electron may be estimated by means of the collisional cross section, where we ignore the radiative energy loss:

$$\sigma_E = \sigma_{E,dir} + \sigma_{E,exc} = \frac{\pi e^4}{T+I_i+E_i}\left[\left(\frac{1}{E^2}+\frac{4E_i}{3E^3}\right) + \left\{\frac{1}{(T+I_i-E)^2}+\frac{1}{3(T+I_i-E)^3}\right\}\right] \quad \text{(I)}$$

for $T+I_i-E \geq 0$. Here, σ_E is the differential cross section per unit of energy for the energy loss (E) of the incident electron with the energy T, while E_i and I_i are, respectively, the average kinetic energy and the binding energy of the atomic electron under consideration. If the atomic electron is in the outermost shell of the atom, I_i is the ionization potential of the atom (I). The first term in the square bracket on the right-hand side of Eq. (I) corresponds to the direct excitation, and the second term, to the excitation induced by the exchange between the incident electron and an atomic electron. In the formulation of Vriens, there is another term, called "interference." This term results from the difference in the scattering angle between the direct and the exchange excitations. In the present calculation, though, we ignore it because the estimation is somewhat arbitrary when it is taken into account in the calculation[9] and because the contribution of this term to the whole calculation is very small, as will be shown later.

By using Eq. (I), we can derive the total ionization cross section per atomic electron:

$$Q_{ion} = \frac{1}{2}\int_{I_i}^{T}\sigma_E dE = \int_{I_i}^{(T+I_i)/2}\sigma_E dE = \int_{I_i}^{T}\sigma_{E,dir}dE = \frac{\pi e^4}{T+I_i+E_i}\left[\left(\frac{1}{I_i}-\frac{1}{T}\right)+\frac{2E_i}{3}\left(\frac{1}{I_i^2}-\frac{1}{T^2}\right)\right] \quad \text{(II)}$$

The factor of 1/2 has to be introduced because we cannot distinguish the origin of the scattered electron, whether it is originally the incident electron or the atomic electron.

For the cross sections of excitations, we use the following formula according to the treatment of Vriens.[10] Here, E_s and E_t are the energies of the lowest singlet and triplet levels respectively:

$$Q_{singl} = Q_{de} + \frac{1}{2}Q_{ee};\ Q_{tripl} = \frac{1}{2}Q'_{ee} \qquad \text{(III)}$$

Here,

$$Q_{de} = \int_{E_s}^{I} \sigma_{E,dir} dE$$

$$= \frac{\pi e^4}{T+I+E_i}\left[\left(\frac{1}{E_s}-\frac{1}{I}\right)+\frac{2E_i}{3}\left(\frac{1}{E_s^2}-\frac{1}{I^2}\right)\right]$$

for $T \geq I$, and

$$Q_{de} = \int_{E_s}^{T} \sigma_{E,dir} dE$$

for $I > T \geq E_s$. When $T < E_s$, Q_{de} is set equal to zero.

$$Q_{ee} = \int_{E_s}^{I} \sigma_{E,exc} dE$$

$$= \frac{\pi e^4}{T+I+E_i}\left[\left(\frac{1}{T}-\frac{1}{T+I-E_s}\right)+\frac{2E_i}{3}\left\{\frac{1}{T^2}-\frac{1}{(T+I-E_s)^2}\right\}\right]$$

for $T \geq I$, and similarly

$$Q_{ee} = \int_{E_s}^{T} \sigma_{E,exc} dE$$

for $I > T \geq E_s$. When $T < E_s$, Q_{ee} is set equal to zero.

$$Q'_{ee} = \int_{E_t}^{I} \sigma_{E,exc} dE$$

for $T > I$ and

$$Q'_{ee} = \int_{E_t}^{T} \sigma_{E,exc} dE$$

for $I > T \geq E_t$. When $T < E_t$, Q'_{ee} is set equal to zero. These equations are very tentative, as Vriens has already mentioned, and should be replaced by better equations when they become available.

Stopping Power. In the present paper, we consider the energy loss resulting in the atomic excitation or ionization. Therefore, the stopping power of the medium which consists of a single kind of atom may be expressed as follows:

$$S(T) = N\left\{\sum_i n_i \int_{I_1}^{(T+I_1)/2} E\sigma_E dE + n\left(\int_{E_s}^{I} E\sigma_E dE + \frac{1}{2}\int_{E_t}^{E_s} E\sigma_{E,exc} dE\right)\right\} \qquad \text{(IV)}$$

for $T \geq I$. Here, $S(T)$ is the stopping power, N is the number of atoms in a unit volume, n_i is the number of electrons in the i-th shell, and n is the number of electrons in the outermost shell. When the energy of the incident electron is smaller than I, the first term in Eq. (IV) disappears and the upper limit of the second integral should be replaced by T. Similarly, when $T < E_s$, the first and second terms dissappear and the E_s in the third integral should be replaced by T.

Degradation Spectrum. When a high-energy electron with the energy of T_0 passes through a medium, various types of ionizations take place and secondary electrons are ejected, the energies ranging from zero to T_0-I. If the kinetic energy of the secondary electrons thus produced is higher than I, they will induce another ionization. From the point of view of the medium, there is a spectrum of the electrons which have a wide range of kinetic energies. Such a spectrum is called a degradation spectrum. Spencer and Fano may have been the first to discuss the quantitative method for the calculation of the degradation spectrum.[11] Schneider and Cormack also investigated the method and performed the calculation for helium.[12] This method was used by Oda and Nishimura to obtain the degradation spectrum produced by ^{60}Co-γ rays in water.[13] Klots and Wright have also carried out the calculation on a simple atomic model and investigated the assumption of the continuous slowing-down which is involved in the calculation.[14] The method used here is essentially the same as that used by Oda and Nishimura.

On the assumption of a continuous slowing-down, the degradation spectrum of the incident electron may be expressed in this form:

$$y_1(T) = 1/S(T) \qquad \text{(V)}$$

On the way to the formation of this spectrum, the secondary electrons are ejected. To describe the degradation spectrum of these secondary electrons, it is more convenient to modify the differential cross section of ionization as follows:

$$\sigma(T_1T_2) = \frac{\pi e^4}{T_1+I_1+E_i}\left\{\left(\frac{1}{(T_2+I_1)^2}+\frac{4E_i}{3(T_2+I_1)^3}\right)+\left(\frac{1}{(T_1-T_2)^2}+\frac{4E_i}{3(T_1-T_2)^3}\right)\right\} \qquad \text{(VI)}$$

Here, $\sigma(T_1T_2)$ is the differential cross section for the production of the secondary electron with the energy of T_2 in the collision between the incident electron with the energy of T_1 and an atomic electron in the i-th shell. Therefore, the degradation spectrum of the secondary electrons may be expressed in this form:

$$y_2(T) = \frac{N}{S(T)}\sum_i n_i \int_T^{1/2(T_0-I_1)} \int_{2T_2+I_1}^{T_0} y_1(T_1)\sigma(T_1T_2)dT_1dT_2 \qquad \text{(VII)}$$

Here, the upper limit of the first integral, $1/2(T_0-I_i)$, comes from the fact that the electrons having energies higher than this value are counted as primary. Similarly, the degradation spectrum of tertiary electrons is expressed as follows:

$$y_3(T) = \frac{N}{S(T)}\sum_i n_i \int_T^{1/4(T_0-3I_1)} \int_{2T_2+I_1}^{1/2(T_0-I_1)} y_2(T_1)\sigma(T_1T_2)dT_1dT_2 \qquad \text{(VIII)}$$

Similar equations may be constructed for the electrons ejected in the later steps.

The total degradation spectrum is obviously the sum of the above spectra:

$$y(T) = \sum y_m(T) \qquad \text{(IX)}$$

In the actual calculation, this series rapidly converges, and the sum of the first five terms is probably accurate enough, but in the following calculation we took the sum of the six terms.

G-Values of Excitation and Ionization. Once $y(T)$ is obtained, the calculation of the yields of excitation and ionization per incident electron is straightforward

if we use the total cross section for each process:

$$N_s = Nn_i\int_{T_s}^{T_0} y(T)\cdot Q_s(T)\mathrm{d}T \qquad (X)$$

$$= Nn_i\int_{T_s}^{T_0} T\cdot y(T)\cdot Q_s(T)\mathrm{d}\ln T \qquad (XI)$$

Here, N_s is the number of the species produced in the s process, T_s is the threshold energy of the incident electron for the s process, and $Q_s(T)$ is the total cross section. According to the expression used by Platzman,[3] the results thus obtained can be shown, as they will be later, in the $T\cdot y(T)\cdot Q_s(T)$ *vs.* ln T plots, so that the area under the curve of $T\cdot y(T)\cdot Q_s(T)$ is proportional to the yield of the s process. Thus, we can estimate the G-values of each process by means of the equation:

$$G_s = \frac{100N_s}{T_0} \qquad (XII)$$

Constants Used for Calculation

In order to carry out the calculation, we have to know the constants which appear in the equations, the singlet and triplet excitation energies of the atom under consideration (E_s and E_t), the binding energies of the atomic electrons (I_i),[15] and their kinetic energies (E_i). Tables 1 and 2 summarize the values of E_s, E_t, and I_i used. The minimum I_i value for an atom is the ionization potential of the atom, for which the spectroscopic values may be better than those obtained by the technique of ESCA using X-rays.

TABLE 1. THE LOWEST SINGLET AND TRIPLET LEVELS (eV)

Atom	E_s	E_t
He	21.2	19.8
Ne	16.8	16.7
Ar	11.8	11.6
Kr	10.6	10.0
Xe	9.6	8.5

TABLE 2. THE BINDING ENERGY OF ELECTRON, I_i (eV)

Shell	He	Ne	Ar	Kr	Xe
1s	24.581	867	3203	14326	34561

4s				24	208
4p				13.996	147
4d					63
5s					18
5p					12.127

Since we have no experimental data for E_i, we have to calculate them. For the noble gases from He to Kr[16] and later for Xe and Rn atoms,[17] Hartree-Fock SCF wave functions based on the single zeta Slater-type function for each electron have been reported. The value of E_i, therefore, may be calculated by using this equation:

TABLE 3. THE KINETIC ENERGY OF ELECTRON, E_i (eV)

Shell	He	Ne	Ar	Kr	Xe

−(Total energy)[a]	77.00	3456	14217	74211	195223

a) Ref. 16 and 17

$$E_i = -\frac{1}{2}\int\phi_i\nabla^{*2}\phi_i\mathrm{d}\tau \qquad (XIII)$$

Table 3 summarizes the calculated values. According to the virial theorem, the total kinetic energy should be equal to the −(total energy) of the atom. The calculated total kinetic energy and the total energy reported[16,17] are compared in Table 3. The agreement is satisfactory for the present calculation.

Results

Figures 1 and 2 show the $y(T)$ and $T\cdot y(T)\cdot Q_s(T)$ *vs.* ln T plots obtained with helium. Figure 2 is very similar to that presented by Platzman.[3]

Table 4 summarizes all of the G-values obtained in the present calculation. All the integrations were carried out by means of a computer, HITAC 8700, with a mesh of $(0.5)^{1/40}$ for the energy. With the increase in mesh, the G-values obtained decreased slightly. In the case of He, the G-value of ionization obtained with the mesh of $(0.5)^{1/80}$ was 2.26; this value agreed within 0.3% with the G-value listed in Table 4.

As has been stated in the previous section, a calculation including the interference term in the cross section

5p					2.03

was also carried out. The G-value of ionization in He was 2.25. The difference from the G-value listed in Table 4 is within 1%.

The degradation spectra in Ne, Ar, Kr, and Xe are shown in Fig. 3. All of the spectra are alike, though there are small differences in the energy region lower than 100 eV. This difference might play an important role in a radiation-induced chemical reaction when these gases are used as the solvents.

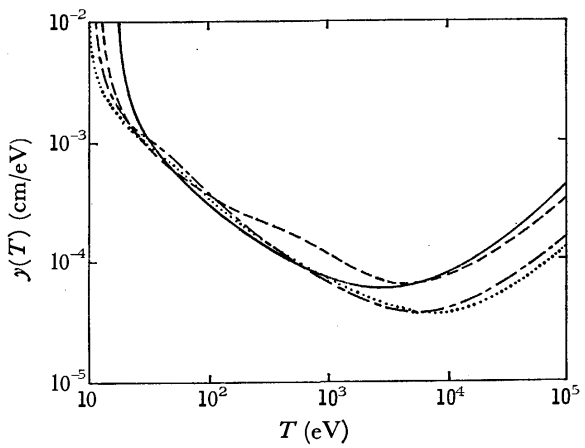

Fig. 3. Slowing-down spectra in Ne (——), Ar (----), Kr (-·-·-), and Xe (·····).

Figures 4 to 7 show the $T \cdot y(T) \cdot Q_i(T)$ *vs.* ln T plots for Ne, Ar, Kr, and Xe. They clearly show that the

ionizations from the inner shells become more important with an increase in the atomic number. Consequently, in order to estimate the G-values of electrons, we have to consider the Auger effect. For example, an excited Ar ion with the ejection of the 2p electron has energy enough for the auto-ionization:

$$Ar^+(2p) \longrightarrow Ar^{5+} + 4e^- \qquad (1)$$

To calculate the total G-value of electrons, the ionization from the 2p shell in Ar should be taken as corresponding to $5e^-$. Here, the yield of the fluorescence, which is often observed with the Auger effect, is ignored. For such a calculation, we need exact data for the multiple-ionizations of the noble gases. Most of the data we need are not available. Therefore, the G-values of electrons were estimated by using a tentative equation:

$$G(e^-) = \sum_i f_i G_i(M^+) \qquad (XIV)$$

Here, f_i is the largest integer which satisfies the equation:

$$I_i/I \geq \sum_{x=1}^{f_i} x \qquad (XV)^{18)}$$

and $G_i(M^+)$ is the G-value of the $M^+(i$-th shell) ion. Table 5 shows the results, together with the W-values calculated from the G-values and the W-values reported previously.[3,5] We believe that the agreement is satisfactory.

It may be worthwhile to notice here that the G-values of the electrons calculated here do not contain any contribution from the Hornbeck-Molnar process:[19]

$$M^* + M \longrightarrow M_2^+ + e^- \qquad (2)$$

Here, M* represents the excited state of a noble gas.

Discussion

For fast collisions ($T \geq 10^4$ eV), it is well known that the binary-encounter collision theory is an approximation to the Bethe theory,[8,20] because the model used for the binary-encounter collision theory can deal only with close collisions, not with distant collisions. However, since the energy distribution of secondary electrons is mainly determined by the close collisions, the binary-encounter collision theory may not be a bad approximation for the estimation of the degradation spectrum. On the other hand, the Bethe theory, although it is a quantum mechanical treatment, cannot properly estimate the close collisions within the Born approximation. Moreover, special treatment has to be applied to take the exchange effect into account.[20]

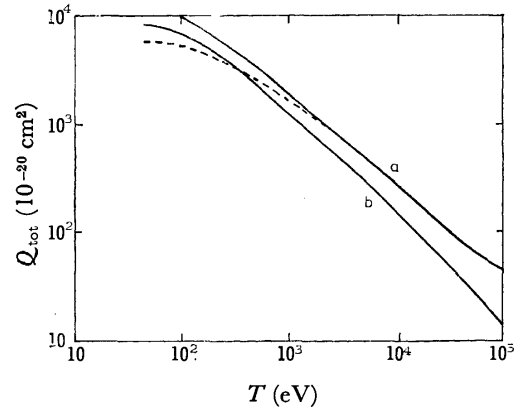

Fig. 8. Comparison of the total inelastic scattering cross sections derived from the Bethe theory (a) and from the binary-encounter collision theory (b). Broken line is experimental.

Figure 8 shows a comparison of the total inelastic scattering cross sections as calculated by the two theories for helium. Although, in the calculation of the degradation spectrum, the absolute value of the total inelastic scattering cross section does not directly affect the final result, the comparison of these values may be worthwhile in order to compare the two theories.

The a curve in Fig. 8 was drawn by using the Bethe asymptotic cross section theoretically estimated by Inokuti *et al.*:[21]

$$Q_{tot} = \frac{1}{\beta^2}\left\{1.410\left[\ln\left(\frac{\beta^2}{1-\beta^2}\right) - \beta^2\right] + 15.118\right\} \times 10^{-20}\ \text{cm}^2 \qquad (XVI)$$

Here, β is the ratio of the velocity of the incident electron and the velocity of light. The b curve was drawn by means of the equation used for the present calculation:

$$Q_{tot} = \sum_i n_i Q_{ion} + n(Q_{singl} + Q_{tripl}) \qquad (XVII)$$

Obviously, the present method underestimates the cross sections, especially at higher energies. On the other

hand, the Bethe asymptotic cross section deviates from the experimental value at lower energies of the incident electron and gives too high values.[22] The total inelastic scattering cross section obtained by the binary-encounter collision theory seems to compensate itself between higher energies and lower energies.

For noble gases other than He and Ne,[23] no theoretical cross sections are obtained by the Bethe theory. However, experimental values for 0.1—2.7 MeV electrons have been reported in the forms of M^2 and C in the following equation:[24]

$$Q = 4\pi\left(\frac{\hbar}{mc}\right)^2 (M^2 x_1 + C x_2) \qquad \text{(XVIII)}$$

Here, $4\pi(\hbar/mc)^2 = 1.874 \times 10^{-20}$ cm^2 and

$$x_1 = \beta^{-2} \ln [\beta^2/(1-\beta^2)] - 1, \quad x_2 = \beta^{-2}$$

Table 6. Comparison of the binary-encounter collision theory with the experiment in the total inelastic scattering cross section of electrons at the energy of 10^5 eV

Atom	$Q_{tot} \times 10^{20}$cm^2 calculated	$Q_{tot} \times 10^{20}$cm^2 experimental
He	13.62	45.09
Ne	132.0	107.6
Ar	106.2	225.3
Kr	145.2	305.9
Xe	143.6	433.5

In Table 6, the total inelastic scattering cross sections of the electrons at the energy of 10^5 eV as calculated by the binary-encounter collision theory are compared with the experimental values. Obviously, most of the cross sections calculated are smaller than the experimental values. In the case of Ne, though, the binary-encounter collision theory predicted a cross section larger than the experimental value. This anomaly seems to result from the overestimation of $E_i(2p)$. The discrepancy in the cross section shown in Table 6 as an example may be one of the most serious shortcomings of the present calculation, although this discrepancy is not directly reflected in the final G-values.

Table 7. The ratios of the G-value of excitation and the G-value of electrons

Atom	$G_{exc}/G(e^-)$
He	0.45
Ne	0.74
Ar	0.73
Kr	0.59
Xe	0.55

We believe that the G-values of ionization, at least the relative values of each process, shown in Table 4 are reliable; however, the G-values of excitations are much less reliable. Platzman assumed $G_{exc}/G(e^-) = 0.4$ for all noble gases.[3] The ratios calculated by the present method are listed in Table 7. The reliability of these ratios may be discussed in comparison with the experimental data for the mixture of noble gases, in which such Penning ionization as:

Table 8. The sum of $G(e^-)$ and G_{exc}. Comparison with the value calculated from Klots' data

Atom	present	Klots' data
He	3.29	3.50~3.66
Ne	3.81	3.98~4.01

$$He^* + Ar \longrightarrow He + Ar^+ + e^- \qquad (3)$$

occur. Such data, however, are not abundant. By using the α particles from ^{239}Pu as the exciting source. Klots measured the W-values of a mixture of two noble gases. From his data,[25] the G-values of the excited states of He and Ne can be estimated; they are shown in Table 8. The calculated G-values of excitations are not so bad as had been expected.

In conclusion, we would like to summarize two of our conclusions of the present calculation, points which are often overlooked by experimental radiation chemists, including us: 1) the ionization from inner shells cannot be ignored even in the molecules composed of atoms with low atomic numbers, and 2) the yields of the forbidden states, the triplet states in the present calculation, are very much dependent upon the $y(T)$ at low energies; *i.e.*, the yield greatly depends on the solvent in which the chemical reactions are taking place.

The authors are indebted to Professor Kazuo Hisatake and Dr. Yoshihiko Hatano for their valuable discussions.

Linear Free Energy Relationships in Heterogeneous Catalysis. XII.[1] Interpretation of the Catalytic Activity of Decomposition of Hydrogen Peroxide over Nickel Oxide on the Basis of Oxidation Power Distribution

Toshio UCHIJIMA and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo
Hongo, Bunkyo-ku, Tokyo 113

(Received November 10, 1972)

Kinetic studies have been carried out on the heterogeneous decomposition of hydrogen peroxide over several nickel oxide catalysts calcined at different temperatures. Kinetic parameters such as reaction order and apparent activation energy depend somewhat on the reaction conditions, but show practically no change with catalyst. The catalytic activity changes with calcination temperature, becoming minimum at 550 °C and maximum at 600 °C. The trend does not change with pretreatment of the catalyst, resembling the behavior of surface excess oxygen having a relatively higher oxidation power. Thus the distribution of oxidation power is closely related to catalytic activity for the decomposition of hydrogen peroxide. We therefore applied the regional analysis assuming that the surface excess oxygen represents active sites for catalysis, and a specific regional activity corresponds to each regional oxygen. It was found that the fifth region (the range of free energy change of adsorption of oxygen being from −11.1 to −12.6 kcal/mol) markedly contributes to the reaction rate, and the calculated rates agree with the observed ones. The nature of the active site was discussed as regards pretreatment of the catalyst.

Of the reactions studied extensively on various catalytic materials including heterogeneous and homogeneous systems,[2] the catalytic decomposition of hydrogen peroxide is one of the most typical. Investigations were carried out with several metal oxide catalysts, aimed at understanding the catalysis on the basis of semiconductive properties,[3] activity order,[4] and the correlation between catalytic activities and the amounts of excess oxygen.[5,6] The amounts of excess oxygen are valuable for account for the catalytic activities of pure or doped, supported or unsupported chromium oxides[5] and the γ-irradiated nickel oxides.[6] Such correlation is reasonable in this reaction, since hydrogen peroxide acts as a reducing reagent as well as an oxidizing one.

A large number of metal oxides have more or less heterogeneous surfaces, certain parts of which contribute to catalysis as active sites. We developed a method to determine the distribution of oxidation power on the oxide surfaces, and applied it to a series of nickel oxide catalysts.[7] In the present study, we measured the catalytic activities for hydrogen peroxide decomposition in an aqueous solution under various reaction conditions using the same lots of nickel oxide catalysts. We found that they possess a similar pattern against the calcination temperature as in the surface excess oxygen of relatively higher oxidation power. This suggests that the distribution of oxidation power is closely related to catalytic activity for the decomposition of hydrogen peroxide. Regarding the regional surface excess oxygen as an active site having a specific activity characteristic of the respective region, the catalytic activities were analyzed by the regional analysis method[8] to estimate the most effective region for catalysis. The nature of the active site was discussed in reference to the fact that pretreatment such as reduction or oxidation affects the catalytic activities, giving rise to deactivation during the course of catalysis.

Experimental

Catalysts and Reagents. The same lots of catalysts as described previously,[7] *i.e.*, a series of pure nickel oxide and Li_2O-doped catalysts, were used. The oxidation power distribution of these oxides has been determined by the aqueous reduction method using hydrazine and KI(pH x) systems.[7] 30% hydrogen peroxide containing no stabilizer (Mitsubishi-Edogawa Co., Ltd.) was used. All the other reagents were commerical products of G.R. grade.

Procedures. The reaction rates of hydrogen peroxide decomposition were determined by following the pressure changes due to oxygen gas evolved, with a conventional reactor of constant volume (about 150 ml). The hydrogen peroxide solution (50 ml) was introduced into the reactor containing a weighed amount of catalyst at a constant temperature (within ±0.2 °C). The speed of stirring was chosen so as to provide a state in which true reaction rate was obtained but not the diffusion-controlled one. The reaction was carried out at temperatures 10—50 °C and concentrations 0.1—10 mol/l H_2O_2. In some cases, pure hydrogen peroxide solution was used without any additives, and in other cases, the solution buffered with potassium hydroxide or sodium tetraborate solution in the pH range 6—11.5.

When necessary, the catalysts were pretreated *in vacuo* or in oxygen gas of 1 atm at 300 °C in the reactor, and their effects on catalytic activities were examined.

Results

Reaction Order. The reaction curves can be analyzed on the basis of a certain reaction order except for their initial unsteady parts. The reaction orders for hydrogen peroxide were also obtained by varying its initial concentration. These values depend largely on the type of solution (additives or pH) and the conditions of pretreatment whereas they are mostly constant among the catalysts except for a few cases. The mean values of reaction order are given in Table 1. For

TABLE 1. REACTION ORDERS OF DECOMPOSITION OF HYDROGEN PEROXIDE UNDER VARIOUS CONDITIONS (30°C)

Reaction orders were obtained from analysis of the reaction curves (method 1) and also by varying the initial concentration of hydrogen peroxide (method 2).

Catalyst pretreatment	Solution	Reaction order[a]	
		Method 1	Method 2
Untreated	No additives	0.4	0.4[b]
Untreated	0.1 N KOH	0.6	—
Untreated	0.005 N $Na_2B_4O_7$	0.6	0.6[c]
Evacuated at 300°C	No additives	0.1[d]	—

a) Unless otherwise stated, the mean values are listed since variation among catalysts is relatively small. b) Ni-2-350-8. c) Ni-2-500-8. d) For Ni-2-600-8 and Ni-2-700-8 only, the reaction follows the order of 0.5 during the first run but gives the value of 0.1 after the second run.

example, the values of the untreated catalysts are 0.57—0.62 in a solution buffered with 0.005 mol/l sodium tetraborate. The only exception is the case of the first run on Ni-2-600-8 and Ni-2-700-8, subjected previously to evacuation at 300 °C, which yield much higher values than the others. The cause of this anomaly is not clear.

Table 1 also shows good agreement between the values obtained by the two independent methods. The kinetic curve would accompany the effect due to the changes of pH and the deactivation of catalysts during reaction. Both effects may compensate each other, yielding the agreement.

The reaction orders are reasonably lower than unity in all the cases and the reduced state is accompanied by the much lower order as compared with the oxidized one.

Dependency on pH. The decomposition rate of hydrogen peroxide varies with pH, where pH was controlled with potassium hydroxide or sodium tetraborate-potassium hydroxide solution. The additives affect the reaction rate not only through the pH changes but also through other effects possibly due to complex formation. In 1 mol/l H_2O_2 solution, addition of 10^{-5} M potassium hydroxide retards the rate slightly, while a remarkable accelerating effect is found above 10^{-4} M. A satisfactory linear relationship exists between log(rate) and log(H^+) in the concentration range 10^{-4}—10^{-1} M potassium hydroxide, yielding a value of −0.17 as the order with respect to (H^+). Similarly, pH was changed from 8.7 to 9.5 by the addition of potassium hydroxide to the solution buffered with sodium tetraborate of constant concentration. Analysis of the results gives a value of −0.31. Retardation of the reaction by hydrogen ion is in line with the well-examined case in homogeneous metal ion-catalyzed systems.[2]

A comparison of the system containing potassium hydroxide as an additive with that containing sodium tetraborate and potassium hydroxide each with the same pH shows that the rate of the latter is much lower. This suggests that the added ion blocks the active sites according to its coordination tendency.

TABLE 2. VARIATION OF CATALYTIC ACTIVITY DUE TO VARIOUS PRETREATMENTS OF CATALYST

Catalyst; Ni-2-350-8. Temperature; 30°C. Solution; 1 mol/l H_2O_2 solution

Pretreatment	Initial rate (10^{-2} mol/min·g)
Untreated	0.83
Evacuated at 200°C for 1 hr	2.23
Evacuated at 300°C for 1 hr	3.04
Treated with oxygen of 600 mmHg at 300°C for 14 hr after evacuation at 300°C for 9 hr.	0.61

Pretreatment Effects and Deactivation during Catalysis. Variation of catalytic activity due to pretreatment such as evacuation and oxidation at high temperature, which is comparable with the case of untreated catalysts, is shown in Table 2. The catalytic activity is largely enhanced after evacuation at high temperature. By oxidation of the evacuated catalyst in one atmospheric oxygen at 300 °C, the activity decreases to a level slightly lower than that of the untreated catalyst.

After the first run was completed on the catalyst evacuated at 300 °C using an unbuffered 1 mol/l H_2O_2 solution, 5 ml of 10 mol/l H_2O_2 solution was added and the reaction was then repeated under the same conditions. The variation of catalytic activity during these repeated runs is presented in Fig. 1. The activity declines gradually with each run and approaches a certain level which is approximated to the value of the fully oxidized catalyst. This might help clarify the nature of active sites.

Effects of Catalyst Variations. Catalyst activity, plotted against calcination temperature (a) and the amount of the doped lithium (b), is shown in Fig. 2. The results are obtained on the untreated catalysts using a 1 mol/l H_2O_2 solution with no additives at 25 °C. The curves show a complex dependency on

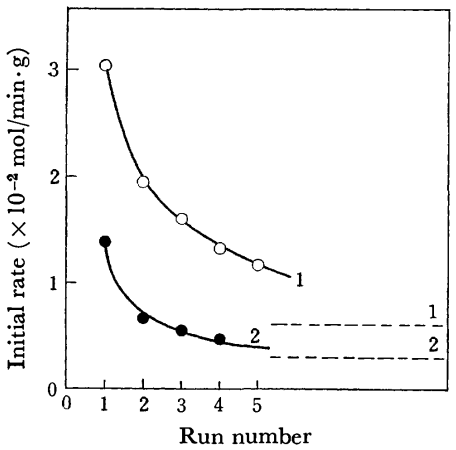

Fig. 1. Deterioration of the catalytic activities during repeated runs
The catalysts are pretreated at 300 °C *in vacuo* for 1 hr. Dotted lines show the rates over the fully oxidized catalysts.
Solution; 1.0 mol/l H_2O_2, Temperature; 30 °C, 1; Ni-2-350-8, 2; Ni-2-450-8

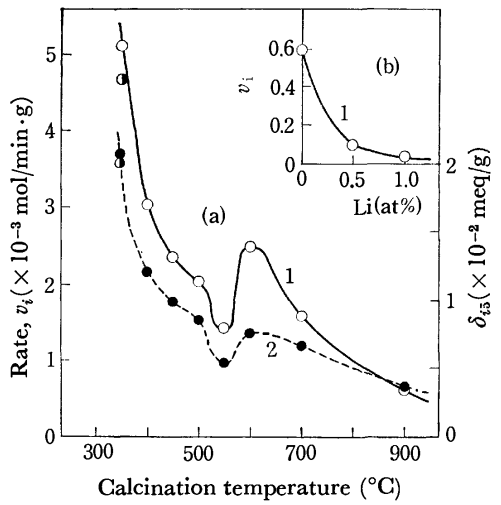

Fig. 2. Dependency of the catalytic activity on the calcination temperature (a) and the lithium content (b) of nickel oxide
Solution; 1.0 mol/l H_2O_2, Reaction temperature; 25 °C
Curve 1 shows the reaction rate, v_i, and curve 2 the amount of the surface excess oxygen of the fifth region, δ_{i5}. The values of the catalyst calcined for 16 hr are marked as ◑.

the calcination temperature characterized by a minimum at 550 °C and a maximum at 600 °C. As the lithium content is increased, the activity decreases monotonously. This is in line with the case of surface excess oxygen with relatively higher oxidation power, *e.g.*, the regional oxygen given as a difference between the ones measured by the KI (pH 10.8) and KI (pH 11.3) methods, which is also plotted in Fig. 2. Similar curves were obtained for both calcination temperature and lithium content under other reaction conditions such as in a buffered or unbuffered solution on the pretreated or untreated catalysts. The absolute values differ largely according to the reaction conditions.

The activation energies are obtained on several catalysts using a solution buffered with sodium tetraborate at temperatures 30—50 °C. The results are summarized in Table 3. The catalyst variations do not seem to affect activation energy, addition of lithium oxide having little effect.

Table 3. Apparent activation energies for decomposition of hydrogen peroxide over some nickel oxides
Solution; 0.1 mol/l H_2O_2, 0.005 mol/l $Na_2B_4O_7$.

Catalyst	Activation energy (kcal/mol)
Ni-2-350-8	17.2
Ni-2-500-8	17.5
Ni-2-600-8	16.8
Ni-2-900-8	16.8
Ni-2-Li-0.5-900-8	16.1

Discussion

In order to account for the catalytic activity of metal oxides for oxidation catalysis, a number of parameters such as dissociation pressure of oxide,[9] enthalpy change of formation of oxide,[10] homomolecular isotope exchange of oxygen,[11] reducibility of oxide[12] and excess oxygen[5,6] have been extensively examined. The surface of most metal oxides has been generally accepted to be of more or less heterogeneous distribution. In oxidation catalysis, however, such heterogeneity has not been introduced explicitly into quantitative analysis of catalytic activity except for a few studies.[9] The distribution of oxidation power represents the amount[7] of surface excess oxygen as a function of its oxidation power, which can be determined on the basis of oxidation-reduction equilibrium with a certain reducing reagent in an aqueous phase. It is interesting to examine whether catalytic activity can be accounted for by this oxidation power distribution, and if so to what extent.

As shown in Fig. 2, the catalytic activity of nickel oxide catalysts for the decomposition of hydrogen peroxide shows a complex curve against calcination temperature, and a monotonously decreasing curve against lithium oxide content. Since these relations are very similar to the behaviors in the surface excess oxygen of relatively higher oxidation power, the distribution of oxidation power is closely related to the catalytic activity for the decomposition of hydrogen peroxide. The regional analysis method[8] was applied assuming that the surface excess oxygen of oxides represents their active site for catalysis and a specific regional activity corresponds to each regional oxygen. The catalytic activity of the i-th catalyst, v_i (mol/min·g), can be represented by

$$v_i = \sum_j v_{0j} \times \delta_{ij} \qquad (1)$$

where v_{0j} (mol/min·meq) denotes the specific activity characteristic of surface excess oxygen of the j-th region (suffix 0 indicates its independency of the type of catalyst) and δ_{ij} (meq/g) the amount of surface excess oxygen of the j-th region of the i-th catalyst. Surface excess oxygen over these catalysts has been classified experimentally into six regions.[7] Each region is defined by the free energy change of adsorption of oxygen (ΔG) as follows.

Region 1; $-\Delta G = 141.5—29.9$ kcal/mol.
Region 2; $-\Delta G = 29.9—19.8$ 〃
Region 3; $-\Delta G = 19.8—14.6$ 〃
Region 4; $-\Delta G = 14.6—12.6$ 〃
Region 5; $-\Delta G = 12.6—11.1$ 〃
Region 6; $-\Delta G < 11.1$ 〃

For the lithium-doped nickel oxides, the fifth and sixth regions could not be determined separately and had to be excluded. Since Eq. (1) holds, consequently, over nine kinds of the pure nickel oxide catalysts, a set of probable values of v_{0j} corresponding to six regions can be estimated by means of the method of least squares. However, the degree of freedom for analysis is too small and the treatment provides too erroneous results. Thus, regional analysis is applied to all the possible combinations from two to five regions combining some

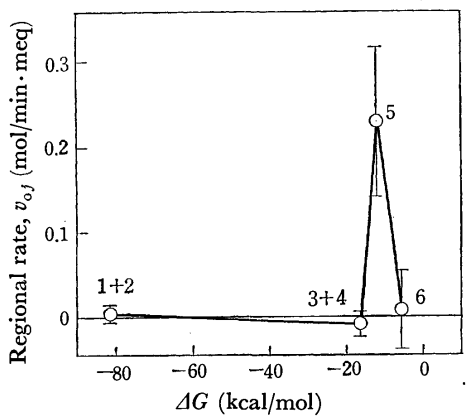

Fig. 3. Correlation between the regional rate calculated by Eq. (1) and the mean free energy change of the respective region.
Numerals in the Figure mean the numbers of regions. The range of errors is also shown.

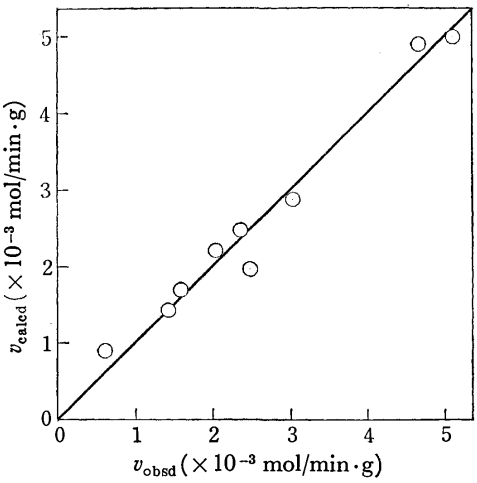

Fig. 4. Comparison of the rates calculated by Eq. (1), v_{calcd}, with the observed ones, v_{obsd}.

neighboring regions. From these the most acceptable one is picked to provide a solution having tolerable errors as well as reasonable physical meaning. In Fig. 3, the regional rates are plotted against the free energy changes of adsorption of oxygen. The result corresponds to such combination of regions as 1+2, 3+4, 5 and 6, and shows that the fifth region ($-\Delta G=$ 11.1—12.6) has a marked contribution to the reaction rate. The overall rates calculated with the above results by means of Eq. (1) are plotted against the observed ones in Fig. 4. A good agreement is observed.

Since oxidation power distribution implies the energy distribution of surface oxygen over the fully oxidized catalysts, the distribution should be caused by the difference of the energy states of adsorption sites for oxygen, *i.e.*, probably bare metal ion, which will be caused by the removal of surface oxygen. Oxidation power distribution corresponds also to discrimination of the energy states of bare metal ion sites. The fifth region provides the largest contribution to catalytic activity, but it is not clear whether the actual active site during catalysis is the surface oxygen or the bare metal ion.

The reaction mechanism of the decomposition of hydrogen peroxide over the oxide catalysts is not known, but information on the homogeneous system catalyzed by ferrous or ferric ion can be referred to.[2] The decomposition of hydrogen peroxide is initiated by the formation of HO_2 or OH radical by oxidation or reduction with ferric or ferrous ion, and proceeds through radical chain mechanism. Ferrous ion catalyzes the decomposition much more effectively than ferric ion, and the same final steady state having a particular ferrous/ferric ratio is obtained, regardless of whether the initial feed is ferrous or ferric ion. As shown in Fig. 1, the catalytic activity of nickel oxide increases markedly by prior evacuation at high temperature, and decreases gradually towards the final constant value with repetition of reaction. Contrarily, the fully oxidized catalyst shows about the same catalytic activity as in the catalyst which underwent no pretreatment. The nickel oxide shows a much higher catalytic activity in the reduced state than in the oxidized state.

Dependency of catalytic activity of these nickel oxides on calcination temperature is not altered by any pretreatment. Therefore, in the light of regional analysis, it will be assumed that both the bare nickel ion and the surface excess oxygen catalyzes the decomposition of hydrogen peroxide more effectively as long as they belong to the fifth region, the former being much more active than the latter. Since the mode of catalytic activity in the pretreatment is similar to that of the ferrous/ferric ion catalyzed system, the catalytic reaction and deterioration of the active sites over the nickel oxide follow a similar mechanism to that in the homogeneous system.

The catalytic activity of lithium-doped nickel oxide decreases monotonously with the amount of lithium added. We might suggest that this tendency is in parallel to the summed surface excess oxygen of the fifth and sixth regions, and the activation energy does not differ from that of the other pure nickel oxides. These facts also give evidence to the usefulness of oxidation power distribution for understanding the catalytic activity of oxide catalysts.

The authors wish to express their sincere thanks to Dr. Y. Saito for his helpful discussions and to Mr. N. Nojiri for his kind help in the course of this experiment. The reagent was supplied by the Mitsubishi-Edogawa Co., Ltd. The work was partly defrayed by a Grant in Aid of The Kawakami Foundation.

Interactions of 1-Substituted 2,4-Dinitrobenzenes with Methoxide and Hydroxide Ions in Dimethyl Sulfoxide with a Rapid Scan Spectrophotometer

Yoshinori HASEGAWA
College of General Education, Tohoku University, Kawauchi, Sendai 980
(Received January 7, 1974)

The interactions of *m*-dinitrobenzene and 1-substituted 2,4-dinitrobenzenes with sodium methoxide in methanolic dimethyl sulfoxide were studied with a rapid scan spectrophotometer. A similar study of 1-substituted 2,4-dinitrobenzenes with sodium hydroxide in aqueous dimethyl sulfoxide was carried out. Except for a few cases, the first transient colored-complexes of 3-substituted 2,6-dinitrocyclohexadienates were observed at initial stages before the complete formation of second colored-complexes having the π-electronic structures of 1,3-dinitropentadienyl anion.

In the interactions of aromatic dinitro compounds with nucleophiles, the initial formation of the kinetically-favored colored-complexes has been detected before the appearance of the thermodynamically-stable colored-complexes.[1,2] In the methoxide additions to *m*-dinitrobenzene and 2,4-dinitroanisole, thermodynamically-stable 1-methoxy-2,4-dinitrocyclohexadienate and 1,1-dimethoxy-2,4-dinitrocyclohexadienate, respectively, were detected by NMR and visible spectroscopy, but no kinetically-favored colored-complexes were detected.[3]

Studies have been made on the interactions of *m*-dinitrobenzene and 1-substituted 2,4-dinitrobenzenes with sodium methoxide in methanolic dimethyl sulfoxide (DMSO) with a rapid scan spectrophotometer. In order to extend the preceding study on the interactions of 1-substituted 2,4-dinitrobenzenes with sodium hydroxide,[1] the spectral changes of the DMSO solutions of some 1-substituted 2,4-dinitrobenzenes in the presence of sodium hydroxide have also been given.

Experimental

The dinitrobenzenes used are presented in Table 1. 2,4-Dinitrophenyl phenyl ether and 2,4-dinitrophenyl *p*-nitrophenyl ether were prepared according to Bost and Nicholson[4] and were recrystallized from methanol. Commercial dinitrobenzenes were purified by recrystallization or distillation.

Methanol was used for spectrophotometry. Sodium methoxide solutions were prepared by the reaction of clean sodium with methanol. Concentrations were determined by titration with a standard acid. DMSO was dried with calcium hydride and fractionated under reduced pressure.

A Hitachi rapid scan spectrophotometer RSP-2 was used to measure visible absorption spectra at various stages of a reaction path in solution. The mixing cell having a path length of 1.0 cm was controlled at 25 °C with a thermocirculater. Details of the apparatus and measurement were given in a previous paper.[1]

Results and Discussion

Interactions of m-*Dinitrobenzene and 2,4-Dinitroanisole with Sodium Methoxide.* When *m*-dinitrobenzene (6.4×10^{-5} M) was mixed with excess sodium methoxide (2.3×10^{-2} M) in DMSO-methanol (98/2, v/v), two colored-species having absorption maxima at 525 and 605 nm appeared 32 ms after mixing. 1/3 s after mixing, the first colored-species (λ_{max}=605 nm) disappeared and formation of the second (λ_{max}=525 nm) was complete. The second colored-species has been assigned to 1-methoxy-2,4-dinitrocyclohexadienate.[3a] It is known that the methoxide complexes having the π-electronic structures of 1,5-dinitropentadienyl anion in media rich in DMSO show longer wavelength bands in the range 585—640 nm.[1,5] The first colored-species is assigned to 1-methoxy-2,6-dinitrocyclohexadienate.

Spectra of 2,4-dinitroanisole in the presence of sodium methoxide showed the first (λ_{max}=560 nm) and second (λ_{max}=505 nm) colored-species, attributed to 1,3-dimethoxy-2,6-dinitrocyclohexadienate and 1,1-dimethoxy-2,4-dinitrocyclohexadienate, respectively.

Interactions of 2,4-Dinitrofluorobenzene, 2,4-Dinitrochlorobenzene, 2,4-Dinitrophenyl Phenyl Ether and 2,4-Dinitrophenyl p-*Nitrophenyl Ether with Sodium Methoxide.* All the solutions of these nitro compounds, containing sodium methoxide in a large excess, finally showed spectra similar to the spectrum of 1,1-dimethoxy-2,4-dinitrocyclohexadienate due to further reaction of methoxide ion with the resulting product of 2,4-dinitroanisole. In order to observe only the spectra of the colored-species formed from sodium methoxide and the nitro compounds, spectral measurements were carried

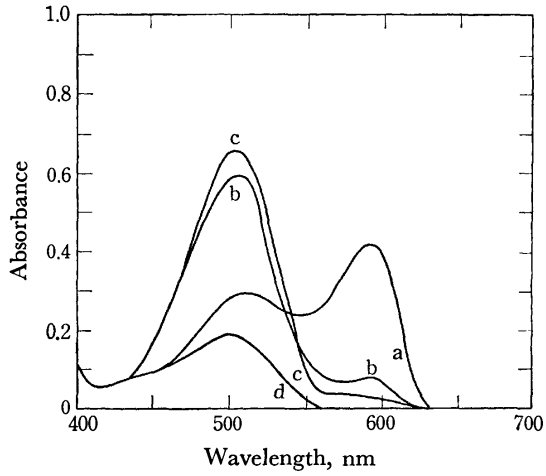

Fig. 1. Spectra observed with the DMSO solution containing 2,4-dinitrochlorobenzene (1.7×10^{-3}M), sodium methoxide (2.3×10^{-4} M) and methanol (2% by volume). Times measured after mixing: a, 30 ms; b, 1/3 s; c, 5 s; d, 30 s.

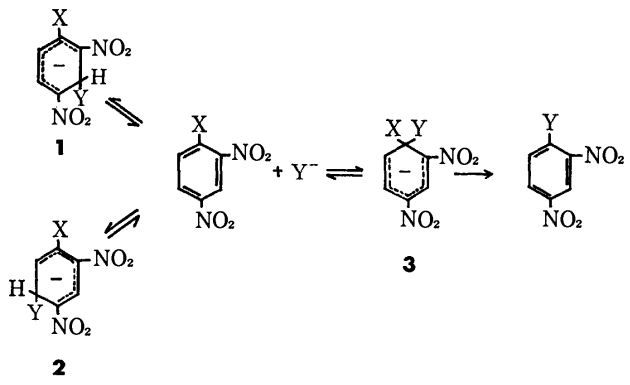
out under conditions where the concentration of the nitro compounds was several times larger than that of sodium methoxide.

The spectra observed with the DMSO solution containing 2,4-dinitrochlorobenzene (1.7×10^{-3} M), sodium methoxide (2.3×10^{-4} M) and methanol (2% by volume) are shown in Fig. 1. The first colored-species having an absorption peak at 590 nm appeared at initial stages and disappeared several seconds after mixing. Afterward the second colored-species having a peak at 505 nm gradually disappeared. The first colored-species is 1-methoxy-3-chloro-2,6-dinitrocyclohexadienate (**1**; X=Cl, Y=OMe). The second colored-species can be assigned to 2,4-dinitrocyclohexadienate which has the same π-electronic structures as 1,3-dinitropentadienyl anion of type **2** or **3** (X=Cl, Y=OMe).



According to Crampton *et al.*,[6] the second colored-species should be ascribed to 1-methoxy-2,4-dinitro-5-chlorocyclohexadienate (**2**; X=Cl, Y=OMe).[1]

Spectra of 2,4-dinitrofluorobenzene, 2,4-dinitrophenyl phenyl ether and 2,4-dinitrophenyl *p*-nitrophenyl ether in the presence of sodium methoxide showed similar changes in the range 450—650 nm. The absorption maxima are listed in Table 1.

Interaction of 2,4-Dinitrotoluene with Sodium Methoxide. Spectra of 2,4-dinitrotoluene in the presence of sodium methoxide are shown in Fig. 2. At 3 s after mixing, the absorption bands initially observed at 530 and 600 nm disappeared and the bands at 410 and 650 nm remained. The bands at 530 and 600 nm are assigned to 2,4-dinitrocyclohexadienate of type **2** or **3** (X=CH_3, Y=OMe) and to 1-methoxy-3-methyl-2,6-dinitrocyclohexadienate (**1**; X=CH_3, Y=OMe), respectively. According to Pollitt and Saunders,[7] the bands at 410 and 650 nm are assigned to 2,4-dinitrobenzyl anion produced from 2,4-dinitrotoluene by loss of a proton.

Interactions of 2,4-Dinitrobenzoic Acid, 2,4-Dinitrobenzenesulfonic Acid, 2,4-Dinitrophenyl Thiocyanate and 2-(2,4-Dinitrophenylthio)benzothiazole with Sodium Methoxide. The absorption maxima of the colored-species obtained are listed and assigned in Table 1.

Interactions of 2,4-Dinitrophenyl Phenyl Ether, 2,4-Dinitrophenyl p*-Nitrophenyl Ether, 2,4-Dinitrophenyl Thiocyanate and 2-(2,4-Dinitrophenylthio)-benzothiazole with Sodium Hydroxide.* The spectra observed with the DMSO solution containing 2,4-dinitrophenyl phenyl ether (4.9×10^{-5} M), sodium hydroxide (2.3×10^{-3} M) and water (2% by volume) are shown in Fig. 3. The first colored-species having an absorption peak at 580 nm appeared at initial stages and disappeared within a minute. After the complete disappearance of the first colored-species, the second colored-species having a peak at 520 nm remained and then gradually disappeared. As the peak of the second colored-species decreased in intensity, the intensities of two peaks at 375 and 430 nm increased. The first and second colored-species are assigned to 1-hydroxy-3-phenoxy-2,6-dinitrocyclohexadienate (**1**; X=OPh, Y=OH) and to 2,4-dinitrocyclohexadienate of type **2** or **3** (X=OPh, Y=OH), respectively. The bands at 375 and 430 nm are due to 2,4-dinitrophenoxide ion.[1]

Spectra of 2,4-dinitrophenyl *p*-nitrophenyl ether, 2,4-dinitrophenyl thiocyanate and 2-(2,4-dinitrophenylthio)benzothiazole in the presence of sodium hydroxide

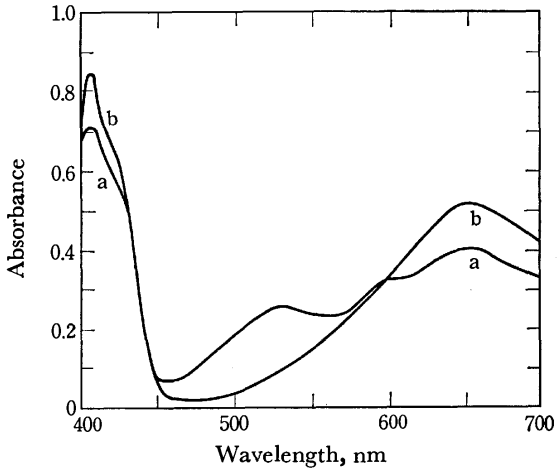


Fig. 2. Spectra observed with the DMSO solution containing 2,4-dinitrotoluene (4.0×10^{-5} M), sodium methoxide (5.9×10^{-3} M) and methanol (0.5% by volume) Times measured after mixing: a, 28 ms; b, 3 s.

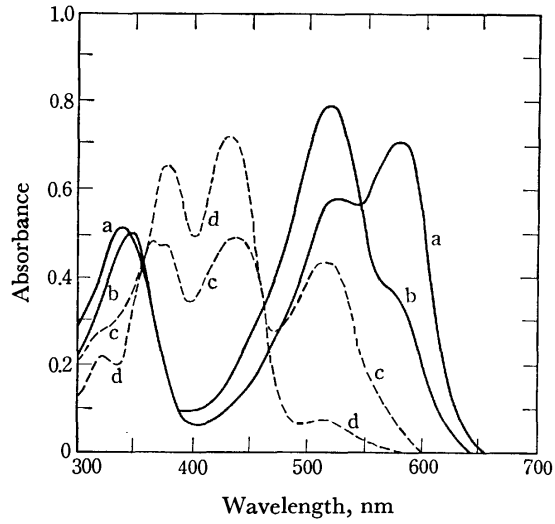

Fig. 3. Spectra observed with the DMSO solution containing 2,4-dinitrophenyl phenyl ether (4.9×10^{-5} M), sodium hydroxide (2.3×10^{-3} M) and water (2% by volume). Times measured after mixing: a, 1/3 s; b, 10 s; c, 4 min; d, 20 min.

showed similar changes. The absorption maxima of the colored-species are listed in Table 1.

Interactions of 2,4-Dinitrobenzoic Acid, 2,4-Dinitrobenzenesulfonic Acid and 2,4-Dinitrotoluene with Sodium Hydroxide. The absorption maxima of the colored-species obtained are listed in Table 1. In the presence of sodium hydroxide, 2,4-dinitrotoluene has bands at 410 and 650 nm attributed to 2,4-dinitrobenzyl anion, giving no hydroxide complex.

Substituent Effect on 2,6-Dinitrocyclohexadienate. We see from Table 1 that the substituents such as F and Cl except COO^- at 3-position shift the absorption bands of both 1-methoxy-2,6-dinitrocyclohexadienate and 1-hydroxy-2,6-dinitrocyclohexadienate towards blue. In contrast, the spectra of 4-substituted 2,6-dinitroanisole with methoxide ion show that the substituents such as F and Cl shift the band of 1,1-dimethoxy-2,6-dinitrocyclohexadienate towards red,[5b] and that electron-withdrawing substituents such as CF_3 shift it towards blue.[5b] The substituents at 3-position may produce a blue shift by twisting the nitro-groups from the planes of the rings, as described by Pollitt and Saunders in their studies on the Janovsky reaction.[7]

The author thanks Professor T. Abe for valuable suggestions.

Thermochemical Studies on Platinum-Olefin Complexes. I

Manabu SENŌ, Kazutoshi IWAMOTO, and Teruzo ASAHARA
Institute of Industrial Science, The University of Tokyo, Minato-ku, Tokyo 106

(Received February 5, 1974)

Using a twin-type calorimeter, the enthalpy changes of solutions and reactions with aqueous KCN solution of Zeise's salts, $K[PtCl_3(olefin)]$, were measured. As ligand olefins, ethylene, propylene, 1-butene, 1-pentene, and 1-hexene were employed. It was estimated from a thermochemical analysis that the order of strength of platinum-olefin bonding is as follows; $K[PtCl_3(C_3H_6)] \gtrsim K[PtCl_3(C_2H_4)] \gtrsim K[PtCl_3(1\text{-}C_6H_{12})] \gtrsim K[PtCl_3(1\text{-}C_4H_8)] \gtrsim K[PtCl_3(1\text{-}C_5H_{10})]$. This order was compared with the data of infrared spectra and both the results coincide with each other.

In 1953, the nature of the bonding between an olefinic ligand and platinum atom in Zeise's salt, $K[PtCl_3(olefin)]$, was first interpreted by Chatt and Duncanson,[1] by applying the model for the bonding between Ag(I) and olefin ligands proposed by Dewar.[2] According to their model, besides a molecular μ-bond formed between the filled olefin π-molecular orbital and one of the vacant $5d6s6p^2$ platinum hybrid orbitals, the overlap between the vacant olefinic antibonding π^*-molecular orbital and one of the filled 5d6s platinum hybrid atomic orbitals was considered as an addition bonding to account for the stability of these metal-olefin complexes. Since then, theoretical and experimental studies on this metal-olefin bonding have been made through measurements of IR,[3] UV,[4] and NMR.[5] In order to get a further information, it would be useful to measure the enthalpy changes of the reactions (1) and (2).

$$K_2PtCl_4(c) + \text{olefin}(g) \longrightarrow K[PtCl_3(\text{olefin})](c) + KCl(c) \quad (1)$$

$$[PtCl_4]^{2-}(s) + \text{olefin}(g) \longrightarrow [PtCl_3(\text{olefin})]^-(s) + Cl^-(s) \quad (2)$$

Notations (c), (s), and (g) refer to crystalline, solvated and gaseous state, respectively. The calorimetric measurements of heats of reactions (1) and (2) with water-soluble olefins such as $CH_2{=}CH(CH_2)_nNH_3^+$ were carried out by Denning *et al.*[6] and Orchin,[7] but no measurement was yet done on Zeise's salts having simple olefins such as ethylene and propylene as ligands. The aim of this paper is to present the result of this measurement.

Experimental

Synthesis of $K[PtCl_3(olefin)]$. $K[PtCl_3(C_2H_4)]$, $K[PtCl_3(C_3H_6)]$, and $K[PtCl_3(1\text{-}C_4H_8)]$ were prepared from K_2PtCl_4 according to the method described by MacNevin *et al.*[8] The products were recrystallized twice from an aqueous 3% HCl solutions and the purity was checked by elemental analysis. $K[PtCl_3(1\text{-}C_5H_{10})]$ and $K[PtCl_3(1\text{-}C_6H_{12})]$ were prepared as follows; 5 g of K_2PtCl_4 was dissolved in 50 ml of an aqueous 3% HCl solution and stirred with introducing 1-pentene or 1-hexene for a few weeks in a sealed flask. After filtering, the filtrate was concentrated under low pressure and cooled to get yellow crystals. The crystals were washed with cold water and recrystallized twice from an aqueous 3% HCl solutions and the purity was checked by elemental analyses.

Calorimetric Measurements. A twin-type microcalorimeter, Tokyo Rico Type TCC-65, was used for the following calorimetric measurements. All the measurements were carried out at 25 °C. Anderson reported the next reaction.[9]

$$K[PtCl_3(C_2H_4)](c) + 4KCN(s) \longrightarrow K_2Pt(CN)_4(s) + C_2H_4 + 3KCl(s) \quad (3)$$

The reaction in an aqueous KCN solution proceeds rapidly and quantitatively at room temperature. The next reaction is also known to proceed in an aqueous KCN solution.

$$K_2PtCl_4(c) + 4KCN(s) \longrightarrow K_2Pt(CN)_4(s) + 4KCl(s) \quad (4)$$

Here, the following reaction schemes are supposed for convenience of construction of thermodynamic cycles.

$$K_2PtCl_4(c) + 4CN^-(s) \xrightarrow{\Delta H_I} 2K^+(s) + [Pt(CN)_4]^{2-}(s) + 4Cl^-(s) \quad (I)$$

$$K[PtCl_3(\text{olefin})](c) + 4CN^-(s) \xrightarrow{\Delta H_{II}} K^+(s) + [Pt(CN)_4]^{2-}(s) + 3Cl^-(s) + \text{olefin}(g) \quad (II)$$

$$K_2PtCl_4(c) \xrightarrow{\Delta H_{III}} 2K^+(s) + [PtCl_4]^{2-}(s) \quad (III)$$

$$K[PtCl_3(\text{olefin})](c) \xrightarrow{\Delta H_{IV}} K^+(s) + [PtCl_3(\text{olefin})]^-(s) \quad (IV)$$

$$KCl(c) \xrightarrow{\Delta H_V} K^+(s) + Cl^-(s) \quad (V)$$

By combining reactions (I), (II), and (V), we got

$$K_2PtCl_4(c) + \text{olefin}(g) \xrightarrow{\Delta H_1} K[PtCl_3(\text{olefin})](c) + KCl(c) \quad (1)$$

$$\Delta H_1 = \Delta H_I - \Delta H_{II} - \Delta H_V \quad (5)$$

By combining reactions (I), (II), (III), (IV), and (V), we got

$$[PtCl_4]^{2-}(s) + \text{olefin}(g) \xrightarrow{\Delta H_2} [PtCl_3(\text{olefin})]^-(s) + Cl^-(s) \quad (2)$$

$$\Delta H_2 = \Delta H_I - \Delta H_{II} - \Delta H_{III} + \Delta H_{IV} \quad (6)$$

The heats of Reactions (1) and (2) can be obtained from (5) and (b) by using measured values for Reactions (I)—(V).

Heats of Solution. The heat of solution of potassium chloride was measured when an accurately weighed sample (about 37.7 mg) of potassium chloride (guaranteed reagent) was dissolved in 50 ml of pure water in the microcalorimeter. The sample was dried beforehand to constant weight by heating under high vacuum. The heat of solution of potassium tetrachloroplatinate was measured when about 49.8mg (1.2×10^{-4} mol) of potassium tetrachloroplatinate was dissolved in 40 ml of an aqueous 3% HCl solution. Potassium tetrachloroplatinate was used after twice recrystallization.

The heats of solution of $K[PtCl_3(olefin)]$ was determined when about 1.2×10^{-4} mol of $K[PtCl_3(olefin)]$ was dissolved in 40 ml of an aqueous 3% HCl solutions in the microcalorimeter.

Heats of Reactions. An aqueous KCN solution used hereafter was prepared by dissolving about 800 mg of KCN (guaranteed reagent) into 40 ml of pure water. The heat of reaction between potassium tetrachloroplatinate and the aqueous KCN solution was measured when about 200 mg (4.8×10^{-4} mol) of K_2PtCl_4 was put into the KCN solution and reacted. The heats of reaction between $K[PtCl_3(olefin)]$ and the aqueous KCN solution was measured when about 4.8×10^{-4} mol of $K[PtCl_3(olefin)]$ was put into the KCN solutions and reacted in the microcalorimeter.

Results and Discussion

The enthalpy change of potassium chloride at 25 °C was measured thirty times, and the average $\Delta\bar{H}_V$ and the dispersion σ^2 of measured values ΔH_V were determined as follows.

$$\Delta\bar{H}_V = 4.490\ \text{kcal}\cdot\text{mol}^{-1}$$

$$\sigma^2 = 1/(30-1)\sum(\Delta H_V-\Delta\bar{H}_V)^2 = 0.07748$$

We adopted this σ^2 value as a mother dispersion of heat measurements. On the other hand, as the standard value of the heat of solution of potassium chloride at 25 °C was reported to be 4.146 kcal·mol^{-1}, we corrected the measured values by using this standard value.[10]

The corrected values of the enthalpy changes of solutions of complexes are shown in Table 1 and the enthalpy changes of complexes with an aqueous KCN solution were given in Table 2. The enthalpy changes of reactions (1) and (2) were calculated by using Eqs. (5) and (6) from these values and listed in Table 3.

Let's consider the following thermodynamic cycles to get an information for the bond strength of Pt-olefin in gaseous state.

Table 1. Enthalpy changes of solution of complexes

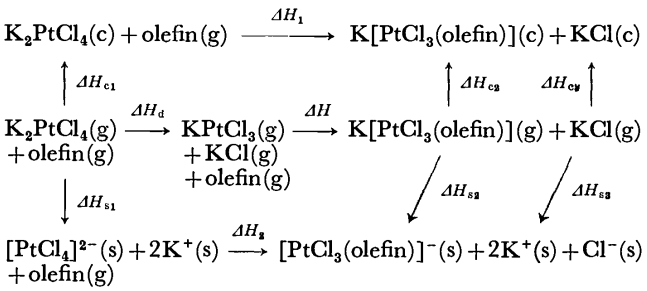
Molecular formula of complexes	Enthalpy changes of solution ΔH_{III} or ΔH_{IV} (kcal·mol^{-1})
K_2PtCl_4	12.6±0.2
$K[PtCl_3(C_2H_4)]$	10.2±0.2
$K[PtCl_3(C_3H_6)]$	10.5±0.2
$K[PtCl_3(1\text{-}C_4H_8)]$	10.4±0.2
$K[PtCl_3(1\text{-}C_5H_{10})]$	10.9±0.2
$K[PtCl_3(1\text{-}C_6H_{12})]$	10.8±0.2

Table 2. Enthalpy changes of reactions of complexes with aqueous KCN solution

Molecular formula of complexes	Enthalpy changes of reactions ΔH_I or ΔH_{II} (kcal·mol^{-1})
K_2PtCl_4	−87.8±0.3
$K[PtCl_3(C_2H_4)]$	−79.3±0.4
$K[PtCl_3(C_3H_6)]$	−77.0±0.6
$K[PtCl_3(1\text{-}C_4H_8)]$	−80.7±0.4
$K[PtCl_3(1\text{-}C_5H_{10})]$	−79.2±0.4
$K[PtCl_3(1\text{-}C_6H_{12})]$	−80.8±0.5

Table 3. Enthalpy changes of Reactions (1) and (2)

Olefin	ΔH_1 (kcal·mol^{-1})	ΔH_2 (kcal·mol^{-1})
Ethylene	−12.6±0.5	−10.9±0.6
Propylene	−14.9±0.7	−13.2±0.7
1-Butene	−11.3±0.5	−9.3±0.6
1-Pentene	−12.7±0.5	−10.2±0.6
1-Hexene	−11.1±0.7	−8.8±0.7



$$\Delta H = \Delta H_1 + \Delta H_{c1} - \Delta H_{c2} - \Delta H_{c3} - \Delta H_d$$
$$= \Delta H_2 + \Delta H_{s1} - \Delta H_{s2} - \Delta H_{s3} - \Delta H_d \qquad (7)$$

Here, ΔH_{c1}, ΔH_{c2}, and ΔH_{c3} are enthalpy changes of crystallization, and ΔH_{s1}, ΔH_{s2}, and ΔH_{s3} are enthalpy changes of electrolytic dissolution of K_2PtCl_4, KCl, and $K[PtCl_3(olefin)]$, respectively. ΔH_{c1}, ΔH_{c3}, ΔH_{s1}, ΔH_{s3} and ΔH_d are independent of olefin. By collecting these olefin-independent terms, Eq. (7) is rearranged as follows.

$$\Delta H = \Delta H_1 - \Delta H_{c2} + \Delta H'$$
$$= \Delta H_2 - \Delta H_{s2} + \Delta H''$$

where

$$\Delta H' = \Delta H_{c1} - \Delta H_{c3} - \Delta H_d$$
$$\Delta H'' = \Delta H_{s1} - \Delta H_{s3} - \Delta H_d$$

The value of ΔH_{c2} is the lattice energy of $K[PtCl_3(olefin)]$ and the value of ΔH_{s2} contains the dissociation energy of $K[PtCl_3(olefin)]$ and the solvating energies of resulting ions, K^+ and $[PtCl_3(olefin)]^-$. It would be tentatively assumed that these values are not influenced by the kind of olefin to a greater extent. Under this assumption, we get the following strength order of platinum-olefin bonds.

$$K[PtCl_3(C_3H_6)] \gtrsim K[PtCl_3(C_2H_4)] \gtrsim K[PtCl_3(1\text{-}C_6H_{12})]$$
$$\gtrsim K[PtCl_3(1\text{-}C_4H_8)] \gtrsim K[PtCl_3(1\text{-}C_5H_{10})]$$

We may compare this result with that of infrared spectrum. Sorzano[11] reported that the band of 491 cm^{-1} in $K[PtCl_3(C_2H_4)]$ is assigned to the Pt-‖ stretching vibration. Some authors[3,12] assigned the 1526 cm^{-1} band to the C=C stretching vibration. Recently, Hiraishi[13] assigned the 1250 cm^{-1} band to this mode by considering the Raman spectrum, and assigned the 1526 cm^{-1} band to the C–H scissoring vibration. The values of the infrared spectra of various complexes measured in the present investigation are listed in Table 4. It is seen from this table that the frequency of Pt-‖ stretching vibration in the propylene complex is higher than that in the other complexes. The higher the frequency of Pt-‖ stretching vibration is,

Table 4. Infrared data of $K[PtCl_3(olefin)]$

Molecular formula	Pt-|| stretching vib. cm^{-1}	C=C stretching vib. cm^{-1}	
$K[PtCl_3(C_2H_4)]$	490	1250	1526
$K[PtCl_3(C_3H_6)]$	495	1245	1506
$K[PtCl_3(1\text{-}C_4H_8)]$	490	1250	1504
$K[PtCl_3(1\text{-}C_5H_{10})]$	492	1252	1501
$K[PtCl_3(1\text{-}C_6H_{12})]$	490	1251	1500

the stronger the bonding is and, therefore, the bonding between platinum-propylene is considered to be stronger than the others. Moreover, it is known that the C=C stretching vibration shifts to lower frequencies upon coordination to the Pt atom. According to Hiraishi, the C=C stretching vibration is in a region near 1250 cm^{-1}. This band is 1250 cm^{-1} in the case of the ethylene complex and 1245 cm^{-1} in the case of the propylene complex. These values mean that propylene coordinates to the Pt atom stronger than ethylene. These results coincide with our data of calorimetric measurements.

Heat Capacity of Nematogenic *N*-*p*-Ethoxybenzylidene-*p'*-butylaniline between 14 and 375 K

Michio Sorai, Teruo Nakamura,* and Syûzô Seki
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 24, 1974)

The heat capacity of a low-temperature liquid crystal EBBA (*N*-*p*-ethoxybenzylidene-*p'*-butylaniline) of 99.75% (mol) purity was measured in the range 14—375 K with an adiabatic calorimeter. The melting point T_m was 305.62 K, and the enthalpy and entropy of fusion 27.09 kJ mol^{-1} and 88.71 J K^{-1} mol^{-1}, respectively. The temperature of mesomorphic transition T_c from nematic to isotropic liquid was 349.08 K, and the enthalpy and the entropy changes due to the mesomorphic transition were 1.553 kJ mol^{-1} and 4.524 J K^{-1} mol^{-1}, respectively. Excess heat capacity due to the mesophase transition, C(excess), is represented by $C(\text{excess}) \sim \varepsilon^{-0.7}$ in the range $10^{-4} < \varepsilon < 10^{-1.5}$, where $\varepsilon \equiv |T - T_c|/T_c$. This implies that the mesomorphic transition of EBBA can be regarded as of critical phenomena, characterized by a second-order rather than a first-order nature.

Liquid crystals are recently being reinvestigated both experimentally and theoretically. Studies on thermotropic liquid crystals are mainly devoted to elucidating the relationship between molecular geometry and liquid crystallinity and to clarifying the mechanism of mesomorphic transition based on the intermolecular forces and the order of molecular arrangements. The revival has been partially promoted by recent development in the industrial application of liquid crystals.

From a thermodynamic point of view the study of liquid crystals is interesting in the sense that a cooperative phase transition can be realized even in a liquid state. Thermodynamic quantities such as heat capacity, enthalpy, entropy, and free energy provide useful information on the energetic aspects inherent to a mesophase transition and are indispensable for understanding of the mesophase transition.

Compared with thermal analytic studies, precise calorimetric investigations are extremely scarce, which is partly due to the simplicity of thermal analyses. Mesophase transitions can be estimated qualitatively by simple thermal analyses, but quantitative information can be obtained only by significant calorimetric measurements.

As an extension of previous studies[1-4] we deal in this paper with the heat capacity of *N*-*p*-ethoxybenzylidene-*p'*-butylaniline (EBBA), which is known to exhibit a nematic mesophase in the range 36—80 °C.[5-7] The heat capacity of a more simple compound in this homologous series, MBBA (*N*-*p*-methoxybenzylidene-*p'*-butylaniline), has been measured by Mayer *et al.*[8] and Shinoda *et al.*[9] We have determined the heat capacity of OHMBBA, an *o*-hydroxy analog of MBBA, and found a glassy state of the nematic phase.[2,3] We attempted to establish a glassy liquid crystalline state for EBBA without success, though a glass transition phenomenon was found in many compounds of this homologous series.[4]

The order of mesomorphic transitions in liquid crystals is a current problem. We have attempted to analyze the mesophase transition from nematic to isotropic liquid in terms of critical phenomena.

* Present address: Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Osaka 558.

Experimental

Material. The nematogenic substance EBBA was prepared by the usual condensation reaction of *p*-butylaniline (Wako Pure Chemical Industries, Ltd.) with *p*-ethoxybenzaldehyde (Tokyo Kasei Kogyo Co., Ltd.) in ethanol. The product was recrystallized twice from ethanol and then twice from *n*-hexane. Found: C, 81.14; H, 8.30; N, 4.98%. Calcd for $C_{19}H_{23}NO$: C, 81.10; H, 8.24; N, 4.98%.

Thermal Analysis. Differential thermal analysis (DTA)[10] was carried out between −170 and 100 °C for a preliminary study of the thermal behavior of EBBA, about 500 mg of specimen being used.

Heat Capacity Measurement. The heat capacity of EBBA was measured with an adiabatic calorimeter[11] in the range 14—275 K. The all-gold calorimeter cell of approximately 35 cm^3 internal volume contained 17.8685 g (0.0634983 mol) of EBBA. The empty space was filled with helium gas at 1 atm pressure and room temperature to aid the heat transfer. A platinum resistance thermometer has been calibrated based on IPTS-68 scale.

Results and Discussion

Thermal Behavior. The thermal behavior of EBBA is illustrated in Fig. 1. A heating curve at the rate 2.5 K min^{-1} is shown by run 1. Melting point T_m of the stable crystal is 32.5 °C and the transition point T_c from nematic to isotropic liquid is 79.5

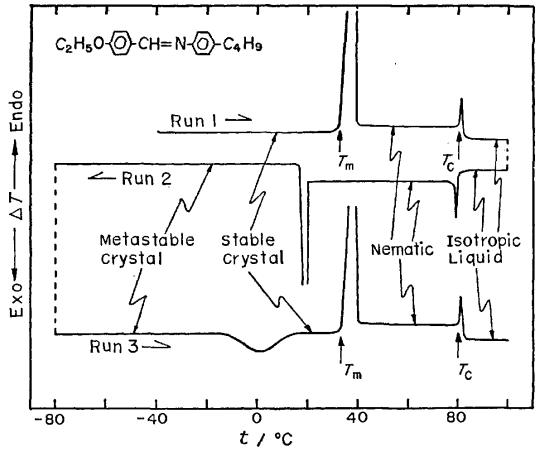

Fig. 1. DTA curves for EBBA.

°C. The values of T_m and T_c are approximately the same as those previously given.[5-7] A cooling curve of the isotropic liquid at the rate $-2\sim-500$ K min^{-1} is shown by run 2. Within this range the isotropic liquid was transformed into the nematic phase at the same temperature T_c without indication of thermal hysteresis. The sample in nematic state was supercooled to 20 °C at which temperature it crystallized into a metastable crystalline form. The cooling rate -500 K min^{-1} was not great enough attaining a glassy state of liquid crystal.[1-4] A heating curve at the rate 2.5 K min^{-1} is shown by run 3. The metastable crystal was irreversibly transformed into a stable one with heat evolution between -15 and 15 °C. Once stabilized, the thermal behavior remained the same as that shown by run 1.

Heat Capacity. The results of calorimetric measurements have not been converted into molar heat capacity under the saturation vapor pressure C_{sat}, due to the lack of data on density, vapor pressure, and heat of vaporization. The present results (Table 1, Fig. 2) correspond approximately to the molar heat capacity at constant pressure C_p, although a minor effect of vaporization of the specimen into the narrow empty space of the calorimeter cell might be included in the liquid state.

The temperature of the triple point and a concentration of impurity involved in the sample were evaluated from a series of temperature measurements with various fractions of the sample in the liquid state (Table 2). The values obtained closely follow the Mastrangelo-Dornte equation,[12] derived by assuming the formation of solid solution, rather than the ideal solution equation based on Raoult's law. The variation of temperature with the fraction melted could be represented by

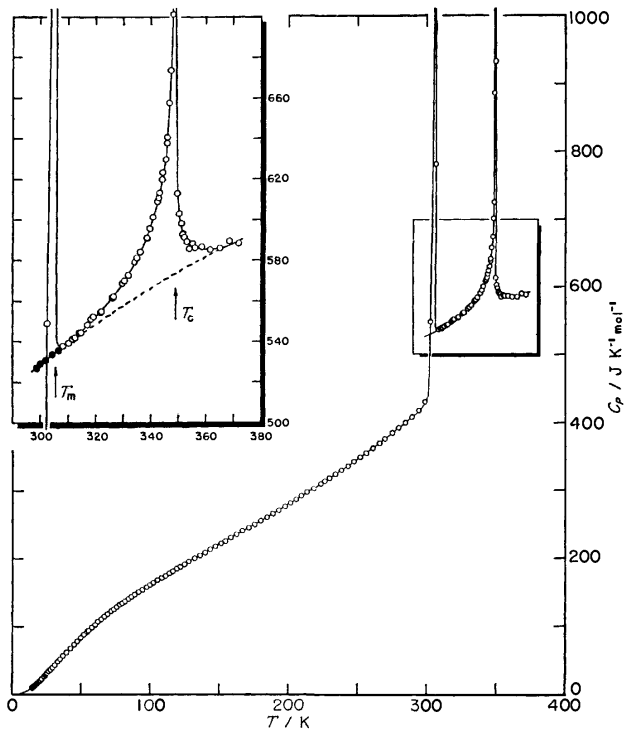

Fig. 2. Molar heat capacity of EBBA. Solid circles correspond to the heat capacity of supercooled nematic phase. Broken line indicates a normal heat capacity which separates the excess heat capacity due to phase transition from the total C_p.

Triple point of sample		305.621
Triple point of pure EBBA		305.688

$$T = 305.6876 - 0.06928/(0.04388+F),$$

where F is the fraction melted. The most probable numerical values were determined by computer-iteration. The melting point of EBBA could be derived from the value of triple point by means of Clausius-Clapeyron's equation if the data of molar volume were available for both solid and liquid states. Lack of such data prevented us from making the evaluation and the triple point is approximately regarded as equal to melting point. The concentration of impurity was determined to be 0.25 mol percent.

The thermodynamic functions of EBBA were calculated from heat capacity data and the calorimetric enthalpies of fusion and mesomorphic transition (Table 3). Values are given for heat capacity $C_p°$, entropy $S°$, enthalpy function $(H°-H_0°)/T$, and the Gibbs energy function $-(G°-H_0°)/T$, at selected temperatures. The values at 5 and 10 K were estimated by means of an effective frequency-distribution method.[13]

Enthalpy and entropy of fusion are listed in Table 4 together with changes due to mesomorphic transition.

Mesomorphic Transition. As in the case of OHMBBA,[3] the present mesomorphic transition is

characterized by a remarkable effect of pretransition. The effect, which results from easy fluctuation of the orientational order parameter in the vicinity of T_C, is obviously reflected in a large tail of the heat capacity curve below the transition point T_C. Recently, Goren *et al.*[14] measured the proton spin-lattice relaxation time of this compound in a wide temperature range and found that fluctuation of the order parameter is predominant around the mesomorphic transition point. The present result obtained from the heat capacity measurements is quite compatible with that of their nuclear magnetic resonance experiment.

The excess heat capacity, C(excess), due to the mesophase transition was determined by subtracting a normal heat capacity, C_p(normal), from the experimental one, C_p. The following quadratic equation was assumed for C_p(normal):

$$C_p(\text{normal}) = -2.6387\times10^{-3}T^2+2.6284T-22.214,$$

which corresponds to a curve passing through the three experimental C_p points at 300.138, 304.415, and 364.965 K. The enthalpy and entropy of transition were determined by integrating the C(excess) with respect to T and ln T, respectively (Table 4).

Table 4. Enthalpy and entropy of transition for EBBA

Transition	T / K	ΔH / kJ mol^{-1}	ΔS / J K^{-1} mol^{-1}
Crystal→Nematic (T_m)	305.62[a]	27.09	88.71
Nematic→Isotropic Liquid (T_C)	349.08	1.553	4.524

a) Melting point for the pure material T_m°=305.69 K.

With a differential scanning calorimeter (DSC) Smith and Gardlund[7] determined the enthalpy of mesophase transition to be 523 J mol^{-1}, which amounts to only one third of the present calorimetric value. A shortcoming inherent to thermal analysis with DSC is inability to detect a mild thermal change occurring gradually. In a mesomorphic transition, the contribution from the pretransitional region to ΔH is considerably large. In the DSC method, however, only a truncated part of a heat-capacity peak is detected. The large discrepancy between the DSC method and the present calorimetric measurement is therfore attributable to the underestimation of ΔH in the former method.

The order of phase transition provides useful information on the nature of transition. Except for the smectic-A to nematic (S_AN) transition[15,16] all other mesomorphic transitions are believed to be of first-order. No paper seems to have appeared dealing with the examination of the order of the nematic to isotropic liquid (NI) transition. It was difficult to decide whether the NI transition of EBBA is first-order or not, since, we have not measured the heat capacity in a cooling direction to examine the existence of thermal hysteresis, and the enthalpy of transition was too small to detect a latent heat.

We attempted to analyze the NI mesomorphic transition according to the treatment of critical phenomena.[17-19] If C(excess) is varied with the critical-point exponents α' and α for $\varepsilon(\equiv|T-T_C|/T_C)$, when $T\to T_C\pm0$, by

$$C(\text{excess}) \sim \varepsilon^{-\alpha'} \quad \text{for } T < T_C$$

and

$$C(\text{excess}) \sim \varepsilon^{-\alpha} \quad \text{for } T > T_C,$$

linearity is expected in the vicinity of the critical point T_C in a log C(excess) *versus* log ε plot (Fig. 3). We see that there is a linear region ($10^{-1.5}>\varepsilon>10^{-4}$) for both $T<T_C$ and $T>T_C$. The critical-point exponents were determined to be $\alpha'=\alpha=0.7$ as the slopes of these straight lines. This implies that the present NI transition can be treated as a critical phenomenon fulfilling apparently a scaling relation $\alpha'=\alpha$. The NI transition in EBBA can be characterized by a second-order phase transition rather than a first-order one, though the numerical value of 0.7 seems to be rather large as compared with the values obtained for typical critical phenomena such as the gas-liquid or the ferromagnetic critical phenomena.

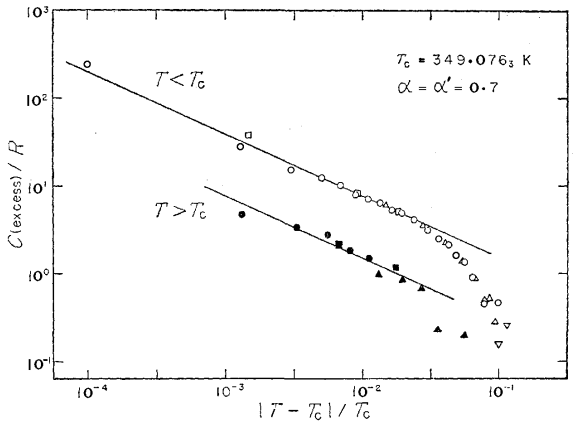

Fig. 3. Variation of excess heat capacity, C(excess), due to mesomorphic transition with the reduced temperature. Different symbols indicate different series of measurements.

McMillan[20] proposed a theory for the S_AN phase transition based on a simple microscopic model for the intermolecular interaction potential. One of the most interesting features of his theory is its prediction that the S_AN transition can be of first or second order, depending on the magnitude of the molecular interaction constants. Although this theoretical argument cannot be directly applied to the NI transition, it is very likely that the order of the NI transition depends on the nature of molecular interaction.

Existing chemical or physical impurity is also a dominant factor to control the transition behavior. High concentration of these impurities generally brings about (i) appreciable reduction of "a first-order character" in an intrinsic first-order phase transition[21] and (ii) incompleteness of the critical-exponent description for ideal critical phenomena.[22,23] We cannot determine whether a 0.25 mol percent concentration of chemical impurity is high enough to violate the intrinsic nature of the present NI transition or not, or what the physical impurity in a mesomorphic transition occurring in a liquid state is. Although a liquid crystalline state is characterized by an ordered trend of molecular

orientation, no regularity such as a lattice structure in crystal exists. Lattice defects or vacancies therefore do not belong to physical impurity in a liquid crystalline state. Only the physical impurity to bring about a significant effect in the vicinity of T_c may be the heterophase fluctuation. The mechanism of a mesomorphic transition, occurring cooperatively in a liquid state, should be understood in terms of the fluctuation of order parameter as well as the intermolecular interaction.

An X-Ray Diffraction Study of the Structure of Hydrated Copper(II) Ion in a Copper(II) Perchlorate Solution

Hitoshi OHTAKI and Masunobu MAEDA

Laboratory of Solution Chemistry, Faculty of Engineering, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received March 13, 1974)

The structure of hydrated copper(II) ion was determined by means of the X-ray diffraction of a 3.55 M copper(II) perchlorate solution. The radial distribution curve showed that the copper(II) ion has a distorted octahedral structure with six water molecules. Four water molecules occupy the equatorial sites of the octahedron at a distance of 1.94±0.02 Å from the Cu(II) ion and the other two water molecules at the axial sites are 2.43±0.03 Å distant from the central ion.

A number of X-ray investigations have been carried out on crystal structures of various copper(II) complexes, and anisotropic electron distributions of copper(II) have been observed in many complexes of Cu(II).[1-3]

X-Ray crystal studies of copper(II) hydrates disclosed the fact that the Cu^{2+} ion coordinated to six water molecules possesses a distorted octahedral configuration. Four water molecules are located at the equatorial positions with the Cu–O bond distance of 1.94—2.16 Å, and the other two water molecules are at the axial positions with the Cu–O distance of 2.2—2.5 Å.[4-8]

The distortion in the structure of hydrated copper(II) ion has also been observed in aqueous solution by Shapovalov and Radchenko,[9] who carried out X-ray diffraction measurements of an aqueous copper(II) sulfate solution, and determined that the Cu^{2+} ion is surrounded by six water molecules, four of which lie at a distance of 2.15 Å from the central ion and the other two occupy the opposite ends of the axis of the octahedron at a distance of 2.5 Å from the ion.

The present paper deals with an X-ray diffraction study of a copper(II) perchlorate solution, and the results are compared with those obtained for the sulfate solution.[9]

Experimental

Preparation and Analysis of Copper(II) Perchlorate Aqueous Solution. Copper(II) perchlorate was prepared by dissolving copper(II) oxide of p.a. quality (Wako Pure Chemicals Co.) in a hot perchloric acid and was recrystallized twice from water. A copper(II) perchlorate solution was prepared by dissolving the copper(II) perchlorate crystals in water containing a small amount of perchloric acid in order to prevent the hydrolysis of Cu^{2+} ion.

The concentration of Cu^{2+} ion in the sample solution was determined by means of electrodeposition of copper on a platinum gauze electrode. The amount of perchlorate ion was determined by an acid-base titration of a perchloric acid effluent obtained by passing an aliquot of the solution through a cation-exchanger column (Dowex 50W-X12) of the H^+ form. The concentration of hydrogen ion was determined from the relation, $[H^+]=[ClO_4^-]-2[Cu^{2+}]$. The density of the solution was measured with a pycnometer. The composition of the sample solution is given in Table 1.

Measurements and Treatment of X-Ray Diffraction Intensities. X-Ray diffraction measurements were carried out with an X-ray diffractometer (JEOL Co., Tokyo).[10]

Table 1. Composition of the sample solution (in g atoms/l)

Cu	3.550
Cl	7.357
O	69.86
H	81.12

The surface of the solution thermostated at 25±1 °C was irradiated with a divergent beam of MoKα radiation (λ= 0.7107 Å) emitted from a Philips PW210500 Mo X-ray tube.

The diffraction was measured at discrete points between θ=1 and 70°, where θ is half the scattering angle. Three different slit combinations, with divergent slits 1/12°, 1/4°, and 1°, were used. The diffracted intensities were measured as times used for preset 40000 counts (which contain a statistical error of 0.5%) at angular intervals of 0.125° in the low angle range θ=1—6° with a combination of a 1/12° divergent slit, 0.25° in the intermediate range θ=3—20° with a 1/4° divergent slit, and 0.5° in the high angle range θ=16—70° with a 1° divergent slit. The whole angle range was scanned twice in order to examine the reproducibility of the results. The intensities measured at the same angle usually agreed within 2%.

The measured intensities with the three different slit combinations were corrected for background radiation and were normalized to the intensities obtained with a 1° divergent slit by comparing them with those measured in the overlapping regions. The normalized intensities were corrected for absorption in the solution and polarization in the solution and in the monochromator and then scaled to absolute intensities in such a way that the asymptote became equal to the sum of the calculated coherent and incoherent intensities at high scattering angles (θ>50°). The scaling factor thus calculated agreed with that calculated by the method of Krogh-Moe[11] and Norman[12] within less than 1% accuracy.

Intensities $i(s)$ due to combinations of any pairs of atoms were evaluated from the scaled intensities $I(s)$ after correction of the independent atom- and incoherent-scattering according to the equation

$$i(s) = I(s) - \sum_i n_i[(f_i(s)+\Delta f_i')^2 + (\Delta f_i'')^2 + \Phi(s)\cdot I_i^{inco}(s)] \quad (1)$$

where s denotes $4\pi\sin\theta/\lambda$ (λ=0.7107 Å), n_i the number of atom i, $f_i(s)$ the scattering factor of atom i at angle s, $\Delta f_i'$ and $\Delta f_i''$ the real and imaginary parts, respectively, of the anomalous dispersion, and $\Phi(s)$ the fraction of the incoherent radiation reaching the counter. The reduced intensities $i(s)$ thus evaluated are shown in Fig. 1 in the form of $s\cdot i(s)$ *vs.* s.

The coherent scattering factors of Cu, Cl, and O were taken from Cromer and Waber,[13] and those of H from the

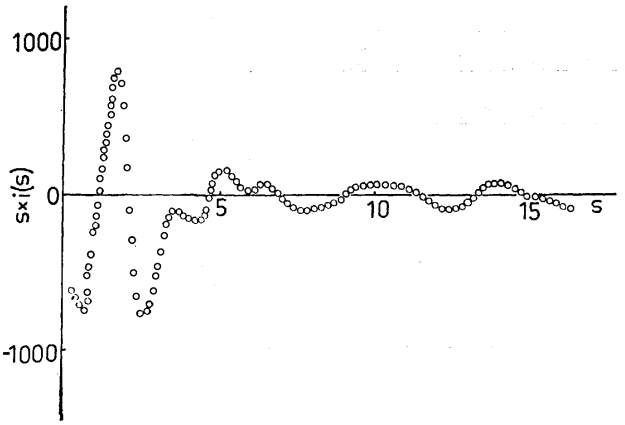

Fig. 1. The reduced intensities $i(s)$ multiplied by s as a function of s. For clarity not all of the experimental points are shown.

International Tables.[14] The incoherent scattering factors for Cu were those given by Cromer and Mann,[15] those for Cl and O by Cromer[16] and those for H by Compton and Allison.[17] The incoherent scattering factors were corrected by the Breit-Dirac factors. The values used for anomalous dispersion were taken from Cromer and Lieberman.[18]

Results and Discussion

The radial distribution curve $D(r)$ was calculated from the reduced intensity data $i(s)$ according to Eq. (2). The calculations were carried out with the help of the computer program KURVLR specially written for the analysis of X-ray diffraction data in solution.[19]

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_0^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(sr)\mathrm{d}s \qquad (2)$$

Here ρ_0 denotes the average scattering density of the solution in electron unit and the modification function $M(s)$ was chosen to be

$$\sum_i n_i f_i(0)^2/\sum_i n_i f_i(s)^2 \exp(-0.01s^2).$$

The $D(r)$ function thus calculated showed spurious peaks in the range less than 1 Å, which has no relation with any interatomic distance. These spurious peaks were eliminated by the Fourier inversion of the $D(r)$ function below 1 Å on the assumption that the $D(r)$ function below 1 Å consisting of contributions only from the O-H bonds within H_2O and the Cl-O bonds within ClO_4^-.

Figure 2(a) shows the final radial distribution function $D(r)$ thus calculated. It shows four peaks at around 1.4, 1.95, 2.4, and 3 Å. The peak at around 1.4 Å is due to the Cl–O bonds within ClO_4^-, that at 1.95 Å can be attributed to the bonds between Cu and O at an equatorial position within the hydrated Cu^{2+} ion, and the one at 2.4 Å is due to both the axial Cu–O bond within the hydrated Cu^{2+} ion and the O–O contact within ClO_4^-.

The distances and the numbers of equatorial and axial Cu-O bonds were determined from the residual peaks after subtraction of the contributions from the Cl–O and O-O contacts at 1.43 and 2.43 Å, respectively, within ClO_4^- ion and the O-H bond at 1.01 Å within H_2O. The theoretical peak shapes for the

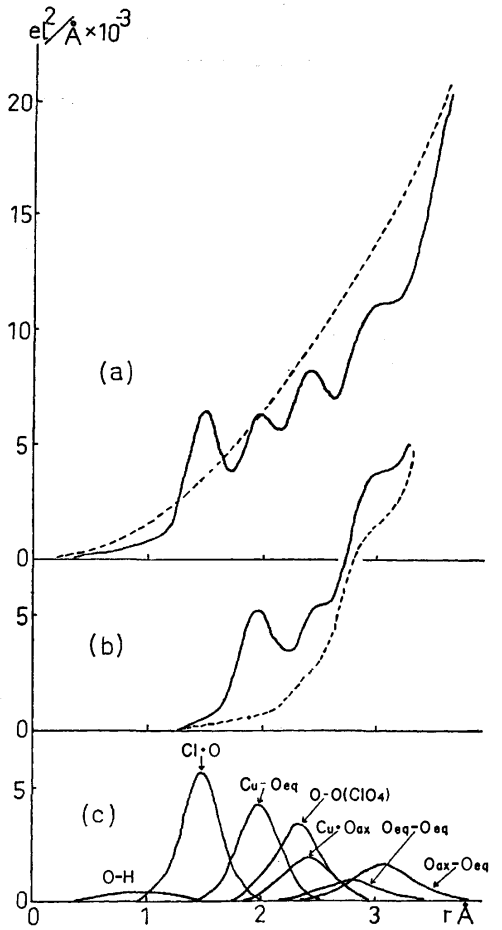

Fig. 2. (a) The radial distribution curve. The broken curve denotes $4\pi r^2\rho_0$. (b) The full curve gives the difference between $D(r)$ and the calculated peak shapes for the Cl–O and O–O atom pairs within ClO_4^-, and the broken curve the residual distribution function obtained by subtraction of the theoretical peak shapes shown in (c) from the $D(r)$ curve. (c) The calculated peak shapes with the parameters given in Table 2.

Cl–O, O–O, and O–H contacts were evaluated as follows.

Theoretical intensities caused by any i-j atom pair can be calculated by

$$i(s) = \sum_i\sum_j n_{ij} f_i(s) f_j(s) \frac{\sin(r_{ij}s)}{r_{ij}s} \exp(-b_{ij}s^2) \qquad (3)$$

where n_{ij}, r_{ij}, and b_{ij} represent the frequency factor, the distance, and the temperature factor, respectively, of the interaction between any atoms i and j.

The values of r, b, and n for the Cl–O and O–O pairs[10] and those for the O–H bond are given in Table 2.

The theoretical intensities thus calculated were converted into atomic pair distribution functions by means of the Fourier integration with Eq. (2). The calculated functions are reproduced in Fig. 2(c). Figure 2(b) gives the residual radial distribution curve (full line) obtained by subtracting these peaks from the $D(r)$ curve. Three peaks still remain at the positions 1.94, 2.43, and 3 Å. The area under the peak at 1.94 Å was estimated with a planimeter. The number of

Table 2. Final parameter values for the copper(II) ion coordinated to six water molecules, perchlorate ion, and water molecule

	r(Å)	b	n
$Cu(H_2O)_6^{2+}$			
$Cu-O_{eq}$	1.94	0.002	4

H_2O			
O-H	1.01	0.001	2

water molecules around Cu was evaluated to be about four, which corresponds to the number of Cu-O bonds in an equatorial plane. The area under the peak at 2.43 Å, which may correspond to the number of bonds between Cu and water molecules at the axial coordination sites, was difficult to estimate, since contributions from atom pairs at longer distances were overlapped. The broad peak ranging from 2.7 to 3.2 Å is ascribable to both the equatorial O–O contacts at *cis*-position and the contacts between axial and equatorial oxygens within the distorted octahedron of the hydrated copper(II) ion.

From the results, it was assumed that the Cu^{2+} ion is bound by six water molecules and the length of four Cu–O bonds in the plane is 1.94 Å and that of the other two along the axis is 2.43 Å. The values of r, b, and n were evaluated for four kinds of atom pairs (the equatorial Cu–O, the axial Cu–O, the *cis*-contacts of the equatorial O–O and the equatorial O–axial O) within $Cu(H_2O)_6^{2+}$. They are given in Table 2, together with the values for the Cl-O and O–O pairs within ClO_4^- and for the O-H pair within H_2O.

In order to see if the proposed structure and the values of the parameters given in Table 2 can satisfactorily explain the experimental data, the theoretical peaks were calculated with the parameters according to Eqs. (3) and (2) (the calculated peaks for the interactions within $Cu(H_2O)_6^{2+}$ are shown in Fig. 2(c)). The peaks were subtracted from the residual curve (full line, Fig. 2(b)) which had been obtained by subtraction of the contributions of ClO_4^- from the $D(r)$ curve. The curve thus obtained (broken line, Fig. 2(b)) gives a smooth curve with no dominant peak in the region less than 2.8 Å. The broad peak remaining at around 2.9 Å may be due to the contacts between oxygen atoms of water molecules and oxygen atoms of ClO_4^-.[10,20,21]

It is thus concluded that the copper(II) ion, which is coordinated to six water molecules in the first coordination sphere, has a distorted octahedral structure with the values of the parameters given in Table 2.

Shapovalov and Radchenko[9] obtained 2.15 and 2.5 Å as the distrances from Cu to O occupying an equatorial and an axial site, respectively, in the sulfate solution. These distances are greater than the corresponding ones, 1.94 ± 0.02 Å and 2.43 ± 0.03 Å, we found in the perchlorate solution. The uncertainties of the distances were estimated from the shape of the distribution curve in Fig. 2(b).

The present work was supported by the Ministry of Education.

Kinetics of Multidentate Ligand Substitution Reactions. XVII.* Substitution Reactions of Diethylenetriaminepentaacetate (DTPA) with Aminopolycarboxylate Complexes of Nickel(II) and Cobalt(II)

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036

(Received March 20, 1974)

The kinetics of the substitution reactions of DTPA with *N*-(2-hydroxyethyl)iminodiacetate (HIDA) and *N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetate (EDTA-OH) complexes of nickel(II) and EDTA-OH and 2,2'-ethylenedioxydi(ethylamine)-*N,N,N',N'*-tetraacetate (GEDTA) complexes of cobalt(II) were studied systematically by employing the polarographic technique. The reaction of ethylenediaminetetraacetate (EDTA) with the nitrilotriacetate (NTA) complex of nickel(II) in an alkaline medium was also studied. All the substitution reactions were found to have a common reaction mechanism. They were first-order with respect to DTPA or EDTA and also first-order with respect to the 1 : 1 ratio metal(II) complex of HIDA, NTA, EDTA-OH, or GEDTA. From a comparison of the observed rate constants with those estimated on the basis of the proposed reaction intermediate, the detailed reaction mechanism and the steric effect of the DTPA anion on the reaction rates were studied. The DTPA anion had practically no effect on the rates of the substitution reactions of the aminopolycarboxylate complexes of metal (II) ions.

Previously,[1] the present author studied the kinetics of the substitution reaction of DTPA with the nickel(II)–NTA complex and discussed the effect of the protonation of the DTPA anion on its reaction rate. However, no detailed reaction mechanism was investigated in that paper. He also studied the kinetics of the substitution reactions of cyclohexane-1,2-diamine-*N,N,N',N'*-tetraacetate(CyDTA) with the aminopolycarboxylate complexes of zinc(II) and cobalt(II), and discussed the nature of the steric effect of the CyDTA anion on their reaction rates.[2] Consequently, in order to understand more precisely the nature of the steric effect of the entering group on the rate of the substitution reaction involving an aminopolycarboxylate complex, it seems to be necessary and important to conduct a kinetic study of the substitution reaction involving DTPA. This paper will describe a kinetic study of the substitution reactions of DTPA with the nickel(II)–HIDA and –EDTA-OH and cobalt(II)–EDTA-OH and –GEDTA complexes, using the polarographic technique. The substitution reaction of EDTA with the nickel(II)–NTA complex in an alkaline solution will also be studied in this paper, and its reaction rate will be compared with those of the DTPA reactions.

Experimental

Reagents. The methods of preparing and standardizing the nickel(II) and cobalt(II) nitrate solutions were given previously.[3] The EDTA, DTPA, EDTA-OH, and GEDTA used in this study were recrystallized as their acids from their aqueous solutions. The preparation and recrystallization of the acid form of HIDA were also given previously.[4] All the other chemicals used were of an analytical reagent grade and were used without further purification.

Apparatus and Experimental Procedures. The apparatus and experimental procedures employed were the same as those given previously.[2] In this study, no buffer reagent was used, because all the sample solutions always contained a large excess of uncomplexed HIDA, NTA, EDTA-OH, or GEDTA, and had enough buffer capacity over the entire pH range covered ($8.30<$pH<9.00 in the HIDA system, $9.00<$pH<10.00 in the NTA system, $9.00<$pH<10.40 in the EDTA-OH system, and $9.40<$pH<10.40 in the GEDTA system). All the kinetic measurements were conducted under experimental conditions where all the reactions could be treated as pseudo first-order reactions. The rate of the substitution reaction was determined by measuring the change in the dissolution wave-height due to the uncomplexed DTPA or EDTA. The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate amount of $NaClO_4$.

Results and Discussion

The substitution reactions of DTPA with the nickel(II)–HIDA and cobalt(II)–GEDTA complexes and the reaction of EDTA with the nickel(II)–NTA complex showed kinetic behavior quite similar to that of the reaction of DTPA with the nickel(II)–NTA complex.[1] This fact suggests that the reaction mechanism for the above reactions can be formulated as:

$$MX_2^{(2-2m)+} \rightleftharpoons MX^{(2-m)+} + X^{m-} \quad \text{(a) in a rapid equil.}$$

$$MX^{(2-m)+} + \begin{cases} HY^{1-n} \overset{k_H}{\rightleftharpoons} MY^{2-n} + HX^{1-m} & \text{(b)} \\ Y^{n-} \overset{k_0}{\rightleftharpoons} MY^{2-n} + X^{m-} & \text{(c)} \end{cases} \quad \text{rds}$$

corresponding to Relation (1):

$$k_{ap}^{+} = \frac{[\mathrm{Me(II)}] \times \left(k_0 + k_H \cdot \frac{[H^+]}{K_n}\right)}{(\alpha_H)_Y \cdot \left(1 + \frac{K_2 \cdot [X]_f}{(\alpha_H)_X}\right)} \qquad (1)$$

where k_{ap}, [Me(II)], and K_n are, respectively, the pseudo first-order rate constant, the metal(II) concentration, and the fifth dissociation constant of diethylenetriaminepentaacetic acid or the fourth dissociation constant of ethylenediaminetetraacetic acid; all the other symbols used have their usual meanings.[2] The k_0 and k_H values for the above reactions were determined from the intercepts and slopes of the linear relations between $k_{ap}^{+} \times (1 + K_2 \cdot [X]_f/(\alpha_H)_X)(\alpha_H)_Y/[\mathrm{Me(II)}]$ and $[H^+]$; they are listed in Tables 1 and 2.

HIDA-DTPA	1.1×10^{5}	1.50×10^{4}	1.87	1.81	2.08
EDTA-OH-DTPA	2.3×10^{-3}	3.76×10^{-3}	−4.82	−4.80	−5.14

a) Calculated on the basis of the Gly reaction mechanism.

Table 2. Substitution rate constants of Co(II) complexes
μ=0.30, 25°C

System	Rate constant		Log rate constant ratio		
			Obsd		
	k_0	k_H	k_0	k_H	Calcd[a]
EDTA-OH	2.1×10^{1}	3.8	0	0	0
GEDTA	1.0×10^{4} [b]	2.0×10^{3}	2.70	2.72	2.60

a) Calculated on the basis of the Gly reaction mechanism. b) Less accurate.

In the substitution reactions involving metal(II)-EDTA-OH complexes, the pseudo first-order rate constant, k_{ap}^{+}, was 1) proportional to the metal(II) concentration, 2) independent of the initial concentration of DTPA, and also 3) independent of the concentration of uncomplexed EDTA-OH. Furthermore, the plot of the k_{ap}^{+} value multiplied by $(\alpha_H)_Y/[Me(II)]$ against $[H^+]$ gave a linear relation with an intercept of a finite value (Fig. 1). These facts imply that the substitution reactions of DTPA with the metal(II)-EDTA-OH

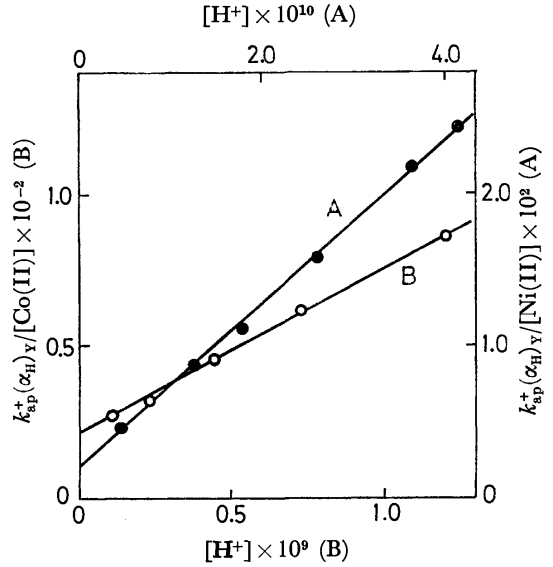

Fig. 1. The plot of $k_{ap}^{+}\times(\alpha_H)_Y/[Me(II)]$ against $[H^+]$
μ=0.30, 25 °C
A) Ni(II) system
$[Ni(II)]=18.2$ mM, $[EDTA\text{-}OH]_f=18.2$ mM, $[DTPA]_i=1.82$ mM
B) Co(II) system
$[Co(II)]=6.37$ mM, $[EDTA\text{-}OH]_f=21.0$ mM, $[DTPA]_i=0.546$ mM

$$k_{ap}^{+}=\frac{[Me(II)]}{(\alpha_H)_Y}\cdot\left(k_0+k_H\cdot\frac{[H^+]}{K_n}\right) \quad (2)$$

complexes proceed through (b) and (c), corresponding to Relation (2):
Therefore, the k_0 and k_H values were estimated from the intercepts and slopes of the straight lines in Fig. 1; they are listed in Tables 1 and 2.

As was discussed in connection with the dissociation[5] and substitution reactions[6] of the ethylenediaminemonoacetate (EDMA) complex of nickel(II), the entering group in the ligand substitution reaction just assists the dissociation of the leaving group without effecting any change in the detailed dissociation mechanism. Previously,[3] the present author established that the nickel(II)-NTA complex dissociates through the Gly reaction intermediate, in which the leaving NTA anion is bonded to the nickel(II) ion through the glycinate chelate ring (Gly mechanism). Therefore, it is natural to believe that the substitution reaction of the nickel(II)-NTA complex with EDTA also proceeds through a Gly mechanism.[2,7,8] If the Gly mechanism can be assumed for the reaction of the nickel(II)-NTA complex with EDTA, the rate constant ratio between the dissociation reaction of the nickel(II)-NTA complex,[9] and its substitution reaction with EDTA should be $1:10^{7.58}$. The above rate constant ratio was calculated with the aid of the $k=k_{rds}K_AK_LK_{st}K_{elec}/K_{MX}$ relation[2,10] by using the K_A value of $10^{9.27}$, the K_{st} ratio of 2, and the K_{elec} ratio of $10^{2.0}$. The observed ratio was $1:10^{7.76}$ (Table 1). The good agreement between the observed and calculated ratios supports the above Gly-mechanism explanation, suggesting that the EDTA anion had practically no steric effect on its substitution reaction with the nickel(II)-NTA complex. As is illustrated in Table 1, the k_0 and k_H values for the reaction of DTPA with the nickel(II)-NTA complex can also be understood in terms of a simple

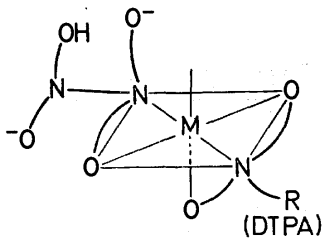

Fig. 2. A possible intermediate for the substitution reaction of DTPA with metal(II)-EDTA-OH complex, $[Me^{II}(EDTA\text{-}OH)(DTPA)]^{-n}$

Gly mechanism. The k_0 and k_H values of the substitution reaction of DTPA with the nickel(II)–HIDA complex can also be understood by assuming the Gly mechanism. The rate constant ratio between the DTPA reactions with the nickel(II)–HIDA and –NTA complexes estimated on the basis of the Gly mechanism was $1 : 10^{2.08}$, and the good agreement with the observed k_0 ratio of $1 : 10^{1.87}$ or the k_H ratio of $1 : 10^{1.82}$ (Table 1). Similarly, the k_0 and k_H values of the reaction of DTPA with the nickel(II)–EDTA-OH complex could also be understood by assuming the Gly reaction mechanism (the reaction intermediate in Fig. 2). The rate constant ratio between the nickel(II)–NTA and –EDTA-OH systems, as calculated on the basis of the proposed reaction mechanism, was $1 : 10^{-5.14}$. The observed k_0 and k_H ratios were $1 : 10^{-4.80}$ and $1 : 10^{-4.81}$ respectively. The agreement between the observed and calculated ratios can be regarded as satisfactory. As was mentioned above, the rates of the DTPA reactions studied could be understood by assuming the Gly reaction mechanism. This evidently implies that, irrespective of its large molecular size, the entering DTPA anion exerts practically no steric effect on the rate of its substitution reaction with the aminopolycarboxylate complex of nickel(II). The result obtained in the kinetic study of the DTPA substitution reactions of cobalt(II)–EDTA-OH and –GEDTA complexes proved the above conclusion to be true. Since the cobalt(II) complex shows kinetic behavior quite similar to that of the nickel(II) complex,[11] one can safely assume the Gly reaction mechanism for the DTPA reactions of the cobalt(II)–EDTA-OH and –GEDTA complexes. On the basis of the Gly mechanism, the rate constant ratio between the EDTA-OH and GEDTA systems could be estimated to be $1 : 10^{2.60}$. The observed k_0 and k_H ratios were $1 : 10^{2.70}$ and $1 : 10^{2.72}$ respectively. The agreement between the calculated and observed ratios can be regarded as satisfactory (Table 2). The conclusion that the DTPA anion has no practical effect on its substitution reaction rates could also be confirmed by an examination of the molecular model. A close examination of the molecular model revealed that, for all the DTPA system, the glycinate reaction intermediate in which the leaving aminopolycarboxylate and entering DTPA anions are, respectively, bonded to the metal(II) ion through the glycinate and iminodiacetate chelate rings could be formed without any difficulty. This can be ascribed chiefly to the free bond rotation of the DTPA and aminopolycarboxylate anions involved in the substitution reactions.

Differential Thermal Analysis of Some Tervalent Metal Chelates of 1,5-Dialkylpentane-2,4-dionates*

Isao YOSHIDA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received April 16, 1974)

In connection with the purification of metal chelates by zone refining, thermal properties of the following β-diketone chelates of tervalent cobalt(III), aluminum(III), iron(III), manganese(III), and chromium(III) were investigated by differential thermal analysis (DTA). The β-diketones used in this study were heptane-3,5-dione, nonane-4,6-dione, 2,6-dimethylheptane-3,5-dione, 2,8-dimethylnonane-4,6-dione, 2,2,6,6-tetramethylheptane-3,5-dione, and tridecane-6,8-dione. Metal chelates of the alkyl substituted pentane-2,4-diones showed a lower melting- and higher decomposition temperature in comparison with the pentane-2,4-dionates. Discussion is given on the effects due to the structures of the alkyl substituents upon thermal properties of the hexacoordinate metal chelates.

The criteria for thermal properties of the samples which are to be subjected to zone melting process are the moderate melting temperature convenient for the operation, as well as the thermal durabilty and less volatility under prolonged heating at a molten state. Most of metal chelate compounds, however, decompose prior to melting with a few exceptions:[1,2] Metal oxinates belong to a group of metal chelates of the highest thermal stability; however, they are not found in a stable molten form because of their high melting points.[3,4] Although pentane-2,4-dionates are also regarded as thermally stable and low melting chelates, only the chromium(III),[5] beryllium(II)[6] and aluminum(III)[7] chelates were reported to give melts durable under prolonged heating. Fluoro-substituted pentane-2,4-dionates show lower melting temperatures than the pentane-2,4-dionates,[8,9] but the electron-withdrawing effect of the fluoroalkyl groups decreases the thermal stability of the metal chelates.[10,11] On the other hand, a large number of alkyl-substituted pentane-2,4-dione chelates of copper(II) were reported to melt in a lower temperature region and to be enough stable to melt without decomposition.[12-14]

In the continuation of the previous reports[15,16] on the thermal properties of some bivalent metal chelates of a range of β-diketones, this paper reports on the same aspects of some tervalent metal chelates of the following 1,5-dialkylpentane-2,4-diones.

The β-diketones chosen in this serial study are heptane-3,5-dione(or dipropionylmethane, DNPM), nonane-4,6-dione(or di-*n*-butyrylmethane, DNBM), 2,6-dimethylheptane-3,5-dione(or diisobutyrylmethane, DIBM), 2,8-dimethylnonane-4,6-dione (or diisovalerylmethane, DIVM), 2,2,6,6-tetramethylheptane-3,5-dione(or dipivaloylmethane, DPVM), and tridecane-6,8-dione(or di-*n*-caproylmethane, DNCM), and metal ions are cobalt(III), aluminum(III), iron(III), manganese (III), and chromium(III).

Melting, decomposing and some additional phase transition temperatures were determined by DTA measurements in the air and nitrogen atmosphere. Both melting and pyrolytic degradation reaction gave endothermic DTA peaks. The former peak was characterized as follows: 1) The peak position was reproducible upon repeated DTA runs of a sample. 2) Atmosphere did not affect the position and shape of the peak. 3) IR, UV, and visible spectra were identical on the samples before and after the DTA run. 4) After the endotherm, the base line returned to the same level as before. An endotherm which did not satisfy either of the above qualifications, was regarded as that due to the degradation reactions.[15]

Experimental

Synthesis of 1,5-dialkylpentane-2,4-diones[17] and their cobalt(III) chelates[18] were reported in our previous papers. Pentane-2,4-dione and all of the inorganic reagents were obtained commercially, and used without any further purifications. Analytical results and solvents used for recrystallization of the following metal chelates are summarized in Table 1.

Aluminum(III) Chelates. Tris(acetylacetonato)aluminum(III), $Al(AA)_3$, was prepared according to a standard method.[19] $Al(DIBM)_3$, $Al(DIVM)_3$, and $Al(DPVM)_3$ were prepared according to the modified Jones' method.[20] To a 50 ml of 3M-sodium hydroxide aqueous solution containing 1.25 g (0.003 mol) of aluminum nitrate nonahydrate was added 0.01 mol of each ligands. White precipitate was obtained immediately. These were collected by filtration, and then recrystallized from appropriate solvents which are listed in Table 1. DNPM, DNBM, and DNCM chelates could not be obtained by the above methods.

Iron(III) Chelates. To a 10 ml of an aqueous methanol solution containing 1.35 g (0.003 mol) of ferric nitrate hexahydrate was added 0.01 mol of a ligand, and then 6 ml of 2.5M-sodium hydroxide solution was added dropwise under vigorous stirring. AA, DIBM, DIVM, and DPVM gave red-orange solid, while DNPM, DNBM, and DNCM red-orange oil, respectively. Solid chelates were collected by filtration, and then recrystallized from appropriate solvents as listed in Table 1. The oily product was extracted with chloroform, and the chloroform extract was eluted from silica gel and alumina columns, each 10 cm long, successively. The eluate was evaporated, to give an oily liquid chelate.

Manganese(III) Chelates.[21] To 20 ml of an aqueous methanol was added 0.54 g of manganese(II) chloride tetrahydrate and 0.11 g of potassium permanganate. The resulting solution was adjusted to pH 6—7 by the addition of 0.8 M ammonium hydroxide. Then 0.01 mol of a ligand was added into the solution with vigorous stirring. Dark brown precipitate was afforded with AA, DIBM, DIVM,

$Cr(DPVM)_3$	$C_{33}H_{57}O_6Cr$	65.81	9.55	65.91	9.48	Acetone+Water

and DPVM. The solid precipitate was collected by filtration, and then recrystallized from an appropriate solvent. DNPM and DNBM gave oily chelates. These were extracted with benzene from the reaction mixture. After the extract was evaporated, the oily residue was dissolved again in an ether–methanol mixture. Then the solution was purified by elution in a similar manner to that for the oily iron(III) chelates. Manganese(II) acetylacetonate was prepared according to a standard method.[22]

Chromium(III) Chelates.[23] To 20 ml of an aqueous methanol solution containing 1.3 g (0.003 mol) of chromium nitrate hexahydrate and 7 g of urea was added 0.01 mol of a ligand. Then mixture was maintained at about 95 °C for 10 hr with stirring. AA, DIBM, and DPVM afforded solid precipitate. These were collected by filtration, and then recrystallized from an appropriate solvent. The remaining ligands gave oily products, which were hardly purified except $Cr(DNPM)_3$. The last chelate, $Cr(DNPM)_3$, was purified in a similar manner to those for the manganese(III) chelates.

Measurements. DTA curves were recorded on a Rigaku Denki Thermoflex 8001 in the air and nitrogen atmosphere. A hermetic-sealed sample holder was used for volatile and sublimable chelates; otherwise a pressure-capped one was used.** Procedure of the thermoanalysis was the same as described previously.[15]

Evolved ligand vapor upon the pyrolysis of a metal chelate was identified by means of gas-liquid chromatography by direct injection of the metal chelate as a solution into the GC vaporizing port maintained at 300 or 370 °C, or by injection of the solution of a vapor condensate upon the pyrolysis in a sealed tube at 300 °C for 10 min. Some of the vapor condensate were also identified by infrared spectral comparison as a carbon tetrachloride solution. IR spectra were measured on a JASCO-DS-403G spectrophotometer.

** Details of the two types of sample holders were given in the previous paper.[15]

Results and Discussion

Cobalt(III) Chelates. Figure 1 shows DTA curves of the cobalt(III) chelates measured in nitrogen atmosphere. $Co(DNPM)_3$, $Co(DIVM)_3$, and $Co(DPVM)_3$ show definite melting points, all of which are assignable to the reversible endotherms (A). The remaining solid

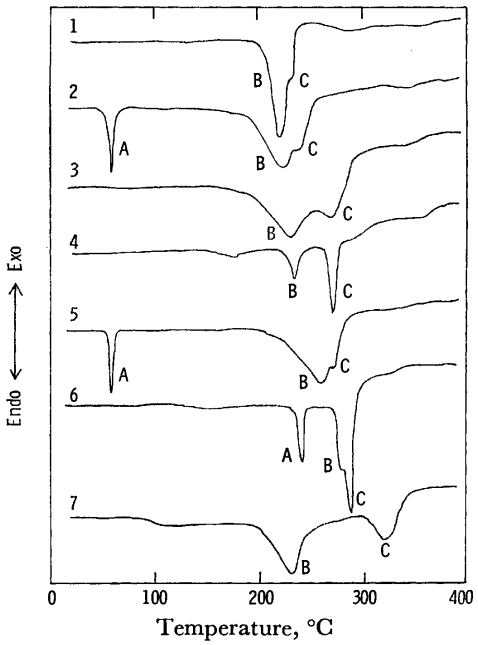

Fig. 1. DTA curves of the cobalt(III) chelates obtained in nitrogen atmosphere at heating rate of 10 °C/min. 1, $Co(AA)_3$; 2, $Co(DNPM)_3$; 3, $Co(DNBM)_3$; 4, $Co(DIBM)_3$; 5, $Co(DIVM)_3$; 6, $Co(DPVM)_3$; 7, $Co(DNCM)_3$.

chelates, $Co(AA)_3$ and $Co(DIBM)_3$, decompose without showing any melting peak. All the chelates show two irreversible endotherms (B) and (C) above 200 °C.

Green tris-β-diketonato cobalt(III) chelates turn to blood-red or pink solid after DTA scanning up to the temperature of the first irreversible endotherm (B). Figure 2 shows, as an example, IR spectra of the cobalt-DNPM chelates before and after the above transition. The latter, differing from the former, rather resembles that of the cobalt(II) chelate of the same ligand, $Co(DNPM)_2 \cdot H_2O$.[18] When the present cobalt(III) chelate was heated above the peak (B) temperature, the evolution of the free ligand was confirmed. The irreversible endotherm (B) is, therefore, considered due to a thermal degradation accompanied by the reduction of the central metal ion, to give an anhydrous cobalt(II) β-diketonate, which may become hydrated subsequently by atmospheric moisture.

The last peak (C) is presumably due to the decomposition of the resulting bis(β-diketonato)cobalt(II).

Aluminum(III) Chelates. The aluminum(III) chelates are highly volatile, and DTA curves were, therefore, obtained by use of a hermetic-sealed sample holder in nitrogen atmosphere. The results are shown in Fig. 3.

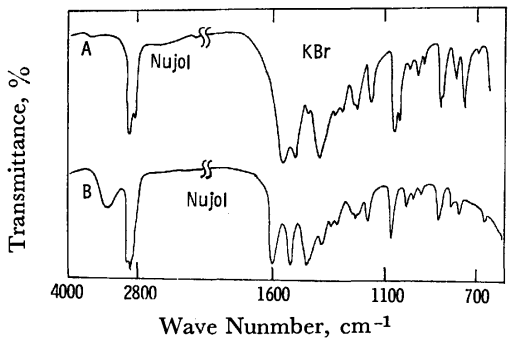

Fig. 2. IR spectrum of $Co(DNPM)_3$, A, and of the product from pyrolysis of the above chelate at 230 °C, B.

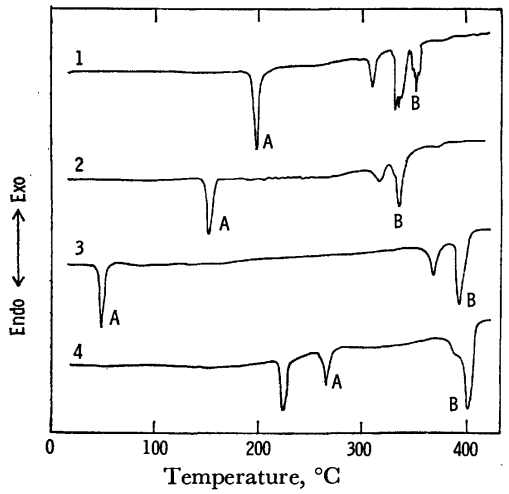

Fig. 3. DTA curves of the aluminum(III) chelates obtained in nitrogen atmosphere at heating rate of 10 °C/min.
1, $Al(AA)_3$; 2, $Al(DIBM)_3$; 3, $Al(DIVM)_3$; 4, $Al(DPVM)_3$.

In a temperature range below 300 °C, $Al(AA)_3$, $Al(DIBM)_3$, and $Al(DIVM)_3$ show single endothermic peaks (A), which agree well with their melting points. The peaks (A) were reproducible in the repeated DTA runs, being ascribable to the melting process. On the other hand, $Al(DPVM)_3$ shows two endothermic peaks in the same temperature region and that at the higher temperature is related to the melting points.[19] Irreversible endotherms (B) above 300 °C were probably due to the thermal degradation of the chelates, except $Al(AA)_3$. Endotherms (B) due to thermal degradation of $Al(AA)_3$ was probably accompanied by different kind of endotherms such as due to vaporization of the molten chelate.

Iron(III) Chelates. Analytical and IR data show that the DIBM and DPVM chelates of iron(III) have the composition of $FeL_2(CH_3O)$,[24] where L denotes the anionic ligand. Thermal behaviors of the two chelates are, therefore, not comparable to those of the other chelates of ML_3 form.

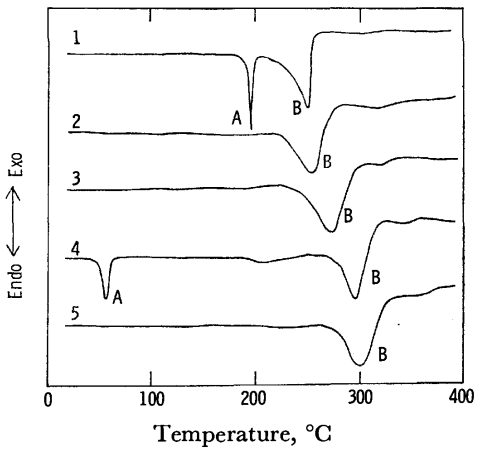

Fig. 4. DTA curves of the iron(III) chelates obtained in nitrogen atmosphere at heating rate of 10 °C/min.
1, $Fe(AA)_3$; 2, $Fe(DNPM)_3$; 3, $Fe(DNBM)_3$; 4, $Fe(DIVM)_3$; 5, $Fe(DNCM)_3$.

Figure 4 shows the DTA curves of the ML_3-type iron(III) chelates obtained in nitrogen atmosphere. $Fe(DIVM)_3$ and $Fe(AA)_3$ show reversible endotherms at 57 and 199 °C, respectively, which are related to their melting points. The corresponding endotherms of $Fe(DNCM)_3$ and $Fe(DNBM)_3$ occur below room temperature, which can not be detected on our DTA apparatus. The irreversible broad endotherms (B) at a higher temperature region are related to thermal decomposition. The melting process of $Fe(AA)_3$ chelate is immediately followed by a thermal degradation, indicating its poor thermal stability in a molten state. The decomposition temperature of the iron(III) chelates seemed to increase with the increasing size of alkyl substituents as observed in the case of cobalt(III) chelates.

Manganese(III) Chelates. DTA curves of manganese(III) chelates measured in nitrogen atmosphere are shown in Fig. 5. Reversible endotherms (A) of the $Mn(DIBM)_3$, $Mn(DIVM)_3$, and $Mn(DPVM)_3$ are ascribable to their melting processes. $Mn(AA)_3$ shows

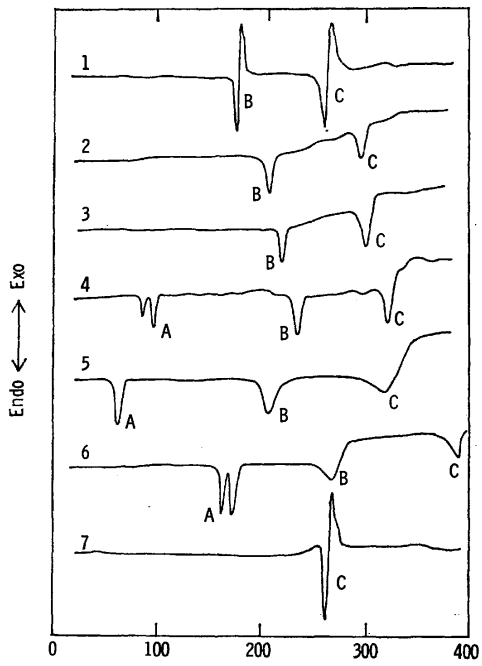

Fig. 5. DTA curves of the manganese(III) and manganese(II) chelates obtained in nitrogen atmosphere at heating rate of 10 °C/min. 1, $Mn(AA)_3$; 2, $Mn(DNPM)_3$; 3, $Mn(DNBM)_3$; 4, $Mn(DIBM)_3$; 5, $Mn(DIVM)_3$; 6, $Mn(DPVM)_3$; 7, $Mn(AA)_2$.

two irreversible endotherms immediately followed by exotherms. DTA characteristics of the second inflection (C) at 250—260 °C[22] seems quite similar to those observed on manganese(II) acetylacetonate, $Mn(AA)_2$, DTA curve of which was obtained separately, as shown in Fig. 5. When the $Mn(AA)_3$ was heated slightly above the first inflection (B) temperature, the resulting product showed an IR spectrum quite resembled that of $Mn(AA)_2$, and the evolution of acetylacetone was also confirmed upon the above thermal process.

The remaining manganese(III) chelates also liberate the ligand molecules when heated up to the peak (B) temperature. Thus the endotherms (B) can be ascribed to the reductive degradation from the tris(β-diketonato)-manganese(III) to the bis(β-diketonato)manganese(II), just so as observed in the cobalt(III) chelates.

The irreversible endotherms (C) at a higher temperature region may be due to the pyrolytic decomposition of the manganese(II) chelates which resulted at the endotherms (B).

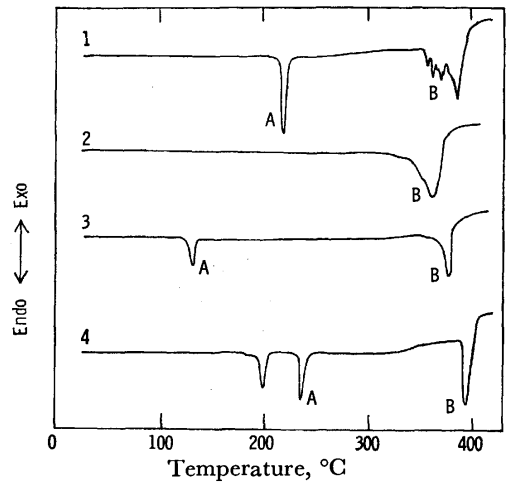

Fig. 6. DTA curves of the chromium(III) chelates obtained in nitrogen atmosphere at heating rate of 10 °C/min. 1, $Cr(AA)_3$; 2, $Cr(DNPM)_3$; 3, $Cr(DIBM)_3$; 4, $Cr(DPVM)_3$.

Chromium(III) Chelates. Figure 6 shows the DTA curves of the chromium(III) chelates measured with a hermetic-sealed sample holder in nitrogen atmosphere. $Cr(AA)_3$ and $Cr(DIBM)_3$ show reversible endotherms (A), which are related to their melting process. On the other hand, $Cr(DPVM)_3$ shows two reversible endotherms at about 200 °C, of which an endotherm at the higher temperature is ascribed to its melting process.[19]

In a higher temperature region, each chromium(III) chelate shows an irreversible endotherm (B). This was due to their decomposition process.

Table 2 summarizes the melting- and decomposition temperatures of the present chelates determined by DTA method. $Al(AA)_3$, $Cr(AA)_3$, and $Fe(AA)_3$ show characteristic melting points, respectively. The last acetylacetonate is, however, not very durable in the molten form. $Co(AA)_3$ and $Mn(AA)_3$ decompose prior to melting.

If one considers the thermal stability of a compound in terms of its pyrolytic decomposition temperature, the thermal stability of the pentane-2,4-dionates decreases in the order of Cr(III)>Al(III)>Fe(III)>Co(III)>Mn(III) so far as studied. A similar tendency in the thermal stability of pentane-2,4-dionates of the same tervalent metal ions was also observed by a different

Table 2. Melting- and decomposition temperature (°C) of chelates

method.[25] The present 1,5-dialkylpentane-2,4-dione chelates gave the same order of the thermal stability in respect to the kind of the central metal ion.

Regarding to the structures of β-diketones, one can see a general trend that the branched-alkyl derivatives afford metal chelates of higher melting temperatures than that of the linear-alkyl substituted ligands: DNPM, DNBM, and DNCM give liquid chelates with an exception of $Co(DNPM)_3$, while DIBM, DIVM, and DPVM solid chelates at room temperature.

For the cobalt(III) chelates, thermal stability increased in the order of AA<DNPM<DNBM< DIBM<DNCM<DIVM<DPVM, which agreed with the order of bulkiness of alkyl substituents. Similar tendencies were also obtained for the other tervalent metal chelates. The thermal stabilities of the present chelates are, therefore, considered to be partly due to the electron releasing effect of the alkyl groups. Such effect increases the basicity of the ligand oxygen atoms to form increasingly stable metal-oxygen bonding,[18] and this kind of thermodynamic stabilization effect was also observed with some bivalent metal chelates.[15] On the other hand, kinetic destabilization effect by the alkyl substituents such as observed in the copper(II) and palladium(II) chelate[15] was unlikely to operate on the present octahedral hexacoordinate chelates.

As described before, the pyrolytic degradation of the manganese(III) and cobalt(III) chelates is accompanied by the reduction of the central metal ion from tervalent to bivalent and the liberation of the free ligand.[26,27] Although the stoichiometry of the whole scheme of the reaction is unknown at this moment, it is most likely that the metal-oxygen bonding in the tervalent metal chelates may be homolytically cleaved at the endotherm (B) to form the bivalent metal chelates, meanwhile the liberated ligand radical regenerates as the ligand molecule through hydrogenation processes such as hydrogen-abstraction from neighboring matrix or disproportionation with other radical.

Such radical termination processes are usually exothermic, and the exothermic branch of the inflection (B) on the DTA curve of $Mn(III)(AA)_3$ might be an indication of such a kind of process. The other DTA curves lack apparent exotherms subsequent to the endotherms (B), and this might possibly result from that the exotherms overlaps on the endotherms or diffuse widely.

Similar pyrolytic reduction reaction was observed also in $Fe(III)(AA)_3$,[28] and these facts seem to suggest that the pyrolytic reduction occurs in the chelate of such a metal ion that in the bivalent state can also form a stable chelate of the same ligand. Although an LCAO-MO calculation on the tervalent metal pentane-2,4-dionates[29] might provide an explanation for the ease with which $Mn(III)(AA)_3$ could be reduced to $Mn(II)(AA)_2$, a consistent understanding is not attained for the reason why these particular metal ions are labile to be reduced in the tris(β-diketonato)metal chelates.

ESR Studies of the Triplet State Dimers of the Salicylaldehyde Schiff Base Complexes of Copper(II) in Toluene and in Chloroform

Makoto CHIKIRA, Hiroshi YOKOI, and Taro ISOBE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received February 1, 1974)

The ESR spectra of triplet-state dimers have been obtained for various bidentate and quadridentate salicylaldehyde Schiff base complexes of copper(II) in frozen solutions. The spectra have been analysed on the basis of the previously-obtained results concerning the non-coaxial g and fine-structure tensors. The results indicate that the angles between the $g_{\parallel}$ axis and the copper-copper axis of the dimers for the quadridentate Schiff base complexes are considerably smaller than those for the bidentate ones. Each of the actually-measured ESR spectra, however, consisted of two mutually-overlapping spectra; one is due to dimers (M_2), and the other, to monomers (M). The equilibrium constant for $2M \rightleftharpoons M_2$ has been estimated by comparing the ESR spectral intensities of the two species. The factors which govern the dimer formations have been discussed in some detail.

In our previous paper,[1] it has been revealed, through computer simulations of the triplet ESR spectra that the dimeric structure of Bis-(*N*-salicylidenemethylaminato)copper(II) in toluene is similar to that in its γ-form crystals,[2] and that it is necessary to take into account the non-coincidence of the principal axes of the g tensor with those of the fine-structure tensor in order to estimate such dimeric structures. A considerable number of copper(II) chelates are known to have dimeric structures in crystals such as those shown schematically in Fig. 1. Hatfield and his co-workers extensively studied the magnetic interaction within the dimers of this type by means of ESR and magnetic susceptibility measurements.[3] The factors which govern the dimer formations, the nature of the dimerization forces, and the mechanisms of the spin-exchange interaction within the dimers, however, have not yet been established in full detail. In order to study these problems, we systematically measured the ESR spectra of various salicylaldehyde Schiff base complexes of copper(II) in toluene and in chloroform, and discussed the influence of various substituent groups at the iminoic nitrogens and in the phenyl-rings on the dimer formation and dimeric structure.

X: Me–, CH_3–; MeO–, CH_3O–
R: Me, CH_3; Et, C_2H_5; n-Pr, C_3H_6
B: en, C_2H_2; pn, $(CH_3)CHCH_2$; bn, $(CH_3)CHCH(CH_3)$; ibn, $(CH_3)_2CCH_2$

Experimental

The salicylaldehyde Schiff base complexes of copper(II) with the general formulae of Cu(nX-RSal) and Cu(nX-SalB) (see Fig. 2) were prepared, where X, R, and B are the generalized ring, nitrogen, and bridging group substituents respectively, and where n represents the position of X in the phenyl ring. These complexes were obtained by refluxing salicylaldehyde or X-substituted salicylaldehyde copper(II) complexes with the appropriate amines or diamines in ethanol. The methyl-substituted salicylaldehyde was synthesized by Duff's reaction.[4] The other salicylaldehyde derivatives were commercially obtained.

The toluene and chloroform were purified according to the usual method,[5] and the chloroform was used immediately after the purification. The ESR of the quadridentate Schiff base complexes in chloroform solutions were measured at 77 K after the frozen solutions had been crushed to fine powders according to a method described previously.[6]

Results and Discussion

The Magnetic Parameters and the Dimeric Structure. The g and A values observed for the monomers of the salicylaldehyde Schiff base complexes of copper(II) were not changed greatly with the substituents ether at the iminoic nitrogens or in the phenyl rings. These magnetic parameters for the bidentate salicylaldehyde Schiff base complexes of copper(II) are in the range of $2.23 > g_{\parallel} > 2.21$, $2.06 > g_{\perp} > 2.04$, and $0.0195\ cm^{-1} > |A_{\parallel}| > 0.0185\ cm^{-1}$, while those for the quadridentate ones are in the range of $2.20 > g_{\parallel} > 2.18$, $2.06 > g_{\perp} > 2.04$, and $0.0215\ cm^{-1} > |A_{\parallel}| > 0.0205\ cm^{-1}$.

The ESR spectra of Cu(5Br–MeSal) and Cu(3Me-Salpn) in toluene are shown in Fig. 3. The magnetic parameters of the triplet-state dimers are defined in Fig. 3 as has been previously described,[1] and their values are tabulated in Table 1. The values of g_1 and g_2 are defined from the centers of the so-called full-field perpendicular and parallel lines respectively. The A_1 and A_h values express the hyperfine-splittings of the low-field and high-field parallel lines respec-

tively. The D_1 and D_2 values express the observed fine-structure splittings of the perpendicular and parallel lines respectively. As Table 1 shows, the magnetic parameters of the triplet dimers do not change markedly with the substituents. The line shapes and the magnetic parameters of the bidentate Schiff base complexes are characterized by the non-coaxial g and fine-structure tensors; that is, $(A_{\parallel}/2)>A_1>A_h$, and $g_2<g_{\parallel}$. Therefore, the dimeric structures of the bidentate complexes are considered to be similar to those of Cu(MeSal) in γ-form crystals, where the angle between the $g_{\parallel}$ axis and the copper-copper axis is about 30°.[1] On the other hand, the triplet-state dimers of the quadridentate Schiff base complexes show the typical ESR line shapes for the indication of the near co-axial g and fine-structure tensors; that is, A_1 and A_h are almost equal to the $A_{\parallel}/2$ of the monomers, while g_2 is almost equal to the $g_{\parallel}$ of the monomers.

a) Medium; chloroform. All the other data were obtained in frozen toluene solutions.

It is well known that Cu(Salen) has a dimeric structure in crystals similar to that of Cu(MeSal).[2,7] There are two possible explantions for the near coincidence between the principal axes of the g and fine-structure tensors. One is that the dimeric structure in the frozen solutions is so different from those in the crystals of Cu(Salen) or Cu(MeSal) that the $g_{\parallel}$ axis almost coincides with the copper-copper axis. The other is that, although the dimeric structure similar to that found in the crystals of Cu(Salen) is retained even in frozen solutions, the so-called pseudo-dipole interaction whose principal axes coincide with those of the g tensor cancels the effect of the non-coaxial g and fine-structure tensors in the spin-dipole interaction.

The magnitudes of the pseudo-dipole and spin-dipole interaction can be estimated from Eqs. (1) and (2), where J is the energy difference between a triplet state and a singlet state, and where r is the distance between the two copper ions.

$$D_{\text{pseudo}} = \frac{-1}{8} J \left\{ \frac{1}{4} (g_{//}-2)^2 - (g_{\perp}-2)^2 \right\} \qquad (1)^{8}$$

$$D_{\text{dd}} = \frac{-0.65 g_2^2}{r^3} \qquad (2)^{9}$$

The J value for the dimers of Cu(Salen) in crystals had been estimated at 5 cm^{-1}.[10] From this J value and the magnetic parameters for the triplet dimers of Cu(Salen), that is, $g_{\parallel}=g_2=2.19$, $g_{\perp}=2.05$, and $r=3.5$ Å, D_{pseudo} and D_{dd} can be estimated at -0.0041 and -0.0700 cm^{-1} respectively. It is clear that the obtained value of D_{pseudo} is too small to cancel the effect of the spin-dipole interaction. It may be concluded, therefore, that the first explanation is more reasonable than the second one in this case. It has been reported that the dimeric structure of $Cu(Etacest)_2$ in toluene is also different from that in crystals,[11] where Etacest is the anion of ethylacetoacetate. These facts indicate that the dimeric structures in crystals are often different from those in solutions: the dimeric structures in crystals depend to a greater or lesser degree upon the ways of molecular packing. The polymorphism of Cu(MeSal) is regarded as an example of such phenomena.

Two papers have appeared during the preparation of our report concerning the triplet-state dimers of the salicylaldehyde Schiff base complexes of copper(II) in solutions.[10,12] In both papers, the parameters of the spin Hamiltonian tensors were estimated on the basis of the computer simulations of the ESR spectra only for $\Delta M=2$ transitions. Toy *et al.* estimated the copper-copper distance and the angle between the $g_{\parallel}$ axis and the copper-copper axis for the Cu(Salen) dimers in chloroform at 4.55 Å and $40\pm5°$ respectively.[12] However, it is evident from the results of our computer simulation previously described that the spectral patterns for the $\Delta M=1$ transitions of Cu(Salen) cannot be reproduced by the use of such non-coaxial g and spin-dipole interaction tensors. On the other hand, Hatfield *et al.* concluded that the principal axes of the g and fine-structure tensors are coincident with each other. This conclusion is in accord with our results. However, they had previously assumed that the dimeric

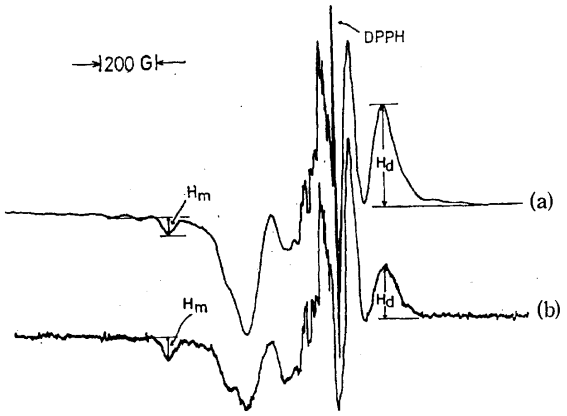

Fig. 4. Concentration dependence of ESR spectra of Cu(Salpn) in toluene at 77 K. a) 3.1×10^{-3} M, b) 0.5×10^{-3} M.

structure of Cu(Salen) in crystals is retained in frozen chloroform solutions, and had estimated the contribution of the spin-dipole interaction to the observed fine-structure splittings at 0.036 cm^{-1}.[13] This value seems too small to agree with the value calculated from Eq. (2). A further detailed report on the relation between the dimeric structure and the relative orientations of the g and fine-structure tensors will soon be published.

The Equilibrium between Dimers and Monomers. In order to obtain quantitative information on the effects of various substituents on the dimer formations, we have estimated the equilibrium constants for $2M \rightleftharpoons M_2$, where M and M_2 represent monomer and dimer species respectively. In our previous paper, we have already presented the following relation:[11]

$$2Q^2 + qQ = Kq^2c^\circ \tag{3}$$

where the equilibrium constant, K, is expressed as follows:

$$K = \frac{[M_2]}{[M]^2} \tag{4}$$

where c° is the initial concentration of a complex and where the Q and q values are defined as:

$$Q = \frac{H_d}{H_m} = q\frac{[M_2]}{[M]} \tag{5}$$

H_d and H_m in Eq. (5) are the peak heights of certain absorption lines due to the dimers and monomers respectively in the first derivative ESR spectra, as is shown in Fig. (4) in the case of Cu(Salpn) in toluene. It may reasonably be supposed that the magnitude of the spin exchange interaction within the present dimers is much smaller than the thermal energy at 77 K. Then, we can derive Eq. (6):

$$\frac{I_d}{I_m} = \frac{2[M_2]}{[M]} \tag{6}$$

where I_d is the total integrated intensities of the ESR spectra due to the dimers, and I_m, the total of those due to the monomers, respectively. I_d and I_m were obtained as has been described previously.[11]

The plots of $(2q^2+qQ)/q^2$ *vs.* c° for the toluene solutions of Cu(MeSal), Cu(EtSal), Cu(nPrSal), and Cu(Salpn) are shown in Figs. 5 and 6. Since the magnetic parameters of the triplet dimers of the salicylaldehyde Schiff base complexes of copper(II) do not change markedly with the substituents, it may reasonably be supposed that the q values do not change with the substituents. Then, we can estimate the values of K using the Q values obtained from the ESR spectra measured at only one concentration. The K values thus obtained for other salicylaldehyde Schiff base complexes by the use of the q values determined for Cu(MeSal) and Cu(Salpn) are listed in Tables 2 and 3. The salicylaldehyde Schiff base complexes of copper(II) employed here are soluble in many coordinating solvents, such as methanol, ethanol, and pyridine. However, the ESR signals due to the triplet dimers were not observed in these solutions. In general, the K values of the quadridentate complexes are much larger than those of the bidentate ones. The chloroform solutions of the bidentate complexes did not exhibit any signals due to triplet dimers, but those of the quadridentate ones did, though the spectral intensities due to the dimers were very weak as compared with those due to the monomers.

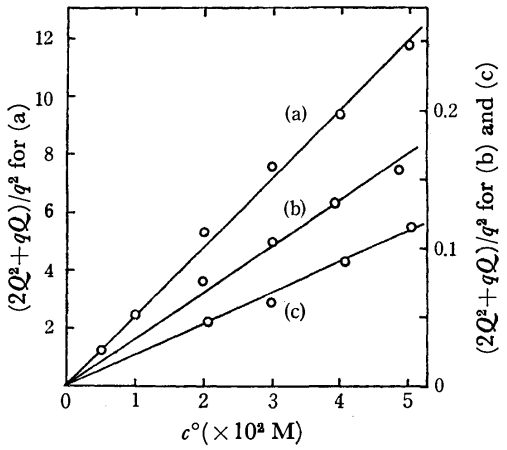

Fig. 5. The plot of $(2Q^2+qQ)/q^2$ *vs.* c° for the 77 K frozen toluene solutions. (q=2.0)
a) Cu(MeSal), b) Cu(EtSal), c) Cu(*n*PrSal)

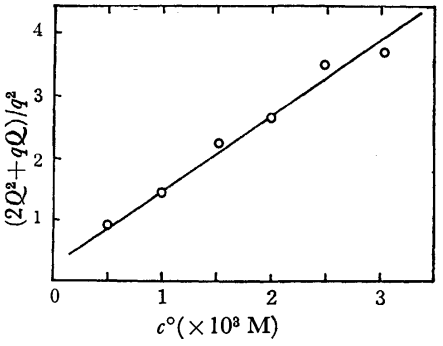

Fig. 6. The plot of $(2Q^2+qQ)/q^2$ *vs.* c° for the 77 K frozen toluene solutions of Cu(Salpn). (q=4.0)

Table 2 indicates the variation in the K values with the substituents at the iminoic nitrogens. In the case of the bidentate complexes, it is clear that the more bulky the substituent at the iminoic nitrogen becomes, the less the K value becomes. When the R in Fig. 2 was replaced by the isopropyl or *tert*-butyl group, no signals due to the triplet-state dimers could be detected.

Table 2. The dependence of the K values on the substituent groups at the iminoic nitrogens of salicylaldehyde Schiff bases

	Toluene	Chloroform
Cu(MeSal)	2.4×10^2	0
Cu(EtSal)	3.2	0
Cu(nPrSal)	2.3	0
Cu(Salen)	—[a]	41
Cu(Salpn)	1.3×10^3	28
Cu(Salbn)	1.1×10^3	0
Cu(Salibn)	7.8×10^2	0

a) Cu(Salen) is scarcely soluble in toluene.

Table 3. The dependence of the K values on the substituent groups at the phenyl rings of the salicylaldehyde Schiff bases

X	MeSal	Salpn		Salen
	Toluene	Toluene	Chloroform	Chloroform
H	2.4×10^2	1.3×10^3	28	41
3Me	21	1.2×10^4	28	24
4Me	4.7×10^2	2.4×10^2	49	1.2×10^2
5Me	1.8×10^2	6.6×10^3	54	54
5Br	2.3×10^3	3.2×10^4	71	—[b]
3MeO	0	—[c]	8.4×10^2	1.3×10^3
5MeO	2.1×10^3	—[c]	94	76

a) The q values for bidentate Schiff base complexes were put equal to that for Cu(MeSal) (2.0), and those for quadridentate ones, to that for Cu(Salpn) (4.0) in toluene. b) Cu(5Br-Salen) is scarcely soluble in chloroform. c) The spectral patterns correspond to crystalline powders were obtained.

On the other hand, when the R was replaced by proton, no evidence for the dimer formation could be obtained because of the low solubility of the complex in toluene. The K values for the quadridentate complexes in toluene were not changed by the methyl groups at the ethylene bridge. When the iminoic nitrogens were bridged with the trimethylene group, however, no signals due to the triplet-state dimers could be detected. These experimental facts suggest that the dimer formations are inhibited by the direct steric hindrance of bulky substituents near the first coordination sphere and/or by the tetrahedral deformation of coordination due to such bulky substituents.

Table 3 indicates the changes in the K values with substituents in the phenyl rings. We may clearly recognize large differences between the bidentate and quadridentate complexes in the effect of substituents in the phenyl rings on the K values. The 3-methyl and 3-methoxy groups of the bidentate complexes severely inhibited the dimer formation, whereas those of the quadridentate ones did not. For instance, the K values of Cu(3MeO-Salpn) and Cu(3Me-Salpn) become larger than those of the unsubstituted complexes. It should be further noticed that the influence of the substituents on the K values are markedly dependent upon the solvents. For instance, the K values for the toluene solutions of Cu(3Me-Salpn) and Cu(5Me-Salpn) were considerably larger than that of Cu(Salpn), whereas those of the chloroform solutions of the former did not increase so much as that of the latter. It may naturally be supposed that toluene molecules have a strong affinity for the phenyl rings of the complexes rather than for the copper ions and coordinating atoms. It seems likely that the dependence upon solvents for such changes in the influence of substituents in the phenyl rings is to be attributed to the changes in solvation. These experimental results suggest that the phenyl rings of the salicylaldehyde Schiff bases play an important role in determining the dimer formation. These estimations are further supported by the fact that no ESR signals of the triplet dimers were observed for a toluene solution of *N*, *N'*-ethylenebis(4-amino-3-penten-2-ono)copper(II) at 77 K. Recently, Yokoi indicated that the K values of bis(*t*-butylacetoacetato)copper(II) and Cu(Etacest)$_2$ change markedly with slight changes in the properties of the solvents.[14] Thus, it seems natural that the K values change greatly with a slight change in the properties of the substituents and the solvents.

Conclusion

In the solutions of various Schiff base complexes of copper(II), the K values for $2M \rightleftharpoons M_2$ depend on many delicate factors, although the triplet-state ESR spectral patterns do not change markedly with the substituents. It was also revealed that the dimeric structure of the quadridentate Schiff base complexes in frozen solutions is different from that of Cu(Salen) in crystals. These facts, besides similar results previously obtained, suggest that the dimerization force must be weak, and that the forces are generated not only by the coordination of the oxygen atoms to the apical positions of adjacent complexes, as is shown schematicaly in Fig. 1, but also by the wholly-molecular electric dipole or dispersion interaction between the monomeric halves in the dimers. It may be expected, accordingly, that the dimeric structures of these types of complexes change sensitively with the nature of such dimerization forces and with their environments.

The Chemistry of Protactinium. XI. A Study of the Solvent Extraction of Protactinium(IV) Reduced with Europium(II) from a Perchloric Acid Solution, Using Thenoyltrifluoroacetone as the Extractant

Isamu KAWASUJI, Akiko SATO, and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira, Sendai 980

(Received February 19, 1974)

Europium(II) was found to be an excellent reductant for reducing protactinium in microquantities to the tetravalent state. The behavior of Pa(IV) in the perchloric acid solution was investigated by the TTA–benzene extraction method. It was found that the $PaOH^{3+}$ ion existed predominantly in a 0.03—3 M perchloric acid solution at the ionic strength of 3. The reaction of TTA extraction may proceed as:

$$PaOH^{3+} + 4HA = PaA_4 + H_2O + 3H^+$$

or

$$PaOH^{3+} + 4HA = Pa(OH)A_3(HA) + 3H^+$$

The distribution ratio of Pa(IV) in the system using Eu(II) as the reductant is about ten times as large as that in the system using Cr(II) as the reductant. It was considered that a non-extractable complex may be formed between Pa(IV) and Cr(III), while such a complex may not be formed when Eu(II) is used as the reductant.

Chromium(II) has been used for reducing protactinium in microquantities to the tetravalent state. Guillaumont[1] investigated the behavior of Pa(IV) reduced with Cr(II) in a perchlorate solution by means of the TTA–benzene extraction method and showed that Pa^{4+} was gradually hydrolyzed to $Pa(OH)_3^+$ in the pH range from −0.3 to 3.0 at the ionic strength of 3. Mitsuji[2] also investigated the behavior of Pa(IV) reduced with Cr(II) in a perchlorate solution by means of TTA–benzene extraction in the pH range from 0.4 to 1.1 at the ionic strength of 0.5; he suggested that $Pa(OH)_2^{2+}$ was the most probable ionic species in the perchlorate solution. However, in a previous report[3] we ourselves suggested that a multi-nuclear complex between Pa(IV) and Cr(II) or Cr(III) might be formed, because the distribution ratio of Pa(IV) decreased with an increase in the concentration of Cr(II). We also tried to measure the absorption spectra of Pa(IV), but could not find any influence of Cr(II) on it.

In the present experiment, we tried to use another reagent to reduce the protactinium in place of Cr(II); Eu(II) was found to be an excellent reductant. The standard oxidation-reduction potential of Pa(IV)–Pa(V) has been reported to be about −0.25 V,[4] and that of Eu(II)–Eu(III), −0.43 V.[5]

After ^{233}Pa in a perchloric acid solution was reduced to the tetravalent state by means of a liquid zinc amalgam in the presence of Eu(III), the oxidation state of protactinium was examined by the co-precipitation method with thorium fluoride reported by Mitsuji[6] and it was found that the complete reduction of $^{233}Pa(V)$ was readily attained. The chemical behavior of the $^{233}Pa(IV)$ thus obtained in the perchloric acid solution was investigated by the solvent extraction method, using TTA as the extractant.

In order to examine the difference in the extraction behavior of Pa(IV) caused by the difference in reductant between Cr(II) and Eu(II), experiments were also carried out on the extraction behavior of Pa(IV) reduced with Cr(II) under the same conditions as in the case of Eu(II).

Cr(II)[1,3] was extracted from a perchloric acid solution with TTA–benzene, but Eu(II) was not extracted from a 0.03—3 M perchloric acid solution at the ionic strength of 3. Therefore, Eu(II) can not act as a "holding reductant" in the organic phase. The present authors tried to measure the stability of the Pa(IV)–TTA chelate in the benzene solution by means of spectrophotometric measurements.

Experimental

Reagents. ^{231}Pa was purified by a method reported previously,[7] and its radiochemical purity was certified by α- and γ-ray spectrometry. The concentration of protactinium in the ^{231}Pa solution was determined as Pa_2O_5 by gravimetry and by the absolute α-counting method. These two results agreed well within the limits of experimental error, so we could confirm that there was no contamination by non-radioactive impurities. ^{233}Pa was prepared by the method reported by Suzuki and Inoue.[7]

The extraction behavior of Cr(II) and Eu(II) was examined by the use of ^{51}Cr and ^{152}Eu respectively as the tracers. The radiochemical purity of ^{51}Cr or ^{152}Eu was certified by γ-ray spectrometry.

The lithium perchlorate was prepared by the method reported by Biedermann and Ciavatta.[8] The water used was purified by distillation, followed by ion-exchange treatment. TTA and the other reagents used in this experiment were of the highest purity.

Apparatus. Both the reduction and the extraction of protactinium were carried out in the reduction apparatus described in a previous report.[9] For the solvent extraction procedure, an Iwaki universal mechanical shaker, Model V-S, was used. The α-ray spectra were measured with an ORTEC silicon surface-barrier detector (active area: 450 mm^2; resolution: 30 KeV), coupled with a Tōshiba 4096-channel pulse-height analyzer. The α-ray counting was carried out by measuring the area of its energy peak and the counting efficiency of the detector with reference to the IAEA standard α-ray source ($^{239}Pu+^{241}Am+^{244}Cm$). The γ-ray spectra were measured with an ORTEC Ge(Li) coaxial detector (volume: 57 cc; resolution: 1.97 KeV), coupled with a Tōshiba 4096-channel pulse-height analyzer. For the γ-ray energy calibration, the IAEA standard γ-ray sources-^{60}Co,

^{57}Co, ^{137}Cs, ^{241}Am, ^{54}Mn, and ^{22}Na- were used. For the on-line data analysis, a Tōshiba TOSBAC-40 mini-computer was used. A Hitachi Model SP-3 well-type NaI(Tl) scintillation probe coupled with a Kōbe Kōgyō Model SA-250 scaler was used for the γ-activity measurements. For measuring the absorption spectrum, a Hitachi Model EPS-3 recording spectrophotometer and a 1 cm quartz cell were used.

Procedure. The Co-precipitation with Thorium Fluoride: Four milliliters of a perchloric acid solution of ^{233}Pa(V) containing a definite amount of Eu(III) were introduced into a reduction apparatus and thoroughly deoxygenated by bubbling with argon gas which had been passed through a dilute sulfuric acid solution of ammonium metavanadate. By shaking the reduction apparatus for about 15 min, the protactinium and europium were reduced with a freshly-prepared liquid zinc amalgam. After the amalgam had been excluded from the apparatus, 2 ml portions of a 0.05 M thorium chloride solution and of a 0.7 M potassium fluoride solution, which had been thoroughly deoxygenated, were added and thorium fluoride was precipitated. Then, the precipitate was separated by centrifuging the mixture for 3 min at 3000 rpm. The γ-activities of both the solution and the precipitate were measured, and the co-precipitation ratio was calculated.

The Absorption Spectra of the Pa(IV)-TTA Chelate: A sulfuric acid solution of ^{231}Pa was reduced by shaking with a liquid zinc amalgam for about 6 hr. After the ^{231}Pa(IV) had been extracted by shaking with a 0.5 M TTA-benzene solution for 10 min, the ^{231}Pa(IV)-TTA chelate in the organic phase was introduced into the quartz cell and the absorption spectrum was immediately measured with reference to a 0.5 M TTA-benzene solution.

The ^{233}Pa(IV) Extraction: Ten milliliters of a perchloric acid solution of ^{233}Pa(V) containing a definite amount of Eu(III) were reduced with a liquid zinc amalgam. Then, the solvent extraction of Pa(IV) was carried out by shaking it with 10 ml of TTA-benzene solution for 10 min. We had confirmed previously that the equilibrium was established sufficiently in that time. After the two phases had been completely separated, an aliquot of each phase was placed in a polyethylene test tube and its γ-radioactivity was counted. The distribution ratio(D) was calculated by means of the usual equation:

$$D = \frac{\gamma\text{-activity per ml of the organic phase}}{\gamma\text{-activity per ml of the aqueous phase}} \quad (1)$$

As Cr(II) was extracted with TTA, we needed to correct the concentration of the TTA-benzene solution resulting from the co-existence of Cr(II). Therefore, the TTA extraction was carried out after ^{51}Cr had been added to the ^{233}Pa solution, and the distribution ratios of Cr(II) and Pa(IV) were obtained at the same time by measuring their γ-radioactivities at the characteristic energy peaks of 319.8 KeV and 311.9 KeV respectively. The concentration of TTA was corrected by means of a method reported previously.[3]

The ionic strength was kept constant by the use of lithium perchlorate. All the experiments were carried out in an argon atmosphere at room temperature, 20—23 °C.

Results

The Co-precipitation with Thorium Fluoride. The co-precipitation of ^{233}Pa(IV) was almost complete in the presence of more than 10^{-3} M of europium, as is shown in Fig. 1. This means that protactinium can be reduced quantitatively to the tetravalent state on a tracer scale by the addition of europium. On the other hand, the co-precipitation of Pa(V) was about 15% when the concentration of europium was less than 3×10^{-4} M; this value then increased with an increase in the europium concentration when the concentration of europium was higher than 3×10^{-4} M; this was because of the contribution of Pa(V) co-precipitated with europium fluoride.

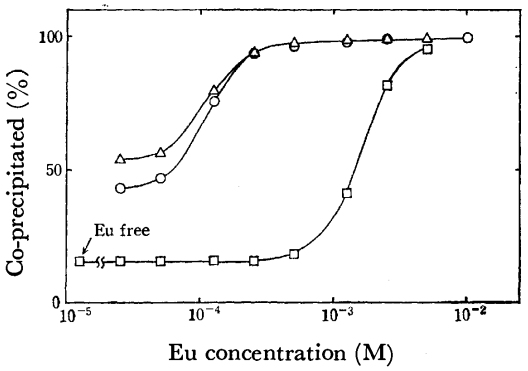

Fig. 1. Relation between Eu concentration and % co-precipitated with ThF_4
△: ^{233}Pa in 0.05 M $HClO_4$ reduced with Zn(Hg),
○: ^{233}Pa in 1 M $HClO_4$ reduced with Zn(Hg),
□: ^{233}Pa(V) in 0.3 M $HClO_4$.

The TTA Extraction of Europium. The extraction behavior of Eu(II) and Eu(III) was investigated using ^{152}Eu as a tracer. They were not extracted at all by the TTA-benzene solution from a perchloric acid solution when the acid concentration was 0.03—3 M at the ionic strength of 3.

The Stability of the Pa(IV)-TTA Chelate. The absorption spectra of the Pa(IV)-TTA chelate in benzene are shown in Fig. 2. The molar extinction coefficients at the main peaks of 730, 840, and 1980 nm were 1.50×10^3, 1.24×10^3, and 7.0×10^2 respectively. The molar extinction coefficient of the Pa(V)-TTA chelate was 1.76×10^4 at the characteristic peak of 418 nm. The stability of the Pa(IV)-TTA chelate was calculated on the basis of the decreasing rates of the intensities of the absorption peaks of the Pa(IV)-TTA chelate and the increasing rate of that of the

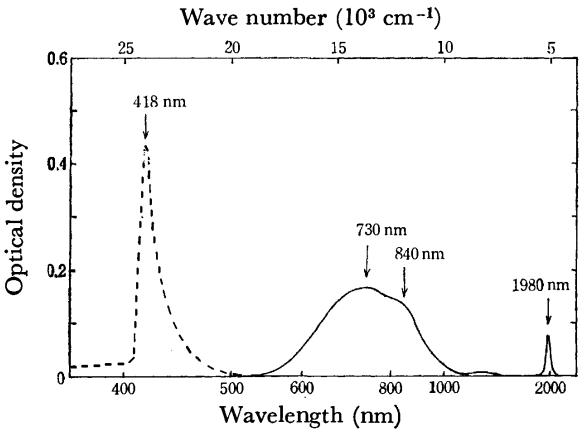

Fig. 2. Absorption spectra of Pa(IV)-TTA and Pa(V)-TTA chelates in benzene
----: Pa(V)-TTA chelate, ——: Pa(IV)-TTA chelate.

Pa(V)–TTA chelate as a function of the time. The oxidation rate of the Pa(IV)–TTA chelate was about 1%/hr, as is shown in Fig. 3. Therefore, we can confirm that Pa(IV) in a benzene solution is stable enough for us to carry out experiments without any effects of re-oxidation as long as all the atmospheric oxygen is excluded.

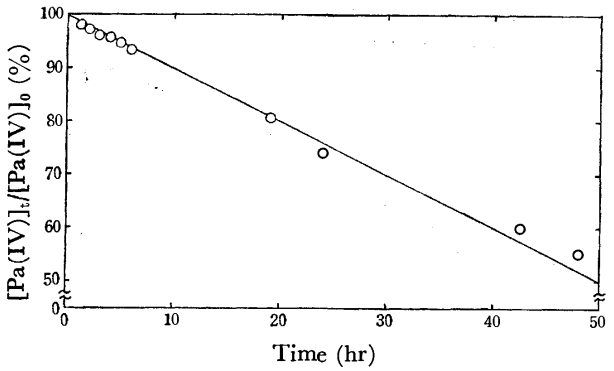

Fig. 3. Oxidation rate of Pa(IV)–TTA chelate in benzene

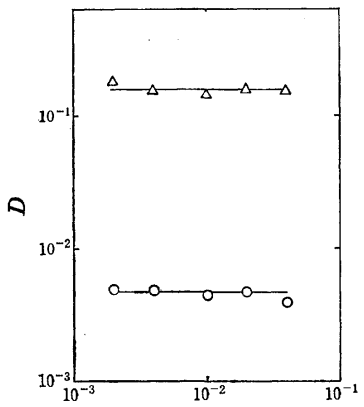

Fig. 4. Effect of Eu concentration on extraction of Pa(IV).
△: Org. phase: 0.04 M TTA-benzene, Aq. phase: I=2, 1 M $HClO_4$
○: Org. phase: 0.003 M TTA-benzene, Aq. phase: I=3, 0.1 M $HClO_4$

The Influence of the Europium Concentration on the TTA Extraction of Pa(IV). As is shown in Fig. 4, the log-log plot of the distribution ratio of Pa(IV) and the concentration of europium is constant within the limits of experimental error. This means that europium does not affect the TTA extraction of Pa(IV).

It is very useful that the performance of the reduction of Pa(V) can be checked by means of the color change of the solution. The absorption maxima of Eu(II) in the 1 M perchloric acid solution were at 250 nm ($\varepsilon = 2.6\times10^3$) and 322 nm ($\varepsilon = 7\times10^2$), and the color of the solution was yellow. About 2×10^{-2} M of europium is needed to observe the effective reduction of europium to the divalent state.

The Relation between the Distribution Ratio and the TTA Activity. The activity of TTA in the benzene phase at equilibrium is calculated from its initial concentration by means of the following equations:

$$\frac{(HA)_i}{(HA)_f} = 1.02 + \frac{10^{-8}}{(H^+)} \quad (2)\ [10]$$

$$f_{HA} = 1 - 0.25(HA)_f^{0.48} \quad (3)\ [11]$$

where f_{HA} is the activity coefficient of TTA in benzene; $(HA)_f$, the final concentration in benzene when equilibrated with an equal volume of an aqueous phase, and $(HA)_i$, the initial concentration.

When the perchloric acid concentration is 0.03—3 M at the ionic strength of 3, the log-log plot of the distribution ratio and the activity of TTA in benzene show a linear relationship, with a slope of 4 over a wide range of TTA activity, as is shown in Fig. 5.

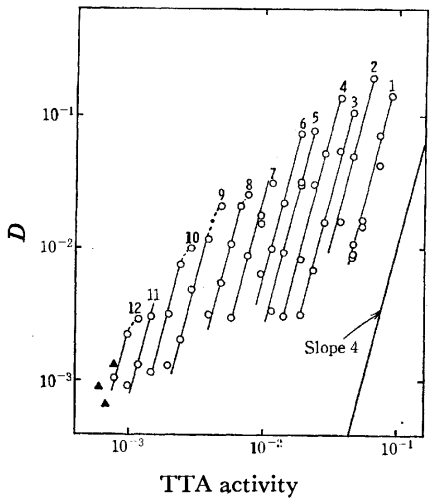

Fig. 5. Dependence of distribution ratio on TTA activity in benzene.

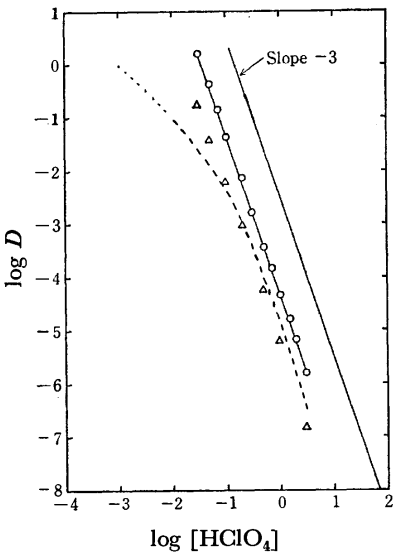

Fig. 6. Dependence of distribution ratio on $HClO_4$ concentration.
○: reduced with Eu(II), △: reduced with Cr(II), ----: by Guillaumont; TTA activity=5×10^{-3} M.

The Relation between the Distribution Ratio and the Perchloric Acid Concentration. The log-log plot of the distribution ratio and the perchloric acid concentration shows a linear relationship, with a slope of −3, as is shown in Fig. 6. The distribution ratios were calculated from the results shown in Fig. 5, and their values were normalized at the TTA activity of 5×10^{-3} M.

The relation between the distribution ratio of Pa(IV) reduced with Cr(II) and the perchloric acid concentration was examined under the conditions described above. The distribution ratio of Pa(IV) reduced with Cr(II) was about 1/10, compared to that of Pa(IV) reduced with Eu(II), as is shown in Fig. 6. The results obtained by Guillaumont[1] are also shown by a broken line in Fig. 6.

Discussion

The TTA Extraction of Pa(IV). From the results shown in Figs. 5 and 6, the equation for the TTA extraction reaction can be written as:

$$PaOH^{3+}(aq.) + 4HA(org.) = PaO_p(OH)_qA_{4-2p-q}(HA)_r(org.) + (1-p-q)H_2O + 3H^+(aq.) \quad (4)$$

where HA and A^- are used to denote the TTA molecule and the dissociated TTA anion respectively. If the coefficient of water represented in Eq. (4) is not negative, and if the oxygen which does not coordinate with Pa(IV) in the aqueous phase does not coordinate with Pa(IV) in the organic phase, we can say that:

$$p = 0,\ q = 0 \text{ or } 1 \quad (5)$$

Therefore, Eq. (4) may be rewritten as:

$$PaOH^{3+}(aq.) + 4HA(org.) = PaA_4(org.) + H_2O + 3H^+(aq.) \quad (6)$$

or

$$PaOH^{3+}(aq.) + 4HA(org.) = Pa(OH)A_3(HA)(org.) + 3H^+(aq.) \quad (7)$$

The Difference between the Distribution Ratio Obtained by This Experiment and That Obtained by Guillaumont.[1] The distribution ratio obtained by Guillaumont becomes lower than that obtained by the present authors as the acidity decreases. This may be caused by two factors. One is the incomplete reduction of Pa(V); that is, the distribution ratio of Pa(IV) is higher than that of Pa(V) when the acidity is lower than 1 M at the ionic strength of 3.[1,12] The other is due to the Cr(II)-TTA chelate; its low distribution ratio, which is known by the fact that the aqueous phase is the yellow color of Cr(II)–TTA chelate after extraction, leads to the incomplete correction of the concentration of the TTA–benzene solution, because its correction was done on the supposition that the Cr(II)–TTA chelate is extracted quantitatively into the benzene phase.

The Chromium-Protactinium Complex. The distribution ratio of Pa(IV) in the system using Eu(II) as the reductant is about ten times as large as that in the system using Cr(II) as the reductant, as is shown in Fig. 6. Moreover, the distribution ratio of Pa(IV) decreases with an increase in the concentration of chromium, as has been reported previously.[3] One of the most reliable explanations of the above facts is the possibility that a multi-nuclear complex between Pa(IV) and Cr(II) or Cr(III) is formed. Taube *et al.*[13,14] reported that, when $Co(III)(NH_3)_5X$ (X is a ligand; *i.e.* Cl^-, Br^-, or H_2O) was reduced with Cr(II), a bridged activated complex for an electron-transfer reaction like $[Co(NH_3)_5\text{-}X\text{-}Cr]$ was found. This reaction proceeds by means of an inner-sphere reaction mechanism. It has been established that when the actinoid ions are reduced with Cr(II) some binuclear intermediates are found. For instance, a 1 : 1 cationic complex[15] $[O\text{–}Np\text{–}O\text{–}Cr(H_2O)_5]^{4+}$ was formed, and this inner sphere complex was fairly stable because of a sufficiently slow substitution reaction on Cr(III) when Np(VI) was reduced with Cr(II) in a perchloric acid solution; the binuclear intermediate[16] was also found in the investigation concerned with the reduction of U(VI) with Cr(II).

From the above facts, it may be considered that the Cr(III)–Pa(IV) complex, with the structure mentioned above, may be formed when Pa(V) is reduced with Cr(II) and that the complex is difficult to extract by an extractant. On the contrary, Pa(IV) forms no cationic complexes with Eu(III), because the ligand within the coordination sphere of Eu(III) is not so substitutional inert as that of Cr(III).

A part of the expenses for this investigation has been defrayed by a grant-in-aid from the Ministry of Education.

X-Ray Diffraction Studies of Aqueous Solutions of Cadmium Perchlorate and Sodium Tetraiodocadmate

Hitoshi OHTAKI, Masunobu MAEDA, and Satoshi ITO

Laboratory of Solution Chemistry, Faculty of Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received March 13, 1974)

X-Ray diffraction measurements were carried out for aqueous solutions of cadmium perchlorate and sodium tetraiodocadmate. X-Ray scattering data showed that the hydrated Cd^{2+} ion is coordinated to six water molecules, the distance between Cd^{2+} and H_2O being 2.31 ± 0.02 Å, and that the CdI_4^{2-} complex has a tetrahedral configuration with a Cd–I distance of 2.79 ± 0.01 Å. The tetrahedral structure of the CdI_4^{2-} complex was confirmed by Raman spectroscopy.

X-Ray diffraction for investigation of crystal structures was extended to the analysis of the structures of fused salts and pure liquids.[1-4] Its application to electrolytic solutions of relatively high concentration has since been undertaken to determine the structures of ionic species such as hydrated metal ions,[5-9] metal halide complexes[10-16] and polymerized hydrolysis species of metal ions.[17-22]

The structures of hydrated alkali metal,[5] alkaline-earth metal,[6] and transition-metal ions from Mn^{2+} to Zn^{2+} ions[7-9] were investigated in aqueous solutions of chloride, nitrate and sulphate ions.

Few studies, however, seem to have been made on the hydrated cadmium ion. The study by Bol *et al.*[9] of an aqueous cadmium nitrate solution, in which they showed that a cadmium ion is bound to six water molecules with the Cd–OH_2 distance 2.289 Å, appears to be the only case.

A number of equilibrium studies have been made on the cadmium iodide complexes in aqueous solution with various experimental techniques,[26] the results of which are consistent with the formation of only mononuclear complexes of CdI^+, CdI_2, CdI_3^-, and CdI_4^{2-}. From Raman spectroscopic measurements[27-29] it was found that CdI_4^{2-} has a tetrahedral configuration (T_d symmetry) in aqueous solution and organic solvents.

As far as we know, no X-ray diffraction measurement has been carried out for a study of the structures of the cadmium iodide complexes in aqueous solution.

In the present work we deal with aqueous cadmium perchlorate and sodium tetraiodocadmate solutions, the latter being also examined by Raman spectroscopy.

Experimental

Preparation and Analysis of Sample Solutions. Cadmium perchlorate was prepared by dissolving cadmium oxide in dilute perchloric acid and recrystallizing the cadmium perchlorate twice from water. The crystals thus prepared were dissolved in water containing a small amount of perchloric acid in order to prevent the hydrolysis of the Cd^{2+} ions.

The concentration of cadmium ion in the solution was determined both by gravimetry as $CdSO_4$ and by titration with EDTA. The results obtained by the two methods agreed within 0.2%. The perchlorate content of the solution was determined by using a column of cation exchange resin (Dowex 50 W-X12) of the hydrogen form. The hydrogen-ion concentration was calculated from the relation, $[H]^+ = [ClO^-_4] - 2[Cd^{2+}]$.

The cadmium iodide solution in which the tetraiodocadmate ion was predominant was prepared by the addition of NaI to a CdI_2 solution. The amount of NaI to be added was estimated from the distribution of cadmium iodide complexes calculated from the stability constants given by Leden.[30]

The total amount of cadmium in the cadmium iodide test solution was determined by EDTA titration, that of iodide being determined gravimetrically as AgI. The concentration of sodium ion was estimated from the material balance of ions in the solution. The density of the solutions was measured with a pycnometer. The composition of the solutions investigated is given in Table 1.

TABLE 1. COMPOSITIONS OF THE SOLUTIONS (in g atoms/l)

	Cadmium perchlorate soln.	Cadmium iodide soln.
Cd	2.920	2.246
I	—	11.39
Cl	6.303	—
Na	—	6.899
O	66.02	30.60
H	81.15	61.21

X-Ray Scattering Measurements. The X-ray diffractometer (JEOL Co., Tokyo) used is so designed that diffraction patterns are obtained from the free surface of the solution and that the X-ray tube and detector move symmetrically in a direction opposite the horizontal axis at the surface of the solution, *i.e.*, the Bragg–Brentano geometry is applied. The sample solution is contained in a flat glass tray, diameter 40 mm and depth 10 mm, covered tightly with a Teflon-coated stainless steel cover with a beryllium window for X-rays to protect the solution from evaporation and contamination. A LiF focusing monochromator is placed between a receiving slit and scintillation counter. A pulse-height analyzer is used for further monochromatization.

MoKα radiation ($\lambda=0.7107$ Å) was used, a Philips PW210500 X-ray tube being employed. The scattered intensity was measured at discrete points (about 200 points in all) between $\theta=1°$ and 70°, where 2θ is the scattering angle. The time required to accumulate 40000 counts was measured at angular intervals; 0.125° to $\theta=6°$, 0.25° to 20° and 0.5° to 70°. Three slit combinations, with 1/12°, 1/4° and 1° divergent slits, were employed. The whole angle range was scanned twice in order to detect the variation of measured intensities during the course of continuous operation. The variation was usually less than 2% of the measured intensities

and the intensities measured at each angle were averaged. The intensities for each slit combination were corrected for background radiation, determined by placing a lead plate just behind the receiving slit, and were normalized to the intensities measured with the 1° divergent slit from the data of overlapping regions.

The amount of incoherent radiation passing through the monochromator was estimated from the spectrum of the X-ray and the resolving power of the monochromator. It was also measured with a zirconium filter at large scattering angles. The Zr filter was first placed between the X-ray tube and the solution and the scattered intensity was measured. It was then placed between the solution and the detector and another measurement was carried out at the same scattering angle.

Raman Spectroscopic Measurements. Raman spectra for the tetraiodocadmate solution were measured with a JEOL Laser Raman Spectrophotometer JRS-Sl and a Shimadzu Laser Raman Spectrophotometer R-2D with use of the 4880 Å excitation line of Ar.

The composition of the sample solution was the same as that of the solution used for the X-ray measurements except that it contained ClO_4^- ion as an internal standard (A_1 line of ClO_4^-).

Treatment of X-Ray Intensity Data

The measured intensities were corrected for polarization in both the sample solution and monochromator and for absorption of the sample, and were scaled to absolute intensities (electron units) by comparing the asymptote with the sum of the calculated coherent and incoherent radiations at large scattering angles ($\theta \gtrsim 50°$). The scale factors thus calculated agreed within 1% with those calculated by the method of Norman[31] and Krogh-Moe.[32]

The scattering factors for Cd, I, Cl, Na, and O were taken from Cromer and Waber,[33] and those for H from the International Tables.[34] The values used for the incoherent scattering were those given by Cromer and Mann[35] for Cd and Na, by Cromer[36] for I, Cl, and O, and by Compton and Allison[37] for H. The incoherent scattering values were corrected by the Breit-Dirac factors. The values used for anomalous dispersion were taken from Cromer and Liberman.[38]

The reduced intensities $i(s)$ due to interatomic interactions in the system were evaluated from the measured intensities $I(s)$ which had been corrected for polarization and absorption, and also for scaling to electron unit, by subtracting intensities due to component atoms. The calculations were made by the equation

$$i(s) = I(s) - \sum_i n_i[(f_i(s)+\Delta f_i')^2 + (\Delta f_i'')^2 + \Phi(s)\cdot I_i^{\mathrm{inco}}(s)] \quad (1)$$

where s represents $4\pi\sin\theta/\lambda$ (λ=0.7107 Å), n_i the number of atom i, $\Delta f_i'$ and $\Delta f_i''$ the real and imaginary parts of the anomalous dispersion, respectively, $\Phi(s)$ the fraction of the incoherent radiation reaching the counter.

All the calculations were referred to a stoichiometric volume of a solution containing one cadmium atom. The reduced intensities $i(s)$ thus calculated are shown in Fig. 1 after being multiplied by s.

The radial distribution curves $D(r)$ were calculated

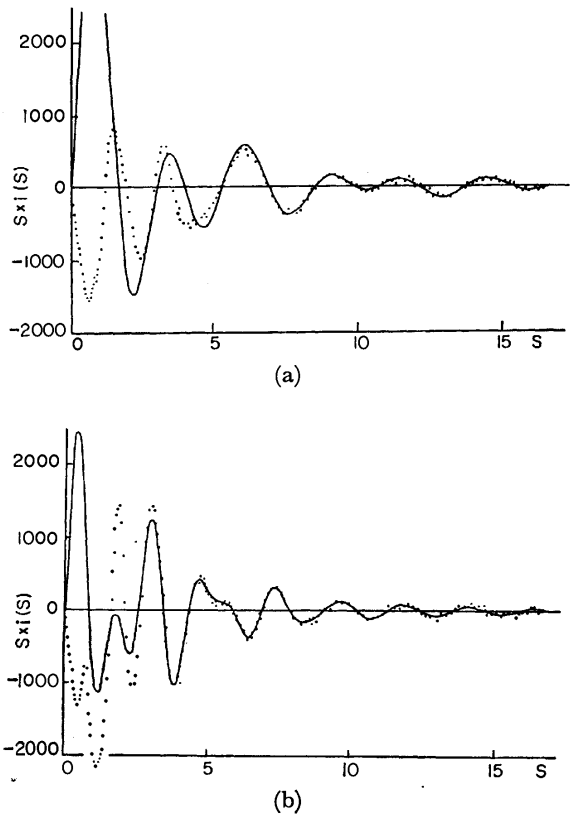

Fig. 1. Values $s\cdot i(s)$ for the two solutions as a function of s. Full circles are experimental points and full curves are calculated with the parameters given in Tables 2 and 4.
(a) the cadmium perchlorate solution, (b) the sodium tetraiodocadmate solution.

from the intensity curves by the integral formula

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_0^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(rs)\mathrm{d}s \quad (2)$$

where ρ_0 denotes the average scattering density of the sample in electron unit, the modification function $M(s)$ being chosen to be $(f_{Cd}^2(0)/f_{Cd}^2(s))\exp(-0.01s^2)$.

The calculated radial distribution curve showed small spurious peaks in the range less than 1 Å, which can not be related to any interatomic distance. Thus the reduced intensities were corrected for spurious peaks by means of the Fourier inversion of the radial distribution curve below 1 Å by taking into account the contributions from water and the perchlorate ion.

Theoretical intensities due to interatomic interactions were calculated by

$$i(s) = \sum_i\sum_j n_{ij}f_i(s)f_j(s)\frac{\sin(r_{ij}s)}{r_{ij}s}\exp(-b_{ij}s^2) \quad (3)$$

where $f_i(s)$ and $f_j(s)$ denote the scattering factors of atoms i and j, respectively, and n_{ij}, r_{ij}, and b_{ij} represent the frequency factor, the distance and the temperature factor of the interaction between any atoms i and j, respectively.

The calculations were carried out with the help of the KURVLR program specially compiled for the analysis of X-ray diffraction data by Johansson and Sandström.[39]

Analysis of Intensity Data and Results

Cadmium Perchlorate Solution. The radial distribution curve $D(r)$ is shown in Fig. 2(a). Two distinct peaks are seen at around 1.4 and 2.3 Å. The former peak is attributed to the Cl-O bonds within the perchlorate ion, which has been confirmed by several investigators.[17,40,41] The latter might be due to the Cd–O bonds within the hydrated cadmium ion, as expected from X-ray diffraction data for the crystal[42] and cadmium nitrate solution,[9] and contains a contribution from the O–O contact within ClO_4^- ion which has a tetrahedral structure. The distance and frequency factor of the Cd–O bond within the hydrated cadmium ion were estimated from the residual peak after subtraction of the O–O contribution from the second peak according to the following procedures. The theoretical intensities due to the O–O contact within ClO_4^- ion were calculated by means of Eq. (3) assuming that $r_{O-O}=2.33$ Å (which corresponds to $\sqrt{8/3}\times 1.43$ Å), $n_{O-O}=6$ and $b_{O-O}=0.002$. The theoretical peak corresponding to the O-O contact was evaluated by the Fourier inversion of the theoretical intensities according to Eq. (2) and was subtracted from the second peak. The area under the residual peak was estimated by a graphical technique with use of a planimeter and was correlated with the number of oxygen atoms around cadmium n_{Cd-O} by the relation $A_{Cd-O}=2x_{Cd}n_{Cd-O}Z_{Cd}Z_O$.[2] Here A_{Cd-O} denotes the area under the peak of the $D(r)$ curve caused by the Cd-O interaction, x_{Cd} the concentration of the cadmium ion, and Z_{Cd} and Z_O the atomic numbers of Cd and O, respectively. The frequency factor n_{Cd-O} thus evaluated was about six, and the Cd–O distance was found to be 2.31 ± 0.02 Å. The temperature factor for the Cd–O bond was estimated to be 0.002 from the peak shape.

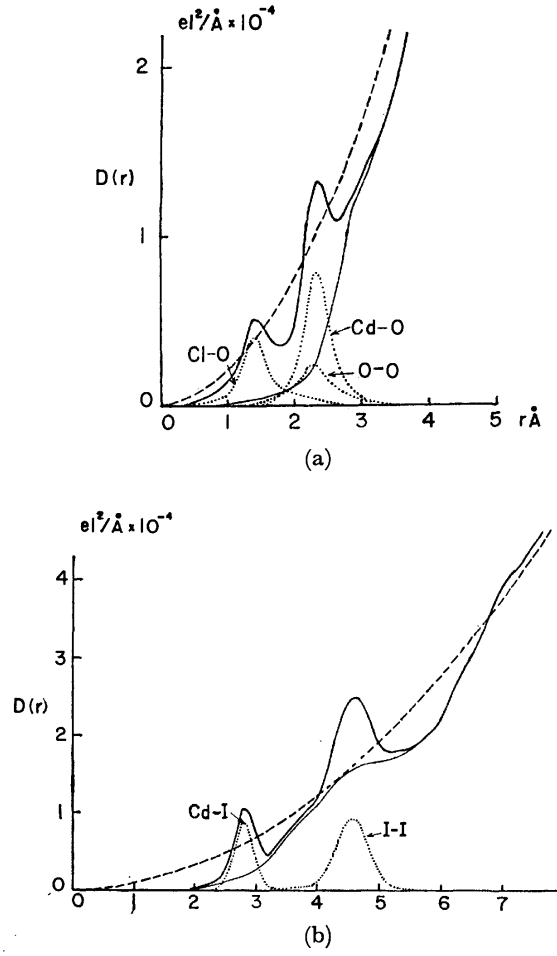

Fig. 2. Radial distribution curves $D(r)$ for the two solutions. The thick curves give $D(r)$ functions, the smooth brocken curves $4\pi r^2\rho_0$ functions, and the thin curves the difference curves obtained by subtraction of the theoretical peaks (dotted curves) from the $D(r)$ functions. The theoretical peaks (dotted curves) are calculated with the parameters listed in Tables 2 and 4.
(a) the cadmium perchlorate solution, (b) the sodium tetraiodocadmate solution.

The values for r, b, and n for the Cd–O bond within the cadmium hydrate and for the Cl–O and the O–O contacts within the tetrahedral perchlorate ion are given in Table 2.

Table 2. Final parameter values for the cadmium ion coordinated to six water molecules and the perchlorate

	r(Å)	b	n
Cd-O	2.31	0.002	6
Cl-O	1.43	0.001	4
O-O	2.33	0.002	6

The peaks calculated with these values were compared with those of the radial distribution curve (Fig. 2(a)). Subtraction of the calculated peaks from the radial distribution curve gives a smooth curve in the region less than 2.8 Å. This shows that the values of the parameters are reasonable and that other interatomic distances within the hydrated cadmium ion are ruled out. The intensities calculated with the parameters are also compared with the observed intensities (Fig. 1(a)). The agreement is satisfactory except in the low s region where contributions from the intermolecular atom pair interactions to the intensities are significant.

The residual curve obtained by subtraction of the calculated peaks from the residual distribution curve shows a very broad peak over the range 2.7—3.4 Å. If we assume that the hydrated cadmium ion possesses a regular octahedron, the distance between adjacent oxygen atoms should be 3.27 Å, which may be consistent with the present results. However, the configuration of water molecules around a cadmium atom could not be determined from the radial distribution curve, since the broad peak would be due to not only the contribution from the O-O contact within the hydrated cadmium ion, but also to contributions from the O-O distances between a ClO_4^- ion and a water molecule[40] and also from other atom pairs of longer distances.

The Cd–O distance 2.31 Å found in the present work is close to the values found in the crystal of

$Cd(NH_4)_2(SO_4)_2 \cdot 6H_2O$[43] and in the cadmium nitrate solution,[9] which are 2.28 Å on the average and 2.289 Å, respectively.

Sodium Tetraiodocadmate Solution. The radial distribution curve $D(r)$ is shown in Fig. 2(b). It shows two prominent peaks in the region less than 6 Å. The peak at around 2.8 Å can be ascribed to the Cd-I bonds, and that at about 4.6 Å to the distance between iodide ions within the tetraiodocadmate complex. The ratio between these two distances is in good agreement with that expected for a tetrahedral structure. The number of iodide ions coordinated to a cadmium ion was estimated to be about four from the area under the peak at around 2.8 Å according to graphical procedure. It was not possible to determine the number of pairs of the adjacent iodide ions within the cadmium iodide complex, since other long-range interactions largely contribute to the peak at around 4.6 Å.

In order to confirm the structure of the CdI_4^{2-} complex deduced from the radial distribution curve and to refine the distances, analysis of the reduced intensity curve was carried out by means of a least squares method. For each pair of the Cd–I and I–I interactions three parameters were introduced, distance r, temperature factor b, and frequency factor n. These parameters were allowed to change so that the error square sum $U=\sum s^2(i(s)-i_{calc}(s))^2$ becomes a minimum, where $i(s_{calc})$ denotes the intensity theoretically calculated by means of Eq. (3). Different subsets of the intensity data were used for the refinement in order to detect errors in the refined parameters caused by a contribution to the intensity by the intermolecular interactions and experimental errors contained in the data. The least squares calculations were carried out by means of PUTSLR,[39] the generalized least squares program for X-ray diffraction of solution.

Two types of refinement (A and B) were carried out. The calculated results are summarized in Table 3.

In type A, all the six parameters for the Cd–I and the I–I interactions were allowed to change simultaneously. The frequency factor of the Cd–I bond is close to four, which is the value expected from the CdI_4^{2-} complex in any sets of data over the various s regions except the set of data in the region $2.5<s<16.5$ in which large contributions are included.

The ratio between the I–I and the Cd–I distances is about 1.63, which corresponds to $\sqrt{8/3}$ for the complex of the tetrahedral configuration.

The frequency factor n_{I-I} of the I–I pair was not definitely determined by the least squares method; n_{I-I} fell in the range $6<n_{I-I}<23$ when the standard deviations were taken into account (see Table 3).

In type B a tetrahedral structure was assumed, and the Cd–I distance and the two temperature factors for the Cd–I and I–I contacts were refined. The refined parameters are almost the same as those in type A.

TABLE 4. FINAL PARAMETER VALUES FOR THE TETRAHEDRAL CADMIUM TETRAIODIDE COMPLEX

	r(Å)	b	n
Cd–I	2.79	0.004	4
I–I	4.56	0.025	6

The distances and temperature factors for the Cd–I and I–I contacts for the CdI_4^{2-} complex are listed in Table 4, a tetrahedral structure of the complex being assumed. The assumption was supported by Raman spectroscopic measurements.

The observed intensities are compared with the calculated ones in Fig. 1(b) with use of the parameters in Table 4. It is seen that the agreement is satisfactory except at the low-angle part of the curve where the intermolecular interactions significantly contribute to the $s \cdot i(s)$ curve.

The calculated Cd–I and I–I peaks with use of the parameters given in Table 4 are compared with the radial distribution curve in Fig. 2(b). The residual curve obtained by subtraction of the calculated peaks from the radial distribution curve shows a broad peak in the range 4—5.5 Å. The peak is so broad that it can not be due to the interaction of any one kind of pairs of atoms, but to various kinds of interactions; one of them might be H_2O-H_2O interactions in bulk water.

A Raman spectrum of the CdI_4^{2-} solution is reproduced in Fig. 3, along with the resolved bands on a horizontal background. It shows four bands at around 36, 47, 110, and 145 cm^{-1}. The polarization measurements indicate that the strong band at 110 cm^{-1} is polarized and the other three bands are depolarized. This suggests that the CdI_4^{2-} complex has T_d symmetry. These results are in good agreement with those obtained by means of the Raman effect in which a tetrahedral structure was proposed for the CdI_4^{2-} complex.[27-29]

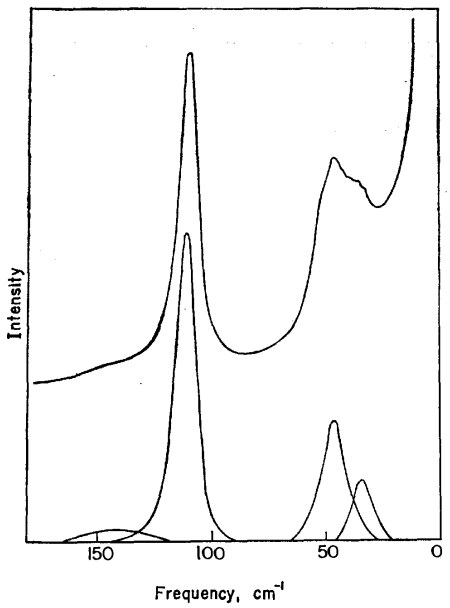

Fig. 3. A Raman spectrum of the CdI_4^{2-} solution, with resolved bands based on the horizontal background.

The authors express their sincere thanks to Prof. Georg Johansson, the Royal Institute of Technology, Stockholm, for his helpful advice throughout this work.

Polarographic Study of Catalytic Reduction of Tris(2,2′-bipyridine)-copper(II) in the Presence of Nitrite Ion

Kazuyoshi TANAKA and Kunio NAKANO

Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received December 19, 1973)

The rigorously derived equation for a catalytic current was applied to the evaluation of the rate constant for the oxidation reaction of bis(2,2′-bipyridine)copper(I) by nitrite ion by use of a computer and subroutine program for the curve-fitting method. This method made it possible to calculate the rate constant from low limiting current in the presence of nitrite ion. The rate in acetate buffer solutions has first-order dependence on each reactant and hydrogen ion, and the apparent rate constant is 1×10^6 M^{-2} s^{-1} at 25 °C.

A polarographic catalytic process can be schematically represented by

$$O + ne \longrightarrow R \quad (1)$$

$$R + Z \longrightarrow O \quad (2)$$

This refers to a post-electron transfer chemical reaction (2) which regenerates the original electrochemical species O. The reaction must be pseudo-unimolecular with respect to species R, when the oxidizing agent Z is present at a high and constant concentration at the electode surface. The theoretical equations describing a catalytic current have been developed by several workers[1-4] and derived on the assumption that a steady state at the dropping mercury surface set up by the combination of diffusion and chemical reaction, *i.e.*, a linear diffusion approximation concerning the concentration gradient at the electrode surface has been made. These equations should be used to evaluate a rate constant for a fast chemical reaction, such as the oxidation of titanium(III) by chlorate ion.[5] However, there are many slow reactions which cause a smaller catalytic current, such as the oxidation of titanium(III) by hydroxylamine,[6] and vanadium(II) by chlorate ion[7] and by vanadium(IV).[8]

Koutecky[9,10] has treated the diffusion problem using a more rigorous expanding sphere approximation and proposed a theoretical expression for the catalytic current. Since this equation is complicated and its application is very tedious to evaluate a rate constant, the graphical treatment of the equation has been carried out for some systems.[1,9] However, the curve-fitting method developed recently by use of a computer has been available for solving the equation, and, in the present work, this method was employed for determining the rate constant for the oxidation reaction of copper(I) by nitrite ion.

Experimental

Materials. Copper(II) stock solution was prepared by dissolving recrystallized $CuSO_4\cdot2H_2O$ into the redistilled water and its concentration was determined by measuring the second diffusion current in ammonia-ammonium chloride solutions compared with that of standard copper(II) solution which was made from high purity copper metal(99.999%). The weighed amount of reagent grade 2,2′-bipyridine was dissolved into an acetic acid solution and then the buffer solution was made by adding sodium acetate, which was also used as a supporting electrolyte. Sodium nitrite solution was prepared by dissolving an appropriate amount of reagent grade chemicals in the water.

Apparatus and Procedure. A Yanagimoto polarograph Model P-8 was used to record the polarograms. Catalytic current appeared when sodium nitrite solution was injected into acetate buffered solution containing 2,2′-bipyridine with a micropipet. Ionic strength was kept 0.2 M throughout the present work. All the pH values were measured by a Toa Dempa pH meter Model HM-5A.

Results and Discussion

Evaluation of Rate Constant. Koutecký and Cizek[10] have proposed the theoretical equation for the catalytic current

$$\frac{i}{i_d} = \Psi(\chi) + \xi[\Theta(\chi) - 0.78680\Psi(\chi)] = \Psi(\chi) - \xi\Phi(\chi) \quad (3)$$

and

$$\Psi(\chi) = e^{-\chi}\sum_{i=0}^{\infty} a_i\chi^i \quad (4)$$

$$\Theta(\chi) = e^{-\chi}\sum_{i=0}^{\infty} a_i r_i\chi^i \quad (5)$$

$$\xi = \sqrt{\frac{12D}{7r_1^2}}\,t^{1/6} \quad (6)$$

where i and i_d are the experimentally observed instantaneous currents for the reduction of species O in the presence and in the absence of Z, respectively. The parameter, ξ, corresponds to the function involving the diffusion coefficient, D, drop time, t, and mercury drop radius, r_1, at $t=1$ s, and in the present work the value of ξ was found to be 0.187. The parameter, a_i, is a complicated gamma function, whose values for $i=0$ to 15 are tabulated in the literature,[10] and the values of $\Phi(\chi)$ corresponding χ are also listed. The parameter, χ, in above equation is related to the apparent second-order rate constant, k_{app}, with respect to each reactant.

$$\chi = k_{app}C_z t \quad (7)$$

where C_z denotes the concentration of oxidizing agent, Z, nitrite ion in the present work. The rate constant can be evaluated from this equation if the consumed amount of Z by the chemical reaction is negligibly small, and if an appreciable change of the concentration of Z takes place, another theoretical equation derived on the basis of the stoichiometric consideration[11] must be applied to obtain the rate constant.

The evaluation of χ from the observed value of i/i_d

was made as follow: equation (3) was simplified by the first assumption that the term $\xi\Phi(\chi)$ could be neglected. This is verified by our experimental results as mentioned below. In the course of the calculation an approximate value of χ, which is given in Koutecký's Table,[9] is necessary to solve the function $\Phi(\chi)$ by use of a subroutine programs for the curve-fitting method. Thus, a more accurate value of χ can be obtained and used to evaluate the term $\Phi(\chi)$ by using the value in the table on the assumption that a linearity of $\Phi(\chi)$ with χ holds in the narrow range. Using this trial $\Phi(\chi)$ and the observed value of ξ, the value of χ is recalculated by use of Eq. (3) until the consistent value can be obtained. In the present work, one or two cycles were sufficient to define the value of χ within experimental error. This method is very convenient to evaluate the rate constant from the low value of i/i_d.

Kinetic Results. The typical polarograms are shown in Fig. 1. The two reduction waves with a polarographic maximum in the absence of nitrite ion appeared and it is concluded from their half-wave potentials that the first wave corresponds to the one-electron reduction of $Cu(bipy)_3^{2+}$ to $Cu(bipy)_2^{1+}$ and the second wave to that of $Cu(bipy)_2^{1+}$ to copper metal. The polarographic behavior of these species has been studied systematically by Onstott and Laitinen.[12] The first wave was increased by adding nitrite ion, indicating the catalytic current. When nitrite ion was in sufficiently high concentration compared with that of copper(II) ion, the first wave became larger than the second one, showing that the catalytic nature is specific to the first wave. The maximum at rising portion of the second wave increased with increasing concentration of copper(II) ion. The maximum suppressor was not used in this experiment, because the substance adsorbed on the mercury electrode would disturb the reaction layer at the electrode surface and make the experimental data inaccurate. However, the presence of this maximum and the large catalytic wave caused a narrow plateau of the first wave and made it difficult to measure the limiting current. Thus, it is necessary in the present system to evaluate the rate constant from the comparably small limiting current, *i.e.*, the low value of i/i_d.

Values of the catalytic current obtained at various concentrations of nitrite ion are presented in Table 1.

Table 1. Apparent rate constants of the oxidation of copper(I) by nitrite ion in acetate buffer solution of 1.94×10^{-4} M Cu(II)+1×10^{-2} M bipy, at 25 °C

a) Parenthesized values of k were calculated by using the simplified equation as described in this article.

The value of secondly difined χ' is about 10% larger than that of the first one and little differences can be observed between χ' and χ'', or χ'' and χ''' for a given condition, where χ'' and χ''' are thirdly and fourthly defined values of χ. In the case of $\chi>10$, Eq. (4) diversed and a finite value of χ could not be given by the present method. This was caused by using only the sixteen values of a_i involved in the function $\Phi(\chi)$. In this case, the value of k_{app} shown in the parenthesis was calculated from the simplified equation proposed by Koutecký[9] and corrected by employing the value of $\xi\Phi(\chi)$ in order to obtain a more accurate value. As shown in Table 1, though the half-wave potentials obtained in the presence of nitrite ion is thought to shift slightly to a more negative potential compared

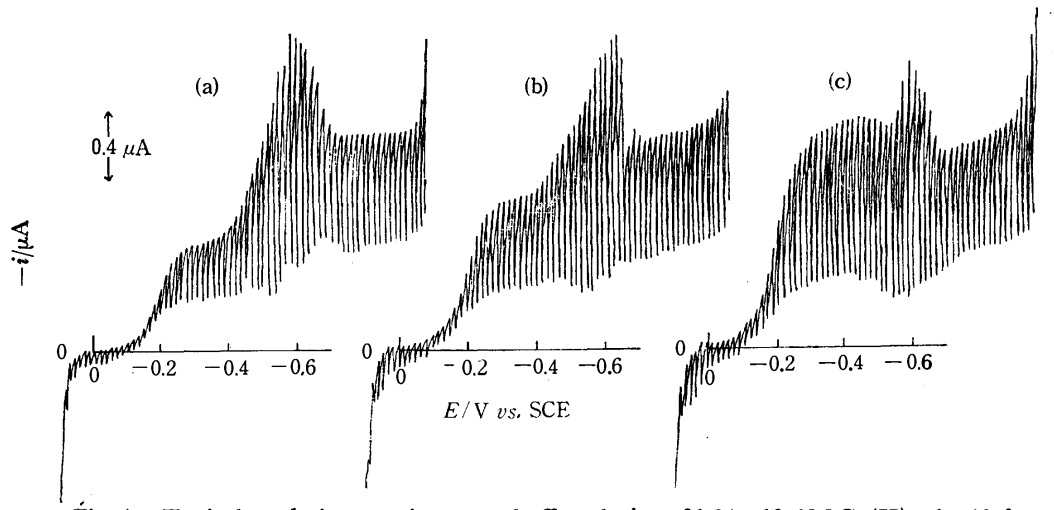

Fig. 1. Typical catalytic waves in acetate buffer solution of 1.94×10^{-4} M Cu(II)+1×10^{-2} M bipy, pH 5.3. The concentrations of nitrite ion are (a) 0, (b) 4.37×10^{-2}, (c) 1.63×10^{-1} M.

with that of the wave in the absence of oxidizing agent, no significant effect was observed.

Taking into account relative inaccuracy of the experimental data, it was concluded that almost consistent values of rate constants at the same pH value could be obtained. This supports the validity that the present method is useful to evaluate the rate constant from the small catalytic current, *i.e.*, $i/i_d<3$. The rate constants obtained under the condition of low nitrite ion concentration from 7.95 to 21.8 mM were 22.9 ± 1.6 $M^{-1}s^{-1}$ at pH 4.90. In this calculation, Eq. (3) was used provided that the change in nitrite ion concentration consumed by the chemical reaction could be practically neglected. This condition was comfirmed by the presence of at least twenty times larger amount of nitrite ion than that of copper(II), though the consistent value could not be obtained in the presence of 3.99 mM nitrite ion. The rate constants are much smaller than those of the oxidation reaction of bis(2,2'-bipyridine)copper(I) by oxygen and hydrogen peroxide.[13]

Effects of Drop-time and Bipyridine. The effect of the corrected height of mercury reservoir, h_{corr}, or the effect of drop time, on the limiting currents is seen in Fig. 2. Since the limiting current in the absence of

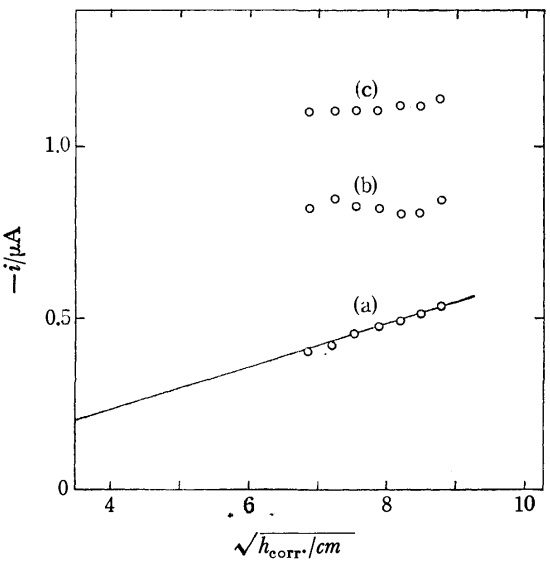

Fig. 2. Dependence of limiting currents on the corrected height of mercury reservoir in the acetate buffer solution of 1.94×10^{-4} M Cu(II) $+1\times10^{-2}$ M bipy, pH 5.3. The concentrations of nitrite ion are (a) 0, (b) 8.49×10^{-2}, (c) 1.65×10^{-1} M.

nitrite ion is linearly proportional to the square root of h_{corr}, it is diffusion-controlled. On the other hand, the limiting current in the presence of 0.163 M nitrite ion was independent of h_{corr}, indicating the dominant contribution of catalytic nature to total current. The apparent rate constant was found to be 4.06 ± 0.19 $M^{-1}s^{-1}$ at pH 5.28. Though the wave is essentially of catalytic nature, the small variation of the limiting currents observed in the presence of 0.0849 M nitrite ion is likely to result from the adsorption of depolarizer or bipyridine on mercury electrode.

The effect of 2,2'-bipyridine concentration on the rate constans is shown in Table 2. This shows that

Table 2. Apparent rate constants at various concentrations of 2,2'-bipyridine in acetate buffer solution of 1.94×10^{-4} M Cu(II) at pH 5.2

bipy mM	$[NO_2^-]$ mM	$-E_{1/2}$ V*vs.* SCE	i μA	i/i_d	k_{app} $M^{-1}s^{-1}$
1.28	—	0.142	0.486	—	—
	21.8	0.144	0.550	1.132	2.93
	43.7	0.145	0.640	1.317	3.69
2.18	—	0.166	0.490	—	—
	21.8	0.160	0.596	1.216	4.91
	43.7	0.160	0.670	1.367	4.35
	84.9	0.156	0.846	1.727	4.89
5.13	—	0.175	0.490	—	—
	21.8	0.165	0.600	1.224	5.21
	43.7	0.170	0.722	1.473	5.78
	84.9	0.174	0.910	1.857	5.97
	163.5	0.172	1.142	2.331	5.47

the value of rate constant increased somewhat with increasing bipyridine concentration and approached the consistent value obtained at 1×10^{-2} M bipyridine. Since the wave in 1.28×10^{-3} M bipyridine was poorly defined and the limiting current became inaccurate, it was not clear from the present data that bipyridine participated in the chemical reaction. Futhermore, the considerably low rate constant could not be explained. However, the shift of the half-wave potentials in the absence of nitrite ion corresponded to the dissociation of one bipyridine molecule in the electrode reaction, which could be substantiated by the reported value of the half-wave potential for the system of copper(II) and bipyridine.[12]

Catalytic Reaction Mechanism. In view of the above results the electrode reaction scheme can be written as

$$Cu(bipy)_3^{2+} \xrightarrow[-bipy]{+1e} Cu(bipy)_2^{1+} \xrightarrow[-2bipy]{+1e} Cu(0) \qquad (8)$$
$$\uparrow \qquad\qquad\qquad \downarrow +NO_2^-$$

This shows that the catalytic current due to nitrite ion is concerned only with the first wave and is quite indifferent to the second wave which corresponds to the reduction current of copper(I) to amalgamated copper metal. The value of rate constant decreased about 15% with a two-hold increase of copper(II) concentration. Further reaction between copper(I) and products of nitrite ion must be considered, and if the reaction product is bis(2,2'-bipyridine)copper(II), this species would undergo the electroreduction and cause the increase of catalytic current. Though the oxidation product of copper(I) is not clear from the present data, the rate law for the chemical reaction can be represented as

$$-\frac{d[Cu(bipy)_2^{1+}]}{dt} = k_{app}[Cu(bipy)_2^{1+}][NO_2^-]. \qquad (9)$$

Neverthless, it is not necessary that the rate corresponds to the increment of tris(2,2'-bipyridine)copper(II). A plot of $\log k_{app}$ against $\log [H^+]$ was approximately linear and yields a best straight line of slope 1.19 ± 0.04, from which it can be deduced that the rate has

also first-order dependence with respect to hydrogen ion, *i.e.*, $k_{app}=k'_{app}[H^+]$, and the value of k'_{app} is *ca.* $1\times10^6\ M^{-2}s^{-1}$ at 25 °C. This suggests that the equilibrium between nitrite ion and nitrous acid exists and nitrous acid should participate in the chemical oxidation. Nitrous acid is, in general, a more powerful oxidizing agent than nitrite ion.[14] Though the reaction is thought to be non-complementary, there is insufficient information about the reaction stoichiometry and the possibility that nitrite ion acts as a two-equivalent oxidizing agent to copper(I).

Formation of Cubic Molybdenum Carbide by the Carbonization of MoO_3 with Plasma Arc and Properties of the Products

Osamu MATSUMOTO, Michio SAITO, and Takashi YOSHINO

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received March 8, 1974)

The formation of cubic molybdenum carbide (α-MoC_{1-x}) by the carbonization of MoO_3 with graphite by heating with argon plasma arc was studied. α-MoC_{1-x} including a small amount of hexagoanl η-MoC_{1-x} was formed. By the carbonization of mixture of MoO_3 and TiO_2 with graphite, a cubic solid solution of Mo–Ti–C system was formed. Chemical and X-ray analyses showed that the cubic form is defective in carbon content. The density of the cubic form was in agreement with that determined by means of X-ray diffraction. The products were found to be superconductors, the transition temperature varying with composition. The highest transition temperature 11.7 K was obtained for $Mo_{0.95}TiO_{0.05}C_{0.75}$.

A high temperature phase of composition MoC with a hexagonal unit cell is known to exist. Recently, a cubic modification (α-MoC_{1-x}) has been found. The cubic molybdenum carbide is stable above 2200 °C and decomposes into hexagonal η-MoC_{1-x} and graphite below 2200 °C.[1] Thus rapid quenching from high temperatures is necessary to obtain cubic α-MoC_{1-x}.

Cubic α-MoC_{1-x} has been prepared by quenching MoC, prepared by melting a mixture of molybdenum and carbon, from higher temperatures.[2-5] The products could not be obtained as a stoichiometric or complete single phase. The cubic form is always defective in carbon content, the maximum carbon content being given to be 40 atomic %. MoC forms the extended cubic solid solution with various carbide such as TiC, ZrC, NbC, TaC, and WC.[6,7]

α-MoC_{1-x} and cubic MoC–TiC solid solution are superconductors. The superconducting transition temperature of α-MoC_{1-x} is reported to be from 12.5 to 14.3 K.[2-4,7] It is the highest among the known transition temperatures for carbides. The transition temperature of MoC–TiC solid solution decreased with increasing TiC content.[7]

The authors have studied the formation of carbides such as ZrC,[8,9] TiC,[10] and NbC,[11] by the carbonization of respective oxides with graphite by heating with a plasma arc. α-MoC_{1-x} and cubic solid solution of Mo–Ti–C system were obtained by the carbonization of respective oxides with graphite. The products are confirmed and their properties such as density and superconducting transition temperature are described in this paper.

Experimental

Materials. MoO_3 (purity above 98%, Japan Heavy Metal Co.), TiO_2 (rutile type powder, purity above 99.5%, Toho Titanium Mfg. Co.) and graphite (spectroscopic grade, Tokai Electrode Co.) were mixed at the desired molar ratio (C/MoO_3, $C/(MoO_3+TiO_2)$). About one gram of the mixture was pressed into a tablet. Purified argon was used as plasma gas.

Apparatus. The plasma arc furnace and heating procedure are the same as described previously.[9] The temperature of the surface of the tablet under the plasma was measured with a micropyrometer (PYRO-WERK). An ADG-101 type X-ray diffractometer (Tokyo Shibaura Electric Co.) was used for identifying the products. Gaseous products were identified with a GLC-550 gas chromatograph (Yanagimoto Mfg. Co.).

Experimental Procedure. Temperature of the sample in the plasma arc was about 3000 °C, higher than the melting point of α-MoC_{1-x}. Heating was continued for 3 min. The plasma arc was then stopped and the melt was quenched.

The products were investigated by X-ray diffraction and chemical analysis. Chemical analyses of molybdenum and titanium were carried out by the redox titration method. Carbon content was determined by a combustion method. The density of the product was measured picnometrically at 25 °C using water as a reference liquid. The superconducting transition temperature of products was measured with a 21 Hz mutual inductance bridge.[12] Temperature was measured with a germanium thermometer calibrated against a superconducting standard and the vapour pressure of hydrogen.

Results and Discussion

Confirmation of Products. By quenching the MoO_3-graphite mixture from the melt, a silver white metallic cake was obtained on the graphite hearth anode. Chemical analysis data and crystal structures of the cake formed on the graphite anode with various C/MoO_3 values are given in Table 1. The product obtained at $C/MoO_3=3.9$ (sample No. 1) was hexagonal η-MoC_{1-x}, while the products obtained at $C/MoO_3=4.0$ and 4.3 (sample Nos. 2 and 3) were

Table 1. Chemical and X-ray analysis data of $Mo_xTi_yC_z$

11	0.41	0.15	0.44	100.2	cub.

α-MoC_{1-x} containing a small amount of η-MoC_{1-x}. The maximum atomic ratio of combined carbon to molybednum was 0.84 in the product obtained at $C/MoO_3=4.3$ (sample No. 3). It was found that pure α-MoC_{1-x} was not prepared by the carbonization of MoO_3 with graphite.

MoC forms an extended cubic solid solution with TiC. The MoC–TiC cubic solid solution was formed by the carbonization of a mixture of MoO_3 and TiO_2 with graphite by heating with a plasma arc. MoO_3, TiO_2 and graphite were mixed in desired molar ratios to form cubic solid solution with various compositions (Table 1). The hexagonal phase disappeared and a single cubic phase was obtained in the products containing Ti more than 1 atomic %.

The sum of Mo, Ti, and C contents of the products exceeded 100 wt% except for $Mo_{0.71}C_{0.29}$. It seems that oxygen contained in the products is small in each case.*

CO was the only detectable gaseous product by gaschromatography. The carbonization reaction of oxide can be carried out almost completely at high temperatures.

Properties of Products. Lattice Parameter and Density of Cubic Phase: The relation between the lattice parameter of the cubic phase (a) in the product and the Ti content is shown in Fig. 1. The lattice parameter gradually increased with increasing Ti content.

The relation between the density of product at 25 °C and the Ti content is shown in Fig. 2. The density decreased with increasing Ti content. In the case of the single cubic phase, the density agreed with that determined by means of X-ray diffraction, if we assume that the Mo position in cubic lattice is substituted by Ti and the C position is vacant.

From the changes of the lattice parameter and density caused by the addition of Ti, it seems that Ti added in Mo–C system replaces the Mo atom in the Mo–C lattice and stabilizes the cubic form.

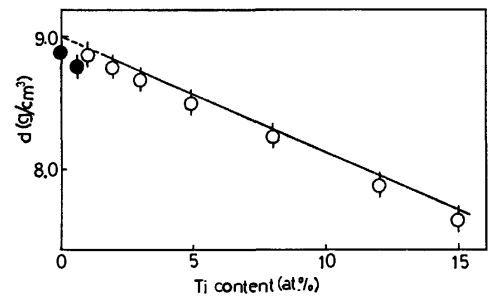

Fig. 2. Density *vs.* Ti content.
—— X-ray density, ○ measured density
● cubic+hexagonal, ○ cubic

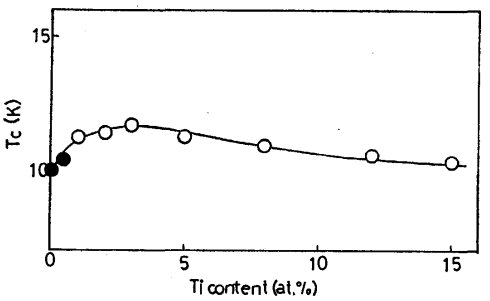

Fig. 3. T_c *vs.* Ti content.
● cubic+hexagonal, ○ cubic

Superconducting Transition Temperature: The relation between the superconducting transition temperature (T_c) of the product and the Ti content is shown in Fig. 3. η-MoC_{1-x} is normal down to 4.2 K. T_c of the mixture of α-MoC_{1-x} and η-MoC_{1-x} is 10.45 K, being somewhat lower than the value given in the literature.[2-4,7] With increasing Ti content T_c increased up to 11.7 K (3 at%), and then decreased. The values were about 2 degrees lower than those obtained by Willens *et al.*[7] If the major part of the curve is extrapolated to pure α-MoC_{1-x}, the resulting temperature becomes about 13 K. This is nearly equal to that of cubic MoC.

T_c of the cubic single phase of Mo–Ti–C system increased with increasing Ti content up to 3 atomic % Ti. As the Ti content was lower than 5 at%, T_c of Mo–Ti–C system was higher than that of the mixture of α-MoC_{1-x} and η-MoC_{1-x}. Thus it seems that the stabilization of the cubic phase of Mo–C system by a small amount of Ti raises T_c.

In the case of niobium and tantalum carbides, the

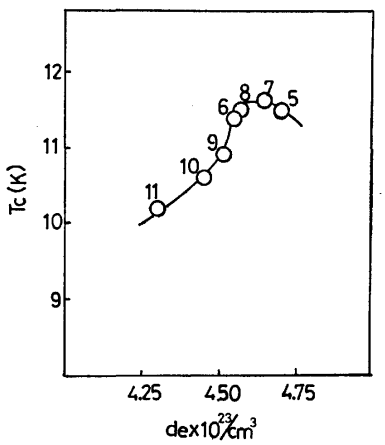

Fig. 4. T_c *vs.* de.
Numbers in this figure represent those of the sample in Table 1.

* In NbC formation by the carbonization of Nb_2O_5, the oxygen content in the product was 0.008 wt. % by radioactivation analysis.[11]

defficiecy of carbon site in the cubic lattice remarkably lowers T_c.[11,13] However, α-MoC_{1-x} and cubic MoC–TiC solid solution which are nonstoichiometric show high superconducting transition temperature. The relation between T_c and the electron density (de)** [14] of cubic Mo–Ti–C system is shown in Fig. 4. The addition of Ti to Mo–C system changes the electron density of the cubic lattice. T_c was maximum at about $4.6\times10^{23}/cm^3$ of de. The tendency is similar to that for various NaCl type compounds.[15,16]

The oxygen contained in the carbide or nitride in a small amount lowers T_c.[15] The oxygen content of the products formed in this study was found to be small. Thus it seems that T_c of Mo–C and Mo–Ti–C systems is affected by the crystal structure and the electron density.

The authors wish to thank Professor N. Kitamura and Mr. Y. Inada, Department of Physics, Aoyama Gakuin University, for their suggestions as regards the superconducting transition temperature measurement.

** The electron density was defined as

$$de = \frac{p\sum c_i N_i}{a^3}$$

where p is the number of atoms per unit cell, c_i and N_i are the fractional concentration and the valence electron of ith component, respectively, and a is the lattice parameter.
