One of these reactions is a ring-opening reaction at C-2 in the pyrimidine of the purine ring to give AICA-riboside. The cleavage has been found to occur predominantly at C-2 rather than at the glycosyl bond at pH 10. Shaw[1] and Montgomery *et al.*[2] have reported that the N-1 substitution of inosine makes it susceptible to a nucleophilic attack of a hydroxide ion at C-2 in alkali, while they considered that inosine itself is extremely stable to alkali.[3] Therefore, what the present author found is somewhat contradictory to their considerations. A brief account of the present work has already appeared elsewhere.[4]

It was once considered, without actual isolation and identification, that purine ribonucleosides undergo an attack by the hydroxide ion at C-8, resulting in the opening of the imidazole ring without the hydrolysis of the *N*-glycosyl bond. For instance, 5-amino-4-ribosylaminopyrimidine is considered to be formed from 9-β-D-ribofuranosylpurine,[5] and also a reaction product, from 7-[β-(*N*-methyl-*N*-4-formylphenylamino) ethyl] guanosine.[6] It is considered that whether the ring-opening reaction takes place at C-2 or at C-8 depends upon the nature of the purine ribosides.

Another remarkable reaction in an alkaline solution would be an isomerization in the ribose moiety to give mainly 9-β-D-ribopyranosyl hypoxanthine. Although an isomerization of the riboside has been shown for aniline riboside[7] in alcohol, no such isomerization has yet been reported in the literature for usual ribonucleosides. This is probably because the *N*-glycosyl bond is labile in the usual nucleosides, so that this bond is cleaved before the isomerization takes place. On the other hand, for an abnormal ribonucleoside, such as pseudouridine, which involves the C-C glycosyl bond in the molecule, the isomerization has been found in acid and alkali.[8] This is probably because the C-glycosyl bond is stable. 9-β-D-Ribopyranosyl hypoxanthine has been obtained by Baddiley *et al.*[9] by the deamination of the 9-β-D-ribopyranosyl adenine which had been synthesized from 4,6-diaminopyrimidine and D-ribose.

Results and Discussion

The three reactions found in the action of alkali on inosine are summarized in Fig. 1. The results of the paper chromatography of the reaction mixture are shown in Table 1. The spots were revealed by the color development of diazotizable amine and by UV absorption. The two spots on the paper chromatogram, named X_1 and Y in Table 1, were coincident with

Y: 9-β-D-Ribopyranosyl hypoxanthine, I: Inosine, X_1: AICA-riboside, H: Hypoxanthine, (a) water, (b) 0.004 M NH_4Cl, (c) 0.01 M NH_4OH, (d) 0.05 M NH_4OH, (e) 0.1 M NH_4OH.

those of AICA-riboside and 9-β-D-ribopyranosyl hypoxanthine respectively. They were later identified by isolation through column chromatography using Dowex 50 W (Fig. 2).

The analytical data, the UV spectrum and the melting point of X_1 agreed with those reported for AICA-riboside by Greenberg and Spilman.[10] The X-ray diffraction data agreed with those of authentic AICA-riboside (Table 2).

On the other hand, the melting point (253 °C, decomp., uncorrected) of Y agreed with that (259—260 °C decomp., only available datum) reported for 9-β-D-ribopyranosyl hypoxanthine by Baddiley.[9] Elementary analysis data supported the assumption that Y was 9-β-D-ribopyranosyl hypoxanthine. The acid hydrolysis of Y gave two components, hypoxanthine and D-ribose. The fact that the UV spectrum of Y is similar to that of inosine indicated that the glycosyl bond of Y was attached at N-9. Therefore, Y may be considered to be 9-ribosyl hypoxanthine. By examining the periodate oxidation, the ring structure of Y

was assumed to have a pyranosyl form; the slow velocity on acid hydrolysis as compared with inosine supported this assumption. (Ribopyranosyl adenine has been known to be hydrolyzed by acid slower than ribofuranosyl adenine.[11]) The optical rotation data are shown in Table 3, along with some available data on adenosine derivatives. As β-pyranosyl adenine has about one-half the value of β-furanosyl adenine, Y also showed about one-half the value of inosine (β-furanoside). Thus, it is very likely that Y is 9-β-D-ribopyranosyl hypoxanthine. The X-ray diffraction patterns of Y were obtained in two forms (Table 2). One of the forms seems to be unstable (named the α-form) and to be changed into another stable form (named the β-form) during storage. The crystals of the α-form were obtained on the first experimental run; afterward they were never obtainable in several succeeding experimental runs. These facts suggest that there is a large energy difference between the two crystal forms.

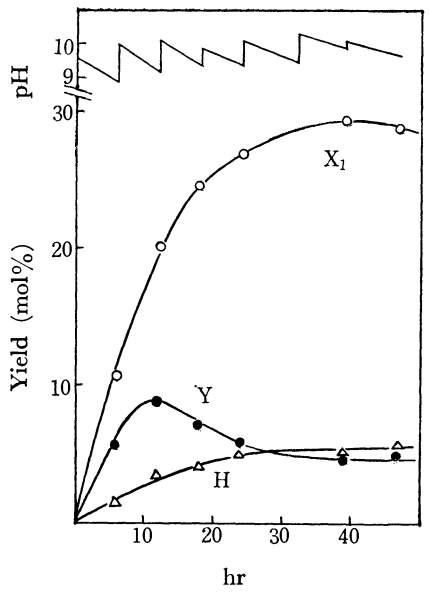

Fig. 3. Dependence of the yield of three major products on the reaction period in alkaline treatment of inosine at 130 °C (pH between 10 and 9).

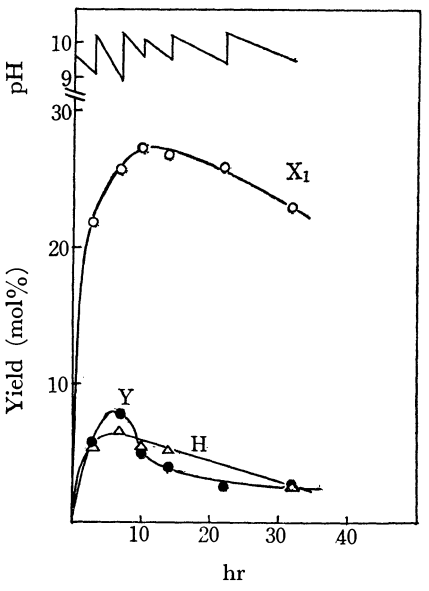

Fig. 4. Dependence of the yield of three major products on the reaction period in alkaline treatment of inosine at 150 °C (pH between 10 and 9).
X_1(○): AICA-riboside, Y(●): 9-β-D-Ribopyranosyl hypoxanthine, H(△): Hypoxanthine

In the alkaline treatment of inosine, the dependence of the yield of the three major UV-absorbing products on the reaction time is shown in Figs. 3 and 4. When the pH's of the solutions were kept between 9 and 10, the maximum yield of AICA-riboside reached 28—30% and that of 9-β-D-ribopyranosyl hypoxanthine, 8—9% (that of hypoxanthine was 6—7%). The relative amount of the yield was found to be independent of the temperature in the 130 °C—150 °C range. The reaction time for the maximum yield, however, depends on the temperature. The higher the temperature, the shorter was the reaction period needed to give the maximum yield of both compounds. The amounts of the three major products (including hypoxanthine) all decreased when too long a reaction period was employed. This fact suggested that a further degradation occurs into simple compounds which have no more UV-absorption.

Among the minor reaction products of the alkaline treatment of inosine, X_2 in Table 1 is considered to be 5-amino-4-imidazolecarboxamide (AICA) on the basis of its UV spectrum, the characteristic orange color caused by the NBDF reagent,* and the R_f value on the paper chromatogram (compared with the authentic standard of AICA). Undoubtedly AICA is obtained by a base-catalyzed hydrolysis at the glycosyl bond of AICA-riboside. AICA may be also obtainable by a base-catalyzed ring-opening reaction at C-2 in the pyrimidine ring of hypoxanthine (Fig. 1). In an acid solution AICA has been obtained from hypoxanthine both in the presence of zinc[12] and in its absence.[13] In this report the AICA formation from hypoxanthine in 0.4 M NaOH at 150 °C is shown (Table 4) in a yield of 30%, corresponding with the reaction period of 4 hr. Under these conditions, the original hypoxanthine remained 52%, though 99% of the hypoxanthine has been reported by Albert and Brown[14] to remain unreacted in 10 M NaOH at 100 °C for 1 hr.

A ring-opening reaction at C-2 in the pyrimidine section of the purine ring was also postulated for 5'-inosinic acid to give 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide-5'-monophosphate (AICA-ribotide) on the basis of a characteristic color reaction found by the NBDF reagent and a comparison of its R_f value with that of authentic AICA-ribotide (Table 5). It should be pointed out here that, for the purpose

* See Experimental Section.

of obtaining AICA-ribotide through the ring-opening at C-2, Shaw[1c] made the N-1 substitution of isopropylidene-inosine-5′-di(*p*-nitrophenyl)phosphate and left out the direct cleavage of inosinic acid. Also, Magrath and Brown[15] reported a ring-opening reaction at C-8 in the imidazole section of the purine ring on 9-β-D-ribofuranosylpurine-5′-phosphate in dilute aqueous alkali.

Guanosine and adenosine were subjected to alkaline treatment under the same conditions as those used for inosine. By the NBDF reagent, however, no compounds with the ring opened at C-2 were detected on the chromatogram. The amino group at the 2 position of guanosine probably interferes with the approach of the hydroxide ion and prevents its attack at C-2. In adenosine, on the other hand, the amino group at the 6 position may increase the electron density at C-2, and this would prevent a nucleophilic attack at C-2; the attack may take place, however, at C-8.[3] However, it is known that the alkaline treatment of adenosine causes some deamination, thus giving inosine,[3] so that it may be expected that a little AICA-riboside can be obtained, through inosine. It may need longer reaction period than that in the present study. The characteristic spots corresponding with β-pyranoside in the case of inosine were detected in both nucleosides with UV light on the chromatogram. The mechanism of the alkaline isomerization of these usual ribonucleosides including inosine is expected to occur through an intermediate of the oxide anion, whose negative charge is located on one of the oxygen atoms in the ribose moiety. Such an intermediate, *i. e.*, a mono oxide anion in which an electron is shared by the ring oxygen and the 5′-oxygen in the ribose moiety, is suspected to induce the formation of β-pyranoside. However, if the case of pseudouridine, examined by Chambers *et al.*[8a] is taken into consideration, the concomitant formation of the α-anomer can be expected in the present experiments. The α-anomer was not isolated here, probably because too little of it was formed to be perceived in this brief period of detection. In this respect, detailed experimental results and a discussion will be given in a later paper.

Experimental

Material and Equipment. Inosine, hypoxanthine, disodium 5′-inosinic acid, adenosine, and guanosine crystals, all indicated free from any impurities by paper chromatography, and the authentic standard samples of AICA, AICA-riboside, and AICA-ribotide were all prepared by the Ajinomoto Co., Inc. The ultraviolet absorbance was measured with a Hitachi 139 spectrophotometer, and the pH's of the solutions were measured at room temperature with a Toa Dempa pH meter HM-5A. Automatic Polarimeter Bendix-NPL 143-A was used for the measurement of the optical rotation. The X-ray powder diffraction patterns were obtained by means of a Rigaku Denki X-ray diffractometer.

Paper Chromatography. One-dimensional ascending paper chromatography was carried out on Toyo-Roshi No. 51A, the following two solvent systems being used: Solvent A, *n*-butanol-acetic acid-water (4 : 1 : 1); Solvent B, distilled-*i*-butylic acid-*n*-butanol-28% ammonia aq.-water (36 : 30 : 3 : 31). The papers were developed thrice if necessary for the complete separation of the components on the chromatogram. The components of the reaction mixture were detected on the paper by two different methods: (a) absorption in ultraviolet light was used to detect the ultraviolet absorbing compounds, (b) color development with NBDF reagent was used to detect the diazotizable amines. The NBDF reagent was prepared by an addition of 100 mg of *p*-nitrobenzenediazonium fluoroborate to 100 ml of 2 M acetic acid.

Alkaline Treatment on Inosine. Inosine (0.6 g) was dissolved in 20 ml of 0.1 M NaOH and heated in a sealed stainless steel tube at 120 °C on an oil bath for 16 hr. The pH of the solution was varied from 9.6 to 9.1 during the reaction period. The reaction mixture was paperchromatographed in Solvent A three times (Table 1).

Isolation of Y (9-β-D-ribopyranosyl hypoxanthine) and X_1 (AICA-riboside) in the Crystalline Form. Potassium hydroxide (4.1g) and inosine (20 g) were dissolved in 45 ml of water, and the mixture was heated in a sealed tube at 130 °C for 6 hr. The pH of the solution was varied from 10.1 to 9.5 during the reaction period. A granule of potassium hydroxide was added to correct the pH of the solution to 10.0. Then, the reaction was continued for 6 hr more. The reaction mixture was acidified (pH 2) by 10 ml of conc. HCl and applied to a column (95 cm × 3.7 cm) of Dowex 50W X-8 (H^+-form, 50—100 mesh, 1 l). The column was developed with 13 l of water and 36 l of 0.004 M NH_4Cl, 36 l of 0.01 M NH_4OH, 6 l of 0.05 M NH_4OH, and 23 l of 0.1 M NH_4OH in turn. The fraction was collected every 1 l. The optical densities of the fractions at 250 nm were measured. The first and the second UV-absorbing peaks appeared in the fractions with NH_4Cl. The first peak contained Y, and the second, inosine. The third peak appeared in the fractions with 0.1 M NH_4OH; it was found to be a mixture of a large amount of X_1 and a little hypoxanthine. The fractions between No. 17 and No. 25 (9 l) in the first peak were neutralized with ammonia and concentrated *in vacuo* until 20 ml. When the concentrated solution was cooled, crystallization occurred. The crystals were washed with cold 50% aqueous methanol and weighed (1.5 g). Recrystallization from water gave 0.7 g (dry) of plate-like crystals (Y). The fractions between No. 101 and No. 107 (7 l) in the third peak were concentrated *in vacuo* until 90 ml. The concentrated solution was neutralized (pH 7) with a drop of dil. HCl and cooled for precipitation. After the removal of the precipitated fine powder of hypoxanthine, the filtrate was concentrated *in vacuo* until 5 ml and then cooled again. The precipitated powder crystals were triturated with water and the insoluble parts (hypoxanthine) removed by filtration. The filtrate was evaporated in a desiccator; thus some large cubic crystals and fine powder crystals different in appearance from each other were obtained. On filtration with a fiber net of 50 mesh, the fine powder crystals were passed out through the net with the mother liquor. The large cubic crystals remaining on the net were collected and recrystallized from water. The filtration with a fiber net was repeated again; subsequent recrystallization gave 1.4 g of large cubic crystals (X_1) which were free from any contaminant on the paper chromatogram.

Characterization of AICA-riboside. The large cubic crystals (X_1) were analyzed as follows. (a) Paper chromatography. The R_f agreed with the authentic standard in Solvent A; 0.64 (thrice developed). (b) UV spectrum. Agreed with the data of Greenberg and Spilman in 0.1 M HCl and in 0.1 M NaOH. (c) Melting point. Found; 213 °C (decomp.) uncorrected. (d) X-ray diffraction data (Cu K_α). Identical with the authentic standard under a diffraction angle of 30 degrees (2θ).

Characterization of 9-β-D-Ribopyranosyl Hypoxanthine. The

plate-like crystals (Y) were analyzed as follows. (a) Paper chromatography. The R_f was a little lower than that of inosine in Solvent A [0.43 (thrice-developed)] and the same as that of inosine in Solvent B [0.55 (twice-developed)]. (b) UV spectrum. The same behavior as inosine in 0.1 M HCl, H_2O, and 0.1 M NaOH. (c) Elementary analysis. Agreed with inosine or 9-β-D-ribopyranosyl hypoxanthine. Found: C, 44.49; H, 4.57; N, 21.15%. Calcd for $C_{10}H_{22}O_5N_4$: C, 44.78; H, 4.51; N, 20.89%. (d) Components of acid hydrolysate. In 1 ml of water 10 mg of crystals were dissolved, and then 1 ml of conc. HCl was added. The mixture was heated at 80 °C for 1 hr and chromatographed in Solvent A. Hypoxanthine (R_f 0.29) was revealed by UV light and D-ribose (R_f 0.25), by periodate oxidation, by Ohkuma.[16] (e) Periodate oxidation. The Fleury-Lange[17] method was employed for a 1% solution of crystals. The consumptive mole number of periodate was 1.92, which could be regarded as nearly 2. (f) Velocity of acid hydrolysis. In 1 ml of 0.1 M HCl, 10 mg of crystals were dissolved, and then the mixture was heated at 85 °C for 1 hr. Inosine was also used for control. Paper chromatogram in Solvent A showed two UV-absorbing spots, hypoxanthine (R_f 0.40) and the original compounds (R_f 0.22). The spots were cut off and eluted with 0.1 M HCl, and the absorbance of the eluate was measured at 250 nm. The absorption ratio of hypoxanthine to the original compounds was 12 : 88 for these plate crystals and 90 : 10 for ionsine. (g) Optical rotation. Found: $[\alpha]_D^{25}$ −26.5° (*c*, 1 water). (h) Melting point. 252—254 °C (decomp.) uncorrected. (i) X-ray diffraction data (Cu K_α). The measurements were carried out under a diffraction angle of 30 degrees (2θ).

Dependence of the Yields of the Three Major Reaction Products on the Reaction Period on the Alkaline Treatment of Inosine. Potassium hydroxide (7.5 g) and inosine (40 g) were dissolved in 90 ml of water to obtain a clear alkaline solution (pH 9.6). After the solution had been heated in a sealed tube at 130 °C or 150 °C for an appropriate period of several hours, it was cooled quickly and sampled (1 ml). The pH's of the solutions were usually decreased to some extent. A granule of potassium hydroxide was added to correct the pH to about 10, and the solution was again heated for several hours; these treatments were repeated many times over. Aliquots of 1 ml samples were diluted to 25 ml, and 10 μl of the diluted solution was spotted on the paper for chromatography in Solvent A (thrice-developed). Ten microliters of a 1% solution of three compounds, hypoxanthine, AICA-riboside, and inosine (used in place of 9-β-D-ribopyranosyl hypoxanthine), were also spotted on the same paper as the standard. The UV-absorbing spots on the chromatogram corresponding to the three compounds were cut off, together with their appropriate blanks, and eluted with 0.1 M HCl, and the absorbances of the eluates were measured at 267 nm for AICA-riboside and at 250 nm for the hypoxanthine derivatives. The concentration of each component in the reaction mixture was calculated from the absorbance compared with that of the standard references. The yields of the three compounds in mol% were computed from the known concentration of the initial solution.

Identification of X_2 as AICA. The R_f of the X_2 spot on the chromatogram shown in Table 1 was identical with that of the authentic reference sample of AICA. The spot was cut off and eluted with water, and the spectra of the eluate were measured in 0.1 M HCl (λ_{max} 267 nm and 240 nm; λ_{min} 250 nm and 220 nm) and in 0.1 M NaOH (λ_{max} 278 nm and λ_{min} 240 nm). An orange color development which was characteristic of AICA was found on the paper with the NBDF reagent.

Formation of AICA from Alkaline-treated Hypoxanthine. Hypoxanthine (0.8 g) was dissolved in 20 ml of 0.4 M NaOH and heated in a sealed tube at 150 °C for 4 hr. The pH of the solution varied from 11.8 to 10.6 during the reaction period. The reaction mixture showed two major UV-absorbing spots on the paper; one was estimated to be AICA, and the other, unreacted hypoxanthine. A clear separation of the two spots was achieved in Solvent B (AICA, R_f 0.71; hypoxanthine, R_f 0.50); three developments were required in Solvent A (AICA, R_f 0.83; hypoxanthine, R_f 0.74). The R_f value, a characteristic orange color development with the NBDF reagent, and the behavior of the UV spectra in acid and alkali were all in accordance with the authentic reference sample of AICA and also with the X_2 described before. The spots on the paper were cut off, together with their appropriate blanks, and eluted with 0.1 M HCl, and the absorbances of the eluates were measured at 267 nm for AICA and at 250 nm for hypoxanthine. The yield of AICA was determined to be 30%, and that of the unreacted hypoxanthine, 52%.

Formation of AICA-ribotide from 5′-Inosinic Acid. Disodium 5′-inosinic acid crystals (0.28 g) were dissolved in 20 ml of water and heated in a sealed tube at 120 °C for 8 hr. The pH value of the solution was varied from 7.8 to 7.2 during the reaction period. The chromatography with UV light of the resultant solution in Solvent A revealed the formation of as much inosine (R_f 0.23) as of unreacted 5′-inosinic acid (R_f 0.07), along with other minor reaction products. On the spot corresponding with 5′-inosinic acid, a pale purple-red color development was found with the NBDF reagent. The R_f value of the authentic AICA-ribotide was superimposed on 5′-inosinic acid in Solvent A.

Alkaline Treatment on Adenosine and Guanosine. Adenosine (0.1 g) was added to 20 ml of 0.008 M NaOH and heated in a sealed tube at 130 °C for 3 hr. The reaction mixture showed three UV-absorbing spots on the chromatogram in Solvent A: R_f 0.6 Adenine; R_f 0.47 Unreacted adenosine; R_f 0.34 presumably pyranoside. Nothing of the colored spot with the NBDF reagent was detected. Guanosine (0.5 g) was added to 20 ml of 0.038 M NaOH, and the mixture was heated in a sealed tube at 130 °C for 8 hr. The pH of the solution was varied from 11.0 to 9.8. The reaction mixture showed five UV-absorbing spots on the chromatogram in Solvent A (thrice developed): R_f 0.7 Guanine; R_f 0.54 Unreacted Guanosine; R_f 0.43 Presumably pyranoside; R_f 0.34 Unknown; R_f 0.27 Unknown. Nothing of the spot with the NBDF reagent was detected.

The author wishes to thank Mr. Kentaro Hara and Mr. Takashi Sato for their technical assistance, and also Dr. Akihiro Yamazaki for his interest in this work. He is also indebted to Prof. Dr. Masamichi Tsuboi for reading the manuscript.

Reactions of 2-Cyano-2-dimethylamino-1,3-dithiolane[1]

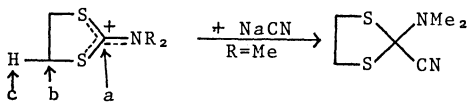
Kazuhisa HIRATANI, Takeshi NAKAI, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received October 23, 1973)

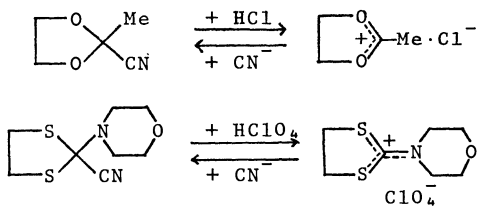
The reactions of 2-cyano-2-dimethylamino-1,3-dithiolane (**2**) with electrophiles (organic halides and perchloric acid) and nucleophiles were investigated. It was found that **2** dissociated partially to 2-dimethylamino-1,3-dithiolan-2-ylium (**1**) and cyanide ions in polar solvents. In the reactions of **2** with electrophiles, nitriles were obtained along with the formation of salts of **1**. The reactions of **2** with nucleophiles were studied since **2** was expected to be a precursor of the cation **1**. In some cases, its reactivity differs from that of perchlorate of **1**. A mechanism was discussed in which the cyanide ion might behave as a base to abstract a proton from the nucleophiles.

In a previous paper[2] it was reported that 2-dialkylamino-1,3-dithiolan-2-ylium ions (**1**) were ambident electrophiles capable of undergoing reactions with nucleophiles at three sites, a, b, and c. In the case of the reaction of perchlorate of **1** (R=Me) with cyanide ion as a nucleophile, 2-cyano-2-dimethylamino-1,3-dithiolane (**2**) was obtained in a good yield.[3] In this work the reactions of **2** with various electrophiles and nucleophiles have been studied.



1 **2**

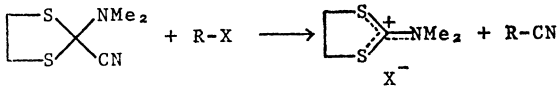
Little information has been given on the reactions of α-cyanoacetal and α-cyanoorthoester derivatives. It has only been reported that treatment of 2-cyano-2-methyl 1,3-dioxolane[4] and 2-cyano-2-morpholino-1,3-dithiolane[5] with acids gives 2-methyl-1,3-dioxolan-2-ylium ion and 2-morpholino-1,3-dithiolan-2-ylium ion, respectively.



Thus, compound **2** is expected to be capable of cyanogenating electrophiles along with the formation of the cation **1**. On the other hand, **2** is expected to behave as a precursor of **1** in the reaction with nucleophiles. The limitation of the use of **2** in this reaction was also studied by comparing the reactivity of **2** with that of perchlorate of **1**.

Results and Discussion

Reactions of 2 with Electrophiles. The reactions of **2** with the following electrophiles were studied: methyl iodide, *n*-butyl iodide, benzyl bromide, benzoyl chloride, phenacyl bromide, and perchloric acid. Firstly, in order to find the influence of solvent on the reactions of **2** with electrophiles, the reaction of **2** with methyl iodide was carried out in ethyl ether, acetonitrile, and nitromethane[6] to obtain iodide of **1** in all cases. It was found that the yield of iodide of **1** was higher in polar solvents (acetonitrile and nitromethane) than in nonpolar one (ethyl ether). Thus, the reactions of **2** with other electrophiles were carried out in polar solvents. The yields of salts of **1** and nitrile **3** obtained simultaneously are summarized in Table 1. These products were found to be identical with authentic samples.[7]



2 **1** **3**

Thus, electrophile can react with **2** giving nitrile along with the formation of salt of **1**. It should be noted that **2** is useful as a precursor of cyanide ion which is soluble in organic solvents and product **3** can readily be isolated from another product, salt of **1**.

The fact that the yield of salts of **1** increases with the increase in polarity of solvent as observed in the case of the reaction of **2** with methyl iodide suggests that **2** dissociates first to cation **1** and cyanide ion, and then cyanide ion attacks methyl iodide giving acetonitrile and iodide of **1**. In order to investigate the influence of solvents on the dissociation of **2** to cation **1** and cyanide ion, the UV spectrum of **2** was measured in the following solvents: cyclohexane, tetrahydrofuran, chloroform (containing 1% ethanol), 99% etha-

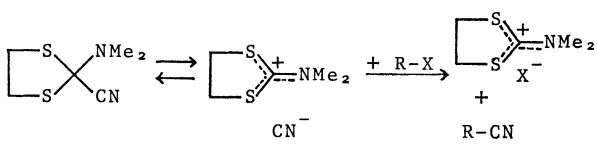
a) Containing 1% ethanol. b) The apparent molecular extinction coefficient at absorption maxima. c) Shoulder band.

nol, acetonitrile, and methanol (Fig. 1). The absorption maxima (λ_{max}) and the molecular extinction coefficients (ε) of **2** and perchlorate of **1** in various solvents are given in Table 2. The absorption band (λ_{max}~250 nm) in Fig. 1 is evidently assigned to the cation **1** since salts (iodide, perchlorate, and tetrafluoroborate) of **1** show the same absorption band as that of **2** in the same solvents. It was observed that the values of the apparent molecular extinction coefficient (ε) at λ_{max} (~250 nm) of **2** were larger in polar solvents than in nonpolar solvents. The values of apparent ε at λmax of **2** in acetonitrile and methanol are smaller than those of perchlorate of **1** in the same solvents (Table 2). Thus it can be concluded that **2** dissociates partially to the cation **1** and cyanide ion in polar solvents. The reactions of **2** with electrophiles can be interpreted by the following scheme.



Reactions of 2 with Nucleophiles. Compound **2**, soluble in organic solvents, is expected to be useful as a precursor of cation **1** since **2** can dissociate partially to cation **1** and cyanide ion in polar solvents. The reactions of **2** with the following nucleophiles were studied: aniline, *p*-nitroaniline, 2,4-dinitroaniline, benzamide, *p*-toluenesulfonylamide (tosylamide), phenylhydrazine, *p*-toluenesulfonylhydrazide (tosylhydrazide), sodium thiophenoxide, and sodium *N*,*N*-dimethyldithiocarbamate. The difference in the reactivity of **2** from that of perchlorate of **1** was also investigated.

The equimolar reaction of **1** with nucleophiles was carried out in benzene or acetonitrile at refluxing temperature for 5 hr giving the products shown in Table 3. In the cases of aniline, *p*-nitroaniline, 2,4-dinitroaniline, and benzamide, the reactants were recovered unchanged. Treatment of **2** with tosylamide, phenylhydrazine, and tosylhydrazide gave 2-tosylimino-1,3-dithiolane, 2-phenylhydrazo-1,3-dithiolane, and 2-tosylhydrazo-1,3-

Table 3. Reactions of 2 with nucleophiles

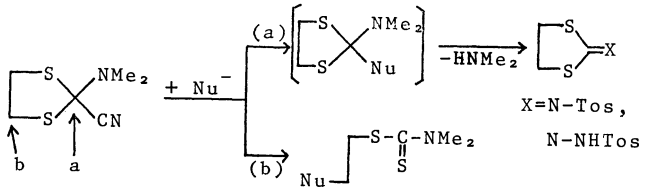
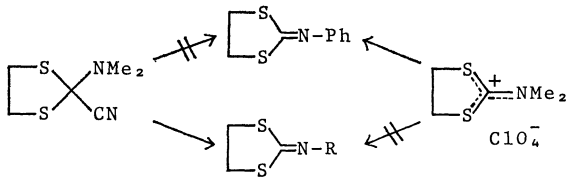
dithiolane, respectively, in moderate yields (path a). On the other hand, treatment of **2** with sodium thiophenoxide and sodium *N,N*-dimethyldithiocarbamate gave β-(phenylthio)ethyl-*N,N*-dimethyldithiocarbamate and ethylenebis(*N,N*-dimethyldithiocarbamate), respectively (path b). The structures of the products were elucidated by elemental analysis and spectroscopic methods. The yield and melting point of the products are summarized in Table 3.



2

The salt of **1** reacts with aniline, sodium thiophenoxide, and sodium *N,N*-dimethyldithiocarbamate giving 2-phenylimino-1,3-dithiolane, β-(phenylthio)ethyl-*N,N*-dimethyldithiocarbamate, and ethylenebis(*N,N*-dimethyldithiocarbamate), respectively.[2] On the other hand, perchlorate of **1** does not react with tosylamide and tosylhydrazide at all.

From these results it was found that i) compound **2** reacted with some nucleophiles along with the elimination of cyanide ion; ii) it reacted with nucleophiles at two sites, a and b, in formula (**2**); iii) in the case of sodium thiophenoxide and sodium *N,N*-dimethyldithiocarbamate as nucleophile, both **2** and perchlorate of **1** reacted with them giving the same products; and iv) **2** reacted with nucleophiles such as tosylamide and tosylhydrazide, with which perchlorate of **1** did not react, but it did not react at all with nucleophiles such as aniline with which perchlorate of **1** reacted to give 2-phenylimino-1,3-dithiolane.[2]

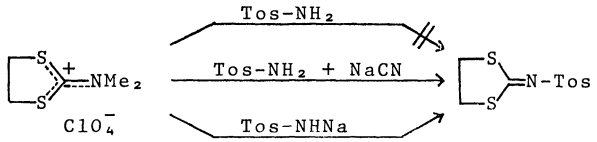


R = Tos, NHTos

It is to be noted that the reactivity of **2** differs from that of salt of **1**. It is considered that cyanide ion participates in the reaction of **2** with nucleophiles. In order to clarify the difference in reactivity between **2** and salt of **1**, the following reactions were attempted with tosylamide and tosylhydrazide as nucleophiles.

The equimolar reaction of **2** with tosylhydrazide at refluxing temperature for 5 hr in a polar solvent (acetonitrile) and a nonpolar solvent (benzene) gave 2-tosylhydrazo-1,3-dithiolane in 47 and 28% yields, respectively. Under the same conditions, the reaction of **2** with tosylamide in acetonitrile and benzene gave 2-tosylimino-1,3-dithiolane in 70 and 47% yields, respectively (Table 3). The reaction seems to be more favorable in a polar solvent than in a nonpolar one.

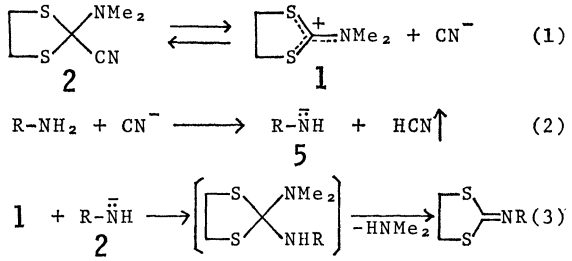
The reactants were quantitatively recovered unchanged in the reaction of perchlorate of **1** with tosylhydrazide at refluxing temperature for 5 hr in acetonitrile and dimethylformamide and also in the case of tosylamide in acetonitrile. The reaction of salt of **1** with tosylamide including sodium cyanide was attempted. The reactions in the presence of equimolar, 0.6 molar, and 0.4 molar of sodium cyanide at refluxing temperature for 5 hr in acetonitrile gave 2-tosylimino-1,3-dithiolane in 34, 25, and 14% yields, respectively. The reaction of salt of **1** with sodium tosylamide prepared by the treatment of tosylamide with sodium hydride in tetrahydrofuran, at refluxing temperature for 5 hr in the mixture of acetonitrile and tetrahydrofuran also gave 2-tosylimino-1,3-dithiolane in 17% yield.



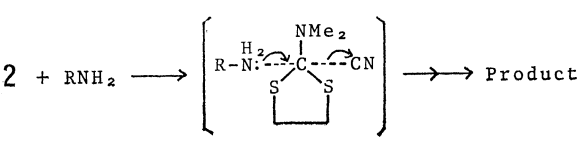
1

It can thus be concluded that cyanide ion evidently participates in the reaction of **2** with tosylamide. The result of the reaction of salt of **1** with sodium tosylamide suggests that cyanide ion behaves as a base in the reaction of **2** with tosylamide to abstract a proton from the amide. This assumption may be supported by the fact that compound **2** tends to react with tosylamide ($pK_a=10.2$)[8] which has a smaller basicity than aniline ($pK_a=27$).[9]

The reaction of **2** with tosylamide and tosylhydrazide can be interpreted by the following processes: i) compound **2** dissociates partially to 2-dimethylamino-1,3-dithiolan-2-ylium ion (**1**) and cyanide ion in solution (Eq. 1); ii) cyanide ion abstracts a proton from the nucleophiles to give anion **5** and hydrogen cyanide (Eq. 2); and iii) the cation **1** reacts with the anion **5** to afford the corresponding product (Eq. 3). An important point in this reaction seems to be that the hydrogen cyanide formed is removed from the reaction mixture to displace the equilibrium (Eq. 2).



An alternative formation of the product arising from the direct reaction of **2** with nucleophiles ($R-NH_2$) *via* S_N2 type mechanism might be disregarded since the reaction was slow in nonpolar solvent and nucleophiles having small nucleophilicity reacted preferentially with **2**.



Thus, it was proved that cyanide ion behaved as a base, and **2** could react with nucleophiles having small nucleophilicity with which salt of **1** did not react.

Experimental

General. All melting and boiling points are uncorrected. IR and UV spectra were recorded with Hitachi EPI-S2 and EPS-3T spectrophotometers, respectively. NMR spectra were obtained with Japan Electron Optics JNN PS-100 and MH-60 spectrometers. Chemical shifts are given in ppm from tetramethylsilane as an internal standard.

2-Cyano-2-dimethylamino-1,3-dithiolane (2). Dithiolane **2** was prepared by the procedure previously reported:[2] bp 119—121 °C/2.0 mmHg, yield 74%.

Reaction of 2 with Methyl Iodide. a) In Acetonitrile. In a 50-ml round-bottomed flask equipped with reflux condenser was placed 0.58 g (3.3 mmol) of **2** and 2.0 g (14 mmol) of methyl iodide in 20 ml of acetonitrile (MeCN). The solution was stirred for 4 hr at 40 °C. After MeCN was removed by distillation, the residue (white precipitates) was washed with ether and dried *in vacuo*. Recrystallization of the precipitates from ethanol gave 0.32 g (35%) of 2-dimethylamino-1,3-dithiolan-2-ylium iodide; mp 191—192 °C. NMR (DMSO-d_6); δ 3.47(s, 6H, NCH_3) and 3.98 (s, 4H, SCH_2).

b) In Ether. In a similar manner, the reaction of **2** (0.58 g) with methyl iodide (2.0 g) in 20 ml of ether at refluxing temperature for 4 hr gave 0.05 g (5%) of iodide of **1**.

c) In Nitromethane. In a similar manner, the reaction of **2** (1.9 g) with methyl iodide (4.0 g) in 50 ml of $MeNO_2$ at room temperature for 2 days gave 1.6 g (53%) of iodide of **1**.

Reactions of 2 with Other Electrophiles. In a similar manner, the reaction of **2** with equimolar electorphile under the conditions shown in Table 1 gave salt of **1** in a moderate yield along with nitrile **3**. The products were identified by spectroscopic methods and comparison of their physical properties with those of authentic samples.

Reaction of 2 with Perchloric Acid. To a solution of **2** (1.74 g, 10 mmol) in 20 ml of ethanol with stirring at room temperature was added dropwise 70% aqueous perchloric acid (1.5 g, 15 mmol), and the solution was stirred for 1 hr at room temperature. The precipitates formed were filtered off and washed with cooled ethanol. 2.0 g (80%) of perchlorate of **1** was obtained and recrystallized with ethanol. The IR spectrum of the product was in complete agreement with that of an authentic sample.

Reaction of 2 with p-Toluenesulfonylhydrazide. In a 100-ml flask was placed a solution of 1.74 g (10 mmol) of **2** and 1.86 g (10 mmol) of *p*-toluenesulfonylhydrazide (tosylhydrazide) in 40 ml of MeCN. The reaction mixture was refluxed for 8 hr. After removal of MeCN, a small amount of chloroform was added to the liquid residue. The white precipitates were filtered off and recrystallized from benzene giving 0.45 g of 2-tosylhydrazo-1,3-dithiolane. The filtrate was subjected to chromatography on silica gel with chloroform. The first eluent gave 0.24 g of a pale yellow liquid (unidentified). The second eluent gave 0.23 g of 2-tosylhydrazo-1,3-dithiolane:[10] total yield 0.68 g (47%); mp 193—195 °C. UV (EtOH): λ_{max} 225 and 254 (sh.)nm; NMR ($CDCl_3$): δ 2.30 (s, 3H, CH_3), 3.43 (s, 4H, $S-CH_2$), 7.22 (d, 2H, aromatic-H), 7.51 (d, 2H, aromatic-H), and 10.05 (s, 1H, N–H).

Found: C, 41.72; H, 3.99; N, 10.09%. Calcd for $C_{10}H_{12}NS_3O_2$: C, 41.67; H, 4.06; N, 9.92%.

In the case of benzene as solvent, 2-tosylhydrazo-1,3-dithiolane was obtained in 28% yield.

Reaction of 2 with Phenylhydrazine. In a similar manner, the reaction of **2** (0.35 g, 2.0 mmol) with phenylhydrazine (0.22 g, 2.0 mmol) in 20 ml of benzene at refluxing temperature for 5 hr gave 0.37 g (88%) of 2-phenylhydrazo-1,3-dithiolane which was isolated by means of column chromatography (alumina, chloroform) and recrystallized from ethanol: 90—92 °C (lit,[11] 91 °C). UV (EtOH): λ_{max}=242, 288, and 315 (sh.)nm; NMR ($CDCl_3$): δ 3.16—3.56 (m, 4H, $S-CH_2$), 6.53(s, 1H, N–H), and 6.70—7.30 (m, 5H, aromatic-H).

Found: C, 50.56; H, 4.95; N, 13.12%. Calcd for $C_9H_{10}N_2S_2$: C, 51.42; H, 4.76; N, 13.33%.

Reaction of 2 with p-Toluenesulfonylamide. a) In MeCN: In a similar manner, the reaction of **2** (0.58 g, 3.3 mmol) with *p*-toluenesulfonylamide (tosylamide) (0.57 g, 3.3 mmol) in 20 ml of MeCN at refluxing temperature for 5 hr gave 0.64 g (70%) of 2-tosylimino-1,3-dithiolane which was recrystallized from the mixture of benzene and cyclohexane; mp 121—123 °C (lit,[12] 126—127 °C). UV (EtOH): λ_{max}=228 and 268 nm; NMR ($CDCl_3$): δ 2.42 (s, 3H, CH_3), 3.58 (s, 4H, $S-CH_2$), 7.47 (d, 2H, aromatic-H), and 7.87 (d, 2H, aromatic-H).

Found: C, 44.56; H, 4.21; N, 5.43%. Calcd for $C_{10}H_{11}NO_2S_3$: C, 43.96; H, 4.03; N, 5.13%.

b) In Benzene: In a similar manner, the reaction of **2** (0.30 g, 1.7 mmol) with tosylamide (0.30 g, 1.7 mmol) in 20 ml of benzene at refluxing temperature for 5 hr gave 0.22 g (47%) of 2-tosylimino-1,3-dithiolane. The IR spectrum of the product was in complete agreement with that of an authentic sample.

Reaction of 2 with Sodium N,N-*Dimethyldithiocarbamate.* In a similar manner, the reaction of **2** (0.35 g, 2.0 mmol) with sodium *N,N*-dimethyldithiocarbamate (0.50 g, 2.8 mmol) in 20 ml of MeCN at refluxing temperature for 5 hr gave 0.09 g (17%) of ethylenebis(*N,N*-dimethyldithiocarbamate) which was recrystallized from ethanol giving colorless crystals, mp 187—190 °C (lit,[2] 188—189 °C). The IR spectrum was in complete agreement with that of an authentic sample.

Reaction of 2 with Sodium Thiophenoxide. In a similar manner, the reaction of **2** (0.35 g, 2.0 mmol) with sodium thiophenoxide (0.40 g, 3.0 mmol) in 20 ml of MeCN at refluxing temperature for 5 hr gave 0.43 g (84%) of β-phenylthioethyl-*N,N*-dimethyldithiocarbamate which was purified by means of column chromatography (alumina, $CHCl_3$) giving a pale yellow liquid. NMR (CCl_4): δ 3.15 and 3.35 (s, 6H, $N-CH_3$), 2.96—3.56 (m, 4H, SCH_2), and 6.94—7.44 (m, 5H, aromatic-H).

Reaction of Perchlorate of 1 with Tosylhydrazide. A mixture of **1** (2.48 g, 0.01 mol) and tosylhydrazide (1.86 g, 0.01 mol) in 40 ml of MeCN was refluxed for 8 hr. After removal of MeCN, the residual solid was dried (weight: 4.30 g). It was then poured into water and the white precipitates were filtered and dried *in vacuo*. The product (1.80 g) was identified to be tosylhydrazide by comparison of the IR spectrum with that of an authentic sample.

In a similar manner, the reaction of **1** with tosylhydrazide in dimethylformamide (DMF) was attempted. The reactants were recovered unchanged.

Reaction of Perchlorate of 1 with Tosylamide. The reaction of perchlorate of **1** (1.24 g, 5.0 mmol) with tosylamide (0.86 g, 5.0 mmol) in 20 ml of MeCN at refluxing temperature for 5 hr resulted in the recovery of perchlorate of **1** (1.16 g) and tosylamide (0.83 g).

Reaction of Perchlorate of 1 with Tosylamide and Sodium Cyanide. In a 50-ml round-bottomed flask equipped with reflux con-

denser was placed a solution of perchlorate of **1** (1.24 g, 5.0 ml), tosylamide (0.86 g, 5.0 mmol), and sodium cyanide (0.25 g, 5.0 mmol) in 20 ml of MeCN. After the solution was refluxed for 5 hr, the solvent was removed by distillation. The residue was subjected to chromatography on alumina with chloroform. The first eluent gave 0.46 g (34%) of 2-tosylimino-1,3-dithiolane. The second eluent contained 0.46 g of the starting material, tosylamide. The IR spectrum of the product was in complete agreement with that of an authentic sample.

In a similar manner, the reaction of perchlorate of **1** (1.24 g) with tosylamide (0.86 g) and sodium cyanide (0.15 g, 3.0 mmol) gave 0.34 g (25%) of 2-tosylimino-1,3-dithiolane. On addition of 0.10 g (2.0 mmol) of sodium cyanide, the product was obtained in 14% yield.

*Reaction of Perchlorate of **1** with Sodium Tosylamide.* To a suspension of sodium tosylamide prepared *in situ* by the treatment of 0.83 g (4.8 mmol) of tosylamide with 0.15 g of 50% sodium hydride in 50 ml of tetrahydrofuran, was added 1.24 g (5.0 mmol) of perchlorate of **1** in 20 ml of MeCN. The mixture was stirred at 60—70 °C for 5 hr. After removal of the solvents by distillation, water was added to the residue. White precipitates separated were filtered off and washed with a small amount of ether. 2-Tosylimino-1,3-dithiolane (0.23 g, 17%) was obtained and recrystallized from the mixture of benzene and cyclohexane. The IR spectrum of the product was in complete agreement with that of an authentic sample.

Synthesis and Reactions of 4-Dimethylsulfuranylidene-2,3-dioxotetrahydrofuran Derivatives

Katsuaki HAGIO, Naoto YONEDA, and Hisashi TAKEI*

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka 532

**Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received, November 5, 1973)

The cyclic sulfonium ylides, 4-dimethylsulfuranylidene-2,3-dioxotetrahydrofuran derivatives (**8**), were synthesized in good yields by reactions of methyl and ethyl dimethylsulfuranylidenepyruvates (**3** and **4**) with carbonyl compounds. The reactions of **8** with *p*-toluenesulfonyl chloride and benzoyl chloride gave 4-methylthio-3-(*p*-toluenesulfonyloxy)- and 4-methylthio-3-benzoyloxy-2-oxo-2,5-dihydrofuran derivatives respectively in high yields. The ylides (**8**) reacted with mercaptans to afford 4-substituted products (**14**—**16**), whereas, on the reactions with thiourea, the demethylation of the dimethylsulfonium group proceeded exclusively.

Recently, a number of carbonyl-stabilized sulfonium ylides have been synthesized and their properties studied.[1-3] These ylides are of interest because reactions using them provide useful methods for the syntheses of many organic compounds.[1,2,4,5] Among the synthetic methods of cyclic sulfonium ylides, the conversion of simple carbonyl-stabilized sulfonium ylides into cyclic sulfonium ylides, such as 3-dimethylsulfuranylidene-2,4,5-pyrrolidinetrione and 5-dimethylsulfuranylidene-2,6-diacetyl-2,6-dimethyl-4-oxo-1,3-dioxane, have been reported only by Howard[6] and Payne.[7]

In the course of the synthetic study of sulfonium ylides in our laboratory,[5] the cyclic sulfonium ylides, 4-dimethylsulfuranylidene-2,3-dioxotetrahydrofuran derivatives (**8**), were successfully synthesized by the reactions of methyl and ethyl dimethylsulfuranylidenepyruvates (**3** and **4**), and their reactivity was investigated.

Synthesis of 8. The sulfonium ylides, **3** and **4**, were prepared from the corresponding sulfonium bromides or picrates (**1** and **2**) by a procedure similar to that used for ordinary carbonyl-stabilized sulfonium ylides.[2] The use of stable sulfonium picrates (**1** and **2**, X=$(NO_2)_3C_6H_2O$) was advantageous for this conversion, since the corresponding bromides (**1** and **2**, X=Br)[8] were very hygroscopic and were less stable compounds which decomposed slowly upon exposure to air.

The treatment of **2** (X=$(NO_2)_3C_6H_2O$) with 1 equivalent of 50% aqueous sodium hydroxide and saturated potassium carbonate solution in methylene chloride gave ethyl dimethylsulfuranylidenepyruvate (**4**) as pale yellow hygroscopic crystals. The IR spectrum showed bands at 1720 and 1550 cm^{-1} attributable to the ester and the ylide carbonyl group[9] respectively. The NMR spectrum was consistent with the structure of **4**; a singlet at δ 4.68 (1H) for the methine proton and a singlet at δ 3.00 (6H) for the two methyl groups attached to the sulfonium group. In a similar way, **3** was prepared from the corresponding sulfonium salt (**1**) in a 64% yield. The treatment of **3** and **4** with picric acid in ethanol yielded the corresponding sulfonium picrates quantitatively.

The reactions of **3** and **4** with carbonyl compounds were carried out in expectation of the formation of 4-dimethylsulfuranylidene-2,3-dioxotetrahydrofuran derivatives (**8**) *via* the intermediate betaine (**6**), which would be cyclized by an intramolecular nucleophilic

attack of the alkoxide anion on the alkoxycarbonyl group.

The reaction of **4** with ethyl pyruvate proceeded at room temperature. However, an attempt to isolate the new sulfonium ylide directly from the reaction mixture failed. The addition of picric acid to the mixture gave yellow crystals (mp 142—143 °C (dec)), whose elemental analysis agreed with the expected picrate of **8a**. The IR spectrum showed the characteristic bands of a five-membered lactone and an ester at 1790 and 1775 cm^{-1}. The picrate in methylene chloride was treated with 50% aqueous sodium hydroxide to give 5-ethoxycarbonyl-4-dimethylsulfuranylidene-5-methyl-2,3-dioxotetrahydrofuran (**8a**) (mp 132—134 °C (dec)), which was then recrystallized from ethanol–ether. The ylide (**8a**) reverted to the picrate quantitatively by means of picric acid in ethanol. The IR spectrum showed an absorption at 1620 cm^{-1} attributable to the ylide carbonyl,[9] and the NMR spectrum (δ, in $CDCl_3$) showed two singlets, at 3.30 (3H) and 3.14 (3H), ascribable to the two methyl groups of the sulfonium group. The nonequivalence of the two methyl groups at the sulfonium group was observed also in DMSO-d_6 or at temperature between 30 and 100 °C. It may be due to the assymentric carbon (C_5).

In a similar manner, the reactions of **4** with carbonyl compounds (**5b—d**) gave the corresponding new sulfonium ylides (**8b—d**), which were isolated as their picrates.

The reaction of **4** with benzylthioacetaldehyde in methanol precipitated the new sulfonium ylide (**8e**) as crystals (mp 147—148 °C (dec)) directly from the reaction mixture. The structural assignment of **8e**

was made on the basis of its spectral data and elemental analysis. However, the two methyl groups at the sulfonium group of **8e** appeared as a single peak at δ 3.02, which was in striking contrast to that of **8a**. In the case of the reaction with *p*-nitrobenzaldehyde or paraformaldehyde, the ylides (**8f** and **8g**) were also obtained as stable crystals. The results and physical data of **8** are shown in Tables 1 and 2 respectively. Further attempts were made to improve the yields of **8** in the reactions with diacetyl and *p*-nitrobenzaldehyde. As is shown in Table 1, methanol was proved to be the best solvent among the solvents examined, and **3** was more favorable than **4** to these reactions. Although the reaction of **3** or **4** in methanol with 1 equivalent of the carbonyl compound at room temperature produced good results in each case, at an elevated temperature or in the presence of excess carbonyl compound the desired products were not obtained.

The results are different from those for carbonyl-stabilized sulfonium ylides, such as dimethylsulfuranylideneacetophenone and ethyl dimethylsulfuranylideneacetate, which have been reported to be relatively unreactive toward ordinary carbonyl compounds.[2,3] It is reasonable to consider that the reaction of **3** or **4** with carbonyl compounds proceed through the intermediate betaine (**6**), which in turn cyclizes to form **8**, as is shown in Scheme 1. The cyclization, effected by the formation of a stable five-membered ring from **6**, must be the driving force of this reaction.

Reactivities of 8. In the presence of a catalytic amount of pyridine, the treatment of **8a** with *p*-toluenesulfonyl chloride in methylene chloride at room temperature afforded 5-ethoxycarbonyl-5-methyl-4-methylthio-2-oxo-3-(*p*-toluenesulfonyloxy)-2,5-dihydrofuran (**10a**) as colorless needles (mp 69—70 °C). The IR spectrum showed absorptions at 1785 (five-membered lactone), 1745 (ester), and 1615 cm^{-1} (double bond). The NMR spectrum exhibited two singlets, at δ 2.45 (3H) and 2.75 (3H), attributable to the methylthio group and the methyl protons of the tolyl group. Similar reactions of **8b** and **8g** afforded 3-*O*-tosylate (**10b** and **10g**) in good yields (see Table 3). The reaction of **8a** with benzoyl chloride in methylene chloride was completed in 30 min under ice-cooling to give 3-benzoyloxy-5-ethoxycarbonyl-5-methyl-4-methylthio-2-oxo-2,5-dihydrofuran (**11a**) as colorless needles (mp 95—96 °C). Similarly, **11b** and **11e—g** were readily obtained from the corresponding sulfonium ylides **8** (see Table 3). Although the evolution of methyl chloride was not detected, it seems likely that the formations of **10** and **11** result from the loss of methyl chloride from the intermediate sulfonium salt (**9**) derived from the betaine structure in **8**.

O-Benzoate (**11a**) was relatively stable under acidic conditions, whereas hydrolysis occurred in ethanolic sodium hydroxide to yield 5-ethoxycarbonyl-3-

Table 3. Reactions of **8** with *p*-toluenesulfonyl chloride and benzoyl chloride

Compound **8**	R^1	R^2	Chloride[a]	Product	Yield (%)	Mp (°C)

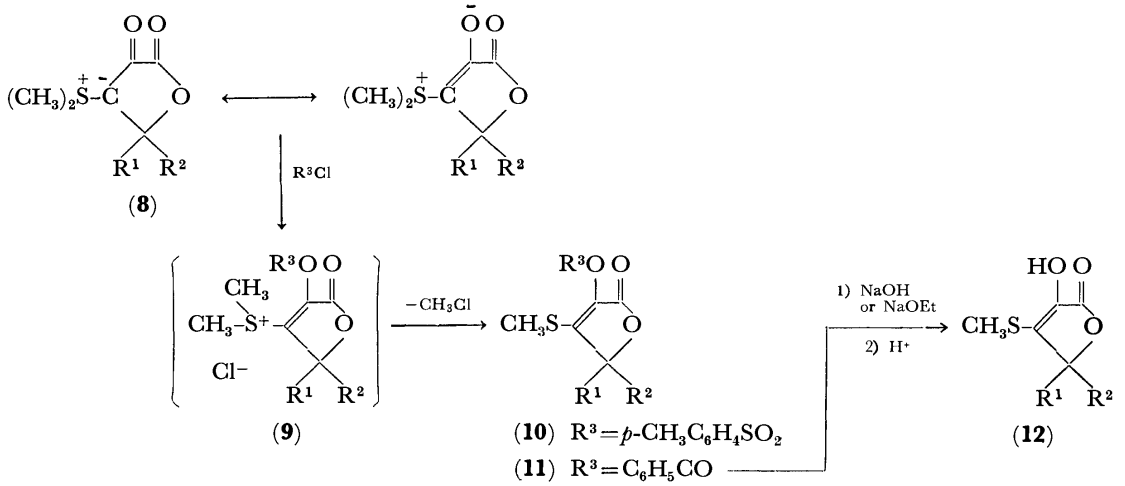


Scheme 2.

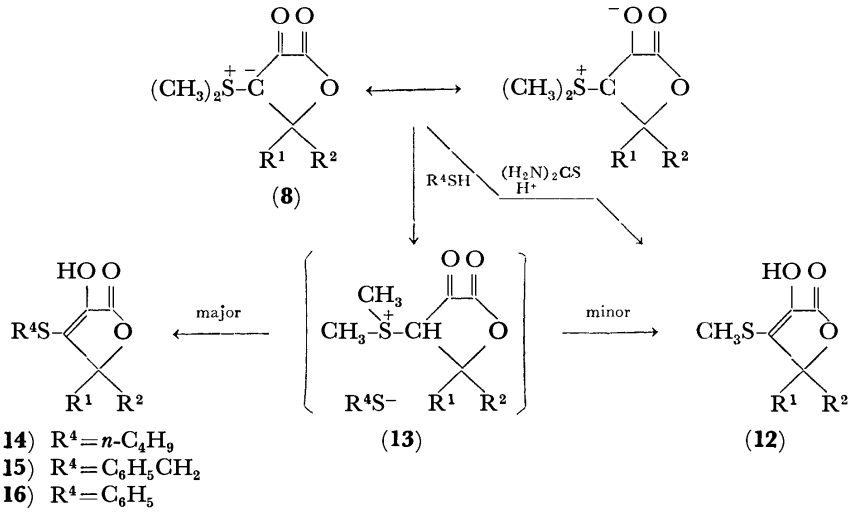
hydroxy-5-methyl-4-methylthio-2-oxo-2,5-dihydrofuran (**12a**) (mp 67—68 °C), which gave a blue color with ferric chloride. Under similar conditions, **11e** was also converted into the 3-hydroxy derivative (**12e**) in a good yield.

Methyl iodide and benzyl bromide, unexpectedly, were unreactive toward **8** under similar conditions. A prolonged reaction at an elevated temperature resulted in the formation of intractable products.

The reactions with nucleophilic reagents, such as mercaptans or thiourea, were also examined. When a mixture of **8e** and benzylmercaptan in 90% aqueous ethanol was refluxed, 4-benzylthio-5-benzylthiomethyl-3-hydroxy-2-oxo-2,5-dihydrofuran (**15e**) was obtained in a 67% yield (mp 89—91 °C). The product combined with ferric chloride to give a blue color. The structural assignment for **15e** was made on the basis of the elemental analysis and its spectral properties. In this manner, various 4-substituted products (**14**—**16**) were obtained from **8** and mercaptans (see Table 4). As is shown in Table 4, the yields increase with a decrease in the bulkiness of the mercaptans and substituents at the C_5-position of **8**. The reactions probably proceed through the nucleophilic displacement of the dimethylsulfonium group by the mercaptide anion of the intermediate sulfonium salt (**13**) formed by protonation. The reaction of **8a** which has two substituents at C_5, however, afforded the 4-substituted product in a low yield. In this case, the nucleophilic attack of the mercaptide anion on the C_4-position of **13** is unfavorable because of the steric hindrance.

On the other hand, the reaction of **8e** with thiourea in the presence of *p*-toluenesulfonic acid in refluxing ethanol yielded **12e** (95%) and *S*-methylisothiouronium *p*-toluenesulfonate. The analogous reactions of picrate of **8a** and **8c** gave demethylated products exclusively in a good yield. However, complicated reactions occurred in the absence of an acid.

In this reaction, it seems not unreasonable to explain that the preferential attack of thiourea on the less reactive methyl group rather than on the C_4-position



Scheme 3.

TABLE 4. REACTIONS OF **8** WITH MERCAPTANS AND THIOUREA

Compound **8**	R^1	R^2	Nucleophilic reagent	Product	Yield (%)	Mp (°C)

8g	H	H	C_6H_5SH	**16g**	85	140—142

a) The reactions were carried out in the presence of acid. b) The mixture of **12a** and **16a** in the ratio of 1 : 2.

is due to a steric hindrance.

Furthermore, although the reactions with active methylene compounds, such as malononitrile and ethyl cyanoacetate, were examined under similar conditions, the desired reaction did not proceed. However, the cyclic sulfonium ylides (**8**) can be used as intermediates for the synthesis of 3-hydroxy-4-mercapto-2-oxo-2,5-dihydrofuran derivatives.[10]

Experimental

All the melting points are uncorrected. The IR spectra were determined with a Shimadzu IR-27G spectrophotometer. The NMR spectra were recorded on a Hitachi R-20A instrument, using TMS as the internal standard. The elemental analyses of all the new compounds except for **1** and **2** are listed in Table 7.

*Dimethyl(methoxalylmethyl)sulfonium Picrate (**1**) and Dimethyl(ethoxalylmethyl)sulfonium Pictrate (**2**).* Dimethyl(ethoxalylmethyl)sulfonium bromide[8] (194 g, 0.753 mol) and picric acid (174 g, 0.76 mol) in water were stirred for 1 hr at room temperature. The precipitate thus formed was collected by filtration and washed with ethyl acetate to give 261 g (81%) of the picrate (**2**, X=$(NO_2)_3C_6H_2O$). Recrystallization from ethyl acetate gave a pure sample as yellow needles; mp 95—97 °C (dec), $\nu_{C=O}$ (KBr) 1740 cm^{-1}.

Found: C, 36.93; H, 3.67; N, 9.88; S, 7.78%. Calcd for $C_{13}H_{15}N_3O_{10}S\cdot H_2O$: C, 36.89; H, 3.62; N, 9.93; S, 7.75%.

In a similar manner, 70.3 g of dimethyl(methoxalylmethyl)sulfonium picrate (**1**, X=$(NO_2)_3C_6H_2O$) was prepared from 86.5 g of the bromide (**1**, X=Br)[8] and 82 g of picric acid. Recrystallization from acetone-ether gave yellow needles; mp 106—108 °C (dec), $\nu_{C=O}$ (KBr) 1745 cm^{-1}.

Found: C, 35.24; H, 3.69; N, 10.18; S, 7.59%. Calcd for $C_{12}H_{13}N_3O_{10}S\cdot H_2O$: C, 35.21; H, 3.69; N, 10.26; S, 7.83%.

*Methyl and Ethyl Dimethylsulfuranylidenepyruvate (**3** and **4**).* *a) Preparation of **4** from the Picrate (**2**):* A mixture of the picrate (**2**, X=$(NO_2)_3C_6H_2O$, 11.15 g, 0.0265 mol), 50% aqueous sodium hydroxide (2.15 g, 0.0265 mol), and a saturated potassium carbonate solution (6.5 ml) in methylene chloride (50 ml) was stirred vigorously under ice-cooling for 30 min. After the removal of the inorganic precipitate by filtration, the methylene chloride layer was separated and dried over potassium carbonate. The removal of the solvent under reduced pressure at room temperature gave 3.69 g (80%) of **4** as pale yellow hygroscopic crystals: $\nu_{C=O}$ (KBr) 1720 and 1550 cm^{-1}; NMR (δ in $CDCl_3$) 4.68 (1H, s), 4.25 (2H, q), 3.00 (6H, s) and 1.34 (3H, t). This ylide was treated with picric acid in ethanol to give the picrate (**2**) quantitatively.

*b) Preparation of **4** from the Bromide (**2**):* By the same procedure, the bromide (**2**, X=Br, 2.57 g, 0.01 mol) afforded 1.27 g (72%) of **4**.

*c) Preparation of **3** from the Picrate (**1**):* According to the procedure described above, 3.95 g (64%) of **3** was obtained from 15.7 g of the picrate (**1**, X=$(NO_2)_3C_6H_2O$): pale yellow crystals; $\nu_{C=O}$ (KBr) 1725 and 1565 cm^{-1}; NMR (δ in $CDCl_3$) 4.68 (1H, s), 3.78 (3H, s) and 2.99 (6H, s). This ylide was converted to the picrate (**1**) quantitatively by treatment with picric acid in methanol.

*4-Dimethylsulfuranylidene-2,3-dioxotetrahydrofuran Derivatives(**8**).* *a) Preparation of **8a—d**:* A solution of **4** (1.76 g, 0.01 mol) and ethyl pyruvate (**5a**, 1.16 g, 0.01 mol) in ethanol was allowed to stand at ambient temperature for 2 days. The addition of picric acid (2.3 g) to the reaction mixture and the removal of the solvent under reduced pressure left a syrup, which was crystallized by the addition of ethyl acetate. Filtration and washing with ethyl acetate gave 3.37 g (71%) of the picrate of 4-dimethylsulfuranylidene-5-ethoxycarbonyl-5-methyl-2,3-dioxotetrahydrofuran (**8a**), which was subsequently recrystallized from ethanol to afford a pure sample as yellow needles; mp 142—143 °C (dec), $\nu_{C=O}$ (KBr) 1790 and 1775 cm^{-1}. The analytical data are shown in Table 7.

To a vigorously stirred suspension of the picrate of **8a** (1.80 g, 3.8 mmol) in methylene chloride (10 ml) was added, in one portion, 50% aqueous sodium hydroxide (0.31 g, 3.8 mmol) and a saturated potassium carbonate solution (3 ml). After 30 min the methylene chloride layer was separated and dried over potassium carbonate. The subsequent removal of the solvent gave 0.71 g (76%) of the sulfonium ylide (**8a**) as pale yellow needles which was crystallized from ethanol-ether (mp 132—134 °C (dec)). The ylide was treated with picric acid in ethanol to give the picrate of **8a** quantitatively.

Similarly, the reactions of **3** and **4** with **5b—d** afforded picrates of **8b—d**, which were converted into **8b—d** in 82, 78, and 72% yields respectively. The results and the spectral data are listed in Tables 1 and 2.

*b) Preparation of **8e—g**:* A solution of **4** (21.0 g, 0.119 mol) and benzylthioacetaldehyde (**5e**, 19.6 g, 0.119 mol) in methanol (100 ml) was allowed to stand at room temperature for 24 hr. The precipitates thus formed were collected by filtration and washed with methanol to give 27.3 g (78%) of 4-dimethylsulfuranylidene-5-benzylthiomethyl-2,3-dioxotetrahydrofuran (**8e**) as light yellow needles; it was subsequently recrystallized from aqueous methanol; mp 147—148 °C (dec).

In this way, **8f** and **8g** were obtained by the reactions of **3** and **4** with *p*-nitrobenzaldehyde (**5f**) and paraformaldehyde (**5g**) respectively. The results and the spectral properties are shown in Tables 1 and 2.

*Reactions of **8** with p-Toluenesulfonyl Chloride.* A solution of **8a** (2.31 g, 9.4 mmol), *p*-toluenesulfonyl chloride (1.82 g, 9.5 mmol), and 3 drops of pyridine in methylene chloride (10 ml) was refluxed for 1 hr, and then washed with water and dried over sodium sulfate. The removal of the solvent gave 2.56 g (87%) of 5-ethoxycarbonyl-5-methyl-4-methylthio-2-oxo-3-(*p*-toluenesulfonyloxy)-2,5-dihydrofuran (**10a**) (mp 69—70 °C), which was subsequently recrystallized from benzene-cyclohexane.

By a similar procedure, **10b** and **10g** were obtained from the corresponding **8**. The results and the spectral data are given in Tables 3 and 5.

*Reactions of **8** with Benzoyl Chloride.* To a solution of **8a** (1.37 g, 5.85 mmol) in methylene chloride (7 ml) stirred under ice-cooling was added drop by drop benzoyl chloride (0.84 g, 5.9 mmol). After stirring for 30 min, the reaction mixture was washed with water, dried, and then evaporated to give a solid. Recrystallization from benzene-cyclohexane afforded 1.64 g (84%) of 3-benzoyloxy-5-ethoxycarbonyl-5-methyl-4-methylthio-2-oxo-2,5-dihydrofuran (**11a**) as colorless needles; mp 95—96 °C. Similarly, **8b** and **8e—g** furnished the corresponding benzoates (**11**). The results and the spectral properties are shown in Tables 3 and 5.

The structural assignment of the syrupy product (**11b**) was made on the basis of the IR and NMR spectra with a sample purified by the chromatography of silica gel G (methylene chloride).

*Hydrolysis of **11**.* To a solution of **11a** (1.67 g, 5 mmol) in ethanol (9 ml) stirred under ice-cooling was added drop by drop a solution of sodium hydroxide (0.20 g, 5 mmol)

a) Measured as a film. b) D_2O-exchangeable peak.

in ethanol (4 ml). After stirring for 30 min at room temperature, the reaction mixture was concentrated to dryness under reduced pressure. The residue was dissolved in water and washed with ether. The aqueous solution was acidified with hydrochloric acid and then extracted with ether. The removal of the solvent left a syrup, which was subsequently crystallized by the addition of cyclohexane. Recrystallization from benzene–cyclohexane afforded 0.95 g (81%) of 5-ethoxycarbonyl-3-hydroxy-5-methyl-4-methylthio-2-oxo-2,5-dihydrofuran (**12a**); colorless needles; mp 67—68 °C.

When sodium ethoxide was employed, **11a** (1.67 g) gave **12a** (0.88 g) in a 76% yield.

Similarly, the treatment of **11e** (1.93 g) with ethanolic sodium hydroxide gave **12e** (1.14 g, 81%); mp 85—86 °C.

Both products were treated with ferric chloride in ethanol to give a blue color.

The IR and NMR spectra are shown in Table 6.

Reactions of 8 with Mercaptans. A solution of **8c** (1.01 g, 5 mmol) and *n*-butylmercaptan (0.63 g, 7 mmol) in ethanol (10 ml) was refluxed for 1 hr and evaporated under reduced pressure to give a colorless syrup. The resulting residue was dissolved in warm cyclohexane and allowed to stand overnight at room temperature. Filtration and washing with cyclohexane afforded 0.87 g (76%) of 4-butylthio-3-hydroxy-5-isopropyl-2-oxo-2,5-dihydrofuran (**14c**) as colorless needles; it gave a blue color with ferric chloride.

According to the procedure described above, the reactions of **8** with mercaptans furnished 4-substituted products (**14**—**16**) except for the treatment of **8a** with phenylmercaptan. The results and the spectral data are summarized in Tables 4 and 6 respectively. The structures of the syrupy products (**14e** and **16e**) were confirmed by the IR and NMR spectra of the sample purified by column chromatography on silica gel G (methylene chloride).

The reaction of **8a** (1.00 g, 4.07 mmol) with phenylmercaptan (0.66 g, 6 mmol) in refluxing ethanol (10 ml) for 9 hr gave 0.34 g of a mixture of **12a** and **16a** in the ratio of 1 : 2 (total yield of 30%) as a viscous syrup. Since the separation of the mixture was unsuccessful, the product composition was determined from the peak areas of the protons of the methylthio group (δ 2.66) and the phenylthio group (δ 7.2—7.6) in the NMR spectrum.

Reactions of 8 with Thiourea. A mixture of **8e** (2.96 g, 10 mmol), thiourea (1.14 g, 15 mmol), and *p*-toluenesulfonic acid in 90% ethanol (30 ml) was refluxed for 4 hr and then evaporated to dryness. The residue was combined with water and extracted with benzene, and the organic layer was washed with water, dried, and evaporated to give 2.68 g (95%) of 4-benzylthio-5-benzylthiomethyl-3-hydroxy-2-oxo-2,5-dihydrofuran (**12e**) as colorless needles after recrystallization from benzene–cyclohexane. The ethanolic solution of **12e** was combined with ferric chloride to give a blue color. The aqueous phase which was separated from the organic layer was treated with picric acid (2.3 g) to afford *S*-methylisothiuronium picrate (2.52 g, 79%) as yellow needles (mp 223 °C) after recrystallization from ethanol.

By the procedure described above, **12a** and **12c** were obtained from the picrates of **8a** and **8c** in 84 and 65% yields respectively.

The IR and NMR spectra are shown in Table 6.

Synthesis of 6-(2-Amino-2-deoxy-β-D-glucopyranosylamino)- and 6-(β-D-Glucopyranosylamino)purine

Shunzo FUKATSU,* Aiko SAWA,** and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received November 17, 1973)

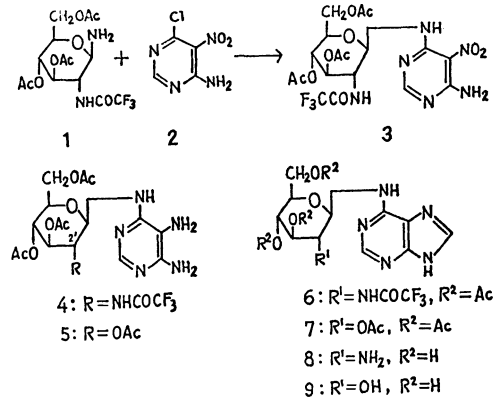
6-(β-Glycosylamino)purines have been synthesized in good yields by condensation of 4-amino-5-nitro-6-chloropyrimidine with masked glycosylamines followed by hydrogenation of nitro group, cyclization with triethyl orthoformate and removal of protecting groups.

Since kinetin[1] and zeatin,[2] factors inducing cell division, were discovered, many related compounds such as 6-acylaminopurines,[3] reversed nucleosides,[4] and modified nucleosides,[5] have been synthesized. Furthermore, 6-(aminoheptosylamino)purine was found in septacidin,[6] an antifungal and cytotoxic antibiotic. In order to investigate further the structure-activity relationships, we have synthesized the title compounds.

The synthesis of 6-(glycosylamino)purines has rarely been reported. The elegant synthesis of reversed nucleosides by Leonard and Carraway[4] involved condensation of a 9-masked derivative of 6-chloropurine with a masked derivative of 5-amino-5-deoxyribose. Ikehara and Tada[7] found that carbon disulfide ring-closure of 6-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylamino)-4,5-diaminopyrimidine gave a mixture of masked derivatives of 9-(β-D-glucopyranosyl)purine and 6-(β-D-glucopyranosyl)purine.

For the preparation of 6-substituted purines, the condensation of 6-chloropurine[8] or 6-mercaptopurine[1,9] with an amine, and the direct alkylation of adenine derivatives[1] have been developed. Our attempts to prepare 6-(glycosylamino)purines by these procedures were unsuccessful. However, we have found that the 6-(β-glycosylamino)purines could be synthesized in good yields by condensation of 4-amino-6-chloro-5-nitropyrimidine with masked glycosylamines followed by cyclization with triethyl orthoformate.

We have prepared 6-(2-amino-2-deoxy-β-D-glucopyranosylamino)purine (**8**) as an aminonucleoside (Scheme 1). In this synthesis, the base-labile *N*-trifluoroacetyl group was used for the protection of the amino group of the sugar. Ikehara and Tada[7] discussed the formation of N^6-glucosyladenine together with N^9-isomer and ascribed it to the presence of hydrogen bond between the 2′-*O*-acetyl and 6-NH group of pyrimidine base. Since the *N*-trifluoroacetyl group is known to be less participating, we were interested in the influence of this function on the ring-closure.



Scheme 1

3,4,6-Tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucopyranosyl azide[10,11] was hydrogenated with Raney nickel to give the glycosylamine (**1**) in high yield. Condensation of **1** with 4-amino-6-chloro-5-nitropyrimidine[12] (**2**) in dioxane afforded 6-(3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucopyranosylamino)-4-amino-5-nitropyrimidine (**3**) in a 58% yield. Catalytic reduction with Raney nickel then gave 6-(3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucopyranosylamino)-4,5-diaminopyrimidine (**4**). Cyclization of **4** with triethyl orthoformate and acetic anhydride afforded, in a 66% yield, 6-(3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucopyranosylamino)purine (**6**), which, after removal of the protecting groups by treatment with methanolic ammonia at room temperatures, led to 6-(2-amino-2-deoxy-β-D-glucopyranosylamino)purine (**8**) in a 39% overall yield from **1**.

Next, we prepared 6-(β-D-glucopyranosylamino)-purine (**9**) by the analogous procedure. 6-(2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosylamino)-4,5-diaminopyrimidine (**5**) was prepared by the method described by Ikehara and Tada,[7] and, in the present paper, we have described purification of this compound and its physical properties. Cyclization of **5** with triethyl

a) Determined at room temperatures, m: methanol, c: chloroform, w: water

or thoformate and acetic anhydride gave, in a 60% yield, 6-(2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosylamino)purine (**7**), which, after deblocking, gave **9** in a 33% overall yield from **2**.

The above-mentioned yields of **6** and **7** suggested that the hydrogen bonding of 2′-*O*-acyl or 2′-*N*-acyl group with 6-NH group in the pyrimidine compounds (**4**, **5**) did not exert substantial influence on the ring-closure with triethyl orthoformate.

The structure and stereochemistry of the above-described products have been confirmed by UV (Table 1), IR and NMR spectral studies.

Experimental

*3,4,6-Tri-O-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucosylamine (**1**).* A solution of 3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-*β*-D-glucopyranosyl azide[11] (2.66 g, 6.24 mmol) in ethyl acetate (50 ml) was shaken with Raney nickel (W-2, 2 ml) and hydrogen (55 kg/cm²) at room temperatures for 18 hr. The catalyst was filtered off, and the filtrate was evaporated to dryness *in vacuo*. The residue was crystallized from 2-propanol-ethyl acetate (1 : 1) to yield 2.39 g (5.97 mmol, 96.5%) of **1** as needles; mp 174—176 °C, $[\alpha]_D^{15}$ −20.2° (*c* 1.12, MeOH) [lit,[11] mp 158 °C, $[\alpha]_D^{22}$ −14.4° (*c* 0.6, MeOH)]; ν_{max}^{KBr} (cm⁻¹), 1750, 1710 (-$COCH_3$, -$COCF_3$), 1230 (C-O-C); tlc, R_f 0.75 (benzene-ethyl acetate 1 : 6).

*6-(3,4,6-Tri-O-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucopyranosylamino)-4-amino-5-nitropyrimidine (**3**).* To a solution of **1** (2.22 g, 5.55 mmol) in anhydrous dioxane (5 ml) and triethylamine (0.77 ml, 5.55 mmol), a suspension of 4-amino-6-chloro-5-nitropyrimidine[12] (**2**) in anhydrous dioxane (30 ml) was added with stirring. The mixture was heated at 60—65 °C for 15 hr and filtered. The filtrate was evaporated to dryness *in vacuo*. The residue (3.78 g) was chromatographed on a column (3×38 cm) of silica gel (100 g, Wakogel C-200) and eluted with ether. The fractions containing **3** were combined and evaporated to dryness *in vacuo*. The residue was crystallized from ethanol to give **3** (1.73 g, 58%) as needles; ν_{max}^{KBr} (cm⁻¹), 1760, 1715 (-$COCH_3$, -$COCF_3$), 1625, 1595 (-C=N-), 1525, 1370 (-NO_2), 1235 (C-O-C); tlc R_f 0.6 (ethyl acetate-benzene 3 : 1).

*6-(3,4,6-Tri-O-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucosylamino)-4,5-diaminopyrimidine (**4**).* A sample of **3** (1.24 g, 2.31 mmol) was hydrogenated in the presence of Raney nickel as described in the preparation of **5**. The catalyst was filtered off and the filtrate was evaporated to dryness *in vacuo* to give a colorless glass of **4** (1.11 g, 96%); ν_{max}^{KBr} (cm⁻¹), 1760, 1740 (-$COCH_3$, -$COCF_3$), 1650, 1600 (-C=N-); tlc R_f 0.2 (ethyl acetate).

*6-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosylamino)-4,5-diaminopyrimidine (**5**).* A sample of 6-(2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranosylamino)-4-amino-5-nitropyrimidine[7] (1.52 g, 3.15 mmol) was dissolved in anhydrous methanol (55 ml) at 60 °C and cooled. To the solution Raney nickel (3.8 ml, W-2) was added and the mixture was shaken with hydrogen (hydrogen pressure 60 kg/cm²) at room temperature for 6 hr. The catalyst was filtered off and washed with methanol. The filtrate and washings were combined and evaporated to dryness *in vacuo*. The resulting solid (1.37 g) was crystallized from ethyl acetate to give colorless needles of **5** (1.01 g, 95.5%); ν_{max}^{KBr} (cm⁻¹), 3380 (-NH), 1750 (-$COCH_3$), 1660, 1630, 1595 (-C=N-); tlc R_f 0.5 (ethyl acetate-ethanol 6 : 1).

*6-(3,4,6-Tri-O-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucopyranosylamino)purine (**6**).* A solution of **4** (1.26 g, 2.31 mmol) in triethyl orthoformate and acetic anhydride (11.2 ml, 1 : 1) was refluxed for 85 min and the reaction mixture was evaporated to sirup *in vacuo*. The residue was chromatographed on a column (2.8×24 cm) of silica gel (70 g, Wakogel C-200) and eluted with ethyl acetate-ethanol (20 : 1). Fractions containing the product of R_f 0.5 (tlc, ethyl acetate-ethanol 20 : 1) were combined and evaporated to dryness. The residue was crystallized from ethyl acetate-isopropyl ether (1 : 1) to yield **6** (0.792 g, 66%) as colorless needles; ν_{max}^{KBr} (cm⁻¹), 1760 1725 (-$COCH_3$, -$COCF_3$), 1625, 1600 (-C=N-), 1245 (C-O-C); tlc R_f 0.5 (ethyl acetate-ethanol 6 : 1), 0.3 (ethyl acetate).

*6-(2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosylamino)purine (**7**).* A solution of **4** (1.733 g, 3.82 mmol) in triethyl orthoformate and acetic anhydride (19 ml, 1 : 1) was heated at 125 °C (bath temperature) for 1.5 hr and the solution was evaporated to dryness *in vacuo*. The residue was chromatographed on a column of silica gel (50 g, Wakogel C-200) and eluted with benzene-ethanol (9 : 1). Fractions containing of the product of R_f 0.35 (tlc, benzene-ethanol 9 : 1) were combined and evaporated to dryness *in vacuo* to give **7** (1.074 g, 60%) as colorless needles, which were recrystallized from ethyl acetate; ν_{max}^{KBr} (cm⁻¹), 3430 (-NH), 1760 (-$COCH_3$), 1625, 1600 (-C=N-), 1060, 1035 (C-O-C); NMR (DMSO-d_6), δ 8.70 (1H s, purine H_2), 8.64 (1H d, J=8—9 Hz, purine C_6-NH), 8.50 (1H s, purine H_8), 5.85 (1H d, J=8—9 Hz, $C_{1'}$-H), 2.02 (3H s, -$OCOCH_3$), 1.97 (6H s, -$OCOCH_3$), 1.88 (3H s, -$OCOCH_3$); tlc R_f 0.35 (benzene-ethanol 9 : 1), 0.30 (ethyl acetate).

*6-(2-Amino-2-deoxy-β-D-glucopyranosylamino)purine (**8**).* A portion of **6** (0.60 g, 1.16 mmol) was treated with saturated methanolic ammonia (35 ml) at room temperature for 5 days. The solution was evaporated to dryness *in vacuo*. The resulting solid was recrystallized from water-ethanol to give 6-(2-amino-2-deoxy-*β*-D-glucopyranosyl)purine (**8**) (290 mg, 84%) as colorless needles; ν_{max}^{KBr} (cm⁻¹), 3380, 3320,

3180 (-NH, -OH), 1635, 1595 (-C=N-), 1105, 1080, 1057, 1048, 1026 (C-O-C); NMR (DMSO-d_6), δ 8.27 (1H s, purine H_2), 8.17 (1H s, purine H_8), 8.01 (1H d, J=9 Hz, purine C_6-NH), 5.43 (1H d, J=9 Hz, $C_{1'}$-H); tlc R_f 0.2 (*n*-butanol-water 86 : 14).

*6-(β-D-Glucopyranosylamino)purine (**9**).* A solution of **7** (335 mg, 0.715 mmol) in anhydrous methanol (35 ml) was saturated at 0 °C with dry ammonia. After storage in a refrigerator for 18 hr, the solution was evaporated to dryness *in vacuo*. The residue was recrystallized from water-ethanol to give 6-(β-D-glucopyranosylamino)purine (**9**) (148 mg, 70%) as colorless needles; ν_{max}^{KBr} (cm^{-1}), 3400, 3350, 3140 (-NH, -OH), 1625, 1600 (-N=C-), 1105, 1080, 1070 (C-O-C) NMR (DMSO-d_6), δ 8.26 (1H s, purine H_2), 8.17 (1H s, purine H_8), 7.84 (1H d, J=8.5 Hz, purine C_6-NH), 5.52 (1H broad, $C_{1'}$-H); tlc R_f 0.17 (*n*-butanol saturated with 2 M ammonia).

Synthesis of Alkoxythallium(III) Compounds of Olefins and Their Reaction with Copper Halides and Pseudohalides

Sakae UEMURA,* Kazuo ZUSHI, Akira TABATA, Akio TOSHIMITSU, and Masaya OKANO

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

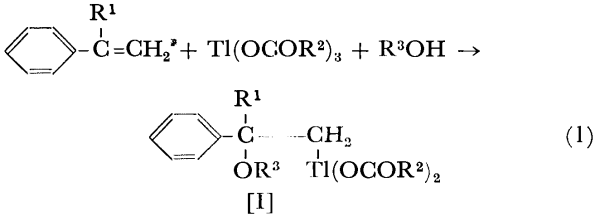
(Received January 23, 1974)

Some new alkoxythallium(III) compounds of olefins, $C_6H_5C(R^1)(OR^3)CH_2Tl(OCOR^2)_2$ [I], are prepared from styrene and α-methylstyrene with thallium(III) acetate and isobutyrate in various alcohols. I(R^1=H) reacts with copper(I) iodide, bromide, chloride, cyanide and thiocyanate to afford the corresponding alkyl halides and pseudohalides, $C_6H_5CH(OR^3)CH_2X$ [II], in various organic solvents, acetonitrile being the solvent of choice for the purpose of preparing II. The addition of potassium salt has a remarkable effect in improving the yield of II. The halo- and pseudohalodethallation occur at the position where thallium is attached previously to alkyl carbon. An ionic concerted intermolecular scheme is proposed as a reaction mechanism for the preparation of II. The data of NMR and IR spectra of I are briefly discussed.

Compared to the corresponding mercury(II) compounds, oxythallium(III) compounds of olefins are known to be unstable, and so far only a few compounds have been isolated since the first report by Criegee.[1] The compounds from styrene,[2] *o*-allylphenol,[2] norbornene,[3] norbornadiene[3] and isobutylene[4] are the known examples. Recently oxythallation products from acetylene[5,6b] and allene[6a] have also been isolated from the reaction mixture in methanol or acetic acid. Earlier work on the decomposition of oxythallium(III) compounds of olefins has revealed that the carbon-thallium bond is cleaved to leave a carbonium cation which gives the oxidation products of olefins.[2] A recent report by Mitani *et al.*[7] that carbon-thallium bond fission of the compound occurs easily with potassium thiocyanate to give 1-methoxy-2-thiocyanoalkanes in good yield may add another use of oxythallation in organic synthesis. We have reported some reactions of arylthallium(III) compounds with copper halides and pseudohalides where the aryl carbon-thallium bond was cleaved, resulting in the introduction of halogens[8a] or pseudohalogens[8b,c] to the aromatic ring. In connection with this observation, it might be interesting to examine how alkyl carbon-thallium bonds of oxythallium(III) compounds of olefins behave to these copper salts. We have investigated the synthesis of some new oxythallium(III) compounds of olefins and also some reactions of the resulting compounds with copper(I) iodide, chloride, bromide, cyanide, and thiocyanate. As a result a number of new oxythallium(III) compounds have been isolated from styrene and α-methylstyrene and the replacement of thallium group in these compounds by halogens or pseudohalogens has been achieved in good yield.

Results and Discussion

Synthesis of Alkoxythallium(III) Compounds of Olefins. Kabbe has reported the synthesis of α-methoxy-β-diacetatothallium ethylbenzene from styrene and thallium(III) acetate in methanol.[2] Similarly we obtained various α-alkoxy-β-diacetatothallium ethylbenzenes in 60—86% yield by stirring a mixture of styrene and thallium(III) acetate in various alcohols at room temperature for 0.5—24 hr. The reaction proceeded with decreasing order through the following series of alcohols as solvent; methyl>ethyl>*n*-propyl, *n*-butyl>*i*-propyl, *i*-butyl≫*t*-butyl, reflecting both steric and polar factors of the solvents. Thus in methanol the reaction was almost completed at 0 °C after 15 min, while the corresponding compound was scarcely obtained in *t*-butanol even by stirring at 20 °C for 2 days. Thallium(III) isobutyrate could also be used instead of the acetate for the preparation of methoxy- and ethoxy-thallium(III) compounds of styrene, but a longer reaction time was required. Similar oxythallium(III) compounds were obtained from α-methylstyrene using thallium(III) acetate in methanol or ethanol, but not in higher alcohols under similar reaction conditions. All the compounds isolated were white amorphous solids, soluble in polar solvents and recrystallized from benzene. The reaction conditions for the preparation of I and the yields, melting points, and analytical data of I are summarized in Table 1 (Eq. (1)).



(1)

[I]

IR spectra (paraffin and hexachlorobutadiene mulls) of I (R^1=H, R^2=R^3=CH_3) showed four strong absorption bands in the acetate region which are assignable to two ν_{asym} (CO_2) (1600 and 1525 cm^{-1}) and two ν_{sym} (CO_2) (1422 and 1390 cm^{-1}) (Table 2). This suggests the presence of two types of acetate group, namely a bridging acetate group (1525 and 1422 cm^{-1}; strong and slightly broad) and a non-bridging one (1600 and 1390 cm^{-1}; strong and sharp), as in the case of methyl, ethyl and phenylthallium(III) dicarboxylates which were reported by Kurosawa and Okawara,[9] and Lee.[10] The expected large Tl–H spin-spin couplings were observed in NMR spectra (in $CDCl_3$ or CD_3OD) of I, but the clear separation of $J_{^{205}Tl-H}$ and $J_{^{203}Tl-H}$ was not obtained. Contrary to the known result that in ethyl-or *n*-propylthallium(III) compounds $J_{Tl-\beta-H}$ is generally larger than $J_{Tl-\alpha-H}$,[9a,11] the coupling constants of Tl-methylene protons ($J_{Tl-H_B \text{ or } H_C}$) in I were larger than that of Tl-methine proton (J_{Tl-H_A}) (Table 2). Similar result has been reported in the acetoxythallated compound of norbornene where

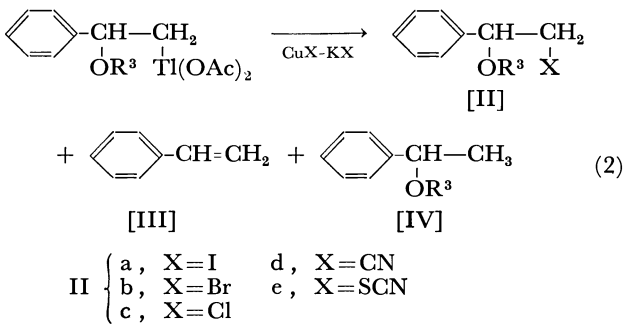
a) Paraffin and hexachlorobutadiene mulls. In methylthallium(III) diacetate, 1613(s), 1530(s), 1428(s), and 1375(s) cm^{-1} were the observed bands.[9b] b) $CDCl_3$ and CD_3OD solvent; TMS as the internal standard. c) In ethylthallium (III) diisobutyrate, $J_{Tl-CH_2\underline{CH_3}}$ of 1626 Hz and $J_{Tl-\underline{CH_2}}$ of 822 Hz were reported.[9a]

$J_{Tl-\alpha-H}$ is larger than $J_{Tl-\beta-H}$ and this was attributed to a possible geometric effect in rigid molecule.[12] Since the interaction between mercury and oxygen is proposed in the oxymercuration of cycloalkenols,[13] it may be possible to assume that in I thallium interacts with oxygen of alkoxy group to restrict free rotation of C_α–C_β bond in some extent. This may be one reason for the unexpected small value of J_{Tl-H_A} in I. Electronic absorption spectra (in EtOH) of I showed a maximum at 226 mμ, and ε of I (R^1=H, R^2=R^3=CH_3), I (R^1=H, R^2=CH_3, R^3=C_2H_5) and I (R^1=H, R^2=i-C_3H_7, R^3=CH_3) were 1.8×10^4, 1.4×10^4 and 2.1×10^4, respectively.

From β-methylstyrene no alkoxythallium(III) compounds were isolated using methanol and ethanol as solvents after stirring at 20 °C for 5 hr. Similarly, attempts to isolate oxythallium(III) compounds from cyclohexene were unsuccessful either with thallium(III) acetate in chloroform or chloroform–acetic acid (10 : 1) as solvents, or with thallium(III) trifluoro-

acetate in trifluoroacetic acid–*n*-pentane (1 : 5) as solvent at 15 °C.

Reaction of Alkoxythallium(III) Compounds of Styrene with Copper Salts. A mixture of I (R^1=H, R^2=CH_3) and the copper(I) salt and/or potassium salt was stirred for 5 hr under reflux in various organic solvents such as acetonitrile, 1,4-dioxane, THF, methanol, chloroform, and DMF. As a result thallium was replaced by halogen or pseudohalogen to afford II along with small amounts of styrene [III] and α-alkoxyethylbenzene [IV], acetonitrile being the solvent of choice for the preparation of II (Eq. (2)). Although in the cases of iodide and thiocyanate the reaction



(2)

proceeded with the potassium salt alone as reported by Mitani *et al.*[7] in thiocyanate case, the addition of the corresponding copper(I) salts was found to increase the yield of II in both cases. For chloride, bromide, and cyanide, however, a replacement of thallium by halogen or pseudohalogen scarcely occurred with the potassium salt alone, while II was obtained in good yield using the corresponding copper(I) salts. Interestingly, the addition of the potassium salt to the reaction system containing copper(I) salt caused a remarkable improvement in the yield of II. In contrast to the aryl carbon–Tl bond,[8] the alkyl carbon–Tl bond of I was cleaved usually by copper(I) salts, and not so readily by copper(II) salts.

From the reaction using I (R^1=H, R^2=R^3=CH_3), the by-products such as phenylacetaldehyde [V], α-methoxy-β-acetoxy- [VI], β-acetoxy-β-methoxy- [VII], and β,β-dimethoxyethylbenzenes[VIII] were sometimes obtained, the distribution and the amount of these depending on the reaction conditions. These compounds are obviously the decomposition products of I, because, for example, Kabbe[2] reported the formation of VIII by stirring I (R^1=H, R^2=R^3=CH_3) in methanol at 65 °C for 4 days (64% yield). We have also examined the decomposition of I (R^1=H, R^2=R^3 CH_3) in various solvents by refluxing for 5 hr (without any copper and/or potassium salts) and the results in acetonitrile, 1,4-dioxane and methanol were shown in Eq. (3) where the yields of III and V were less than 3%. Only a slight amount of the decomposition products was formed in DMF, THF, CH_2Cl_2, and CCl_4.

a. Iodination (Table 3). Although the reaction mixture was heterogeneous in acetonitrile because of the insolubility of copper(I) iodide, the good yield of IIa was obtained in this solvent. Small or trace amounts of III and IV were always detected as by-products. Though IIa was obtained using either po-

a) Based on I. b) s. a.=a small amount (1—2%).

tassium iodide or copper(I) iodide alone, it was found that the reaction in the presence of both salts gave the best yield of IIa. The reaction of I with iodine or lithium iodide in acetonitrile gave only a trace amount of IIa.

b. Bromination and Chlorination (Table 4). In contrast to the iodination the reaction of I with potassium bromide alone gave only a small amount of IIb, while copper(I) bromide reacted with I to afford IIb in fairly good yield together with small amounts of III, IV, and bis(2-alkoxy-2-phenylethyl)thallium bromide, the disproportionation product of I (see Experimental). The yield of IIb was increased by the addition of potassium bromide as in the case of iodination. The addition of potassium chloride instead of the bromide also improved the yield of IIb and an additional formation of a small amount of IIc was observed in this case. Acetonitrile and methanol were revealed to be the solvent of choice, and 1,4-dioxane, DMF, and $CHCl_3$ could also be used as solvents, although the selectivity for IIb was low in the last three solvents. While it has been reported that methyl thallium diacetate reacted readily with aqueous solution of sodium chloride, bromide, or iodide to give the corresponding methyl halide,[9a] the reaction of I with potassium bromide in water at 20 °C or 100 °C for 1 hr afforded III, V, a trace amount of IIb, and thallium(I) bromide. The yields of III and V were 3% and 56% at 20 °C, and 2% and 31% at 100 °C respectively. This fact means that in water as solvent the decomposition of I to V and III is much faster than the formation of alkyl halide and that the nature of C–Tl bonds of I and methylthallium diacetate is different in some way. None of IIb was obtained from the reaction of I with copper(II) bromide in acetonitrile as solvent. The reaction of I with bromine in acetonitrile did not give any of IIb at 81 °C for 5 hr.

While only a slight amount of IIc was obtained from the reaction of I with potassium chloride in acetonitrile, the reaction proceeded smoothly in the presence of both copper(I) and potassium chlorides in the same solvent to afford IIc, III and IV. Here, the selectivity and also the yield of IIc were slightly lower than those of iodination and bromination. When the reaction of I with copper(I) chloride was carried out in the presence of potassium bromide, IIb and IIc were obtained, being the former predoninant. Bis(2-alkoxy-2-phenylethyl) thallium chloride was also obtained in a small amount as in the case of bromination and it became apparent that such disproportionated compounds could be formed in the presence of copper(I) halide and irrespective of the presence of potassium halide. Thus, bis-(2-methoxy-2-phenylethyl) thallium bromide and chloride were obtained in 15—20% yield by refluxing I (R^1=H, R^2=R^3=CH_3) and copper(I) bromide or chloride in acetonitrile respectively (see experimental part), and the disproportionation product[14] of I (R^1=H, R^2=CH_3, R^3=*n*-C_3H_7) was obtained in 10% yield

a) Based on I. b) CuCN-pyridine (1 : 1) complex. c) CuCN-KCN (1 : 1) complex.

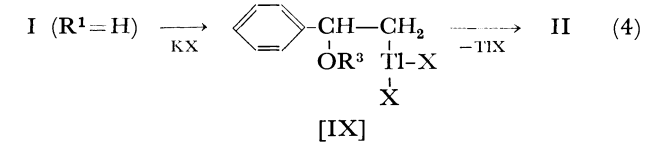
(after recrystallization from methanol) together with IIc (35%) and small amounts of III, IV, and VI by refluxing I (10 mmol) and copper(I) chloride (20 mmol) in acetonitrile for 5 hr. None of IIc was obtained from the reaction of I with copper(II) chloride in acetonitrile as solvent.

c. Cyanation and Thiocyanation (Table 5). I did not react with potassium cyanide to give IId, while a good yield of IId was obtained from the reaction of I with copper(I) cyanide in acetonitrile. In contrast to the halogenation described above, the addition of potassium cyanide to the reaction mixture of I and copper(I) cyanide lowered strongly the yield of IId. Instead of potassium cyanide, potassium bromide showed some effect for improving the yield of IId with a formation of only a trace amount of IIb. Small amounts of disproportionated organothallium(III) compounds were sometimes detected as in the case of halogenation. The reaction seemed to be strongly affected by the kind of solvent and almost no reaction was observed in other solvents such as pyridine, 1,4-dioxane, and methanol which were the good solvents for the reaction of arylthallium(III) compounds with copper cyanide.[8b] Copper(II) cyanide could also be used for this reaction, but the activity was inferior to copper(I) salt. No isonitrile compounds were detected in all cases.

For thiocyanation, I(R^1=H, R^2=R^3=CH_3) is known to react easily with potassium thiocyanate to give IIe.[7] We found that copper(I) thiocyanate also reacted with I to give IIe, the best yield of which was obtained in the presence of both of copper(I) and potassium thiocyanates. The reaction with copper(II) thiocyanate afforded IIe in a low yield together with considerable amounts of the decomposition products. None of isothiocyanate compounds were obtained in all cases.

d. Attempts of the Reactions of I with Copper(II) Fluoride and Some Other Metal Salts. The reaction of I (R^1=H, R^2=R^3=CH_3) with copper(II) fluoride dihydrate in dioxane at refluxing temperature gave only the decomposition products such as V and VI together with α-methoxyethylbenzene. Similarly none of fluorinated compounds were obtained from the reaction even in the presence of potassium fluoride in DMF or acetonitrile as solvents. No appreciable reaction of I was observed with copper(II) acetate or acetylacetonate. In acetonitrile as solvent mercury(II) and silver cyanides or iron(II) chloride hydrate did not react with I to give IId or IIc respectively.

e. Some Consideration on the Reaction Scheme of Halogenation and Pseudohalogenation. Although it has been known that no substitution of mercury by halogen or pseudohalogen occurs in the reaction of oxymercurated compounds of olefins with potassium iodide, cyanide, or thiocyanate,[15] thallium in I was readily substituted by iodide or thiocyanate to afford IIa or IIe as described above. As proposed by Mitani *et al.*,[7] this reaction may proceed through the exchange of the acetate ligand of I by group X giving very unstable alkylthallium(III) diiodide or dithiocyanate [IX] followed by an intramolecular migration of X to alkyl carbon (Eq. (4)). For chloride and bromide, IX seemed to be rather stable and did not give II readily. We will describe in a separate paper about the isolation of IX (X=Cl or Br).



(4)

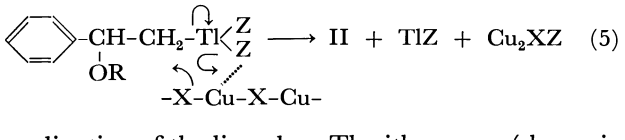
[IX]

In connection to this observation, it should be noted here that mercury in the oxymercurated compound of olefins has been known to be substituted electrophilically by iodine or bromine molecule,[15] while no such reaction was observed with I as described above. These facts may be explained by the difference of the oxidation potential between Hg and Tl; namely a reductive

cleavage of carbon-metal bonds would be much easier in thallium compound than in mercury one and so a favorable nucleophilic attack on carbon can be expected for the former and a favorable electrophilic attack for the latter.

Next the reaction scheme of I with copper salts should be considered. In contrast to the reaction of arylthallium(III) salt with copper salts,[8] it is not necessary to use copper(II) salt in this case. This fact may be explained as follows. Since it has been stated[16] that Pd(II) aryls are more stable than Pd(II) alkyls and require stronger oxidants to decompose them, it seems reasonable to assume that Tl(III) alkyls do not require stronger oxidant compared to Tl(III) aryls if the latter is more stable than the former. In fact arylthallium(III) compounds were quite stable and did not give any appreciable amount of decomposition products under the conditions shown in Eq. (3) where I gave many products. The reason why I did not react with copper(II) salts in acetonitrile so readily is not certain at present but the choice of a suitable solvent may improve the yield of II. Thus, the reaction of I with copper(II) bromide in the presence of potassium bromide in pyridine at refluxing temperature for 1 hr gave a 20% yield of IIb, while IIc was obtained in 30—50% yield by the reaction using copper (II) chloride in pyridine or dioxane as solvent.

As to the halogenation and pseudohalogenation of I with copper(I) salts, first, the reaction does not appear to involve radicals because the reaction of I (5 mmol) with copper(I) and potassium bromides (both of 10 mmol) in the presence of acrylonitile (10 mmol) at 81 °C for 5 hr in acetonitrile as solvent under N_2 gave neither polyacrylonitrile nor alkylated acrylonitrile[17] even though an appreciable amount of IIb (53% yield) was still obtained. Second there is no evidence of the substitution of thallium with copper salt, because none of α-alkoxystyrene or acetophenone and copper metal was obtained which may be derived from alkylcopper compound if formed.[18] Third a free carbonium cation is not formed in the reaction because halogenation or pseudohalogenation occurred at the position where thallium was attached previously, and none of phenyl migrated compounds was detected in the products. Fourth there is a clear difference in product distributions between the reaction with potassium salt alone and that with copper(I) salt alone in polar acetonitrile solvent. This may suggest that direct attack of unionized copper(I) species is operative. Considering all these facts an ionic concerted intermolecular scheme shown in Eq. (5) seems to be most reasonable.



$$\longrightarrow \text{II} + \text{TlZ} + \text{Cu}_2\text{XZ} \quad (5)$$

Coordination of the ligand on Tl with copper (shown in dotted line) may be one of the driving forces of the reaction. In fact the reaction of I with copper(I) bromide in strong complexing solvent such as pyridine or *N,N*-tetramethylethylenediamine gave none of II at refluxing temperature for 5 hr, while IId was obtained in good yield (65%) in acetonitrile from the reaction of I with copper(I) cyanide–pyridine (1 : 1) complex where a coordination site of copper is still vacant.

As has been described above, the addition of potassium salt to the reaction mixture showed a remarkable effect for improving the yield of II. The reasons for this effect may be as follows. The solubility of copper(I) salt in solvents is increased by the coordination between potassium and copper salts, and the coordination makes Cu–X bond loosen and the attack of X on carbon easy. For example, 1.15 g out of 1.43 g (10 mmol) of copper(I) bromide or only 0.05 g out of 1.19 g (10 mmol) of potassium bromide was soluble in 25 ml of acetonitrile at 81 °C, while 1.51 g out of 2.62 g of a mixture of both bromides (each of 10 mmol) was soluble in the same amount of acetonitrile at 81 °C. It should be also noted that the deoxythallation of I to give styrene was prevented in the presence of potassium iodide, bromide, or thiocyanate. For cyanation with copper(I) cyanide, however, the addition of potassium cyanide prevented the formation of IId. This may be due to the formation of the unreactive coordination compound, $K[Cu(CN)_2]$, which is known to have a spiral polymeric structure in which each Cu atom is covalently bound to two carbon atoms and one nitrogen atom.[19] In fact the reaction of I with this compound prepared separately gave only 1% yield of IId in acetonitrile as solvent. When the reaction of I with copper(I) cyanide and potassium bromide was carried out in acetonitrile, IId was the main product and IIb was obtained only in a trace amount. In contrast to this, it may be interesting to note that the reaction of I with a mixture of copper(I) bromide and potassium cyanide in the same solvent, which was refluxed for 1 hr before the addition of I, gave a small amount of IIb and the main product was IId in this case. In connection to this the following observations are worth to refer. As shown in Table 4, the reaction of I with copper(I) bromide in the presence of potassium chloride gave almost IIb, while with copper(I) chloride and potassium bromide a mixture of IIc and IIb was obtained under similar conditions, the former being a minor product. These results can be explained by the consideration of the equilibrium shown in Eqs. (6) and (7) which are based on the HSAB principle;[20] *i.e.*, Cu^+ is soft acid and $CN^- > Br^- > Cl^-$ are soft bases with decreasing order of softness.

$$\text{CuCl} + \text{KBr} \rightleftarrows \text{CuBr} + \text{KCl} \quad (6)$$

$$\text{CuBr} + \text{KCN} \rightleftarrows \text{CuCN} + \text{KBr} \quad (7)$$

Although the precise nature of the formation of III and IV is uncertain at present, it is noteworthy to refer to the following facts. As to the formation of III, it is clear that the deoxythallation of I giving III was catalyzed by copper salt, because the amount of III formed is larger at the reactions in the presence of copper salt than at those without it. Halogen acid such as hydrogen chloride has been known to accelerate the deoxymercuration of alkoxymercurated compounds of olefins[21] and the elimination of the alkoxy group giving mercurinium ion followed by demercuration has been proposed as the reaction mechanism.[21] We

observed similar phenomena in I (R^1=H, R^2=R^3=CH_3) which gave 73% yield of III and 93% of Tl^{3+} salt by the reaction with hydrogen chloride (0.2 M) in an aqueous ethanol solvent under stirring at 20 °C for 2 hr. This fact suggests that similar reaction mechanism may be operative for the formation of III in Tl case as well. Copper salt may help the elimination of alkoxy group in the present reactions. In connection to the formation of IV, it is interesting to note that the action of water[22] or hydrogen iodide[23] on trialkylthallium split off the corresponding hydrocarbon RH and that the reaction of diorganothallium(III) carboxylate with tetramethyltin in methanol[24] gave also a hydrocarbon. This protodethallation can be explained by an electrophilic substitution on carbon by hydrogen. The action of water, which may exist in solvent or metal salts, on I might give IV by similar reaction scheme, but more work should be necessary to discuss it.

Experimental

The IR spectra were taken with Hitachi EPI-S2 and Perkin-Elmer 521 spectrometers in paraffin and hexachlorobutadiene mulls. The UV and visible spectra were taken with Hitachi EPS-2U spectrometer using ethanol as solvent. The NMR spectra were recorded by a Varian A-60 spectrometer in $CDCl_3$ or CD_3OD as solvents, using TMS as the internal standard. The glc analyses were carried out on Shimadzu 5APTF and 4BMPF apparatus, using PEG 6000 (25%)-Chromosorb W (3m) and Apiezon L (30%)-Celite (1 and 3m) columns (N_2 as the carrier gas).

Materials. All the organic materials except the alkoxythallium(III) compounds of olefins were purified before use by distillation, while commercially available copper and and potassium salts and other inorganic materials were used without further purification. $Cu(NCS)_2$ was prepared by the reported method from $CuSO_4 \cdot 5H_2O$ and KSCN.[25] Copper(I) cyanide-pyridine (1 : 1) complex was prepared by the same method reported previously.[8a] $K[Cu(CN)_2]$[26] was prepared by stirring 77 mmol of KCN and 39 mmol of CuCN in 20 ml of water at 20 °C for 2 hr, collecting white crystals (3.3 g) precipitated after evaporating the reaction mixture to 5 ml, washing with a small amount of water and drying over silica gel; yield 54% (Found: C, 15.66; N, 18.68%. Calcd for C_2N_2KCu: C, 15.53; N, 18.11%). Thallium(III) acetate and isobutyrate were prepared by stirring thallium(III) oxide in acetic acid and isobutyric acid at 65 °C for 20 hr and at 90 °C for 2 hr respectively, collecting white amorphous crystals formed after cooling, and drying over CaO.

Preparation of Alkoxythallium(III) Compounds of Olefins, I. The following example of I (R^1=R^2=R^3=CH_3) shows a typical experimental procedure. To a yellow-orange homogeneous solution of thallium(III) acetate (19.4 g, 0.05 mol) in methanol (50 ml), α-methylstyrene (11.8 g, 0.1 mol) was added drop by drop at 15—20 °C. The mixture was stirred at 20 °C for 30 min during which period the color of the homogeneous solution turned to colorless. The mixture was added by 200 ml of petroleum ether (30—70 °C), stored in an ice-box at −10 °C for 2 hr. The white precipitates of I (R^1=R^2=R^3=CH_3) (16.0 g, 70% yield) thus formed were collected by filtration and were recrystallized from benzene. I is very soluble in pyridine, DMF, DMSO, carbon disulfide, methanol, acetic acid, and dichloromethane, soluble in acetone, acetonitrile, dioxane, nitromethane, chloroform, dichloroethane, ethanol, ethyl acetate, diglyme, THF, and sparingly soluble in ether, benzene, petroleum ether (30—70 °C), carbon tetrachloride, and water. NMR spectral data of I except those of methine and methylene protons shown in Table 2 are as follows: δ 2.0 (s, 6H, $OCOCH_3$) when R^2 is methyl; 1.23 (d, 12H, J_{H-H}=7 Hz, $-COCH(CH_3)_2$) and 2.57 (septet, 2H, J_{H-H}=7 Hz, $OCOCH(CH_3)_2$) when R^2 is isopropyl; some peaks due to respective alkoxy group; 6.9—7.7 (m, 5H, phenyl).

Decomposition of I (R^1=H, R^2=R^3=CH_3) in Dioxane. A mixture of I (4.58 g, 10 mmol) and dioxane (50 ml) was stirred for 5 hr at 100 °C. The precipitates thus formed (TlOAc: 1.53 g, 5.8 mmol) were filtered off after cooling and the filtrate was added by 200 ml of water and extracted with *n*-hexane. Glc analysis of a part of the extract using ethyl cinnamate as the internal standard showed that the products were VI (81%) and slight amounts of III and V. After drying over Na_2SO_4, the extract was distilled to give 1.0 g (52% yield) of VI; bp 103—110 °C/8 mmHg. NMR δ 2.07 (s, 3H, $OCOCH_3$), 3.30 (s. 3H, OCH_3), 4.12—4.48 (m, 3H, $>CHCH_2-$), 7.35 (s, 5H, phenyl). Found: C, 67.99; H, 7.43%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

Decomposition of I (R^1=H, R^2=R^3=CH_3) in Acetonitrile. After I (4.58 g, 10 mmol) was stirred in acetonitrile (50 ml) for 5 hr at 80 °C, the reaction mixture was worked up as described above. Glc analysis of the extract showed that the products were III (1.5%), VI (6%) and VII (38%). Distillation of the extract gave a mixture of VI and VII (VI : VII=1 : 3.5; 0.3 g); bp 65—76 °C/5 mmHg. NMR of VII, δ 2.00 (s, 3H, $OCOCH_3$), 2.93 (d, 2H, J_{H-H}=5.5 Hz, $-CH_2-$), 3.33 (s, 3H, OCH_3), 5.81 (t, 1H, J_{H-H}=5.5 Hz, $-CH<$), 7.17 (s, 5H, phenyl). Analysis of the mixture of VI and VII; Found: C, 67.78; H, 7.40. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

Formation of Bis(2-methoxy-2-phenylethyl)thallium Bromide and Chloride. A pale green heterogeneous mixture of I (R^1=H, R^2=R^3=CH_3) (2.29 g, 5 mmol) and copper(I) bromide (1.43 g, 10 mmol) in acetonitrile (25 ml) was stirred at 81 °C for 1 hr during which period the colour of the solution turned to deep green. After the reaction mixture was cooled down, the pale yellow precipitates (1.59 g, IR inactive) thus formed were filtered off and water (200 ml) was added to the filtrate to afford 0.40 g of white solids which were revealed to be bis(2-methoxy-2-phenylethyl)thallium bromide. Recrystallization from acetonitrile gave 0.27 g of pure white needle crystals (19.5% yield based on I). IR; 1088 (s)cm^{-1} (ν_{C-O}); mp>300 °C. Found: C, 38.82; H, 4.02%. Calcd for $C_{18}H_{22}O_2BrTl$: C, 38.98; H, 4.00%.

The same procedure using copper(I) chloride gave white amorphous solid of bis(2-methoxy-2-phenylethyl)thallium chloride (0.19 g after recrystallization from acetonitrile; 14.9 % yield based on I). IR; 1090 (s)cm^{-1} (ν_{C-O}); mp, slowly decomposed over 205 °C. Found: C, 42.02; H, 4.42%. Calcd for $C_{18}H_{22}O_2ClTl$ C, 42.38; H, 4.35%.

Reaction of I with Copper Salts. The following example shows a typical experimental procedure.

Reaction of I(R^1=H, R^2=R^3=CH_3) with Copper(I) Cyanide in the Presence of Potassium Bromide. A white heterogeneous solution of I (2.29 g, 5 mmol), copper(I) cyanide (0.89 g, 10 mmol), and potassium bromide (1.19 g, 10 mmol) in acetonitrile (25 ml) was stirred at 81 °C for 5 hr during which period the blue precipitates came out gradually. The reaction mixture was worked up as in the case of the decomposition of I in dioxane and glc analysis of the benzene extract showed that the products were IId (R^3=CH_3) (86%), III (4%), IV (R^3=CH_3) (4%) and a trace amount of IIb. Distillation of the extract gave 0.76 g of pure IId; bp 109—

110 °C/5 mmHg. IR; 2250 (ν_{CN}) 1106 (ν_{C-O}), 760 and 703 (phenyl) cm^{-1}. NMR: δ 2.70 (d, 2H, J=6 Hz), 3.29 (s, 3H), 4.44 (t, 1H, J=6 Hz), 7.36 (s, 5H). All the other cyano compounds were isolated by distillation respectively, and explained reasonably by IR and NMR spectra. IId (R^3=C_2H_5), bp 140—142 °C/18 mmHg. IId (R^3=n-C_3H_7), bp 120—122 °C/6 mmHg. IId (R^3=n-C_4H_9), bp 139—140 °C/9 mmHg. Some spectroscopic data and boiling point of other II are as follows. IIa (R^3=CH_3), bp 105—108 °C/6 mmHg (lit,[27] bp 107—108 °C/5 mmHg). IIa (R^3=C_2H_5), bp 110—112 °C/6 mmHg [lit,[28] bp 142—144 °C/14 mmHg]. IIa (R^3=n-C_3H_7), bp 121—122 °C/6 mmHg, IR: 1110 (ν_{C-O}), 760 (phenyl), 700 (phenyl) and 580 (ν_{C-I}) cm^{-1}. NMR: δ 0.73 (t, 3H, J=7 Hz), 1.60 (m, 2H, J=7 Hz), 3.31 (d, 2H, J=6 Hz), 3.32 (t, 2H, J=7 Hz), 4.38 (t, 1H, J=6 Hz) and 7.32 (s, 5H). Found: C, 41.09; H, 4.24%. Calcd for $C_9H_{11}OI$: C, 41.24; H, 4.23%. IIa (R^3=n-C_4H_9), bp 124—125 °C/5 mmHg. NMR: δ 3.17 (d, 1H, J=6 Hz), 3.18 (d, 1H, J=7 Hz), 3.27 (s, 3H), 4.41 (q. 1H, J=7 Hz and 6 Hz) and 7.33 (s. 5H).

Authentic Samples for Glc Analysis. IV and IIc were prepared by the reported method[32] from styrene, copper(II) chloride and alcohols. α-Methoxyethylbenzene (IV, R^3=CH_3) was also prepared by alkaline $NaBH_4$ reduction of α-methoxy-β-acetoxymercuriethylbenzene: bp 71—72 °C/23 mmHg; NMR δ 1.42 (d, 3H, J=6.5 Hz), 3.20 (s. 3H), 4.28 (q, 1H, J=6.5 Hz) and 7.30 (s, 5H). VIII was prepared by refluxing 5 mmol of I (R^1=H, R^2=R^3=CH_3) for 5 hr in methanol (25 ml) containing 5 mmol of BF_3 etherate; yield 92%, bp 103—108 °C/28 mmHg, NMR δ 2.90 (d. 2H), 3.33 (s, 6H), 4.55 (t, 1H) and 7.28 (s, 5H). All of IIa were also obtained in pure state from the reaction of styrene with copper(II) chloride and potassium iodide in alcohols (at refluxing temperature for 2—3 hr).[33]

The authors are very grateful to Professor Katsuhiko Ichikawa, Kyoto University, for his helpful discussions.

The Cyclocopolymerization of Triallyl Citrate with Several Vinyl Monomers

Tetsuji OHATA, Akira MATSUMOTO, and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 565

(Received June 12, 1973)

Triallyl citrate (TAC) was copolymerized with allyl benzoate (ABz), vinyl acetate (VAc), vinyl chloride (VC), acrylonitrile (AN), and styrene (St) at 60 °C with benzoyl peroxide or 2,2′-azobisisobutyronitrile as the initiator; it was considered kinetically in terms of cyclocopolymerization. The following monomer reactivity ratios were obtained: VAc: $r_1=1.29$, $r_2=0.76$, $r_c=0.61$; ABz: $r_1=1.63$, $r_2=1.10$, $r_c=0.47$; VC: $r_1=0.40$; $r_2=1.90$, $r_c=0.31$; AN: $r_1=0.01$, $r_2=8.7$; St: $r_1=0.03$, $r_2=53.0$, where r_1, r_c and r_2 denote the monomer reactivity ratio of the uncyclized, cyclized, and monovinyl radicals respectively. In the copolymerization of TAC with AN, the penultimate effect was also observed: $r_1=r_1'=0.01$, $r_2=k_{122}/k_{121}=11$, $r_2'=k_{222}/k_{221}=5$.

In a previous paper[1] we have suggested that the polymerization of triallyl citrate (TAC) proceeds by means of a cyclopolymerization mechanism analogous to that[2-4] proposed for the polymerization of the diallyl ester. It may, therefore, be expected that the behavior of the copolymerization of TAC with monovinyl monomers can also be accounted in terms of the extension of the cyclocopolymerization mechanism for the copolymerization of the diallyl ester with monovinyl monomer.[2-4]

Thus, this paper is concerned with the copolymerizations of TAC with several monovinyl monomers, including allyl benzoate (ABz), vinyl acetate (VAc), vinyl chloride (VC), acrylonitrile (AN), and styrene (St); radical copolymerizations were conducted, and the results thus obtained will be kinetically discussed in detail. It will deal also with the penultimate effect observed in the copolymerization of TAC with AN.

Experimental

Materials. TAC was prepared by the reaction of citric acid with allyl alcohol according to the method described in the literature.[1]

ABz was obtained as has been described in a previous paper.[2]

VAc,[4] AN,[6] St,[7] and VC[8] as comonomers, 2,2′-azobisisobutyronitrile (AIBN)[8] as an initiator, and *N*,*N*-dimethylformamide[6] as a solvent—these reagents were purified as has been described respectively.

Copolymerization Procedure. The copolymerizations of TAC with VAc,[4] ABz,[2] AN,[6] St,[7] and VC[8] were allowed to proceed in a sealed glass ampoule. After a definite reaction time, the copolymer thus produced was precipitated by pouring the reaction mixture into a large amount of a ethyl ether-petroleum ether mixture (1 : 4 by volume); it was then washed repeatedly with the mixed ether and dried *in vacuo* until a constant weight was obtained. The copolymer was then purified by dissolving in acetone and by subsequently reprecipitating with the mixed ether.

Analyses of Copolymers. The compositions of the purified copolymers were determined by elemental analyses. In the case of the copolymerization of TAC with VAc, the composition of the copolymer was indirectly calculated from the amounts of the unreacted monomer because of the difficulty of direct determination from the analyses of the copolymer; after a definite reaction time, the unreacted VAc monomer was determined by removing it at room temperature from the reaction mixture with a vacuum pump, after which the unreacted TAC monomer was determined by pouring the reaction mixture into a large amount of the ether. The unreacted pendant allyl groups of the TAC-VC copolymer were calculated from the iodine value using the Wijs method,[8] while in the other copolymers, it was calculated from the bromine value determined by the bromide-bromate technique.[1]

The residual unsaturation, R_{us}, was then exhibited as the molar ratio of the unreacted pendant allyl group to the total allyl groups of the TAC incorporated into the copolymer.

Results and Discussion

Figure 1 shows the relations between the relative rate of copolymerization, which is presented as a ratio of the rate of copolymerization to that of the homopolymerization of TAC under the same conditions, and the feed-monomer composition.

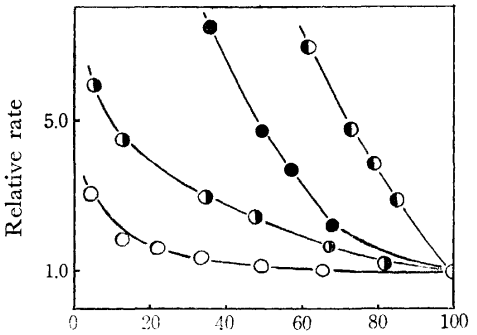

Fig. 1. Relation between the relative rate of copolymerization and the feed-monomer composition.
◐: St, ●: AN, ◑: VC, ○: VAc

The relative rate tended to decrease, as a whole, with an increase in the mole fraction of TAC in the feed; this may be ascribable to the degradative chain transfer of the growing chain end to TAC. On the other hand, its decreasing tendencies changed with the kind of comonomer from the linear lowering for the conjugated monomer (St) to the abrupt one in the low feed-mole fraction of TAC for the unconjugated monomer (VAc); this may be interpreted by considering that the ability of the growing radicals to abstract the allylic hydrogen of TAC decreases with an increase in the conjugation of comonomer, while the possibility of the allyl radical's re-initiating the comonomer is the reverse.

Figure 2 shows the copolymer composition curves based on the data shown in Tables 1—5. In the

Table 1. Copolymerization of TAC (M_1) with VAc (M_2)[a]

◐: St, ●: AN, ○: VAc, ◒: ABz, ◑: VC

copolymerization with ABz, VAc, and VC, the mole fraction of TAC in the copolymer is always larger than that in the feed, but in the other copolymerization systems (M_2: AN and St) it is always smaller. These tendencies were also observed in the copolymerizations of diallyl phthalate.[2,4,6-8]

The relations between R_{us} and the mole fraction of TAC in the feed are shown in Fig. 3, where the different values of R_{us} denoted for the homopolymerization of TAC are due to the difference in the possibility of cyclization reaction between the bulk copolymerization for the TAC–St, VAc, and ABz copolymerization systems and the solution copolymerization for the TAC–AN and VC systems. In the copolymer of TAC with St, AN, and VC(M_2), R_{us} increases with an increase in mole fraction of M_2 in the feed, while with ABz and VAc (M_2) it decreases with an increase in the mole fraction of M_2. Now, it should be noted that R_{us} must be 0.667 if no cyclization and crosslinking reactions occur. On the other hand, in the early stage of polymerization the crosslinking reaction is probably negligible. The deviation of R_{us} from 0.667 may, therefore, be attributed predominantly to the intramolecular cyclization reaction. Thus, the above results suggest that, in the copolymerizations with St, AN, and VC, the cyclization reaction has a tendency to be hindered with an increase in the mole fraction of the comonomer in the feed, while in the copolymerizations with ABz and VAc the cyclization reaction comes to be promoted with an increase in the mole fraction of the comonomer. Similar results were also obtained in the copolymerizations of the diallyl ester;[2-4,6,8] these results can be understood by considering the competition among the unimolecular cyclizations with the allyl group of the same monomer unit, the bimolecular propagation with another diallyl-ester monomer or with the comonomer of the uncyclized radical produced by the radical attack on one allyl group of the diallyl ester.

Determination of the Monomer Reactivity Ratio. In the copolymerizations of TAC with several monovinyl monomers, the cyclization reaction of TAC is not negligible, as may be seen in Fig. 3. On considering the copolymerization mechanism of the triallyl ester (M_1) with the monovinyl monomer(M_2), it is necessary to discuss the possibility of a bicyclo-intramolecular propagation of M_1. However, in the copolymerization of TAC the occurrence of the bicyclo-intramolecular propagation reaction is negligible, as can be seen from the results of the homopolymerization of TAC in our previous paper.[1]

Thus, these copolymerizations may be treated as extensions of the mechanism of the cyclocopolymerization of the divinyl monomer with the monovinyl monomer.[4] The reactions, (1)—(7), can, then, be given as the propagation reactions for copolymerization.

$$M_1\cdot + M_1 \longrightarrow M_1\cdot \qquad 3k_{11}[M_1\cdot][M_1] \qquad (1)$$

$$M_1\cdot + M_2 \longrightarrow M_2\cdot \qquad k_{12}[M_1\cdot][M_2] \qquad (2)$$

$$M_1\cdot \longrightarrow m\cdot \qquad 2k_c[M_1\cdot] \qquad (3)$$

$$m\cdot + M_1 \longrightarrow M_1\cdot \qquad 3k_{c1}[m\cdot][M_1] \qquad (4)$$

$$m\cdot + M_2 \longrightarrow M_2\cdot \qquad k_{c2}[m\cdot][M_2] \qquad (5)$$

$$M_2\cdot + M_1 \longrightarrow M_1\cdot \qquad 3k_{21}[M_2\cdot][M_1] \qquad (6)$$

$$M_2\cdot + M_2 \longrightarrow M_2\cdot \qquad k_{22}[M_2\cdot][M_2] \qquad (7)$$

where M_1 is the TAC monomer; M_2, the monovinyl monomer, and m·, the cyclized radical formed by the intramolecular cyclization of M·. On the basis of the seven propagation reactions presented above, Eqs. (8)—(10) were derived:

$$\frac{3(2-3R_{us})}{3R_{us}+\alpha-1}[M_1]=2K_c-\frac{1}{r_1}\cdot\frac{2-3R_{us}}{3R_{us}+\alpha-1}\cdot[M_2] \qquad (8)$$

$$r_2=\frac{F}{f}\cdot\frac{(1+r_cF)(1+r_1F+2K_c'/[M_2])}{1+r_cF+2K_c'/[M_2]}-F \qquad (9)$$

$$r_2=\frac{F^2}{f(2-3R_{us})}\cdot\frac{2K_c'(r_c+1/F)}{2K_c'+3[M_1](r_c+1/F)}-F \qquad (10)$$

where $r_1=k_{11}/k_{12}$, $r_2=k_{22}/k_{21}$, $r_c=k_{c1}/k_{c2}$, $K_c=k_c/k_{11}$ $K_c'=k_c/k_{12}$ $(r_1\times K_c)$, $f=d[M_1]/d[M_2]$, and $F=3[M_1]/[M_2]$. Here, α is the ratio of the non-consecutive cyclization to the intramolecular cyclization in the same monomer unit, as in the homopolymerization of TAC.[1]

The experimental results may be discussed on the basis of Eqs. (8)—(10). First, in the copolymerizations of TAC with VC, VAc, and ABz, the values of r_1 and K were evaluated by using Eq. (8), and consequently K_c' was determined from $r_1\times K_c$. By using the results thus obtained, we can further evaluate the values of r_2 and r_c from Eq. (9) or (10). The results thus obtained are summarized in Table 6.

Table 6. Monomer reactivity ratios

M_2	r_1	r_2	r_c
VAc[a]	1.29	0.76	0.61
VBz[a]	1.63	1.10	0.47
VC[a]	0.40	1.90	0.31
AN[b]	0.01	8.7	—
St[b]	0.03	53.0	—

a) Estimated on the basis of cyclocopolymerization mechanism. b) Estimated from the general copolymer composition equation.

On the other hand, to the copolymerization of TAC with St the treatment of cyclocopolymerization could not be applied since the copolymerizability was very low; therefore, the accuracy of the analyses was significantly influenced by scatter of the experimental data. As a result, the value shown in Table 6 was obtained by using the usual copolymer composition equation.

Now, it should be noted that the penultimate effect was observed in the copolymerization of TAC with AN. Therefore, the relation between d[AN]/d[TAC] and [AN]/[TAC] was plotted in order to estimate the values of r_2 and r_2' using the method of Joshi[9] (Fig. 4); thus, $r_1=r_1'=0.01$, $r_2=11$, and $r_2'=5$. This suggests that the rate of the addition of the AN monomer to the AN radical with the penultimate TAC unit is twice as large as that with the penultimate AN unit.

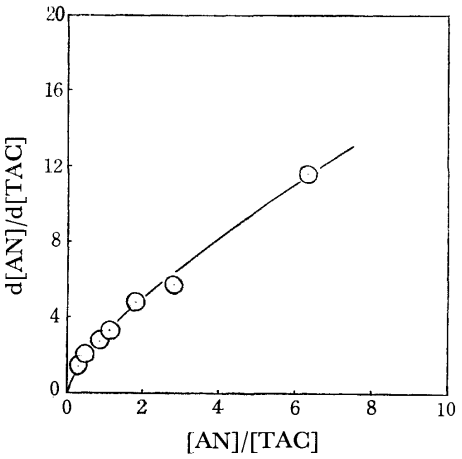

Fig. 4. Evalution of r_2 and r_2' in the copolymerization of TAC with AN.

The difference between r_1 and r_c is also a matter of interest, since r_1 and r_c correspond to the reactivities of the uncyclized and the cyclized radicals respectively. The experimental results show that r_1 is considerably larger than r_c; this may be due to the fact that the existence of steric hindrance in the addition reaction of the cyclized radical with TAC can be expected in light of the molecular model. Such a tendency has also been observed in the copolymerizations of diallyl phthalate with several monovinyl monomers, as has been reported previously.[2,4,8]

The Reduction of Methyl Acetate with Several Hydrosilanes under γ Irradiation

Ren NAKAO, Tsugio FUKUMOTO, and Jitsuo TSURUGI

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

(Received July 13, 1973)

The reduction of methyl acetate with chlorinated hydrosilanes, $HSiCl_{3-n}R_n$ ($R=CH_3$ or OCH_3, $n=0$—2), and triethylsilane under γ irradiation has been studied. The hydrosilanes other than triethylsilane reduce the ester to ethyl methyl ether. The reaction rate is proportional to the hydrosilane concentration and is independent of the methyl acetate concentration. The results indicate that the rate-determining step in the reduction reaction is the hydrogen abstraction from the hydrosilanes. The reactivities of the chlorinated hydrosilanes in the reaction increase with the progressive chlorine substitution on the silicon atom and may be due to the susceptibility of each H–Si bond toward free radicals, $CH_3\text{–}\dot{C}(\text{–}O\text{–}SiX_3)\text{–}OCH_3$.

Previously, we reported that the aliphatic carboxylates can be reduced to dialkyl ethers with trichlorosilane under γ irradiation.[1] Kinetic work[2] on this reduction and the reduction of acetals[3] with trichlorosilane have indicated that the mechanism for the reduction of the ester with trichlorosilane consists of three sequences. The first is the radical-chain addition of trichlorosilane to a carbonyl group of a carboxylate (Eqs. (1) and (2)). The second is the ionic chlorination of the adduct (I) by chlorosilanes, giving an α-chloro ether (II) (Eq. (3)). The third is the reduction of α-chloro ether to an ether with trichlorosilane (Eqs. (4) and (5)).

$$\cdot SiX_3 + R\text{-}\underset{\underset{O}{\|}}{C}\text{-}OR' \rightarrow R\text{-}\underset{\underset{O\text{-}SiX_3}{|}}{\dot{C}}\text{-}OR' \quad (1)$$

$$R\text{-}\underset{\underset{OSiX_3}{|}}{\dot{C}}\text{-}OR' + HSiX_3 \rightarrow R\text{-}\underset{\underset{O\text{-}SiX_3}{|}}{CH}\text{-}OR' \ (I) + \cdot SiX_3 \quad (2)$$

$$(I) + Cl\text{-}Si\lessgtr \rightarrow R\text{-}CHCl\text{-}OR' \ (II) + X_3SiOSi\lessgtr \quad (3)$$

$$(II) + \cdot SiX_3 \rightarrow R\text{-}\dot{C}H\text{-}OR' + ClSiX_3 \quad (4)$$

$$R\text{-}\dot{C}H\text{-}OR' + HSiX_3 \rightarrow R\text{-}CH_2\text{-}OR' + \cdot SiX_3 \quad (5)$$

It seems interesting to examine whether chlorinated hydrosilanes containing the general formula $HSiCl_{3-n}R_n$ ($R=CH_3$ or OCH_3, $n=0$—2) can be used in the reduction of the ester, and, if so, which is the most efficient reagent. With these points in view, trichlorosilane, methyldichlorosilane, dimethylchlorosilane, methoxydichlorosilane, dimethoxychlorosilane, and triethylsilane were allowed to react with methyl acetate and acetaldehyde dimethyl acetal under γ irradiation.[4]

Results and Discussion

All the reactions were carried out in tetrachlorosilane as a solvent. Our previous paper[3] reported that all chlorinated silanes including tetrachlorosilane can chlorinate an acetal-type intermediate (I) to an α-chloro ether (II) in Eq. (3), and that the chlorination is instantaneous. In the present experiments, tetrachlorosilane as a solvent behaves as the chlorinating agent[5] in Eq. (3), and the chlorinated hydrosilanes ($HSiCl_{3-n}R_n$) used may be regarded as participating only in the first sequence (Eqs. (1) and (2)) and the third sequence (Eqs. (4) and (5)).

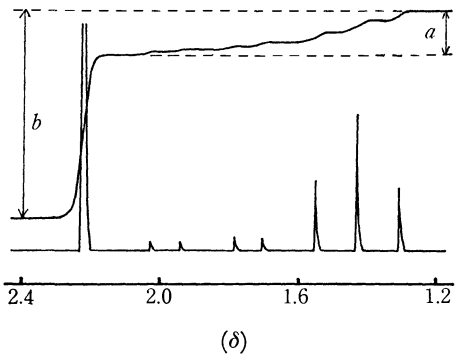

Fig. 1. NMR spectrum and integration curve of an irradiated mixture of methyl acetate and trichlorosilane (see the footnote (a) in Table 1), where singlet at δ 2.22 was attributable to $CH_3C(O)$- of methyl acetate, and two doublets at δ 1.74 and 1.98, and triplet at δ 1.43 were assigned to the corresponding methyl protons of the adduct, α-chloroethyl methyl ether, and ethyl methyl ether, respectively. Dose rate; 1.7 M rad/h and dose; 0.9 M rad.

A typical example of the NMR spectrum of a γ-irradiated mixture of methyl acetate and trichlorosilane in tetrachlorosilane is shown in Fig. 1. Small amounts of the adduct ((I), in which $R=R'=CH_3$ and $X=Cl$) and α-chloroethyl methyl ether were detected, together with the unchanged ester and the ethyl methyl ether produced.

In order to shed light on the mechanism, it seems necessary to determine the rates of the first sequence (adduct formation) and the third sequence (the reduction of α-chloro ether) separately. Because of the (ester→I→II→ether) sequence and the equimolar relationship[2] between species, the rate of the adduct formation at any given reactant concentration can be obtained by determining the total sum of the adduct, the α-chloro ether, and the ether in the reaction system. When a mixture of a hydrosilane and methyl acetate (3 : 1 molar ratio) in tetrachlorosilane was irradiated for various time periods, a plot of the total sum against the irradiation time was found to be a straight line up to *ca.* a 30% conversion of methyl acetate. The rates of the adduct formation, which were calculated from

Table 1. Rates of the reactions with several hydrosilanes

Hydrosilane	Rate of reduction[a] (mol/l·h), (A)	Rate of reduction[b] (mol/l·h), (B)	R_{add}/R_{red}[c] (2A/3B)
$HSiCl_3$	0.76	0.77	0.66
$HSiCl_2Me$	0.15	0.13	0.79
$HSiCl_2OMe$	0.09	0.14	0.44
$HSiClMe_2$	0.05	0.08	0.41
$HSiCl(OMe)_2$	0.03	0.05	0.39

Dose rate; 1.7 M rad/h. a) CH_3COOCH_3; 0.7 mmol; hydrosilane; 2.1 mmol, $SiCl_4$; 1 ml. b) $CH_3CH(OCH_3)_2$; 0.7 mmol, hydrosilane; 1.4 mmol, $SiCl_4$; 1 ml. c) This value was corrected by a factor of 2/3, since the addition and reduction reactions were carried out with 3 : 1 aad 2 : 1 molar excess of each hydrosilane, respectively, and the rates of both reactions were proportional to hydrosilane concentration as described in the text. Detailed calculations on the concentrations of each hydrosilane in both the addition and reduction reactions show that the factor 2/3 is approximately correct to obtain the ratio R_{add}/R_{red} at the same concentration.

the respective slopes of the straight lines for five hydrosilanes, are shown in Table 1.

As to the third sequence, we can utilize the following reaction. Our previous paper[3] reported that the simple mixing of acetaldehyde dimethyl acetal and tetrachlorosilane gave α-chloroethyl methyl ether.

$$CH_3CH(OCH_3)_2 + Cl_4Si \rightarrow CH_3CHClOCH_3 + Cl_3SiOCH_3$$

Therefore, acetaldehyde dimethyl acetal in tetrachlorosilane was allowed to react with hydrosilanes (1 : 2 molar ratio) under γ irradiation. The rates of the reduction of the α-chloro ether at given reactant concentrations can be obtained by determining the amount of ethyl methyl ether produced, these rates are shown in Table 1 (the time plot is a straight line in this case also). In both reactions (the addition to the carboxylate and the reduction of the α-chloro ether), the reactivities of the hydrosilanes increase with progressive chlorine substitution on the silicon atom, as Table 1 shows.

R_{add}/R_{red}, the ratio of the rate of the addition to that of the reduction at the same hydrosilane concentration for the individual hydrosilane, is given in the last column of Table 1. All of the ratios are smaller than unity. This result clearly indicates that the adduct formation is rate-determining. This is consistent with the fact that little α-chloroethyl methyl ether was detected in the reaction mixture when hydrosilanes other than methyldichlorosilane were used. When methyldichlorosilane was used, however, the α-chloro ether was detected by NMR. This result coincides with the R_{add}/R_{red} ratio for methyldichlorosilane, which is 0.79—the largest in the series.

The dependence of both rates on the reactant concentrations was investigated by using methoxydichlorosilane as a representative. The results for the addition to methyl acetate and for the reduction of α-chloroethyl

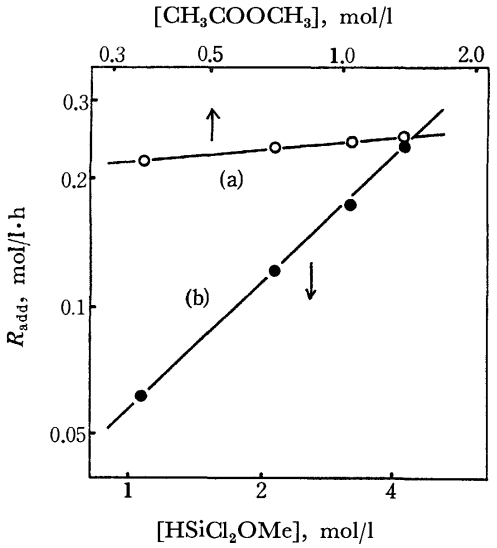

Fig. 2. Variation in the rate of the adduct formation with reactant concentrations under a given dose rate of 1.7 M rad/h. (a); $[HSiCl_2OMe]=4$ mol/l, (b); $[CH_3COOCH_3]=0.7$ mol/l.

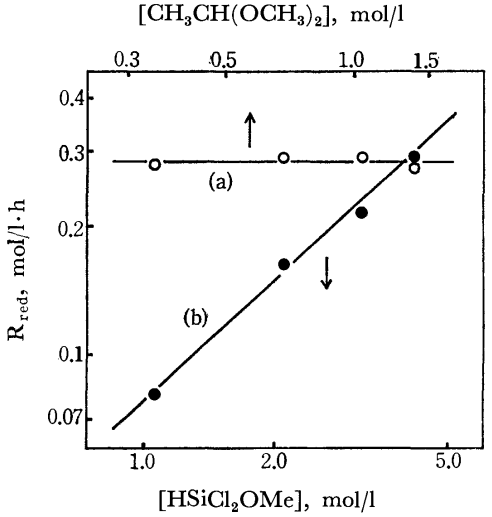

Fig. 3. Variation in the rate of the reduction of α-chloroethyl methyl ether with reactant concentrations under a given dose rate of 1.7 M rad/h. (a); $[HSiCl_2OMe]=4$ mol/l, (b); $[CH_3CH(OCH_3)_2]=0.7$ mol/l.

methyl ether are shown in Figs. 2 and 3 respectively, where the (a) lines give a run with a constant methoxydichlorosilane concentration and with various concentrations of methyl acetate or acetaldehyde dimethyl acetal, while the (b) lines show one with a constant concentration of the ester or the acetal and with various concentrations of the hydrosilane. The two slopes calculated from the (a) and (b) lines in Fig. 2 were 0.05 and 0.97, while those obtained from Fig. 3 were zero and 0.93, respectively. Thus, both the addition and reduction reaction rates were proportional to the methoxydichlorosilane concentration and were independent of the carboxylate or acetal concentration. The same dependence had been observed in the addition reaction of trichlorosilane[2] to the ester (the first sequence in the reduction of the ester). The results

presented above suggest that the rate-determining step of the addition sequence is Eq. (2), while that of the reduction sequence of the α-chloro ether is Eq. (5). The results mean that the hydrogen abstraction steps are rate-determining in both sequences.

When γ irradiation is carried out under the same conditions, the rate of the radical formation may be regarded as identical in all the reactions using any hydrosilane. Therefore, we concluded that the rates in Table 1 correspond to the reactivities of each Si–H bond toward either $CH_3-\dot{C}(O-SiX_3)-OCH_3$ or $CH_3-\dot{C}H-OCH_3$. The reactivity increases with the progressive introduction of chlorine, which is an electron-withdrawing atom, on the silicon atom. The reactivities of Me_3SiH, $MeCl_2SiH$, and Cl_3SiH for hydrogen abstraction by methyl radicals have been reported[6] to increase consistently with an increase in the amount of chlorine on the silicon atom. Nagai and Sakurai[7] described that an electron-withdrawing group on a silicon atom decreases the contribution of $\rangle Si^+H^-$ in the resonance formula: $\rangle Si-H \leftrightarrow \rangle Si^+H^-$, thus causing the bond strength of Si–H to become weak. In this connection, the reactivities of hydrosilanes on the hydrogen abstraction by the attack of halogenated methyl radicals, $Cl_3C\cdot$ or $Cl_2HC\cdot$, have been reported[8] to decrease with the progressive introduction of an electron-withdrawing group on the silicon atom. Kerr *et al.*[9] reported that the reaction rates of $F_2HC\cdot$ and $FH_2C\cdot$ radicals toward hydrogen abstraction from $HSiCl_3$ were lower than the corresponding rate for $H_3C\cdot$ radicals and explained the result in terms of a polar repulsion between $HSiCl_3$ and the fluorinated methyl radicals. It is clear from the above literature[6-9] that the $CH_3-\dot{C}(O-SiEt_3)-OCH_3$ and $CH_3-\dot{C}H-OCH_3$ radicals in this paper behave like methyl radicals rather than like halogenated methyl radicals.

We attempted the γ-induced reduction of methyl acetate with triethylsilane in tetrachlorosilane, but ethyl methyl ether was not detected by gas chromatography. On the other hand, acetaldehyde dimethyl acetal could be reduced to ethyl methyl ether in a high yield under the same conditions.[3] If the adduct, $CH_3-CH(O-Si_3)-OCH_3$, were produced, the adduct had to be reduced *via* α-chloroethyl methyl ether[10] to ethyl methyl ether under the same conditions. Consequently, these facts indicate that triethylsilane, containing no chlorine atom, cannot be added to the carbonyl group of methyl acetate.

Experimental

The NMR spectra were recorded on JNM 3H-60, with tetramethylsilane as the external standard. Gas chromatographies were determined by means of a Yanagimoto GCG-5DH, with a 3-m column containing 30% dioctyl phthalate on Celite 545 and using helium as the carrier gas.

Materials. The methoxydichlorosilane (bp 51 °C) was prepared by the methanolysis of trichlorosilane.[3] The dimethoxychlorosilane was synthesized in a similar manner: bp 70 °C (lit,[11] 70.5 °C).

The other reagents, commercial materials, were previously distilled and stored in an ampoule.

Procedure for γ Irradiation. To an NMR tube which was attached to a vacuum line, given amounts of tetrachlorosilane, methyl acetate, and hydrosilane were transferred successively by means of the vacuum line. Although the procedure on using acetaldehyde dimethyl acetal as a starting material was almost identical with those described above, a hydrosilane was added after the mixture of tetrachlorosilane and the acetal had stood for 30 min. The tube, after being sealed, was irradiated by γ-rays from a ^{60}Co source.

Estimation of Products. The adduct was estimated by the use of the NMR intensity of the methyl proton which resulted from the $CH_3C(O)$ in methyl acetate. The results were obtained from the average values of ten scannings. For example, the yield of the addition reaction was calculated by the use of the a/b ratio in Fig. 1, where (a) showed the total methyl intensity of the adduct, α-chloroethyl methyl ether, and ethyl methyl ether, and where (b) gave the sum of (a) and the intensity of the unchanged methyl acetate. The yield of the reduction reaction was estimated in the same manner as above by a comparison of the corresponding methyl intensity of the ether with that of α-chloroethyl methyl ether.

4) The photoinduced decomposition of di-*tert*-butyl peroxide and UV irratiation can initiate the reduction as well as γ irradiation can. However, the use of the peroxide is inconveniently followed by the side reaction of hydrosilane with the acetone produced by the decomposition of the peroxide, and UV irradiation has to be carried out in a quartz NMR tube.

5) An earlier article (B. G. Gowenlock and K. E. Thomas, *J. Chem. Soc.*, **1965**, 5068) has reported an unusually weak Cl_3Si-Cl bond in tetrachlorosilane, leading to the view that tetrachlorosilane behaves exclusively as a chlorinating agent.

Chemistry of Nitrosoimines. VI.[1] Attempted Syntheses of Some[1] Resonance Stabilized Nitrosoimines and Their UV Spectra

Kin-ya AKIBA, Satoru MATSUNAMI, Chikahiko EGUCHI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received October 27, 1973)

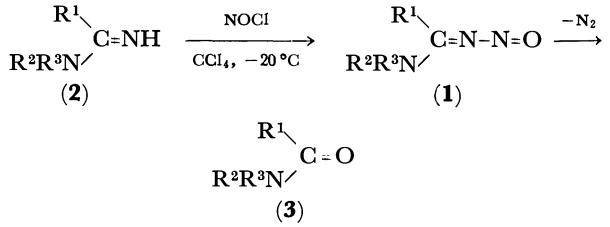
1,1,3,3-Tetrasubstituted 2-nitrosoguanidines, the attempted syntheses and UV spectra of which are reported, are unstable, and decomposed into the corresponding ureas and nitrogen, only 2-nitroso-1,1,3,3-tetraphenylguanidine (**1f**) being obtained as a pure compound. The reaction of **1f** with phenyl isocyanate gave pentaphenylguanidine, probably through 1,4-cycloaddition.

N-Nitrosoaldimines were suggested as being intermediates to explain the formation of aldehydes during the course of reaction of alkylidenetriphenylphosphoranes with nitric oxide.[2] Thoman and Hunsberger reported the syntheses of sterically hindered *N*-nitrosoketimines and showed basic characters of *N*-nitrosoimines for the first time.[3]

We report herewith on the attempted syntheses of resonance stabilized *N*-nitrosoimines such as 1,1,3,3-tetrasubstituted 2-nitrosoguanidines, their UV spectra, decomposition rates of one of them in a few solvents and some reactions of 2-nitroso-1,1,3,3-tetraphenylguanidine (**1f**).

1,1,3,3-Tetrasubstituted guanidines (**2a—f**) and *S*-benzyl-*N*-ethyl-*N*-phenylisothiourea (**2g**) were nitrosated with nitrosyl chloride in carbon tetrachloride in the presence of anhydrous sodium acetate at *ca.* −20 °C according to the reported procedure.[3] Upon the mixing of two reagents, a yellow to orange red color appeared in the solution according to the structure of the product.

All the nitrosoimines (**1a—e,g**) except 2-nitroso-1,1,3,3-tetraphenylguanidine (**1f**) decomposed to the corresponding carbonyl compounds, *i.e.*, ureas (**3a—e**) and thiolcarbamate (**3g**), during the course of reaction and isolation.



Scheme 1.

	R^1	R^2	R^3	Yield (%)
a :	Me_2N	Me	Me	53
b :	Et_2N	Et	Et	11*
e :		$(CH_2)_5$		65
d :		$(CH_2)_2O(CH_2)_2$		57
e :	PhMeN	Me	Ph	61
f :	Ph_2N	Ph	Ph	91
g :	$PhCH_2S$	Et	Ph	86

* The low yield is due to isolation procedure, during which the reaction mixture was kept at low pressure for a long time to evaporate the solvent before distillation.

Ths isolated yields of carbonyl compounds (**3**) are shown in Scheme 1.

Nitrosation of **2a—d** and **2g** was attempted at lower temperatures (−60 to −70 °C) in dichloromethane.

Table 1. Absorption spectra of nitrosoimines (**1**)

	Nitrosoimine	Solvent	λ_{max} (nm)[a] $\pi\rightarrow\pi^*$	$n\rightarrow\pi^*$
1a	$(Me_2N)_2C=N-N=O$	CH_2Cl_2	277 (sh)	[b]
1b	$(Et_2N)_2C=N-N=O$	CH_2Cl_2	277	458
1c		CH_2Cl_2	276	462
1d		CH_2Cl_2	276	473
1e	$(PhMeN)_2C=N-N=O$	$CHCl_3$	289 (sh)	488
1f	$(Ph_2N)_2C=N-N=O$	$CHCl_3$	330 (9550)	519 (183)

Table 2. UV spectra of guanidines (**2**)

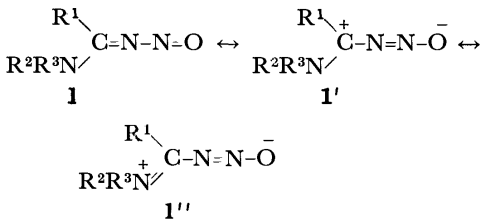
	Guanidine	Solvent	λ_{max} (nm)	ε
2b	$(Et_2N)_2C=NH$	EtOH	225	9.5×10^3
2c		EtOH	224	7.0×10^3
2d		EtOH	224	1.1×10^4
2e	$(PhMeN)_2C=NH$	EtOH	231 250	1.5×10^4 1.2×10^4
2f	$(Ph_2N)_2C=NH$	EtOH	265 (broad)	2.3×10^4
2j		$CHCl_3$	281 288	5.3×10^3 5.9×10^3

The color of the resulting *N*-nitrosoimines (**1**) was deeper and more intense, yellow orange to red brown.

UV spectra of nitrosoimines are shown in Table 1 together with those of three reference compounds (**1h**—**j**).

Nitrosoimines have two characteristic bands (π-π^* and n-π^*). The π-π^* bands are shifted to longer wavelengths than those of the corresponding imines by 50—70 nm (Table 2).

These π-π^* bands can be attributed to neither the separate imino nor nitroso groups,[4] and are probably due to the nitrosoimino group with a large contribution of canonical structures **1'** and **1''**.



The π-π^* band shifts further toward a longer wavelength with substitution by a phenyl on the nitrogen (**1e**, **f**, **g**). The effect is common to the parent imines (**2**), but larger in the case of nitrosoimines (**1**).

It might be of interest to note that n-π^* bands of **1a**—**d** are shifted toward longer wavelengths while their π-π^* bands remain constant.

The n-π^* bands of **1** are expected to consist of two components at least, *viz.*, $_{N(C=N)}$n-π^* and $_{N(N=O)}$n-π^*. This was found in the case of nitrosoketimines (**1h**, **i**),[3] but not in our case (Table 1).

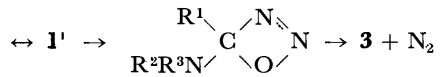
UV spectra and rates of decomposition of bis(morpholino)-*N*-nitrosomethyleneimine (**1d**) were measured in four solvents. The results are shown in Table 3. The blue shift of the n-π^* band is very large (473 nm in CH_2Cl_2 and 418 nm in H_2O). Three peaks appear as n-π^* bands in alcohols but the reason is not clear.

TABLE 3. SOLVENT EFFECT ON ABSORPTION SPECTRA AND DECOMPOSITION RATES OF BIS(MORPHOLINO)-*N*-NITROSOMETHYLENEIMINE (**1d**)

Solvent	λ_{max} (nm)		k (s^{-1}) (13.5 °C)
	$\pi\rightarrow\pi^*$	n$\rightarrow\pi^*$	
CH_2Cl_2	276	473	3.5×10^{-3}
EtOH	276 (sh)	404, 423.5, 443 (sh)	2.8×10^{-4}
MeOH	274.5	404, 425.5, 441 (sh)	4.0×10^{-4}
H_2O	268.5	418	1.5×10^{-5}

1d is fairly stable in water at room temperature, though the yellowish green color of **1d** fades rapidly with evolution of gas (N_2) at 90 °C. The rates of decomposition were followed by the decrease in π-π^* absorption. Plots of absorption intensity *vs.* time indicates that the rate of decomposition follows first-order kinetics and decreases with the increase in polarity of the solvents (Table 3).

This is consistent with the unimolecular decomposition mechanism in which a non-polar four-membered ring is assumed to be a transition state starting from a polar ground state.



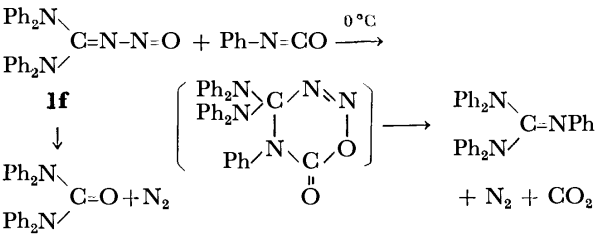
Thoman and Hunsberger also observed that the rate of decomposition of *N*-nitroso-2,4'-dimethyldiphenylmethyleneimine (**1i**) in cyclohexane indicates a first-order mechanism, followed by the rate of evolution of nitrogen.[3]

Guanidines are stable against hydrolysis, so there is no need to consider hydrolysis in contrast to the case of *N*-nitrosoketimines.

If nitrosoimines have a considerable polar character in ground state, they are expected to undergo 1,4-cycloaddition with appropriate dienophiles.

Attempts to react 2-nitroso-1,1,3,3-tetraphenylguanidine (**1f**) with ethyl vinyl ether and maleic anhydride in chloroform at 0 °C for a month were unsuccessful, tetraphenylurea being recovered quantitatively (thermal decomposition product).

Reaction of **1f** with phenyl isocyanate under the same conditions gave pentaphenylguanidine in 38% yield together with 43% of tetraphenylurea as shown below.



1,1,3,3-Tetramethyl-2-phenylguanidine reacted with *p*-toluenesulfonyl isocyanate to give 1,2-cycloaddition product.[5] 1,4-Cycloaddition mechanism might be preferred in the reaction.

Experimental

Materials. *(a) Guanidines*: Commercial 1,1,3,3-tetramethylguanidine (**2a**) was distilled before use (bp 160—161 °C). 1,1,3,3-Tetraethylguanidine (**2b**) was prepared from diethylcyanamide and diethylamine (bp 92 °C/13 mmHg).[6,7] Bis(piperidino)methyleneimine (**2c**) was prepared from piperidine and cyanogen bromide (bp 110—116 °C/0.15—0.2 mmHg).[7] Bis(morpholino)methyleneimine (**2d**) was prepared by the same method (mp 87—93 °C).[7] 1,3-Dimethyl-1,3-diphenylguanidine (**2e**) was prepared as follows: *N*-methylaniline hydrochloride (21.6 g) and *N*-methyl-*N*-phenylcyanamide (20 g) were heated in a sealed tube at 180—190 °C for 2 hr. The resulting mass was dissolved in ethanol. Sodium hydroxide was added to the solution until the pH of the solution became 11. The resulting NaCl was filtered off and ethanol was evaporated. The residue was extracted with benzene, and the residual liquid was distilled under reduced pressure after evaporation of benzene. Bp 124.5—127 °C/0.15 mmHg,[8] yield 51%. The yield decreased when the sealed tube was heated longer (4 or 6 hr) and it was necessary to adjust the pH of the solution to around 11. 1,1,3,3-Tetraphenylguanidine (**2f**) was prepared from diphenylcyanamide[9] (34 g) and diphenylamine hydrochloride (36 g) which were heated in a sealed tube at 175 °C for 6 hr. The resulting mass was extracted with aq. hydrochloric acid and the aq. solution was made alkaline with NaOH.

The resulting precipitates were filtered and recrystallized from ligroin, mp 132.0—132.5 °C, yield 32%.[10] Larger scale preparations gave lower yields (5—20%).

(b) Ureas and Thiolcarbamate: Ureas and thiolcarbamate were prepared from the corresponding secondary amines and phosgene according to methods given in literature; tetramethylurea (**3a**: bp 170.5—173.0 °C),[11] tetraethylurea (**3b**: 61—62 °C/6 mmHg),[12] bispiperidinoketone (**3c**: mp 39—42 °C),[13] bismorpholinoketone (**3d**: mp 139—141 °C)[13] *sym*-dimethyldiphenylurea (**3e**: mp 120—122 °C),[14] tetraphenylurea (**3f**: mp 179.5—180.0 °C),[14] and benzyl *N*-ethyl-*N*-phenylthiolcarbamate (**3g**: mp 46.2—47.0 °C).[15]

General Procedure of Nitrosation. (a) A solution of nitrosyl chloride (4.9 g, 75 mmol) in carbon tetrachloride (50 ml) was cooled under stirring to *ca.* −20 °C in a dry ice-acetone bath with anhydrous sodium acetate (14.8 g, 145 mmol). A cold solution of guanidine (50 mmol) in carbon tetrachloride (20 mmol) was then added dropwise for 20 min, the internal temperature being kept below −10 °C. The mixture was stirred for 20 min at −10 °C, and washed with cold 10% potassium hydrogen carbonate (150 ml) and then with ice-water (150 ml). The dried solution (with anhydrous magnesium sulfate) was evaporated under reduced pressure and the residue was distilled or recrystallized. Ureas thus produced were identified by a comparison with authentic samples.

(b) For UV measurement, dichloromethane was used as a solvent, and nitrosation was performed at *ca.* −70 °C, the dried solution being then used for the measurement. For the kinetic study of decomposition of **1d**, dichloromethane was evaporated below 0 °C, and the resulting yellow slurry was dissolved in an appropriate solvent.

(c) 1,1,3,3-Tetraphenylguanidine (**2f**) was nitrosated according to procedure (a). A red solid appeared during nitrosation which was quickly filtered off after addition of cold 10% potassium hydrogen carbonate. The filtered solid was dried in a vacuum desiccator over P_2O_5. The red solid (**1f**) was then recrystallized from chloroform–ether–petroleum ether at *ca.* −60 °C. Mp 80 °C (dec.); $\lambda_{max}^{CHCl_3}$ 330 (ε 9550) and 519 nm (183); yield, 81—92%.

The compound **1f** is stable in solid state at −20 °C but decomposes fairly rapidly in chloroform at room temperature. Decomposition was not detected when it was left to stand for a day in chloroform at −60 to −70 °C.

Found: C, 76.30; H, 5.43; N, 14.65%. Calcd for $C_{25}H_{20}N_4O$: C, 76.51; H, 5.14; N, 14.28%.

*Thermal Decomposition of 2-Nitroso-1,1,3,3-tetraphenylguanidine (**1f**).* A solution of **1f** (0.9 g, 2.3 mmol) in chloroform (20 ml) was left to stand at 0 °C for a month. The residue, after evaporation of chloroform, was chromatographed on silica gel, and tetraphenylurea (0.762 g, 2.1 mmol, 91%) was eluted with dichloromethane.

*Reaction of **1f** with Phenyl Isocyanate.* Phenyl isocyanate (1.83 g, 15.3 mmol) and **1f** (3.0 g, 7.7 mmol) were dissolved in chloroform (25 ml) and the solution was left to stand at 0 °C for a month. Ethanol (5 ml) was added to convert the residual phenyl isocyanate into the urethane, and the solvent was evaporated. The residue was chromatographed on silica gel to elute urethane and tetraphenylurea (1.19 g, 3.3 mmol, 43%) with dichloromethane. The residual component was eluted with ethanol and again chromatographed on alumina to elute pentaphenylguanidine (1.26 g, 2.9 mmol, 38%), mp 180.0—180.5 °C, $\nu_{C=N}$ 1625 cm^{-1}; M^+(437).

Found: C, 84.77; H, 5.90; N, 9.85%. Calcd for $C_{31}H_{25}N_3$: C, 84.71; H, 5.73; N, 9.56%.

Preparation of Stable 2,3-Dihydroindolizines by the Reactions of Pyridinium Methylides with Various Acrylates

Akikazu KAKEHI and Suketaka ITO

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received November 17, 1973)

Pyridinium methoxycarbonylmethylides(**5**—**8**), readily obtainable from their corresponding salts(**1**—**4**), reacted with various acrylates to afford dimethyl 2,3-*trans*-dihydroindolizine-1,3-dicarboxylate derivatives(**9**—**20**) in moderate yields. These dihydroindolizines were very stable and were not aromatized by heating. However, treatment with lead tetraacetate gave the corresponding indolizine derivatives(**21**—**32**) in good yields. The configuration at C-2 and C-3 positions in these dihydroindolizines was assigned to *trans* from their NMR and by comparison with an authentic specimen(**12**).

Cycloaddition and cyclization of various pyridinium ylides are useful methods for synthesizing nitrogen-bridged heteroaromatics such as indolizines and pyrazolopyridines. However, because of their sensitiveness to air, hardly any reports have appeared on the isolation of primary dihydroadducts formed.

Sasaki *et al.*,[1] and Tamura *et al.*[2] have reported that 1,5-dipolar cyclization of pyridinium allylides gave only their aromatized indolizine derivatives. Pohjala[3] reported on the isolation of the primary dihydroadducts, 1,8a-dihydroindolizines by similar cyclization reactions.

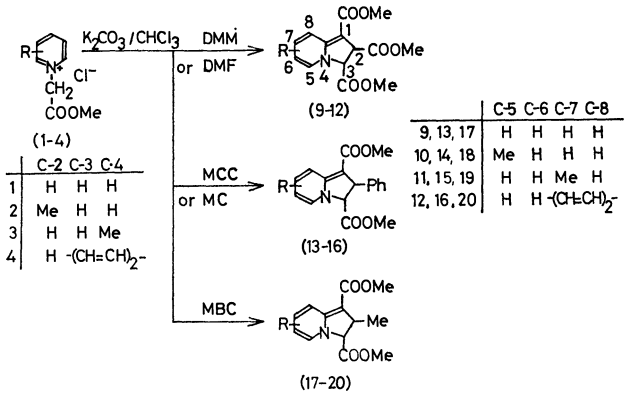
Kabayashi *et al.*[4] obtained 2,3- and 3,8a-dihydro isomers from the 1,3-dipolar cycloaddition of isoquinolinium disubstituted methylides with dimethyl acetylenedicarboxylate.

This paper deals with 1,3-dipolar cycloaddition of pyridinium methoxycarbonylmethylides with various acrylates, and the isolation of the resulting stable 2,3-dihydroindolizines.

Results and Discussion

Reactions of Pyridinium Salts(1)-(4) with Various Acrylates in the Presence of Alkali. An equimolar mixture each of pyridinium salt(**1**)—(**4**) and dimethyl maleate (DMM) were stirred with excess potassium carbonate in chloroform at room temperature for 2—3 days to afford 2,3-dihydroindolizine derivatives(**9**)—(**12**) in 20—50% yields respectively. The same products(**9**) and (**10**) were obtained in 29 and 35% yields, respectively, when dimethyl fumarate(DMF) was used in place of DMM for the reactions with salts(**1**) and (**2**). Similar treatments of the salts(**1**)—(**4**) with methyl α-chlorocinnamate (MCC) and methyl α-bromocrotonate(MBC) also afforded the corresponding 2,3-dihydroindolizines(**13**)—(**20**). Compound (**13**) was also prepared from salt(**1**) and methyl cinnamate(MC), but the yield was low (6%). In these reactions, no product generated through the Micheal-type reaction of the pyridinium methylides(**5**)—(**8**) with the acrylates, such as observed in the reaction of *N*-ethoxycarbonyliminopyridinium ylide,[5] was detected. The results are shown in Scheme 1.

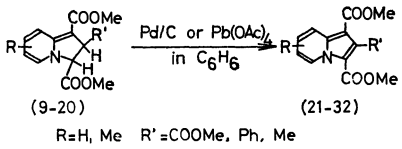
In contrast with the instability of the known 1,8a- and 3,8a-dihydroindolizine derivatives, 2,3-dihydroindolizines (**9**)—(**20**) were very stable. Compounds (**9**)—(**20**) remained unchanged on being put to stand for a few months on contact with air or when their



Scheme 1.

benzene solutions were refluxed. However, treatment with dehydrogenating agents gave the corresponding indolizine derivatives (**21**)—(**32**).

Aromatization of Dihydroindolizines(9)—(20). Dihydroindolizines(**9**)—(**20**) were treated with palladium on carbon in benzene at reflux temperature to afford the corresponding indolizine derivatives(**21**)—(**32**) in only 10—20% yields. However, increased yields were observed when lead tetraacetate was used as a dehydrogenating agent(Scheme 2).



Scheme 2.

Structural Elucidation of 2,3-Dihydroindolizines(9)—(20). Structures of products(**9**)—(**20**) were established mainly by their physical and spectral data and by comparison with the authentic specimen(**12**) reported by Kobayashi.[4] The elemental analyses of the products (**9**), (**10**), (**12**)—(**14**), (**16**)—(**18**) and (**20**) were in good accordance with their proposed structures. The analyses of products(**11**), (**15**) and (**19**) were not performed, since the compounds were amorphous and preparation of the samples for analyses was unsuccessful. The spectral patterns of products (**9**)—(**20**), were extremely similar to each other. The NMR spectra, in particular, strongly supported the presence of the 2,3-dihydroindolizine skeleton; for example, compound(**9**) exhibited signals at δ 5.95, 6.99, 7.03 and

Table 1. NMR spectral data of 2,3-dihydroindolizines

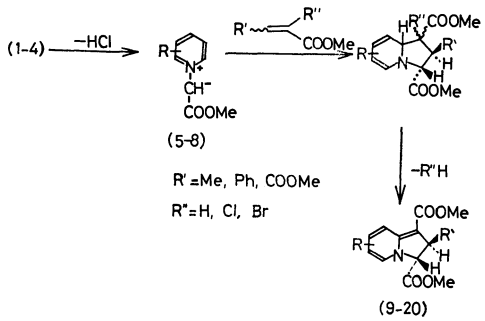
a) All compounds were measured in deuteriochloroform. b) Plus 9.74(1H, d, J=8.0). c) Overlapped with phenyl protons. d) Plus 9.78(1H, d, J=7.5). e) Plus 9.81(1H, d, J=7.5).

7.35 due to the four protons on the six-membered ring, and at δ 4.18 and 5.01 attributable to the two protons on the five-membered ring, together with three methoxycarbonyl proton signals at δ 3.67, 3.75 and 3.80. The latter signals at δ 4.18 and 5.01 coupled with 3.5 Hz, which is indicative of its *trans* configuration. In the cases of compounds(**17**)—(**20**) the proposed structure, 2,3-dihydroindolizine, was verified by the presence of the coupling(J=7.0 Hz) between a proton and a methyl group at C-2 position. The NMR data of compounds (**9**)—(**20**) are listed in Table 1. Compound (**12**) was entirely in accord with an authentic specimen prepared by the alkali-methanolysis of the corresponding adduct of isoquinolinium bis(methoxycarbonyl)methylide and dimethyl acetylenedicarboxylate.[4]

From the results, products(**9**)—(**20**) were concluded to be dimethyl 2,3-*trans*-dihydroindolizine-1,3-dicarboxylate derivatives.

*Structural Elucidation of Indolizines(**21**)—(**32**).* The structures of the indolizine derivatives(**21**)—(**32**) were determined by their unequivocal syntheses(**21**)—(**28**) and by comparison with authentic specimens(**21**) and (**24**). Compounds(**21**)—(**28**) were in accord with the indolizines obtained from the 1,3-dipolar cycloaddition of pyridinium methoxycarbonylmethylides(**5**)—(**8**) with dimethyl acetylenedicarboxylate and methyl phenylpropiolate respectively.[6]

Reaction Mechanism. The formation of 2,3-dihydroindolizines (**9**)—(**20**) seems to proceed *via* the well-known 1,3-dipolar cycloaddition of pyridinium methoxycarbonylmethylides(**5**)—(**8**) with acrylates, followed by elimination of two hydrogen atoms or a hydrogen halide from C-1 and C-8a positions of the resulting tetrahydroindolizine derivatives(Scheme 3).



Scheme 3.

In these reactions, the appearance of the only *trans*-adducts at C-2 and C-3 positions may be considered as the result of the approach from each less hindered site of the reactants in the transition state, and rapid conversion from 1,2,3,8a-tetrahydro- into 2,3-dihydroindolizine can be ascribed to be parallel with the

instability of 1,8a-dihydroindolizine, which gave smoothly indolizine.[3] Although the primary tetrahydroadducts could not be detected and isolated, the pyridinium methylides reacted with various acrylates to afford the corresponding cycloadducts. 1,3-Dipolar cycloaddition of pyridinium ylides with such olefinic dipolarophiles has not been reported.

Experimental

Mps were measured with a Yanagimoto micromelting point apparatus and are uncorrected. Microanalyses were performed on a Perkin-Elmer 240 Elemental Analyser. The NMR spectra were determined with a JEOL JNM-4H-100 spectrometer in deuteriochloroform with tetramethylsilane as an internal standard. The chemical shifts are expressed in δ values. The IR spectra were taken with a JASCO DS-301 spectrophotometer.

*Preparation of Pyridinium Salts(**1**)—(**4**).* A mixture of a pyridine base and methyl chloroacetate was kept at room temperature without any solvent and the resulting mass of pyridinium salt was filtered and washed 3—4 times with ether. The corresponding pyridinium salts (pyridinium, α-, γ-picolinium and isoquinolinium salt, **1**—**4**) were obtained as very hygroscopic colorless crystals almost quantitatively. The salts were used for subsequent reactions without further purification.

*Reactions of Salts(**1**)—(**4**) with Various Acrylates in the Presence of Alkali.* A solution of the salt(4 mmol) and an acrylic derivative(4 mmol) in chloroform(50 ml) was stirred with potassium carbonate(10 g) at room temperature for 2—4 days. The reaction mixture was filtered to remove inorganic substances and the filtrate was concentrated under reduced pressure. The resulting yellowish or reddish oil was then separated by column chromatography (alumina) using ether as an eluent. Recrystallization from chloroform–ether–*n*-hexane gave the corresponding 2,3-dihydroindolizine derivatives(**9**)—(**20**) as yellow or red crystals, but not compounds (**11**), (**15**) and (**19**). The results and properties of 2,3-dihydroindolizines are listed in Table 2.

*Aromatization of 2,3-Dihydroindolizines(**9**)—(**20**).* A benzene solution of 2,3-dihydroindolizine was stirred with an equimolar amount of lead tetraacetate at room temperature for 6—12 hrs, the reaction mixture then being filtered.

The filtrate was concentrated under reduced pressure and the residue was separated by column chromatography (silica gel) using benzene as an eluent. Recrystallization from ether–*n*-hexane or methanol gave the corresponding indolizine derivative as colorless crystals. The results and properties of indolizines(**21**)—(**32**) are listed in Table 3. Compounds (**21**)—(**28**) were in accord with the products prepared from the 1,3-dipolar cycloaddition of the pyridinium salts(**1**)—(**4**) with dimethyl acetylenedicarboxylate and methyl phenylpropiolate in the presence of potassium carbonate. Compounds (**21**) and (**24**) were also in accord with the products reported by Kobayashi.[4]

The authors are grateful to Professor Tadashi Sasaki and Assistant Professor Ken Kanematsu of Nagoya University for their helpful advice and discussions.

The Photochemistry of 2-Quinolinecarbonitriles. II. A Mechanism of the Photoinduced Substitution Reaction

Norisuke HATA and Tsugio SAITO

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

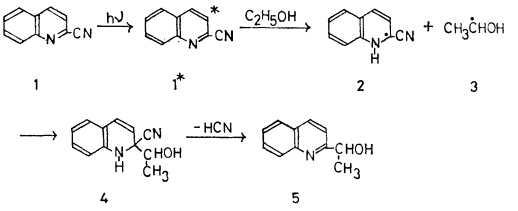
(Received March 17, 1973)

In order to elucidate the mechanism of the photoinduced substitution reaction of 2-quinolinecarbonitrile in alcohols or ethers, measurements of the absorption and fluorescence spectra and the photochemical reactions were carried out in ethanol, *t*-butyl alcohol, or diethyl ether; consequently, an interesting relationship has been found to exist between the fluorescence intensity and the photoreactivity. The photosubstitution reaction can reasonably be assumed to be initiated by a hydrogen-atom abstraction from an alcohol or ether by the nitrogen atom of the quinoline nucleus. The experimental results indicated that such a hydrogen-atom abstraction was markedly facilitated by a hydrogen-bond formation of the nitrogen lone pair of the quinoline nucleus with ethanol or water: further, the reactive excited singlet state (S_1) was presumed to be of a π,π^* nature.

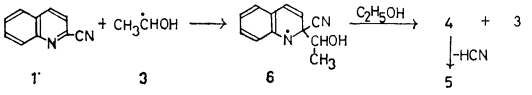
As has been reported in previous papers,[1,2] the irradiation of 2-quinolinecarbonitrile with ultraviolet light longer than 300 nm in alcohol (ethanol, 1-propanol, 2-propanol, or *t*-butyl alcohol) under an oxygen or nitrogen atmosphere resulted in the replacement of the cyano group at the 2-position of a quinoline nucleus by the hydroxyalkyl group. Under a nitrogen atmosphere, however, a certain triazapentaphene was also produced in addition to the photosubstitution product, except for the case of the *t*-butyl alcohol solution. Further, the photosubstitution reaction has been revealed, by triplet-quenching studies, to proceed directly from the lowest excited singlet state (S_1) of 2-quinolinecarbonitrile, whereas the lowest triplet state (T_1) was responsible for the formation of a triazapentaphene. The purpose of the present investigation is to elucidate the mechanism of such a photochemical substitution reaction.

Results and Discussion

It has recently been shown that the ultraviolet irradiation of quinoline itself in ethanol or *t*-butyl alcohol resulted in the corresponding hydroxyalkyl substituted products,[3] and also that 3,5-dicarbomethoxypyridines in alcohol were susceptible to the photochemical addition of alcohol.[4] These photoinduced reactions have been anticipated to be initiated by a hydrogen-atom abstraction from the solvent by the nitrogen atom of heterocycles. Such an assumption has been primarily supported by a flash-spectroscopic detection of the acridanyl radical formed during the photoreduction of acridine in hydrocarbon solvents,[5] and also by the observation of a corresponding radical from pyridine, quinoline, and isoquinoline during their photoreduction in alcohol or ether.[6] In view of these facts, it seems reasonable to assume that the photosubstitution reaction of 2-quinolinecarbonitrile is likewise initiated by a hydrogen abstraction from an alcohol or ether by the nitrogen atom of the quinoline nucleus; for example, as is shown in Scheme 1, an excited 2-quinolinecarbonitrile **1*** in ethanol abstracts a hydrogen atom from ethanol to give a quinolinium radical **2** which is then coupled with the 1-hydroxyethyl radical **3**, after which it loses a hydrogen cyanide to afford a 2-(1-hydroxyethyl)quinoline **5**.[7] In addition, an alternate pathway (Scheme 2), in which the 1-hydroxyethyl radical **3** thus formed attacks an unexcited 2-quinolinecarbonitrile **1**, can also be supposed to account for the substitution reaction.



Scheme 1



Scheme 2

In order to clarify whether or not the mechanism of Scheme 2 is operative in the photosubstitution reaction, the following experiments were undertaken. To a solution of 2-quinolinecarbonitrile (70 mg) in anhydrous ethanol (20 ml), we added 20 mg of di-*t*-butyl peroxyoxalate (DTBP); the mixture was kept at 35 °C for 4 hr under bubbling in oxygen or nitrogen, because DTBP is well known to decompose thermally to produce a *t*-butoxyl radical, which then abstracts a hydrogen atom from an ethanol to give a 1-hydroxyethyl radical.[8] Consequently, not even trace amounts of the substituted product, 2-(1-hydroxyethyl)-quinoline, were detected by means of gas chromatography (column: Silicone SE-30 on Chromosorb P). This appears to indicate that the mechanism of Scheme 2 is not responsible for the photosubstitution reaction.

Next, in order to obtain information about the nature of the reactive excited singlet state (S_1) of 2-quinolinecarbonitrile, measurements of the absorption and and fluorescence spectra and the photochemical reactions were carried out under various conditions at room temperature. The ultraviolet absorption spectrum of 2-quinolinecarbonitrile in anhydrous ethanol is shown in Fig. 1. Both the spectral shape and the maximum wavelength were essentially unchanged in either anhydrous diethyl ether or anhydrous *t*-butyl

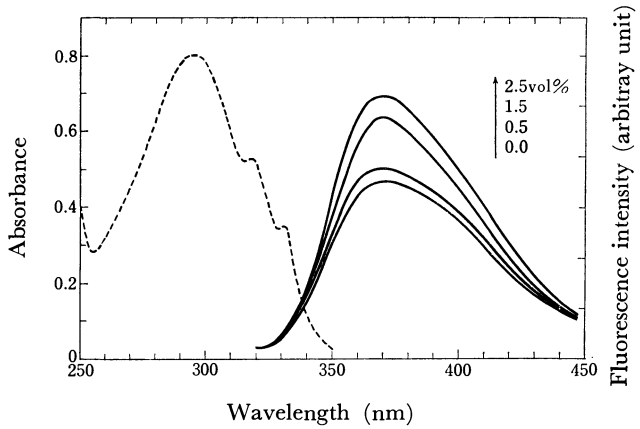


Fig. 1. The absorption and the fluorescence spectra of 2-quinolinecarbonitrile in ethanol at room temperature (concentration of 2-quinolinecarbonitrile: 1.9×10^{-4} M).
----: The absorption spectrum.
——: The fluorescence spectrum. Numbers refer to the concentration of water (vol%).

alcohol, although a slight change in the molar extinction coefficient was observed. On the other hand, the fluorescence spectrum of 2-quinolinecarbonitrile showed a markable dependence on the solvent used. A fairly strong fluorescence specturm was observed around 370 nm in anhydrous ethanol (Fig. 1), but the intensity was greatly diminished in anhydrous *t*-butyl alcohol and much more so in anhydrous diethyl ether. Moreover, the introduction of small amounts of water into these solutions caused the fluorescence intensity to increase, just as in the case of quinoline itself.[9] As an example, Fig. 1 shows the fluorescence enhancement with an increase in the concentration of water in ethanol, but the absorption spectrum of 2-quinolinecarbonitrile remained entirely unchanged under these circumstances. Curve (a) in Fig. 2 shows the results when the degree of increase in the fluorescence intensity is plotted against

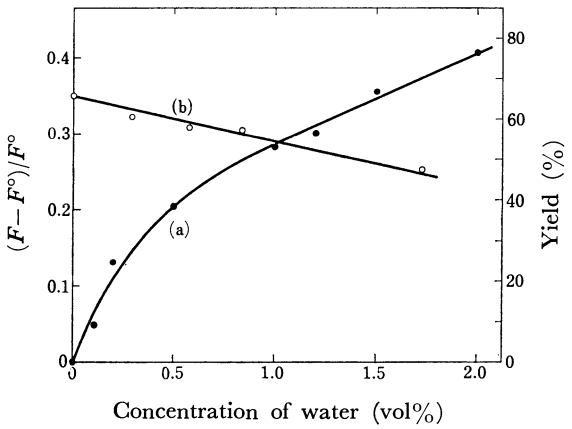

Fig. 2. The effect of small amounts of water on both the yield of photoproduct and the fluorescence intensity in ethanol at room temperature. F and F° represent the relative fluorescence intensity in the presence and the absence of water.

the concentration of water. Quite similar results were also obtained in the case of the *t*-butyl alcohol solution (Curve (a) in Fig. 3). The results described above indicate clearly that the 2-quinolinecarbonitrile becomes fluorescent in hydroxylic solvents, except in *t*-butyl alcohol, which can form a hydrogen bond with the nitrogen lone pair of the quinoline nucleus. The very weak fluorescence in anhydrous *t*-butyl alcohol, however, is probably to be ascribed to the shielding of the hydroxyl group responsible for the hydrogen-bond formation by the bulky *t*-butyl group.

The fluorescence activation of quinoline by hydroxylic solvents has been accounted for by assuming that the lowest excited singlet state $S_1(n, \pi^*)$ is raised considerably by the hydrogen-bonding interaction, so that the relative positions of the singlet n,π^* and π,π^* states are reversed and decrease the spin-orbit coupling and, hence, the rate of the intersystem crossing to the triplet manifold.[9] Recent studies by means of photoelectron spectroscopy,[10] however, appear to suggest that the lowest excited singlet state (S_1) of quinoline is of a π,π^* rather than n,π^* nature. Therefore, the fluorescence activation of quinoline by hydroxylic solvents may be interpreted as follows. The $S_1(\pi,\pi^*)$ state is probably close to the upper singlet n,π^* state, so that some mixing between them may occur through the vibronic coupling. Lim and Yu have described that such a vibronic coupling between the singlet π,π^* and n,π^* states can possibly occur in nitrogen heterocycles.[11] This mixing could become smaller in hydroxylic solvents, because the energy difference between the π,π^* and n,π^* states beomes larger because of a hydrogen bonding interaction, and could decrease the n,π^* character in the $S_1(\pi,\pi^*)$ state, resulting in a decrease in the rate of the intersystem crossing to the triplet manifold. Quite similar considerations can possibly account for the fluorescence activation of 2-quinolinecarbonitrile by hydroxylic solvents; that is, the S_1 state of 2-quinolinecarbonitrile is also assumed to be of a π,π^* configuration mixed with the n,π^* singlet state through the vibronic coupling; such an n,π^* nature in the $S_1(\pi,\pi^*)$ state may decrease in hydroxy-

lic solvents, which can form a hydrogen bond with the nitrogen atom of the quinoline nucleus, resulting in the fluorescence enhancement.

As has been reported in a previous paper,[2] the 2-quinolinecarbonitrile in commercial diethyl ether (containing *ca.* 0.2 vol% of water) undergoes photochemical substitution to afford the 2-(2-ethoxyethyl)quinoline in a 32% yield. When anhydrous diethyl ether was used as the reaction medium, however, the yield was greatly reduced to *ca.* 3.6%. In the case of the anhydrous *t*-butyl alcohol solution, also, the yield of the photoproduct, 2-(2-hydroxy-2-methylpropyl)quinoline, was found to be vanishingly low (*ca.* 0.8%), but it increased markedly as small amounts of water were introduced into the solution (Curve (b) in Fig. 3). These results imply that the presence of minute amounts of water in the solution (therefore leading to the hydrogen-bond formation with the nitrogen atom of quinoline nucleus) serves to facilitate remarkably the photosubstitution reaction of 2-quinolinecarbonitrile. In addition, it should be noticed that such an effect of water on the photoreactivity is closely parallel to that on the fluorescence intensity, indicating that the hydrogen-atom abstraction leading to the substitution reaction takes place in the fluorescent state $S_1(\pi,\pi^*)$.

On the other hand, the photosubstitution reaction in anhydrous ethanol occurred in a good yield (*ca.* 66%);[2] however, interestingly, the yield was found to decrease with the addition of small amounts of water to the solution (Curve (b) in Fig. 2). The results could be well explained as follows. In anhydrous ethanol, an excited 2-quinolinecarbonitrile can form a hydrogen bond with an ethanol; such a hydrogen-bonded ethanol molecule may be inferred to be subject to α-hydrogen abstraction by the nitrogen atom, thus resulting in the photosubstitution product in a good yield. When small amounts of water are present in the solution, the hydrogen bonding interaction also exists between excited 2-quinolinecarbonitrile and water. Such an excited 2-quinolinecarbonitrile hydrogen-bonded with water instead of ethanol is also assumed to be responsible for the hydrogen-atom abstraction from a solvent, just as in the case of diethyl ether or *t*-butyl alcohol solution. Therefore, it may be expected that, with an increase in the concentration of water, the yield approaches the value in a *t*-butyl alcohol or diethyl ether solution. In fact, the yield in an ethanol solution containing *ca.* 1.7 vol% of water was about 47%, a value approximately comparable in *t*-butyl alcohol containing *ca.* 1.7 vol% of water (*ca.* 45%) or in commercial diethyl ether (*ca.* 32%). This seems to support the above assumption. Quite similar considerations can be also made in the case of an 1-propanol solution, where the photosubstitution product arising from the β-hydrogen abstraction, different from that in an ethanol solution, may be expected in addition to that from the α-hydrogen abstraction. However, it has been shown in a previous paper[2] that only the 2-(1-hydroxy-2-methylethyl)quinoline arising from the α-hydrogen abstraction was obtained in a yield of 45%. This is probably because the β-hydrogen abstraction is quite difficult because of the steric hindrance of a cyano group at the 2-position of the quinoline nucleus. As will be described in a later paper,[13] the photochemical reaction of 4-quinolinecarbonitrile in 1-propanol provides a 2-(1-hydroxy-2-methylethyl)quinoline-4-carbonitrile and a 2-(1-hydroxymethylethyl)quinoline-4-carbonitrile in yields of 24% and 16%, indicating that the β-hydrogen abstraction takes place as well as the α-hydrogen abstraction. This also supports the idea that the photosubstitution reaction of quinolinecarbonitriles in such anhydrous alcohols as ethanol and 1-propanol is initiated by a hydrogen-atom were abstraction from the alcohol hydrogen-bonded with the nitrogen atom of the quinoline nucleus.

Experimental

The 2-quinolinecarbonitrile used in this experiment was prepared and purified according to the method given in the literature.[14] The ethanol, *t*-butyl alcohol, and diethyl ether used as solvents were reagent-grade products of Wako Pure Chemical Industries; the first two were refluxed over magnesium for dehydration, while the last was dehydrated by sodium and then calcium hydride. The di-*t*-butyl peroxyoxalate used in the thermal reaction of 2-quinolinecarbonitrile in anhydrous ethanol was kindly supplied by Dr. Katsumi Tokumaru of the University of Tokyo.

The ultraviolet absorption and fluorescence spectra were, respectively, measured with a Hitachi recording spectrophotometer EPS-3T and a Hitachi fluorescence spectrophotometer MPF-2A.

The photolytic procedure was similar to that described in a previous paper;[2] 2-quinolinecarbonitrile (0.5 g) dissolved in 350 ml of ethanol, *t*-butyl alcohol, or diethyl ether containing various amounts of water in a Pyrex vessel was irradiated with a 100W high-pressure immersion mercury lamp (Riko Kagaku Sangyo Co.) for 2 hr while oxygen was being bubbled in; the photoproduct and the starting material were then separated by means of silica gel chromatography.

In conclusion, the authors wish to thank Dr. Katsumi Tokumaru and Mr. Hiroyuki Ohta of the University of Tokyo and Professor Akira Sugimori of Sophia University for their kind discussions.

2,3,5,6-Tetra-aryl-1,2,4,5-tetra-azapentalenes.[1] A New Heteroaromatic System

Akira MATSUMOTO, Joung Hee LEE, Masayuki YOSHIDA, and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received November 27, 1973)

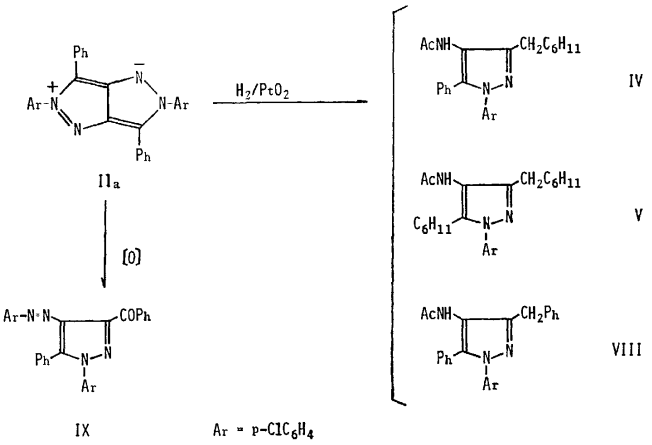
2,3,5,6-Tetra-aryl-1,2,4,5-tetra-azapentalenes (II) have been prepared by the dimerization of arylazoethynylarenes (I). The properties of the new ring system are discussed on the basis of their reactivities.

1-Methylpentalene[2] was found so unstable as to dimerize even at −100 °C, but pentalene dianion,[3] a 10π-electron system, is known to show aromatic character. Thus, replacement of the ring carbon atoms of pentalenes by nitrogen atoms may yield stable azapentalenes containing 10π-electrons. We have recently synthesized 2,3,5,6-tetra-aryl-1,2,4,5-tetra-azapentalenes[4] (II) and 2-aryl-5-phenyl-*v*-triazolo[4,5-*d*]-*v*-triazoles,[5] both new *meso*-ionic heteroaromatics. These azapentalenes contain nitrogens at non-fused positions and examples of *meso*-ionic azapentalenes with nitrogens at fused positions have recently been described.[6] This paper presents the synthesis, structure, and properties of 2,3,5,6-tetra-aryl-1,2,4,5-tetra-azapentalenes.

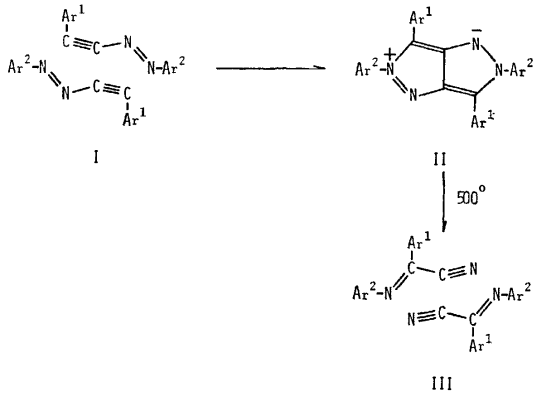
p-Chlorophenylazoethynylbenzene[7] (Ia: Ar^1=Ph, Ar^2=*p*-ClC_6H_4), prepared from *p*-chlorobenzenediazonium chloride and silver phenylacetylide, on heating in cyclohexane deposited 2,5-bis-(*p*-chlorophenyl)-3,6-diphenyl-1,2,4,5-tetra-azapentalene (IIa: Ar^1=Ph, Ar^2=*p*-ClC_6H_4) in 60% yield. This compound shows ultraviolet absorption maxima at 292 and 398 nm (log ε=4.37 and 4.33, respectively) in chloroform. Tetra-azapentalene IIa is pale yellow crystalline solid, mp 328 °C, which is sparingly soluble in ordinary organic solvents giving strongly fluorescent solutions. It is weakly basic, being insoluble in dilute mineral acids, but dissolves readily in concentrated sulphuric acid and is reprecipitated when the solution is diluted with water. It is unaffected by heating in 65% sulphuric acid and can be sublimed unchanged *in vacuo* at about 300 °C. On prolonged heating with methyl iodide, it gives a crystalline methiodide, which is decomposed into its components at about 200 °C or when dissolved in solvents other than methyl iodide. Treatment of tetra-azapentalene IIa with silver nitrate in a mixture of acetonitrile and tetrahydrofuran gives a 1 : 1 adduct, mp 314 °C (decomp.).

Evidence for the structure of compound IIa was provided by its mode of formation, its spectral and analytical data, and the following degradations.

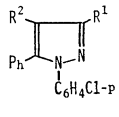
Its pyrolysis *in vacuo* at about 500 °C afforded pale yellow needles (26%), mp 93.5—94.5 °C, identified with α-(*p*-chlorophenylimino)phenylacetonitrile[8] (IIIa: Ar^1=Ph, Ar^2=*p*-ClC_6H_4).



When compound IIa was hydrogenated in acetic acid at 60 °C with platinum oxide, two pyrazole derivatives, $C_{24}H_{26}ClN_3O$ (IV, 25%), mp 233—235 °C (decomp.), and $C_{24}H_{32}ClN_3O$ (V, 10%), mp 214—215 °C, were isolated, and they were assigned the structures of 4-acetamino-1-*p*-chlorophenyl-3-cyclohexylmethyl-5-phenylpyrazole (IV) and 4-acetamino-1-*p*-chlorophenyl-5-cyclohexyl-3-cyclohexylmethylpyrazole (V), respectively, on the basis of their spectral and analytical data and of the degradation of compound IV. Hydrolysis of compound IV and deamination of the resulting amine by reduction of the corresponding diazonium fluoroborate with sodium borohydride yielded 1-*p*-chlorophenyl-3-cyclohexylmethyl-5-phenylpyrazole (VI), mp 113—114 °C. The structure of this compound was established by an independent synthesis, in which condensation of *p*-chlorophenylhydrazine with 1,4-diphenylbutane-1,3-dione in ethanol yielded 3-benzyl-1-*p*-chlorophenyl-5-phenylpyrazole (VII), mp 111—112 °C. Catalytic hydrogenation of this pyrazole (VII) with platinum oxide in acetic acid at room temperature gave a product, which was identical with compound VI. Evidence for the presence of a cyclohexylmethyl instead of a benzyl group in compound VI is furnished by its NMR spectrum with a doublet at τ 7.41 (2H, J=6 Hz), whereas the NMR spectrum of compound VII shows a singlet at τ 5.94 due to a benzylic methylene. The observed spectral data are not incompatible with the isomeric structure of 1-*p*-chlorophenyl-5-cyclohexylmethyl-3-phenylpyrazole, which could be expected from



the above synthetic route. However, the fact that compound VI was obtained from the degradation of IIa excludes such an assignment to VI, and thus, supports the structure of 3-benzyl-1-*p*-chlorophenyl-5-phenylpyrazole for compound VII. Separate hydrogenation of IIa under similar conditions resulted in the cleavage of the parent ring to give another pyrazole derivative, 4-acetamino-3-benzyl-1-*p*-chlorophenyl-5-phenylpyrazole (VIII, 12%), mp 217—218 °C. Comparison of the NMR spectra of VII and VIII (a singlet signal at τ 5.90 due to a benzylic methylene) reveals their close similarity, and supports the above structure for compound VIII.



VI: R^1 = $C_6H_{11}CH_2$, R^2 = H
VII: R^1 = $PhCH_2$, R^2 = H
XI: R^1 = PhCO, R^2 = NH_2

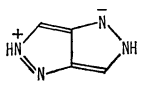
Compound IIa was oxidized with potassium permanganate in a mixture of pyridine and water at 95 °C to yield 3-benzoyl-1-*p*-chlorophenyl-4-*p*-chlorophenylazo-5-phenylpyrazole (IX, 64%), mp 208—209.5 °C, the structure being determined on the basis of its spectral and analytical data and of its degradation. The IR spectrum of IX shows a band at 1665 cm^{-1} due to a carbonyl stretching vibration. The NMR spectrum shows a multiplet at τ 2.4—2.7. The mass spectrum shows the molecular ion *m/e* 496, and major fragments *m/e* 385($M^+-C_6H_4Cl$), 105(C_6H_5CO), and 77(C_6H_5). Compound IX was hydrogenated in acetic acid with 10% palladium on carbon to yield two products, 4-acetamino-3-benzyl-1-*p*-chlorophenyl-5-phenylpyrazole (VIII, 12%) and 4-amino-3-benzoyl-1-*p*-chlorophenyl-5-phenylpyrazole (XI, 16%), mp 182 °C. With peroxyacetic acid in chloroform, compound IIa also gave this arylazobenzoylpyrazole (IX, 9%).

Nitration of compound IIa with nitric acid (d= 1.38) in concentrated sulphuric acid at room temperature gave a dinitro derivative (IId: Ar^1=*p*-NO_2-C_6H_4, Ar^2=*p*-ClC_6H_4), mp 365 °C.

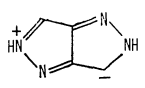
Treatment of compound IIa with bromine in chloroform gave a monobromo derivative (XII, 38%), mp 294.5—295.5 °C, together with a small quantity (6%) of a dibromo derivative (IIe: Ar^1=*p*-BrC_6H_4, Ar^2=*p*-ClC_6H_4), mp 349 °C. The structures of IId and IIe were substantiated by separate syntheses through dimerization of 4-(*p*-chlorophenylazoethynyl)-substituted nitro- and bromobenzene, respectively. The monobromide (XII) was assigned the structure of 2,5-bis-(*p*-chlorophenyl)-3-*p*-bromophenyl-6-phenyl-1,2,4,5-tetra-azapentalene. The position of the bromo substituent in the benzene ring was established by examination of the IR spectrum (ν_{max} 760 and 675 cm^{-1}, and 840 cm^{-1} due to mono- and 1,4-disubstituted benzene, respectively).

The tetra-azapentalenes listed in the Table have been prepared by dimerization of arylazoethynylarenes.

The parent structure, 2*H*,5*H*-pyrazolo[4,3-*c*]pyrazole, is *meso*-ionic, being satisfactorily represented only by several charge-separated structures such as XIII and XIV. The preferential electrophilic substitution observed at the *para* positions in the phenyl substituents of compound IIa indicates an electron-donating character of the parent structure due to the contribution of resonance structures such as XIV.



XIII



XIV

Experimental

*2,5-Bis-(*p*-chlorophenyl)-3,6-diphenyl-1,2,4,5-tetra-azapentalene (IIa).* A solution of *p*-chlorophenylazoethynylbenzene (Ia, 6.0 g) in 200 ml of cyclohexane was heated under reflux for 5 hr, and the solvent was removed by distillation. The crystalline residue was washed with acetone and recrystallized from benzene to yield 3.6 g (60%) of compound IIa (Found: C, 69.88; H, 3.77; N, 11.92%. Calcd for $C_{28}H_{18}Cl_2N_4$: C, 69.86; H, 3.77; N, 11.64%), mp 328 °C; λ_{max} (chloroform) 292 and 398 (log ε 4.37 and 4.33, respectively), and mass-spectral M, 480.

Other tetra-aryl-tetra-azapentalenes prepared in similar ways are listed in Table 1.

*2,5-Bis-(*p*-chlorophenyl)-3,6-diphenyl-1-methyl-1,2,4,5-tetra-azapentalenium Iodide.* A mixture of IIa (0.90 g) and methyl iodide (50 ml) was heated under reflux for one week. The mixture was filtered and the filtrate, on evaporation of solvent, gave 0.90 g (77%) of the methiodide as orange crystals. The crude material was dissolved in methyl iodide and the solvent was removed under reduced pressure. The residual crystals were similarly treated repeatedly with methyl iodide, and subjected to analysis (Found: C, 56.05; H, 3.51; N, 8.71%. Calcd for $C_{28}H_{18}Cl_2N_4 \cdot CH_3I$: C, 55.88; H, 3.40; N, 8.99%) The methiodide, heated at about 200 °C or dissolved in solvents other than methyl iodide, decomposed into methyl iodide and compound IIa.

Complex Formation of Compound IIa with Silver Nitrate. To a solution of compound IIa (0.22 g) in 100 ml of tetrahydrofuran was added a solution of silver nitrate (1.0 g) in 20 ml of acetonitrile. The mixture was stirred for 3 hr at room temperature, and the pale yellow precipitate was collected and washed with fresh acetonitrile and tetrahydrofuran to yield 0.3 g of the silver nitrate complex. Recrystallization from dimethylformamide gave a pure sample (Found: C, 52.00; H, 2.62; N, 11.02%. Calcd for $C_{28}H_{18}Cl_2N_4 \cdot AgNO_3$: C, 51.64; H, 2.79; N, 10.75%), mp 314 °C (decomp.).

Pyrolysis of Compounds IIa and IIb. α-(p-Chlorophenylimino)- and α-(p-Bromophenylimino)phenylacetonitrile (IIIa and IIIb): Compound IIa (1.2 g), when heated at about 500 °C under reduced pressure of 1 mmHg in a quartz tube, deposited yellow silky crystals on a cold part of the tube. The organic materials were dissolved in ether, and subjected to chromatography on silica gel in benzene. Evaporation of the eluate followed by recrystallization from ethanol gave 0.31 g (26%) of compound IIIa as yellow needles (Found: C, 70.37; H, 4.24; N, 11.66%. Calcd for $C_{14}H_9ClN_2$: C, 69.86; H, 3.77; N, 11.64%), mp 93.5—94.5 °C (lit,[8] mp 94 °C), ν_{max} (KBr) 1595, 1570, 1480, 1445, 1280, 1090, 1015, 1000, 835, 770, 740, 680, and 520 cm^{-1}. The product was identical (mixed melting point, and IR spectrum) with an authentic specimen.

Pyrolysis of compound IIb (1.0 g) in a similar way gave 0.159 g of α-(*p*-bromophenylimino)phenylacetonitrile[9] (Found: C, 59.16; H, 2.88; N, 10.00%. Calcd for $C_{14}H_9BrN_2$: C, 58.97; H, 3.18; N, 9.83%), mp 115.0—115.5 °C (lit,[9] mp 118 °C); ν_{max} (KBr) 1595, 1570, 1475, 1445, 1280, 1200, 1065, 1010, 840, 775, 740, 685, and 520 cm^{-1}.

Catalytic Hydrogenation of Compound IIa. (a) 4-Acetamino-1-p-chlorophenyl-3-cyclohexylmethyl-5-phenylpyrazole (IV) and 4-Acetamino-1-p-chlorophenyl-5-cyclohexyl-3-cyclohexylmethylpyrazole (V): A suspension of IIa (4.4 g) in 285 ml of acetic acid was hydrogenated over platinum oxide (0.44 g) with hydrogen (60 kg/cm²) at 60 °C for 2 days. The insoluble material was removed by filtration and the filtrate was concentrated under reduced pressure. The residue was poured into 100 ml of water and the mixture was neutralized with sodium bicarbonate. The brownish white solid was collected on a filter, washed with water, and dried. The crude product was chromatographed on silica gel in chloroform as eluant. Evaporation of the eluate followed by fractional recrystallization from ethanol gave two pyrazole derivatives: Compound VI (25 %) (Found: C, 70.89; H, 5.87; N, 10.38%. Calcd for $C_{24}H_{26}ClN_3O$: C, 70.66; H, 6.42; N, 10.30%), mp 233—235 °C (white needles), mass *m/e* 407 (M^+, 23%), 401(29), 359(17), 325(100), 283(17), 214(69), 141(15), 123(16), 111 (50), and 77(20); and compound V (10%) (Found: C, 69.81; H, 7.86; N, 10.02%. Calcd for $C_{24}H_{32}ClN_3O$: C, 69.63; H, 7.79; N, 10.15%), mp 214—215 °C (white leaflets), mass *m/e* 413 (M^+, 15%), 407(10), 331(100), 138(23), and 111(12).

(b) 4-Acetamino-3-benzyl-1-p-chlorophenyl-5-phenylpyrazole (VIII): Separate hydrogenation of IIa (1.0 g) over 0.1 g of platinum oxide with hydrogen (90 kg/cm²) at 60 °C for 47 hr followed by similar treatment to that described above yielded 0.1 g (12%) of compound VIII (Found: C, 71.71; H, 4.96; N, 10.31%. Calcd for $C_{24}H_{20}ClN_3O$: C, 71.73; H, 5.02; N, 10.46%), mp 217—218 °C (from chloroform and pentane).

Deamination of Compound IV. 1-p-Chlorophenyl-3-cyclohexylmethyl-5-phenylpyrazole (VI): Crude compound IV (1.0 g) was hydrolyzed by heating under reflux in 200 ml of 30% sulphuric acid for 45 min. After cooling, the solution was neutralized with aqueous sodium hydroxide, and the organic material was extracted with ether. After evaporation of the solvent, the residue was dissolved in a mixture of 8 ml of concentrated hydrochloric acid and 50 ml of water and treated with sodium nitrite (0.18 g) at 0—3 °C. The solution was stirred for 3 hr and filtered to remove insoluble matter. Fluoroboric acid (48%, 5 ml) was added to the filtrate, and the white precipitate of the resulting diazonium tetrafluoroborate was collected on a filter and washed with a small portion of tetrafluoroboric acid. Sodium borohydride (1 g) was added in small portions with stirring to a solution of the diazonium tetrafluoroborate in about 10 ml of dimethylformamide at 0—3 °C. Stirring was continued for 2 hr at 0 °C and for another 2 hr at room temperature. The reaction mixture was poured into a solution of 10 ml of concentrated hydrochloric acid and 20 ml of ice water. Gummy materials, which were separated by filtration were digested with ether, and the ethereal extract was evaporated to yield yellowish orange oil. The oil was chromatographed on silica gel in benzene. The eluate was concentrated and subjected to purification by preparative thin layer chromatography on silica gel. After development with benzene, the faster moving substance was collected and recrystallized from aqueous ethanol giving 4 mg of compound VI as white needles, mp 113.1—114.1 °C, which is identical (mixed mp and IR spectrum) with material described later.

3-Benzyl-1-p-chlorophenyl-5-phenylpyrazole (VII). A mixture of 1,4-diphenylbutane-1,3-dione (6.7 g) and *p*-chlorophenylhydrazine (5.4 g) in 75 ml of ethanol was heated under reflux for 3 hr. The reaction mixture was concentrated, and the product was separated by filtration and washed with dilute acetic acid and then with water. Recrystallization of the crude product from aqueous ethanol with active charcoal gave 7.4 g (77%) of compound VII (Found: C, 76.48; H, 4.90; N, 8.12%. Calcd for $C_{22}H_{17}ClN_2$: C, 76.62; H, 4.97; N, 8.13%), mp 109.2—110.2 °C (white needles).

Catalytic Hydrogenation of Compound VII. 1-p-Chlorophenyl-3-cyclohexylmethyl-5-phenylpyrazole (VI): A solution of compound VII (3.44 g) in 200 ml of acetic acid was hydrogenated with 0.4 g of platinum oxide with hydrogen (60 kg/cm²) for 48 hr. Removal of the catalyst and solvent left an oily residue. Chromatography on activated alumina in benzene gave a colourless oily product. Distillation at about 205 °C/1.5 mmHg gave 0.57 g (16.3%) of compound VI (Found: C, 75.53; H, 6.65; N, 7.68%. Calcd for

$C_{22}H_{23}ClN_2$: C, 75.31; H, 6.61; N, 7.99%, mp 113.1—114.5 °C; ν_{max} (KBr) 3050, 2920, 2840, 1595, 1550, 1490, 1440, 1370, 1170, 1095, 1000, 970, 830, 760, 700, 600, 560, 535, and 500 cm^{-1}.

*Oxidation of Compound IIa. 3-Benzoyl-1-*p*-chlorophenyl-4-*p*-chlorophenylazo-5-phenylpyrazole (IX). (a) With Potassium Permanganate*: To a mixture of compound IIa (2.50 g), 300 ml of pyridine, and 150 ml of water was added potassium permanganate (*ca.* 3 g) in small portions over a period of 4 days, the temperature being kept at about 95 °C. The resulting mixture was filtered while hot, and the filtrate was cooled to yield 1.60 g (64%) of 3-benzoyl-1-*p*-chlorophenyl-4-chlorophenylazo-5-phenylpyrazole (IX) (Found: C, 67.49; H, 3.80; N, 10.98%. Calcd for $C_{28}H_{18}Cl_2N_4O$: C, 67.62; H, 3.65; N, 11.26%), mp 208—209.5 °C (yellow needles from ethanol and acetone); λ_{max} (ethanol) 244 and 344 nm (log ε=4.65 and 4.33, respectively); mass *m/e* 496(M^+, 38%), 385(64), 214(53), 141(44), 105(82), and 77(100).

(b) With Peroxyacetic Acid: Compound IIa (1.50 g) in a mixture of 200 ml of chloroform and 280 ml of a solution (total activity, 2.2%) prepared from 30 ml of 30% hydrogen peroxide and 300 ml of acetic acid was heated under reflux for 11 hr. The mixture was cooled and poured into a large amount of cold aqueous sodium hydroxide solution. The organic layer was separated and evaporated to dryness. The residue was treated as described above to yield 0.13 g (9%) of compound IX and some starting material.

*Catalytic Hydrogenation of Compound IX. 4-Amino-3-benzoyl-1-*p*-chlorophenyl-5-phenylpyrazole (XI)*: Compound IX (0.82 g) in 100 ml of acetic acid was hydrogenated over 0.10 g of 10% palladium on carbon at a hydrogen pressure of 70 kg/cm^2 at 45 °C for 17 hr. The insoluble material was removed by filtration, and the filtrate was concentrated to dryness under reduced pressure. The residue was digested with ether and the ethereal extract was washed with dilute aqueous sodium bicarbonate. The ether was evaporated, and the residue was chromatographed on silica gel in dichloromethane and eluted with ether. The faster moving fraction gave 100 mg (16%) of compound XI on recrystallization from methanol (with active charcoal). It was subjected to purification by preparative thin layer chromatography on silica gel to give an analytical sample (Found: C, 70.64; H, 4.26; N, 11.38%. Calcd for $C_{22}H_{16}ClN_3O$: C, 70.69; H, 4.31; N, 11.24%), mp 182 °C (pale yellow); λ_{max} (ethanol) 259, 276(shoulder), and 369 nm (log ε=4.41, 4.35, and 3.64, respectively); ν_{max} (KBr) 3460, 3370, 1625, and 835 cm^{-1}; mass *m/e* 373(M^+, 19%) and 105(100); NMR ($CDCl_3$) τ 5.62(broad singlet, 2H, NH), 2.38—2.90(multiplet, 12H, aryl H), and 1.60(multiplet, 2H, aryl H). The later fraction gave 80 mg (12%) of compound VIII as white crystals on recrystallization from benzene, mp 217—218 °C, whose IR spectrum was identical with that of the product obtained by hydrogenation of compound IIa.

*Nitration of Compound IIa. 2,5-Bis-(*p*-chlorophenyl)-3,6-bis-(*p*-nitrophenyl)-1,2,4,5-tetra-azapentalene (IId)*: Nitric acid (0.33 ml, d=1.38) was added to a solution of compound IIa (1.0 g) in 11 ml of concentrated sulphuric acid. The mixture was stirred for 10 hr at room temperature and poured onto 200 ml of ice water. The yellow solid was collected, washed thoroughly with water, and dried to yield 1.27 g of a dinitro compound. Recrystallization from acetone gave a pure specimen (Found: C, 59.34; H, 2.92; N, 13.95%. Calcd for $C_{28}H_{16}Cl_2N_6O_4$: C, 58.86; H, 2.82; N, 14.71%), mp> 365 °C, whose IR spectrum was identical with that of compound IId, prepared by dimerization of 4-(*p*-chlorophenylazoethynyl)nitrobenzene.

*Bromination of Compound IIa. 3,6-Bis-(*p*-bromophenyl)-2,5-bis-(*p*-chlorophenyl)-1,2,4,5-tetra-azapentalene (IIe) and 3-(*p*-Bromophenyl-2,5-bis(*p*-chlorophenyl)-6-phenyl-1,2,4,5-tetra-azapentalene (XII)*: Bromine (0.19 g) in 31 ml of chloroform was added with stirring to a solution of compound IIa (0.29 g) in 20 ml of chloroform, and the mixture was allowed to stand overnight. It was then heated under reflux for 15 min to complete the reaction. After cooling, it was washed with aqueous sodium thiosulphate solution to remove excess of bromine. The organic layer was dried over anhydrous sodium sulphate, and the solvent was removed by distillation to yield 0.3 g of yellow solid. A part of the solid (10 mg) was subjected to preparative thin layer chromatography on silica gel in benzene. The first, the second, and the third bands were scraped off the plate and extracted with dichloromethane and evaporation of the extracts gave 0.8 mg (6%) of the dibromine, 4.3 mg (38%) of the monobromide, and 4.7 mg of the starting material, respectively. The dibromide, mp 349 °C, was identified with IIe by mixed melting point and comparison of its IR spectrum with that of an authentic sample. The monobromide (XII) (Found: C, 56.58; H, 3.05; N, 10.74%. Calcd for $C_{24}H_{17}BrCl_2N_4$: C, 56.28; H, 3.25; N, 10.94%) showed mp 294.5—295.5 °C (yellow needles); ν_{max} (KBr) 1515, 1485, 1465, 1400, 1340, 1190, 1160, 1010, 965, 840, 760, and 675 cm^{-1}.

Mechanisms for the Reaction of Phenol with Methanol over the $ZnO-Fe_2O_3$ Catalyst

Takeshi KOTANIGAWA

The Government Industrial Development Laboratory, Hokkaido, Higashi-Tsukisamu, Toyohiraku, Sapporo 061-01

(Received May 7, 1973)

It was confirmed from the infrared spectra of phenol chemisorbed on $ZnO-Fe_2O_3$ that the surface species were characterized by a loss of O-H stretching (3250 cm^{-1}) and by in-plane bending vibration (1370 cm^{-1}) as well as by a phenol ring vibration (1472 cm^{-1}) and a shift of the C-O stretching mode from 1230 cm^{-1} to 1248 cm^{-1}. From these data, phenoxide surface species were proposed. Furthermore, the dissociative adsorption of phenol was discussed by taking account of the acidity and basicity of the catalyst. That is, in the case of the adsorption, phenol was thought to sit on the acid and the base site. Based on the above discussion, a mechanism for the selective methylation at the *ortho* position of phenol was proposed. On the other hand, it was found from the infrared spectrum that a surface species similar to zinc formate appears on the chemisorption of methanol. Therefore, it may be possible to consider that methanol adsorbed on the base site decomposes *via* formate-like surface species to form carbon dioxide, carbon monoxide, and hydrogen.

Phenol reacts with alcohol over solid acidic catalysts such as alumina by means of vapor phase reaction to yield ring-alkylated products.[1] However, because of its low selectivity for a desired alkylphenol, the application of the reaction has not attracted special attention in industry. Since selective alkylation is of special interest[2] (mainly *ortho*-methylation), various catalysts have been reported.[3] These catalysts consist mainly of a solid basic component, such as magnesium oxide or zinc oxide. The products by the alkylation over solid acidic catalysts and solid basic catalysts differ significantly. This interest led to an attempt to study the mechanism of the alkylation of phenol. The mechanism of alkylation was studied by Cullinane and Chard.[4] As the intermediate of alkylation, Klemm and Taylor reported on cyclohexadienone[5] and Nishizaki *et al.* reported on alcoxybenzene.[6] Recently, Nishizaki and Tanabe studied the mechanism of the methylation of phenol over alumina, silica-alumina,[7] and $MgO-Al_2O_3$.[8] Taylor and Ludlum studied the structure of phenols chemisorbed on alumina by infrared techniques.[9]

Previously, the present author found that the $ZnO-Fe_2O_3$ catalyst promoted the selective methylation at the *ortho* position of phenol with methanol and also the simultaneous decomposition of methanol.[10] It is the purpose of this paper to report the mechanisms of the *ortho*-methylation of phenol and the decomposition of methanol over the $ZnO-Fe_2O_3$ catalyst.

Experimental

Materials. Phenol and benzene of an analytical reagent grade were distilled once. Because of the high solidifying point of phenol, an equimolar solution of phenol with benzene was used for measuring the basicity. Pyridine of an analytical reagent grade was dehydrated in potassium hydroxide, distilled, and used for measuring the acidity.

Equipment. The equipment employed for measuring the basicity and the acidity of the present catalyst was a conventional gas chromatograph constructed in our laboratories (Column; Silicone Oil DC 550, 2 m, 150 °C, 7 ml/min, TCD: 80 mA). The only modification was the incorporation of a special furnace designed to hold a 40 cm U-tube, made of 3mm-i.d. stainless steel pipe. Electric heating was supplied by means of a nickelchrome wire wound on the ceramic tube; the temperature of U-tube had a deviation range of 0.2 °C. The weight of the catalyst in the bed was about 500 mg (approximately 5 cm). Before adsorption, catalyst was heated in a stream of helium gas at 400 °C for 3 hr. Then, the catalyst bed was controlled at the prescribed temperature of 200 °C and 375 °C. The chromatogram was counted by using a digital integrator of the Takeda Riken Co., Ltd.

Measurement of the Basicity and the Acidity. As the present catalyst was colored, the acidity and the basicity could not be measured by the Benesi method (indicator method). Therefore, the basicity was measured by means of the adsorption of phenol vapor,[11] while the acidity was measured by means of the adsorption of pyridine vapor.[12]

A given phenol-benzene solution was injected into the catalyst bed in the U-tube by means of a microliter injector of the Hamilton type. The peak of phenol in the chromatogram is not observed upon the initial injection, but the peak is gradually observed on successive injections and finally reaches a constant height. Thus, the irreversible adsorption of phenol, *i. e.*, the basicity, can be evaluated. Similarly, the irreversible adsorption of pyridine, *i. e.*, the acidity, can also be evaluated.

Catalysts. The catalysts ($ZnO-ZnFe_2O_4$) used for the reaction of phenol with methanol were prepared by the procedures described in a previous report.[13] The methods of preparation and the properties of the catalysts are briefly summarized in Table 1. Zinc oxide and zinc ferrite were used for observations of the adsorption of phenol and methanol. The zinc oxide (4 m^2/g) was of an analytical reagent grade, and the zinc ferrite (24.2 m^2/g) was coprecipitated by adding

Table 1. Preparations and properties of $ZnO-Fe_2O_3$ catalysts

Starting materials Zn-Fe	Calcination temperature (°C)	Surface area (m^2/g)
O-O	600	7.5
CO_3-O	600	18.8
O-OH	600	14.5
	700	8.2
CO_3-OH	500	21.2
	600	19.6
	700	5.3
OH-OH	500	36.6
	600	12.6
	700	3.3

a 14% aqueous ammonium solution to a solution containing one mole of zinc nitrate and two moles of ferric nitrate.[10]

Infrared Spectrometry of Catalysts. A double-beam infrared spectrometer (Model 402G; Japan Spectroscopic Co., Ltd.) was used for measuring the spectra in the wave-number region between 4000 cm^{-1} and 430 cm^{-1}. The *in situ* cell used for the measurement of the adsorption spectra of phenol and methanol was the same as that described previously.[16] The cell was made from quartz, and its heating was electrically supplied by means of a nickelchrome wire wound outside the quartz tube. The catalyst disk placed in the cell was heated under a vacuum (10^{-4} Torr) up to 400 °C. The disk was made in the following manner: the catalyst was ground to a fine powder (325 mesh, 44 μ), and then about 150 mg of the catalyst powder was pressed into a disk. The adsorption spectra on the catalyst disk were measured under a vacuum at room temperature.

Results

Phenol Chemisorption. Before measuring the adsorption spectra of phenol, the background spectra were measured. The zinc ferrite and the zinc oxide were heated for 3 hr under a vacuum (10^{-4} Torr) at 200 °C and then cooled to room temperature. The zinc ferrite showed a broad band at about 3100 cm^{-1}, this band may be attributed to the surface O–H stretching frequencies. However, the zinc oxide did not show the background spectrum in the wave-number region 1150 and 4000 cm^{-1}. Then, after the exposure of the disk of zinc ferrite in the cell to phenol vapor for 30 minutes at room temperature, evacuation was carried out for 3 hr at room temperature and at 100, 350, and 400 °C. Similarly, after the exposure of the disk of zinc oxide in the cell to phenol vapor for 30 minutes at room temperature, evacuation was carried out for 3 hr at 200 °C. The infrared spectra are shown in Figs. 1 and 2. A comparison of the spectra in Fig. 1 with the spectrum of phenol in KBr indicates that the phenol O–H stretching vibration (3250 cm^{-1}) and the in-plane bending vibration (1370 cm^{-1}) as well as the phenol ring vibration (1472 cm^{-1}) disappeared upon chemisorption. Furthermore, the phenol C–O stretching vibration (1230 cm^{-1}) shifts at 1248 cm^{-1}. These results are quite similar to the results of the chemisorption of phenol on alumina reported by Taylor and Ludlum.[9] Variations in the chemisorption spectra with a rise in the evacuation

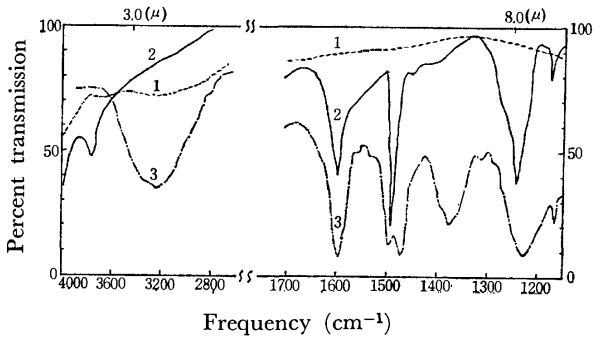

Fig. 1. Infrared spectra of phenol chemisorbed on ZnO.
(1) background, (2) phenol chemisorbed on ZnO, (3) phenol in KBr.

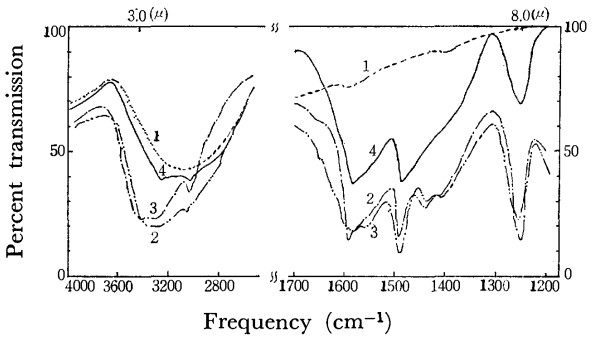

Fig. 2. Infrared spectra of phenol chemisorbed on $ZnFe_2O_4$.
(1) background, (2) phenol evacuated at 100 °C, (3) phenol evacuated at 350 °C, (4) phenol evacuated at 400 °C.

temperature are observed in Fig. 2. The phenol O–H stretching vibration gradually shifts from 3400 to 3150 cm^{-1} and disappears at the same time when the phenol O–H in-plane bending vibration (1390 cm^{-1}) disappears. The chemisorption spectra of phenol on zinc ferrite at 350 and 400 °C are similar to the spectrum on zinc oxide in Fig. 1. It is clear from these observations and the results of Taylor and Ludlum that the phenol molecule loses a proton on the surface and that the phenoxide anion is chemisorbed on the metal ion.

Methanol Chemisorption. Before measuring the adsorption spectrum of methanol, the background spectra were measured. The zinc ferrite and the zinc oxide were heated for 3 hr under a vacuum (10^{-4} Torr) at 200 °C and then cooled to room temperature. The background spectra of the zinc ferrite and zinc oxide were not observed in the wave-number region between 1300 and 1800 cm^{-1}. Then, the disk of zinc oxide in the cell was exposed to 30 Torr of methanol vapor for 5 minutes at 150 °C and then evacuated for 1 hr at 165, 200, and 315 °C. Similarly, the disk of zinc ferrite was also exposed to 30 Torr of methanol vapor for 5 minutes at 150 °C and then evacuated for 1 hr at 200 °C. The spectra are compared

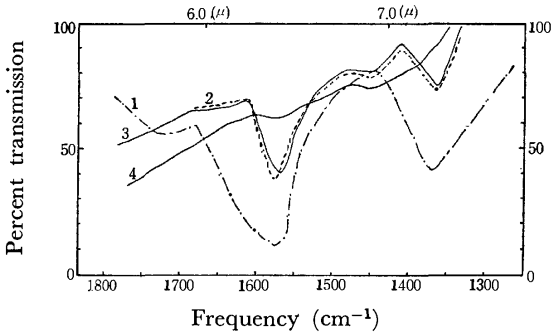

Fig. 3. Infrared spectra of methanol chemisorbed on ZnO and $ZnFe_2O_4$.
(1) zinc formate, (2) methanol evacuated at 200 °C on $ZnFe_2O_4$ (3) methanol evacuated at 165 and 200 °C on ZnO, (4) methanol evacuated at 315 °C on ZnO
* Background spectra of ZnO and $ZnFe_2O_4$ are shown in Figs. 1 and 2.

with the spectrum of zinc formate in Fig. 3. All of the spectra in Fig. 3 are quite similar to the spectrum of zinc formate. Tamaru *et al.* have reported that the methanol adsorbed on zinc oxide decomposes *via* the formate intermediate to form carbon monoxide, carbon dioxide, and hydrogen.[14] It can, therefore, be expected that the observed spectra (Fig. 3) are attributable to the intermediate of the decomposition of methanol over the present catalyst. However, no information about methylation was obtained from the present infrared spectra of methanol.

Acidic and Basic Properties. A typical relation between the acidic and basic properties of the catalyst is shown in Fig. 4. In obtaining the results in Fig. 4, we measured: (1) the saturated adsorption of pyridine on the fresh catalyst without the pre-adsorption of phenol (the acidity was 24.5 μmol/g-cat.); (2) the saturated adsorption of phenol on the fresh catalyst (the basicity was 98.5 μmol/g-cat.), and the adsorption of pyridine after the saturated adsorption of phenol (9.2 μmol/g-cat.); and (3) the adsorption of pyridine after the pre-adsorption of phenol. In those procedures, the amount of the adsorption of pyridine gradually decreased from 24.5 μmol/g-cat. to 9.2 μmol/g-cat. It is clear from these results that phenol is adsorbed on both the acid site and the base site of the catalyst.

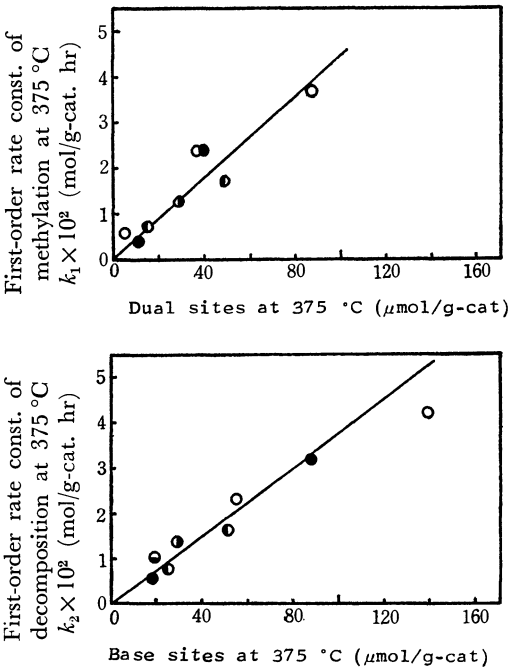

Fig. 6. Relations between rate constants and active sites of ZnO-Fe_2O_3 catalyst in several preparations. (-○-) prepared from $Zn(OH)_2$-$Fe(OH)_3$, (-●-) from $ZnCO_3$-$Fe(OH)_3$, (-◑-) from $ZnCO_3$-Fe_2O_3, (-◐-) from ZnO-$Fe(OH)_3$, (-◒-) from ZnO-Fe_2O_3.

In order to confirm the above results, the poisoning effects by pyridine were examined; the results are given in Fig. 5. The fresh catalyst was first placed in contact with small amounts of pyridine under the present reaction conditions. Then, the reaction of phenol with methanol was carried out under the same conditions. According to the experimental results, the methylation was considerably hindered by the first poisoning operation, but no further decrease in the activity occurred upon the second poisoning operation. Further, the experimental results show that the active site for the methylation is permanently poisoned by the first addition of pyridine. On the other hand, the decomposition of methanol was found to be temporarily poisoned by each operation and the activity was easily recovered. The relations between the number of active sites for the individual reaction and the first-order rate constant are given in Fig. 6. These facts seem to suggest that the methylation occurs on a dual site composed of an acid site and a base site, while the decomposition of methanol occurs only on a base site.

Discussion

With respect to the identification of the active sites for the methylation of phenol and the decomposition

of methanol, the above experimental results give obvious evidence. Now, let us discuss the mechanism for the selective methylation at the *ortho* position of phenol and the decomposition of methanol. It has been reported that the methylation of phenol over alumina proceeds *via* anisole as a key intermediate.[6] However, no reaction was found to take place when only anisole vapor or a mixed vapor of anisole and methanol was placed in contact with the present catalyst. Therefore, the methylation of phenol over the present catalyst cannot be considered to proceed *via* anisole.

The selective methylation of phenol at the *ortho* position may proceed by means of the following mechanism: phenol may dissociate into the phenoxide anion and proton on the catalyst surface, and methanol may be adsorbed onto the proton to form the methyl cation.[15] As the distance between the phenoxide species and the proton is inevitably governed by the O–H bond length of phenol, the methyl cation may be located at a site neighboring the *ortho* position of the phenoxide species. On the other hand, Fig. 3 strongly supports the idea that the decomposition of methanol proceeds *via* formate on both zinc oxide and zinc ferrite.[14] Therefore, the proposed mechanism is applicable to the reactions which occur on both zinc oxide and zinc ferrite.

The author is very grateful to Mr. Katsuyoshi Shimokawa for his assistance with the experiments.

The Pore Structure of the $ZnO-Fe_2O_3$ Catalyst

Takeshi KOTANIGAWA and Mitsuyoshi YAMAMOTO

The Government Industrial Development Laboratory, Hokkaido, Higashi-Tsukisamu, Toyohiraku, Sapporo 061-01

(Received May 7, 1973)

With regard to the $ZnO-Fe_2O_3$ catalyst used for the selective methylation at the *ortho* position of phenol, the pore structures of the catalysts prepared by five processes were studied. The pore structures of these catalysts were determined by converting the detailed nitrogen desorption isotherm data to the pore-volume distribution. These catalysts had two types of pores, a micropore at about 20 Å and a macropore at 80 Å or more. These pores were sensitive to the sintering conditions. The micropore sizes were independent of the calcination temperature, but the macropore sizes were made proportionally larger with a rise in the calcination temperature. The macropore sizes were related to the particle sizes of the zinc ferrite formed by the solid reaction of ZnO with Fe_2O_3.

As part of a series of studies of catalysts for the synthesis of 2,6-xylenol, we previously reported that the $ZnO-Fe_2O_3$ catalyst promoted selective methylation at the *ortho* position of phenol and that simultaneously the decomposition of methanol took place as a side reaction.[1] The present catalyst was used in the above reaction without a supporter. It is, therefore, of considerable importance for the preparation of the most-favored catalyst to clarify the relations between the preparative methods of the catalyst and their pore structures. As information of this type is useful in the estimation of effective diffusion coefficients,[2] the details of pore structure have been studied on industrially-important catalysts such as alumina.[3,4] However, papers on the pore structure of the $ZnO-Fe_2O_3$ system as a catalyst for the selective methylation of phenol are not available in the literature.

We have attempt here to clarify the pore structures of $ZnO-Fe_2O_3$ catalysts prepared by various processes.

Experimental

Measurement of the Pore Structure. The adsorption-desorption isotherms were measured by using conventional volumetric equipment, as has previously been described.[5] The desorption isotherms have been used to calculate the pore-size distribution by Barrett, Joyner, and Halenda.[6] Mercury porosimeter was used for measuring the large pore-size distribution.[7] The total pore volume was measured by helium-mercury techniques.[8]

X-Ray Analysis of the Catalyst. Rigaku Denki X-ray diffractometer, with Fe$K\alpha$ radiation, was used for this purpose. Using the Scherrer equation, the crystalline sizes were calculated from the half-width of the peak of the angles (2θ) of 42°, 44.8°, and 46.1° for ferric oxide, zinc ferrite, and zinc oxide respectively. The percentage of a given crystal can be measured by calculating the area under a suitable diffraction peak and by comparing this with the corresponding area for a known sample.

Catalyst Preparation. Catalysts were prepared by the following five processes: (A) After mixing 1 mol of ferric oxide with 2 mol of zinc oxide, the mixed powder was pressed into a tablet 3 mm in diameter under pressures up to 150 kg/cm^2. (B) After the addition of 71 g of water to a mixture of 1 mol of ferric oxide and 2 mol of zinc carbonate, the mixture was kneaded for six hours at 50 °C. The paste thus prepared was forced out in a wire form 3 mm in diameter by extrusion. (C) After the addition of 67 g of water to a mixture of 1 mol of ferric hydroxide and 1 mol of zinc oxide, the mixture and the paste were treated by the method used for the (B) catalyst. (D) After the addition of 85 g of water to a mixture of 1 mol of ferric hydroxide and 1 mol of zinc carbonate, the mixture and the paste were treated by the method used for the (B) catalyst. (E) After the dissolution of 1 mol of ferric nitrate and 1 mol of zinc nitrate in water, a 14% aqueous ammonium solution was added to the solution until it gave a pH value of 6.85 at room temperature. The coprecipitate was filtered, washed several times with water, and kneaded for six hours at 50 °C. The paste was then treated by the method used for the (B) catalyst.

These wires and tablets prepared by the five processes were first heated at 150 °C for several hours to remove any moisture and then individually calcined in an electric furnace at 500, 600, 700, and 800 °C respectively for three hours with dry air being pumped into the container. They were then crushed and sieved to 12—14 mesh-size particles.

Results

Catalyst (A). The catalyst calcined at 500 °C consists of 61% ZnO, 23% Fe_2O_3, and 16% $ZnFe_2O_4$, judging from X-ray analysis. In the previous study,[1] it was confirmed through thermal analysis that the solid reaction of ZnO and Fe_2O_3 occurred at 645 °C.

	800	772	562	—

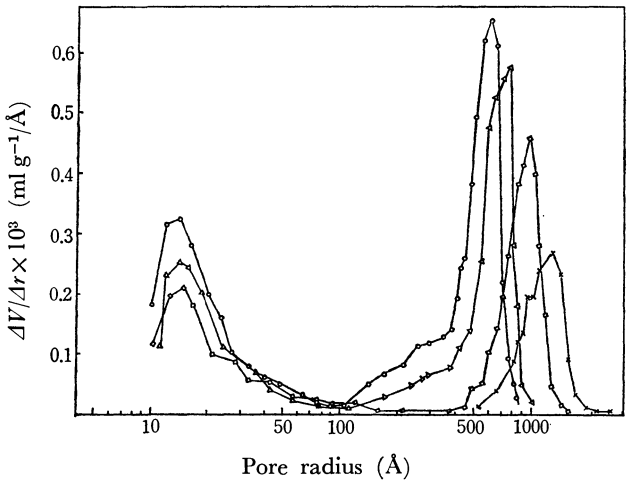

Fig. 1. Pore distribution of catalyst (A)
(-○-) at 500 °C, (-△-) at 600 °C,
(-□-) at 700 °C, (-×-) at 800 °C.

In the catalyst at 600 °C, 5% Fe_2O_3 is still present, but Fe_2O_3 is no longer present in it at 700 °C or more. The components in it are ZnO and $ZnFe_2O_4$. These crystalline sizes are shown in Table 1. The distribution of pore sizes is shown in Fig. 1. The fraction of the micropore volume per total pore volume is about 4% and is not drastically changed by the calcination temperature.

Catalyst (B). The X-ray diffraction pattern of the catalyst calcined at 500 °C does not show the line of $ZnFe_2O_4$; that is, the components in it are still ZnO and Fe_2O_3. The catalyst at 600 °C consists of 26% Fe_2O_3, 11% $ZnFe_2O_4$, and 63% ZnO. The catalyst at 700 °C consists of 24% Fe_2O_3, 14% $ZnFe_2O_4$, and 62% ZnO. However, Fe_2O_3 is no longer present in it at 800 °C. The distribution of pore sizes is shown in Fig. 2. The fraction of the micropore volume per total pore volume is 20.6% in the catalyst at 500 °C, 7.6% at 600 °C, and 6.3% at 700 °C. The micropore disappears rapidly with a rise in the calcination temperature.

Catalyst (C). In the X-ray analysis, the only components in the catalyst are found to be ZnO and $ZnFe_2O_4$, even in the catalyst calcined at 500 °C; that is, Fe_2O_3 is not detected in any catalyst. These crystalline sizes are shown in Table 1. The distribution of pore sizes is shown in Fig. 3. The fraction of the micropore volume per total pore volume is 22.7% in the calcined at 500 °C, 14.2% at 600 °C, 8.6% at

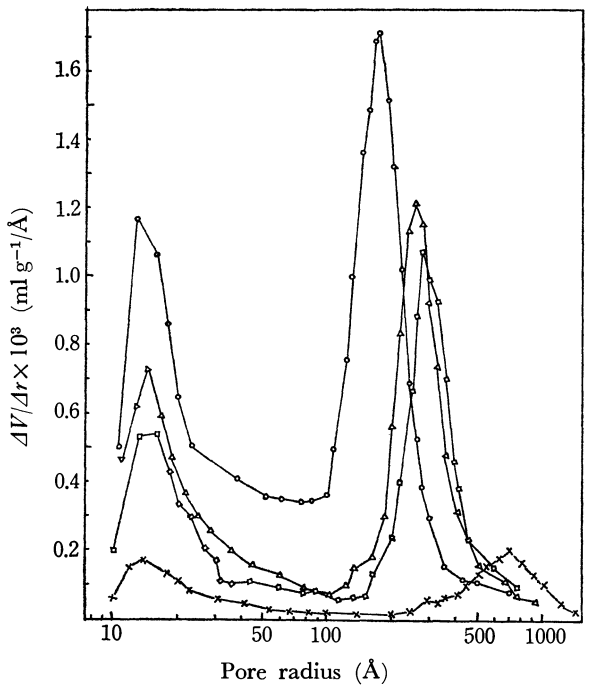

Fig. 2. Pore distribution of catalyst (B)

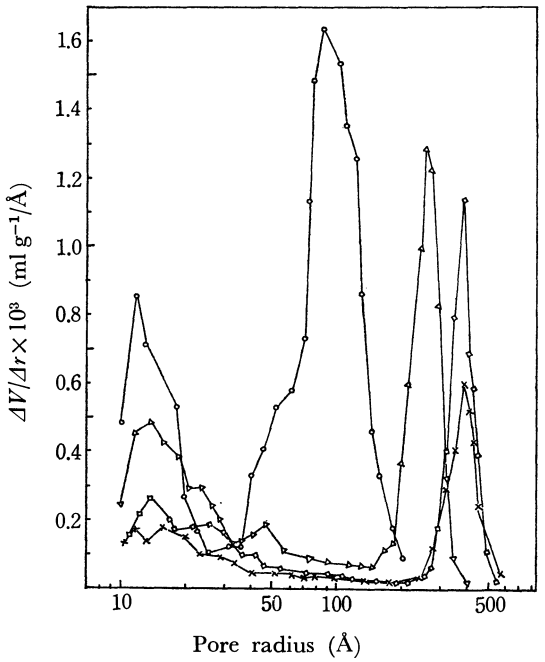

Fig. 3. Pore distribution of catalyst (C)
(-○-) at 500 °C, (-△-) at 600 °C,
(-□-) at 700 °C, (-×-) at 800 °C.

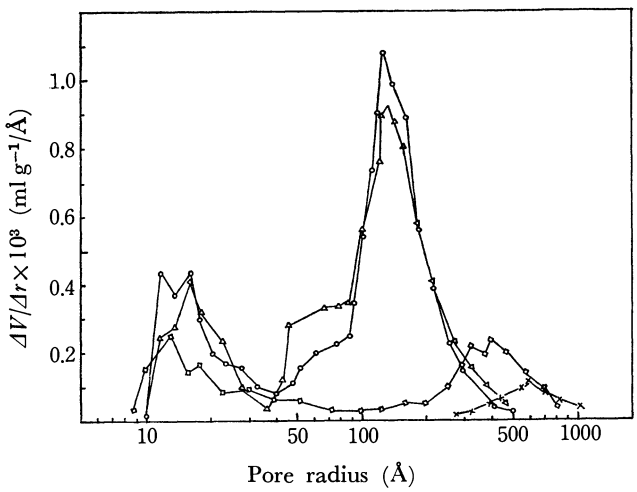

Fig. 4. Pore distribution of catalyst (D)
(-○-) at 500 °C, (-△-) at 600 °C,
(-□-) at 700 °C, (-×-) at 800 °C.

700 °C, and 8.4% at 800 °C. The disappearance of the micropore occurs rapidly with a rise in the calcination temperature.

Catalyst (D). In the X-ray analysis, the same components as in the (C) catalyst are obtained; that is, Fe_2O_3 is not detected in any catalyst. These crystalline sizes are shown in Table 1. The distribution of pore sizes is shown in Fig. 4. The fraction of the micropore volume per total pore volume is 35.1% in the catalyst calcined at 500 °C, 34.8% at 600 °C, 8.0% at 700 °C. The disappearance of the micropore occurs rapidly at 700 °C or more.

Catalyst (E). It has been reported that the formation of ferrite by the wet method depends upon pH value of the solution, but at a pH value below 10.0 the coprecipitate consists of hydroxides.[9] As the coprecipitate in the (E) catalyst is formed at a pH value of 6.85, it consists of zinc hydroxide and ferric hydroxide. In the X-ray analysis, Fe_2O_3 is not detected in any catalyst. The only components in the catalyst are ZnO and $ZnFe_2O_4$. The distribution of pore sizes is shown in Fig. 5. The fraction of the micropore volume per total pore volume is 16.6% in the catalyst calcined at 500 °C, 13.8% at 600 °C, and 6.5% at 700 °C. These crystalline sizes are shown in Table 1.

The pore volumes and surface areas of the present catalysts are summarized in Table 2. It may be concluded from Table 2 that the present catalysts are very sensitive to sintering.

Discussion

Three types of pores (the dehydration pore, the small interparticle pore, and the macropore (which consists of the voids between particles)) have previously been confirmed from a study of the origin of pores in the alumina.[3] However, the catalysts prepared by the five processes outlined above clearly form two types of pores, the micropore at about 20 Å and the macropore at 80 Å or more. With regard to the micropore, water and/or carbon dioxide are loosed from starting materials during the calcination. The amounts of the loss increase in the order of (D)→(B)→(E)→(C)→(A). The fraction of the micropore volume per total pore volume also corresponds to the order of the amounts of the loss of the small molecules from the starting materials. The micropore is considered to be formed by the loss of water and/or carbon dioxide from the starting materials and is considered to be a dehydration pore or a decarbonation pore.

On the other hand, the macropore becomes proportionally larger with a rise in the calcination temperature and with the growth of these crystalline sizes, as shown in Tables 1 and 2. Hence, the macropore is considered to consist of the voids between particles. In the present catalyst, zinc ferrite is formed by the

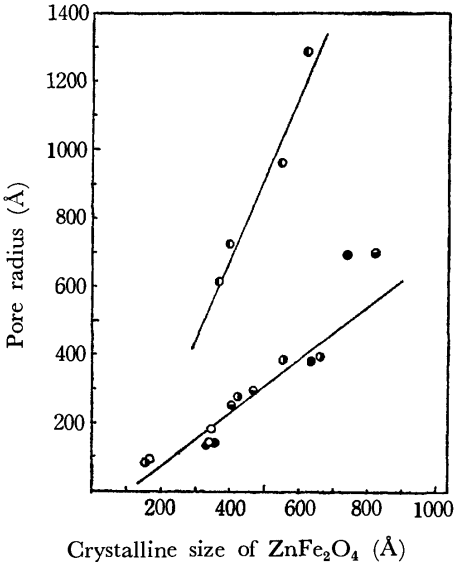

Fig. 6. Relations between pore radius and crystalline size of zinc ferrite
(-◐-) Catalyst A, (-◒-) Catalyst B, (-◑-) Catalyst C, (-●-) Catalyst D, (-○-) Catalyst E.

solid reaction of zinc oxide with ferric oxide.[1] In Table 1, the solid reaction may be seen to proceed easily in the (C), (D), and (E) catalysts, which include ferric hydroxide as a starting material. The crystalline sizes of the zinc ferrite grow considerably with a rise in the calcination temperature. Therefore, the crystalline sizes of zinc ferrite must be estimated for the formation of the macropore. The relationship between the macropore radius of these catalysts and the crystalline sizes of zinc ferrite is shown in Fig. 6. The plots of the catalysts prepared by the extrusion technique are on the same linear line, but the plot of the catalyst prepared by the tableting technique is on the other linear line. This may be expected to be due to the conditions of the preparation.

The micropore and the macropore volumes can be calculated by means of the total pore volumes and the distribution of pore sizes. From these results, the micropore may be determined to disappear mainly at temperatures below 700 °C and the macropore, to disappear suddenly at 800 °C. It may be found from the results in Table 2 that considerable decreases in the pore volume and the surface area occur with a rise in the calcination temperature. As a result, it may be concluded that the present catalyst is well crystallized and sensitive to sintering conditions.

Vacuum Ultraviolet Absorption and Photoelectron Spectra of Aliphatic Ketones

Hitoshi OGATA, Jun KITAYAMA, Masanori KOTO, Shinji KOJIMA, Yoshimasa NIHEI, and Hitoshi KAMADA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received December 1, 1972)

The vacuum ultraviolet absorption spectra down to 65000 cm^{-1} and HeI photoelectron spectra were measured for CH_3CHO and $RCOCH_3$ ($R=CH_3$ to t-C_4H_9). Assignments of the absorption bands are proposed with the aid of photoelectron spectra and CNDO/2 type molecular orbital calculations. Special notice has been paid to the similarity of the vibrational structure between the lowest ionization potential bands of photoelectron spectra and the second bands of vacuum ultraviolet absorption spectra.

Many experimental and theoretical studies have been made on the interpretation of the vacuum ultraviolet absorption spectra of aliphatic ketones and aldehydes.[1-8] Although some interpretation has been given, there is no agreement on the assignment of bands to electronic transitions. Recently, Lucazeau and Sandorfy measured the spectra of acetaldehyde and its deuterated homologues in the ultraviolet down to 85000 cm^{-1}, and gave detailed assignments to the individual absorption bands.[9] As for ketones, Ito *et al.* measured the spectra of aliphatic ketones, mainly methyl alkyl ketones, in the region from 50000 cm^{-1} to 60500 cm^{-1}, but they gave no definite assignment.[10] The present paper deals with the interpretation of these spectra with the aid of the photoelectron spectra (pes) of these molecules and CNDO/2 type SCF MO calculations.

Experimental

The vacuum ultraviolet absorption spectra were measured on a Jasco model VUV-2 vacuum ultraviolet self-recording spectrophotometer mounted with 1 m radius concave grating having 1200 grooves per mm, equipped with a ratio recording double beam system using the rotating-cell method. 3 cm gas cell blocks containing a sample cell and a reference cell with CaF_2 windows rotate at 8 Hz and function as a rotating sector.[11] The light sources were a hydrogen discharge tube and a zenon discharge tube. The spectra were measured in the vapor state at room temperature and recorded photoelectrically down to 65000 cm^{-1}.

A Jasco model PE-1 photoelectron spectrometer was used for measurements of the photoelectron spectra. The resonance line of He (584Å) was emitted by means of DC glow discharge. A hemispherical electrostatic condenser with 100mm diameter was used for electron energy analysis, a channel electron multiplier for detection and a pulse counting method for signal processing system. The terrestrial magnetic field and fluctuating magnetic field around the apparatus were removed by μ-metal shielding. In order to obtain ionization potentials from spectra, Xe gas was fed into the sample gas as an internal standard of ionization potential. The spectra were measured in gas phase at room temperature.

We have measured the absorption and photoelectron spectra of CH_3CHO, CH_3COCH_3, $C_2H_5COCH_3$, n-$C_3H_7COCH_3$, i-$C_3H_7COCH_3$, n-$C_4H_9COCH_3$, i-$C_4H_9COCH_3$, s-$C_4H_9COCH_3$ and t-$C_4H_9COCH_3$. These compounds were commercial products and used without further purification. Theoretical calculations were based on the CNDO/2 method.

Results and Discussion

Photoelectron Spectra. The photoelectron (pe) spectra of acetaldehyde and eight aliphatic ketones are shown in Fig. 1. Each pe spectrum of these molecules contains relatively a sharp peak located at the lowest ionization potential side (called the first band) and a series of broader peaks at the higher ionization potential region. We assume the validity of the Koopmans' theorem throughout.[12] Since the calculations have been performed in the ground state geometries, the calculated ionization potentials are compared with the experimental vertical ionization potentials throughout. Observed vertical ionization potentials and calculated ionization potentials of acetone and acetaldehyde are summarized in Table 1. For the sake of convenience,

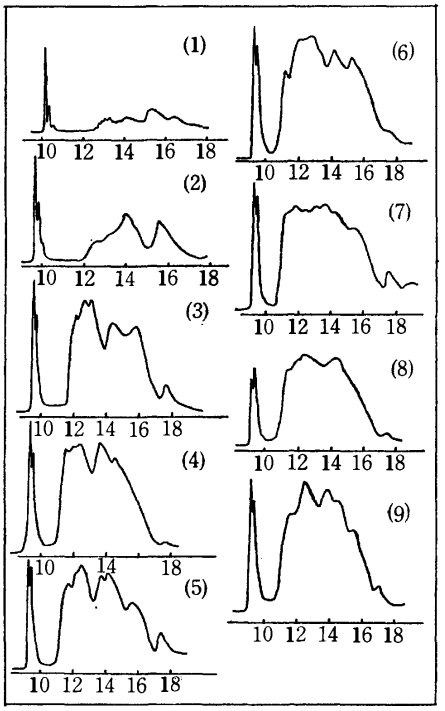

Fig. 1. The photoelectron spectra of ketones and acetaldehyde, Abscissa; ionization potential (eV). Ordinate; arbitrary unit. 20.86	5a' (σ)	15.09

Table 2. The first pe bands and the second absorption bands of acetone and acetaldehyde

Acetone				
pes	peak position (eV)	9.71	9.86	10.02
	intensity (cps)	360	200	70
VUV	peak position (eV)	6.35	6.50	6.65
	intensity ($\varepsilon\times10^{-3}$)	10.30	6.10	2.05
Acetaldehyde				
pes	peak position (eV)	10.19	10.33	10.50
	intensity (cps)	690	250	60
VUV	peak position (eV)	6.83	6.96	7.13
	intensity ($\varepsilon\times10^{-3}$)	9.8	3.0	2.3

the types of molecular orbitals are roughly classified into n, π, and σ. The first bands of the pe spectra of acetone and acetaldehyde can be assigned to the ionization from the non-bonding orbital localized on the respective oxygen atom on the basis of their spectral features and calculated eigenvectors. The first bands of other aliphatic ketones can also be assigned to non-bonding orbitals from the same reason.

All the first bands of aliphatic ketones and aldehyde show vibrational fine structures. Peak positions and intensities of the fine structures for acetone and acetaldehyde are shown in Table 2. Three peaks can be found for acetone with spacings 0.15 and 0.16 eV and two peaks for other ketones with spacings ranging from 0.15 to 0.08 eV. In the spectrum of acetaldehyde, three peaks with spacings of 0.14 and 0.17 eV can be identified.

Results of calculations show that the second ionization bands of acetone and acetaldehyde can be assigned to the C=O π orbitals and the third bands to the C=O σ orbitals, other types of σ orbitals largely contributing to the third bands.

General Description of the VUV Spectra. The absorption spectra of acetone, first studied by Scheibe *et al.*,[13] have been investigated in detail by Lawson and Duncan,[14] Lake and Harrison,[5] and Ito *et al.*[10] Absorption spectra of acetone and acetaldehyde we obtained are shown in Fig. 2. For acetone, the absorption bands near 50000, 60000, and 65000 cm^{-1} are denoted by the second, third, and fourth absorption bands respectively, since aliphatic ketones have an

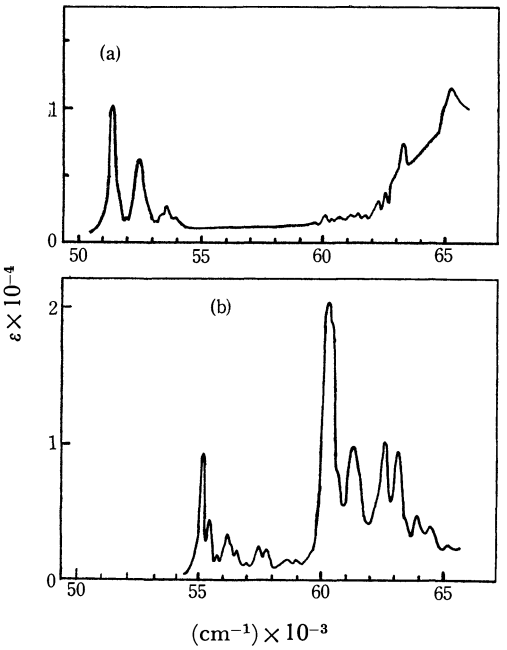

Fig. 2. The VUV absorption spectra of (a) acetone and (b) acetaldehyde.

absorption band near 36000 cm^{-1} assigned to the n-π^* transition. In the case of acetone, the third and fourth absorption bands are rather difficult to separate, but are separated at 62200 cm^{-1} by taking spectra of other ketones into consideration. The reproducibility of *f*-values is almost within 10 per cent and *f*-values are in fairly good agreement with those reported by Ito *et al.*,[10] except for methyl isobutyl ketone, methyl s-butyl ketone and methyl t-butyl ketone.[15] Because of overlapping with Ref. 10, the absorption spectra of aliphatic ketones are not shown except for acetone.

The Second and Third Absorption Bands of Ketones. The first problem in the spectral region beyond 50000 cm^{-1} is to distinguish the Rydberg bands from the valence shell bands. Duncan[16] assigned 65000 cm^{-1} band of acetone to the Rydberg band whose quantum defect is 0.495, but its limit was not confirmed by the photoionization experiments of Watanabe,[17] who made a different assignment and obtained a series leading to an ionization potential of 9.705 eV. In contrast, Barnes and Simpson[7] assigned the weak band near 60000 cm^{-1} to the 2p-3s Rydberg transition and the strong band near 65000 cm^{-1} to the π-π^* transition. Barnes and Simpson[7] and Ito *et al.*[10] assigned the sharp peaks locating from 50000 cm^{-1} to 55000 cm^{-1} to the n-σ^* valence shell transition.

The equilibrium geometries of the excited Rydberg species and the ionic species lacking one non-bonding electron are expected to be considerably close. A similarity of the Franck-Condon factors is therefore expected between the pe spectra and optical spectra assigned to Rydberg transitions. The vibrational structure of the pe band assigned to non-bonding orbital is thought to be very much alike that of a Rydberg transition which converges into the corresponding ionization.

The fine structures of the second absorption band and

of the first pe band of acetone are summarized in Table 2. As might be expected, the vibrational structure of first pe band bears a striking resemblance to that of the second absorption band. Fine structures of the second absorption bands of other ketones are considerably complicated, but the corresponding peaks can be found in the first pe bands with a few exceptions. This evidence strongly supports the assignment that the second absorption bands of aliphatic ketones are the Rydberg transitions. If we take the 51300 cm^{-1} peak of acetone for the first member of the Rydberg series and use the values obtained by Watanabe,[17] transition energies of each absorption peak satisfy the Rydberg equation, giving the quantum defect $\delta=1.02$. In other words, the peaks observed by Watanabe belong to the s-type Rydberg series in the range $n\geq 4$, and the 51300 cm^{-1} band is the $n=3$ Rydberg transition of the same series.

As regards the variation of the second absorption bands of aliphatic ketones by alkyl groupes, Ito *et al.* pointed out that methyl alkyl ketones could be classified into Group I, methyl *n*-alkyl ketones (including methyl isobutyl ketone) and Group II, the methyl alkyl ketones in which the α-carbons of the alkyl groups are the secondary or tertiary carbons, the shapes of these second bands being sensitive to alkyl groups.[10] In the second bands of Group I molecules, there are main vibrational progressions with frequencies *ca.* 1200 cm^{-1}. Hardly any vibrational fine structures can be seen in Group II molecules with the exception of methyl isopropyl ketone. In particular, the difference in band shape between methyl isobutyl ketone and methyl *s*-butyl ketone is remarkable. Although the former has a fairly distinct fine structure the latter has practically no structure. This is thought to be due to the existence of conformational isomers and the characteristics of the Rydberg orbitals.

The first member of the Rydberg transition series is related to the smallest Rydberg orbitals. The first Rydberg state undergoes a larger perturbation from the molecular skelton than higher members. Because of the localization character of the lone pair orbitals, the Rydberg spectra of methyl alkyl ketones caused by the transitions from the lone pair to Rydberg orbitals are mainly affected by the structure near the carbonyl group. In the case of Group I molecules, the methyl alkyl ketones with large normal alkyl groups have essentially the same vibrational structures as methyl ethyl ketone. On the other hand, Rydberg states of Group II molecules which have branched alkyl groups at α-position are strongly perturbed by their internal rotations. In the case of methyl isobutyl ketone which has a branched alkyl group at β-position, the absorption band is considered to show several vibrational fine structures, since the Rydberg state is not much perturbed.

The vacuum ultraviolet absorption spectra of aliphatic alcohols, ROH, and amines, RNH_2 were also measured R = (CH_3 to t-C_4H_9). Important results alone are presented here. The first electronic transition bands of ROH located at about 55500 cm^{-1} and of RNH_2 at about 47600 cm^{-1} can be assigned to the n-σ^* transitions. The variation of oscillator strengths f of the first

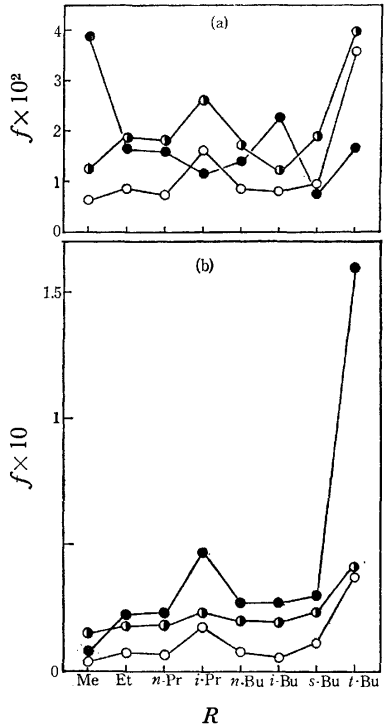

Fig. 3. The oscillator strengths of (a) the second and (b) the third absorption bands of $RCOCH_3$ and those of n-σ^* transitions of RNH_2 and ROH.
○: ROH, ◑: RNH_2, ●: $RCOCH_3$.

bands of ROH and RNH_2, and the oscillator strengths of the second absorption bands of $RCOCH_3$ are shown in Fig. 3(a). The f-values of the n-σ^* bands of alcohols and those of amines undergo the same variation by alkyl substituents, the second bands of ketones showing a different tendency. Similar plots for the n-σ^* bands of alcohols and amines and for the third absorption bands of ketones are shown in Fig. 3(b). The oscillator strengths vary considerably with the alkyl group, the methyl group giving the smallest f-value and the *t*-butyl group the largest f-value. However, the three series of molecules show the same variation by alkyl groups.

Taking into account the vibrational structure of the second absorption bands of ketones and the varation of the oscillator strentghs of the second and third bands, it seems reasonable to assign the second bands of ketones to the Rydberg transition and the third bands to the n-σ^* transition. The assignment is based only on experimental results, and therefore, attention should be paid to whether the lowest Rydberg orbital is distinguishable from the lowest σ^* orbital. For example, the $3sa_1$ Rydberg orbital of H_2O is identical with the antibonding orbital $4a_1$. However, in larger molecules with lower symmetry the lowest Rydberg orbital might not be identical with the lowest σ^* orbital, though mixing may occur. In this regard, the theoretical investigation by Salahub[18] is prerequisite.

In order to obtain further proof that the second bands can be assigned to the Rydberg transition, further measurements are necessary.[19-21] As for the second band of acetone, it was pointed out[19] that the upper state of the transition has the characteristic of a big

orbit, but the pressure effect by the use of nitrogen gas is not so extreme as methyl iodide, a well-known example. According to the assignment by Lucazeau and Sandorfy[9] acetaldehyde has the n-3s Rydberg state at 55045 cm^{-1}, the n-3p Rydberg state at 60154 cm^{-1} and the n-3d Rydberg state at 67985 cm^{-1}. Their spectra show that these peaks are very sharp and intense. In the case of acetone, on the contrary, no sharp and intense peak corresponding to n-3p or n-3d Rydberg peak of acetaldehyde can be found in this spectral region.

The Fourth Absorption Bands of Ketones. The fourth band starting at 62200 cm^{-1} could not be experimentally examined. The spectra obtained by Barnes and Simpson[7] show that this band extends to about 69000 cm^{-1} and has a large f-value. In the assignment of this band, CNDO/2 calculations were performed, orbitals with a higher principal quantum number being not included in the basis functions.

On the basis of experimental results, the third bands have been assigned to n-σ^* transitions. But CNDO/2 calculations show that the third band is π-π^* and the fourth band n-σ^*. If absorption intensities are taken into consideration and, further, from the fact that the calculated transition energies for π-π^* and n-σ^* are very close, it may not be appropriate to make direct use of calculations to assignments. The spectrum reported by Barnes and Simpson[7] shows that the f-value of the fourth band is more than ten times larger than that of the third band. Our calculations show that the f-value of π-π^* is about ten times larger than that of n-σ^*. This may support the assignment that the fourth band is the π-π^* transition.

Acetaldehyde. The first band of the pe spectrum of acetaldehyde can be assigned to the ionization from the non-bonding orbital localized on an oxygen atom. Fine structures of the first pe band and the 60000 cm^{-1} absorption band of acetaldehyde assigned to n-3s Rydberg state are summarized in Table 2. As in the case of acetone, similarity of the vibrational structure between pe and absorption spectra is recognized.

Though we could not identify it, Lucazeau and Sandorfy[9] found a very weak band in the region 53677—58254 cm^{-1} and assigned it to the n-σ^* transition on the basis of the following (1) In Rydberg series, the 0–0 component usually has maximum intensity. (2) The σ^* orbital has a conspicuous 3s Rydberg character. The f-value of this n-σ^* transition is calculated to be 0.12. This value is too large for an explanation of the weakness of this band. Our results show that the σ-π^* transition is the second transition having an f-value one tenth of the n-σ^* transition. It may thus be reasonable to assign this band to the σ-π^* rather than the n-σ^* transition, where the σ orbital has mainly CO bonding character. Calculations show that in the case of acetone the second lowest transition is also σ-π^*. In contrast with the presence of the weak band in the absorption spectrum of acetaldehyde in the region 53677—58254 cm^{-1}, no corresponding band has been found. Concerning transition energies, calculated results for acetaldehyde are consistent with the experimental results, the n-σ^* transition having lower energy than the π-π^* transition. Observed transition energies and assignments for acetone and acetaldehyde are shown in Table 3.

Table 3. The observed transition energies, ΔE, and oscillator strengths, f

Obsd		Assign.

The Effects of the Composition of Raw Cadmium Sulfide on the Characteristics of Cadmium Pigments

Makoto TSUNASHIMA and Hiroshi TAKAHASHI*

Omiya Plant, Mitsubishi Metal Corporation, Kitabukuro, Omiya 330

** Institute of Industrial Science, The University of Tokyo, Roppongi, Minato, Tokyo 106*

(Received April 6, 1973)

The effects of the S/Cd mol ratios of cadmium sulfide precipitates on the particle size, the hexagonality, and the brightness of cadmium pigments were studied. The precipitates were prepared by mixing an aqueous solution of cadmium nitrate with either sodium sulfide or hydrogen sulfide. Then, cadmium pigments were made of these precipitates by heat-treatment under an atmosphere of oxygen or nitrogen. The characteristics of the pigments were affected by the following three factors; particle size, hexagonality, and brightness. These factors were closely related to the S/Cd mol ratio of the precipitates of the cadmium pigments. We found the minimum points on the curves of the particle size, the hexagonality, and the brightness in relation to the S/Cd mol ratio. From these results, it was concluded that the optimum range of the S/Cd mol ratios of the precipitates for the characteristics of the cadmium pigments was 0.98 ± 0.01.

Cadmium pigments are ordinarily composed of CdS or solid solutions of CdS and either ZnS, CdSe, or HgS. These pigments are mainly formed by two processes, precipitation and calcination. The former process is the precipitation reaction of a metal salt solution with alkali sulfide (selenium is sometimes dissolved in this solution); the latter, the calcination of the precipitates at 500—700 °C in a non-oxidizing atmosphere.

The characteristics of cadmium pigments have been reported in many papers[1-5] and patents.[6] Most of these reports have been concerned with the two processes mentioned above. The effects of the temperature, pH, additions, *etc.* on the pigments have been studied for the precipitation process, and those of the temperature, the atmosphere, the time, additions, *etc.*, for the calcination. However, the characteristics of the precipitated powders and their effects on the final pigments have been little investigated.

We have previously reported that on heat-treatment oxygen and sulfur affected the particle size, the hexagonality, and the color.[7,8] The results showed that the changes in the particle size and hexagonality were very similar to the conditions of heat-treatment. Especially in the heat-treatment, oxygen in an atmosphere distinctly brought about a brighter color than did nitrogen or helium. Therefore, the effects on the pigment characteristics in relation to the amount of cadmium hydroxide and sulfur in precipitates and that of oxygen in an atmosphere were studied.

In this paper, the effects of the S/Cd mol ratio of the CdS precipitates before heat-treatment of the pigment characteristics will be discussed. Some interesting correlations between the S/Cd mol ratios and the pigment characteristics were obtained.

Experimental

Raw Materials. The raw materials were precipitated by the reaction of cadmium sulfate and a sodium sulfide solution of each 1 molar concentration. Precipitates with various S/Cd mol ratios were prepared by the use of the sodium sulfides, dissolved sulfur powder for precipitates including excess sulfur, and mixed sodium hydroxide for those with excess cadmium. After the solution had been stirred for 3 hr at 80 °C, the precipitate was dried at 100 °C, then, it was pulverized to a fine powder. It was considered that all these, including cadmium polysulfides or cadmium hydroxide, were coprecipitated with CdS.

In addition to these materials, other raw materials were prepared by the bubbling of hydrogen sulfide gas. Sulfur or cadmium hydroxide powder was mixed with the suspension after it had been washed to obtain Cd or S excess raw materials. The precipitates prepared by sodium sulfide were classified as Group A, and those prepared by hydrogen sulfide, as Group B.

These raw materials were analyzed by the gravimetric method for sulfur and by the EDTA titration method for cadmium.

Heat-treatment. Each raw material was degassed at 200 °C for an hour under a pressure of 10^{-3} mmHg and then heat-treated for an hour at a constant temperature in pure nitrogen or oxygen gas of an atmospheric pressure. The temperature of the heat-treatment was fixed at 500 °C for Group B, for the precipitates of Group B were stable and no changes in hexagonality occurred at 500 °C, as has previously been reported.[9]

Properties of Products. The particle size was measured by the BET method, from the nitrogen gas adsorption at the temperature of liquid nitrogen, after the raw materials had been pretreated at 200 °C under a pressure of 10^{-3} mmHg.

CdS crystals have two polymorphic forms, *i. e.*, a hexagonal closely-packed structure (wurtzite) and a face-centered cubic (zincblende).

CdS polycrystals usually include both of the forms, and the term 'hexagonality' has been previously used[10,11] to describe the fraction of the hexagonal form in the crystal. We have also used this term 'hexagonality'.

Short and Steward[10] have shown that the 'hexagonality' (H) of CdS polycrystal is related to the ratio (R) between the integrated intensities (I) of the first and second Debye-Sherrer rings:

$$H = 4R/(3R+1.33)$$

where:

$$R = I(100)/I(002+111)$$

As is shown in the previous paper, in this equation the constant value, 1.33, was the lower estimation. From the many experimental results, the most reliable value was 1.70. Therefore, the above equation was modified as follows:

$$H = 4R/(3R+1.70)$$

The X-ray diffraction patterns were recorded by means of a Philips X-ray diffractometer, model PW. As an X-ray radiation source, nickel-filtered copper radiation at 30 kV and 20 mA was used.

The brightness of the specimen was investigated as one pig-

ment characteristic.

Specimens were mixed and kneaded with varnish on Hoover muller* by hand or by four times 25 revolutions under a 150 lb. weight. The spectral reflectance curve of each of these sheets was then measured by means of a spectrophotometer.

The brightness was represented by the slope of the spectral reflectance curve at the 50 percent reflectance point (in arbitrary units), but it agreed well with both the 'excitation purity' from the chromaticity diagram** and with observations. As the slope is proportional to the crystallinity, the brightness represents the purity of the color.[12]

Results and Discussion

Particle Size. The raw materials had particle sizes (surface area diameter) of 10—20 nm for Group A and of 150 nm for Group B. The particle sizes of the heat-treated specimens are shown in Fig. 1.

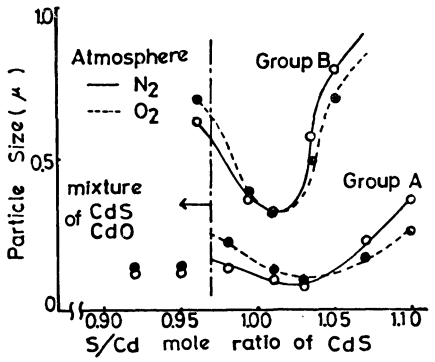

Fig. 1. The correlation between the S/Cd mol ratio of CdS precipitate and particle size of heat-treated specimen.

In Fig. 1, the changes in particle size according to the S/Cd mol ratio of the raw materials describe a curve with a minimum in the range from 1.02 to 1.03. The particle sizes also differed with the atmospheric gas.

It seems to be general that particles grow remarkably on heat-treatment in an excess of either S or Cd. Therefore, it is natural that a miniumm point exists on the curve. Parravano[13] showed that ZnO particles grew by the recombinations of zinc diffused in the crystal with oxygen on the surface. Further, Woodbury[14] and Whelan[15] reported that the diffusion of Cd in the CdS crystal was in proportion to the Cd vapor pressure.

These facts prove that an increase in particle size is promoted by the excess of either S or Cd, and that, because sulfur was more volatile than Cd and was reactive with atmospheric oxygen,*** the position of the minimum point in the curve shifts to a somewhat lower value of the S/Cd mol ratio.

Hexagonality. Changes in the hexagonality of heat-treated specimens of Group A are shown in Fig.

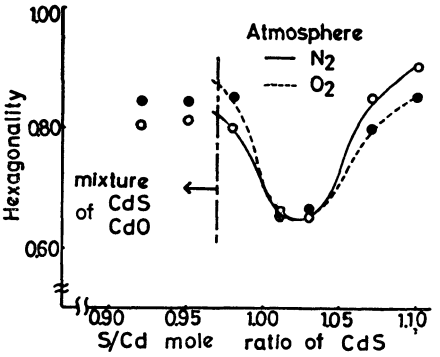

Fig. 2. The correlation between the S/Cd mol ratio of CdS precipitate and hexagonality of heat-treated specimen.

2 in relation to the S/Cd mol ratios of the original specimens. The curve of Group B has been abbreviated to be almost the same as for Group A. The changes in hexagonality showed the same tendency toward particle size.

According to Holt and Wilcox,[16] phase transformation to the hexagonal form was accelerated by the quantities of defects. It was supposed that specimens of Group A had more defects than those of Group B, since the particles of the former were fine.

The effect of the oxygen in the atmosphere on the hexagonality was almost the same as that on the particle growth.

Brightness. CdS pigments, prepared under similar conditions, took various hues, brightness, tinting strength, and hiding powers according to the differences in crystal structure, particle size, *etc.*

The correlation with the brightness and the S/Cd mol ratio is shown in Fig. 3 in the case of Group A; the curve is almost the same as Group B.

The changes in brightness showed results similar to those for both particle size and hexagonality, but the minimum point of the curve was less clear compared with the previous two characteristics.

The brightness of heat-treated specimens in an atmosphere of oxygen was higher than that in one of nitrogen. In general, cadmium pigments were pulverized and mixed with vehicles for practical use. As

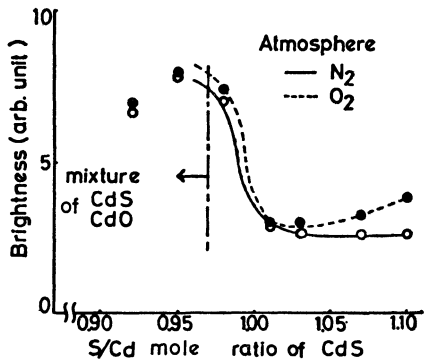

Fig. 3. The correlation between the S/Cd mol ratio of CdS precipipate and the brightness of heat-treated specimen.

** Japanese Industrial Standard, JIS Z8701.

*** Observed by the generation of SO_2 gas.

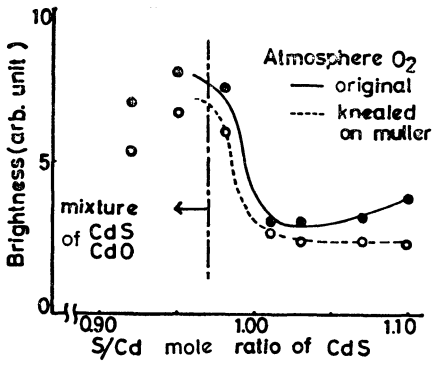

Fig. 4. Effects on brightness by the grinding of heat-treated specimens.

has previously been reported,[12] the brightness decreased upon such treatments, distortion also occurring in a crystal.

As is shown by the dotted lines in Fig. 4, the brightness of the specimens in this study was also reduced by kneading on muller; the reduction was especially remarkable in the specimens with a S/Cd mol ratio of over 1.00 and which has been heat-treated in an atmosphere of nitrogen.

Conclusion. Cadmium pigments with excellent characteristics must have the range in the particle size of 0.1—0.5 μ and as much high hexagonality and brightness as possible.

It has been established in this report that the value of the S/Cd mol ratio of the raw materials has a great effect on the quality of pigments obtained; the optimum value was 0.98±0.01. Under a ratio of 0.97, black cadmium oxide was formed by the decomposition of cadmium hydroxide; over one oxide of 0.99, the products were unsuitable as pigments because of their low brightness.

Further,if oxygen was present in the calcining atmosphere, it caused not only a decrease in the S/Cd mol ratio by the consumption of sulfur, but also an increase in the brightness. However, we could not confirm by any quantitative methods whether or not the oxygen was substituted for sulfur in a crystal.

Molecular Vibrations and Force Fields of Alkyl Sulfides. VII. Polythiomethylene (PTM) and Polythiomethylene-d_2 (PTM-D2), and Their Model Compounds: $CH_3S(CH_2S)_nCH_3$ ($n=1-3$)

Masaru OHSAKU

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received June 20, 1973)

Infrared spectra of polythiomethylene (PTM) and polythiomethylene-d_2 (PTM-D2) observed by a Nujol mull method are reported, and their spectra are assigned. Normal coordinates of bis(methylthio)methane, $CH_3SCH_2SCH_3$, bis(methylthiomethyl) sulfide, $CH_3SCH_2SCH_2SCH_3$, bis[methylthio(methylthio)]methane, $CH_3SCH_2SCH_2SCH_2SCH_3$, PTM, and PTM-D2 have been treated. The force field used in the computation is a modified Urey-Bradley type. The skeletal conformation of these model compounds in the solid state is confirmed to be the [G] form. The relations between the degree of n and their CH_2 deformation fundamentals are explained by the concept of the frequency-phase difference. The calculated frequencies are compared with those of experiment. A comparison of the force fields of PTM and polyoxymethylene (POM) is also briefly made.

Vibrational analyses[1-5] of the hexagonal polyoxymethylene (POM) and polyoxymethylene-d_2 (POM-D2), and those of their model compounds,[6,7] $CH_3O(CH_2O)_nCH_3$ ($n=1$—5), have been extensively treated. The X-ray analyses of the hexagonal POM have also been made.[8-11] For the sulfur analogs, in the first paper of this series[12] it has been described that the interaction terms on the methyl groups are indispensable in the force fields of dimethyl sulfide. In the second paper,[13] the analyses were made on the infrared spectra of this series: $CH_3S(CH_2S)_nCH_3$ ($n=0$—3). These are model compounds of polythiomethylene (PTM). The preparation methods of PTM have been investigated.[14,15] An identification by means of the infrared spectra of PTM, which was obtained by the polymerization of *s*-trithiane, was very briefly made.[16] Recently, Hendra *et al.*[17] reported the Raman and infrared spectra of PTM and polyselenomethylene (PSeM). They also tentatively assigned the observed bands. However, no reports on normal coordinates of PTM have been published. The vibrational treatments of deuterated PTM (PTM-D2) have not been reported either. The molecular structure of the hexagonal PTM has already examined by Carazzolo and Valle by means of X-ray analysis,[10] as is shown in Fig. 1. The PTM is only known in the hexagonal form. They suggest that polymer chains are helicoidal, with the axis of the helix parallel to *c*, and that the unit cell is comprised of seventeen $-CH_2S-$ units and nine turns of the helix: $a=5.07$ Å, and $c=36.52$ Å. They have also estimated the internal rotation angle to be 65°59′, *i. e.*, the [G] form. The infrared spectra of PTM and its deuterated species, which were prepared according to the method of Ref. 14, have been recorded. Then, we tried to discuss the transferability of the set of the force constants obtained on dimethyl sulfide. Another purpose of this paper is to clarify the skeletal conformation of $CH_3S(CH_2S)_nCH_3$ ($n=1$—3) in relation to the conformation of PTM. Still another purpose of this paper is to find the relations in the vibrational frequencies between PTM and POM. In the present paper, the molecular vibrations of the $CH_3S(CH_2S)_nCH_3$ ($n=1-3$), PTM, and PTM-D2 series are treated with a potential function of the modified Urey-Bradley type, assuming that all of the potential constants are common in this series.

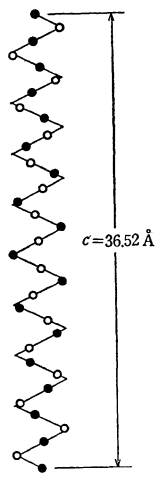

Fig. 1. Molecular structure of polythiomethylene (PTM) determined by the X-ray analysis.[10]
Open circle: methylene group. Closed circle: sulfur atom.

Experimental

The preparation of PTM and PTM-D2 was done by the method of Schmidt *et al.*[14] The melting point of the purified PTM was 195—200 °C, while that of PTM-D2 was 175—180 °C. The infrared spectra were recorded by a Nujol mull method in the 4000—200 cm^{-1} region at room temperature.

Vibrational Assignment

The obtained infrared data are summarized in Table 1. The spectroscopically active vibrations of the hexagonal PTM or PTM-D2 are subdivided into A_1, A_2, and E species. Seven vibrations (the C–H or C–D stretching, methylene bending, twisting, C–S stretching, CSC bending, and the torsional vibrations) belong to the A_1 species. Five vibrations (the C–H or C–D stretching, methylene wagging, rocking, C–S stretching, and the torsional vibrations) belong to the A_2 species. Twelve degenerate vibrations belong to the E species. The vibrations belonging to the A_1 species are infrared-inactive. The vibrations of the A_2 and E species are

infrared-active. Table 2 shows the numbers of the bands and the band types. The following bands may, then, be expected in our spectral region: one methylene bending, two wagging, one twisting, two rocking, three C–S stretching, and one skeletal bending vibrations. The numbers of the obtained bands correspond well with those expected.

Polythiomethylene. The spectra of PTM obtained are closely similar to those of polymethylene disulfide.[18] The spectra are virtually identical with those of Hendra *et al.*[17] As for the CH_2 deformation modes, the bands of the CH_2 bending, wagging, twisting, and rocking are expected in the 1400—740 cm^{-1} region. Hendra *et al.* did not completely assign the infrared bands obtained in this region. In the 1400—1100 cm^{-1} region, one CH_2 bending, two wagging, and one twisting bands may appear. The band at 1225 cm^{-1} is assignable to the CH_2 wagging vibration. This band, however, might be due to the other vibration. The result of the normal-coordinates fairly well reproduced this frequency. Although the CH_2 twisting band is expected around 1150 cm^{-1}, no effectively sharp bands appear around this region. There, the weak shoulder band around 1150 cm^{-1} may be identified to the CH_2 twisting vibration. To the CH_2 rocking vibrations, two bands, at 882 and 742 cm^{-1}, were assigned. To the C–S stretching vibrations, three bands at 735, 708, and 671 cm^{-1} are assignable. The bands at 742 and 735 cm^{-1} are very close to each other. These vibrations of the bands may be strongly coupled. Therefore, the assignments of these bands are ambiguous. Hendra *et al.*[17] did not assign the band at 742 cm^{-1} (their value—738 cm^{-1}) to any vibrational mode. They assigned the bands at 748 and 739 cm^{-1}, observed from the Raman spectra, to the C–S stretching vibrations belonging to the E_2 species, though. In the skeletal deformation region, below 400 cm^{-1}, none of the sharp bands appear. The extremely weak band at 511 cm^{-1} may be due to the vibration of the S–S bond. In that case, the PTM obtained is not completely constructed by the head-to-tail combination.

Polythiomethylene-d_2. Most of the bands of the fully-deuterated PTM shift to a frequency region lower than those of the normal species. To assign the bands, it is useful to ascertain the frequency ratios of $\nu_{PTM}/\nu_{PTM\text{-}D2}$. The CD_2 deformation band is conspicuous in the frequency shift. The band at 1012 cm^{-1} was assigned to the CD_2 bending vibration. The bands at 962 and 908 cm^{-1}, and the shoulder band at 885 cm^{-1} were assigned to the CD_2 wagging and twisting vibrations. In the 700—550 cm^{-1} region, the obtained spectra are more complicated than those of the normal species. Although, in this region, we can expect the CD_2 rocking and C–S stretching bands, each assignment is difficult since the vibrations may be strongly coupled with each other. In conclusion, we have assigned the fairly strong bands to the C–S stretching vibrations.

Normal Coordinate Treatment

In order to confirm the previous assignments, the normal coordinates, including all of the vibrational degrees of freedom, were treated for the n=1—3 species using a force function of the modified Urey-Bradley type. The force constants in relation to the methyl group were transferred from those of dimethyl sulfide,[12] while the other constants were referred to those of 1,2-ethanedithiol,[19] polymethylene disulfide,[18] and (methylthio)methanethiol.[20] The molecular parameters used in the computations were: r(C–H)=1.09 Å, r(C–S)=1.81 Å, and ϕ(CSC)=99°; the other bond angles were assumed to be tetrahedral. The correction terms used were p, p', n, t, g, t', g', and l. The corrections of p, p', n, t, g, and l have been explained in a previous paper.[20] Additional terms, t' and g', which were the *trans* and *gauche* coupling constants between the HCS and CSC angles in the methylene group, were introduced in order to explain the separation width of the CH_2 deformation bands. The force constants used in the computations are summarized in Table 3. The diagonal elements of the potential energy matrix, $\boldsymbol{F}$, are also listed in Table 4. The calculated frequencies are listed in Tables 5—7, toge-

ther with the experimental frequencies.

In order to confirm the transferability of the force constants, the normal coordinates of PTM and PTM-D2 were also treated with the common force field of the model compounds. Calculations were made according to the analogous method of Tadokoro *et al.*[1] The molecular parameters used were: r(C-H)=1.09 Å, r(C-S)=1.815 Å, ϕ(CSC) and ϕ(SCS)=106°52′, and ϕ(HCH)=109°28′, and the internal rotation angle was assumed to be 65°59′.

Molecular Forms. At first we will try to determine the stable conformation which exists in the solid state of the series of $n=1-3$. For the molecule of $n=1$, four forms are possible: TT, TG, GG, and GG′. For the $n=2$ and 3 species, a large number of forms are possible. In this treatment, however, we took into consideration the six most probable forms of TTTT, GGGG, TGTG, TTGT, TGGT, and TTGG for the $n=2$ species and of TTTTTT, GGGGGG, TGTGTG, TTGTTG, TGGTGG, and TTGGTT for the $n=3$ species. The calculated frequencies of the CH_2 rocking, C–S stretching, and skeletal deformation are fairly much affected by their internal angles. The observed frequencies are taken from the previous paper.[13] In the previous paper, however, more bands than those expected for one form are described in the 400—200 cm^{-1} region, even in the solid state. The bands of this region are essentially weak. Moreover, the reliability of the spectrophotometer is not very good in this region. Still another difficulty is due to the bands of water vapor in the atmosphere. A few of the bands which decrease in intensity in the solid state may be due to the imperfect annealing. Figure 2 shows the observed and calculated frequencies in relation to the skeletal vibrations through the $n=1-3$ species. On the molecule of $n=1$ the bands at 341 and 314 cm^{-1} are obviously due to the stable form in the solid state. The frequencies calculated for the GG form explain these bands well. On the species of $n=2$, the three bands at 339, 318, and 247 cm^{-1} can be assigned to the stable form in the solid state. These bands fit well to the frequencies calculated for the [G] form. In the same way, the calculated frequencies of the [G]

Notations are the same as in Table 5.

form explain well the bands which are observed in the solid state of the $n=3$ species. Therefore, it is likely that these three molecules stay in the [G] form in the solid state. In the C–S stretching region, the calculated frequencies of the [G] form fit the observed frequencies well.

The molecular conformations existing in the liquid state will now be briefly described. We will first consider the molecular species of $n=1$. In the region below 400 cm^{-1}, which was observed in the liquid state, there are bands which correspond to at least three forms. In a previous paper,[13] the GG′ form was excluded from the stable forms. In Table 5, however, the frequencies calculated for the GG′ form are listed for reference. The GG form, which is the stable form in the solid state, was also excluded from consideration in this section. Two forms then remain: TT and TG. In the C–S stretching region, the band at 758 cm^{-1} observed in the liquid state fits fairly well to the frequencies calculated for the TT and/or TG form. The band at 705 cm^{-1} fits well to the frequencies calculated for the TT and/or TG form. The weak band at 669 cm^{-1} fits well to the frequency calculated for the TT form. In the skeletal deformation region, nine bands appear in the liquid state. Two bands which disappear in the unannealed film were excluded from the fundamentals, since, around this region, there are not the corresponding calculated frequencies, although these bands may be due to the GG′ form. Four bands then remain at 270, 260, 235, and 220 cm^{-1}. Among these bands, the two bands at 270 and 260 cm^{-1} fit well to the frequencies calculated for the TT form, while the bands at 235 and 220 cm^{-1} fit well to the frequencies calculated for the TG form. Therefore, it may be concluded that three conformations, TT, TG, and GG, coexist in the liquid or gaseous state for the $n=1$ species. Moreover, the following descriptions can be postulated. The bands at 235 and

220 cm^{-1} may be identified as imperfect annealing: that is, a small amount of the TG form is present. Here, the order of the stability of the conformation may be supposed to be: GG>TG>TT.

The treatment was also extended to discuss the species of $n=2$ and 3. On the molecular species of $n=2$ and 3, the results are nearly the same as in the case of $n=1$. That is, if these three forms coexist in the species of $n=1$, the six forms now considered for the $n=2$ and 3 species are fully acceptable. However, we cannot give any more detailed descriptions on the basis of only the data thus for obtained.

Model Compounds. The C–H stretching, CH_3 deformation, C–S stretching, and skeletal deformation vibrations are reproduced well by this set. For the CH_2 deformation vibrations, on the species of $n=1$, one each of the CH_2 bending, CH_2 wagging, CH_2 twisting, and CH_2 rocking vibrations are expected for each form. These four bands are fairly well reproduced by the calculations. In the cases of the $n=2$ and 3 species, the separation widths between or among the same methylene deformation bands are not so well reproduced. However, in general the transferability of the force constants is very good.

PTM and PTM-D2. The calculated data of PTM and PTM-D2 are listed in Tables 8 and 9, along with the observed data. A part of the Raman and infrared data of PTM which were obtained by Hendra *et al.*[17] are also listed. It is shown that the calculated frequencies agree satisfactorily well with the observed frequencies. It is also shown that the transferability of the force constants used on the model compounds is very good. The vibrations in relation to the methylene group shifted directly upon deuteration. The observed shifts correspond well with those expected.

Frequency-phase Difference Curves

It has been seen[13] that the observed CH_2 deformation frequencies of the $CH_3S(CH_2S)_nCH_3$ ($n=1-3$) series have some regularities between the degree of n and their fundamentals. Table 10 shows the observed frequencies of the model compounds and PTM in the methylene deformation region. The CH_2 bending or twisting band of PTM is at nearly the same frequency as that of the central bands of the $n=3$ species. On the other hand, the wagging and rocking bands of PTM lie outside of the bands of the $n=3$ species. These will be explained more quantitatively in the following section.

From the concept of the frequency-phase difference,[21] when the degree of n and the molecular conformation are confirmed, the infrared-active bands of the species become easily recognizable. On the species of $-(CH_2S)_n-$, the number of atoms per polymer unit is four; the vibrational degrees of freedom, therefore, are $3\times4=12$. The phase-difference, δ_a, is defined thus: $\delta_a=(a-1)\pi/n$ ($a=1, 2, 3, \ldots, n$), where n denotes the degree of polymerization. The species of $n=1$ correspond to $CH_3SCH_2SCH_3$; $n=2$, to $CH_3SCH_2SCH_2SCH_3$, and $n=3$, to $CH_3SCH_2SCH_2SCH_2SCH_3$. Figure 3 shows the frequency-phase difference curves in relation to the CH_2 deformation modes. The curves show the [G]-type frequency-phase dif-

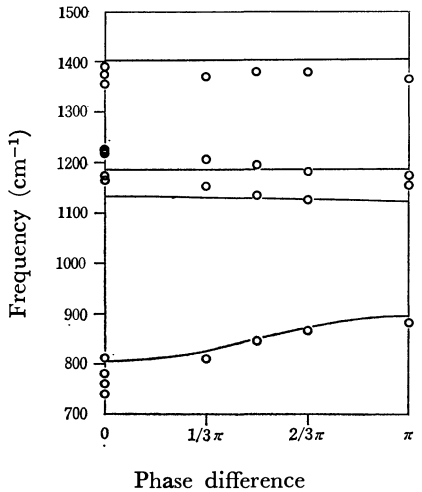

Fig. 3. Frequency-phase difference curves for the CH_2 bending, wagging, twisting, and rocking modes.

ference of PTM, and the plots are the observed ones. From this figure, the observed plots can be seen to correspond well with the calculated ones. The separation width of the observed CH_2 deformation bands can also be explained well by these curves. The tendency of the frequency-phase difference curve is conspicuous in the CH_2 rocking vibrations. For the [T]-type frequency-phase difference, detailed investigations have previously been made on polyethylene,[22] for example. The [T]-type frequency-phase difference curve is different from that of the [G] type. This is also conspicuous in the CH_2 rocking vibrations. In the [T] type, the frequency change due to phase difference is less than that of the [G] type. It is natural that the curves of the PTM resemble those of the hexagonal POM; the frequencies themselves are very different, though. Since the CH_2 deformation frequencies of the molecular species of $n=1$—3 are explained well by the [G]-type curves, it is also confirmed that these model molecules exist in the [G] form in the solid state. This shows also that the force fields in PTM and its model compounds are nearly the same, and that, in the determination of the force fields of polymers, it is important to determine the force fields of their model compounds.

Discussion

The regularities lying between the degree of n and the CH_2 deformation frequencies are reasonably explained by the frequency-phase difference curves. The relations lying between n and the terminal methyl deformation frequencies do not appear very clearly in the calculated frequencies. That is, the calculated frequencies of the CH_3 degenerate deformation, the CH_3 symmetrical deformation, and the CH_3 rocking vibrations are around 1440, 1317, and 990—970 cm^{-1}. In the observed frequencies, very interesting results were obtained. For the CH_3 symmetrical deformation in the annealed spectra, the separation widths of the two bands are 28, 14, 6, and 21 cm^{-1} for the $n=0$, $n=1$, 2, and 3 species respectively. For the CH_3 rocking vibrations, the separations of the side bands are 129, 43, 14, and 17 cm^{-1} respectively in the above-mentioned species. That is, the separation width between side bands rapidly decreases from the $n=0$ to $n=2$ species, and then increases a little. As has previously been described, the stable conformation of these molecules is the [G] form. The skeletal form of these compounds is shown in Fig. 4. Two methyl groups of the $n=1$ species stand at the same edge, and the methylene group stands at the opposite position. Therefore, the interactions between the methyl and methylene groups are small. In the case of the $n=2$ species, things are the same in the $n=1$ species. In the species of $n=3$, the distance between the methyl groups at both ends becomes large. However, the central methylene and two methyl groups are on the same side, and the interactions among these groups become large. In the potential energy distribution, PED, or in the L-matrix, however, this tend-

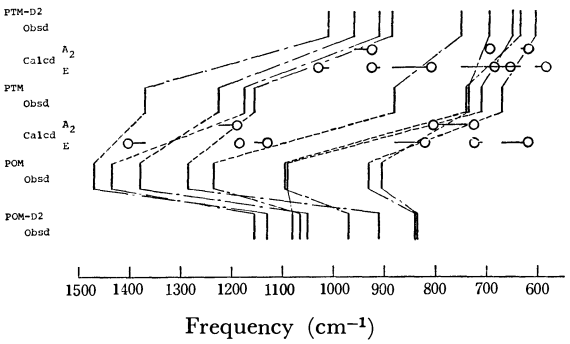

Fig. 5. Observed and calculated frequencies of PTM and PTM-D2, and obserbed frequencies of POM and POM-D2.

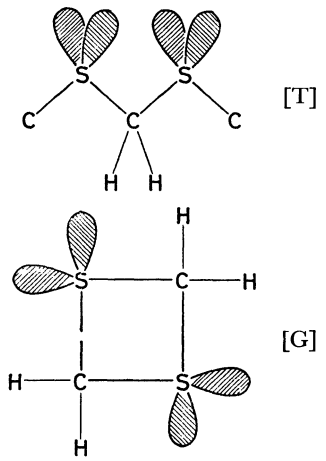
ency does not appear so clearly.

The vibrational spectra between PTM and POM will be briefly compared here. Figure 5 shows the observed frequencies of PTM, PTM-D2, POM, and POM-D2, along with the calculated frequencies of PTM and PTM-D2. The assignments of the observed bands of POM and POM-D2 have been made by several authors.[1,4,5] In this figure, the data obtained by Tadokoro *et al.*[1] are cited. The CH_2 bending, CH_2 wagging, and CH_2 twisting vibrations of PTM appear at frequencies lower by *ca.* 150—300 cm^{-1} than those of POM. In the case of the CH_2 rocking vibrations, the bands of PTM are much lower than the corresponding POM bands. However, the separation widths of the bands correspond well with PTM and POM. The stretching bands of PTM appear in a different spectral region from those of POM. The frequency shifts upon deuteration show nearly the same tendency.

The force constants of PTM may now be compared with the constants of POM, which are listed in Table 3 of Ref. 1. The set of No. 17 is used for comparison. The constants of PTM are much smaller than the corresponding constants of POM. The smaller values of the stretching constants show the weaker binding forces. The bending and repulsion constants, except for the constant of F(HCH), are also much smaller than the corresponding constants of POM. From these results it is seen that the binding forces in PTM are much weaker than those in POM, and that the interatomic interacitons in PTM are smaller than those in POM.

For the $CH_3O(CH_2O)_nCH_3$ (n=1—5) species, the stable conformation in the solid state is confirmed to be the [G] form; in the liquid state the [G] form may also persist.[6,7] In the same way, it may be concluded that the conformation of the sulfur analogs is the [G] form in the solid state. In the liquid state, the [G] form may persist. On the other hand, n-alkane and polyethylene[23] exist in the [T] form. Moreover, in the cases of normal alkyl ethers[24] and normal alkyl sulfides,[25-27] the skeletal conformation is confirmed to be the [T] form. In the cases of n-alkane and polyethylene, the lone-pair electrons are not involved. For n-ethers and n-sulfides, the directions of the lone pairs on the oxygen or sulfur atoms coincide with those of the C–H bonds of n-alkane and polyethylene. The present author has previously described[27] that the sulfur atom with lone-pair electrons can be regarded as a CH_2 group in the conformational analyses of alkyl sulfides. In the case of PTM, the molecular conformations of the [T] and [G] forms are shown below. In the case



of the [G] form, the lone-pair electrons are coordinated in the center of the C–H bond directions. On the other hand, in the case of the [T] form, the lone-pair electrons on the sulfur atoms are in the same directions and the repulsion forces between lone pairs become large (rabbit-ear effect);[28] in consequence the [G] form may be stable. In the species of alkyl disulfides, sulfur atoms combine with each other. Therefore, the lone pairs on the sulfur atoms produce a powerful effect on the structure of these molecules. In conclusion, these molecules easily have a form which has almost a rectangle (*e.g.*, the internal angle of *ca.* 85° has been proposed for dimethyl disulfide[29]). Therefore, the analysis of the conformation has been done with reference to the concept of the lone pairs.

Conclusion

The results for the infrared spectra of PTM and PTM-D2, and the normal coordinates of $CH_3S(CH_2S)_n$-CH_3 (n=1—3), PTM, and PTM-D2 reveal that the molecular form and the force fields of the model compounds fit well with those of PTM. On the molecular form in the solid state, the model compounds and PTM are confirmed to be the [G] form. On the molecular species of n=1, three forms are confirmed to exist in the liquid or gaseous state: GG, TG, and TT. On the species of n=2 and 3, many of the forms may coexist in the liquid or gaseous state. A comparison of the force fields between PTM and POM reveals that, in PTM, the intramolecular binding forces and non-bonded interatomic interactions are much weaker than those in POM.

The author wishes to thank Professor Hiromu Murata and Associate Professor Yuji Shiro for their helpful advice and encouragement. The author is also indebted to Miss Kuniko Fujiwara for her help in the preparation of the samples.

The Derivation of the r_s Structure by the Use of a Nondiagonal Weight Matrix for Rotational Constants

Chiaki HIROSE

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received July 7, 1973)

The use of a nondiagonal weight matrix in a least-squares analysis of the quantities which themselves are derived from another least-squares analysis is discussed in relation to the analysis of rotational constants in determining molecular geometry. The method is applied to the calculation of the r_s structure of ethylene oxide, and the result is compared with those obtained by Kraitchman's formula and by a least-squares fit by the use of a diagonal weight matrix.

Least-squares procedure are commonly used in microwave spectroscopy in two ways: (1) for deriving rotational constants and centrifugal distortion constants from observed transition frequencies, and (2) for deriving structural parameters and/or force constants from rotational or centrifugal distortion constants. In these procedures, however, not all the parameters to be determined are always linearly independent. Lees[1] described a procedure to diagonalize a matrix of the normal equation in order to decouple the equations which correlate the parameters. When the limits of uncertainties in the parameters can be estimated, a *diagonostic least-squares* described by Curl[2] can replace the estimated limits for those calculated by means of a least-squares fit.

As Kirchhoff[3] has pointed out, there is another difficulty in the correlated data. The values derived from a least-squares fit or from a linear combination of directly-observed values (*i.e.*, indirect or secondary observations) are, in general, correlated with one another. Since rotational constants are derived from transition frequencies, correlations among them should be accounted for in a calculation of structural parameters. Similar circumstances are encountered in a structure analysis of gas-electron diffraction,[4–6] where correlations are dealt with by the use of a nondiagonal weight matrix. The present paper will describe the use of a nondiagonal weight matrix in the least-squares fit of rotational constants for determining molecular geometry. The derivation of an r_s structure from the rotational constants for various isotopic species is considered. Following the definition of the r_s structure,[7] no explicit account of the systematic errors due to the neglect of zero-point vibrations is made. Though such systematic errors are usually much larger than the uncertainties originating from errors in the measurement, the correction requires knowledge of the force field; such an undertaking is beyond the range of the present statistical treatment. In the absence of a complete force field, as in the case of ethylene oxide, effective structures, such as r_0 and r_s, are the best one can derive from spectroscopic measurements.

Below, the r_s structure obtained by using a nondiagonal weight matrix will be compared with those derived by neglecting the correlations among rotational constants. The r_s structure calculated by Kraitchman's method is also examined: the formulation for the error analysis in this case is described in the Appendix.

Weight Matrix for Indirect Observations

As Morino *et al.* have pointed out,[4] when a set of observations, μ, which are linear combinations of direct observations, $\mathbf{y}$, is used as the data in the least-squares fit, the weight matrix is expressed by:

$$\mathbf{W} = (\mathbf{G}\mathbf{P}^{-1}\tilde{\mathbf{G}})^{-1} \tag{1}$$

where $\mathbf{G}$ is the matrix which relates $\mathbf{y}$ to μ as:

$$\mu = \mathbf{G}\mathbf{y}, \tag{2}$$

and where $\tilde{\mathbf{G}}$ is the transpose of $\mathbf{G}$. $\mathbf{P}$ is a weight matrix for the direct observations, $\mathbf{y}$, and is diagonal provided each direct observation is measured independently.

This idea can readily be applied to the case where a set of indirect observations, μ (rotational constants, for example), are derived from a set of direct observations, $\mathbf{y}$ (transition frequencies), by way of a least-squares fit. In that case, the matrix, $\mathbf{G}$, to be used is expressed as:

$$\mathbf{G} = \mathbf{B}^{-1}\tilde{\mathbf{J}}\mathbf{P}, \tag{3}$$

where:

$$\mathbf{B} = \tilde{\mathbf{J}}\mathbf{P}\mathbf{J}. \tag{4}$$

$\mathbf{J}$ is the Jacobian matrix used in deriving μ from $\mathbf{y}$, and matrix element, J_{ik}, is the first derivatives of the i-th observation, y_i, with respect to the k-th parameter, μ_k, at the point of convergence, that is, $J_{ik}=(\partial y_i/\partial \mu_k)_0$. Since the $\mathbf{P}$ and $\mathbf{B}$ matrices are symmetric, the substitution of Eq. 3 into Eq. 1 gives:

$$\mathbf{W} = (\mathbf{B}^{-1}\mathbf{J}\mathbf{P}\mathbf{P}^{-1}\mathbf{P}\mathbf{J}\mathbf{B}^{-1})^{-1} = \mathbf{B}. \tag{5}$$

Furthermore, when a set of indirect observations, γ, is a linear combination of the μ set like isotopic changes of rotational constants:

$$\gamma = \mathbf{F}\mu, \tag{6}$$

the weight matrix to be used for the γ set is given by:

$$\mathbf{W} = (\mathbf{F}\mathbf{G}\mathbf{P}^{-1}\tilde{\mathbf{G}}\tilde{\mathbf{F}})^{-1} = (\mathbf{F}\mathbf{B}^{-1}\tilde{\mathbf{F}})^{-1}. \tag{7}$$

In this scheme, the diagonal elements of the matrix $\mathbf{W}$ expressed in Eqs. 1, 5 and 7 account for the propagation of errors, and the off-diagonal terms represent correlations among the indirect observations.[4–6] When a set of indirect observations are composed of subsets, each obtained independently, such as the rotational constants for each isotopic species, the $\mathbf{W}$

matrix splits into submatrices.

Calculation of Structural Parameters

The r_0 structure of a molecule is the one which makes a best fit to the rotational constants in its ground state. In this case, the J_{ik} element of $\mathbf{J}$ is $(\partial\nu_i/\partial A_k)_0$, where ν_i and A_k are the i-th transition frequency and the k-th rotational constant (*i.e.*, A, B, or C) respectively. The i-th element, P_{ii}, of a diagonal matrix, $\mathbf{P}$, is inversely proportional to the square of the measurement error for the i-th frequency. Since an independent analysis is made for each isotopic species, the weight matrix is calculated by the use of Eqs. 4 and 5:

$$\mathbf{W}(r_0)=\begin{bmatrix}\mathbf{B}^{(1)} & & & \mathbf{0}\\ & \mathbf{B}^{(2)} & & \\ & & \cdots\cdots & \\ \mathbf{0} & & & \mathbf{B}^{(n)}\end{bmatrix}^{-1}, \tag{8}$$

where $\mathbf{B}^{(s)}=\mathbf{J}_s\mathbf{P}_s\mathbf{J}_s$ (s=1,2,..., n) is a 3×3 submatrix for the s-th isotopic species and where n is the number of isotopic species for which the rotational constants are obtained.

The r_s structure is defined as a set of parameters derived from isotopic changes in the rotational constants:

$$\Delta A_\alpha^{(s)} = A_\alpha^{(ref)} - A_\alpha^{(s)}, \tag{9}$$

where $A_\alpha^{(s)}$ is the rotational constants along the principal axis, α, for the s-th isotopic species. The value for the reference species (normal ethylene oxide in the present study) is denoted as $A_\alpha^{(ref)}$. The matrix, $\mathbf{F}$ (Eq. 6), consists of $3(n-1)$ rows and $3n$ columns:

$$\mathbf{F}=\begin{bmatrix}\mathbf{E} & -\mathbf{E} & \mathbf{0} & \mathbf{0} & \cdots\cdots & \mathbf{0}\\ \mathbf{E} & \mathbf{0} & -\mathbf{E} & \mathbf{0} & \cdots\cdots & \mathbf{0}\\ & & \cdots\cdots & & & \\ \mathbf{E} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \cdots\cdots & -\mathbf{E}\end{bmatrix}, \tag{10}$$

where $\mathbf{E}$ is a three-dimensional unit matrix. From Eq. 7, the following weight matrix of rank $3(n-1)$ is obtained:

$$\mathbf{W}(r_s)=\begin{bmatrix}\mathbf{B}^{(ref)}+\mathbf{B}^{(1)} & \mathbf{B}^{(ref)} & \cdots\cdots & \mathbf{B}^{(ref)}\\ \mathbf{B}^{(ref)} & \mathbf{B}^{(ref)}+\mathbf{B}^{(2)} & \cdots\cdots & \mathbf{B}^{(ref)}\\ \cdots\cdots & \cdots\cdots & \cdots\cdots & \cdots\cdots\\ \mathbf{B}^{(ref)} & \mathbf{B}^{(ref)} & \cdots\cdots & \mathbf{B}^{(ref)}+\mathbf{B}^{(n-1)}\end{bmatrix}^{-1}. \tag{11}$$

This matrix represents the correlation among the ΔA_α values used for the r_s structure.

The r_s Structure of Ethylene Oxide. As an ap-

θ[f]	21.99(15)	22.01(10)	21.95(28)	——

a) Bond lengths are in Å and the angles are in degrees. C_{2v} symmetry is assumed for the normal ethylene oxide. Uncertainties given in parentheses are 2.5 times the standard errors attached to the last digit. b) Derived from the least-squares analysis using the nondiagonal weight matrix given in Eq. (11). c) Derived from the least-squares analysis using a diagonal weight matrix following the law of propagation of errors. d) Derived from Kraitchman's method by combination of *normal*, ^{13}C-, ^{18}O-, and monodeutero ethylene oxide. e) Derived from Kraitchman's method by combination of *trans*-D_2-, *trans*-D_2-^{13}C-, *trans*-D_2-^{18}O-, and monodeutero ethylene oxide. f) θ is the dihedral angle of the C-C bond to the H_2C plane.

plication of the present method, the r_s structure of ethylene oxide was calculated by the use of the rotational constants of ten isotopic species.[8)] The observed rotational constants and the elements of $\mathbf{B}^{(s)}$ are shown in Tables 1 and 2 respectively.*

Calculation of the r_s structure were made with a nondiagonal weight matrix and with a diagonal matrix set up by leaving out the diagonal elements of the former. The molecule is assumed to have C_{2v} symmetry. Table 3 lists the derived values of the r_s parameters.

The converged values based on the two weight matrices are not significantly different, but the correlation factors based on the nondiagonal matrix are somewhat smaller than those based on the diagonal matrix. On the other hand, similar calculations based on nondiagonal weight matrices gave larger correlation factors in the r_0 and r_m structures.[9)]

For the sake of comparison, the parameter values obtained by Kraitchman's formula[10)] are also shown in Table 3. The reliability intervals of these values were estimated by way of the propagation of errors; the procedure is shown in the Appendix.

The author is grateful to Professor Kozo Kuchitsu for his helpful comments on the manuscript.

Appendix

Error Estimation of the r_s Structure Obtained by Kraitchman's Method. Kraitchman's formula is given in a matrix form as:

$$\mathbf{a} = \mathbf{Ax}\,, \tag{A1}$$

where

$$a_\alpha = (P_\alpha'-P_\alpha)(P_\alpha'-P_\beta)(P_\alpha'-P_\gamma) = p_{\alpha\alpha}p_{\alpha\beta}p_{\alpha\gamma}\,, \tag{A2}$$

$$A_{\alpha\alpha} = \mu(P_\alpha'-P_\beta)(P_\alpha'-P_\gamma) \equiv \mu p_{\alpha\beta}p_{\alpha\gamma}\,, \tag{A3a}$$

$$A_{\alpha\beta} = \mu(P_\alpha'-P_\alpha)(P_\alpha'-P_\gamma) \equiv \mu p_{\alpha\alpha}p_{\alpha\gamma}\,, \tag{A3b}$$

and

$$x_\alpha = \alpha_s^2 \tag{A4}$$

$(\alpha, \beta, \gamma = a, b \text{ or } c \text{ with } \alpha, \beta \neq \gamma \text{ and } \beta \neq \alpha$, and $p_{\alpha\beta} \equiv P_\alpha'-P_\beta)$.

In the above equations, P_α and P_α', are derived from the moments of inertia, I_α and I_α' for the reference and substituted species, respectively, as:

$$P_\alpha = (-I_\alpha+I_\beta+I_\gamma)/2\,, \tag{A5}$$

$$P_\alpha' = (-I_\alpha'+I_\beta'+I_\gamma')/2\,, \tag{A6}$$

μ is the reduced mass difined as $M\Delta m/(M+\Delta m)$, where M is the molecular weight of the reference molecule and Δm is the difference in molecular weight caused by the isotopic substitution, and α_s is the coordinate of the substituted atom referred to the principal axis α of the reference species. One gets from (Al) that

$$\mathbf{x} = \mathbf{A}^{-1}\mathbf{a}\,. \tag{A7}$$

If the moments of inertial, I_α and I_α' (α=a,b or c), contain error limits of ΔI_α and $\Delta I_\alpha'$ which are positive and independent of one another, error limits of P_α and P_α' can be estimated as:

$$\Delta P_\alpha = (\Delta I_\alpha+\Delta I_\beta+\Delta I_\gamma)/2 = \Delta\,, \tag{A8}$$

$$\Delta P_\alpha' = (\Delta I_\alpha'+\Delta I_\beta'+\Delta I_\gamma')/2 = \Delta'\,. \tag{A9}$$

Thus the error in $p_{\alpha\beta}$ is given by

$$\Delta p_{\alpha\beta} = \Delta + \Delta'\,. \tag{A10}$$

The error limits of a_α and $A_{\alpha\beta}$ are obtained by substituting (A10) into A(2) and A(3) to be:

$$\Delta a_\alpha = \Delta p_{\alpha\alpha}|p_{\alpha\beta}^0 p_{\alpha\gamma}^0| + \Delta p_{\alpha\beta}|p_{\alpha\alpha}^0 p_{\alpha\gamma}^0| + \Delta p_{\alpha\gamma}|p_{\alpha\alpha}^0 p_{\alpha\beta}^0|$$
$$= (\Delta+\Delta')(|A_{\alpha\alpha}^0| + |A_{\alpha\beta}^0| + |A_{\alpha\gamma}^0|)/|\mu| \tag{A11}$$

$$\Delta A_{\alpha\alpha} = |\mu|(\Delta+\Delta')(|p_{\alpha\beta}^0| + |p_{\alpha\gamma}^0|) \tag{A12a}$$

$$\Delta A_{\alpha\beta} = |\mu|(\Delta+\Delta')(|p_{\alpha\alpha}^0| + |p_{\alpha\gamma}^0|)\,. \tag{A12b}$$

When some of the $P_{\alpha\alpha}$'s are set to zero from a consideration of symmetry, $\Delta_\alpha'' = |P_{\alpha\alpha}^0|$ should be added to Δ and Δ', where $p_{\alpha\alpha}^0$ is the observed value which is set equal to zero. The errors are modified as:

$$\Delta a_\alpha' = \Delta a_\alpha + \Delta_\alpha''|A_{\alpha\alpha}^0|/|\mu| \tag{A11a}$$

and the corresponding modification on $\Delta A_{\alpha\beta}$. When $\mathbf{A}^0$ and $\mathbf{x}^0$ are given prior to the error analysis, the error limit $\Delta\mathbf{x}$ can be derived by use of the above equations.*

* The correlation factor between A and B, for instance, is given by $c_{AB}=B_{AB}^{-1}/(B_{AA}^{-1}\cdot B_{BB}^{-1})^{1/2}$. The value of c_{AB} for normal ethylene oxide, 0.9299, indicates that A and B in Table 1 are considerably correlated. The $0 \leqq |c_{AB}| \leqq 1$ relation holds, and the upper limit is realized when A and B are in exact linear dependence.

* Since the propagation of errors is dealt with in a matrix representation, the formula $\Delta\mathbf{x} = (\mathbf{A}^0)^{-1}(\Delta\mathbf{a} + \Delta\mathbf{A}\cdot\mathbf{x}^0)$ does not apply here when it is solved algebraically, but correct solutions are given as follows:

Referring to (A4), the error limits of the coordinates are derived following the law of propagation of errors as:

$$\Delta\alpha_s = \Delta x_\alpha / 2(x_\alpha{}^0)^{1/2} \quad (\text{when } x_\alpha{}^0 \neq 0) \ , \tag{A13a}$$

or

$$\Delta\alpha_s = 0 \quad (\text{when } x_\alpha{}^0 = 0 \text{ by symmetry}) \ . \tag{A13b}$$

(footnote continued)

$$\begin{aligned}
\Delta x_a = (&b_1(|A_{22}{}^0A_{33}{}^0| + |A_{23}{}^0A_{32}{}^0|) \\
&+ b_2(|A_{32}{}^0A_{13}{}^0| + |A_{12}{}^0A_{33}{}^0|) \\
&+ b_3(|A_{13}{}^0A_{22}{}^0| + |A_{12}{}^0A_{23}{}^0|))/|A^0|^* \ , \\
\Delta x_b = (&b_1(|A_{23}{}^0A_{31}{}^0| + |A_{21}{}^0A_{33}{}^0|) \\
&+ b_2(|A_{11}{}^0A_{33}{}^0| + |A_{31}{}^0A_{13}{}^0|) \\
&+ b_3(|A_{23}{}^0A_{11}{}^0| + |A_{21}{}^0A_{13}{}^0|))/|A^0|^* \ , \\
\Delta x_c = (&b_1(|A_{31}{}^0A_{22}{}^0| + |A_{21}{}^0A_{32}{}^0|) \\
&+ b_2(|A_{31}{}^0A_{12}{}^0| + |A_{11}{}^0A_{32_0}|) \\
&+ b_3(|A_{11}{}^0A_{22}{}^0| + |A_{12}{}^0A_{21}{}^0|))/|A^0|^* \ ,
\end{aligned}$$

where,

$$\mathbf{b} = \Delta\mathbf{A}\cdot\mathbf{x}^0 + \Delta\mathbf{a} \ ,$$

and $|A^0|^*$ denotes the absolute value of the determinant of the matrix $\mathbf{A}^0$.

The error limits Δr_{ij} of the distance between the i-th and the j-th atoms is given by,

$$\begin{aligned}
\Delta r_{ij} = [&|a_i{}^0 - a_j{}^0|(\Delta a_i + \Delta a_j) + |b_i{}^0 - b_j{}^0|(\Delta b_i + \Delta b_j) \\
&+ |c_i{}^0 - c_j{}^0|(\Delta c_i + \Delta c_j)]/r_{ij}{}^0 \ ,
\end{aligned} \tag{A14}$$

where

$$r_{ij}{}^0 = [(a_i{}^0 - a_j{}^0)^2 + (b_i{}^0 - b_j{}^0)^2 + (c_i{}^0 - c_j{}^0)^2]^{1/2} \ . \tag{A15}$$

Mechanistic Studies on the Photooxidation of Chlorpromazine in Water and Ethanol

Teiki IWAOKA and Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo 140

(Received August 30, 1973)

It has been established that chlorpromazine undergoes photooxidation *via* its cation radical, yielding chlorpromazine 5-sulfoxide as an ultimate photoproduct. Molecular oxygen has been found indispensable not only for the formation of chlorpromazine cation radical but also for the formation of the sulfoxide from the radical. Oxygen atom in the sulfoxide originates from the atmospheric oxygen and not from water, which was ascertained by both tracer experiment and kinetic analysis. It was concluded that phenazathionium ion is not involved in the reaction. The possibility of singlet oxygen participation in the photooxidation was also ruled out. An intermediate, which is formed from the cation radical, was found as a precursor of the sulfoxide and was tentatively assigned as a peroxyl type radical.

Many photochemical and photobiological studies have been carried out on the photooxidation of chlorpromazine, but there are some discrepancies and ambiguities especially in the behavior of paramagnetic species and their assignment.

Lagercrants[1] showed that ultraviolet irradiation of an aqueous solution of chlorpromazine yielded a radical, the ESR signal of which decayed within about one minute in the dark, the resulting solution turning yellow. The ESR absorption could then be reproduced by blue light(435 nm) illumination inactive to initial chlorpromazine. Degassing of the solution had very little influence on the dynamical behavior of the ESR signal caused by the irradiation. The effect of ultraviolet irradiation of an aqueous solution of chlorpromazine was examined also by Boag and Cotzias.[2] They reported a pale pink(λ_{max}; 530 nm) paramagnetic species which was assigned to the semiquinone cation radical identical with the one produced by the action of trace metal ion(Ce^{4+}) or by potentiometric electrolysis. In spite of the fact that the same photochemical technique was employed, Piette and Forrest[3] reported another radical species, differing in color and in the pattern of ESR signal from those observed by Boag and Cotzias.[2] They assigned this paramagnetic species to the same radical as that detected in urinary metabolites from patients dosed with chlorpromazine drug.

Billon[4] carried out the first systematic investigation on the electrochemical oxidation of phenothiazine and its *N*-substituted derivatives, and showed that the two-electron oxidation yielded a very reactive dication (phenazathionium ion) which underwent hydrolysis to form sulfoxide even with a trace of water. Dismutative formation of the phenazathionium ion of chlorpromazine, suggested from the second-order decay of the cation radical of chlorpromazine formed in the enzymic oxidation systems of peroxidase–H_2O_2 was reported by Cavanaugh[5] and by Piette *et al.*[6] Dismutative formation and subsequent hydrolysis of this phenazathionium ion of chlorpromazine was also proposed by Merkle *et al.*,[7] based on the fact that a mixture of chlorpromazine and its sulfoxide was obtained by dissolving solid free radical in water, prepared with perchloric acid as oxidizing reagent. The formation of the sulfoxide through the phenazathionium ion derivatives was proposed for many oxidation systems, the oxidants being bromine,[8] manganic ion under aerobic conditions,[9] lead tetraacetate,[10] and sulfuric acid.[11] Thus, the phenazathionium ions have been assigned to the precursor of the sulfoxide. The indispensable hydrolysis causes the incorporation of oxygen atom into the sulfoxide from water. Though there have been many reports on sulfoxide formation through the phenazathionium ion, no direct evidence for its participation has been obtained except for the case of electrochemical oxidation.[4]

Photosensitized oxidation of chlorpromazine in the biological system is very interesting as regards photoallergic effects.[12] Blois[13] reported that the visible light irradiation of the melanine polymer into which chlorpromazine was incorporated gave a red pigmentation in the spot exposed to light. It may be worthwhile to mention the oxidation of dimethyl sulfide into the sulfoxide by photosensitization with the use of several dyes.[14]

We have investigated the photooxidation of chlorpromazine in water and in ethanol, especially on the dynamic characteristics of the radical cation and other transients formed as the intermediates by means of steady light and flash photolytic techniques. The possibility of the participation of singlet oxygen as an oxidizing agent was also examined. Strong evidence was obtained from tracer experiments for the view that molecular oxygen in air is incorporated as the oxygen atom in the sulfoxide, and the mechanism involving the hydrolysis of the phenazathionium ion was eliminated at least in the photochemical reaction. A peroxyl type radical was tentatively proposed as a favorable intermediate.

Experimental

Materials. Commercial chlorpromazine hydrochloride was used. Triethylamine(Iwaikagaku G. R. grade), ascorbic acid (G. R. grade, Tokyo Daiichikagaku) and ethanol of G. R. grade (Osaka Yukikagaku Kogyo) were used without further purification. Acetic acid-sodium acetate(pH 3.2—6.3) and hydrochloric acid-sodium acetate(pH 0.6—1.7) were used for the buffer systems. H_2O^{18} (40% isotopic content, Miles Laboratory Inc.) was used for the tracer experiment.

Method. The change in absorbance of chlorpromazine was measured by a monitoring light, perpendicular to the exciting light at 253.7 nm. Combinations of a hydrogen arc lamp, grating monochromator(Shimazu GF-16) and photomultiplier (HTV-109) were used. Contamination of the

scattered light from the source in the monitoring light was about 0.5% at the exciting wavelength. The light intensity was measured with a ferric oxalate actinometer. Flash photolytic experiments were carried out with a Ushio UFP-105(500 J) and a hand-made instrument[15] specially designed in our laboratory. Specially designed flash cell and apparatus were used for the bubbling of several gases (Ar, O_2, air) into the solution. The technique of freeze and thaw was applied for complete deaeration. The electrical power of 100 J for one flashing was used unless otherwise stated.

Results

General Features of the Steady Light Photooxidation.

Figure 1 shows the spectral change of chlorpromazine when its aerated solution in water(pH 4.7[16]) is irradiated by 253.7 nm light from a low pressure mercury lamp. Isosbestic points were clearly seen at 247, 263 nm, similar spectral changes with irradiation being observed in ethanol, methanol, 2-propanol, dioxane–water (20 : 1), and mixed solvent systems of water and ethanol. It was found for the sample bubbled with oxygen that these isosbestic points are observable till the later stage of the reaction and that the yield of the photoproduct exceeds the value in the aerated conditions. Lowering the pH of the aqueous solution of chlorpromazine from 4.7 to 0.7 did not alter the characteristics of the spectral change so much but the bleaching rates became smaller.

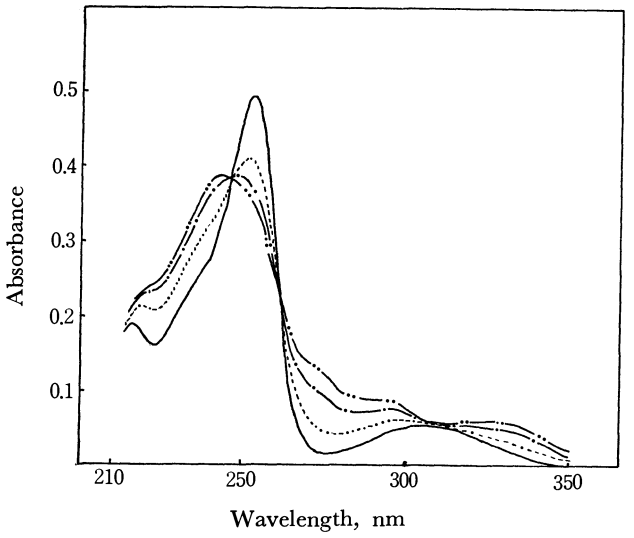

Fig. 1. Spectral change of chlorpromazine in the aerated aqueous solution of pH 4.7.
[CPZ] = 1.4×10^{-5} M. —— 0 s, ---- 8 s, —·— 23 s, —··— 40 s.

The ultraviolet spectrum obtained after the irradiation of 40 seconds in water could be ascribed to chlorpromazine sulfoxide(λ_{max}[17]: 240, 275, 298, and 342 nm) from a comparison with the spectra reported by several workers,[7,17,18] though a considerable amount of the starting chlorpromazine still remained. The mass spectra of the photoproducts in all the systems stated above gave a molecular peak assignable to chlorpromazine sulfoxide. It was established from a comparison of the thin layer chromatogram of the photoproduct with that of chlorpromazine that only one product was formed. Long irradiation which brought about a considerable deviation from the isosbestic point gave the sulfoxide in extremely low yield, the mass spectrum being composed of peaks of low mass number presumably as a consequence of the photochemical decomposition of the photoproduct.

In spite of the similarity in feature of the spectral change and the identity of photoproduct, the quantum yields for the disappearance of chlorpromazine at 253.7 nm are quite different for aqueous solution (Φ_{H_2O}; 5.6×10^{-2}) and ethanol solution($\Phi_{C_2H_5OH}$; 2.7×10^{-3}), suggesting that the solvent effect causes a drastic change in the efficiency in some elementary processes of the photooxidation, or that the formation of the photoproduct by hydrolysis of the reactive transients is involved.

Effect of Degassing and H_2O^{18} Tracer Experiment. Spectral changes upon UV illumination of the completely degassed solutions of chlorpromazine in water (pH 4.7) and ethanol are shown in Fig. 2. The bleaching rate of chlorpromazine at 253.7 nm in the completely degassed aqueous solution was approximately the same as the one in the aerated solution, but in the absorption spectrum no peaks ascribable to the sulfoxide were observed. After prolonged irradiation the absorption spectrum showed absorption increase independent of wavelength but no characteristic peaks.

In the case of the degassed ethanol solution, a different photochemical reaction(Fig. 2(b)) occurs with a negligibly small rate ($\Phi_{\text{degassed } C_2H_5OH}$; *ca.* 8×10^{-5}) as compared with the aerated case. We may say that the photochemical reaction leading to the sulfoxide formation practically does not occur.

The effects of addition of oxygen on the quantum yield for the disappearance of chlorpromazine in water and ethanol are shown in Fig. 3. Even at such a small oxygen concentration as 10^{-5} M, the spectral changes of chlorpromazine in water are essentially the same as those in the air saturated solution as well as in the oxygen saturated one. This supports the view that a small amount of oxygen inhibits the reaction predominating under completely degassed conditions. This was further established by the following observation; the quantum yield for formation of the sulfoxide estimated from the absorption rise at 275 nm of the sulfoxide increases as oxygen concentration is increased, while the quantum yield for the disappearance of chlorpromazine is almost independent of oxygen concentration. The quantum yields for the two reactions, one *in vacuo* and the other in aerated condition, are equal. Dependence of the quantum yields upon oxygen concentration in ethanol differs from the case in the aqueous solution, suggesting a different reaction scheme, especially on the behavior of the dissolved oxygen.

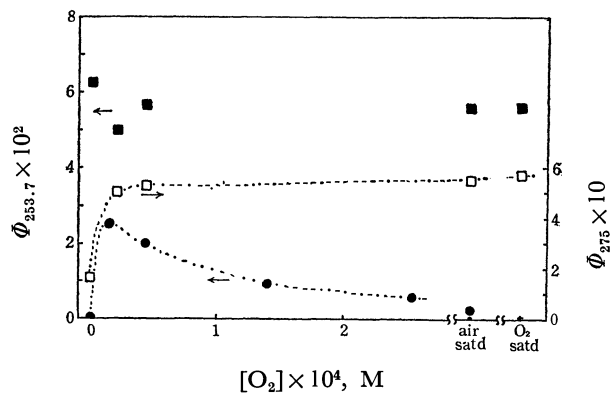

Fig. 3. Dependence of the quantum yields on the oxygen concentration in water and in ethanol. $[CPZ(H_2O)]=2.0\times10^{-5}$ M. $[CPZ(C_2H_5OH)]=1.7\times10^{-5}$ M.

TABLE 1. RELATIVE INTENSITY OF THE MASS PEAKS OF CHLORPROMAZINE SULFOXIDE OBTAINED BY PHOTOOXIDATION IN VARIOUS SOLVENTS

Medium		334	335	336	337
normal	H_2O	100	26	48	9
calcn[a]	H_2O^{18}	100	26	91	
exptl[b]	C_2H_5OH-H_2O^{18}	100	26	48	
exptl	H_2O^{18}	100	24	53	

a) The relative intensities are calculated from the results in normal H_2O on the assumption of 30% in O^{18} concentration. b) C_2H_5OH: $H_2O^{18}=100:1$ in volume ratio.

Tracer experiments using H_2O^{18} instead of normal H_2O were carried out in order to confirm the mechanism proposed by several workers,[4,5,7] according to which the sulfoxide is formed by the hydrolysis of the phenazathionium ion. Photochemical reactions in H_2O^{18} and in ethanol containing a small amount of H_2O^{18} occur with the same rates and with the same spectral changes as in the experiments with normal H_2O. Mass spectrometric measurement, details of which are given in Table 1, definitely excludes the possibility of oxygen incorporation into sulfoxide from H_2O^{18}. It may be concluded that the formation of sulfoxide by way of hydrolysis of the phenazathionium ion[7-11] is not involved in the photochemical oxidation of chlorpromazine and that the oxygen atom in the sulfoxide should originate from molecular oxygen in air, in line with the occurrence of quite different reactions under the degassed conditions.

$$CPZ + O_2(\text{air}) \xrightarrow{h\nu} CPZ{\rightarrow}O \qquad (1)$$

Effects of Light Intensity and Ionic Strength. Further experiments concerning the possible formation of the phenazathionium ion were carried out. In the photochemical reaction where no strong oxidant is involved, formation of the phenazathionium ion, if it occurs at all, should be due to the disproportionation of the cation radical[5,6] or with less probability to the direct photoionization of the cation radical by the absorption of the exciting light. The mechanisms require that the intensity of exciting light considerably affect the quantum yield. However, it was found that the quantum yield does not depend upon the light intensity for the aqueous, ethanol, and acetic acid–water (1 : 1) solutions (Fig. 4). A mechanism involving the quantitative disproportionation of the cation radical, by which no light intensity effect is expected on the quantum yield, was rejected by the dominant first-order decay of the cation radical in our flash photolytic experiments.

The increase of ionic strength which accelerates the reaction between the charged molecules with the same sign[19] should bring about an increase of the quantum yield, provided that the dismutative formation of the reactive phenazathionium ion from the cation radical occurs. However, a decreasing tendency in quantum yield was found with increasing ionic strength.

All these results strongly rejected the possibility of

the dismutative formation of phenazathionium ion from the cation radical. An alternative route for the sulfoxide formation through the cation radical should be considered.

Transient Intermediates by Flash Photolysis. The transient absorption spectra of chlorpromazine flashed in the aerated aqueous solution of pH 4.7 are shown in Fig. 5. A very short-lived intermediate easily discriminated as the absorption at about 515 nm is assigned to the chlorpromazine cation radical. A satisfactory agreement of this spectrum with that in concentrated H_2SO_4 solution of chlorpromazine and also with other spectra reported[2,5,7,9,17] as the chlorpromazine cation radical, supports the assignment. The transient absorption around 575 nm decayed with a little slower rate than that of the cation radical and a realtively slow rise of absorption around 370 nm was observed, acompanied with the decline of the cation radical. Thus three transient intermediates were clearly differentiated. The time characteristics of absorptions at 515, 575 and 370 nm after flashing are shown in Fig. 6(a). From the proportionality between the absorption increment at 370 nm and the decrease at 515 nm (Fig. 6(b)), it is very likely that the absorption at 515 nm due to the cation radical is replaced by the one at 370 nm with one to one correspondence. It should be noted that a small increase in absorption at 575 nm is equivocally observed at an early stage, till about 100 μs after flashing. Deaeration caused the extreme decrease in the yield of the cation radical. This suggests the involvement of oxygen in the reaction yielding the cation radical. No such considerable effect of deaeration on the yield of the 575 nm absorbing intermediate was observed.

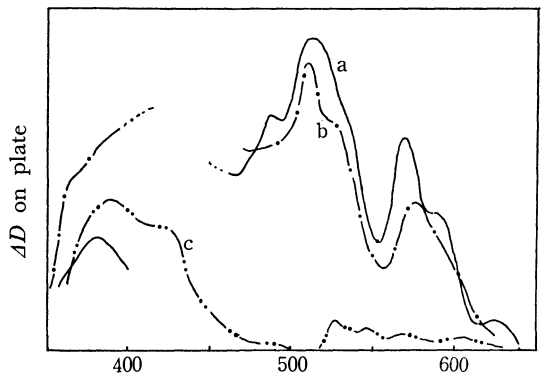

Fig. 5. Transient absorption spectra obtained by the flash photolysis of the aerated aqueous solution of chlorpromazine (pH 4.7).
a: 30 μs, b: 300 μs, c: 1 ms,

Flashing of the degassed ethanol solution of chlorpromazine gave the 575 nm light absorbing species as well as the chlorpromazine triplet state with an absorption around 480 nm, the assignment of which was made from a comparison of its shape and peak position with those of the phenothiazine triplet state[20] and also from the behavior of this species toward oxygen. The absorption around 370 nm was hardly detected in this case. Aerated ethanol solution gave only the cation radical in an extremely small amount upon flashing.

Influence of pH *and Oxygen Concentration on the Kinetics of the Transients.* The spectral change by ultraviolet irradiation is indifferent to the change of pH from 4.7 to 0.7 except for the bleaching rates. This makes it possible to determine the reactive intermediates by kinetical analysis of the reaction mechanism. The effect of pH on the yields and lifetimes of the transient intermediates are summarized in Table 2. The pH effect on the quantum yields for the steady light irradiation is shown in Fig. 7. The 370 nm light absorbing species(370-Int.) has smaller yields at low pH values, while the yield of 575 nm light absorbing species(575-Int.) remains almost constant over the whole pH range examined. The lifetimes of the above two

transients remain almost unchanged over the pH range tested. It is obvious that 370-Int. is a reactive intermediate judging from a similar tendency of decrease of the yield to that of the final product with lowering pH of the medium.

The initial yields of the intermediates upon flashing in our four different samples are shown in Table 3. One sample was degassed completely by the freeze-thaw technique, the others being saturated with argon, air, and oxygen. The absorption at 370 nm is moderately increased by the saturation of oxygen, while that at 575 nm is not much affected. The 370-Int. owes its origin to the cation radical which has been identified as the precursor of the sulfoxide as evidenced by several workers.[7,9] The significant increase of the 370-Int. with oxygen concentration supports the formation of 370-Int. through the reaction of the cation radical with oxygen.

Thus it may be concluded from the effect of pH and oxygen concentration on the reaction that the photoproduct, chlorpromazine sulfoxide, is formed from 370-Int. which comes from the cation radical.

$$CPZ^+ + O_2 \longrightarrow \text{370-Int.} \longrightarrow CPZ{\rightarrow}O \qquad (2)$$

Effect of the Intensity of Flashing Light. The decay curve of the cation radical could be reproduced by the first-order decay formulation, even if a high flashing power was supplied for the large concentration of the intermediates. Figure 8 shows the dependence on the flashing light intensity of the amounts of the transient intermediates in terms of their maxima in absorbance. It is evident that no biphotonic process contributes to the cation radical production nor to the formation of the other two intermediates. This is in line with the results of the light intensity effect in steady

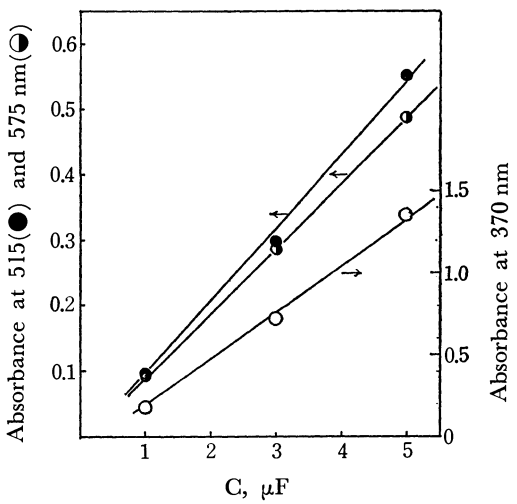

Fig. 8. Dependence of the yields of the transients on the intensity of flashing light in the aerated aqueous solution of pH 4.7. : $CPZ^{\cdot+}$, : 575-Int., ○: 370-Int.

light experiments. The phenazathionium ion, a two electron oxidized form of chlorpromazine, was not detected even in the photolysis of a high flashing light intensity.

Effect of the Addition of Radical Quenchers and of Singlet Oxygen Quencher. The effect of the addition of triethylamine(TEA) on the quantum yield in ethanol is shown in Fig. 9(a). TEA has a considerable affinity to the cation radical on account of its low ionization potential or high reducing power. The result suggests that the two reaction intermediates are involved in the reaction. The plot of $1/\Phi$ against [TEA] gives a curve consisting of two straight lines, which shows unequivocally the existence of two intermediates (Fig. 9(b)). One has a lifetime far longer than that of a typical triplet state in air saturated ethanol and might be assigned to some radical species. Assignment of the other species is unimportant, since the spectral change occuring in such a high concentration of TEA is very small, reflecting the occurrence of different reactions.

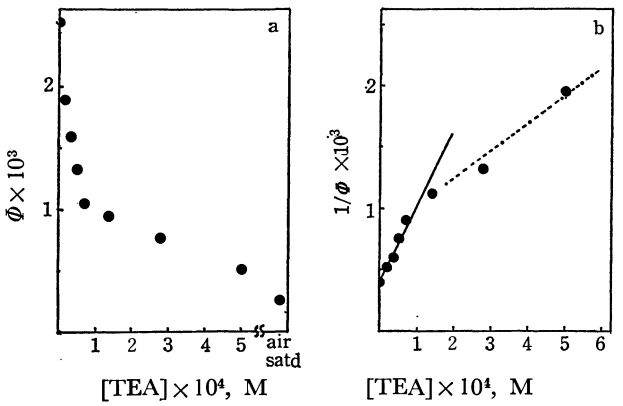

Fig. 9. Dependence of the quantum yield on the triethylamine (TEA) concentration in the aerated ethanol solution.
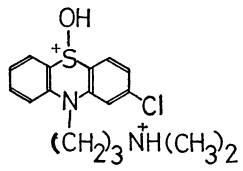
a: Plots of Φ *vs.*[TEA]. b: Plots of $1/\Phi$ *vs.*[TEA]

Similar quenching experiments using ascorbic acid as a radical quencher in the case of aqueous solution were performed in steady light and flash photolytic experiments. The results are summarized in Table 4. The quantum yields of the disappearance of chlorpromazine and the decay rates of the cation radical are affected considerably by the addition of ascorbic acid, which substantiates the mechanism of the sulfoxide formation through the chlorpromazine cation radical.

Tetramethylethylene, a prominent singlet oxygen quencher, showed no inhibitory effect in ethanol against chlorpromazine photooxidation even at a high concentration of 3.4×10^{-1} M. Thus the photooxidation of chlorpromazine *via* singlet oxygen mechanism can be excluded. This is consistent with the independence of quantum yield on the chlorpromazine concentration.

General Discussion

It is impossible to identify the 370-Int. conclusively, but the establishment of oxygen uptake from the atmospheric oxygen into the sulfoxide may reject the possibility of sulfonium ion(I) as the precursor of the sulfoxide. In support of this conclusion, the halosulfonium ion(R_2SX^+), known as a familiar intermediate for sulfoxide formation in the oxidation of the corresponding sulfide by halogen, undergoes hydrolysis and incorporation of the oxygen atom of water is attained.[21] The phenazathionium ion is also excluded definitely for the same reason.



(I)

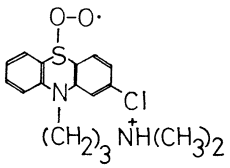
The electrochemical oxidation of phenothiazine leading to the formation of the cation radical requires 270 mV as half-wave potential for one electron oxidation, and 750 mV for the formation of the two electron oxidized form.[4] The reaction of this phenazathionium ion with the initial phenothiazine occurs rapidly and two molecules of the cation radical are obtained.[4] Thus the occurrence of the dismutative reaction of the cation radical of chlorpromazine is not thermodynamically possible. It is to be added that the absorption spectra of the phenazathionium ions have not been reported and the formation of the sulfoxide through the phenazathionium ion of chlorpromazine has been concluded only from the observation of the second-order decay of the cation radical.

Table 4. Effects of addition of ascorbic acid(AA) on the quantum yield and also on the yields of transients in water, and of tetramethyl ethylene(TME) on the quantum yield in ethanol

Solvent	Quencher concn(M)	370-Int.	575-Int.	CPZ^+	$Kd(CPZ^+)$	$\Phi_{253.7}$
H_2O(pH 4.7)	AA 0	0.18_1	0.07_6	0.09_0	6.1×10^3	5.3×10^{-2}
	1.0×10^{-4}	0.15_0	0.05_6	0.07_2	6.1×10^3	4.9×10^{-2}
	3.0×10^{-4}	0.13_8	0.05_0	0.08_0	8.2×10^3	2.9×10^{-2}
	5.0×10^{-4}	0.08_8	0.04_3	0.05_6	1.6×10^4	$8—9\times10^{-3}$ a)
C_2H_5OH	TME 0					2.5×10^{-3}
	5.3×10^{-5}					2.5×10^{-3}
	6.7×10^{-2}					3.0×10^{-3}
	3.0×10^{-1}					— b)

a) Error due to the inner filter effect; $\pm1\times10^{-3}$. b) Absorption overlap is very large but reaction occurs.

The assignment of 370-Int. is difficult in the present stage but we tentatively assume it to be a peroxyl radical(II) from its predominant formation with oxygen bubbling. A similar type of radical species was reported in the formation of dimethyl sulfoxide from dimethyl sulfide.[22]



(II)

As to the formation of the cation radical, ionization by the consecutive absorption of two photons and singlet oxygen mechanism are both excluded, so that the remaining possibility is the electron transfer process with molecular oxygen as an acceptor.

The authors are indebted to Dr. M. Koizumi and Dr. H. Kokubun for their suggestions and encouragement. Thanks are due to Dr. Y. Kishida and T. Kinoshita for their valuable discussions.

Photocyclization of [2.2]Metacyclophane at 2537 Å[1]

Kenji SORIMACHI,[2] Toshifumi MORITA, and Haruo SHIZUKA*

Department of Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho, Kiryu, Gunma 376

(Received October 3, 1973)

The photochemical reaction of [2.2]metacyclophane at 2537 Å has been studied spectrophotometrically. Photocyclization took place to give 4,5,9,10-tetrahydropyrene not only in aerated but also in degassed solutions. The quantum yields for the reaction were independent of the irradiation time, concentration of starting material, light intensity, and addition of piperylene. However, the reaction quantum yields increased with temperature rise. The quantum yields in the aerated system were somewhat larger than those in the degassed system. Radiationless deactivation in $S_1(\pi\pi^*)$ was very efficient, whose quantum yield was assumed to be ~0.99, judging from the small reaction quantum yield (less than 0.01) and the lack of fluorescence and phosphorescence. It is proposed that the photocyclization of the molecule originates from $S_1(\pi\pi^*)$ to give intermediate M which is subsequently convreted into the product or the starting material. Activation energies in these processes were estimated.

The photochemical behavior of [2.2]metacyclophane (MCP) is of interest from the viewpoint of the interaction between the two benzene rings adjacent to each other.[3] The transannular interaction would affect the photochemical and photophysical processes in MCP. In the case of [2.2]paracyclophane, the intramolecular excimer formation (the excimer fluorescence at 3350 Å)[4] and the photochemical cleavage[5] have been reported. The photochemical reactions of MCP in the presence of iodine have been carried out by Sato *et al.*[6,7] and Hayashi and Sato[7] who proposed that the photocyclization of MCP proceeds *via* the CT-complex formation between MCP and I_2. However, no photochemical reaction of MCP without oxidant has been reported.

The photocyclizations of compounds such as *cis*-stilbene[8,9] and diphenylamines[10-14] have been carried out. The bond formation between the proper atoms takes place *via* the lowest excited singlet state $S_1(\pi\pi^*)$ for the former[8,9] and *via* the lowest triplet state $T_1(\pi\pi^*)$ for the latter,[11,13] the intermediate with the central two hydrogen atoms having *trans*- and *cis*-form, respectively, being produced. The photocyclization of the former needs an oxidant such as oxygen. However, the reaction of the latter proceeds with and without oxygen.

This paper reports the photochemical reaction of MCP in degassed and aerated solutions in detail.

Experimental

[2.2]Metacyclophane (MCP) was supplied by Dr. T. Sato of Tokyo Metropolitan University. The starting material, after sublimation, was purified by column chromatography (Al_2O_3 and *n*-hexane) and by repeated recrystallizations. Cyclohexane and methylcyclohexane (G. R. grade, Tokyo Kasei Co., Ltd.) were purified by passing through silica gel column and by distillation. 4,5,9,10-Tetrahydropyrene (4HP) was prepared by the irradiation of MCP solution at 2537 Å and purified by column chromatography and repeated recrystallizations. 4HP was identified by means of NMR, IR, UV, mp and elemental analyses.

A low pressure mercury lamp with a Vycor glass filter was used as the 2537 Å radiation source. A xenon lamp, equipped with a diffraction grating, was used as the 2800 Å radiation source. Actinometry was carried out using a ferric oxalate solution.[15] The quantum yields for the reaction were performed by spectrophotometry. No difference in quantum yield was observed at 20 °C for cyclohexane and methylcyclohexane. Thus methylcyclohexane was used in the temperature range 213—288 K. For the measurement of temperature effect on the quantum yield, a quartz Dewar flask designed for spectrometry was used as a reaction cell which controlled the temperature to within ±2 °C. In the measurements on degassed samples, the solutions were thoroughly degassed on a high-vacuum line by the freeze-pump-thaw-method. Emission spectra were measured with a Hitachi MPF-2 spectrofluorimeter. The conventional μ-s flash apparatus described previously[16] was used.

Results

Figure 1(a) shows the spectral change of cyclohexane solution of [2.2]metacyclophane (MCP) during the course of photolysis at 2537 Å at 20 °C in the degassed system. This change indicates that the reaction product was 4,5,9,10-tetrahydropyrene (4HP). The photoproduct was identified by means of NMR, IR, UV, mp, and elemental analyses.[17] The spectral change of the aerated solution of MCP was similar to that in the degassed system (Fig. 2). However, after long irradiation, a new absorption band appeared in the 320—335 nm range in the aerated system. The

band was assigned to that of pyrene, which was photochemically produced in the aerated solution.[17]

The molar extinction coefficients of MCP and 4HP in cyclohexane are given in Table 1. The quantum yields for the photocyclization of MCP were measured from the increase in the optical density at 293 nm, where there is a characteristic absorption band in the product. The quantum yields for the reaction were measured under various conditions at 20 °C. The results are shown in Fig. 3. The quantum yields for the product formation in cyclohexane at 2537 Å did not change with irradiation time (≤40 min), initial concentration of the starting material ($\leq 3\times10^{-2}$ M), light intensity (10^{14}—10^{15} photons s^{-1} ml^{-1}), and addition of piperylene as a triplet quencher ($\leq 7\times10^{-3}$ M). The quantum yields in degassed and aerated solutions at 2537 Å and 20 °C were $(1.7\pm0.2)\times10^{-3}$ and $(2.3\pm0.2)\times10^{-3}$, respectively. No wavelength effect on the reaction quantum yields at 2537 nad 2800 Å at 20 °C in cyclohexane was observed, but the temperature effect was significant, as shown in Fig. 4. The quantum yields in degassed and aerated conditions increased with temperature rise. A similar tendency to the temperature effect on the yields was observed both in

degassed and aerated solutions. Although the quantum yields for product formation were very small ($\leq 10^{-2}$) as shown in Fig. 4, neither fluorescence in cyclohexane at 20 °C nor phosphorescence in a MP matrix at 77 K was observed. The long-lived intermediate could not be observed by means of conventional μs flash photolysis.

Discussion

The photocyclization of MCP in the degassed system is an intramolecular reaction, since no concentration effect of the starting matrial was observed on the quantum yields (Fig. 3b). The possibility for the charge transfer formation between MCP and dissolved oxygen in the ground state is unlikely, judging from their UV spectra and the concentration effect on the quantum yields. It seems that the photocyclization originates from the lowest excited singlet state $S_1(\pi\pi^*)$, since the addition of piperylene as a triplet quencher (E_T=2.48 eV) did not affect the quantum yields in the concentration range $10^{-4}-7\times10^{-3}$ M (Fig. 3d), dissolved oxygen (2.3×10^{-3} M)[14] increased the quantum yields for the reaction compared with those in the absence of oxygen (Figs. 3 and 4), and no excitation wavelength was observed on the yields.

The experimental results can be accounted for the following scheme, which is simplified in the processes of internal conversion and intersystem crossing.

$$S_0 + h\nu \longrightarrow S_1 \quad (0)$$

$$S_1 \longrightarrow S_0 \quad (1)$$

$$S_1 + O_2 \longrightarrow S_0 + O_2 \quad (1q)$$

$$S_1 \longrightarrow M \quad (2)$$

$$M \longrightarrow P + (H_2) \quad (3)$$

$$M \longrightarrow S_0 \quad (4)$$

$$M + O_2 \longrightarrow P + (HO_2,\ H_2O_2) \quad (5)$$

where S_0 and S_1 are the ground and the lowest excited singlet states of MCP, respectively, M is the intermediate and P is the photoproduct (4HP). The quantum yields for the product formation Φ_0 and Φ in degassed and aerated conditions, respectively, can be expressed by the following equations, using the steady-state approximation.

$$\Phi_0 = \frac{k_2}{k_1+k_2}\cdot\frac{k_3}{k_3+k_4} \quad (6)$$

and

$$\Phi = \frac{k_2}{k_1+k_{1q}[O_2]+k_2}\cdot\frac{k_3+k_5[O_2]}{k_3+k_4+k_5[O_2]} \quad (7)$$

where $k_1 \gg k_2+k_{1q}[O_2]$, because of very small quantum yields for the reaction ($<10^{-2}$) and the lack of fluorescence and phosphorescence. From Eqs. (6) and (7), we obtain

$$\frac{\Phi}{\Phi_0} = \left(1+\frac{k_4}{k_3}\right)\left(\frac{k_3+k_5[O_2]}{k_3+k_4+k_5[O_2]}\right) \quad (8)$$

If $k_3+k_5[O_2] \gg k_4$, we have

$$\frac{\Phi-\Phi_0}{\Phi_0} = \frac{k_4}{k_3} \quad (9)$$

If the rate constants k_3 and k_4 have activation energies E_3 and E_4 and frequency factors A_3 and A_4 respectively, we get the following equation from (9).

$$\log\left(\frac{\Phi-\Phi_0}{\Phi_0}\right) = \log\left(\frac{A_4}{A_3}\right) - \frac{E_4-E_3}{2.3RT} \quad (10)$$

We have no exact data of the E_3 value. However, the value of the activation energy E_3 in the molecular dehydrogenation process is assumed to be smaller than that of E_4, considering a similar process in diphenylamines.[14] Figure 5 shows the plot of $\log\{(\Phi-\Phi_0)/\Phi_0\}$ as a function of T^{-1}. The reason why the plot is bent at about 285 K (Fig. 5) is due to the fact that the relation $k_3+k_5[O_2] \gg k_4$ does not hold at temperatures higher than 285 K where the value of k_4 becomes appreciable in comparison with that of k_3 and $k_5[O_2]$. From the slope of the plot ($T \leq 285$ K) in Fig. 5, we obtain $E_4 = E_3 + 4$ kcal/mol.

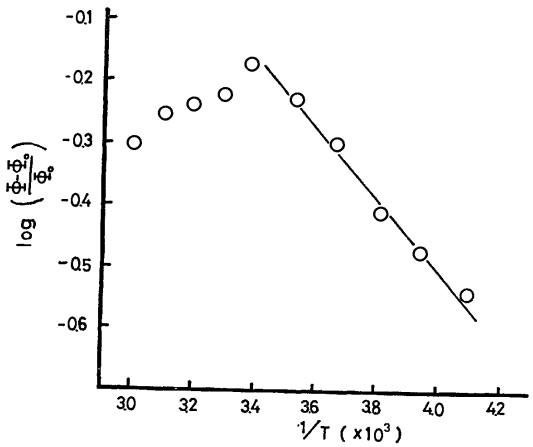

Fig. 5. Plot of $\log\{(\Phi-\Phi_0)/\Phi_0\}$ *vs.* T^{-1}

In the low temperature range ($213 \leq T \leq 285$ K), Eq. (7) is simplified as

$$\Phi = \frac{k_2}{k_1} \quad (7')$$

If the rate constant k_2 has an activation energy E_2 and frequency factor A_2, and the value of k_1 is almost constant in the temperatures ($213 \leq T \leq 285$ K), we obtain the following equation from Eq. 7'.

$$\log\Phi = \log\left(\frac{A_2}{k_1}\right) - \frac{E_2}{2.3RT} \quad (11)$$

Figure 6 shows the plots of $\log\Phi$ *vs.* T^{-1} and of $\log\Phi_0$ *vs.* T^{-1}.

From the slope of the plots, the value of E_2 can be estimated to be about 2 kcal mol^{-1} both in aerated and degassed solutions. This indicates that $k_3 \gg k_4$ in Eq. (6) at low temperatures, and the values of the quantum yields Φ in the aerated system become close to those in the degassed system with the fall of temperature (Fig. 4). Activation energy E_2 in the ring clousre process from S_1 to M is almost the same as that of *cis*-stilbene (2.6 kcal mol^{-1}).[9] MCP undergoes photocyclization to give the cyclized product even in the degassed system. However, in the case of *cis*-stilbene, dissolved oxidant is necessary to yield to corresponding photoproduct. The difference in their reactivities might be due to the intermediate structure: whether the *cis*-form or the *trans*-form of the two central hydrogen atoms in the intermediate would control the mole-

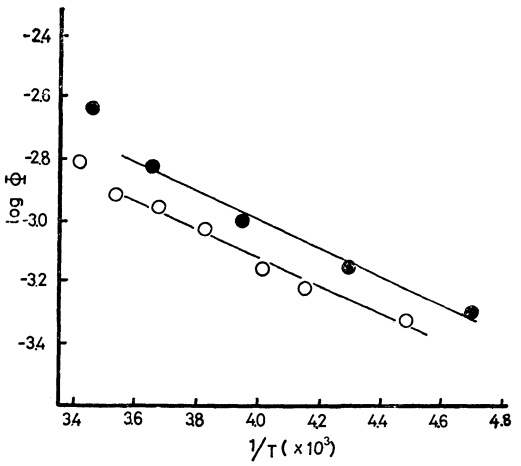

Fig. 6. Plot of $\log \Phi$ (or $\log \Phi_0$) *vs.* T^{-1}
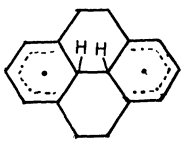
○: $\log \Phi_0$, ●: $\log \Phi$.

cular dehydrogenation process (Eq. (3)). If the intermediate has a *cis*-form, it will thermally split into a cyclized product plus a hydrogen molecule. The photocyclization of MCP corresponds to this case, although we could not observe any transient by means of the conventional μs flash photolysis. It seems that the following structure is probable for the intermediate M.



M

Radiationless deactivation (Eq. 1) is the main process in the excited singlet state of MCP, whose quantum yield is assumed to be ~0.99, on the basis of very low quantum yields for the product formation (>0.01) and the lack of fluorescence and phosphorescence. A small π-electronic interaction between the two benzene rings in the ground state is known, since the lowest transition in the molecule (λ_{max} 272 nm, $\varepsilon=4.4\times10^2$) corresponds to the $^1B_{2u}\leftarrow{}^1A_{1g}$ transition in benzene (λ_{max} 256 nm, $\varepsilon=2.2\times10^2$). It is obvious that the transannular interaction due to the proximity of two benzene rings in MCP causes the large radiationless deactivation and the very small ring-closure in the $S_1(\pi\pi^*)$ state. One explanation for the large deactivation is that the molecular structure of MCP probably promotes the internal conversion in Eq. (1), due to the vibronic coupling between S_1 and S_0 states. Another possibility is that a chemical energy wasting process such as reversible isomerization might be involved in Eq. 1, and responsible for the radiationless deactivation in S_1. The lifetime of S_1 is very short judging from the present results. A similar large radiationless deactivation is known in the case of biphenylene. Lack of photoluminescence of biphenylene has been observed,[18] the first singlet excited state being responsible for the main nonradiative channel on the basis of its lifetime (~10 ps).[19]

The abnormal shifts in the UV spectrum of [2.2] paracyclophane shows a large π-electronic interaction between the parallel planes of two benzene rings in the molecule.[20] An excimer fluorescence in [2.2]paracyclophane at 3550 Å indicates the charge transfer interaction in the emitting state.[4] The photochemical ring-opening reactions of [2.2]paracyclophane take place, which depend upon the excitation wavelengths.[5] The electronic and steric features in these isomers would cause the difference in photochemical and photophysical processes.

The proposed mechanism of the photocyclization of MCP in degassed and aerated cyclohexane is shown in Eqs. 0—5.

The authors wish to thank Dr. Takeo Sato, Tokyo Metropolitan University, for the supply of [2.2]metacyclophane and for valuable discussions.

Photochemistry of the Electron Donor-Acceptor System. I. Exciplex Fluorescence and the Fluorescence of the Charge-Transfer Complex in the Aromatic Hydrocarbon–Fumaronitrile System

Yasuhiko SHIROTA, Isamu TSUSHI, and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received October 8, 1973)

The fluorescence of a series of aromatic hydrocarbons was quenched by the addition of fumaronitrile, which is consistent with the charge-transfer or electron-transfer mechanism. The fluorescence quenching was accompanied by the appearance of a new, broad structureless emission band attributed to the fluorescence from the exciplex in non-polar or slightly polar solvents. In highly polar solvents only quenching of the fluorescence occurred. The energies of the band maxima of the exciplex fluorescences and the magnitude of the ionization potentials of a series of fluorescers showed a good correlation with each other. Solvent and temperature dependence of the exciplex fluorescence was examined and discussed. The present aromatic hydrocarbon–fumaronitrile system also formed a charge-transfer complex in their ground states at relatively high concentrations of each component. The selective excitation of the ground state charge-transfer complex gave rise to the fluorescence emission in a fluid solution at room temperature at the same wavelength region as observed for the exciplex fluorescence. It was susgested that the electronic structure of the fluorescent state of the exciplex and the excited charge-transfer complex is the same.

Since the works by Leonhardt and Weller it has been established that the charge-transfer or electron-transfer process is an important mechanism for the quenching of fluorescence.[1] Detailed studies have since been made, particularly on the mechanism of the electron-transfer process in the excited state in relation to the fluorescence quenching.[2–4] Fluorescence quenching is often accompanied by the appearance of a new fluorescence emission attributed to the exciplex in non-poalr or weakly polar solvents, while in strongly polar solvents only quenching of the fluorescence takes place. The fluorescence emission from the exciplex has so far been observed mostly in the polynuclear aromatic hydrocarbons–aromatic amines systems, where the fluorescer acts as an electron acceptor and the quencher as an electron donor.[1,5,6] The opposite case in which the fluorescer acts as an electron donor and the quencher as an electron acceptor has also been observed in a few systems, *e.g.*, *N*,*N*-dimethyl-β-naphthylamine–methyl benzoate or dimethyl isophthalate systems[7] or *N*-vinylcarbazole–fumaronitrile or diethyl fumarate systems.[8] An examination of the effects of solvent and temperature on the exciplex fluorescence was expected to provide information on the electronic structure of exciplex. Studies from this viewpoint were made by Mataga *et al.*[5] and Beens *et al.*[6] in the polynuclear aromatic hydrocarbon–*N*,*N*-dialkylaniline system, and a dipolar nature of the exciplex with a large dipole moment of more than 10 D was indicated. However, only a few clear-cut experimental data are available.

We have found that the fluorescence of a series of aromatic hydrocarbons is quenched by the addition of fumaronitrile, the fluorescent exciplex being formed between the fluorescer which acts as an electron donor and the quencher which acts as an electron acceptor in non-polar or weakly polar solvents. The effects of solvent and temperature on the exciplex fluorescence were examined. It was found that the present aromatic hydrocarbon–fumaronitrile system shows a charge-transfer interaction in their ground states at a relatively high concentration of each component and that the excited charge-transfer complex formed by the selective excitation of the ground state charge-transfer complex emits the fluorescence in a fluid solution at room temperature. Observation of both the intermolecular exciplex fluorescence and the fluorescence of the charge-transfer complex in the same system enabled us to make a direct comparison of the electronic structures of the exciplex and the excited charge-transfer complex.

Experimental

Materials. Fumaronitrile (*trans*-1,2-dicyanoethylene) of pure grade was recrystallized three times from pure benzene, fractionally sublimed twice *in vacuo*, stored and vacuum-sublimed once more immediately before use. Extra pure grade naphthalene, phenanthrene, acenaphthene, fluorene and anthracene were recrystallized from methanol, chromatographed on an activated alumina column with benzene as an eluent, recrystallized from methanol several times, and then fractionally sublimed twice *in vacuo*. Pyrene of pure grade was recrystallized twice from ethanol and benzene, chromatographed on alumina and then silica gel columns, recrystallized from ethanol several times and then fractionally sublimed twice *in vacuo*. Benzene was purified and dried in the usual way, and then refluxed with metallic sodium for a long time, and distilled from it immediately before use. Chloroform and dichloromethane were shaken with concd. sulfuric acid, water, and 5% sodium hydroxide solution, and washed with water repeatedly, dried over calcium chloride, refluxed with calcium hydride and distilled from it immediately before use. Tetrahydrofuran and α-methyltetrahydrofuran were refluxed with solid potassium hydroxide for a long time, distilled from it, and again distilled from lithium aluminum hydride immediately before use. Acetonitrile was refluxed with phosphorus pentoxide for a long time and distilled twice from it, and then refluxed with anhydrous potassium carbonate and distilled twice from it immediately before use.

Apparatus and Measurements. The ultraviolet and visible absorption spectra were measured with a Hitachi 124 spectrophotometer. The fluorescence emission and excitation spectra were measured with a Hitachi MPF-3 spectrophotofluorometer equipped with a constant-temperature cell holder. Emission measurements were made at 77

and 196 K using a Pyrex tube of about 3.5 mm diameter in a quartz Dewar containing liquid nitrogen and dry ice-methanol, respectively, as a refrigerant. The system used for the measurement was not degassed.

Results and Discussion

The fluorescence of a series of aromatic hydrocarbons, *e.g.*, naphthalene, phenanthrene, fluorene, acenaphthene pyrene, and anthracene, was found to be quenched by the addition of fumaronitrile, new broad structureless fluorescence emissions being observed in non-polar or slightly polar solvents with maxima in the range 21100—17400 cm^{-1}. The intensity of the new emissions increased with quencher concentration with an isoemissive point in each system. The excitation spectra for the new fluorescence were the same as those for the fluorescence of the aromatic hydrocarbons, being in good agreement with the absorption spectra of the corresponding aromatic hydrocarbons. New emissions were, therefore, attributed to the fluorescence from the exciplexes formed between the excited singlet aromatic hydrocarbons which act as electron donors and the ground state fumaronitrile which acts as an electron

acceptor. The corrected fluorescence emission spectra of a few aromatic hydrocarbon–fumaronitrile systems measured in benzene are shown in Figs. 1—3. The emissivity of the exciplex formed in the anthracene–fumaronitrile system was much weaker than that in other systems. The absorption spectra of a series of aromatic hydrocarbons (concentration was the same as that for the measurement of fluorescence emission) are shown in Figs. 4 and 5.

Appearance of the exciplex fluorescence depends on the magnitude of the ionization potential of the aromatic hydrocarbon as well as solvent polarity. Thus, as the polarity of the solvent increased from benzene (dielectric constant 2.27 at 25 °C) to dichloromethane (dielectric constant 8.9 at 25 °C), the exciplex fluorescence was no longer observed with respect to acenaphthene, pyrene and anthracene which possess relatively low ionization potentials (Table 1). In strongly polar solvent like acetonitrile (dielectric constant 37.5 at 20 °C) no exciplex fluorescence was detected, only quenching of the fluorescence of the aromatic hydrocarbon occurring. The wave number of the exciplex fluorescence maximum became smaller with the decrease of the ionization potential of the electron donor. A nearly linear relationship was found between the energies corresponding to the exciplex fluorescence maxima and the magnitude of the ionization potentials of a series of electron donors (Fig. 6).

A remarkable effect of solvent polarity was observed on the exciplex fluorescence maximum. With the increase in the polarity of solvent, the exciplex fluorescence maximum shifted toward the red region accompanied by the decrease in the emission intensity, and the energies corresponding to the exciplex fluorescence maxima were roughly correlated with the static dielectric constant of the solvent (Table 1 and Fig. 7). As the temperature was lowered from 298 K to 196 K, the exciplex fluorescence maximum also showed a red shift accompanied by the decrease in the exciplex fluorescence intensity and the increase in the fluorescence

intensity of the aromatic hydrocarbon (Table 2). In α-methyltetrahydrofuran matrix at 77 K neither the production of the exciplex fluorescence emission nor the quenching of the fluorescence of the aromatic hydrocarbon occurred.[9,10)]

The Stern-Volmer plots of F_0/F against the concentration of the quencher were linear up to *ca.* 5×10^{-2} M concentration of the quencher, where F_0 and F represent the fluorescence intensity of the aromatic hydrocarbon in the absence and presence of the quencher, respectively. When the concentration of the quencher exceeded *ca.* 5×10^{-2} M, the plots deviated upward from the linear relation in all the systems except anthracene probably due to the occurrence of the photoabsorption

by the quencher molecule, since the tail absorption band of fumaronitrile of the concentration above *ca.* 5×10^{-2} M covers the wavelength of the exciting light. This tendency was conspicuous with respect to naphthalene and fluorene since excitation was carried out at a shorter wavelength than with the other aromatic hydrocarbon systems, the deviation occurring at the quencher concentration below 5×10^{-2} M. Some results are shown in Fig. 8. The quenching constants obtained from the slope of the Stern-Volmer plots and the approximate quenching rate constants γk_1 ($\gamma=k_3/(k_2+k_3)$ in Scheme 1) at 298 K in benzene calculated by using the known values of τ_0 (fluorescence lifetime) are summarized in Table 3.

The features of the fluorescence quenching of a series of aromatic hydrocarbons by fumaronitrile are consistent with the charge-transfer or electron-transfer mechanism in the excited state. The present results led to the following conclusions on the exciplex, which are essentially in good agreement with the conception as regards the exciplex formed in the aromatic hydrocarbon–aromatic amine system.[5,6,11)] (a) The exciplex which is stable only in the excited state is produced by the molecular motion of the electron donor and acceptor molecules during the lifetime of the excited state of the fluorescer (here the excited singlet state). Thus, no exciplex formation takes place in the rigid matrix at 77 K in which the molecular motion is restricted. (b) Just as the energies of the exciplex fluorescence maxima are correlated with the magnitude of the electron affinities of the aromatic hydrocarbons for a given aromatic amine,[6b,11)] they are correlated with the magnitude of the ionization potentials of the aromatic hydrocarbons in the present systems where the fluorescers act as electron donors. (c) The electronic structure of the exciplex in the equilibrium state is very polar, and the orientation of the solvent molecules takes place during the lifetime of the exciplex. The red shift of the exciplex fluorescence maximum observed when the temperature is lowered may be explained to be due to the increase in the polarity of the solvent at low temperatures. (d) It is suggested that as the solvent polarity increases the exciplex dis-

sociates into ions to produce solvated ion pairs with no emissivity, and that in strongly polar solvents the electron transfer occurs from the encounter complex.[2-4]

The present aromatic hydrocarbons–fumaronitrile systems also showed a weak charge-transfer interaction in their ground states at relatively high concentrations of each component (*ca.* 10^{-1} M or above), as evidenced from the electronic absorption spectra. Although no distinct charge-transfer bands separated from the component absorptions were observed, the absorption spectra of the aromatic hydrocarbons–furmaronitrile systems shifted to the red region as compared with the sum of the absorptions of each component of the same concentration. It was found that selective excitation of the ground state charge-transfer complex gave rise to the fluorescence emission in a non-polar fluid solution at room temperature in the same wavelength region as observed for the exciplex fluorescence. As an example, the absorption and the fluorescence emission spectra of the charge-transfer complex in the acenaphthene–fumaronitrile system measured at 298 K are shown in Fig. 9. The result is consistent with the known characteristic features of the fluorescence of the charge-transfer complex, *viz.*, a large Stokes shift is observed in a room temperature fluorescence in a fluid solution (the maximum wavelength of the charge-transfer absorption band is shorter than 400 nm). That the emission is not the exciplex fluorescence produced by the local excitation of the tail band of the aromatic hydrocarbon, but the so-called charge-transfer fluorescence from the excited charge-transfer complex, was further confirmed by the measurement at 77 K where no exciplex fluorescence was produced. The fluorescence emission was likewise observed at 77 K by the selective excitation of the ground state charge-transfer complex,

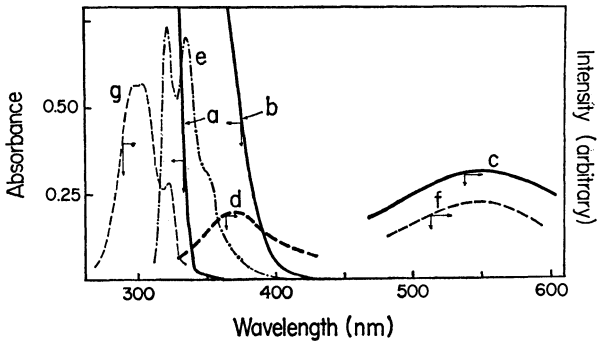

Fig. 9. The absorption and fluorescence emission and excitation spectra of the acenaphthene-fumaronitrile charge-transfer complex measured in α-methyltetrahydrofuran at 298 K. (a) absorption spectrum of acenaphthene(0.1 M); (b) absorption spectrum of the acenaphthene(0.1 M)-fumaronitrile(0.1 M) system; (c) the fluorescence spectrum of the charge-transfer complex produced by the excitation in the charge-transfer band at 370 nm in the above system; (d) excitation spectrum for the charge-transfer fluorescence(c); (e,f) fluorescence spectrum of acenaphthene and exciplex fluorescence spectrum produced by the excitation of acenaphthene (1×10^{-4} M) at 321 nm in the presence of fumaronitrile (2.5×10^{-2} M). (g) excitation spectrum for the fluorescence emissions (e) and (f).

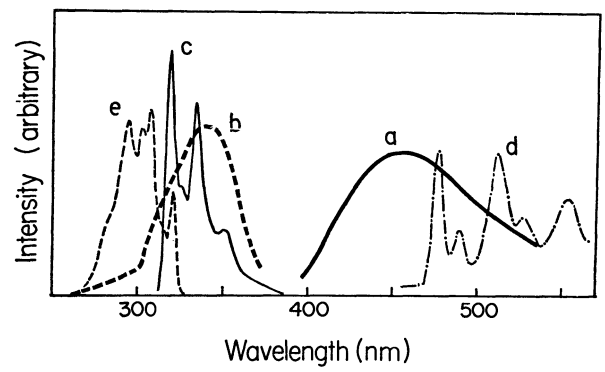

Fig. 10. The charge-transfer fluorescence and excitation spectra of the acenaphthene-fumaronitrile charge-transfer complex measured in α-methyltetrahydrofuran at 77 K. (a) the fluorescence spectrum of the charge-transfer complex produced by the excitation in the charge-transfer band at 370 nm in the acenaphthene-(0.1 M)-fumaronitrile(0.1 M) system; (b) excitation spectrum for the charge-transfer fluorescence (a); (c) fluorescence spectrum of acenaphthene produced by the excitation of acenaphthene (1×10^{-4} M) at 321 nm in the presence of fumaronitrile (2.5×10^{-2} M); (d) phosphorescence spectrum of acenaphthene produced simultaneously with the fluorescence (c); (e) excitation spectrum for the emissions (c) and (d).

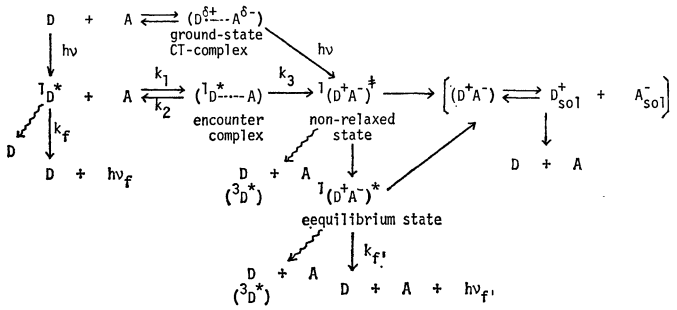
but at a shorter wavelength than that observed at 298 K (Fig. 10). This is understandable since the fluorescence in a rigid medium takes place from the lowest point reached from the excited Franck-Condon state and the fluorescence in a fluid solution from the excited equilibrium state, which is stabilized due to the reorientation of the solute and the solvent molecules.[12d] Measurement of the correct excitation spectrum was difficult due to the effect of the reabsorption of the emission. The fluorescence of the charge-transfer complex was also dependent on the polarity of the solvent: the fluorescence wavelength maximum shifted to the red region accompanied by the decrease in the emission intensity as the polarity of the solvent increased; no fluorescence emission was detected in a strongly polar solvent such as acetonitrile. Observation of a room temperature fluorescence of a charge-transfer complex in a fluid solution has so far been reported only in a few systems.[11,12] Hardley any examples bave been reported except the *s*-tetracyanobenzene–α-methylstyrene system[13] in which both the exciplex fluorescence and the fluorescence of the charge-transfer complex stable in the ground state are observed in the same system. A direct comparison of the exciplex fluorescence and the charge-transfer fluorescence emissions in the same system enabled us to obtain information on the comparable electronic structure or the geometry of the exciplex and the excited charge-transfer complex. In the *s*-tetracyanobenzene–α-methylstyrene system the fluorescence from the excited charge-transfer complex, very weak in its intensity, appears at a different wavelength from the exciplex fluorescence, and different geometries have been suggested for the exciplex and the excited charge-transfer complex. The present result in which the exciplex fluorescence and the charge-

transfer fluorescence emissions were observed at the same wavelength region in a few solvents of different polarity suggests that the electronic structure of the fluorescent state of the exciplex and the excited charge-transfer complex is the same. We have also obtained the same result in the *N*-vinylcarbazole–fumaronitrile system.[8] The photochemical primary processes of the aromatic hydrocarbon–fumaronitrile system are shown in Scheme 1.



Scheme 1. The photochemical primary processes in the aromatic hydrocarbon-fumaronitrile system.

The Gas Chromatographic Determination of Selenium in Plant Material with 4-Nitro-*o*-phenylenediamine

Yasuaki SHIMOISHI*

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama-shi 700

(Received July 16, 1973)

Selenium(IV) reacts with 4-nitro-*o*-phenylenediamine to form 5-nitropiaselenol, which is detected by means of a gas chromatograph equipped with an electron-capture detector. By this highly sensitive method, the determination of very small amounts of selenium in plant materials has been investigated. Fuming nitric acid digests the plant sample completely, and the selenium is converted to the quadrivalent state. No loss of selenium can be found by this treatment. A method is proposed for the determination of selenium in plant materials at levels as low as 0.005 μg/g in dried material.

In earlier studies of the determination of selenium contained in plant material, the interest of research workers has been directed toward the investigation of selenium toxicity for farm animals. In these studies, it was enough that the method could determine only the ppm levels of selenium in dried samples.

Recently, many investigators have demonstrated that selenium is an important micronutrient for farm animals. Scott[1] and Kubota *et al.*[2] have pointed out that the critical level for the deficiency of selenium for farm animal diets is 0.01—0.04 ppm. Therefore, it is necessary to have a method of analysis to determine amounts of selenium as low as 0.01 ppm with reasonable accuracy and reproducibility. To fulfill these requirements, a fluorometric method involving the use of 3,3′-diaminobenzidine[3,4] or 2,3-diaminonaphthalene[5,6] has been widely used in studies of animal nutrition. The neutron-activation[7] and isotope-dilution methods[8] have also been used to check the former method.

On the other hand, it is important to digest the plant material without any loss of selenium, because selenium is volatile. By the low-temperature ashing method, selenium could not be recovered completely.[9] In the oxygen-flask combustion method, selenium is obtained as an elemental state with a small amount of charred tissues in the platinum vessel, and the residue could not be dissolved completely by a bromine-bromide solution. Thus, the wet-digestion method was employed in the following experiments.

The author has recently proposed a far more sensitive method for determining selenium in pure sulfuric acid,[10] pure tellurium,[11] and sea water[12] by means of a gas chromatograph equipped with an electron-capture detector using 4-nitro-*o*-phenylenediamine. The present paper will describe an investigation of the determination of very small amounts of selenium in plant material.

Materials and Method

Reagents. 4-nitro-*o*-phenylenediamine hydrochloride solution: 1 g of the reagent was dissolved in 100 ml of 1 M hydrochloric acid. This solution is so stable that the solution can be used after standing for more than 1 week at room temperature.

Selenium(IV) stock solution: 351.3 mg of selenium dioxide was dissolved in 250 ml of distilled water (1 mg Se/ml). Working solutions were prepared by dilution. Selenium(0) stock solution: About 5 mg of elemental selenium was dissolved in 50 ml of carbon disulfide. The concentration is determined by gas chromatography[10] as 90 μg/ml. Working solutions were prepared by dilution. 7.5 M Hydrochloric acid solution: The acid solution was prepared each time before washing the toluene extract. The other reagents were of an analytical reagent grade.

Apparatus. A Shimadzu Model GC-3AE gas chromatograph equipped with an electron-capture detector was used. A glass column (1 m long, 4 mm bore) was packed with 15% SE-30 on 60—80 mesh Chromosorb W. The column and the detector temperature were maintained at 200 °C. The nitrogen flow-rate was 53 ml/min. A Shimadzu Model 250A recorder was used at a chart speed of 5 mm/min.

Standard Procedure. The whole digestion procedure must be carried out in a fume hood with an efficient extractor fan.

A tenth to 1 g portions of dried samples are put into a 100-ml conical flask. 5 ml of fuming nitric acid is added, and the mixture is heated on a sand bath (130—140 °C) in a fume hood. Vigorous oxidation reactions take place soon thereafter, and a copious brown vapor is evolved. After a few minutes, the main reaction comes to an end and the solution soon becomes clear (a few suspended particle of silicate are often observed). The solution is then heated further with frequent shaking until the white solid separates off and the volume is reduced to about 0.1—0.2 ml. During this procedure the temperature of the sand bath must be raised to 170—180 °C and maintained until the digestion is finished. At this time, if any charred material appears, erroneous results may be obtained. Therefore, special care has to be exercised to prevent the formation of a charred material by frequent shaking. If more than 0.5 g of a plant sample is needed for the determination, the digestion is not complete with the use of 5 ml of fuming nitric acid. Consequently, another 5 ml of fuming nitric acid is added and the digestion procedure has to be repeated. Digestion is usually completed by heating for about 1.5 hr. The flask is then removed and allowed to stand for 3 min. After redissolving the precipitate with 10 ml of distilled water, 2 ml of 1 M urea is added and the mixture is heated on the sand bath for 10 min to decompose the oxides of nitrogen. After cooling, the content is transferred into a 100-ml separatory funnel and the flask is rinsed with 10 ml of distilled water into the funnel. When the selenium content was too much, an aliquot containing 0.01—0.1 μg of selenium was used. Five ml of concentrated hydrochloric acid and 5 ml of toluene are added, and the toluene-soluble material is extracted with vigorous shaking for 5 min.

* Present address: School for X-ray Technicians, Faculty of Medicine, Okayama University, Shikatacho, Okayama-shi.

After standing for 2 hr, the aqueous phase is transferred into another 100-ml separatory funnel, and the initial separatory funnel is rinsed with 10 ml of distilled water into the latter. The color of the solution is pale yellow or colorless. Two milliliters of a 1% 4-nitro-*o*-phenylenediamine solution are added, and the solution is allowed to stand for 2 hr. Then, the 5-nitropiaselenol formed is extracted into 1 ml of toluene by shaking for 5 min; the toluene extract is washed, first with 5 ml of 0.2 M sodium hydroxide and subsequently with 2 ml of 7.5 M hydrochloric acid, by shaking for a minute. Five microliters of the toluene extract are injected into the gas chromatograph and the peak height is measured.

Results and Discussion

Digestion of the Plant Material. A mixture of nitric and sulfuric acids or nitric and perchloric acids is usually used in the digestion method. Gorsuch[13] suggested in his detailed study that a considerable loss of selenium at the 1 ppm level was found when using the former mixture, whereas he obtained a 100% recovery with the latter one. In recent publications, when the digestion mixture containing a catalyst such as dichromate,[14] molybdate[15] or vanadate[16] was used, vigorous bumping was observed in the reactions.

Hall and Gupta[6] used nitric acid, hydrogen peroxide, and perchloric acid in the digestion of the plant samples. They stated that the selenium loss often occurred when the temperature rose too far as a result of the use of perchloric acid. Moreover, when the plant sample was digested with only fuming nitric acid or a mixed solution of fuming nitric and perchloric acids, the recovery of the above two methods showed the same value. Thus, fuming nitric acid was used for the digestion of the plant material.

0.2 g filter paper (Toyo Roshi No. 5B) was impregnated with carbon disulfide containing 0.045 μg elemental selenium and then dried. The filter paper was digested by various amounts of fuming nitric acid. On the other hand, the same filter paper and a 0.2 g stem of wheat containing less than 0.005 μg/g selenium were digested together. Figure 1 shows that more than 4 ml of fuming nitric acid can digest the filter paper and stem of wheat completely, and a good recovery is observed.

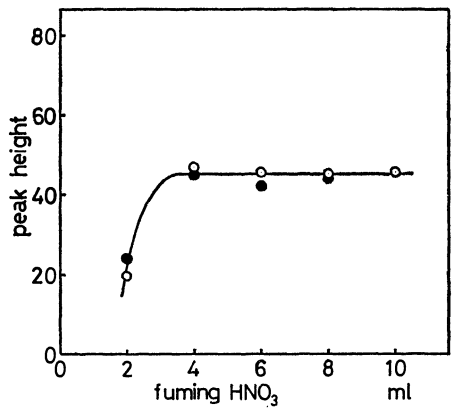

Fig. 1. Effect of the volume of fuming nitric acid.
-○- 0·045 μg selenium(0) permeated in filter paper
-●- 0.045 μg selenium(0) + 0.2 g stem of wheat (selenium content below 0.005 μg/g)

Five ml of fuming nitric acid digest 0.2 g filter paper containing 0.027 μg selenium and a wheat stem which contains less than 0.005 μg Se/g. When a larger amount of wheat is to be digested, the digestion is repeated by the use of another five ml of fuming nitric acid. If charred materials do not appear during the digestion, the determination may be undertaken. The results are shown in Fig. 2. When more than 0.5 g of a sample is digested by 5 ml of fuming nitric acid, the background of gas chromatogram becomes larger. However, this trouble is overcome by further digestion with 5 ml of fuming nitric acid without any loss of selenium.

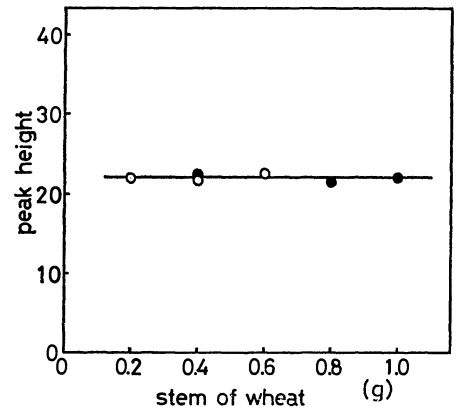

Fig. 2. The amount of the plant sample digested by 5 ml of fuming nitric acid.
-○- 0.027 μg selenium(0) + stem of wheat (selenium content below 0.005 μg/g) digested by 5 ml of fuming nitric acid.
-●- the same sample digested twice another 5 ml of fuming nitric acid

The digestion temperature is examined by the use of 0.2 g filter paper containing 0.045 μg of elemental selenium at 100—110, 160—180, and 210—220 °C (sand bath temperature). At 100—110 °C, the digestion is not enough, and at 210—220 °C the sample is sometimes charred, at which time selenium is lost. When a sample is heated at 160—180 °C for 80 min, digestion is complete. The heating is continued at this temperature till the volume of the digestion liquid reaches 0.1—0.2 ml; the smaller the volume of the liquid is, the better the result becomes. The whole digestion requires about one and half an hour.

In the digestion procedure, a small amount of undecomposed materials such as hydrocarbon constituents remains unchanged; it should be removed before gas chromatography. Five milliliters of toluene are used to eliminate any interfering substances. Selenium is not transferred into toluene by this procedure. Though a major part of the toluene-soluble substances can be eliminated by this treatment, the very small amount of interfering substances remaining disturbs the determination, because the sensitivity of the electron-capture detector is extremely high for the unknown impurities as well as for 5-nitropiaselenol. Thus, 1 ml of the toluene extract after the formation of 5-nitro-

piaselenol should be washed again with 5 ml of 0.2 M sodium hydroxide and then 2 ml of 7.5 M hydrochloric acid. Figure 3 shows the ECD gas chromatogram obtained by the use of the above-mentioned procedure.

Recovery Test. The recovery test by the standard procedure is carried out by the use of two samples: one is a mixed sample of 0.2 g filter paper containing 0.045 μg elemental selenium and 0.2 g of wheat stem which contains less than 0.005 μg Se/g, while the other is foliage leaves of wheat cultivated in a pot. The results, shown in Tables 1 and 2, indicate that fairly good results are obtained by this procedure.

Table 1. Recovery of the selenium added to stem of wheat

Stem of wheat[a] (g)	Added selenium(0) (μg)	Peak height	Selenium determined (μg)	Recovery (%)
0.200	none	2.0	0	
0.200	0.045	41.0	0.043	96
0.200	0.045	45.0	0.047	104
0.200	0.045	42.0	0.044	98
0.200	0.045	44.0	0.046	102

a) Containing less than 0.005 μg Se/g.

Table 2. Reproducibility of selenium in foliage of wheat

Foliage of wheat[a] (g)	Added selenium (μg)	Peak height	Selenium determined (μg/g)
0.200		3.5	0.020
0.200		4.5	0.025
0.500		12.0	0.026
0.500		12.0	0.026
0.500	0.027	35.0	0.024

a) Cultivated in the pot which contains the soil added no selenium.

Selenium(VI) in Plant. The oxidation number of the selenium contained in the plant sample should be −2, 0, or +4. The selenium in these oxidation states can be determined by the above-mentioned procedure. If selenium(VI) is present in the plant, it cannot be determined by the standard procedure as it stands. If selenium(VI) was contained in the plant, it would be reduced to the IV state by heating with 4 M hydrochloric acid on a sand bath for 10 min at about 100 °C, after the addition of 1 M urea to decompose oxides of nitrogen. By this procedure, selenium of the VI state could not be detected in the samples used in the experiment.

Effect of Chloride Ion. No loss of selenium was found during the reduction of selenium(VI) with 4 M hydrochloric acid for 10 min at about 100 °C. When the chloride ion is present together with selenium for a long digestion at 160—180 °C, selenium(VI) volatilizes to form its chloride. Even if the digestion procedure is carried out in the presence of 10 mg of sodium chloride, no loss of selenium is found.

Calibration Curves. The calibration curves are made by the use of four standard samples. The first is made from an acidic solution containing a known amount of selenium(IV). The second is prepared by treating filter paper containing selenium(IV) by the standard procedure. The third is made from filter paper containing elemental selenium. The fourth is made from a mixed sample of filter paper containing a known amount of elemental selenium and a wheat stem containing no selenium. The curves obtained are shown in Fig. 4. These are quite consistent with each other. This fact also shows that no loss of selenium is found in the standard procedure adopted.

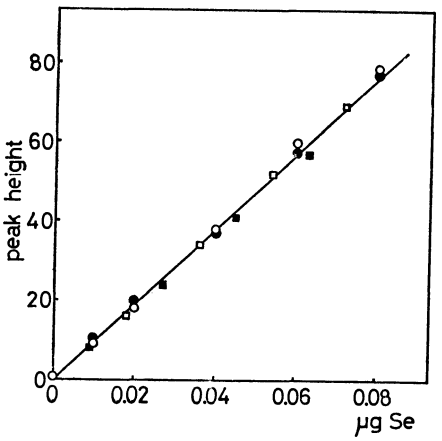

Fig. 4. Calibration curve.

-●- selenium(IV) permeated in filter paper
-⊟- selenium(0) permeated in filter paper
-■- selenium(0) + 0.2 g of stem of wheat (selenium content below 0.005 μg/g)

Determination of Selenium in Plant Material. The determination of the selenium involved in the plant material was carried out for cabbage, Chinese cabbage, wheat, and rice plants. The cabbages and Chinese cabbages were harvested from an ordinary field. The wheats and rice plants were obtained as follows: a seed-

a) Planted soil (added as SeO_2). b) The example, indicates that the solution digested is diluted to 50 ml and 20 ml of it is used. c) A mixture of foliage and stem.

ling grown to 10 cm was transplanted into pots which had 3 kg of soil containing 0, 5, 10, 50, and 100 ppm selenium respectively (added as SeO_2). These plants were harvested after maturity. They were dried in a ventilated oven at 80 °C for 2 day. Subsequently, the dried sample was cut with scissors into portions about 1 mm long and mixed well. The selenium in 0.1—1 g of plant materials was determined by the procedure described above; also, the same sample containing 0.018—0.027 μg of selenium as the elemental form was used for the determination. As the added amount of selenium is always obtained by deducing the former values from the latter values, this method is proved to be usable for the determination of selenium in plant material. The results are shown in Table 3.

Since the sensitivity of an electron-capture detector varies during operation, a series of experiments should be carried out successively and an unknown content of selenium should be determined along with standard samples which contain similar amounts of selenium. The outstanding features are that it is simple, highly sensitive, and rapid, and no special skill is necessary to perform this method.

The author wishes to thank Professor Kyoji Tôei for his encouragement and helpful discussion throughout the work and Professors Shigeo Yoneda and Noboru Shimose for supplying the plant samples.

Copper(II) Complexes of Histidine and Its Related Compounds in Aqueous Solutions

Hiroji AIBA, Akira YOKOYAMA, and Hisashi TANAKA

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received November 1, 1973)

The copper(II) complexes of histidine and its related compounds in aqueous solution were investigated by potentiometric, spectrophotometric, and magnetic methods. The presence of a diolated binuclear copper(II) complex was indicated in the 1 : 1 histamine-copper(II) system by quantitative analysis of the titration data and the antiferromagnetic character of the complex. The titration data could not be quantitatively interpreted owing to precipitation, but the formation of a similar diolated copper(II) complex was also shown in the 1 : 1 histidine-copper(II) system by the magnetic properties of the complex. From a comparison of the spectral properties of the pertinent complexes, it was shown for the neutral 2 : 1 histidine-copper(II) complex that histidine binds to copper-(II) through the amino and imidazole groups in the chelate plane and through the carboxyl group in the apical position. In the copper(II) complexes of histidine and histamine, it was shown that ionization of the pyrrole nitrogen of the imidazole ring is promoted, causing a spectral blue shift.

Elucidation of the complex formation between copper-(II) and histidine in the aqueous solution is not easy, since histidine involves a bulkyl imidazole ring and has three or four coordination sites, and copper(II) requires a tetragonal coordination. This and the biological significance of histidine residue as a metal binding site in protein have prompted many workers to investigate copper(II)-histidine complexes. The presence of various complex species, *viz.*, protonated, normal and hydroxo complexes, has been found to be dependent on pH of medium and histidine-to-copper(II) ratio.[1-6] However, the structures of the complexes have not been completely elucidated. The coordinating groups which occupy four positions in the square coordination sp-here are not elucidated in the ligand to metal ratio 2 : 1 normal complex. In this connection, a weak coordination from the apical direction has been the subject of debate. Questions on the structure of the hydroxo complex formed in the 1 : 1 system remain undetermined and structural changes in the complexes in alkaline solution have not been fully discussed. For the purpose of obtaining further information on the structures of various complexes which may be formed in the reaction of histidine with copper(II) under various conditions, we studied the copper(II) complexes of histidine and its related compounds in aqueous solution by potentiometric, visible spectrophotometric, and magnetic methods.

Experimental

Materials. L-Histidylglycine was synthesized according to the method described previously.[7] Commercial ligands and reagents were used.

Methods. Potentiometric titration was carried out on a solution (10 ml) containing a ligand (10^{-2} M) and copper(II) (10^{-2} M or 0.5×10^{-2} M). Visible spectrophotometric measurements were made on solutions with copper(II) concentrations 4×10^{-3} M—1×10^{-2} M. Details of experimental conditions and method have been described.[7,8] The magnetic susceptibilities of the solutions containing a ligand (10^{-1} M) and copper (10^{-1} M) were measured by the Gouy method at room temperature. The molar susceptibility and magnetic moment of copper(II) in each system was calculated, with the correction of the diamagnetism of water, ligand and other ions present.

Results

Potentiometric Titration. Figure 1 shows the titration curves of L-histidine, histamine, and L-3-benzylhistidine in the presence of equimolar $CuCl_2$. In each 1 : 1 system a pH inflection is observed at $a=2$, followed by an additional deprotonation in neutral region, where a represents moles of KOH added per diprotonated ligand.

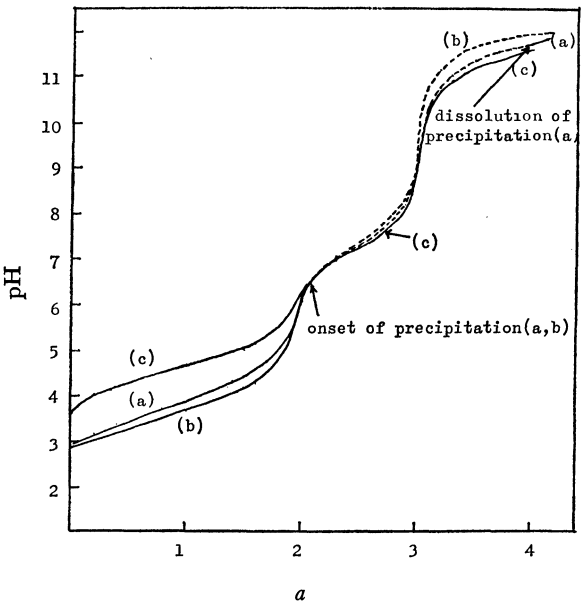

Fig. 1. Titration curves of L-histidine, L-3-benzylhistidine and histamine in the presence of equimolar $CuCl_2$:
(a) histidine, (b) 3-benzylhistidine, (c) histamine, [ligand]=[Cu(II)]=10^{-2} M (at $a=0$).
The dotted line indicates precipitation.

The 1 : 1 complex (CuL'^{2+}) is regarded as the main species in the region, where a value is about 2 in the 1 : 1 histamine-copper(II) system.[1] The following equation was assumed for the deprotonation between $a=2$ and 3 in the histamine-copper(II) system, the equilibrium constant pK_c^1 being calculated at each reaction point:

$$CuL'^{2+} \rightleftharpoons CuL'(OH)^{+} + H^{+}$$

$$K_c^1 = \frac{[CuL'(OH)^{+}][H^{+}]}{[CuL'^{2+}]} \quad (1)$$

where L' represents the neutral species of histamine.

The results given in Table 1 show that the equation does not hold, since the calculated values of pK_c^1 decrease with the increase in a value. The formation of a diolated binuclear complex might be expected with the dissociation of a proton from the complex CuL'^{2+}.[3,9] Thus the followiug reaction was assumed and the equilibrium constant pK_c^2 was calculated at each point.

$$2CuL'^{2+} \rightleftharpoons Cu_2L'_2(OH)_2^{2+} + 2H^{+}$$

$$K_c^2 = \frac{[Cu_2L_2'(OH)_2^{2+}][H^{+}]^2}{[CuL'^{2+}]^2} \quad (2)$$

The values of pK_c^2 (Table 1) remain constant irrespective of a values. In contrast, the values of pK_c^3, pK_c^4, and pK_c^5 which correspond to the formations of the trimer, tetramer, and pentamer respectively increase with the increase in a value in the region a= 2.1—2.7. This suggests the formation of a dimer with the deprotonation between a=2 and 3.

In the histidine-copper(II) 1 : 1 system, the complex precipitates immediately when the solution of KOH was added beyond a=2. The amount of precipitate increased with a value up to a=3, decreased gradually and then dissolved completely at a=4. Precipitation also occurred in the 3-benzylhistidine-copper(II) system, but in this case the precipitate did not dissolve at a=4. Due to precipitation titration data between a=2 and 3 in the histidine-copper(II) and 3-benzylhistidine-copper(II) systems were not interpretated quantitatively. In the 1 : 1 histidine-copper(II) and 1 : 1 histamine-copper(II) systems, pH in the region a=3—4 was lower than that in the systems of the ligand itself,[7] whereas in the 1 : 1 3-benzylhistidine-copper(II) system, no fall in pH was observed. The results suggest further deprotonation between a=3 and 4 in the former two systems. Similar falls of pH were also observed in the region a=2—3 in the 2 : 1 histidine-copper(II) and 2 : 1 histamine-copper(II) systems respectively.

Table 1. Quantitative analysis of the titration curve in the region a=2—3 in the 1:1 histamine-copper(II) system

a value	pH	pK_c^1	pK_c^2	pK_c^3	pK_c^4	pK_c^5

Visible Absorption Spectra. Spectral characteristics of the systems containing a ligand and copper(II) with the molar ratios of 1 : 1 and 2 : 1 are given in Table 2. Each a value corresponds to that in the titration. In the 1 : 1 histamine-copper(II) system, the spectrum at a=2 exhibited an absorption maximum at 665 nm (ε=38). Addition of equimolar KOH caused a significant blue shift (665 nm→615 nm). Addition of equimolar KOH caused another blue shift to show an absorption maximum at 590 nm. In the 1 : 1 histidine-copper(II) system, similar spectral changes were observed, although the spectrum of the solution at a=3 could not be measured owing to the precipitation. The spectrum at a=4 exhibited an absorption maximum at 605 nm. The spectra of the 1 : 1 3-benzylhistidine-copper(II) system in the region a=3—4 could not be measured owing to the precipitation. In the 2 : 1 histamine-copper(II) and 2 : 1 histidine-copper(II) systems, blue shifts were observed in the region a=2—3 by the addition of KOH. No spectral change was observed by the addition of KOH in the 2 : 1 3-benzylhistidine-copper(II) system.

The spectra of the 2 : 1 normal complexes of copper(II) with some related compounds of histidine are shown in Fig. 2, together with those of some 1 : 1 : 1 mixed ligand complexes of these ligands. The charac-

a) Complex precipitated. b) Molar absorptivity is expressed per gram atom of copper(II).

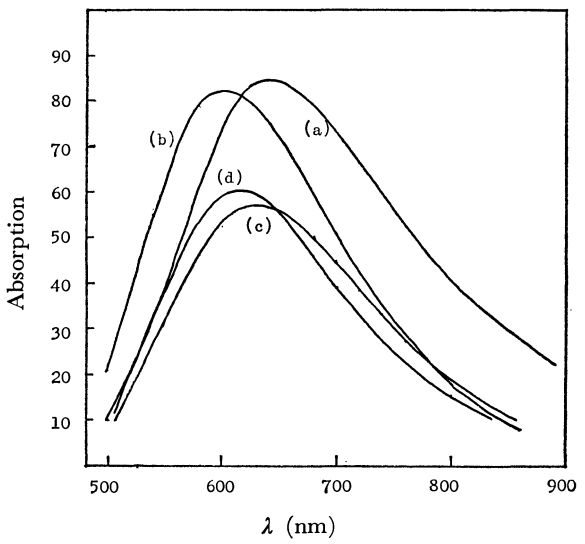

Fig. 2. Visible absorption spectra of normal 2 : 1 copper(II) complexes of histidine related compounds: (a) histidine, (b) histamine, (c) 1-methylhistidine, (d) histidine+1-methylhistidine (1 : 1): The absorbance is expressed on a molar copper(II) basis.

Table 3. Visible absorption characteristics of 2: 1 normal copper(II) complexes

	λ_{max} (nm)	ε_{max} ($cm^{-1}M^{-1}$)	$\Delta\lambda_{1/2}$ (nm)[a]
Histidine	640	84	250
3-Benzylhistidine	642	88	246
Histidylglycine	636	88	237
Histidine methyl ester	629	85	228
Histidine+Histamine (1: 1)	628	83	220
Histamine	601	82	200
1-Methylhistidine	628	57	193
Histidine+1-Methyl-histidine(1: 1)	615	60	194

a) $\Delta\lambda_{1/2}$ represents the width at the half-height of the spectra.

teristics of these spectra are given in Table 3. The molar absorptivities do not differ much from each other among the copper(II) complexes of histidine, 3-benzylhistidine, histidine methyl ester, histidylglycine and histamine. On the other hand, the molar absorptivities 2 : 1 1-methylhistidine-copper(III) and 1 : 1 : 1 1-methylhistidine-copper(II)-histidine complexes are smaller than the molar absorptivity of 2 : 1 histidine-copper (II) complex.

The order of the wavelength of the absorption maximum in the 2 : 1 complexes is : histamine histidine methyl ester, histidylglycine, histidine and 3-benzylhistidine (from shorter to longer wavelength). The width at the half-height of the spectral band increases in the same order. The broadening of the band was observed in the longer wavelength region than the absorption maximum.

Magnetic Moment. The molar susceptibilities and the magnetic moments of the copper(II) in the 1 : 1 ligand-copper(II) systems are shown in Table 4. The magnetic data at $a=3$ in the histidine-copper(II) and at $a=4$ in the histamine-copper(II) were not measured in aqueous solution owing to the precipitation. The magnetic moment decreases with the increase in a value in each system, but the values are always normal in the glycylglycine-copper(II) system. The subnormal values were obtained in the histamine-copper(II) and in the histidine-copper(II) systems when a values are 3 and 4, respectively. This suggests that antiferromagnetic interactions are present in these systems.

Table 4. Room temperature magnetic data on the copper(II) in the ligand-Cu(II) aqueous solutions

System	a value	$\chi_A \times 10^6$ c.g.s. units	T(K)	μ_{eff} (B.M.)

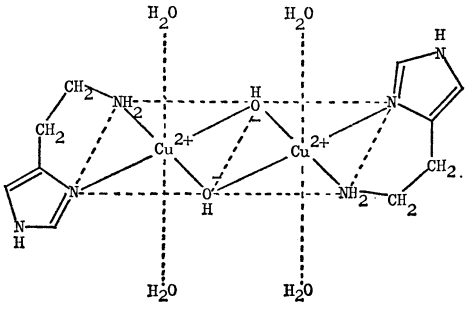
Discussion

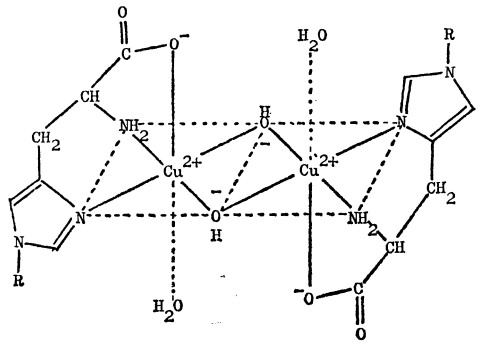
1 : 1 Hydroxo Complexes. Quantitative analysis of the titration data in the 1 : 1 histamine-copper(II) system suggests the formation of a dimer complex with the release of a proton in the region $a=2$—3. This conclusion is compatible with the results reported by Perrin and Sharma.[3,9] The source of the liberated proton is regarded as the coordinated water molecule and a dimer I is presumed to be formed by the olation between two molecules. The antiferromagnetic character of the 1 : 1 histamine-copper(II) system at



I, $Cu_2L_2'(OH)_2^{2+}$

$a=3$ is a strong evidence for the binuclear structure.[10] It is noteworthy that the formation of the diolated complex displaces the absorption maximum at a wavelength about 50 nm shorter than in the mother complex in spite of the lower position of OH^- than H_2O in the spectrochemical series.

Perrin and Sharma suggested from their quantitative analysis of the titration data that a monohydroxo complex CuL(OH), where L^- represents the anionic species of histidine, is a predominant species near $a=3$ in the 1 : 1 histidine-copper(II) system.[3] However, in the 1 : 1 histidine-copper(II) system, the titration data for the region $a=2$—3 can not be analysed quantitatively owing to precipitation, and there may be some uncertainty in their conclusion. The antiferromagnetic character of the 1 : 1 histidine-copper(II) complex at $a=4$ suggests the presence of the binuclear hydroxo complex $Cu_2L_2(OH)_2$ similar to that in the case of 1 : 1 histamine-copper(II) complex. The probable structure for the 1 : 1 histidine-copper(II) complex is shown to be II. The same diolated complex will

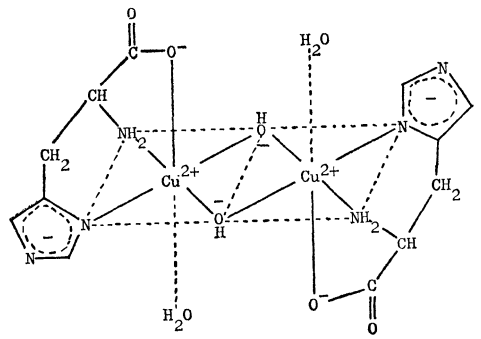


II, $Cu_2L_2(OH)_2$ R=H : histidine

R=CH_2- : 3-benzylhistidine

also be formed in the 1 : 1 3-benzylhistidine-copper(II) system. The steric requirement of the bulky imidazole group is presumed to promote the formation of the binuclear complexes in these systems.[11,12]

The dissolution of the 1 : 1 histidine-copper(II) complex accompanied by deprotonation between $a=3$ and 4 suggests the formation of an anionic complex $Cu_2X_2(OH)_2^{2-}$, where $XH^-=L^-$. The evidence that the source of this proton is imino group of the imidazole ring is given by the fact that no similar behavior was observed in the 3-benzylhistidine-copper(II) system. The structure of the 1 : 1 histidine-copper(II) anionic



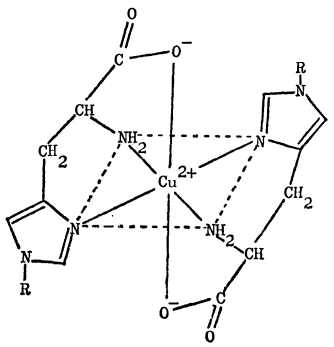
III, $Cu_2X_2(OH)_2^{2-}$

complex is shown by III. Similarly, further deprotonation accompanied by a conspicuous blue shift in absorption spectra for the region $a=3$—4 in the 1 : 1 histamine-copper(II) system suggests the dissociation of the proton from the imino group of imidazole giving a neutral complex $Cu_2X_2'(OH)_2$, where X'H=L'.

The absorption at longer wavelength at $a=4$ in the 1 : 1 histidine-copper(II) complex than in the 1 : 1 histamine-copper(II) complex can be ascribed to the relaxation of the tetragonal distortion due to the apical coordination of the carboxyl groups.[13]

2 : 1 *Complexes.* For the neutral 2 : 1 histidine-copper(II) complex, the following possibilities are taken into account for the group which occupies the four coordination positions in the copper(II) plane. (a) Two histidine molecules bind to copper(II) with the amino and imidazole groups(histamine type).[1,3,5,6,14-18] (b) Two histidine molecules bind to copper(II) with the amino and carboxyl groups (glycine type).[19-21] (c) One histidine molecule coordinates with copper(II) as in the case of histamine, and another as in the case of glycine(mixed type).[22,23]

The larger molar absorptivity of the 2 : 1 histidine-copper(II) complex than in 2 : 1 1-methylhistidine-copper(II) and 1 : 1 : 1 1-methylhistidine-copper(II)-histidine complexes suggests that the coordination is neither a glycine nor a mixed type. Possibility (a) can be accepted in view of the similarity in the molar absorptivities between the 2 : 1 complexes of histidine, 3-benzylhistidine, histidylglycine, histidine methyl ester, and histamine. The presence of the two six-membered chelate ring composed of the amino and imidazole groups in the copper(II) plane seems to give a similar absorptivity. The order of the wavelength of the absorption maximum and that of the increase of the width of the spectral band in these 2 : 1 copper(II) complexes seem to reflect the extent of tetragonal distortion of the copper(II) complexes,[13] since these orders are in agreement with the order of strength of apical coordination among the coordination groups, *viz.*, $-COO^- > \rangle C{=}O > H_2O$. This provides an evidence for apical coordination of the carboxyl group in the histidine-copper(II) and 3-benzylhistidine-copper(II) complexes. A smaller tetragonal distortion of the 2 : 1 histidine-copper(II) complex than in the 1 : 1 : 1 histamine-copper(II)-histidine complex sug-



IV, CuL_2

R=H : histidine

R=CH_2- : 3-benzylhistidine

gests that both carboxyl groups coordinate to copper(II) at apical position in the former, as shown by IV.

Further deprotonation accompanied by the blue shift in the absorption spectra in the range $a=2$—3 in the 2 : 1 histamine-copper(II) and histidine-copper(II) systems, also indicates the ionization of the imino group. No deprotonation and the spectral shift in the 2 : 1 3-benzylhistidine-copper(II) system in the same condition support the conclusion. The relatively easier ionization of the imino group in the 1 : 1 and 2 : 1 copper(II) complexes of histidine and histamine would be due to the electron-withdrawing effect of copper(II) which binds to the pyridine type nitrogen.

The authors wish to express their thanks to Professer M. Kishita and Dr. W. Mori, Osaka University, for their helpful advice in magnetic measurements, and to the staff of the Kyoto University Computer Center for the use of FACOM 203—60 Computer.

Cyclization Reactions of 1,2-Bis(2-cyanophenyl)propionitriles. I. Structure of the "Red Pigment" formed by the Base-catalyzed Cyclization of 1,2-Bis(2-cyano-3-methoxyphenyl)propionitrile in the Presence of Diethyl Carbonate[1]

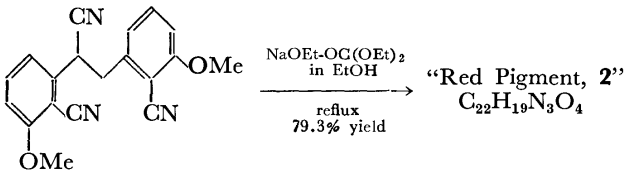
Kazuo ANDO, Takashi TOKORO YAMA, and Takashi KUBOTA*

Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received September 7, 1973)

The reaction of 1,2-bis(2-cyano-3-methoxyphenyl)propionitrile (**1**) with diethyl carbonate and sodium ethoxide gave a red pigment **2**, $C_{22}H_{19}N_3O_4$ in 79% yield. It afforded 5-amino-4,7-dimethoxy-11*H*-indeno[1,2-*c*]-isoquinolin-11-one (**4**) on treatment with alkaline hydrogen peroxide. The "red pigment" has been confirmed to have a novel 5*H*-indeno[1,2-*c*]isoquinoline structure which transforms into colorless 11*H*-indeno-[1,2-*c*]-isoquinoline form in an acidic medium. The mechanism of the formation of **2** from **1** imparts an interesting problem as regards carbanion reactivity.

In the course of synthetic studies[1,2] of compounds related to sclerin, a plant growth hormone,[3] we happened to treat 1,2-bis(2-cyano-3-methoxyphenyl)propionitrile (**1**) with diethyl carbonate and sodium ethoxide in ethanol solution at refluxing temperature. When the brownish black reaction mixture was poured into ice-water, a red pigment **2** was obtained in 79% yield. The reaction was found to be reproducible. This led us to study the structure of **2** and investigate this reaction. In this paper we deal with the structure elucidation of **2**.



Scheme 1

The red pigment **2**, $C_{22}H_{19}N_3O_4$, is slightly soluble in chloroform and dichloromethane, and practically insoluble in other common organic solvents. It is easily soluble in strong acids such as trifluoroacetic acid or ethanolic hydrochloric acid giving a yellow solution with strong blue fluorescence. When this solution was neutralized or diluted with a large amount of water, **2** was recovered, indicating that compound **2** is a weak base. **2** is also soluble in sodium hydroxide, indicating it to be amphoteric in nature. The infrared spectrum indicates the presence of an imino or a hydroxyl group (3340 cm^{-1}), a cyano group (2166 cm^{-1}) and a carbonyl group (1705 cm^{-1}) in **2**. The imino or the hydroxyl group in **2** was found to be inactive on acetylation. It should be noted that the band due to a cyano group appears at unusually low frequency, compared to the normal range 2260—2210 cm^{-1}.[4] Because of the lack of a suitable neutral solvent, the NMR spectrum of **2** was taken in trifluoroacetic acid solution, showing the signals due to an ethoxy group, two methoxy groups and six aromatic protons. An additional signal was observed at δ 5.61 (1H). This could be tentatively assigned to be the methine proton which has a strongly deshielding environment. The results in conjunction with the molecular composition of **2** suggest that **2** is formed from **1** through a complex intramolecular cyclization, incorporating one mole of diethyl carbonate.

Upon alkaline hydrolysis under exlcusion of oxygen and the following treatment with dilute hydrochloric acid, **2** afforded a pale yellow amine hydrochloride **3**, $C_{19}H_{16}N_3O_2Cl$: ν_{max} 3300, 3080—2760 ($-NH_3^+$) and 2245 cm^{-1} (–CN); δ 4.13 ($-OCH_3$), 4.34 ($-OCH_3$) and 5.30 (1H). The IR and NMR spectra of **3** indicate that **3** is the amine hydrochloride formed by hydrolytic cleavage of the carbethoxyamide group originally present in **2**. The transformation of the cyano group in **2** was carried out using alkaline hydrogen peroxide in aqueous ethanol at 55 °C. The product **4** obtained in 92.5% yield exhibited absorption bands at 3460 3280, 3170 and 1670 cm^{-1} in the IR region, showing no band due to the cyano group. The NMR spectrum of **4** showed signals due to two methoxy groups and six aromatic protons, no signals due to ethoxy and groups being observed. In contrast to **2**, **4** was sufficiently basic to give the hydrochloride **5** and monoacetate **6**. The orange-red colored acetate **6** exhibited a UV spectrum similar to that of **4**. The peak in the IR spectrum of **6** were observed at 3330 and 1675 cm^{-1}. From the analytical values for **5** and **6**, **4** was concluded to have a molecular formula of $C_{18}H_{14}N_2O_3$ although the combustion analyses did not give a satisfactory result. This indicates that **4** is not a product of mere hydrolysis but a degraded product with the loss of one carbon, most probably corresponding to the cyano group in **2**. The formation of **5** and **6**, and the band at 3330 cm^{-1} in the IR spectrum of **6** suggest the presence of a primary amino group in **4**, though this compound is resistant to the diazotization reaction. Treatment of **4** with 6 M aqueous ethanolic potassium hydroxide solution under refluxing yielded an orange-red colored product **7**, $C_{18}H_{13}NO_4$, which no longer basic and showed IR peaks at 3380, 1690 and 1665 cm^{-1}, suggesting the presence of a lactam and an additional carbonyl group. Methylation of **7** with sodium methoxide and methyl iodide produced a monomethylation product **8**. The UV spectrum of **8** was similar to that of the strating material **7**. In the IR spectrum of **8**, the NH stretching band present in **7**

7 R=H
8 R=Me

disappeared and the carbonyl frequency was found at 1670 cm^{-1}. Three methyl singlets appeared at δ 3.92, 3.99 and 4.04 in the NMR spectrum. Thus the nitrogen atom of the lactam grouping in **7** is methylated in **8**. The only possible formula for **7**, in line with the above evidence would be **7a** or **7b**, provided that no rearrangement invoving carbon-carbon bonds occurs during the derivation of **7**. The parent compounds this ring system, 5,6-dihydro-11*H*-indeno[1,2-*c*]isoquinoline-5,11-dione (**9**), has been reported to be orange-red colored crystals but no description was of the electronic spectral data.[5] The choice **7a** or **7b** was possible by the consideration of the NH stretching band in **7**. This band was observed as a sharp peak at 3380 cm^{-1} in contrast to that of **9** as a broad band at 3226—2700 cm^{-1}. This would be interpreted by assuming that the intermolecular hydrogen bond existing in **9** becomes difficult in **7** owing to steric hindrance. Thus **7a** turned out to be the more acceptable structure for **7**. Accordingly formula **8** was assigned to the methylation product. In order to verify the structure for **7**, the reduction of the conjugated cyclopentanone group was investigated by treating with zinc dust in refluxing aqueous acetic acid. Two colorless products, **10**, $C_{18}H_{15}NO_3$ and **11**, $C_{18}H_{15}NO_4$ were obtained. When the reduction was carried out with glacial acetic acid, **10** was formed in a good yield. The UV spectra of of **10** and **11** were similar, indicating the presence of the same conjugated system in both products. The former shows the IR peaks at 3420 and 1650 cm^{-1} (lactam group), and NMR signals at δ 3.74 (>CH_2). Thus in **10** the ketonic group of **7** has been transformed into a methylene group. On the other hand **11** is found to be the product in which the ketonic group in **7** was reduced to a hydroxyl group, showing the IR peaks at 3420 (sh., -OH), 3380 (-NH) and 1654 cm^{-1} (-NHCO-). On the basis of the established structure for **7**, three formulas **4**, **4a** and **4b** are taken for the precursor **4**. When **4** was treated with zinc in glacial acetic acid in the same way as for **7**, the reduction product **12**, $C_{18}H_{16}N_2O_2$, was obtained in 70.5% yield. The IR spectrum of **12** revealed the disappearance of the carbonyl group in **4** and the NMR spectrum indicated the formation of the methylene group in **12**. Production of **12** from **4** is compatible only with the assignment of structure **4** for the latter and hence the formula for the reduction product **12**, the hydrochloride **5** and the acetylation product **6** are depicted as shown.

The disclosure of the structure for **4**[6] allows us to discuss the constitution of the "red pigment" **2**. The UV spectrum of the amine hydrochloride **3** closely resembles that of 5-amino-4,7-dimethoxy-11*H*-indeno[1,2-*c*]isoquinoline (**12**), a reduction product of **4** (Fig. 1), indicating the presence of the same chromophore in both compounds. Thus the only position available for the attachment of the cyano group in **3** would be the C-11 of 11*H*-indeno[1,2-*c*]isoquinoline nucleus, suggesting the structure **3** for the hydrochloride. When **3** was catalytically hydrogenated in the presence of palladium-on-charcoal in acetic acid containing hydrochloric acid, two products were obtained (Scheme 2). One product **13**, $C_{19}H_{18}N_2O_2$, was separated easily

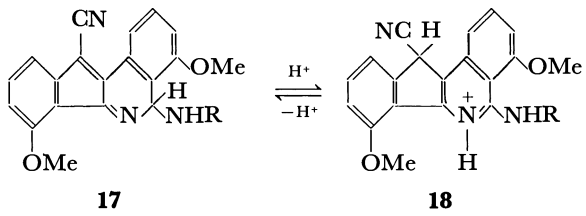
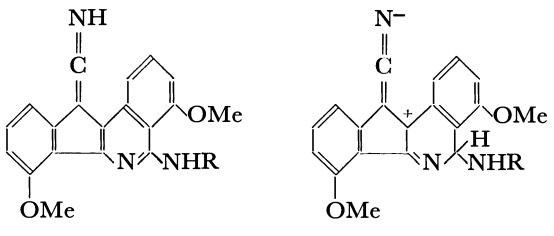
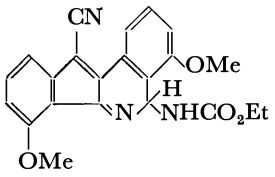


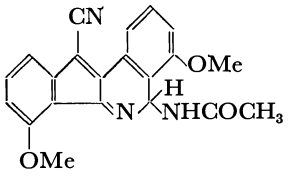
Scheme 3

from the other by treatment as hydrochloride with chloroform since only the former was soluble in this solvent. In the IR spectrum of **13** the band due to the cyano group in **3** has disappeared. A marked feature in the NMR spectrum of **13** is the appearance of the signals due to a secondary methyl groups. The UV spectrum of **13** resembles closely that of **3** and **12** (Fig. 1). This indicates that the secondary cyano group in **3** was transformed into a methyl group during the course of hydrogenation, confirming the position of the cyano group in the indenoisoquinoline skeleton of **3**. Another product obtained as an oil shows the absorption bands at 3460 and 3360 cm^{-1} in the IR spectrum. Insolubility of its hydrochloride in chloroform suggests that it could be the diamine **14** an intermediate product to **13**. Hydrogenation of **2** in the same way as **3** gives rise to the secondary aldehyde **15** though this compound could not be obtained in a pure state. Upon acetylation with acetic anhydride and concd. sulfuric acid, the hydrochloride **3** yielded a red colored acetate **16**. The UV spectrum of **16** resembles markedly that of the "red pigment" **2** (Fig. 2). This indicates that **2** and **16** have a common structure except for the acyl substituents on the primary amino group. For the sake of explanation it would be reasonable to assume that **2** and **16** have an iminoindene structure **17** which is transformed into colorless indenoisoquinoline skeleton **18** on salt formation with an acid. Thus the coloration in **2** and also in **16** is understandable.[7] In this respect the ketimine form **19** might also be taken into consideration.[8] In the IR spectrum of **2** a strong absorption band is observed at 2166 cm^{-1}, which is considerably out of the normal range for the cyano group. Although available data for the IR absorption of ketimines are very much limited, this structure appears to have the absorption band at 2040—2000 cm^{-1}.[9,10] Thus the IR peak of **2** in question would be in favor of a cyano group (conjugated). The chemical stability of the responsible group in **2** on addition reactions[9-13] precludes the ketimine structure.[14] The unusual lowering of the cyano frequency could be attributed to the contribution of the canonical formula like **20**.[15] The low-field singlets in the NMR spectra of **2** and **16** (δ 5.61 and 5.53 respectively) in the acidic conditions are assigned to the methine protons attached to the carbon atoms bearing cyano groups in the indenoisoquinoline structures. The solubility of **2** in alkali to form a light yellow solution with fluorescence is explainable by the formation of the anion **21**. In order to obtain the free amine, **3** was treated with ammonia to afford a product **22**, which has a somewhat dim red color compared to that of **2**. In the IR spectrum **22** exhibits broad bands due to the amino group at 3440 and 3300 cm^{-1} and a strong absorption due to cyano group at 2160 cm^{-1}. The product is presumed to be a tautomeric mixture of the iminoindeno derivative **22a** and the indenoisoquinoline compound **22b**. Fur-

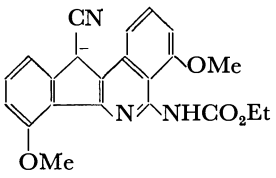




2



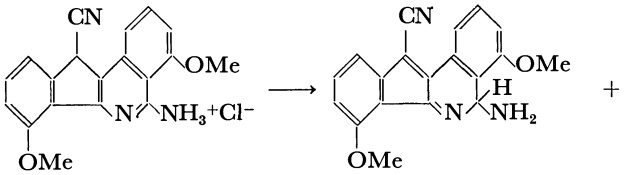
16



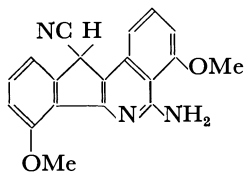
21

ther characterization was difficult since it was quite unstable in the air and converted into the same oxidation product **4** obtained from **2**.

The easy oxidative degradation of **2** by treatment with alkaline hydrogen peroxide to form **4** should be noted in terms of the established formula for **2**. In this connection Happ *et al.*[16] have reported that *N*-methyl-9-cyanoacridane **23** is oxidized by molecular oxygen in alkaline medium to afford *N*-methylacridone **24** with

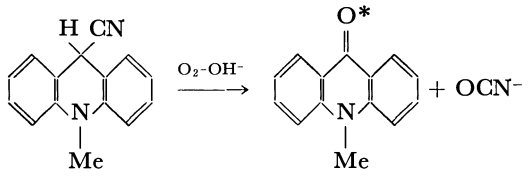


3 22a



22b

Scheme 4



23 24

Scheme 5

chemiluminescence in which a carbanion electron transfer mechanism involving *N*-methyl-9-cyanoacridanyl radical is postulated. The reactions of **2** might proceed in the manner depicted in Scheme 6. The autoxidation of the free amine **22** to **4** could be interpreted similarly.

To our best knowledge, the 5*H*-indeno[1,2-*c*]isoquinoline system is a novel heterocycle. The relative stability of the iminoindene ring system in **2** over the tautomeric indenoisoquinoline would be a subject of interest in view of structural organic chemistry.[7]

Formation of the "red pigment" **2** from **1** provides a fascinating problem also from the side of the reaction mechanism. In the first sight the base-catalyzed reaction of **1** would be anticipated to proceed *via* a Thorp type path initiated by the anion **25**, produced by the removal of the most acidic hydrogen in **1**.[17] However the formation of **2** is accounted for only by the assumption of the path including the anion **26** (Scheme 7). The cyclization of **26** would take place involving the two cyano groups to afford the intermediate **27**, which is transformed into **2** by the redistribution of the double bonds. The reason why **26** mainly participates in the reaction instead of **25** seems to deserve further scrutiny.

Melting points were uncorrected. The IR spectra were measured, unless specified, on Nujol mull on a Nippon Bunko IR-S spectrometer and the electronic spectra on a Hitachi EPS-2 spectrometer. Chemical shifts are reported in δ-values, using TMS as internal references.

Formation Reaction of the Red Pigment 2. A solution of sodium ethoxide in ethanol (prepared from 600 mg of sodium and 11 ml of abs. ethanol) was added to a mixture of 1,2-bis-(2-cyano-3-methoxyphenyl)propionitrile (**1**)[2] (3.6 g) and diethyl carbonate (26 ml) under stirring, and the mixture was refluxed for 2 hr. The reacting solution rapidly turned brownish black. The mixture was poured onto ice-water, providing **2** as red precipitate. Dilute acid may be added when necessary for the completion of precipitation. Recrystallization from chloroform afforded pure **2** as needles, mp 272 °C (dec.), 3.5 g (79.3% yield): λ_{max}^{EtOH} 249 (ε 37900), 283 (27100), 325 (18200), 387 (17100) and 528 nm (5200); ν_{max} 3340 (-NH), 2166(strong, -CN) and 1705 cm^{-1} (-$NHCO_2R$); $\delta(CF_3CO_2H)$, 1.57(3H, t, J=7.5 Hz, -OCH_2-CH_3), 4.33 (3H, s, -OCH_3), 4.42(3H, s, -OCH_3), 4.76(2H, q, J=7.5 Hz, -OCH_2CH_3), and 5.61(1H, s, >CH). Found: C, 67.88; H, 5.04; N, 10.76%. Calcd for $C_{22}H_{19}N_3O_4$: C, 67.85; H, 4.92; N, 10.79%.

Alkaline Hydrolysis of the Red Pigment 2. A mixture of **2** (300 mg) with sodium hydroxide (630 mg), water (12 ml) and ethanol (12 ml) was refluxed under nitrogen atmosphere for 3 hr. After cooling the reaction mixture was acidified with dil. hydrochloric acid. The solution, initially yellow, temporarily yielded a red precipitate which redissolved itself and then finally produced a white precipitate. This was filtered and washed with small amount of ethanol to afford almost pure **2**, 237 mg (87.2% yield). The analytical specimen was recrystallized from methanol: mp 249 °C (dec.); $\lambda_{max}^{H_2SO_4\text{-}EtOH}$ 220(ε 32500), 239(sh., 17400), 263(19600), 287(sh., 7050), 332(sh., 10300), 344(13200), 380(16300) and 398 nm(1500); ν_{max} 3300, 3080—2760(-NH_3^+) and 2245 cm^{-1} (-CN); $\delta(CF_3CO_2H)$, 4.13(3H, s, -OCH_3), 4.34(3H, -OCH_3), 5.30(1H, s, >CH), and 7.20—8.27(6H, m, ArH). Found: C, 64.15; H, 4.76; N, 11.72%. Calcd for $C_{19}H_{16}N_3O_2Cl$: C, 64.50; H, 4.56; N, 11.88%.

Oxidative Degradation of the Red Pigment 2 with Alkaline Hydrogen Peroxide. Hydrogen peroxide (3%) (100 ml) was added to a solution of **2**(980 mg) in ethanol (200 ml) and 10% aq. sodium hydroxide solution (10 ml) under stirring for 15 min. The reaction mixture gradually turned red and finnally gave a red precipitate, mp 288 °C(dec.), 750 mg (92.5% yield). Recrystallization from chloroform provided pure **4**, mp 289—290 °C; $\lambda_{max}^{dioxane}$ 224.5 (ε 22300), 235 (sh., 19000), 290(29700), 350(19600), 364(sh., 10800), 375 (sh., 6880), and 470 nm(3310); ν_{max} 3460, 3280, 3170 (-NH_2), and 1670 cm^{-1} (>CO); $\delta(CF_3CO_2H)$, 3.65(3H, s, -OCH_3), 3.79(3H, s, -OCH_3), and 6.72—7.94(6H, m, ArH). *Hydrochloride* **5** was prepared by stirrring a mixture of **4** (30 mg), ethanol (50 ml) and concd. hydrochloric acid (5 ml). Evaporation of the mixture to dryness and recrystallization of the residue from ethanol yielded **5**, mp 300 °C (dec.); ν_{max} 3320, 3000 (-NH_3^+), and 1705 cm^{-1} (>CO). Found: C, 63.15; H, 4.50; N, 8.16%. Calcd for $C_{18}H_{15}N_2O_3Cl$: C, 63.07; H, 4.41; N, 8.17%. Acetylation of **4** (187 mg) with acetic anhydride (50 mg) and anhyd. pyridine (25 ml) was carried out overnight at room temperature. The resulting orange red precipite (128 mg) was filtered and washed with ethanol. Recrystallization from chloroform afforded *the acetate* **6**, mp 270—273 °C; λ_{max}^{EtOH} 222(ε 21500), 275(33900), 355(19500), 368(sh., 12300), 380(sh., 6650), and 485 nm (2850); ν_{max} 3330(-NH) and 1675(-NHCO- and >CO) cm^{-1}; $\delta(CF_3CO_2H)$, 2.72(3H, s, -$COCH_3$), 4.25(3H, s, -OCH_3), 4.35(3H, s, -OCH_3), and 7.23—8.13 (6H, m, ArH).

Alkaline Hydrolysis of 4. A mixture of **4**(2.0 g), 6M potassium hydroxide solution(300 ml) and ethanol (360 ml) was refluxed for 20 hr, and filtered while hot. The filtrate, after concentration *in vacuo*, was acidified with hydrochloric acid to give almost pure **7** as a red precipitate (1.65 g, 82.% yield), which was recrystallized from ethanol: mp 295.5 °C; λ_{max}^{EtOH} 235(ε 26600), 269(33300), 291(19600), 353(18500), 372(sh., 13100), and 475 nm(3270); ν_{max} 3380 (sharp, -NH), 1690(CO), and 1665 cm^{-1} (-CONH-); $\delta(CF_3CO_2H)$, 4.16 (3H, s, -OCH_3), 4.36(3H, s, -OCH_3) and 7.26—9.00(6H, m, ArH). Found: C, 70.35; H, 4.24; N, 4.53%. Calcd for $C_{18}H_{13}NO_4$: C, 70.35; H, 4.26; N, 4.56%.

Methylation of 7. Sodium methoxide (4.05 g) and methyl iodide (5.1 ml) was alternatively added in three portions to a refluxing solution of **7** (150 mg) in abs. methanol (300 ml) for two days. After removal of most of the solvent, water was added. The red precipitate (200 mg) thus obtained was chromatographed on a column of silica gel (5 g) and the methylated product **8** (128 mg) was isolated from the chloroform eluate in 81.5% yield. Recrystallization from chloroform provided pure **8**, mp 241—242 °C; λ_{max}^{EtOH} 237 (ε 21800), 272(28900), 293(sh., 18200), 355(19500), 374 (sh., 11600) and 485 nm(1490); ν_{max} 1670 cm^{-1} (-CON< and >CO); $\delta(CDCl_3)$, 3.92, 3.99, 4.04(each 3H, s, -OCH_3) and 6.85—8.50(6H, m, ArH). Found: C, 71.06; H, 4.75; N, 4.35%. Calcd for $C_{19}H_{15}NO_4$: C, 71.02; H, 4.71; N, 4.36%.

Zinc Dust Reduction of 7. *a) In Aqeous Acetic Acid*: A mixture of **7**(1.05 g), glacial acetic acid (400 ml), water (15 ml) and zinc dust (2.1 g) was refluxed for 1.5 hr. The reaction mixture was filtered. After concentration *in vacuo*, water (700 ml) was added. The resulting white precipitate (940 mg) was chromatographed on a column of silica gel (30 g). Elution with chloroform yielded 5,6-dihydro-4,7-dimethoxy-11*H*-indeno[1,2-*c*]isoquinolin-5-one (**10**) (306 mg) and subsequent elution with 2% methanol-chloroform gave 5,6-dihydro-11-hydroxy-4,7-dimethoxy-11*H*-indeno[1,2-*c*]isoquinolin-5-one (**11**) (286 mg). **10**(from methanol), mp 275—276 °C; λ_{max}^{EtOH} 215(ε 33900), 255(21200), 274(sh., 5920), 305(sh., 5380), 325(sh., 11200), 353(14300), 369(19700) and 388 nm(16700); ν_{max} 3420(>NH) and 1650 cm^{-1}(-CONH-); $\delta(CDCl_3)$, 3.74(2H, s, $>CH_2$), 3.80(3H, s, -OCH_3) and 3.82 (3H, s, -OCH_3). Found: C, 73.57; H, 5.21; N, 4.78%. Calcd for $C_{18}H_{15}NO_3$: C, 73.70; H, 5.15; N, 4.78%. **11** (from chloroform-methanol): mp 249—250 °C(dec.); λ_{max}^{EtOH} 217(ε 26200), 258(22000), 278(sh., 5300), 312(sh., 3440),

358(14500), 376(19100) and 396 nm (16700); ν_{max} 3420(sh., -OH), 3380(>NH) and 1654 cm^{-1}(-NHCO-). Found: C, 69.46; H, 4.95; N, 4.52%. Calcd for $C_{18}H_{15}NO_4$: C, 69.89; H, 4.89; N, 4.53%.

b) In Glacial Acetic Acid: A mixture of **7**(140 mg), zinc dust (560 mg) and glacial acetic acid (14 ml) was refluxed for 30 min. After working up as above, only **10** (110 mg) was obtained in 82% yield.

Zinc Dust Reduction of 4. **4**(270 mg), zinc dust (550 mg) and glacial acetic acid (10 ml) were mixed and refluxed for 2 hr. The insoluble material was removed by filtration. Water (10 ml) was added to the filtrate, which was then made basic by the addition of ammonia solution under ice-cooling. The precipitate, mp 218—221 °C(dec.) (182 mg, 70.5% yield) was recrystallized from methanol to give pure 5-amino-4,7-dimethoxy-11*H*-indeno[1,2-*c*]isoquinoline **12**, mp 229—230 °C(dec.); $\lambda_{max}^{H_2SO_4}$ 220(ε 36900), 239(sh., 17600), 259 (21300), 289(6960), 328(13500), 342(16200), 386(17600)and 405 nm(16500); ν_{max} 3500 and 3370 cm^{-1} (each $-NH_2$); $\delta(CF_3CO_2H)$, 3.75(2H, s, $>CH_2$), 4.03(3H, s, $-OCH_3$) and 4.13(3H, s, $-OCH_3$). Found: C, 73.73; H, 5.63; N, 9.35%. Calcd for $C_{18}H_{16}N_2O_2$: C, 73.95; H, 5.52; N, 9.58%.

Ammonia Treatment of the Hydrochloride 3. When an aq. solution of 3 (72 mg) was neutralized by dropwise addition of ammonia, red precipitate **22** (52 mg), not as vivid in color as the "red pigment" was obtained. ν_{max} 3440, 3300(broad) and 2160 cm^{-1}. However, attempts to purify **22** failed since it was so unstable that it changed completely to **4** within a few days on standing in air.

Catalytic Hydrogenation of the Hydrochloride 3. A solution of the hydrochloride **3** (100 mg) in acetic acid (8 ml) was stirred for 18 hr under hydrogen atmosphere with 10% palladium-on-charcoal (150 mg) and 2M HCl (8 ml), until the starting material was consumed completely. After the removal of the catalyst by filtration, the filtrate was diluted with water and the product was extracted three times with chloroform. The organic layer was treated with ammonia. After being washed with water and dried, the solvent was evaporated to leave an oil (30 mg) which was crystallized from methanol to afford **13**, mp 189—190 °C; $\lambda_{max}^{H_2SO_4\text{-EtOH}}$ 221(ε 36600), 239(sh., 17100), 260(20500), 289 (7230), 328(13400), 387(17100) and 406 nm(16700); $\nu_{max}^{CHCl_3}$ 3460 and 3360; ν_{max}^{Nujol} 3544 and 3408 cm^{-1}; $\delta(CDCl_3)$, 1.52 (3H, d, J=7 Hz, $>CHCH_3$), 3.93(3H, s, $-OCH_3$), 3.99(1H, q, J=7 Hz, $>CHCH_3$), 4.00(3H, s, $-OCH_3$) and 6.63—7.63 (6H, m ArH). Found: C, 74.19; H, 5.93; N, 9.08%. Calcd for $C_{19}H_{18}N_2O_2$: C, 74.49; H, 5.92; N, 9.15%. The aq. layer was made alkaline by the addition of ammonia and extracted with chloroform. The evaporation of the solvent gave **14** as an oil. $\nu_{max}^{CHCl_3}$ 3460 and 3360 cm^{-1}.

Catalytic Hygrogenation of the "Red Pigment" 2. A solution of **2** (100 mg) in acetic acid (3 ml) and 1 M HCl (2 ml) was hydrogenated over 10% palladized charcoal (60 mg) for 24 hr at room temperature. After removal of the catalyst by filtration, the filtrate was treated with ammonia. The resulting precipitate (80 mg) was crystallized from chloroform to give a red colored product **15** (18 mg), mp 208 °C (dec.); ν_{max}^{Nujol} 3340 (>NH) and 1710 cm^{-1} (>CO); $\delta(CF_3CO_2H)$, 1.54(3H, t, J=7 Hz), 4.24(3H, s), 4.32(3H, s), 4.64(2H, q, J=7 Hz), 5.34(1H, d, J=3 Hz), 6.68—8.16 (6H, m) and 9.42(1H, d, J=3 Hz). The compound was contaminated with another product as revealed by the presence of smaller signals in the NMR spectrum of δ 1.57 (t, J=7 Hz), 4.06(s), 4.34(s) and 4.60(q, J=7 Hz). Attempts to separate both compounds were unsuccessful.

Acetylation of the Hydrochloride 3. To a mixture of **3** (190 mg) and acetic anhydride (15 ml) was added five drops of concd. H_2SO_4 and the total mixture was swirled until an homogeneous yellow solution was obtained. After being left to stand at room temperature overnight, the mixture was poured onto ice-water (200 g) and the resulting red precipitate was recrystallized from chloroform to yield the acetate **16**, mp 292—293 °C(dec.), 120 mg (62.2% yield): λ_{max}^{EtOH} 217(ε 23800), 250(36200), 279(sh., 24300), 286(25400), 325(15300), 384(17100) and 520 nm(4480); λ_{max}^{Nujol} 3300, 2165 and 1680 cm^{-1}; $\delta(CF_3CO_2H)$, 2.73(3H, s, $-COCH_3$), 4.27(3H, s, $-OCH_3$), 4.37(3H, s, $-OCH_3$), 5.53(1H, s, >CH) and 7.20—8.40(6H, m, ArH). Found: C, 69.84; H, 4.86; N, 11.77%. Calcd for $C_{21}H_{17}N_3O_3$: C, 70.18; H, 4.77; N, 11.69%.

17) We have found that cyclization by way of this path does also occur but to a lesser extent and this subject will be dealed with in the forthcoming publications.

Cyclization Reactions of 1,2-Bis(2-cyanophenyl)propionitriles. II. Synthesis of 5-Amino-4,7-dimethoxy-11*H*-indeno[1,2-*c*]isoquinolin-11-one[1)]

Kazuo ANDO, Takashi TOKOROYAMA, and Takashi KUBOTA*

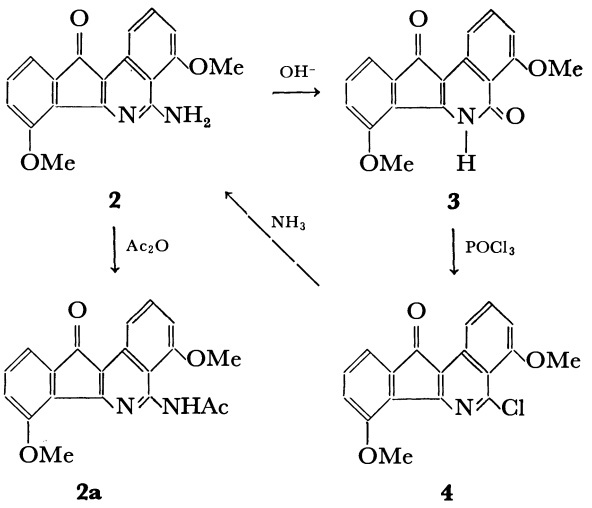
Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received September 7, 1973)

The structure of 5-amino-4,7-dimethoxy-11*H*-indeno-[1,2-*c*]isoquinolin-11-one (**2**) derived by the degradation of the "red pigment" has been confirmed by synthesis. 5,6-Dihydro-4,7-dimethoxy-11*H*-indeno[1,2-*c*]-isoquinoline-5,11-dione (**3**) obtained from **2** was used as a relay compound. This was first converted into **2** by chlorination with phosphorus oxychloride and treatment with ammonia. Subsequently **3** was synthesized from 2-(2-carboxy-3-methoxyphenyl)-4-methoxyindane-1,3-dione (**13**) *via* 4,7-dimethoxy-11*H*-indeno[1,2-*c*]isocoumarin-11-one (**12**).

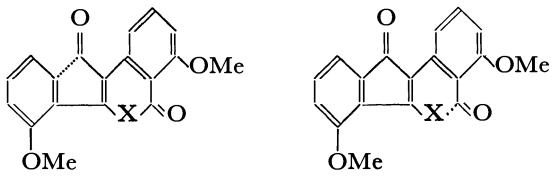
In a previous paper[1)] it was reported that a red pigment **1**, $C_{22}H_{19}N_3O_4$ is obtained in a good yield by the base catalyzed cyclization of 1,2-bis(2-cyano-3-methoxyphenyl)propionitrile in the presence of diethyl carbonate, and its treatment with alkaline hydrogen peroxide leads to the formation of an oxidation product, $C_{18}H_{14}N_2O_3$. We have deduced the structure 5-amino-4,7-dimethoxy-11*H*-indeno-[1,2-*c*]isoquinolin-11-one (**2**) for this compound from spectral and chemical evidences. The crucial role of this assignment in the structure elucidation of **1** led us to confirm the structure of **2** unequivocally by synthesis.

For the synthetic route to **2** it would be reasonable to pass through 5,6-dihydro-4,7-dimethoxy-11*H*-indeno-[1,2-*c*]isoquinoline-5,11-dione (**3**), obtained from **2** by alkaline hydrolysis. Partial synthesis of **2** from **3** was studied first. Treatment of **3** with phosphorus oxychloride at refluxing temperature provided an orange-red colored substance **4**. Since its infrared spectrum revealed the disappearance of the lactam group in **3** and the retainment of the indenone carbonyl group (1705 cm^{-1}), **4** was proved to be the expected chloride, 5-chloro-4,7-dimethoxy-1*H*-indeno[1,2-*c*]isoquinolin-11-one. This was heated with ammonia in ethanol in a sealed tube at 150 °C for 14 hr. The product thus obtained was identified as **3** and the divided acetate as **2a** by comparison of their infrared spectra with those of authentic specimens, mixed thin layer chromatography and mixed melting point determination. These transformations met our first aim and at the same time verified the presumed structural relationship between **2** and **3**.[1)]



Scheme 1

In principle two ways of ring closure as depicted in **5a** and **5b** are conceivable for the construction of 5,6-dihydro-11*H*-indeno[1,2-*c*]isoquinoline-5,11-dione (**5**, X=NH) or 5,6-dihydro-11*H*-indeno[1,2-c]isocoumarin-11-one (**5**, X=O) system. The latter system is convertible to the former by treatment with ammonia.[2)]



Since 4-carboxy-8-methoxy-3-(2-methoxyphenyl)isocarbostyril necessary in route **5a** seemed to be more easily accessible, the synthetic approach in this direction was investigated first. The condensation of 2-cyano-3-methoxyphenylacetonitrile (**6**)[3)] with 2-methoxybenzoyl chloride (**7**) with sodium hydride yielded the product **9**, $C_{26}H_{20}N_2O_5$. The spectral data revealed that **9** was the product, which arose through the enol-benzoylation of once-formed 1-(2-cyano-3-methoxyphenyl)-1-(2-methoxybenzoyl)acetonitrile (**8**). Thus the reaction mixture of the above condensation was directly treated with 40% hydrogen bromide in glacial acetic acid at 70 °C to provide the desired isocoumarin **10**. Treatment of **10** with ammonia at 150 °C in a sealed tube afforded the carbostyril **11**. All attempts to hydrolyse **11** to **12** including treatment with alkaline hydrogen peroxide or the refluxing with potassium hydroxide in ethylene glycol were unsuccessful. The resistance of the cyano group in **11** to hydrolysis remains unclarified.

The synthesis of **2** by way of route **5b** was investigated subsequently. We undertook to prepare 4,7-dimethoxyindenoisocoumarin-11-one (**12**) first. Indenoisocoumarin-11-one (**15**) was synthesized by the dehydrative cyclization of 2-(2-carboxyphenyl)indane-1,3-dione (**14**) by Pailer *et al.*[4)] and we examined the synthesis of **12a** by this method though the cyclizations in two directions would be possible in the intermediate, 2-(2-carboxy-3-methoxyphenyl)-4-methoxyindane-1,3-dione (**13**). The reaction of 6-methoxyphthalaldehydic acid (**16**)[5)] and 7-methoxyphthalide (**17**)[6)] with sodium

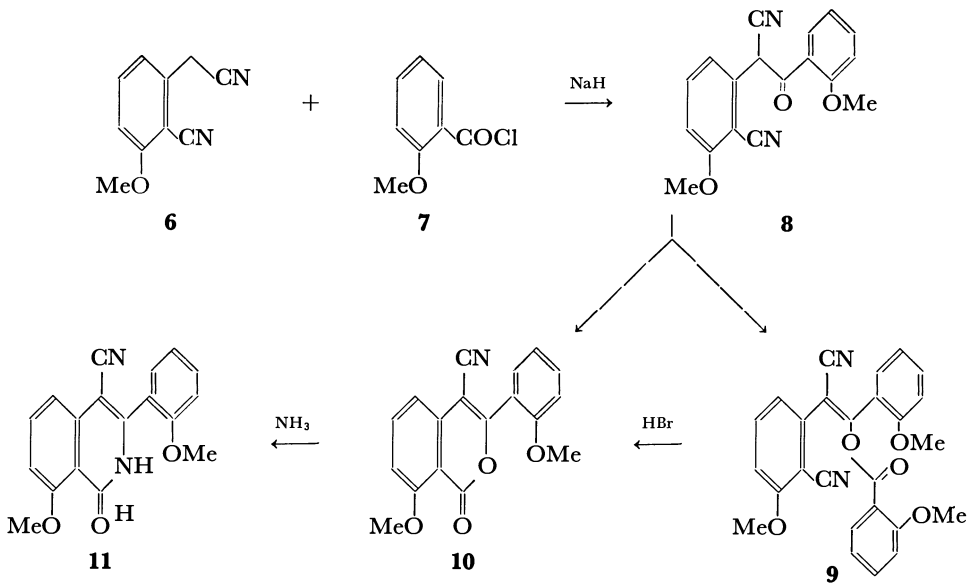
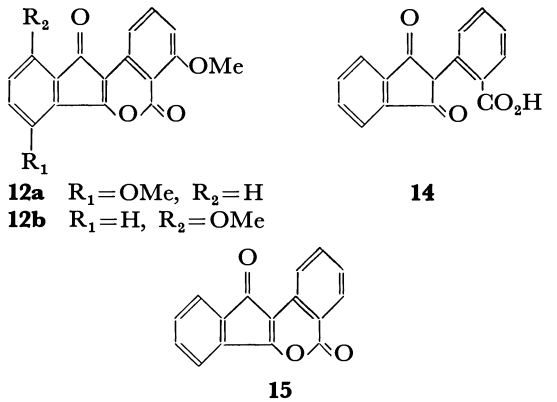
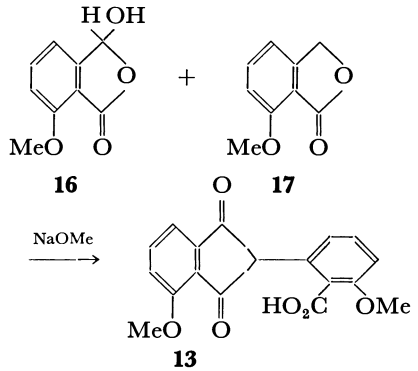


Scheme 2.

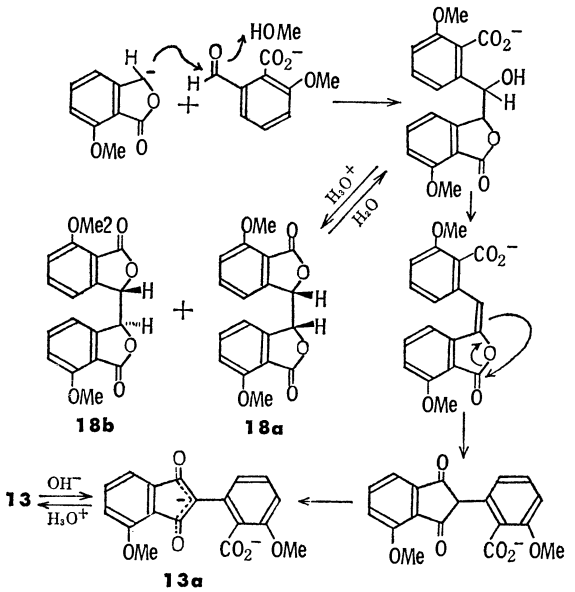


methoxide gave 2-(2-carboxy-3-methoxyphenyl)-4-methoxyindane-1,3-dione (**13**) accompanied by a mixture of the diastereomeric hydrodiphthalyls **18a** and **18b** which were separable by chromatography on a silica gel column. **18a** was more easily eluted on the chromatography than **18b**. Inspection of the models shows that the diastereomeric protons in the *dl*-form would be more susceptible to the shielding anisotropy of the β-phenyl groups in comparison to the *meso*-form in which such effect would be negligible. Thus the methine proton of **18a** resonates at lower filed than that of **18b**, and **18a** could tentatively be assigned to the

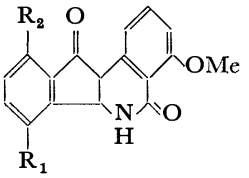


Scheme 3.

meso-form and the latter to the *dl*-form. The hydrodiphthalyls **18a** and **18b**, when treated again with excess sodium methoxide, provide the indanedione **13** which yields a red anion **13a** by treatment with base which on heating gradually turns red above 216 °C. When **13** was heated with acetic anhydride, two kinds of colored products were obtained; a reddish orange compound **12a**, mp 287 °C, ν_{max} 1770 and 1705 cm^{-1}; a yellowish orange compound **12b**, mp 247—247.5 °C, ν_{max} 1760 and 1710 cm^{-1}. Since both compounds have the same molecular composition $C_{18}H_{12}O_5$ and exhibit similar carbonyl bands due to lactonic and ketonic groups in the IR spectra, they represent the 11-oxoindenoisocoumarin isomers formed by the cyclization of **13** in two possible directions. However, it could not be said for the products which were which of the two isomers. On treatment of **12a** and **12b** with ethanolic ammonia at 120 °C for 12 hr both



Scheme 4.



19a R=OMe, R_2=H
19b R_1=H, R_2=OMe

compounds afforded the same products **19a** and **19b** in different ratios, 2.3 : 1 and 1 : 4, respectively. The result suggests that the isocoumarins **12a** and **12b** yield mainly the corresponding isocarbostyrils **19a** and **19b** respectively, though some equilibrium may exist between the isomers during the course of reaction. Actually **19a** was found to be identical with **3** from a comparison of their IR spectra and Tlc, and the mixed melting point determination. The structure of **19b** was verified by elemental analyses and the appearance of the absorption bands at 3100—2600 (broad, lactam), 1705 (ketone) and 1650 cm^{-1} (lactam) in its IR spectrum.

Comparison of NH stretching bands of the lactam groupings in **19a** and **19b** provides important information on the differentiation of both compounds. The NH band in **19a** is observed as a sharp peak at 3380 cm^{-1} owing to the obstruction for the formation of intermolecular hydrogen bond, whereas **19b** exhibits the bonded broad absorption without such hindrance. The contrast in NH stretching bands in **19a** and **19b** rationalizes our assumption made on the assignment of structure **3** for the oxidation product of the "red pigment".[1] The structures of **19a** and **19b** are thus delineated as shown and the formulas **12a** and **12b** are given to the parent isocoumarin isomers. Thus as a matter of course **19a** has to be identical with **3** and this was found to be the case.

In conclusion, the synthesis of **2** has been accomplished using **3** as a relay compound and the structure of **2** has been determined unambiguously.

Experimental[1]

Conversion of 5,6-Dihydro-4,7-dimethoxy-11H-indeno[1,2c]isoquinoline-5,11-dione (3) into 5-Chloro-4,7-dimethoxy-11H-indeno-[1,2-c]isoquinolin-11-one (2). **3** (298 mg) was heated with phosphorus oxychloride (10 ml) under refluxing for 2 hr. After cooling the reaction mixture was poured into ice-water and the resulting reddish orange precipitate was filtered, dried and chromatographed on a silica gel column (10 g). Elution with benzene-chloroform (1 : 1) gave reddish orange crystals (105 mg) which on recrystallization from chloroform gave pure **4**, mp 266—267 °C; λ_{max}^{EtOH} 217 (ε 34700), 273(49600), 358(1820), 394(450) and 460 nm(160); ν_{max} 1705 cm^{-1} (>CO). Found: C, 66.33; H, 3.70; N, 4.26%. Calcd for $C_{18}H_{12}ClNO_3$: C, 66.37; H, 3.71; N, 4.30%.

Treatment of 5-Chloro-4,7-dimethoxy-11H-indeno[1,2-c]isoquinolin-11-one (4) with Ammonia. **4** (130 mg) was heated with saturated ethanolic ammonia solution (18 ml) in a sealed tube at 150 °C for 22 hr. The red colored product, precipitated on cooling, was collected by filtration (110 mg) and recrystallized from chloroform-ethanol to yield 5-amino-4,7-dimethoxy-11*H*-indeno[2,2-*c*]isoquinolin-11-one (**2**), mp 289—290 °C. The IR spectrum of this product was superimposable with that of an authentic sample derived from the red pigment **1**.[1] The result of mixed melting point determination and tlc also corroborated the identity of both compounds. The derived acetate **2a**, mp 270—273 °C, was found to be identical with the one obtained previously.[1]

Condensation of 2-Cyano-3-methoxyphenylacetonitrile (6) with 2-Methoxybenzoyl Chloride (7). 2-Methoxybenzoyl chloride (**7**) (9.00 g) was added to a cooled solution of sodium salt of the acetonitrile **6**, prepared by the addition of **6** (6.75 g) to a mixture of sodium hydride (50% oil-coated, 1.99 g) and dry tetrahydrofuran (200 ml) and the mixture was stirred at room temperature for 2 hr. The reaction mixture was poured into water (400 ml) and the product was extracted with benzene. The organic layer was washed successively with 5% $NaHCO_3$ and water, and then dried over anhyd. Na_2SO_4. Evaporation of the solvent left a gummy residue (*ca.* 14 g), which was then warmed with a mixture of glacial acetic acid (7 ml) and 40% hydrobromic acid (18 ml) at 70 °C for 30 min. After cooling the mixture was poured into ice-water and the product was extracted with chloroform. The extract was washed with 5% $NaHCO_3$ and dried. Evaporation of the solvent provided a solid residue (*ca.* 10 g), which, on crystallization from chloroform-methanol yielded crude 4-cyano-8-methoxy-3-(2-methoxyphenyl)isocoumarin **10**, mp 205—227 °C (3.25 g). Further recrystallization from acetic acid afforded pure **10**, mp 236—237 °C; λ_{max}^{EtOH} 212 (ε 24600), 256(13300) and 342 nm (11800); ν_{max}^{EtOH} 2230 (-CN), 1765 (>CO) and 1755 cm^{-1} (>CO); $\delta^{CF_3CO_2H}$ 4.00 (3H, s, $-OCH_3$), 4.11 (3H, s, $-OCH_3$) and 7.03—8.15 (7H, m, ArOH). Found: C, 70.12; H, 4.33; N, 4.54%. Calcd for $C_{18}H_{13}NO_4$: C, 70.35; H, 4.26; N, 4.56%. Crystallization of the gummy residue from chloroform-ether, without treatment with HBr-AcOH, gave the enol benzoate **9** as needles, mp 155—156 °C; ν_{max} 2225 (-CN) and 1745 cm^{-1} (>CO); δ^{CDCl_3} 3.53 (3H, s, $-OCH_3$), 3.85 (3H, s, $-OCH_3$), 3.90 (3H, s, $-OCH_3$) and 6.65—8.20 (11H, m, ArOH). Found: C, 70.82; H, 4.77; N, 6.39%. Calcd for $C_{26}H_{20}N_2O_5$: C, 70.90; H, 4.58; N, 6.36%.

4-Cyano-8-methoxy-3-(2-methoxyphenyl)isocarbostyril (11). The isocoumarin **10** (200 mg) was treated with saturated ethanolic ammonia solution (15 ml) in a sealed tube at 150 °C for 5 hr. The product (92 mg) precipitated on cooling was collected by filtration. Recrystallization from methanol gave **11**, mp 304—306 °C; ν_{max} 3160 (>NH), 2230 (-CN) and 1670 cm^{-1} (>CO); δ^{CDCl_3} 3.96 (3H, s, $-OCH_3$), 4.38 (3H, s, $-OCH_3$) and 7.11—8.35 (7H, m, ArOH). Found: C, 70.28; H, 4.67; N, 8.88%. Calcd for $C_{18}H_{14}N_2O_3$: C, 70.58; H, 4.61; N, 9.15%.

Condensation of 7-Methoxyphthalide (17) and 6-Methoxyphthalaldehydic Acid (16). **17** (500 mg) was dissolved in a solution of sodium methoxide in methanol (prepared from 103 mg of sodium and 25 ml of abs. methanol) and then **16** (738 mg) was added under nitrogen atmosphere. After the mixture was refluxed for 2.5 hr, the solvent was evaporated *in vacuo* from the reddish reaction mixture. The concentrated mixture was poured into ice-water (50 ml), acidified with 1M H_2SO_4 and then extracted with chloroform. Evaporation of the solvent from the washed and dried organic layer provided colorless gummy residue (1.08 g), which was treated with hot ethanol (40 ml). The insoluble material turned out to be the mixture of the diastereomers **18a** and **18b**, and was separated by chromatography on a silca gel column. Elution with benzene-chloroform (1 : 1) afforded first **18a** and then **18b** in a ratio of 1 : 1. **18a** was crystallized from a mixture of chloroform and ethanol: mp 277—278 °C (dec.); ν_{max} 1705 cm^{-1} (>CO); $\delta^{CF_3CO_2H}$ 4.00 (6H,

s, 2-OCH_3) and 6.20 (2H, s, 2-CO_2CH<). **18b** was crystallized from chloroform: mp 286—286.5 °C; ν_{max} 1770 (sh.) and 1760 cm^{-1} (>CO); $\delta^{CF_3CO_2H}$ 4.06 (6H, s, 2-OCH_3) and 6.00 (2H, s, 2-CO_2CH<). Saturated aq. $NaHCO_3$ was added to the ethanolic solution obtained in the above treatment. The red alkaline solution was, after washing with chloroform, acidified by the addition of 1M H_2SO_4 and extracted with chloroform. The organic layer was washed with water and dried. Evaporation of the solvent yielded an oil (80 mg), which on trituration with ether furnished 4-methoxy-2-(2-carboxy-3-methoxyphenyl)indane-1,3-dione (36 mg): mp 220—222 °C (from ethanol, turned red at (**13**), *ca.* 216 °C); ν_{max} 3260 (broad, -CO_2H), 1740 (weak, >CO) and 1710 cm^{-1} (strong, -CO_2H). When both **18a** (50 mg) and **18b** (50 mg) were treated with excess sodium methoxide in methanone, the indane-1,3-dione **13** was obtained in the yields of 17 mg and 38 mg, respectively.

*Dehydrative Cyclization of 4-Methoxy-2-(2-carboxy-2-methoxyphenyl)indane-1,3-dione (**13**).* The indane-1,3-dione **13** (100 mg) was heated with acetic anhydride (5 ml) on a water bath (90 °C) for 30 min. The solution became red and finally gave a reddish precipitate. The reaction mixture was poured into ice-water and the precipitated product was recrystallized from acetic acid to afford **12a** as reddish orange needles (40 mg): mp 287 °C; λ_{max}^{EtOH} 214 (ε 31800), 236 (31000), 259 (sh., 34400), 266 (44500), 278 (sh., 17300), 354 (14700) and 456 nm (3300); ν_{max} 1770 (lactone) and 1705 cm^{-1} (ketone). Found: C, 69.78; H, 4.01%. Calcd for $C_{18}H_{12}O_5$: C, 70.13; H, 3.92%. After removal of the solvent from the mother liquor of the recrystallization, the residue was recrystallized successively from benzene and acetic acid to yield **12b** as yellowish orange needles (33 mg): mp 247—247.5 °C; λ_{max}^{EtOH} 236 (ε 38700), 254 (39500), 261 (60900), 273 (sh., 18700), 352 (16800) and 430 nm (3200); ν_{max} 1760 (lactone) and 1710 cm^{-1} (ketone). Found: C, 70.10; H, 3.97%. Calcd for $C_{18}H_{12}O_5$: C, 70.13; H, 3.92%.

*Ammonia Treatment of 4,7-Dimethoxy- (**19a**) and 4,10-Dimethoxy-11H-indeno[1,2-c]isocoumarin-11-one (**19b**).* The reddish orange isomer **12a** (50 mg) was heated with saturated ethanolic ammonia in a sealed tube at 120 °C for 12 hr. After cooling the reaction mixture was poured into water and the red colored product, collected by filtration, was chromatographed on a silica gel column (2 g). Elution with chloroform afforded first the orange colored product **19a** (25 mg) and then the yellow colored isomer **19b** (11 mg). The former is more soluble in common organic solvents than the latter. When the yellow isomer **12b** was treated with ammonia in the same way as **12a**, **19a** and **19b** were obtained on fractional crystallization from chloroform in 11 mg and 44 mg yields, respectively. **19a**, mp 29.5 °C, recrystallized from a mixture of chloroform and ethanol, was identical with **3** obtained previously by the degradation of the "red pigment"[1] in the IR spectra, tlc and mixed melting point determination. Found: C, 70.15; H, 4.22; N, 4.70%. Calcd for $C_{18}H_{13}NO_4$: C, 70.35; H, 4.26; N, 4.56%. The yellow isomer **19b** was recrystallized from acetic acid: mp>300 °C; λ_{max}^{EtOH} 232 (ε 32400), 264 (36900), 290 (19700), 348 (20600), 368 (13300) and 450 nm (2500); ν_{max} 3100—2600 (broad, lactam NH), 1705 (ketone) and 1650 (lactam carbonyl) cm^{-1}. Found: C, 70.29; H, 4.33; N, 4.68%. Calcd for $C_{18}H_{13}NO_4$: C, 70.35; H, 4.26; N, 4.56%.

Photoreaction of 2,2-Diphenylvinyl Ketones

Kazuyuki MAEDA, Ichiro MORITANI, and Akio SONODA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka 560

(Received July 4, 1973)

Synopsis. The photoreaction of 2,2-diphenylvinyl ketones leading to 1,1,4,4-tetraphenylbutadiene, which seems to formally involve α-cleavage of vinyl ketones.

Although much attention has been paid to the photochemical dimerization of unsaturated aliphatic ketones,[1-3] and (2+2) cycloaddition to olefins,[4,5] only one case has been reported on the primary photodissociation of α,β-unsaturated ketones at elevated temperature with low efficiency.[6]

We report herewith on the photoreaction of 2,2-diphenylvinyl ketones (**1**) leading to 1,1,4,4-tetraphenylbutadiene (**2**), which formally involves α-cleavage of **1** and dimerization.

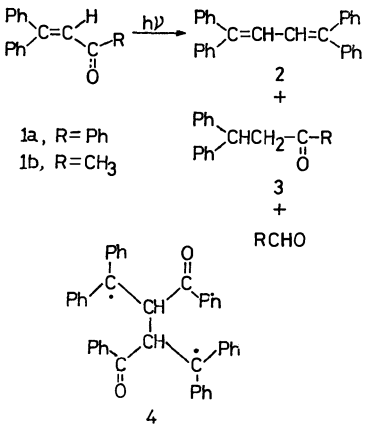

Fig. 1.

Irradiation of a solution of 1,3,3-triphenyl-2-propen-1-one (**1a**) in 2-propanol (2.9×10^{-2} mol/l) with high-pressure mercury arc was carried out for 90 hr under argon atmosphere. Removal of the resulting benzoic acid (7%) by extraction with the base followed by chromatography on Al_2O_3 gave the butadiene **2** (37%) and 1,3,3-triphenylpropan-1-one (**3a**) (27%). The structural assignment of these products was established by comparison of their spectral data with those of the authentic samples. Analogous photoreaction of 4,4-diphenyl-3-buten-2-one (**1b**) in 2-propanol afforded the butadiene **2** (18%) and 4,4-diphenylbutan-2-one (**3b**) (5%).

A probable pathway involves the initial coupling of **1** at the α-position leading to **4**, the most stable biradical of three possible intermediate species. Subsequent cleavage of Norrish Type I of **4** would lead to the butadiene **2** and two benzoyl radicals. Hydrogen abstraction of the latter followed by autoxidation during the work-up may lead to benzoic acid. Although a number of photodimers of unsaturated aliphatic ketones,[2] carboxylic acid,[1] and esters[3] have been isolated, no photodimer could be detected in this photoreaction probably because of extraordinary stability of the biradical **4**.

An alternative mechanism which includes α-cleavage of the ketones **1** affording 2,2-diphenylvinyl radical and subsequent coupling to give **2** seems unlikely, since facile hydrogen abstraction of vinyl radical can overcome the coupling reaction.[7] No product such as diphenylethylene which can be derived from hydrogen abstraction of 2,2-diphenylvinyl radical could be detected during the course of photoreaction.

Ketone **3a**, derived from photoreduction of **1a**,[8,9] could be obtained only in 2-propanol among various solvents as shown in Table 1.[10]

Table 1. Solvent effect of photoreaction of **1a** under nitrogen (30 hr)

Solvent	Conversion (%)	Yield of **2** (%)	Yield of **3a** (%)
2-Propanol	74	26	26
Cyclohexane	28	25	0
Benzene	26	17	0

Experimental

*Irradiation of 1,3,3-Triphenyl-2-propen-1-one (**1a**) in 2-Propanol.* A solution of **1a** (8.25 g), mp 87.5—88.7 °C (lit,[11] mp 84—87 °C), in 2-propanol (1000 ml) was irradiated under argon. The reaction was monitored periodically (UV analysis and tlc technique). After 90 hr irradiation, the solvent was evaporated, and the residue was dissolved in CH_2Cl_2. Extraction of the CH_2Cl_2 solution with a $NaHCO_3$ solution followed by acidification gave benzoic acid (0.20 g). The neutral products were subjected to alumina chromatography (400 g of alumina). Elution with *n*-hexane gave butadiene **2** (1.65 g, 37%), which was identified by comparison with an authentic specimen, mp 201—202 °C (lit,[12] mp 204—205 °C), Found: C, 94.04; H, 6.20%. Calcd for $C_{28}H_{22}$: C, 93.81; H, 6.19%). NMR (CCl_4, δ): 6.65 (2H, s, vinyl), 7.10 (10H, s) and 7.20—7.40 (10H, broad d). Further elution with benzene afforded a yellow oil, which upon fractional distillation under reduced pressure gave **3a** (1.93 g, 27%), bp 205—207 °C/2 mmHg, and recovered **1a** (1.22 g). The structure of **3a** was established by comparison with an authentic sample and mixed mp. Mp 92.8—93.5 °C (lit,[13] 91—92 °C). IR (nujol mull): 1670 cm^{-1} (C=O). NMR (CCl_4, δ): 3.53—3.70 (2H, d), 4.70—4.90 (1H, t) and 7.05—7.95 (15H, m). Finally, elution with ether gave a trace of a crystalline compound (mp 250—254 °C, mol wt. 554) and a tarry material.

Irradiation of ***1a*** *in the Presence of Oxygen.* A solution **1a** (16.50 g) in 2-propanol (1000 ml) was irradiated under a slow stream of dry air for 45 hr. The treatment as described above gave benzoic acid (0.17 g, 3%). An alumina chromatography of the neutral products gave the butadiene **2** (2.26 g, 27%), benzophenone (5.61 g, 66%), acetophenone (2.26 g, 46%), and recovered **1a** (1.10 g) in addition to tarry materials.

*Irradiation of 4,4-Dipheny-3-buten-2-one (**1b**) in 2-Propanol.* A solution of **1b** (2.96 g), bp 168—170 °C/7 mmHg, mp 33.5—34.5 °C (lit,[14] bp 195—205 °C/15 mmHg), in 2-propanol (500 ml) was irradiated for 50 hr under nitrogen. The resulting mixture was subjected to alumina chromatography. Petroleum ether–benzene eluted **2** (0.39 g, 18%). Elution with benzene gave benzoic acid (0.013 g, 1%) and the ketone **3b** (0.11 g, 5%). Mp 47.0—48.0 °C (lit,[15] mp 47.5 °C). IR (nujol mull): 1710 cm^{-1} (C=O). NMR (CS_2, δ): 1.93 (3H, s), 3.01 (2H, d, J=7.5 Hz), 4.44 (1H, t, J=7.5 Hz), 6.90—7.95 (10H, m).

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. VIII.[1] Benzidine–2,4-Dinitrophenol Complexes

Gunzi SAITO* and Yoshio MATSUNAGA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 17, 1973)

Synopsis. The simultaneous operation of charge-transfer and proton-transfer interactions was demonstrated in the orange complex and also in the brown complex of a 3 : 2 composition. The former one quickly becomes the yellow monohydrate of the 1 : 1 salt upon exposure to air.

Buehler and Heap have reported that the benzidine–2,4-dinitrophenol (1 : 1) complex is brown when it is prepared in absolute ethanol, while it is yellow when 95% ethanol is employed as the solvent.[2] The latter complex contains 1 mol of water. As the first pK_a value of the diamine is higher than the value of the dinitrophenol (namely, 4.95 *vs.* 4.09), it does not seem likely that the brown-colored complex is of the charge-transfer (CT) type.[3] We can also eliminate the possibility that this "1 : 1 complex" is of the same type as the brick red-colored *o*-tolidine–picric acid (1 : 1) complex previously described by us.[4] If the brown benzidine–dinitrophenol complex belongs to Case 1 of CPT complexes as defined in a previous paper, a part of the diamine molecule acts as a proton-acceptor, while the other part has a CT interaction with the dinitrophenolate anion. The electron-donor strength of the monoprotonated benzidine can be essentially determined from that of the unprotonated part. By analogy with the case of the picrate anion,[4-7] the acceptor strength of the dinitrophenolate anion can be expected to be close to that of *m*-dinitrobenzene; therefore, the color of the 1 : 1 complex cannot be deeper than that of the aniline–*m*-dinitrobenzene complex. The observation the above-mentioned workers is undoubtedly in disagreement with this expectation.

By mixing equimolar amounts of the component compounds separately dissolved in hot chloroform which contains 0.05% of water according to the manufacturer, a yellow complex was obtained. Calcd for $C_{12}H_{12}N_2 \cdot C_6H_4N_2O_5 \cdot H_2O$: C, 55.96; H, 4.66; N, 14.51%. Found: C, 56.06; H, 4.70; N, 14.37%. When the solvent was dried with calcium chloride and the mixture was kept in a refrigerator, an orange-colored complex appeared. This complex quickly turned yellow upon exposure to air. After the color change, the composition was in good agreement with that of the monohydrate of the 1 : 1 complex. Found: C, 56.06; H, 4.84%. The brown complex was isolated at room temperature from a dried chloroform solution containing the diamine in excess and also from an absolute ethanol solution as has been reported by Buehler and Heap. Calcd for $3C_{12}H_{12}N_2 \cdot 2C_6H_4N_2O_5$: C, 61.69; H, 4.78; N, 15.22%. Found: C, 61.96; H, 4.95% (from chloroform) and C, 62.61; H, 4.78; N, 15.20% (from ethanol).

The vibrational spectrum of the yellow monohydrate clearly indicates the presence of water by a band at

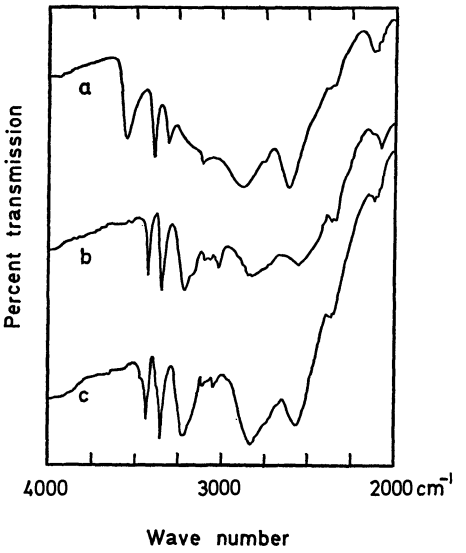

Fig. 1. Vibrational spectra, a) the yellow benzidine–2,4-dinitrophenol complex, b) the orange complex, and c) the brown complex.

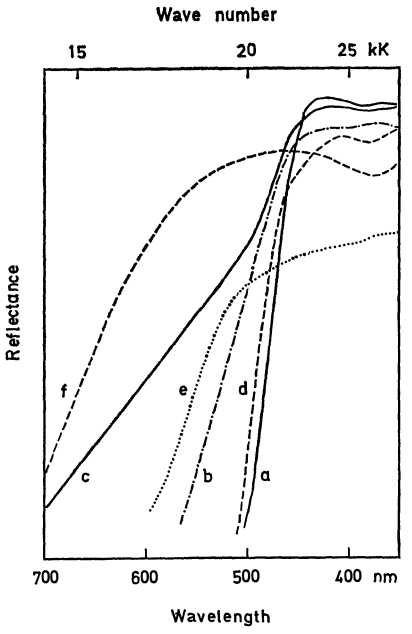

Fig. 2. Reflectance spectra, a) the yellow benzidine–2,4-dinitrophenol complex, b) the orange complex, c) the brown complex, d) sodium 2,4-dinitrophenolate, e) the aniline–*m*-dinitrobenzene complex, and f) the benzidine–*m*-dinitrobenzene complex.

* Present address: Department of Chemistry, Emory University, Atlanta, Georgia, 30322, U.S.A.

** To whom inquiries may be addressed.

3550 cm^{-1}, that of the NH_2 group by bands at 3320 and 3395 cm^{-1}, and that of the NH_3^+ group by those in the region from 2500 to 3000 cm^{-1}. As is shown by the spectrum in Fig. 1, the newly-found orange complex is undoubtedly free from water. In accordance with the composition, bands assignable to both the NH_2 and NH_3^+ groups are also detected in the orange- and brown-colored complexes.

The diffuse reflectance spectrum of the yellow complex is similar to that of sodium dinitrophenolate. Therefore, it may be concluded that the monohydrate is a salt formed by means of the proton-transfer from the phenol to the diamine. The orange complex exhibits an additional absorption band located close to the CT band in the aniline–*m*-dinitrobenzene complex (see Fig. 2). On the other hand, the location of the additional absorption band appearing in the brown 3 : 2 complex can be well compared with that of the CT band in the benzidine–*m*-dinitrobenzene complex. On the basis of these spectroscopic observations, we may conclude that the deeply-colored complexes are of the CPT type, but belong to different cases.[4] In both complexes, the electron-acceptor is the dinitrophenolate anion. The electron-donor in the orange complex is the monoprotonated benzidine cation, while that in the brown complex is the diamine molecule.

Buehler and Heap have concluded the composition of the brown complex to be 1 : 1 on the basis of the nitrogen content, which does not depend much on the mole ratio. Their results, 14.94 and 14.92%, seem not to be inconsistent with the newly-assigned composition, for which N is 15.22%.

Dielectric Relaxation and Molecular Structure. XII. Dipole Moments and Dielectric Relaxation Times of Rigid Molecules in Solutions

Tohru NAGAI, Yoshinori KOGA, Hiroaki TAKAHASHI, and Keniti HIGASI
School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received January 9, 1974)

Synopsis. Dielectric constants and losses of anthrone, xanthone, fluorenone and ten other rigid and almost rigid organic molecules were measured at the frequency of about 100 GHz in benzene at 25 °C. The dielectric relaxation times $\tau(1)$ and $\tau(2)$ and the dipole moments μ of these molecules were obtained and discussed.

Two sets of dielectric relaxation times for thirteen rigid molecules were obtained in benzene from measurements at the frequency of 96.5 GHz at 25 °C and discussion is presented on the results.

Experimental

Dielectric measurements at the frequency of 96.5 GHz were made by use of the apparatus and techniques described previously.[1] Symbols employed in this note have the same definition as that given in the preceding paper.[2]

Purchased materials of the best grade (for solutes) were purified by the usual method. Benzene for solvent was carefully purified in the usual way. All the experimental data are collected in Table 1 including those for optical and dielectric (static) measurements.

TABLE 1. SLOPES a', a'' (100 GHz), a_0 (STATIC) AND a_D (OPTICAL) IN BENZENE, 25 °C

Compound	a'	a''	a_0	a_D
Anthrone	0.847	0.551	7.877	0.417
Xanthone	0.843	0.357	5.373	0.421
Benzophenone	0.852	0.444	5.780	0.277
Fluorenone	0.766	0.549	7.181	0.362
Acetone	4.144	4.932	13.736	−0.473
Methyl ethyl ketone	2.623	3.489	10.973	−0.415
Nitrobenzene	1.077	1.805	14.194	0.109
Chlorobenzene	0.298	0.433	2.465	0.066
Dibenzofuran	0.390	0.046	0.768	0.331
Dibenzothiophene	0.495	0.037	0.803	0.434
Toluene	−0.011	0.030	0.127	−0.036
o-Xylene	0.021	0.057	0.322	0.006
m-Xylene	−0.009	0.021	0.105	−0.025

Discussion

Two dielectric relaxation times $\tau(1)$ and $\tau(2)$ were calculated from

$$\tau(1) = \frac{1}{\omega}\frac{a''}{a'-a_\infty} \quad (1)$$

$$\tau(2) = \frac{1}{\omega}\frac{a_0-a'}{a''} \quad (2)$$

(See Table 2). The first relaxation times $\tau(1)$ calculated on the assumption $a_\infty = a_D$ are found to be much smaller than the second ones $\tau(2)$. This is partly due to the neglect of atomic polarization; a_∞ is expected to be larger than a_D. Besides, the dielectric system considered here is possibly of multi-relaxation times rather than of a single relaxation time. For instance, it was found by Hassel and Walker[3] that even toluene has two relaxation times in cyclohexane. If these molecules in benzene solution are provided with a small but appreciable absorption* in the extremely

* The above-mentioned absorption includes the Poley absorption[5] which differs from the real relaxation phenomenon. We shall assume this small absorption to have a pseudo-relaxation time in order to examine the present dielectric system by use of the method of analysis for the system with two Debye dispersions.[6]

high frequency region[4,5] (for submillimeter wavelengths) and a large and dominant absorption in the lower frequency range, $\tau(1)$ and $\tau(2)$ will give average values with different weights of the two relaxation times. An analysis in the preceding paper[6] shows that the second relaxation times $\tau(2)$ will be fairly close to the relaxation times for the main absorption of molecular rotation.[6] In fact, the literature values obtained from lower frequency measurements compare favorably with $\tau(2)$. Exception may occur, however, if the molecule has a very small polarity.

The dipole moment μ is calculated from $\mu=B(a_0-a_D)^{1/2}$ and $B=(0.3197\times10^{-30}\ \mathrm{Cm})M_2^{1/2}$ in benzene at 25 °C[2], in which a_0 and a_D are slopes for concentrations expressed in weight fraction[2] and M_2 is the molecular weight of the solute. The results of calculation are shown in Table 2. The dipole moment for dibenzofuran is probably a new value and those for the other molecules compare favorably with literature values.[7]

X-Ray Photoelectron Spectroscopy of Oxine-Metal Chelates

Tooru YOSHIDA and Shigemasa SAWADA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received January 25, 1974)

Synopsis. Photoelectron spectra of oxine-metal chelates were measured. The chemical shifts of the N(1s) electron binding energy were smaller than 0.7 eV. There were nearly linear relations between the chemical shifts and the electronegativities of metals or the partial ionic characters of the nitrogen-metal bonds of chelates.

X-Ray photoelectron spectroscopy (ESCA) is rapidly becoming an established method in chemical research. The technique provides a sensitive probe of the electronic environment of atoms in molecule. A number of studies by ESCA have shown that the inner level electron binding energies (B. E.) of an atom are sensitive to the over-all charge on an atom.

The use of the ESCA to determine the effect of coordination on the electron density of a ligand is based on the fact that change in the electron density about an atom is reflected in changes in the binding energies of the core electrons.

It is the aim of this study to determine whether it will be possible to correlate the electronegativity of a metal or the partial ionic character of the bond between a metal and a ligand with the chemical shift of N(1s) binding energy in oxine-metal chelates.

Experimental

The photoelectron spectra were measured using an AEI ES100 electrostatic electron spectrometer under the control of a DS100/32 computer data processing system. The aluminum K_αX-ray line (1486.6 eV) and magnesium K_αX-ray line (1253.6 eV) were used for photoelectron excitation. All the oxine metal chelates, which have 1 : 2 ratio of metal and oxine, were prepared by ordinary procedures. All samples except free oxine were run at room temperature as powder dusted onto double sided adhesive tape under the vacuum of about 10^{-6} Torr. In the case of free oxine a freezing technique was used because of its high volatility.

To compensate for any sample charging effects, the calibration of the spectra was done using the C(1s) electron line from the carbons present in the samples. Its binding energy was taken to be 285.0 eV throughout this study.

Results and Discussion

Figure 1 showed the C(1s) and N(1s) photoelectron spectra of free oxine. The spectra of chelates showed the profiles similar to those of free oxine. All measured binding energy values were given in Table 1. In the table, ΔE is the chemical shift which is the difference between the N(1s) binding energies of free oxine and each chelate compounds, pK the common logarithm of the stability constant of a chelate which is available in the text book,[1] χ the Pauling electronegativity of a metal, I the partial ionic character ($I=1-\exp\{-0.25(\chi_N-\chi_M)^2\}$) of the bond between nitrogen and

metal given by Pauling[2] in which χ_N and χ_M are the electronegativities of nitrogen and metal.

Fig. 2 showed the nearly linear relation between the measured chemical shift (ΔE) and the electronegativity (χ). The increase of the N(1s) chemical shift of chelates with the increase of an electronegativity of a metal could be observed. The chemical shifts of the N(1s) binding energy in all chelates on the complex formation were considered to be due to the decrease of the electron density on the nitrogen atoms caused by the co-ordination of lone-pair electrons of the nitrogen atoms to the metal.

In the charge-potential model,[3] the chemical shift can be expressed in terms of the charge on the atom (Q) and the coulomb potential energy (V) of an electron due to the other atoms of the molecule. Thus:

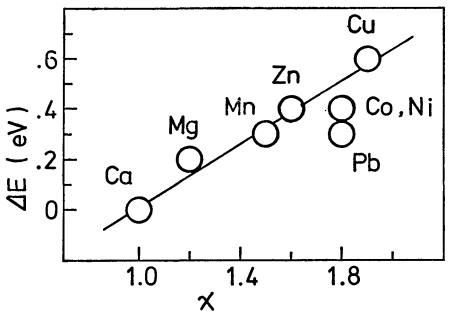

Fig. 2. Relation between the chemical shift of N(1s) binding energy (ΔE) and the electronegativity (χ).

$$\Delta E = k_1 Q + V + k_2 \quad (k_1,\ k_2;\ \text{constants}).$$

In an ionic compound, V includes the contribution from other neighboring ions, that corresponds to a Madelung term. In general, the neglect of V may cause serious error for ionic compounds but for the covalent compound studied here the chemical shift should be dominated by the charge (Q) on the atom concerned.

Here, applying the correlation, $Q=q+\Sigma I$ (Q; charge on an atom, q; formal charge of a concerned atom, ΣI; summation of partial ionic characters of all bonds) proposed by Nordberg *et al.*[4] to the case of oxine chelates, the equation, $Q=I_{C-N}+I_{C=N}+I_{N-M}$, was roughly obtained since q on the nitrogen is zero. Assuming that the summation of the first and second terms of right-hand side in the above equation was constant and V was negligible throughout all the oxine chelates studied here, then the equation, $\Delta E=k_1 I_{N-M}+K$ (K; constant), could be derived.

In practice, it was observed that this relation approximately held in this study. Figure 3 showed a linear relation between the measured chemical shift (ΔE) of the N(ls) binding energy and the calculated partial ionic character (I_{N-M}) of the bond between nitrogen and metal atoms. This indicated that the increase of the ionic character in the bond, or the decrease of the covalent character leads to the smaller chemical shift.

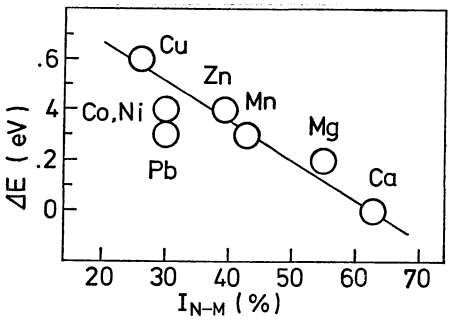

Fig. 3. Relation between the chemical shift of N(1s) binding energy (ΔE) and the partial ionic character ($I=1-\exp\{-0.25(\chi_N-\chi_M)^2\}$).

Thus it was found that the shift of an inner electron binding energy in ESCA, though it is small, give some important knowledge (ionic or covalent character) for the bonds in co-ordination compounds.

Another point, which may be important in analytical chemistry, obtained in this experiment was that there was some relation between the chemical shift (ΔE) measured in solid state and pK value determined in solution; the higher was the stability of a chelate, the larger was the chemical shift of it.

The authors wish to thank Mr. Taichiro Hirohara for the elemental analyses of all samples.

Preparation and Properties of Dimeric Dialkoxo-bridged Chromium(III) Complexes with 3-Bromo-2,4-pentanedione

Kuninobu KASUGA, Tsunao ITOU, and Yasuo YAMAMOTO

Department of Chemistry, Faculty of Literature and Science, Shimane University, Nishikawatsu-cho, Matsue 690

(Recieved November 14, 1973)

Synopsis. μ,μ'-Dialkoxotetraquis(3-bromo-3,4-pentanedionato)dichromium(III), where alkoxo is methoxo, ethoxo, *n*-propoxo or *n*-butoxo, has been prepared. These complexes have been identified by means of the elementary analysis, determination of molecular weight and the spectrometry.

The dimeric dimethoxo bridged copper(II) complex with 2,4-pentanedione has been reported by Bertrand and Kaplan,[1] and dimeric dialkoxo bridged iron(III) complexes with 2,4-pentanedione and 2,2,4,6-tetramethylheptane have been synthesized by Wu, Rossman, Gray, Hammond, and Schugar.[2] In the course of our studies of the substitution reaction of 3-bromo-2,4-pentanedione complexes, we have found the formation of such dimeric dialkoxo bridged chromium(III) complexes as the methoxo, exthoxo, *n*-propoxo and *n*-butoxo dimers.

Experimental

Materials. Tris(3-bromo-2,4-pentanedionato)chromium(III) was refluxed in methyl alcohol for a few days. The dark green precipitates thus formed were recrystallized from benzene. The product(1) consisted of yellowish-green needles. By the same procedure, ethyl, *n*-propyl and *n*-butyl alcohol give similar precipitates. The precipitates in ethyl alcohol were recrystallized from ethanol-dichloromethane, thus giving green crystals(2). Both (3) (the product with *n*-propyl alcohol) and (4) (that with *n*-butyl alcohol) were recrystallized from heptane. These four products show a similar green colour, but of a little different shade. These products are soluble in dichloromethane and chloroform, and a little soluble in alcohol, but insoluble in water. The molecular weights and analytical data of the products are summarized in Table 1.

Measurements. The infrared spectra were measured on a Hitachi 215-type spectrophotometer using KBr pellets. The electronic spectra were measured on a Hitachi 124-type spectrophotometer. The data of the molecular weights were obtained with a Hitachi 115 vapour-pressure osmometer, using chloroform as the solvent. The molecular weight of the methoxo dimer was also measured on a Hitachi Perkin-Elmer RMS-4 single focussing mass spectrometer.

Results and Discussion

In addition to these molecular weights and analytical results, the dimeric forms were identified on the basis of the following facts.

Infrared Spectra. The bands which are not observed for the starting material are shown in Table 2. The bridging alkoxo group is said to have a band at 1040—1070 cm^{-1} which can be assigned to its C–O stretching vibration.[3] The band at 1064 cm^{-1} of (1) should be that of the methoxo group, in view of the IR results on dimeric dimethoxo 2,4-pentanedionato complexes of copper(II)[1] and iron(III).[2] The copper(II) complex shows a band at 1018 cm^{-1} and the iron(III) complex at 1050 cm^{-1}, both of which have been assigned to the C–O stretching of the bridging methoxo group. The similar ethoxo-bridged complex of iron(III) has also been reported to have bands at 1091, 1048 and 885 cm^{-1}, one of which, 1048 cm^{-1}, is assigned to C–O stretching of the ethoxo group.[2] The bands of (2), as shown in Table 2, correspond to these data. By a similar inference, it might be said that the bands at 1095, 1070 and 975 cm^{-1} of (3) as well as 1070 and 970 cm^{-1} of (4) may be attributed to the existence of the bridging propoxo and

butoxo groups respectively.

Electronic Spectra. As is shown in Table 3, the somewhat lower energies of the d-d bands($^4A_{2g}$—$^4T_{2g}$) of the products as compared to those of the starting material are probably due to the decreased ligand-field splitting by the replaced group. In the case of iron(III) with the same environment, the energies of the dimer d-d bands are higher than those of the monomer.[2] Therefore, the inter-electronic repulsion terms should also be considered in these cases.

While the dialkoxo bridged complex was obtained by the reaction of the 3-bromo-2,4-pentanedionato chromium(III) complex with alcohol, the reflux of the 2,4-pentanedionato chromium(III) complex in ethyl alcohol did not show any change even after a month. The bond between the central metal and carbonyl oxygen might be weaker for the 3-bromo-2,4-pentanedionato complex than for the 2,4-pentanedionato complex. Thus, the bond formation between central metal of the bromo compound and the oxygen atoms of alcohol may be promoted as compared with the case of the nonbrominated compound. Therefore, alcohol molecules react more easily with the central metal of the bromo compound.

The authors are grateful to Dr. Mitsuru Nakayama, Hiroshima University, for determining the molecular weights by means of mass spectrometry.

Triisopropoxy Boroxine as a Reducing Agent for Substituted Benzaldehydes

Hirotada IIDA, Hironori KITAMURA, Ken SEITA, and Kazutoshi YAMADA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

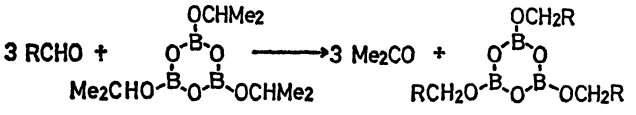
(Received June 5, 1973)

Synopsis. Substituted benzaldehydes could be reduced to corresponding benzyl alcohols in fairly good yield at 130 °C, using triisopropoxy boroxine as a reducing agent. The rates of the reduction of benzaldehyde with triisopropoxy boroxine were about ten times as large as those with triisopropyl borate at 110—130 °C.

The reducing action of various metallic alkoxides on aldehydes and ketones has been examined by Meerwein and his co-workers.[1] Under their reaction conditions, boron alkoxides were ineffective as reducing agents. However, when the reaction temperatures were rasied to 150—170 °C, aromatic aldehydes were reduced to the corresponding alcohols by triisopropyl borate.[2]

The ring structure of trialkoxy boroxines was confirmed in 1951,[3] and a convenient synthesis of trialkoxy boroxines was published in 1966,[4] but their reactivities as reducing agents have not yet been studied.

This paper will report the results of an investigation of the reducing activity of triisopropoxy boroxine toward substituted benzaldehydes and some aromatic ketones, compared with that of triisopropyl borate.



Triisopropoxy boroxine

TABLE 1. REDUCTIONS OF SUBSTITUTED BENZALDEHYDES WITH TRIISOPROPOXY BOROXINE IN XYLENE AT 130 °C FOR 22 hr

RCHO	RCH_2OH (%)
4-Nitrobenzaldehyde	90
Benzaldehyde	64
4-Chlorobenzaldehyde	63
4-Methoxybenzaldehyde	12

Table 1 shows the results obtained from the reductions of substituted benzaldehydes with triisopropoxy boroxine. The yields of alcohols in Table 1 are better than those of the reduction with triisopropyl borate,[2] although they are somewhat lower than those in the Meerwein-Ponndorf-Verley reduction.[5] Neither of the ketones investigated (acetophenone and *p*-nitroacetophenone) was reduced by triisopropoxy boroxine.

The effect of the reaction temperature on this reduction is remarkable. At 80 °C, the usual temperature in the Meerwein-Ponndorf-Verley reduction, practically no reduction occurred with triisopropoxy boroxine.

In order to compare the reducing activity of triisopropoxy boroxine with that of triisopropyl borate, we

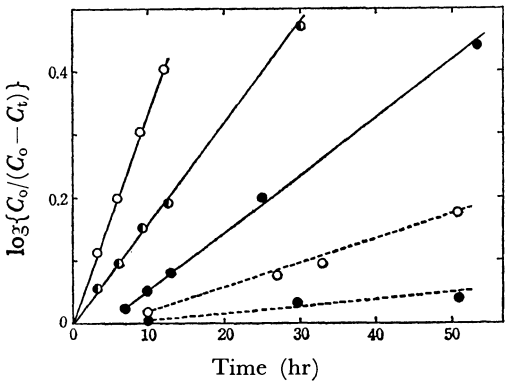


Fig. 1. Pseudo first-order rate plots for the reduction of 0.5 M benzaldehyde with 1.5 M triisopropoxy boroxine or triisopropyl borate in diglyme at these temperature: ●, 110°; ◐, 120°; ○, 130°: solid line, reduction with boroxine; dotted line, reduction with borate.

TABLE 2. THE RATE OF REDUCTION OF BENZALDEHYDE WITH TRIISOPROPOXY BOROXINE OR TRIISOPROPYL BORATE IN DIGLYME

Temp. (°C)	Rate constant, k (hr^{-1})	
	Boroxine	Borate
110	0.020	0.0020
120	0.037	
130	0.076	0.0086

measured the rate of the reduction of benzaldehyde in a diglyme solution under nitrogen, using both reducing reagents separately. A diglyme solution of benzaldehyde and an excess of triisopropoxy boroxine or triisopropyl borate was allowed to react at a constant temperature. The course of the reaction was followed by removing aliquots at appropriate intervals and by measuring the benzyl alcohol and benzaldehyde after hydrolysis by means of gas chromatography. The results are shown in Fig. 1, where C_0 is the concentration of benzaldehyde at time zero and where C_t is that of benzyl alcohol at time t (hr). The plots follow the pseudo first-order reaction for benzaldehyde. An induction period was observed in the reductions with triisopropoxy boroxine at 110 °C and with triisopropyl borate at 110 and 130 °C. The induction period may be due to the establishment of a coordination equilibrium between benzaldehyde and boroxine or borate in the same way as in the Meerwein-Ponndorf-Verley reduction.[6] The psudo first-order rate constants are given in Table 2. The activation energies obtained from the Arrhenius plots were 22.6 and 20.0 kcal/mol for reductions with triisopropyl borate and with triisopro-

poxy boroxine respectively. From these results, it is clear that triisopropoxy boroxine is more effective than triisopropyl borate as a reducing agent.

Experimental

Materials. Triisopropoxy boroxine was prepared according to the literature[4]; mp 51—52 °C (lit, 52 °C).

Triisopropyl borate was prepared by a method modified from the literature[2] as follows: Boric anhydride (0.15 mol) and isopropyl alcohol (1 mol) were mixed in a Soxhlet extracter. In its cylindrical filter paper, calcium oxide (50 g) was placed; the mixture was refluxed for 24 hr and then distilled to obtain the borate (bp 139.5—140.5 °C).

Substituted benzaldehydes were purified by the usual method.

Reduction of Substituted Benzaldehydes. Aldehyde (0.02 mol), triisopropoxy boroxine (0.023 mol), and a solvent (25 ml) were placed in a three-necked, round-bottomed flask (50 ml) fitted with a thermometer, a nitrogen-inlet tube, and a gas-outlet tube. The mixture was heated at 130 °C for 22 hr under an atmosphere of dry nitrogen, while the acetone formed was distilled off through the gas-outlet tube. The acetone was condensed in a spiral tube cooled with an acetone–dry ice mixture and was analyzed by means of gas chromatography. After cooling, the mixture was poured into 100 ml of a 1% aqueous solution of sodium hydrogen carbonate and extracted with 400 ml of ether, after which the ethereal extract was dried over sodium sulfate. The ether was distilled off, and the product was analyzed quantitatively by means of gas chromatography.

Reaction of Ketones and Triisopropoxy Boroxine. Acetophenone (0.1 mol) and triisopropoxy boroxine (0.033 mol) were treated for 14 hr at 110 °C, and *p*-nitroacetophenone was treated similarly at 110 and 125 °C, but no reaction occurred in any case.

Kinetic Procedure. A 60-ml portion of a diglyme solution containing benzaldehyde (0.03 mol) and triisopropoxy boroxine or triisopropyl borate (0.09 mol) was placed in a four-necked, round-bottomed flask (100 ml) and the reaction was carried out as has been described above at a constant temperature. From time to time, 4-ml aliquots were removed, poured into 15 ml of a 1% aqueous solution of sodium hydrogen carbonate, and extracted with 40 ml of ether; the concentrations of benzyl alcohol and benzaldehyde were determined by means of gas chromatography.

Stereospecific Reductions of Isoilludin S and M on Alumina Chromatography

Akitami ICHIHARA* and Takeshi MATSUMOTO

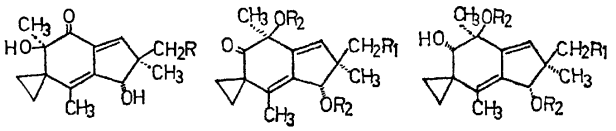
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 4, 1973)

Synopsis. Alumina column chromatography with ethanol as solvent converted planar α-ketols, illudin S and illudin M, to the dihydroxy compounds. The stereospecific reduction was discussed mechanistically as one of the Meerwein-Ponndorf-Verley reduction.

Though a number of reactions caused by alumina are known, very little has been recorded of the reduction of ketones on alumina chromatography.[1] This note describes the Meerwein-Ponndorf-Verley reduction of planar α-ketols, isoilludin S(**3**) and M(**4**), to dihydro compounds **6** and **7** on active alumina with alcohol as solvent.

In the course of structural investigations of illudin S(**1**), it was found that, when illudin S was adsorbed on alumina (Wako, 300 mesh) with ethyl acetate as solvent, only isomerised isoilludin S (**3**) was obtained.[2] However, on being adsorbed on alumina column for two days using ethanol instead of ethyl acetate, isomerized isoilludin S (**3**) was converted into a compound whose IR spectrum indicates the absence of the carbonyl group, the NMR spectrum showing a newly produced signal at τ 6.62 due to α proton to a hydroxyl group. From the results and correlation with the reduction product of isoilludin S with sodium borohydride, the compound was assigned to be dihydroisoilludin S (**6**). This suggests that isoilludin S is reduced to dihydroisoilludin S(**6**) on active alumina.



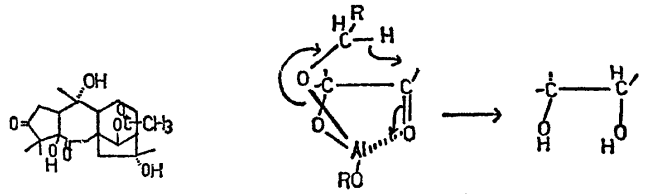
1 R=OH
2 R=H

3 R_1=OH, R_2=H
4 R_1=H, R_2=H
5 R_1=OAc, R_2=Ac

6 R_1=OH, R_2=H
7 R_1=H, R_2=H
8 R_1=H, R_2=Ac

The same kind of reduction on alumina column (Woelm, basic grade I) was observed with isoilludin M(**4**), which was obtained by isomerization of illudin M(**2**) on alumina column (Wako) using benzene, to give dihydroisoilludin M (**7**) in 64% yield. The stereochemistry of C-2 in compounds **6** and **7** was determined to be of *R* configuration since the proton signals due to equatorially oriented hydrogen in dihydro compounds **6** and **7** appear at τ 6.62 and 6.50 respectively, shielded effectively by neighboring cyclopropane ring.[3] This indicates that reduction of the ketols proceeded stereoselectively.

The same treatment on other ketols and ketones, *i.e.*, 3β-acetoxy-5α-hydroxycholestan-6-one (**9**), grayanotoxin derivative (**10**), cyclohexanone (**11**), tri-



(**10**) a

acetylisoilludin S (**5**), benzoin (**12**), was attempted but only the starting material was recovered. This might be due to the difficulty to form the intermediate (a) in the following surface process of the Meerwein-Ponndorf-Verley reduction. In compounds **9** and **10**, the carbonyl and vicinal hydroxyl groups are not planar, since the hydroxyl group is oriented axially in the plane containing the carbonyl group. Since compounds **3** and **4** have a moiety of planar ketols supported by the presence of a strong intramolecular hydrogen bond between the hydroxyl and carbonyl groups (see Experimental), the formation of planar intermediate (a) is possible. In compounds **11** and **5** which have no α hydroxyl group, it is unfavorable to combine with alumina surface. The intermediate arising from benzoin might have a fairly large steric repulsion between the two phenyl groups to cause recovery of the starting material.

Experimental

Reduction of Isoilludin S (3) with Aluminum Oxide. A solution of 50 mg of isoilludin S (**3**) in 1 ml of ethanol and 2 ml of chloroform was adsorbed on a 5 g of aluminum oxide (Wako, neutral 300 mesh) column and allowed to stand for 2 days at room temperature. The column was eluted with methanol and the eluate was evaporated *in vacuo* to give a crystalline material which was recrystallized from ethyl acetate to give 22 mg of dihydroisoilludin S (**6**), m.p. 198.5—199 °C. IR (cm^{-1}, Nujol) 3250, 1745 ($CH_3COOC_2H_5$), 1653, 1033: NMR (D_2O) after heating at 130 °C: τ 8.93 (3H, s, C–CH_3), 8.45 (3H, s, =C–CH_3), 6.62 (1H, s, H
C–OH), 4.27 (1H, s, =C–H).

Found: C, 66.08; H, 8.31%. Calcd for $C_{15}H_{22}O_4$ (1/2 $CH_3COOC_2H_5$); C, 65.78; H, 8.44%.

Reduction of Isoilludin S (3) with Sodium Borohydride. A solution of 100 mg of isoilludin S (**3**) in 3 ml of ethanol was treated with 50 mg of sodium borohydride and allowed to stand for 3 hr at room temperature. The reaction mixture was taken up into ethyl acetate and the extracts were filtered. The filtrate was dissolved in ethyl acetate and again filtered. The filtrate was concentrated *in vacuo* to give an amorphous solid. The solid was dissolved in ethanol and chromatographed on 2 g of aluminum oxide and eluted with ethanol. The eluate was concentrated and the residue was recrystallized from ethyl acetate to give a crystalline

* Present address: Department of Agricultural Chemistry, Faculty of Agriculture, Hokkaido University, Sapporo.

compound, mp 197—198 °C. The IR spectrum was identical with that of dihydroilludin S.

*Isomerization of Illudin M (**2**).* A solution of 50 mg of illudin M in benzene was adsorbed on 2.5 g of alumina (Wako) and allowed to stand for 2 days. The reaction product was eluted with methanol and the eluate was evaporated *in vacuo*. The residue was recrystallized from *n*-hexane-ether. mp 133—134.5 °C. IR (cm^{-1}, Nujol): 3450, 1705, 1605, 1608. NMR ($CDCl_3$) τ 8.97, 8.83, 8.52, 8.34 (each 3H, s, C–CH_3). 5.73 (1H, s, –C(H)–OH). 4.21 (1H, s, =C(H)–).

Found: C, 72.53; H, 8.11%. Calcd for $C_{15}H_{20}O_3$; C, 72.55; H, 8.12%.

*Reduction of Isoilludin M (**4**) with Aluminum Oxide.* A solution of 22 mg of isoilludin M in chloroform containing a small amount of ethanol as stabilizer was adsorbed on 2 g of aluminum oxide for 2 days. The column was eluted with chloroform and 6 mg of unchanged isoilludin M was recovered. Further elution with methanol gave 14 mg of dihydroisoilludin M (**7**). mp 193 °C. IR (cm^{-1}, Nujol) 3480, 1648, 1030. NMR ($CDCl_3$) τ 8.98, 8.87, 8.69, 8.41 (each 3H, s, C–CH_3), 6.50 (1H, s, –C(H)OH), 5.71 (1H, s, –C(H)OH), 4.34 (1H, s, =C(H)–).

*Acetylation of Dihydroisoilludin M (**7**).* A solution of 24 mg of dihydroisoilludin M with 0.5 ml of acetic anhydride 0.5 ml of dry pyridine was allowed to stand overnight at room temperature. The reaction mixture was poured into water, extracted with ether and dried over anhydrous sodium sulfate. The solvent was evaporated *in vacuo* to give 28 mg of oily acetate. IR (cm^{-1}, film) 3480, 1740, 1648, 1235. NMR ($CDCl_3$) τ 9.00, 8.74, 8.68, 8.60 (each 3H, s, C–CH_3), 7.92 (6H, s, OAc), 5.12 (1H, s, –C(H)–OAc), 4.42 (1H, s, C(H)–OAc), 4.33 (1H, s, =C(H)–H).

*Treatment of Compounds **5**, **11**, **12**, **13** and **14** with Aluminum Oxide.* The compounds were treated under the conditions described above but none were reduced.

Thanks are due to Dr. M. Anchel, New York Botanical Garden, for her generous gift of natural illudin M.

Charge-transfer Complex of Sydnones

Akiko CHINONE and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 17, 1973)

Synopsis. The complex formation of 3-methylsydnone, 3-phenylsydnone, and 3,4-diphenylsydnone with TCNE was described. From the electronic absorption spectra of the complexes, ionization potentials of sydnones are estimated.

Due to their unique mesoionic character, sydnones have been the subject of continued study since their discovery in 1935.[1] It was reported[2] that sydnones formed complexes with Friedel-Crafts catalysts, and in all cases the bonding occurred through the exocyclic oxygen atom, which was deduced from the shift of carbonyl absorption in IR spectra. The mole ratio of sydnone to metal chloride was reported to be 1 : 1. It was also reported[3] that 3-phenylsydnone formed a loose complex with iodine in acetonitrile but the complex was not isolated. In this report we describe the complex formation study of sydnone with π-acid.

The electronic-absorption spectrum of a solution of 3-methylsydnone and tetracyanoethylene (TCNE) in dichloromethane showed absorption muximum at 405 nm, which cannot be attributed to the starting materials but to a new molecular species. We assume that the absorption band in this region is due to the presence of 3-methylsydnone–TCNE charge-transfer complex. 3-Phenylsydnone and 3,4-diphenylsydnone also formed charge-transfer complex with TCNE, showing characteristic absorption bands as shown in Table. The concentration dependence of the electronic absorption spectra of these complexes was analyzed by method of Benesi-Hildebrand.[4] From the result, the molar ratio in the complex is assumed to be 1 : 1 as in the case of 3-phenylsydnone–iodine complex.[3]

Ionization potentials (I_p) of sydnones are estimated from the empirical relationship:[5]

$$\tilde{\nu}_{max} = 0.487 I_p - 1.30 \text{ (eV)}$$

as shown in Table 1.

TABLE 1. COMPLEXES FORMED BETWEEN SYDNONES AND TCNE (solvent, CH_2Cl_2; temperature, about 20 °C)

π-Base	λ_{max} (nm)	I_p (eV)
3-Methylsydnone	405	9.0
3-Phenylsydnone	405	9.0
3,4-Diphenylsydnone	495	7.8

The IR spectra of sydnone–TCNE complexes in dichloromethane did not show appreciable differences in comparison with that of each component. These complexes were not isolated as a crystal but dissociated to each component when the solvent was evaporated in a vacuum.

Iminodithiocarbonates. VI.[1] Reaction of Sulfur-substituted Carbonium Ion with Sodium Azide

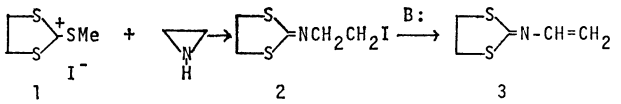
Yoshio UENO and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

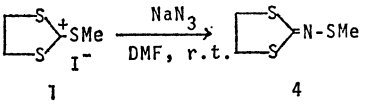
(Received September, 29, 1973)

Synopsis. The reaction of 2-methylthio-1,3-dithiolan-2-ylium iodide **1** with sodium azide gave 2-methylthioimino-1,3-dithiolane **4**. Thiooxime **4** reacted with chloramine T and dimethyl sulfate to give sulfilimine **9** and sulfonium salt **10**, respectively.

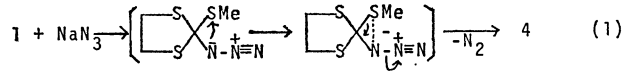
In a previous paper we reported on the reaction of 2-methylthio-1,3-dithiolan-2-ylium iodide **1** with ethyleneimine to produce 2-(β-iodoethylimino)-1,3-dithiolane **2**, which is easily converted into the conjugated *N*-vinyl monomer **3**.[2]



In this paper we wish to report on the reaction of the cation **1** with sodium azide as nitrogen-nucleophile. Cation **1** reacted with sodium azide in DMF at room temperature with evolution of nitrogen gas to give the thiooxime derivative **4** in 49% yield.

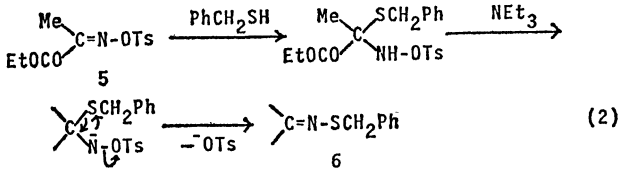


The structure of **4** was confirmed by elemental analysis and spectroscopic data. The NMR spectrum of **4** exibited a singlet peak at δ 2.40 (SMe, 3H) and multiplet peaks centered at δ 3.4 (SCH_2CH_2S, 4H). The IR absorption band due to $\nu C{=}N$ appeared at 1542 cm^{-1}. It is noteworthy that nitrogen gas evolution occurred even at room temperature, since ordinary organic azides do not decompose at such a low temperature. For the sake of explanation we postulate the sulfide participation which could accelerate the elimination of nitrogen gas: The methylthio group interacts with the negative charge on nitrogen atom by means of the vacant d-orbitals and the facile C–S bond cleavage takes place concertedly with the elimination of nitrogen molecule to produce the final product **4** as follows.



(1)

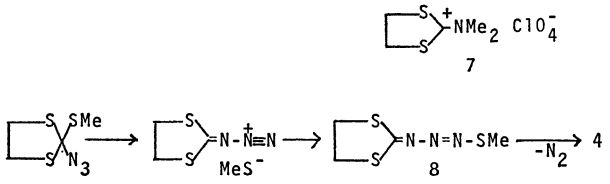
A similar explanation has been employed for the following transformation by Sudo *et al.*.[3]



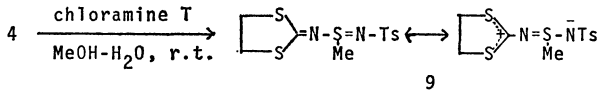
(2)

We see a similarity between the reactions (1) and (2). Thus the nitrogen gas in (1) corresponds to ^-OTs in (2) as eliminating group. 2-Dimethylamino substituted cation **7**, which would not have effective participation toward azide, did not react with sodium azide and was recovered. Participation by a ring-sulfur atom would not be involved due to the steric requirement presumed to be unfavorable.

An alternative scheme for the formation of **4** may be one involving the triazene intermediate **8**.

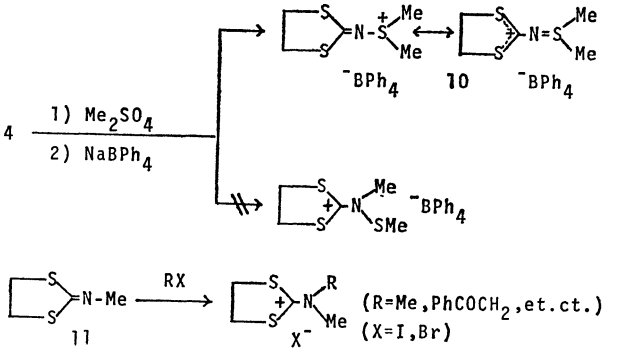


Reactions of thiooxime **4** newly obtained with chloramine T and dimethyl sulfate were undertaken, and **4** was found to react with chloramine T to give the sulfilimine **9** in 34% yield.



The IR absorption bands of **9** appeared at 1478 cm^{-1} (C=N) and at 955 cm^{-1} (S=N). The value due to $\nu C{=}N$ highly shifted to a lower wave number indicating a strong conjugation between the C=N and S=N groups as formulated above. This was supported by the NMR of **9**. Thus the ring methylene protons shifted from δ 3.40 to 3.67 accompanied by the conversion of **4** into **9**.

Thiooxime **4** reacted with dimethyl sulfate at 40—50 °C to give *S*-methylated sulfonium salt **10** in 50% yield. It is surprising that the methylation occurred at S and not at N atom, since ordinary 2-alkylimino-1,3-dithiolanes such as **11** are alkylated at N atom.[4]



The NMR spectrum of **10** exhibited a singlet peak at δ 3.17 (SMe, 6H) and multiplet peaks centered at δ 3.66 (SCH_2CH_2S, 4H) and at δ 6.83(Ph, 20H). The presence of two equivalent methyl group supports *S*-methylation and excludes *N*-methylation. Sulfonium salt **10** is considered to be stabilized by delocalization of its positive charge into 1,3-dithiolane ring as formulated above.

Experimental

2-Methylthioimino-1,3-dithiolane ***4***. To a suspension of 11.2 g (0.04 mol) of 2-methylthio-1,3-dithiolan-2-ylium iodide[5] in 70 ml of DMF was added 2.6 g (0.04 mol) of sodium azide with stirring. Nitrogen gas was evolved and a brown suspension turned into a homogeneous solution. Sodium iodide was then precipitated as white needles. After being left to stand over-night, the solvent was removed under a reduced pressure under nitrogen atmosphere and the residue was poured into water and extracted with ether, dried over $MgSO_4$. Evaporation of ether and distillation gave 3.3 g (49%) of **4**; bp 111—113 °C (1 mmHg), IR: 1541 cm^{-1} (νC=N)„ UV λ_{max}^{EtOH} 231, 295.5, 275(sh), and 448 nm, NMR (see text) Found[6]: C, 28.61; H, 4.23; S, 57.72%. Calcd for $C_4H_7NS_3$: C, 29.10; H, 4.27; S, 58.14%.

Sulfilimine ***9***. 2.3 g (0.014 mol) of thiooxime **4** was added to a solution of 3.4 g (0.012 mol) of chloramine T in (30 ml)–MeOH (20 ml). Acetonitrile (20 ml) was added to the reaction mixture in order to crystallize the oily substance separated. Stirring was continued for 2 hr. Filtration followed by evaporation of the filtrates gave oily residues which were crystallized by washing with ether. **9** (1.24 g, 34%) was obtained as colourless prisms: mp 181—182 °C (recrystallized from ethanol), IR: 1478 cm^{-1} (νC=N), 1279, 1139 cm^{-1} (νSO_2), 955 cm^{-1} (νS=N), 1082 cm^{-1}. NMR (DMSO-d_6) δ: 2.30(Me, s, 3H), 2.45 (SMe, s, 3H), 3.67 (SCH_2CH_2S, m, 4H), 7.50 (Ar, m, 2H), and 7.97 (Ar, m, 2H).

Methylation of Thiooxime ***4***. 0.8 g (4.8 mmol) of **4** and 0.6 g (4.8 mmol) of dimethyl sulfate were heated at 40—50 °C for 1.5 hr. After the mixture was cooled, aq. solution of sodium tetraphenylborate (1.7 g in 50 ml H_2O) was added to give 1.2 g (50%) of **10**: mp, 199—201 °C (recrystallized from acetone-ether), IR; 710 and 740 cm^{-1}, NMR (DMSO-d_6) δ: 3.17 (SMe, s, 6H), 3.66 (SCH_2CH_2S, m, 4H), and 6.83 (Ph, m, 20H), Found: C, 70.09; H, 6.14; N, 2.76; S, 18.73%. Calcd. for $C_{29}H_{30}BNS_3$: C, 69.76; H, 6.06; N, 2.81; S, 19.23%.

Aromatic Substitution of Olefins. XXI.* Reaction of *o*-Alkylstyrenes with Benzene in the Presence of Palladium(II) Acetate

Morio WATANABE, Masaaki YAMAMURA, Ichiro MORITANI, Yuzo FUJIWARA, and Akio SONODA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Recieved October 29, 1973)

Synopsis. In aromatic substitution of olefins, steric factor of *o*-alkyl substituents of styrene was investigated. The formation of arylated products was found to be decreased by introduction of alkyl groups to *ortho* position of styrene.

In previous papers we reported on a new method for the synthesis of stilbene derivatives by the substitution of aromatics for vinylic hydrogen of styrenes in the presence of palladium(II) salts.[1] It was demonstrated that a steric factor plays an important role. The phenylation reactivity was thus found to diminish markedly in the reactions of diphenylethylene and triphenylethylene with benzene as compared with the reaction of styrene with benzene.[1]

In order to elucidate the steric factor in the arylation reaction, we have investigated the reaction of some *ortho*-alkylstyrenes with benzene as well as the reactions of styrene with some alkylbenzenes.

The arylation reactions of *o*-alkylstyrenes with benzene (Reaction(1)) were carried out under normalized conditions.[1] The results are summarized in Table 1. The reactions of *o*-methylstyrene(**1b**), 2,4,6-trimethylstyrene(**1c**), and 2,5-di-*tert*-butylstyrene(**1d**) with benzene gave **2b**, **2c**, and **2d**, respectively, as the usual phenylated products besides small amounts of 1,1-diarylethylenes, **3b** and **3c**.[2] Introduction of alkyl groups into the *ortho* positions of styrene caused a decrease in the yield of arylation products. However, it does not seem likely that the second methyl substituent has any further effect on the arylation from a comparison of the reactions of **1b** and **1c**.

On the other hand, in the reaction of styrene with methyl substituted benzenes (Reaction(2)), the depressing effect on an additional methyl group was found to be more evident. The reaction of mesitylene with styrene was found to be more than five times slower than that of *p*-xylene with styrene (Table 2). It should be noted that a small amount of 1,1-diarylethylene was formed in the reaction of mesitylene as well.

A remarkable contrast is observed between the two similar reactions (1) and (2) which lead to the same reaction product **2c**; arylation reaction of styrene with mesitylene appeared to be five times slower than that of **1c** with benzene.

a) Ref. 1. b) based pn $Pd(OAc)_2$ used. c) 1-Phenyl-1-mesitylethylene **3c** formed.

The results suggest that there is a greater steric hindrance at the site of the arylating species in the transition state involving a palladium-carbon σ bond.[3]

Experimental

The IR and UV spectra were measured with Hitachi EPI-S2 and Hitachi EPS-2U spectrophotometers, respectively. The NMR spectra were recorded on a JEOL Co. C-60HL spectrometer with TMS as an internal standard. Vpc analyses were carried out with a JEOL JGC-20K gas chromatograph.

Starting olefins **1b**, **1c**, and **1d** were prepared by known methods.[4]

The arylation reactions were performed under normalized conditions: A mixed solution of olefin (50 mmol), palladium-(II) acetate (50 mmol), benzene (445 ml), and acetic acid (100 ml) was heated under reflux for 8 hr. After the usual work-up,[1] the product mixture was subjected to vpc analysis, (SE-30, Microwax). Samples for spectral measurement and elemental analysis were collected by means of a preparative vpc. The spectral data of these products are summarized in Table 1. The compounds showed satisfactory elemental analyses.

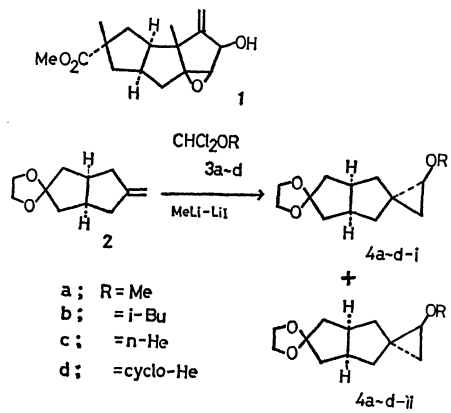
(Received November 1, 1973)

Synopsis. The addition of several alkoxycarbenes on *cis*-bicyclo[3,3,0]octane derivative (**2**) was tried. The bulkier reagent gave the better stereoselectivity and *exo* adducts were obtained more predominantly.

Recently we achieved the total synthesis of methyl hirsutate (**1**),[2] a sesquiterpene derived from a biogenetic intermediate, protoilludane.[3] A carboxylic function correctly oriented was constructed with a certain stereoselectivity by the predominant *exo* attack of methoxycarbene on *cis*-bicyclo[3,3,0]octane derivative (**2**). This paper describes the procedure of the addition of several alkoxycarbenes on *exo* methylene compound **2** and shows how the ratio of *exo* to *endo* adduct varies with alkyl group of alkoxycarbene.



Compound **2** was obtained from known *cis*-bicyclo[3,3,0]octadione.[2a] Addition of alkoxycarbenes, prepared from dichloromethyl alkyl ethers (**3a**—**3d**) and methyllithium–lithium iodide in ether at −20——15 °C,[4] to **2** afforded epimeric mixtures of alkoxycyclopropane derivatives (**4**). The reaction was carried out with four different sizes of alkoxycarbene. Yields and ratios of *exo* to *endo* adduct are listed in Table 1. In the NMR spectra of **4**, signals due to three cyclopropyl protons appeared as typical ABX systems.[5] The configurations were assigned by taking account of the steric course of the reaction.[2b,6]

TABLE 1. RESULTS OF THE ADDITION OF ALKOXYCARBENES ON **2**

Products	Yields (%)[a]	Ratios of *exo* (**i**) to *endo* adduct (**ii**)[b]
4a (R=methyl)	75	2.2
4b (R=isobutyl)	83	2.5
4c (R=*n*-hexyl)	77	2.2
4d (R=cyclohexyl)	73	2.9

a) Isolated yield, not optimized. b) Determined by glc (see Expeeimental).

The results obtained show that the bulkier reagent clearly gave the better stereoselectivity. However, the steric course of the reaction was not so markedly effected by the bulkiness of alkoxycarbene, since the bulky alkyl group might not be close enough to the attacking point of the reagent.

Experimental

NMR spectra were measured at 100 MHz on a JEOL Co. Model PS-100 spectrometer using TMS as an internal standard. IR spectra were taken on a Hitachi Model EPI-G3 with NaCl optics. Glc were carried out on a Yanaco G8-TEP and an Aerograph Autoprep 700.

*3,3-Methoxyethano-7,7-ethylenedioxy-*cis*-bicyclo[3,3,0]octane (**4a**)* A typical procedure for carbene addition. To a solution of **2** (200 mg) and dichloromethyl methyl ether **3a**[7] (1 g) in dry ether (10 ml) was added 0.8 N ether solution of methyllithium–lithium iodide (30 ml) under stirring in an ice-salt bath (−20——15 °C). Addition was completed in 1 hr and the mixture was stirred at −20——15 °C for further 1 hr. Water was added to the resulting mixture and products were taken up with ether. The extracts were washed with brine, dried and evaporated to leave crude material which on chromatography (silica gel, 10% ethyl acetate–*n*-hexane elution) gave a mixture of methoxycyclopropane derivatives (**4a-i**) and (**4a-ii**) (188 mg, 75% yield, *exo* adduct **4a-i**/*endo* adduct **4a-ii**=2.2 by glc). Further purification by preparative glc (5% DC-550 column at 150 °C) gave pure **4a-i** and **4a-ii** as colorless oils. **4a-i**: IR (neat) 3060 cm^{-1}; NMR δ (CCl_4) 0.44, 0.55 and 2.78 (each 1H, ABX with J_{AB}=5.6, J_{AX}=6.1 and J_{BX}=3.8 Hz, CH_2 and CH–O on cyclopropane), 3.22 (3H, s., CH_2–O) and 3.77 (4H, s, O–CH_2CH_2–O); Found: C, 69.42; H, 8.85%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%. **4a-ii**: IR (neat) 3060 cm^{-1}; NMR δ (CCl_4) 0.27, 0.44 and 2.95 (each 1H, ABX with J_{AB}=5.8, J_{AX}=6.0 and J_{BX}=3.4 Hz, CH_2 and CH–O on cyclopropane), 3.28 (3H, s, CH_3O) and 3.77 (4H, s, O–CH_2CH_2–O); Found: C, 69.71; H, 8.93%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

*3,3-Isobutoxyethano-7,7-ethylenedioxy-*cis*-bicyclo[3,3,0]octane (**4b**).* Crude product from **2** (200 mg), dichloromethyl isobutyl ether **3b**[7] (1.4 g) and 0.8 N methyllithium–lithium iodide ether solution (30 ml) gave a mixture of isobutoxy cyclo derivatives (**4b-i**) and (**4b-ii**) (245 mg, 83% yield, *exo* adduct **4b-i**/*endo* adduct **4b-ii**=2.5 by glc) on chromatography. Preparative glc (5% QF-1 column at 165 °C) afforded pure **4b-i** and **4b-ii** as colorless oils. *Exo* adduct **4b-i**: IR (neat) 3054 cm^{-1}; NMR δ (CCl_4) 0.46, 0.58 and 2.81 (each 1H, ABX with J_{AB}=5.7, J_{AX}=6.5 and J_{BX}=3.4 Hz, CH_2 and CH–O on cyclopropane), 0.86 (6H, d with J=6.0 Hz, $CH(C\underline{H}_3)_2$), 3.10 (2H, AB part of ABX,

O–CH$_2$CH) and 3.78 (4H, s, O–CH$_2$CH$_2$–O); Found: C, 72.43; H, 9.57%. Calcd for $C_{16}H_{26}O_3$: C, 72.14; H, 9.84%. *Endo* adduct **4b-ii**: IR (neat) 3040 cm^{-1}; NMR δ(CCl_4) 0.28, 0.42 and 2.96 (each 1H, ABX with J_{AB}= 5.3, J_{AX}=6.2 and J_{BX}=3.1 Hz CH_2 and CH–O on cyclopropane), 0.87 (6H, d with J=6.0 Hz, CH(C$\underline{H}_3$)$_2$), 3.16 (2H, AB part of ABX, O–C$\underline{H}_2$CH) and 3.72 (4H, s, O–CH$_2$CH$_2$–O); Found: C, 72.38; H, 9.86%. Calcd for $C_{16}H_{26}O_3$: C, 72.14; H, 9.84%.

*3,3 - n -Hexoxylthano - 7,7-ethylenedioxy - cis - bicyclo[3,3,0]octane (**4c**).* Epimeric mixture of *n*-hexoxycyclopropane derivatives (**4c-i**) and (**4c-ii**) (248 mg, 77% yield, *exo* adduct **4c-i**/*endo* adduct **4c-ii**=2.2 by glc) was obtained from the reaction of **2** (200 mg), dichloromethyl *n*-hexyl ether **3c**[7] (1.6 g) and 0.8 N methyllithium–lithium iodide ether solution (30 ml). Preparative glc (5% QF-1 column at 180 °C) gave pure **4c-i** and **4c-ii** as colorless oils. *Exo* adduct **4c-i**: IR (neat) 3047 cm^{-1}; NMR δ(CCl_4) 0.46, 0.58 and 2.82 (each 1H, ABX with J_{AB}=5.7, J_{AX}=6.3 and J_{BX}=3.5 Hz, CH_2 and CH–O on cyclopropane), 0.89 (3H, destorted t., $CH_2C\underline{H}_3$), 3.33 (2H, destorted t, O–C$\underline{H}_2$CH$_2$) and 3.78 (4H, s, O–CH$_2$CH$_2$–O); Found: C, 73.55; H, 10.37%. Calcd for $C_{18}H_{30}O_3$: C, 73.43; H, 10.27%. *Endo* adduct **4c-ii**: IR (neat) 3042 cm^{-1}; NMR δ(CCl_4) 0.30, 0.44 and 2.96 (each 1H, ABX with J_{AB}=5.3, J_{AX}=6.9 and J_{BX}=2.7 Hz, CH_2 and O–CH on cyclopropane), 0.87 (3H, destorted t, $CH_2C\underline{H}_3$), 3.38 (2H, m, O–C$\underline{H}_2$CH$_2$) and 3.74 (4H, s, O–CH$_2$CH$_2$–O); Found: C, 73.17; H, 10.49%. Calcd for $C_{18}H_{30}O_3$: C, 73.43; H, 10.27%.

*3,3 - Cyclohexoxyethano - 7,7-ethylenedioxy - cis - bicyclo[3,3,0]octane (**4d**).* **2** (150 mg) and dichloromethyl cyclohexyl ether **3d**[7] (1g), was treated with 0.8 N methyllithium–lithium iodide ether solution (30 ml), gave an epimeric mixture of cyclohexoxycyclopropane derivatives (**4d-i**) and (**4d-ii**) (175 mg, 73% yield, *exo* adduct **4d-i**/*endo* adduct **4d-ii**=2.9 by glc). Pure **4d-i** and **4d-ii** were obtained from this mixture by preparative glc (5% DC-550 at 200 °C) as colorless oils. *Exo* adduct **4d-i**: IR (neat) 3045 cm^{-1}; NMR δ(CCl_4) 0.46, 0.58 and 2.92 (each 1H, ABX with J_{AB}= 5.4, J_{AX}=5.7 and J_{BX}=4.1, CH_2 and CH–O on cyclopropane), 3.20 (1H, m, O–C$\underline{H}$(CH$_2$–)$_2$) and 3.75 (4H, s, O–CH$_2$CH$_2$–O); Found: C, 73.91; H, 9.63%. Calcd for $C_{18}H_{28}O_3$: C, 73.93; H, 9.65%. *Endo* adduct **4d-ii**: IR (neat) 3045 cm^{-1}; NMR δ (CCl_4) 0.32, 0.44 and 3.06 (each 1H, ABX with J_{AB}=5.3, J_{AX}=6.1 and J_{BX}=3.4 Hz, CH_2 and CH–O on cyclopropane), 3.32 (1H, m, O–C$\underline{H}$(CH$_2$–)$_2$) and 3.72 (4H, s, O–CH$_2$CH$_2$–O); Found: C, 73.75; H, 9.61%. Calcd for $C_{18}H_{28}O_3$: C, 73.93; H, 9.65%.

Some Substituted 1*H*,4*H*- and 1*H*,5*H*-Pyrazolo[4,3-*c*]pyrazoles. Syntheses and Properties

Joung Hee LEE, Akira MATSUMOTO, Masayuki YOSHIDA, and Osamu SIMAMURA

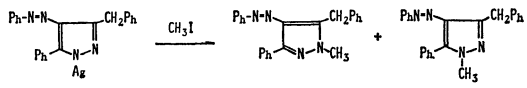
Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113

(Received November 27, 1973)

Syonpsis. 1,4-Dimethyl-3,6-diphenyl-, 1,5-dimethyl-3,3-diphenyl-, and 4-methyl-2,3,6-triphenyl-pyrazolo[4,3-*c*]-pyrazoles(IV, V, and VIII) were prepared and their structures were established on the basis of their spectral data.

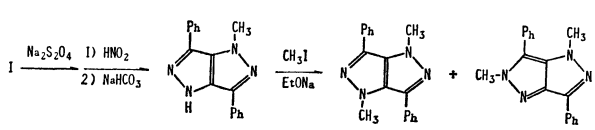
Syntheses of 2,3,5,6-tetra-aryl-1,2,4,5-tetra-azapentalenes, meso-ionic heterocycles, have recently been described.[1] These compounds contain four aryl substituents on the 2*H*,5*H*-pyrazolo[4,3-*c*]pyrazole ring. This paper presents the syntheses and properties of substituted 1*H*,4*H*- and 1*H*,5*H*-pyrazolo[4,3-*c*]pyrazoles.

Condensation of 1,4-diphenyl-2-phenylazobutane-1,3-dione[2] with methylhydrazine in ethanol gave 5-benzyl-1-methyl-3-phenyl-4-phenylazopyrazole(I), mp 151—152 °C, whereas treatment of the silver salt of 3-benzyl-5-phenyl-4-phenylazopyrazole[3] with excess of methyl iodide in boiling benzene afforded a mixture of the above-mentioned pyrazole (I) and its isomer, 3-benzyl 1-methyl-5-phenyl-4-phenylazopyrazole (II), mp 89—91 °C. The structures of these pyrazoles were deduced on the basis of their mass spectra and are consistent with the experimental results described below.



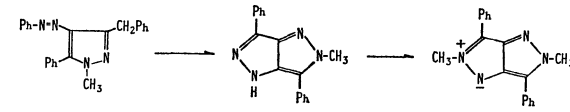
I II

Reduction of compound I with disodium dithionite and diazotization of the resulting amine by means of sodium nitrite in acetic acid followed by treatment with aqueous sodium bicarbonate yielded 3,6-diphenyl-1-methyl-4*H*-pyrazolo[4,3-*c*]pyrazole(III), mp 233—234 °C, which afforded, with excess of methyl iodide and sodium ethoxide in boiling ethanol, two mono-methylated products, 1,4-dimethyl-3,6-diphenylpyrazolo[4,3-*c*]pyrazole (IV), mp 202—204 °C, and the 1,5-dimethyl isomer (V), mp 169—171 °C, the structures being established on the basis of their mass and NMR spectra described in the experimental part.



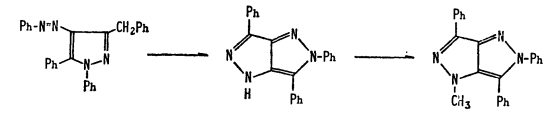
III IV V

If the structure of compound I were 3-benzyl-1-methyl-5-phenyl-4-phenylazopyrazole, the structure of compound III would be 3,6-diphenyl-2-methyl-4*H*-pyrazolo[4,3-*c*]pyrazole (III′) and, consequently, the structure of compound IV, which shows a sharp singlet proton signal from two equivalent methyl groups, would have to be 2,5-dimethyl-3,6-diphenylpyrazolo[4,3-*c*]-pyrazole (IV′); this structure, however, is ruled out, being inconsistent with the observed mass spectrum for compound IV (presence of a peak at *m/e* 82 due to $CH_3NCCNCH_3$). Thus, the structures of compounds I and II are confirmed.



II III′ IV′

3-Benzyl-1,5-diphenyl-4-phenylazopyrazole (VI) prepared by condensation of 1,4-diphenyl-2-phenylazobutane-1,3-dione with phenylhydrazine was similarly cyclized to 2,3,6-triphenyl-4*H*-pyrazolo[4,3-*c*]pyrazole (VII), mp 277—279 °C, which was converted into a mono-methylated product (VIII), mp 191—192 °C. The mass spectrum of compound VIII (presence of a peak at *m/e* 180 due to $C_6H_5CNC_6H_5$) rules out an alternative structure of 5-benzyl-1,3-diphenyl-4-phenylazopyrazole for compound VI, in which the position of the *N*-phenyl group was uncertain in the original literature.[2]



VI VII VIII

The NMR spectrum of compound VIII exhibits two multiplets centered at τ 1.75 (2H) and 2.65 (13H) due to aromatic protons, and this fact indicates that one phenyl ring (τ 1.75, *o*-2H) is coplanar with the nucleus, because Finar and Rackham showed a similar deshielding of the *ortho* protons of 1-phenyl substituted aza-aromatic compounds due to a large electric field associated with the lone pair of electrons of the nitrogen atom at position 2, this effect being operative only when both rings are coplanar.[4] Thus, to compound VIII is assigned the structure of 4-methyl-2,3,6-triphenyl-pyrazolo[4,3-*c*]pyrazole and not that of isomeric 5-methyl-2,3,5-triphenylpyrazolo[4,3-*c*]pyrazole, in which no coplanar phenyl is possible because of steric hindrance. This result is in contrast to the finding that the silver salt of 2-phenyl-4*H*-*v*-triazolo[4,5-*d*]-*v*-triazole affords both 4- and 5-methyl-2-phenyl-*v*-triazolo[4,5-*d*]-*v*-triazoles.[5]

Experimental

5-Benzyl-1-methyl-3-phenyl-4-phenylazopyrazole (I). This compound (Found: C, 78.55; H, 5.77; N, 15.81%; M^+,

352. Calcd for $C_{23}H_{20}N_4$: C, 78.38; H, 5.72; N, 15.90%; M, 352), mp 151—152 °C (from ethanol), *m/e* 352(M^+), 274($M-C_6H_5-H$), 259 ($M-PhCH_2-2H$), 103(PhCN), and 91($PhCH_2$), was prepared according to the directions given for the preparation of 3-benzyl-1,5-diphenyl-4-phenylazopyrazole[2] (VI).

3-Benzyl-1-methyl-5-phenyl-4-phenylazopyrazole (II). The silver salt (0.48 g) prepared from 3-benzyl-5-phenyl-4-phenylazopyrazole (0.36 g) and silver nitrate (1.0 g) in the usual way was heated in a mixture of benzene (15 ml) and methyl iodide (2 ml) under reflux overnight. On cooling, the precipitate was removed by filtration, and the filtrate was concentrated to yield 0.40 g of orange red solid. This crude material was subjected to purification by preparative thin layer chromatography on silica gel. Development with benzene afforded two contiguous bands with R_f lying between 0.32 and 0.47. The band with the larger R_f gave 0.10 g (26%) of compound I, and the one with the smaller R_f 0.06 g (16%) of compound II (Found: C, 78.27; H, 5.48; N, 15.92%. Calcd for $C_{23}H_{20}N_4$: C, 78.38; H, 5.72; N, 15.90%), mp 89—91 °C, *m/e* 352 (M^+), 275 ($M-C_6H_5$), 206 (PhNNCCPh), 179 (PhCHCPh), 118 ($PhCNCH_3$), and 91 ($PhCH_2$).

3,6-Diphenyl-1-methyl-4H-pyrazolo[4,3-c]pyrazole (III). To a suspension of compound I (4.0 g) in 80 ml of boiling 80% ethanol was added powdered disodium dithionite in small portions until the mixture became homogeneous. The mixture was then steam-distilled to remove aniline and ethanol. The remaining crystalline solid was collected and recrystallized from ethanol to yield the starting material (I; 1.08 g). The ethanolic filtrate was concentrated to dryness under reduced pressure. The residue was dissolved in 30 ml of acetic acid and diazotized with sodium nitrite (0.65 g) at 0—5 °C. The mixture was stirred for 15 min at this temperature and poured into cold dilute aqueous sodium bicarbonate. Organic materials were extracted with dichloromethane, and the extract was evaporated under reduced pressure. The residue was dissolved in a small amount of acetic acid and the solution was heated on a water bath for 15 min. On evaporation of the solvent, it gave 0.80 g (34%) of compound III (Found: C, 74.40; H, 5.01; N, 20.46%. Calcd for $C_{17}H_{14}N_4$: C, 74.43; H, 5.14; N, 20.43 %), mp 233—234 °C (white crystals from benzene).

1,4- and 1,5-Dimethyl-3,6-diphenylpyrazolo[4,3-c]pyrazoles (IV and V). Compound III (0.50 g) and methyl iodide (4 ml) were added to ethanolic sodium ethoxide solution prepared from 1 g of sodium and 45 ml of ethanol, and the mixture was heated under reflux overnight. The solvent was evaporated under reduced pressure, and the residue was washed with water and dried to yield 0.67 g of a solid. This crude product (0.50 g) was subjected to purification by preparative thin layer chromatography on silica gel using benzene-ether (10 : 1) as eluent. The band with R_f 0.45—0.53 gave 0.08 g (21%) of the 1,4-dimethyl isomer (IV) (Found: C, 75.14; H, 5.54; N, 19.54%. Calcd for $C_{18}H_{16}N_4$: C, 74.97; H, 5.59; N, 19.43%), mp 202—204 °C (from ethanol), τ 6.00 (6H, s, $2CH_3$), 2.65(6H, multiplet, aromatic), and 2.36(4H, multiplet, aromatic), *m/e* 288 (M^+), 103(PhCN), and 82($CH_3NCCNCH_3$). The band with R_f 0.38—0.44 yielded 0.09 g (23%) of the 1,5-dimethyl isomer (V) (Found: C, 75.11; H, 5.60; N, 19.64%. Calcd for $C_{18}H_{16}N_4$: C, 74.97; H, 5.59; N, 19.43%), mp 169—171 °C (from ethanol), τ 6.20(3H, s, CH_3), 5.95 (3H, s, CH_3), 2.53(8H, multiplet, aromatic), and 1.80(2H, multiplet, aromatic), *m/e* 288(M^+) and 118($PhCNCH_3$).

2,3,6-Triphenyl-4H-pyrazolo[4,3-c]pyrazole (VII). 3-Benzyl-1,5-diphenyl-4-phenylazopyrazole[2] (VI), treated similarly to the preparation of compound III, afforded compound VII (Found: C, 78.75; H, 4.60; N, 16.74%. Calcd for $C_{22}H_{16}N_4$: C, 78.55; H, 4.79; N, 16.66%), mp 277—279 °C (from ethanol).

4-Methyl-2,3,6-triphenylpyrazolo[4,3-c]pyrazole (VIII). Compound VII prepared above was methylated in the same way as in the preparation of compounds IV and V to yield compound VIII (Found: C, 78.56; H, 4.88; N, 16.29%. Calcd for $C_{23}H_{18}N_4$: C, 78.83; H, 5.18; N, 15.99%), mp 191—192 °C (from ethanol), *m/e* 350(M^+), 246($M-PhCNH$), and 180(PhCNPh), τ 6.15(3H, s, CH_3), 2.65(13H, multiplet, aromatic), and 1.75(2H, multiplet, aromatic).

Cycloaddition Reaction of Troponoids with Dimethyl Maleate

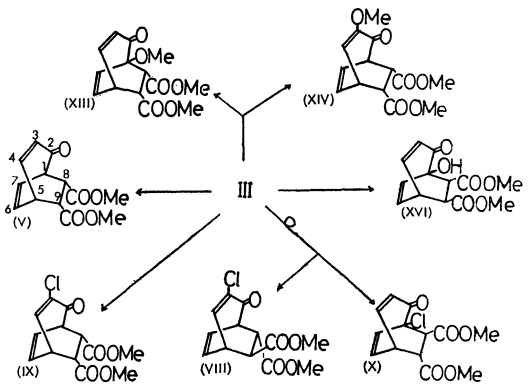
Hitoshi TAKESHITA*, Yoshikazu SHOJI and Shô ITÔ**

Department of Chemistry, Tohoku University, Aramaki-Aoba, Sendai 980

(Received December 3, 1973)

Synopsis. Thermal cycloaddition reaction of methyl maleate with tropone, 2-chloro-, 2-methoxytropone and tropolone was investigated. Each reaction yielded [4+2] type adducts with high peri- and stereospecificities but with less regioselectivity.

In a series of our studies on the Diels-Alder reaction of troponoids, it was shown[1,2] that maleic anhydride (I), a cyclic dienophile with symmetrical structure, yielded the *endo-cis*-adducts except in the case of tropolone(II), while acrylonitrile, an acyclic dienophile with unsymmetrical structure, yielded a mixture of *regio-* and *stereo* isomeric compounds.[3] The contrasting results there observed prompted us to investigate the reaction with another type of dienophiles, an acylic one with symmetrical structure. Thus, we have carried out the reactions with dimethyl maleate(III) for comparison.



When III was heated with tropone(IV), a single product, V, was obtained in 80% yield and its structure was established by direct comparison with the dimethyl ester of the hydrolysate of the adduct(VI) obtained from I and IV.[1]

The reaction of III with 2-chlorotropone(VII) afforded three 1 : 1-adducts, VIII, IX and X in 7, 11 and 7% yield, respectively. IX was shown to be identical with the corresponding dimethyl ester of the adduct(XI) derived from I and VII.[4] VIII exhibits three vinyl proton signals in its NMR spectrum (Table 1), indicating it be a 3-chloro-derivative. The configuration of the substituents was deduced as 8α, 9β-orientation on the basis of the observed coupling constants, $J_{1,8}=1.5$, and $J_{8,9}=6.0$ Hz.[5] Similarly X was identified as 1-chloro-8β,9α-isomer by the NMR evidences (four vinylic hydrogens (Table 1 and $J_{5,9}=2.0$, $J_{8,9}=4.5$ Hz).

Heating of III with 2-methoxytropone(XII), afforded two products, XIII and XIV, in 17 and 6% yield, respectively.[6] Since XIII was chemically correlated with the adduct(XV) obtained from I and XII,[2a] its structure was established to be 1-methoxy-8α,9α-derivative. On the other hand, XIV, having three vinyl proton signals and the coupling constants, $J_{1,8}=0$, $J_{8,9}=10.0$ Hz, in the NMR spectrum, was shown to be 3-methoxy-8α,9α-derivative.

TABLE 1. NMR CHEMICAL SHIFTS OF THE ADDUCTS[5]

	H_1	H_3	H_4	H_5	H_6	H_7
V	3.95	5.80	7.05	3.70	6.53	6.22
VIII	4.10	Cl	7.27	3.4—3.8	6.27	6.17
IX	3.4—4.1	Cl	7.40	3.4—4.1	6.62	6.27
X	Cl	6.05	7.03	3.77	6.53	6.13
XIII	OMe	5.88	7.22	3.97	6.75	6.25
XIV	4.13	OMe	6.02	~3.9	6.52	6.22
XVI	OH	5.98	7.32	3.9—3.5	6.53	6.15

	$H_{8\alpha}$	$H_{8\beta}$	$H_{9\alpha}$	$H_{9\beta}$	Me
V	COOMe	3.32	COOMe	3.60	3.61, 3.65
VIII	COOMe	3.4—3.8	3.4—3.8	COOMe	3.75, 3.75
IX	COOMe	3.4—4.1	COOMe	3.4—4.1	3.69, 3.72

* Present Address: Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka 812.

** To whom all the correspondences should be addressed.

The reaction of III with II was somewhat complicated yielding a mixture, and only the adduct XVI was isolated in 10% yield after the extensive silica-gel column chromatography. The NMR spectrum of XVI revealed the presence of four vinylic hydrogens and *exo-cis*-orientation for the ester groups.[7]

The present result revealed that the reaction of III with troponoids proceeded stereospecifically: All the adduct are free from their stereoisomers with opposite orientation of ester groups. This control of stereoselectivity of substituents on tropone ring is remarkable. Thus, the transition states leading to the *endo-cis* adducts are stabilized more than those to *exo-cis* products. The formation of *exo-cis* product XVI can be rationalized as the result of *endo* addition, followed by an isomerization, which are previously observed in the cycloaddition of tropolone.[2] In spite of the high stereospecificity, the regiospecificity is somewhat reduced: The formation of XIV as a minor adduct contrasts the case of maleic anhydride[1] and resembles with the case of acrylonitrile.[3]

The *trans*-adducts, VIII and X, whose formation apparently conflicts with the general rule of concerted cycloaddition, should be regarded as the adducts of not III but dimethyl fumarate (XVII), since the recovered unsaturated ester fraction in this particular case was consisted of XVII and no trace of III was detected. Some amounts of hydrogen chloride liberated by the decomposition of VII should be sufficient for this isomerization.[8,9]

Experimental

The Reaction of Dimethyl Maleate (III) with Tropone(IV). Formation of endo-cis-*Adduct(V).* IV(2 g) and III (4 g) were heated in a sealed tube(glass) for 18 hr at 130—140 °C. From the reaction mixture, III was removed by distillation *in vacuo*, and the residual mass was sublimed on a cold finger at 120 °C/2 mmHg to give V (3.6 g), colorless crystals, mp 86—88 °C(lit,[1] 83—87 °C), whose identity was confirmed by a direct comparison with the authentic sample.

*The Reaction of III with 2-Chlorotropone (VII). Formation of 3-Chloro-*endo-cis-*adduct(IX), 3-Chloro-8α,9β-*trans-*adduct (VIII) and 1-Chloro-8β,9α-*trans-*adduct(X).* VII(415 mg) and III(1.10 g) were heated in a similar manner for 20 hr at 150 °C. The reaction mixture was sublimed on a cold finger at 70 °C/2 mmHg to separate dimethyl fumarate (XVII), 870 mg. The residue was further distilled at higher temperature(120—140 °C/2 mmHg) to give a colorless liquid, 230 mg, which was then chromatographed on silica gel column to obtain VIII(a colorless liquid, 50 mg) (Found: C, 58.94; H, 4.46%. Calcd for $C_{13}H_{13}O_5Cl$: C, 58.87; H, 4.60%. ν: 1740, 1640, 1610 cm^{-1}), IX (colorless crystals, mp 172—173 °C (lit,[4] mp 172—173 °C), 90 mg, ν 1740, 1642, 1612 cm^{-1}), and X (colorless crystals, mp 177—179 °C, 50 mg) (Found: C, 59.01; H, 4.70%. ν: 1745, 1690 cm^{-1}).

*The Reaction of III with 2-Methoxytropone(XII). Formation of 1-Methoxy-*endo-cis-*adduct(XIII) and 3-Methoxy-*endo-cis-*adduct(XIV).* XII(400 mg) and III(1.0 g) were heated in a similar manner as the above for 15 hr at 150 °C. The reaction mixture was distilled *in vacuo* to remove unreacted III (620 mg). The residue was then distilled on a cold finger to give a colorless semi-soild, from which, a major component, XIII, was obtained by a filtration as colorless crystals (140 mg, mp 148—149 °C) (Found: C, 60.11; H, 5.67%. Calcd for $C_{14}H_{16}O_6$: C, 59.99; H, 5.75%. ν: 1750, 1675 cm^{-1}). The mother liquor of the above was then chromatographed on silica gel to give XIV (colorless crystals, mp 141—142 °C, 50 mg) (Found: C, 60.37; H, 5.60%. ν: 1747, 1680, 1635, 1617 cm^{-1}).

*The Derivation of 1-Methoxy-*endo-cis-*Adduct(XIII) from the adduct(XV) of I and XII.* XV (75 mg) was suspended in distilled water (3 ml) and heated for 30 min at 95—100 °C. After coling, separated colorless crystals were collected by filtration. Weight; 60 mg, mp 184—184.5 °C (Found: C, 57.16; H, 4.84%. Calcd for $C_{12}H_{12}O_6$: C, 57.14; H, 4.80%). The esterification of this specimen by diazomethane gave colorless crystals (mp 148—149 °C, 40 mg), whose identity with XIII has been established by a direct comparison.

*The Reaction of III with Tropolone(II). Isolation of 1-Hydroxy-*exo-cis-*Adduct(XVI).* II(400 mg) and III (1.0 g) were heated in a sealed tube for 15 hr at 145 °C and the reaction mixture was then distilled *in vacuo* to remove the unreacted III. The residue was fractionated by repeated column chromatography to yield XVI, colorless crystals, mp 95—101 °C, 45 mg (Found: C, 58.54; H, 5.22%. Calcd for $C_{13}H_{14}O_6$: C, 58.64; H, 5.30%. ν: 3450, 1745, 1685 cm^{-1}).

Spectral Difference of the A and B Forms of Deoxyribonucleic Acid

Yoshifumi NISHIMURA, Kosuke MORIKAWA, and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 19, 1973)

Synopsis. Infrared absorption spectrum of an oriented film of deoxyribonucleic acid from *Micrococcus lysodeikticus* has been examined in its A and B forms. In the A form a weak band was observed at 807 cm^{-1}, while in the B form this is absent and a broad and weak band appears at 832 cm^{-1}.

The primary purpose of this note is to report on some differences in the infrared absorption spectra in the 1000—750 cm^{-1} region of the A and B forms of deoxyribonucleic acid (DNA). Our experiment was directed by two reports,[1,2] which recently appeared. Erfurth, Kiser, and Peticolas[1] showed that in the Raman spectrum of calf thymus DNA in the A form there is a strong Raman line at 807 cm^{-1}, while in the B form this line is absent and a new line appears at 835 cm^{-1}. For characterizing these frequencies, it is desirable to examine infrared absorption spectra of the A and B forms of DNA in this frequency region, because the selection rule (or intensity rule) in the Raman effect and infrared absorption are different. Pilet and Brahms[2] made a detailed investigation on the infrared spectra of A and B forms of DNA's with various base compositions, and found a marked difference between the two forms in the dichroic properties of the  antisymmetric and symmetric stretching bands (at about 1230 and 1090 cm^{-1}, respectively). They did not show, however, any bands in the frequency region lower than 1000 cm^{-1}.

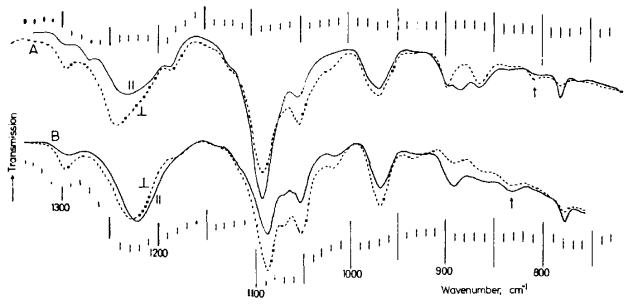

Fig. 1. Infrared absorption curves of oriented films of DNA from *Micrococcus lysodeikticus* in its A and B forms, observed with the polarized radiation. Full line, electric vector of the incident radiation is parallel to the fiber axis. Broken line, electric vector is perpendicular to the fiber axis.

Figure 1 shows the infrared spectra of an oriented DNA film from *Micrococcus lysodeikticus* in its A and B forms observed with the polarized radiation. The film was prepared from an aqueous solution of DNA with 10^{-5} M NaCl onto an AgCl plate. This film was soaked overnight in 73% ethanol with 0.1 M NaCl to add a proper amount of NaCl, and then washed only once by 80% ethanol. The spectrum A was obtained on keeping the film in the air of 75% humidity for a long time, and the spectrum B at 92% humidity. The A—B conversion readily takes place, but for regaining the spectrum A we need to keep the film in the air of 75% humidity for a week or so.

In the 1300—1000 cm^{-1} region, we have observed almost exactly what Pilet and Brahms reported:[2] in the A form the  antisymmetric stretching band (whose // component is at 1230 cm^{-1} and $\perp$ component at 1243 cm^{-1}) shows a perpendicular dichroism and the symmetric stretching band (both // and $\perp$ components are at 1092 cm^{-1}) a parallel dichromism, whereas in the B form the antisymmetric stretching band (// at 1220 cm^{-1} and $\perp$ at 1230 cm^{-1}) is almost non-dichroic and the symmetric stretching band (both // and $\perp$ are at 1088 cm^{-1}) shows a perpendicular dichroism. In the 800—700 cm^{-1} region, we found practically the same frequencies with what Erfurth *et al.*[1] observed in the Raman spectra both for the A and B forms, but with greatly different relative intensities. Thus, in the A form a weak band is observed at 807 cm^{-1}, while in the B form this is absent and a broad and weak band appears at 832 cm^{-1}. The former shows a perpendicular dichroism whereas the latter is almost non-dichroic.

The Raman or infrared frequency, 807 cm^{-1} of the A form or 832 cm^{-1} of the B form, is probably caused by a vibration in which mainly P–O single-bond stretching takes place, because of the following bases:

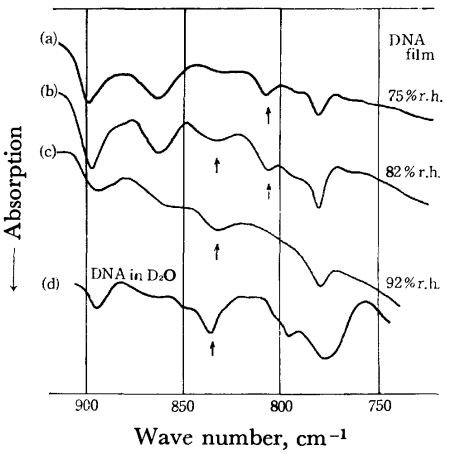

Fig. 2. Infrared absorption spectra in the 920—750 cm^{-1} region with unpolarized radiation. (a) Film of DNA from *M. lysodeikticus* at relative humidity (r.h.) 75%. (b) The same film at 82% r.h. (c) The same film at 92% r.h. (d) Calf thymus DNA in D_2O solution, pD=6 (observed with a Digilab FTS-14 Fourier Transform Infrared Spectrometer).

(1) The Raman line of nucleic acids at about 810 cm^{-1} is in general very strong and its appearence and absence are so sensitive to the mainchain conformation that it is not probable to be caused by a vibration of a base residue.[1,3]

(2) The 807 and 832 cm^{-1} bands of DNA are found to remain almost unchanged when the film is exposed to D_2O vapor. Many other data[3] indicate that the frequency now in question is insensitive to the deuteration of the amino and hydroxy groups of the nucleic acid.

We have conducted a number of experiments in an attempt to establish a correlation (if any) between the P–O stretching frequency and the conformation around this bond in the C–O–[PO_2^-]–O–C system. Unfortunately, however, what was attempted has not so far come out in any neat form. Nevertheless, this band may be useful for finding a gross mainchain-conformation around the phosphate group in a given sample of nucleic acid; it is favorable that we only need to find the position of the band and do not need to examine infrared dichroism here. As seen in Fig. 2 (b), the *M. lysodeikticus* DNA film shows both of the 807 and 832 cm^{-1} bands in the air of 82% humidity. It may be concluded, therefore, that such a film contains both of the A and B forms. This conclusion is reached in a less ambiguous manner than that from a dichroic measurement in the 1250—1000 cm^{-1} region. On the other hand, calf thymus DNA in neutral D_2O solution shows a well-defined band at 840 cm^{-1} but not at 807 cm^{-1} (Fig. 2 (d)), and this fact supports the idea that the DNA molecule is in the B-form in its aqueous solution.

It may be pointed out here that each of the double-helical ribonucleic acid (RNA)[4] and DNA-RNA hybrid[5] shows a medium intensity perpendicular band at 810 cm^{-1} but not at 832 cm^{-1}. By X-ray diffraction studies[5] both of these are known to have structures similar to that of DNA A form, but quite different from the B form. The 810 cm^{-1} band of RNA was once assigned to a nearly symmetrical stretching vibration of the $\begin{matrix}C\\C\end{matrix}>C-O$ structure at the position 2′ of the ribose residue.[6] We now consider that at least a part of this band is caused by the P–O single bond stretching mode. It is not yet excluded, however, that the band due to the ribose vibration is superposed here. Perhaps it is worthwhile to mention here our Raman spectrum of RNA from cytoplasmic polyhedrosis virus (CPV) of silk worm in comparison with that of DNA in their aqueous solutions. CPV RNA is a natural RNA with a complete double-helical structure. As may be seen in Fig. 3, CPV RNA shows a srtong and sharp Raman line at 810 cm^{-1} while DNA does not. This line is insensitive to deuteration. This fact suggests that this RNA has, in its aqueous solution, a structure similar to that of DNA A form.

Lastly, a few comments are to be added on some other band observed in the A- and B-forms of DNA.

In the 900—880 cm^{-1} region, there is another marked difference found between the A and B forms. In the A form, there is a medium intensity band at 881 cm^{-1}

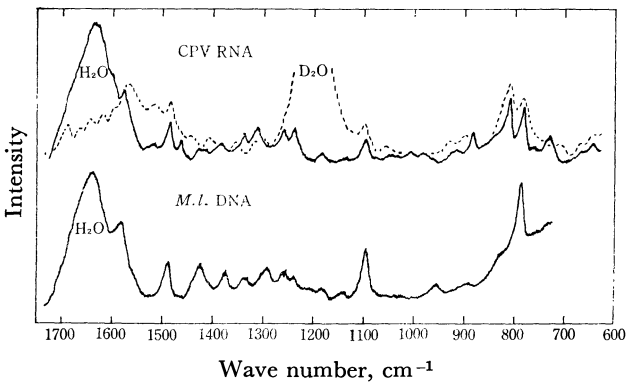

Fig. 3. Upper: Raman spectra of CPV RNA, excited by the 514.5 nm beam of an Ar^+ laser (Coherent Radiation, 52G-A) and observed with a JRS-Ul Raman spectrophotometer of Japan Electron Optics Laboratory, Company (JEOL). — in H_2O, --- in D_2O. The RNA sample was prepared under the direction of Dr. K. Miura, National Institute of Genetics. We thank Dr. Miura for his guidance. We also thank Mr. S. Muraishi, JEOL, for his kindness in the spectroscopic measurements.
Lower: Raman spectrum of DNA from *Micrococcus lysodeikticus* (GC 72%) in H_2O solution (0.02M Tris+ 0.1M NaCl, pH 7.6). The spectrum was observed by the use of a JRS-UlS Raman spectrophotometer of JEOL and 488.0 nm beam of an Ar^+ laser of coherent radiation (52G-A).

which is strongly polarized along the parallel direction with the fiber axis (Fig. 1). This is missing in the B-form; instead, there is a parallel band at 891 cm^{-1}. This is also unaffected by deuteration, and is assignable to another mainchain stretching vibration.

The strong Raman line at 780 cm^{-1} and the medium-intensity infrared band at 780 cm^{-1} should be assigned to different vibrations, in spite of the coincidence in their frequency values. The Raman line is assignable to the ring breathing vibration of the pyrimidine base residues. While, the infrared band which shows a strong parallel dichroism is assignable to an out-of-plane vibration in some base-residues.

A strong band at 1120 cm^{-1} of RNA, which was assigned to the $\begin{matrix}C\\C\end{matrix}>C-O$ "degenerate" stretching,[6] is absent in DNA even in its A form (see Fig. 1). Therefore, the assignment of this band in RNA has been supported by our present work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(4), 1045—1046 (1974)

Nonideality of Ammonia Solutions in *N,N*-Dimethylformamide

Rabindranath PATNAIK* and William G. LLOYD

Department of Chemistry, Western Kentucky University, Bowling Green, KY 42101, USA

(Received January 6, 1973)

Synopsis. Solutions of ammonia at 0—40 °C and 0.2—1.2 atm in *N,N*-dimethylformamide exhibit negative deviations from Raoult's Law and marked departures from Henry's Law. This behavior is shown to be consistent with predictions of a simple model for solute-solute hydrogen bonding.

At moderate temperatures and partial pressures ammonia exhibits a negative deviation from Raoult's Law and a marked departure from Henry's Law solubility in *N,N*-dimethylformamide.

Materials and Methods

Anhydrous ammonia was obtained from Matheson Gas Products Corp. and *N,N*-dimethylformamide (DMF) from Matheson Coleman & Bell Corp. Purities were verified by gas chromatographic analysis. Solubility data were obtained manometrically at 0—40 °C and at 0—1.2 atm. As a check on apparatus and procedures, similar solubility data were obtained with acetylene.

Results and Discussion

The solubility data for acetylene are in the expected good accord with Henry's Law:

$$C_a = k \cdot P_a \quad (1)$$

For this system the pressure-solubility curves are linear with an average correlation coefficient of 0.997. The indicated heat of solution, −4.6 (±0.5) kcal, is in excellent agreement with Ryutani's estimate of 3—5 kcal at higher pressures.[1]

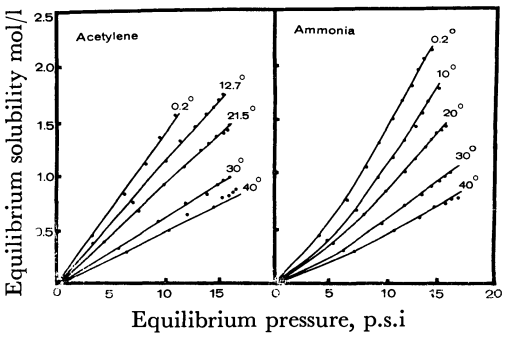

Fig. 1. Solubilities of acetylene and ammonia in *N,N*-dimethylformamide.

The corresponding data for ammonia describe a family of nonlinear curves (Fig. 1) inconsistent with Eq. (1). Under these conditions van der Waals corrections are very small. These data can be explained in terms of hydrogen bonding between solute ammonia molecules:

$$NH_{3(solute)} + NH_{3(solute)} \overset{K_d}{\rightleftharpoons} (NH_3)_{2(solute)} \quad (2)$$

Other calculations indicate a small amount of hydrogen-bonding dimerization in the gas phase;[2] the strength of the bridging bond is estimated to be 2.7—3.7 kcal.[3-5]

DMF, a very weak base,[6] is unlikely to be directly involved. A weak 1:1 ammonia–DMF complex has been detected in the solid state, but above its mp of −87 °C this is substantially dissociated.[7] Also this system shows a negative deviation from Raoult's Law, while ammonia at 0 °C shows marked positive deviations with hydrogen-bonding solvents.[8]

Taking dimerization as a simple model for solute-solute association, the total concentration of solute ammonia is:

$$\sum C = C_a + 2C_d \quad (3)$$

where C_a and C_d are the concentrations of ammonia and of ammonia dimer, respectively. From reaction 2,

$$C_d = K_d \cdot C_a^2 \quad (4)$$

Hence, by Eqs. (1), (3), and (4):

$$\sum C = k \cdot P_a + 2K_d \cdot k \cdot P_a^2 \quad (5)$$

This argument is supported by the good linearity of plots of $\sum C/P_a$ *vs.* P_a. The Henry's Law constant k is evaluated by the intercept of $\sum C/P_a$ at $P_a=0$. Estimates of k are shown in Table 1. The indicated heat of solution, 3.7 (±0.2) kcal, is consistent with those found for ammonia and the polar aprotic solvents adiponitrile (3.4 kcal)[9] and tributyl phosphate (2.5 kcal).[10]

Table 1. Equilibrium constants in *N,N*-dimethylformamide at 0.2—40.0 °C

T, °C	Henry's Law constant			Dimerization constant	
	k	stand. dev.	smoothed k[b,c]	K_d	smoothed K_d[b,d]

Faraday Parameters of the Magnetic Circular Dichroism of Praseodymium Trichloride and Thulium Trichloride in Poly(vinyl alcohol) Film

Yoshifumi KATO and Kyusaku NISHIOKA

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received July 16, 1973)

The magnetic circular dichroism and absorption spectra of $PrCl_3$ and $TmCl_3$ in polyvinylalcohol film are measured in the range of 300—700 nm. The absorption bands observed are five for $PrCl_3$, the transitions from the ground state, $^3H_4$, to the excited states, $^1D_2$, $^3P_0$, $^3P_1$, $^1I_6$, and $^3P_2$, of Pr^{3+}, and four for $TmCl_3$, the transitions from the ground state, $^3H_6$, to the excited states, $^3F_3$, $^3F_2$, $^1G_4$, and $^1D_2$, of Tm^{3+}. In order to separate the *C* term of the Faraday parameters, the temperature variation of the spectra is carried out at room temperature to 77 K. The Faraday parameters are derived from the experiment by the use of three methods; the method of moments, the graphical method, and curve fitting. The characteristics of these methods are discussed, and the uncertainty of the parameters obtained is estimated to be 30% or more. A group-theoretical consideration is applied for the interpretation of the results; this consideration fairly well explains the sign of the *C* terms obtained for $PrCl_3$, but not for $TmCl_3$.

Since the general review of Buckingham and Stephens[1] with respect to the magnetic optical activity, there have been published a number of articles[2] on the magnetic circular dichroism (MCD) with the pervasion of instruments and the utilization of a superconducting magnet. From the results obtained, it has been demonstrated that this technique gives valuable information on the electronic structure of molecules, especially the assignments of the absorption spectra and the magnetic properties of the ground and excited states.

In general, since the spin-orbit coupling of rare-earth ions is much stronger than the crystal field, these ions have appreciable orbital magnetic moments and thus strong MCD spectra may be expected, even under a weak magnetic field. Rare-earth salt is, therefore, considered to be a material favorable to the investigation by MCD; even when direct observation of the Zeeman-effect for a transition is prevented by the absorption band-width, MCD measurement makes it possible to study the effect of a magnetic field on a transition. Since the states of rare-earth ions in a salt are a little affected by the surrounding crystal field, the absorption spectra can be easily assigned by comparing these with the results established by the emission spectra of free ions and the absorption, fluorescence, and Zeeman-spectra of single crystals. However, the MCD study is still useful in confirming the spectral assignment obtained incompletely by various other methods.

Several MCD measurements for the compounds involving Pr^{3+} have already been given. Foss and McCarville[3] and Briat *et al.*[4] separately measured the MCD of $PrCl_3$ in an aqueous solution at room temperature. The former estimated the magnitude of the Zeeman-splitting from the experiment. Ferre *et al.*[5] carried out a detailed MCD measurement of Pr^{3+} diluted in an $AlLaO_3$ crystal at 300—100 K. They obtained a number of spectroscopic splitting factors, together with other information, and made a theoretical argument for the results. There have, however, been no studies of the MCD for the salts involving Tm^{3+}.

In this paper, we will present the MCD and absorption spectra of $PrCl_3$ and $TmCl_3$ dispersed into a polyvinyl alcohol (PVA) film measured in the range of room temperature to 77 K. So far as we know, the MCD measurement in a PVA film was first attempted for $Fe(CN)_6^{3-}$ by Kobayashi *et al.*[6] Since the MCD spectra in a PVA film are very similar to those in an aqueous solution, this technique is considered to be appropriate for observing the temperature variation of the MCD for a soluble salt in water. The Faraday parameters of the MCD spectra are derived from the experiment by the use of several methods proposed by previous authors,[7,8] and some discussion is given of the methods used and of the accuracy of the parameters obtained. A group-theoretical consideration is also attempted for the interpretation of the parameters.

Experimental

Materials. A PVA film of samples was obtained by the addition of an aqueous solution of $PrCl_3 \cdot 7H_2O$ or $TmCl_3 \cdot 6H_2O$ into that of PVA and by allowing it to evaporate to dryness on a glass plate. Several PVA films with different concentrations were prepared for the purpose of the measurement with an appropriate absorption strength. The concentration of a sample was determined from the interpolation in the comparison of the absorption strength of a PVA film with that of the corresponding aqueous solution.

Spectral Measurements. All the measurements were carried out by the use of a JASCO model J-10 instrument with a permanent magnet, which had a pole gap of 12 mm and which produced a magnetic field of 4.6 kG on the average. For the measurement at lower temperatures, a sample film about 1 mm thick was directly immersed in liquid nitrogen or in a mixture of liquid and solid methanol placed in a special quartz Dewar vessel which could be closely inserted between magnetic poles. The bubbles produced in the Dewar vessel were removed skilfully not to disturb the measurements. The temperature was determined within an accuracy of ± 1 K by using a copper-constantan thermocouple in contact with a PVA film. The magnitudes of the MCD bands were calibrated with an aqueous solution of *d*-camphor sulfonic acid.

Method of Analysis

Theoretical. The theoretical expression of the MCD for an absorption band has been formulated by Buckingham and Stephens[1] and used to analyze the experiments by most investigators.[2,3] The ellipticity in an isotropic solution accompanied by an electronic transition, $a \rightarrow j$, is given by;[1,9]

$$\theta = -\frac{8\pi^2 H_z N}{3ch}[f_1 A + f_2(B + C/kT)], \tag{1}$$

$$A = \frac{3}{d_a}\sum_{a,j}[\langle j|\mu_z|j\rangle - \langle a|\mu_z|a\rangle]Im\{\langle a|m_x|j\rangle\langle j|m_y|a\rangle\},$$

$$B = \frac{3}{d_a}\sum_{a,j}\mathrm{Im}\{\sum_{k\neq a}[\langle k|\mu_z|a\rangle/\Delta E_{ka}][\langle a|m_x|j\rangle\langle j|m_y|k\rangle - \langle a|m_y|j\rangle\langle j|m_x|k\rangle] + \sum_{k\neq j}[\langle j|\mu_z|k\rangle/\Delta E_{kj}] \times [\langle a|m_x|j\rangle\langle k|m_y|a\rangle - \langle a|m_y|j\rangle\langle k|m_x|a\rangle]\},$$

$$C = \frac{3}{d_a}\sum_{a,j}\langle a|m_z|a\rangle \mathrm{Im}\{\langle a|m_x|j\rangle\langle j|m_y|a\rangle\}. \tag{2}$$

Here, f_1 and f_2 express the frequency functions defining the band shape, N is the total number of absorption centers per unit of volume in the ground state, a, d_a is the degeneracy of this state, and $\boldsymbol{m}=e\sum_i \boldsymbol{r}_i$ and $\boldsymbol{\mu}=-\beta\sum_i(\boldsymbol{l}_i+2\boldsymbol{s}_i)$ are the electric and magnetic dipole-moment operators respectively. The summations are over all the states degenerate with $a \rightarrow j$. In the conventional units used by previous authors,[2a,9] the molar ellipticity, θ_M, per unit of magnetic field is in units of the degree deciliter decimeter^{-1} mol^{-1}, A in D$^2\beta$, and B and C/kT in D$^2\beta$/cm^{-1} (β=Bohr magneton, D=Debye unit). Then, the coefficient of Eq. (1) becomes -21.346. The A, B, and C Faraday parameters arise from the Zeeman-splitting of $a \rightarrow j$, the mixing of a and j with the other states, k, due to a magnetic field, and the change in the population of the Zeeman-components of the a state respectively. As may be seen in Eq. (2), the C term can arise only when the ground state, a, is degenerate, because the expectation value of μ_z must otherwise be zero; similarly, the A term arises when the ground state, a, and/or the excited state, j, are degenerate. On the other hand, the B term, consisting of an infinite summation about the other states, k, can exist always, although the contribution of the B term to the total θ_M may not be sizable for paramagnetic substances. It is apparent that the MCD of $PrCl_3$ and $TmCl_3$ should have the contributions from all the Faraday parameters, since the ground state of Pr^{3+} is a degenerate state, $^3H_4$, and that of Tm^{3+} is $^3H_6$. In Eq. (1), a dielectric correction is ignored, but this problem is avoided by expressing our results as the ratio of the Faraday parameters to the electric dipole strength, $D(D=(3/d_a)\sum|\langle a|m_x|j\rangle|^2)$. In order to obtain valuable information from the measurement, it is first necessary to extract the values of the Faraday parameters. We have applied the following three methods previously proposed; the method of moments,[7] the graphical method[8] and curve fitting.

Method of Moments. This method was first introduced by Henry, Schnatterly, and Slichter[10] in interpreting the MCD of a color center; later the generalization and application to other types of absorption systems was done by Stephens *et al.*[7,11] The moment of molar extinction coefficient, ε, and of molar ellipticity, θ_M, about the average absorption frequency, ν, are defined as:[7,11a]

$$\langle\varepsilon\rangle_n = \int_{band}(\varepsilon/\nu)(\nu-\bar{\nu})^n d\nu, \quad \langle\theta_M\rangle_n = \int_{band}(\theta_M/\nu)(\nu-\bar{\nu})^n d\nu. \tag{3}$$

With the assumption of the rigid shift model, the zero-th and first-order moments for an isotropic solution of noninteracting molecules are approximated as;

$$\langle\varepsilon\rangle_0 = 108.9D, \quad \langle\varepsilon\rangle_1 = 0, \quad \text{(definition of } \bar{\nu}) \tag{4}$$

$$\langle\theta_M\rangle_0 = -33.53(B + C/kT), \quad \langle\theta_M\rangle_1 = 33.53A. \tag{5}$$

Using these equations, one can evaluate the Faraday parameters from the moments obtained by numerical integrations through the absorption and MCD curves. This method, therefore, does not require any assumption of band shape, position or width, or any model for the vibronic structure of the states.

Graphical Method. This method, proposed by Badoz *et al.*,[8] starts from a special assumption regarding a band shape. If the shape function is taken as a Gaussian form, f_G, the expressions for ε/ν and θ_M/ν are given under the rigid shift model as;

$$\varepsilon/\nu = 108.9Df_G \equiv Y, \tag{6}$$

$$\theta_M/\nu = -33.53[Af_G' + (B + C/kT)f_G] \equiv \Delta Y,$$

where;

$$f_G = 1/(\sqrt{\pi}\delta)\exp[-(\nu-\nu_0)^2/\delta^2]. \tag{7}$$

Now, it can easily be shown from Eq. (6) that;

$$Y'/Y = -(2/\delta^2)(\nu-\nu_0),$$

$$\Delta Y/Y = \theta_M/\varepsilon = 0.3080[(2/\delta^2)(\nu-\nu_0)A/D - (B + C/kT)/D]. \tag{8}$$

Since the values of the left side in Eq. (8) obtained from the experiment are linearly related to the frequency, ν, one can obtain graphically the half-width, δ, at $1/e$ and the frequency, ν_0, of the maximum absorption and the Faraday parameters divided by D. In this procedure, there is no further assumption except for a band-shape function if the derivative of the absorption curve can be obtained accurately.

Curve Fitting. The molar ellipticity, θ_M, is a function involving the Faraday parameters, the frequency of maximum absorption, and the half-width as parameters, P. By assuming a shape function for a band, one can fit an explicit expression of θ_M to an experimental curve. When θ_M is expanded to the first order in terms of these parameters and a least-squares procedure is applied, the final equation to be solved is reduced to be following matrix form;

$$\tilde{\boldsymbol{J}}\boldsymbol{J}\Delta\boldsymbol{P} = \tilde{\boldsymbol{J}}\Delta\boldsymbol{\theta}_M \tag{9}$$

$$\boldsymbol{J} \equiv \partial(\theta_{M1}, \cdots\cdots, \theta_{Mn})/\partial(P_1, \cdots\cdots, P_m), \tag{10}$$

where $\boldsymbol{J}$ and $\tilde{\boldsymbol{J}}$ are the Jacobi and its transposed matrix respectively, n and m being the number of θ_M measured and that of the parameters used respectively. From Eq. (9), the parameter correction, $\Delta\boldsymbol{P}$, to be revised can be evaluated iteratively from the difference, $\Delta\boldsymbol{\theta}_M$, between the measured and calculated ellipticity. This method is already familiar from other spectral analyses.[12]

Throughout all the methods, the separation of the C term has been done by means of the temperature variation of θ_M; the Faraday parameters were derived by means of a FACOM 230-35 computer in Kobe University.

Results and Discussion

Results and the Faraday Parameters. The absorption and MCD spectra observed are given in Fig. 1 for $PrCl_3$ and in Fig. 2 for $TmCl_3$. As may be seen in Figs. 1 and 2, at lower temperatures the widths of the absorption bands generally become more sharp and some bands evidently split into two bands or disappear due to the change in the population of the ground crystal-field levels, while the MCD spectra also exhibit a large temperature dependence.

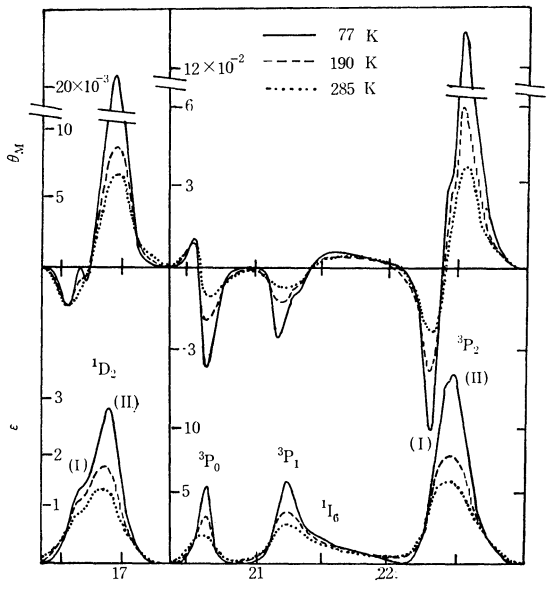

Fig. 1. Temperature variations of the absorption and MCD spectra of $PrCl_3$ in PVA film. θ_M and ε are the MCD in molar ellipticity units (degree deciliter decimeter^{-1} mol^{-1}) per unit Gauss and the molar extinction coefficient, respectively.

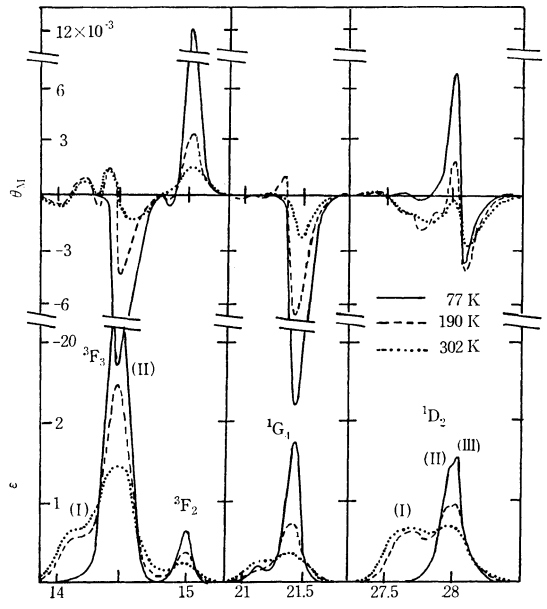

Fig. 2. Temperature variations of the absorption and MCD spectra of $TmCl_3$ in PVA film. Notations and units are the same as Fig. 1.

There are 13 electronic levels for the $4f^2$ configuration of Pr^{3+} as well as for the $4f^{12}$ configuration of Tm^{3+}; the latter being the complementary configuration of the former. Since the energy levels of several single crystals involving Pr^{3+} or Tm^{3+} have been well established,[13] it is easy to assign the absorption bands in PVA by comparison with those of single crystals; the bands of $PrCl_3$ at 16800, 20600, 21400, and 22400 cm^{-1} are identified as transitions from the ground state, $^3H_4$, to the excited states, $^1D_2$, $^3P_0$, $^3P_1$, and $^3P_2$, of Pr^{3+} respectively, the bands of $TmCl_3$ at 14400, 15000, 21300, and 27900 cm^{-1} being the transitions from the ground state, $^3H_6$, to the excited states, $^3F_3$, $^3F_2$, $^1G_4$, and $^1D_2$, of Tm^{3+} respectively. The absorption bands in the ultra-violet region are excluded from present analysis because of the disturbance due to the absorption of PVA itself in this region. (Hereafter, an absorption band will be designated with the relevant excited state.) It is certain that a weak shoulder band on the large-wave number side of the $^3P_1$ band in $PrCl_3$ is the $^1I_6$ band, because of the clear appearance of the small, positive θ_M at the corresponding position of the MCD curve. This assignment is also in agreement with that of Pr^{3+} in $LaCl_3$[14] and of the free ion.[15] Details of the derivation for the Faraday parameters of $PrCl_3$ by the moment analysis and graphical method are given in Tables 1 and 2 respectively. The absorption and MCD curve in PVA and in an aqueous solution for $PrCl_3$ at room temperature are given in Fig. 3, together with the results of the curve fitting. The corresponding tables and figures for $TmCl_3$ are abbreviated. The mean derivation $(\sum_i(\theta_M^{cald})_i/(\theta_M^{obsd})_i \times 100/n)$ for all the curve fittings were within 2%. As may be seen in Fig. 3, in both the absorption and MCD spectra, the spectral wave numbers in PVA commonly shift to a smaller side within 50 cm^{-1} of those

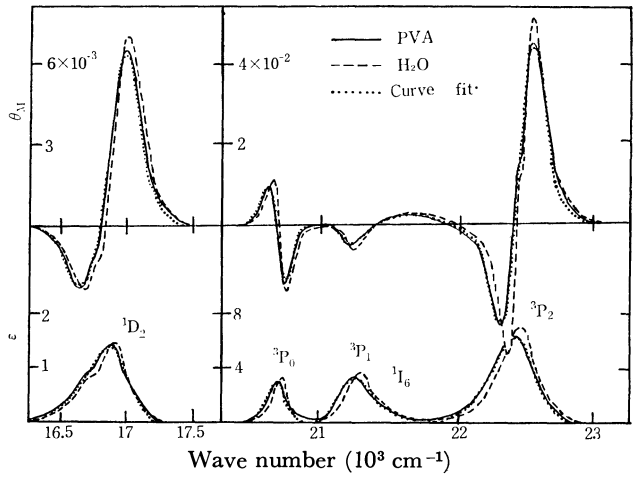

Fig. 3. Absorption and MCD spectra of $PrCl_3$ in PVA film and an aqueous solution at a room temperature, together with the results of the curve fitting. Notations and units are the same as in Fig. 1.

in aqueous solution, but the band shapes in PVA are almost identical with those in an aqueous solution. This fact shows that the electronic environment about a rare-earth ion in PVA is like that in an aqueous solution. Consequently, the site symmetry of a rare-earth ion in PVA could be considered to be C_{3v}.

The plots of $(B+C/kT)/D$ to $1/kT$ obtained by the moment method, graphical method and curve fitting are given in Figs. 4—6 for $PrCl_3$ and in Figs. 7—9 for $TmCl_3$. In these figures, the linear relations are,

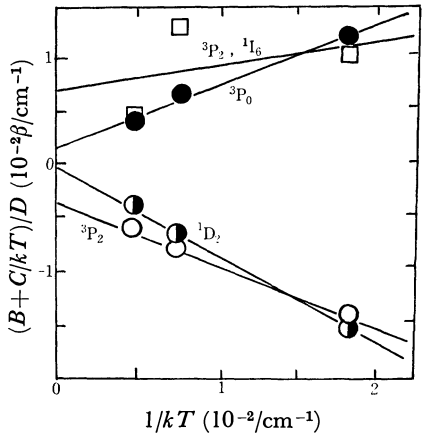

Fig. 4. Temperature dependence of $(B+C/kT)/D$ of $PrCl_3$ by the moment analysis.

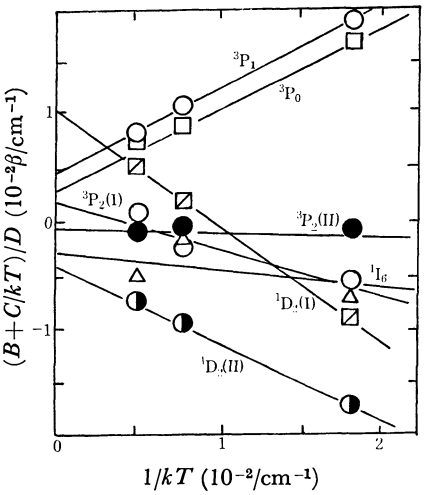

Fig. 5. Temperature dependence of $(B+C/kT)/D$ of $PrCl_3$ by the graphical method.

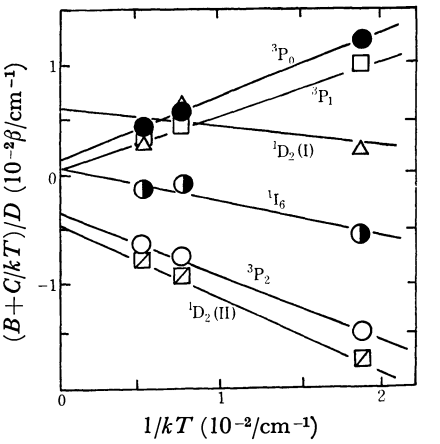

Fig. 6. Temperature dependence of $(B+C/kT)/D$ of $PrCl_3$ by the curve fitting.

in general, well retained except for a few cases. The summaries of the Faraday parameters obtained are shown in Table 3 for $PrCl_3$ and in Table 4 for $TmCl_3$, where the values in parentheses are considered to be less reliable. The values of the B terms for all the bands are considerably smaller than those of the C terms. The ratio of C to B is approximately $\Delta E: kT$, as estimated by others.[1,9] Since ΔE, the order of magnitude of the energy difference between electronic states, is assumed to be $\sim$5000 cm^{-1}, and since kT is

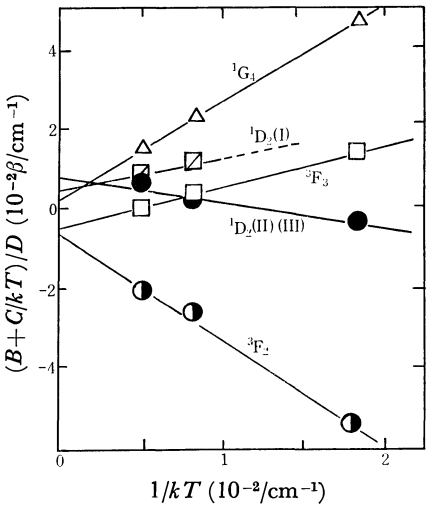

Fig. 9. Temperature dependence of $(B+C/kT)/D$ of $TmCl_3$ by the curve fitting.

$\sim$200 cm^{-1} at room temperature, this ratio becomes larger than 25; thus, the B term can be neglected at lower temperatures. The Faraday parameters obtained by means of the three methods are in fairly good agreement with one another in reliable cases.

The three methods used have some individual characteristics. The moment method may be the most powerful and general technique. In actual application, there is, however, an arbitrariness in the separation of an overlapping band; furthermore, the inclusion of higher-order moments complicates the analysis. The graphical method makes it possible to separate an overlapping band straightforwardly, as has already been pointed out by Badoz *et al.*,[8] but we could not always place trust in the numerical evaluation of the derivative of an absorption band. In the curve fitting, there is no assurance of any definite convergence by an iterative procedure using an assumed formula; in fact, some parameters may be very sensitive to the intial trial values used.

As to the accuracy of the Faraday parameters, it is possible to estimate for the transition to the non-degenerate excited state, $^3P_0$, of $PrCl_3$. In this case, the magnitude of the A/D should be, in principle, equal in absolute value and reverse in sign to that of the C/D, as may be seen in Eq. (2). This fact is not fully satisfied in any of the methods. As may be seen

Table 3. Values of the Faraday parameters of $PrCl_3$ by various methods
Units of A/D and C/D are in β, and those of B/D in 10^{-2} β/cm^{-1}.
Values in parentheses are less reliable.

$^1D_2$(II)	−0.94	1.24	−0.62	(1.56)	(0.81)	(−1.32)	(−0.53)	(0.70)	(−1.07)	positive
$^1D_2$(III)				(−1.74)	(0.85)	(−0.10)				

in Table 3, the ratios of the absolute value of the A/D to that of the C/D are 0.6—0.7. Thus, the uncertainty in the parameters obtained is estimated to be 30% or more. It seems plausible, as Stephens[7a] has deduced, that 30% is the limit of the uncertainty of the parameters by the moment analysis. It is hazardous to conclude simply which method is superior to the others without a further detailed study of a favorable case. It may be pointed out that a careful consideration is necessary to obtain quantitative information on the basis of the experimental Faraday parameters.

Group-Theoretical Consideration. MCD results could be interpreted by considering the split in energy levels due to C_{3v} crystal symmetry. We will treat the A and C terms in terms of group theory, because the B term is considerably smaller than the others and there is difficulty in arriving of an infinite sum. A free-ion level including spin-orbit interaction splits into the sum of several irreducible representations of C_{3v} symmetry, as is shown in Table 5.[16] Since the species of μ_z and that of m_x and m_y in this symmetry are A_2 and E respectively, we can reduce the values of C/D and A/D according to the Wigner-Eckart theorem.[17] The expressions C/D and A/D for the transitions among crystal levels are given in Table 6, where μ_g and μ_e are a reduced matrix element $\langle E||\mu||E\rangle$ of the E species in the ground and excited states respectively.

TABLE 5. IRREDUCIBLE REPRESENTATIONS OF ION LEVELS UNDER C_{3v} SYMMETRY

Ion level	C_{3v} symmetry
$^3P_0$	A_1
$^3P_1$	A_2+E
$^1D_2$, $^3F_2$, $^3P_2$	A_1+2E
$^3F_3$	$2A_1+A_2+2E$
$^1G_4$, $^3H_4$	$2A_1+A_2+3E$
$^1I_6$, $^3H_6$	$3A_1+2A+4E$

TABLE 6. THEORETICAL REDUCTION OF THE VALUES OF C/D AND A/D FOR THE TRANSITIONS AMONG EACH SPECIES OF C_{3v} SYMMETRY

Transition	$C/D(\beta)$	$A/D(\beta)$
$E\rightarrow A_1$	$(i/\sqrt{2})\mu_g$	$-(i/\sqrt{2})\mu_g$
$E\rightarrow A_2$	$-(i/\sqrt{2})\mu_g$	$(i/\sqrt{2})\mu_g$
$E\rightarrow E$	$-(i/\sqrt{2})\mu_g$	$-(i/\sqrt{2})(\mu_e-\mu_g)$
$A_1\rightarrow E$	0	$(i/\sqrt{2})\mu_e$
$A_2\rightarrow E$	0	$-(i/\sqrt{2})\mu_e$

If we assume that the E species of the ground state consist of only f electrons, the value of μ_g comes to be $-\sqrt{2}\,i$ for Pr^{3+} and $i/\sqrt{2}$ for Tm^{3+} (see Appendix). The absorption bands observed are not due to the transitions between crystal levels, but to overall transitions. However, by assuming that the populations of all the E species in ground state are equal, we can estimate the signs of C/D, which are given in the last column in Tables 3 and 4. As may be seen in these tables, the experimental signs of the C/D for $PrCl_3$ are fairly well explained by such a simple consideration, but those for $TmCl_3$, not so well. This seems to arise from the fact that the assumption of equal populations for the four ground E species of $TmCl_3$ is not adequate, because the total splitting due to the crystal field in $TmCl_3\cdot 6H_2O$ crystal is 460 cm^{-1} (Olsen *et al.*);[18] this is twice or more as large as that of $PrCl_3\cdot 7H_2O$.[14] The further application of such a simplified treatment to the estimate of A/D is not appropriate because it involves several approximations.

Although the values of C/D and $(A+C)/D$ obtained are closely related to a weighted sum of the g-factors of the crystal levels in the ground and excited states concerned respectively, it is difficult to compare these values directly with the results obtained by other experiments because of the lack of accurate knowledge of the splitting crystal levels. From this point of view, it will be desirable to investigate the MCD of single crystals involving a rare-earth ion in order to advance further in the field of quantitative treatment.[19]

This work has been supported in part by the Ministry of Education of Japan.

Appendix

It is well known that the $4f^N$ configurations of rare-earth ions can be described satisfactorily in terms of intermediate coupling. In this case, only J and M_J become good quantum numbers and the wavefunction is a linear combination of LS functions with a constant J. If 305.4, 51.88, 5.321, and 729.5 cm^{-1}, values obtained by Margolis from the energy calculation of $PrCl_3$,[20] are taken as the values of the Slater parameters, F_2, F_4, and F_6, and the spin-orbit coupling constant, ζ, the ground state wavefunction, $\psi(J,M_J)$, of Pr^{3+} is given as;

$$\psi(J, M_J) = 0.9873\psi(^3H_4) + 0.1564\psi(^1G_4) - 0.0288\psi(^3F_4). \quad \text{(A1)}$$

Since the mixing among the LS functions is quite small, we

assume that the ground-state wavefunction of Pr^{3+} consists of only the $^3H_4$ state. When this state is put into the crystal field of C_{3v} symmetry, the eigenfunctions $\psi(L,S,J,M_J)$ for the species of C_{3v} become as follows:[16]

$$\begin{aligned} &A_1 \text{ species} \quad \psi(5,1,4,0),\\ &\qquad 1/\sqrt{2}\,[\psi(5,1,4,3)-\psi(5,1,4,-3)],\\ &A_2 \text{ species} \quad 1/\sqrt{2}\,[\psi(5,1,4,3)+\psi(5,1,4,-3)],\\ &E \text{ species} \quad \psi(5,1,4,\pm 4),\ \psi(5,1,4,\pm 1),\\ &\qquad \psi(5,1,4,\mp 2). \end{aligned} \tag{A2}$$

The expectation value of the magnetic dipole-moment operator, $\mu_z=-\beta(L_z+2S_z)$, with respect to a wavefunction, $\psi(L,S,J,M_J)$, is given as;

$$\langle\psi(L,S,J,M_J)|\mu_z|\psi(L,S,J,M_J)\rangle = -M_J g, \quad \text{(in units of } \beta) \tag{A3}$$

where g is a Landé g-factor. Although the value of g varies with the quantum numbers, J, L, and S, we assume it to be ~ 1 for the sake of simplicity, because the order of magnitude of g is about one. This approximation is equivalent to neglecting the contribution from the spin part of μ_z in Eq. (A3). Thus, the expectation values of μ_z for the three E species of the $^3H_4$ state are ∓ 4, ∓ 1, and ± 2 respectively.

On the other hand, when Griffith's coupling coefficient[17] are used, the matrix elements of μ_z with respect to the $E_{\pm 1}$ species are reduced to;

$$\begin{aligned} \langle E_{\pm 1}|\mu_z|E_{\pm 1}\rangle &= V\begin{pmatrix} E & E & A_2 \\ \mp 1 & \pm 1 & \alpha \end{pmatrix}\langle E\|\mu\|E\rangle \\ &= \pm i/\sqrt{2}\,\langle E\|\mu\|E\rangle. \end{aligned} \tag{A4}$$

Noticing that the E_{+1} state corresponds to the $\psi(5,1,4,-4)$, $\psi(5,1,4,-1)$ or $\psi(5,1,4,+2)$ function from their transformations under the symmetry operations of C_{3v}, and that the value of Eq. (A4) should be equal to the mean value of the three direct estimates by Eq. (A3) because the transitions from these three E species of the $^3H_4$ state can not be separated in our observations, we obtain $\langle E||\mu||E\rangle=-\sqrt{2}\,i$ for the $^3H_4$ state of Pr^{3+}; then, $\langle E||\mu||E\rangle=i/\sqrt{2}$ is obtained for the $^3H_6$ state of Tm^{3+} from similar considerations.

Thermodynamic Properties of Moderately-concentrated Poly(γ-benzyl-L-glutamate) Solutions

Akio OKAMOTO,* Kenji KUBO, and Kazuyoshi OGINO

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Meguro-ku, Tokyo 153

(Received August 2, 1973)

The osmotic pressures for poly(γ-benzyl-L-glutamate) solutions in ethylene dichloride and chloroform were measured at 29 °C in the concentration range of 2—15 vol % polymer. The osmotic pressures increased monotonously with an increase in the concentration. No evidence was found for the coexistence of two phases. The results are compared with the theory of the solutions of rodlike molecules. The values of the thermodynamic interaction parameter, χ, for the systems were found to be 0.44—0.47 in the concentration range lower than 6.5 vol% polymer, where the solutions must be isotropic.

Poly(γ-benzyl-L-glutamate) (PBLG) is in the state of a random coil when it is dissolved at low concentrations in dichloroacetic or trifluoroacetic acid. In other solvents, such as chloroform, ethylene dichloride (EDC), and *N*,*N*-dimethylformamide (DMF), the polymer is α-helical. Below a critical concentration (A-point), these solutions are isotropic, while above another concentration (B-point) they are anisotropic. The coexistence of these isotropic and anisotro ic hases occurs in the intermediate concentration range, and these critical concentrations depend on the temperature.

The equilibrium properties of solutions of rodlike molecules have been treated theoretically by Onsager,[1] Isihara,[2] and Flory.[3] These theories predict that, above a critical concentration, rodlike molecules will be packed closely and will all be aligned in one direction, without requiring attraction forces, thus forming a nematic liquid crystal. The molecular distribution methods of Onsager and Isihara have been given for dilute solutions. Flory's lattice theory, however, is regarded as being free from any restriction on the concentration range.

In Flory's theory the enthalpy term in the free energy of mixing is assumed to be of the Van-Laar type and to be characterized by a parameter χ, which is also used in the statistical theory of solutions of randomly-coiled polymers. The phase diagrams are shown for axial ratios of $r=50$ and 100 in Fig. 1. The differences in the two concentrations corresponding to the A- and B-points are small for $\chi<ca.$ 0.1. In the range of $\chi>ca.$ 0.1 for $r=100$, and $\chi>ca.$ 0.25 for $r=50$, the concentrations of the solute in the isotropic phases become extremely low, while the volume fractions of the solute in the anisotropic phase approach unity.

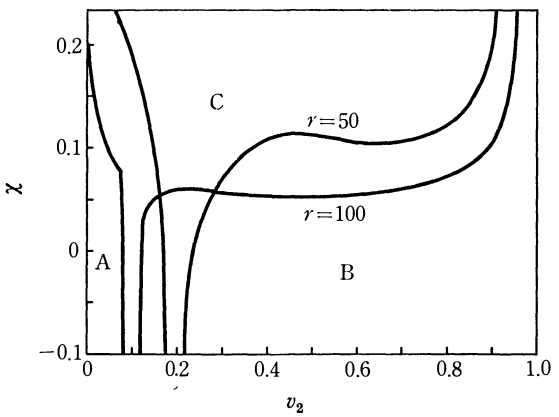

Fig. 1. Phase diagrams for solutions of rodlike molecules: region A, isotropic; B, anisotropic; C, coexistence region; axial ratio (r)=50 and 100.

Robinson *et al.*[4] found the A-point and the B-point for PBLG solutions in methylene chloride and dioxane by polarizing microscope measurements. The molecular-weight dependences of the concentrations of these points were in semiquantitative agreement with Flory's lattice theory, provided the value of χ is sufficiently small. Hermans[5] found the A-point for PBLG solutions in *m*-cresol from the viscosity methods. Nakajima *et al.*[6] discussed the phase diagrams obtained by the observation of the turbidity for the three-component system of the PBLG–DMF–poor solvent, in which the addition of a poor solvent to the polymer-solvent system caused an increase in the thermodynamic parameter, χ. Further, Wee and Miller[7] observed the A-point and the B-point as a function of the temperature by polarizing microscope and NMR spectrum measurements respectively; thus they obtained the phase diagram. These diagrams were in semiquantitative agreement with the prediction of Flory's theory. No direct values of χ, however, were given in these experiments.

The thermodynamic properties of the PBLG–pyridine, PBLG–EDC, and poly(β-benzyl-L-asparatate)–chloroform systems investigated by Flory and Leonard[8] in the concentration range of 60—100 vol% polymer. Their data could not be explained on the basis of Flory's lattice theory, but they could be explained if the mixing of a flexible side chain of the polymer with a solvent was considered. Their data were found to fit reasonably well a modified lattice model if χ_s values of 0.35, 0.20, and zero were assumed for the PBLG–pyridine, PBLG–EDC, and poly(β-benzyl-L-glutamate)–chloroform systems respectively, in which χ_s is a thermodynamic interaction parameter between the solvent and the side chain of the polymer.

There have been reported only a few studies aimed at evaluating the χ parameter in PBLG solutions from thermodynamic experiments. Goebel and Miller[9] obtained 0.5 for χ in dilute solutions of PBLG in DMF

* Present address: Insititute of Space and Aeronautical Science, The University of Tokyo, Meguro-ku, Tokyo 153.

at 22 °C from osmotic-pressure measurements. Rai and Miller[10] obtained 0.8 for χ in the same system in the concentration range of 0—30 vol% polymer from differential scanning calorimetric measurements on the assumption that χ is independent of whether the system is an isotropic or an anisotropic phase, and of the composition.

In this report, we will discuss the results of osmotic-pressure measurements on the PBLG–chloroform and PBLG–EDC systems in moderately concentrated regions and will attempt to obtain A- and B-points thermodynamically and to determine the χ value directly. The results are compared with those of Flory's theory.

Experimental

Materials. Three samples of PBLG (PBLG-A, -B, and -C) different in molecular weight were used. These were prepared by polymerzing γ-benzyl-L-glutamate-*N*-carboxy anhydride in dioxane, with triethylamine as an initiator. The molecular weights of PBLG-A, -B, and -C were found to be 1.88×10^5, 1.78×10^5, and 0.98×10^5 respectively by osmometry in DMF solutions. A high-speed membrane osmometer (Hewlett-Packard Co., Model 501) was employed. The axial ratios of PBLG-A, -B, and -C are 85, 81, and 45 respectively. After DMF was dried over $MgSO_4$ for 2 or 3 days, it was purified by vacuum distillation. The chloroform and EDC were dried over $CaCl_2$ and then distilled.

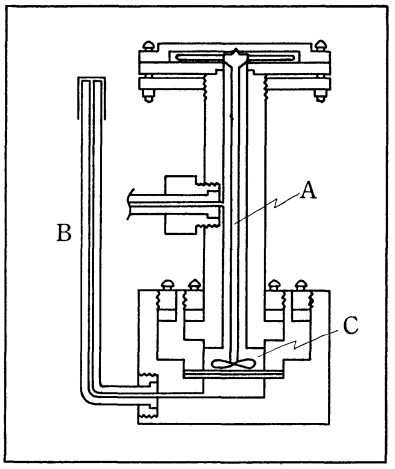

Fig. 2. Osmometer: A, stirrer; B, capillary; C, solution cell.

Osmotic-pressure Measurements. A high-pressure osmometer of the Flory[11]-Kuwahara[12] type was constructed (Fig. 2). It was designed so that highly viscous polymer solutions were stirred thoroughly without a leak in the applied pressure. The stirrer, A, was rotated by means of the outer magnet.

The osmotic pressures were measured at 29 °C by a compensation method. The solution was stirred in an Erlenmeyer flask for 24 hr; then it was put into a solution cell. After the solution had been stirred for 4—6 hr, it took 4—6 hr more until the equilibrium pressure was attained. No significant drift in this pressure was observed for a period of 24 hr. It was found that the polymer did not measurably leak into the solvent cell. In a few instances the pressure was reduced slightly after 30—40 hr; then leakages of the polymer were observed. The concentration of the polymer was estimated after each run. The volume fraction of the polymer, v_2, was obtained on the assumption that no volume change occurred on mixing. The semipermeable membranes used were degenerated cellulose membranes (Schleicher & Schuell Co., Type 08).

Results and Discussion

Table 1 shows the results of the osmotic-pressure measurements. In Fig. 3 the dependence of the osmotic pressure on the concentration is shown for PBLG-A in EDC. No data in the concentration region higher

than the concentration of 8 vol% polymer were obtained, because this system causes gelation at higher concentrations before the attainment of the equilibrium pressure. The data for PBLG-A, -B, and -C in chloroform are shown in Figs. 4, 5, and 6 respectively.

According to the lattice theory of Flory,[3] the free energy of mixing ΔG_m for the system consisting of n_1 mol of a solvent and n_2 mol of a rodlike polymer with an axial ratio, r, is given by:

$$\Delta G_m/RT = n_1 \ln v_1 + n_2 \ln v_2 - (n_1+yn_2) \times \ln\{1-v_2(1-y/r)\} - n_2\{\ln(ry^2)-y+1\} + \chi r n_2 v_1 \quad (1)$$

where v_1 and v_2 are the volume fractions of the solvent and the polymer respectively, and y is a orientation parameter. This equation gives the chemical potentials of the solvent both in the isotropic phase and in the anisotropic phase. The relation for the isotropic phase is:

$$(\mu_1-\mu_1^0)/RT = \ln(1-v_2) + (1-1/r)v_2 + \chi v_2^2 \quad (2)$$

and that for the anisotropic is:

$$(\mu_1-\mu_1^0)/RT = \ln(1-v_2) + \{(y-1)/r\}v_2 + 2/y + \chi v_2^2 \quad (3)$$

where y is given as the solution of the following equation:

$$v_2 = \{r/(r-y)\}\{1-\exp(-2/y)\} \quad (4)$$

The plots of $\Delta\mu_1(=\mu_1-\mu_1^0)$ *versus* v_2, as calculated from Eqs. (1)—(4) for $\chi=0$ with $r=45$ and 85, are shown in Fig. 7. The straight lines parallel to the absissa show that there is no net change in $\Delta\mu_1$ when the isotropic and anisotropic phases co-exist. The rate of change in the chemical potential for the anisotropic phase is much less than for the isotropic phase.

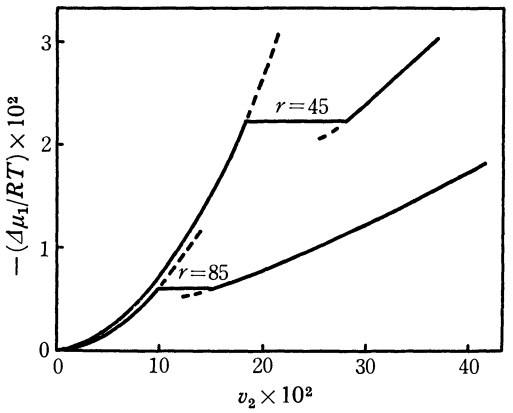

Fig. 7. Calculated curves of $\Delta\mu_1/RT$ plotted against v_2 for solutions of rodlike molecules: axial ratio $(r)=45$ and 85; thermodynamic parameter $(\chi)=0$.

The chemical potential, μ_1, of the solvent is related to the osmotic pressure, π, of the solution by:

$$\mu_1 - \mu_1^0 = -\pi V_1 \quad (5)$$

where V_1 is the molar volume of the solvent. Therefore, Fig. 7 also represents the relation between π and v_2.

In Flory's lattice theory of solutions of rodlike molecules, the concentrations corresponding to A-points for $r=45$ and 85 are respectively given as $v_2=0.18$ and 0.095 for $\chi=0$, as are shown in Fig. 7. The experimental investigations of Robinson *et al.*[4] for the PBLG–methylene chloride and PBLG–dioxane systems showed that the concentrations observed as the A-points are lower than the predicted concentrations when they are compared on the same axial ratios, provided a value of χ is sufficiently small. The concentrations of the A-points corresponding to the axial ratios of the samples used in this work are obtained on the basis of their

data as follows:

	PBLG–methylene chloride	PBLG–dioxane
	$v_2 \times 10^2$	
$r = 45$	9	8
$r = 81$	8	8
$r = 85$	8	8

It was shown in our previous paper[13] that the PBLG-A (r=85)–chloroform system separated into phases at equilibrium in the concentration 8 vol% polymer and at 30 °C.

In the concentration range where a solution is biphasic, some parts of the sample transmit light when placed between crossed polars, while others do not. Although it was difficult to determine clearly the point when no light parts remained in an Erlenmeyer flask, the A-points for the solutions of PBLG-B (r=81) and -C (r=45) in chloroform were found to be at $v_2 \approx$ 0.065—0.070 at 29 °C. The A-points are satisfactorily within the range of the present osmotic-pressure measurements except for the measurements of the PBLG-A solutions in EDC (see Figs. 3—6).

The osmotic pressures for the solutions of PBLG in EDC and chloroform increase monotonously with an increase in the concentration, as are shown in Figs. 3—6. The existence of explicit phase boundaries was not found from the dependence of the osmotic pressure on the concentration.** The reason for this may be considered to be as follows. Since the biphasic region was too narrow to be detected experimentally, and since the difference between the chemical potentials for the isotropic and the anisotropic states was not so much as that predicted by Flory's theory (see Fig. 7), we might have drawn a smooth curve over the region of the two phases in the osmotic *vs.* concentration diagram.

For isotropic solutions, the values of χ are calculated by the substitution of the osmotic-pressure data into these two relations:

$$\chi = -\{\pi V_1/RT + \ln(1-v_2) + (1-1/x)v_2\}/v_2^2 \qquad (6)$$

and:

$$x = V_2/V_1$$

where V_1 and V_2 are the molar volumes of the solvent and the solute respectively. Equation (6) is derived from Eqs. (2) and (5) by replacing r by x. The x thus defined allows the theory to be applied to actual solutions. An idealization adopted in the Flory model for theoretical derivation stipulates that the solvent molecule should be of such a diameter as to be replaceable by a segment of the rodlike solute. This condition is not fulfilled in general; hence, we adopt the definition of x given above in order to permit application to actual solutions. By the use of x, the chemical potential of a solvent at an infinitely dilute solution is of an acceptable form. If we assume that Eq. (2) can also be used in the high concentration region, the values of χ can be similarly obtained from Eq. (6).

The results are shown in Table 1. The values of χ in the concentration range lower than 6.5 vol% polymer, where the solution is isotropic, are found to be 0.44—0.47 for either EDC or chloroform. The values of χ in the concentration range higher than 6.5 vol% polymer are found to be 0.46—0.50. The set of the latter values is slightly larger than that of the former values, on the average. The experimental values of χ for solutions of randomly-coiled polymers have been found to be dependent on the concentration.[11,12,14,15] The assumption of a χ value independent of the concentration is not justified in general for polymer solutions. Therefore, it can not be concluded on the basis of the χ values that the higher concentration region with the slightly larger values of χ is not an isotropic phase.

Flory's lattice theory predicts that a system with a large value of χ will be biphasic at extremely low concentrations. The concentration corresponding to the A-point is given as $v_2 \approx 5 \times 10^{-4}$ for r=45 and χ=0.45; the polymer concentration becomes even lower for higher axial ratios. Since the experimental results are very different from the predictions, it can not be assumed that the phase separation of solutions of rodlike molecules occurs primarily because of the entropic contribution originating from an extremely assymmetric shape of the molecules. We are forced, therefore, to conclude that it is necessary to modify the lattice theory of rodlike molecules.

The authors thank the Ministry of Education for Grant-in-Aid.

** The biphasic region for the PBLG-A–chloroform system is lying near the concentration of 8 vol% polymer. Although the osmotic pressures, as are shown in Fig. 4, were not measured for the concentration range of 6—9 vol% polymer in this experiment, we dared to draw the smoothed curve over the entire region of the measurements for the system.

Isotopic Study of Water Gas Reaction Catalyzed by Platinum

Makihiko MASUDA and Koshiro MIYAHARA
Research Institute for Catalysis, Hokkaido University, Sapporo 060
(Received August 10, 1973)

By the use of ^{13}C- and ^{18}O-labelled carbon dioxide and D_2 gas, water gas reaction over an evaporated Pt film was studied at temperatures 380—450 °C under constant elimination of water vapor with cold traps. The reaction of CO_2 and H_2 was as rapid as that of CO_2 and D_2, the mixture of H_2 and D_2 changing rapidly into an equilibrium mixture of H_2, HD, and D_2 in the course of the reaction with CO_2. The mixture of $C^{18}O_2$ and CO_2 was also rapidly equilibrated by the reaction with H_2. The exchange reactions of ^{18}O and ^{13}C between CO_2 and CO in the course of the water gas reaction were similarly observed. The theory of the stoichiometric number on the rate-determining step was applied to the results. From the results and the observed rate equation of the water gas reaction, $V=k[CO_2]^{0.6}[H_2]^{0.5}[CO]^{-0.5}$, the reaction was supposed to be caused by the sequence of steps, $CO_2 \rightleftarrows CO_2(a)$, $H_2 \rightleftarrows 2H(a)$, $CO_2(a)+H(a) \rightleftarrows X(a)$, $X(a) \rightleftarrows CO(a)+OH(a)$, $CO(a) \rightleftarrows CO$, and $OH(a)+H(a) \rightleftarrows H_2O$, and to be rate-controlled by the third and fourth steps, where (a) denotes the adsorbed state and X(a) is an intermediate to rule out the direct conversion of $CO_2(a)+H(a)$ into $CO(a)+OH(a)$.

The kinetics of water gas reaction,

$$CO_2 + H_2 = CO + H_2O, \quad (1)$$

catalyzed by platinum was observed by Prichard and Hinshelwood[1] and the rate equation was given[2] as

$$V = kP_1P_2/(1+K_1P_1+K_2P_2)^2, \quad (2)$$

where P_1 and P_2 are the partial pressures of CO_2 and H_2, respectively, and k, K_1 and K_2 constants. In this experiment the rate was followed by the total pressure change caused by absorption of formed water vapor by sulfuric acid kept in the reaction vessel. This equation was considered[2] to be a prototype of the so-called Langmuir-Hinshelwood mechanism of catalysis, which assumes the rate of reaction (1) to be determined by a surface reaction of adsorbed CO_2 and adsorbed H_2. However, according to the method of Horiuti *et al.*[3] of estimating the number N^* of active centers on a catalyst surface, Eq. (2) gave an enormous value of N^*, *ca.* 10^{32} cm^{-2}.[3] In a previous work[4] the kinetics was reexamined by the use of a conventional closed circulation apparatus under constant elimination of water vapor, as in the case of Prichard and Hinshelwood, by cold traps:

$$V = k_pP_1^{0.6}P_2^{0.5}P_3^{-0.5}. \quad (3)$$

This differs from Eq. (2) especially with regard to the dependence on P_3, *i.e.*, the partial pressure of CO, and gave[4] the value of N^* at 7.3×10^{14} cm^{-2}, which is of a reasonable order of magnitude as the number of metal atoms exposed on catalyst surface. As regards such a difference in kinetics, Eq. (3) suggests the possibility that the mechanism of (1) differs from those proposed.[1,5] We have followed the redistribution of ^{13}C and/or ^{18}O atoms between carbon dioxide and monoxide, and that of deuterium atoms in hydrogen gas in the course of reaction. The results were analyzed in reference to the theory of the stoichiometric number[6,7] and an appropriate reaction mechanism was proposed.

Experimental

Materials. Pure carbon dioxide (Takachiho Chemical Industrial Co., Ltd.) was purified further by repeated distillation in a vacuum., Pure carbon monoxide (*ibid.*) was purified by being passed through copper gauge heated at *ca.* 300 °C and then a trap cooled by liquid nitrogen. Hydrogen and deuterium gas from cylinders were purified by being passed through heated Pd–Ag thimbles.

Carbon dioxide labelled by ^{13}C (Merck Sharp and Dohme Co., Ltd., Canada) was purified by repeated distillation in a vacuum. Carbon dioxide labelled by ^{18}O (Yeda Research and Development Co., Ltd., Israel) and that supplied by a reaction at *ca.* 300 °C of heavy oxygen gas of *ca.* 90 ^{18}O-atomic percents with active carbon supporting platinum were used. They were purified by distillation in a vacuum. Catalysts were platinum films evaporated on the inner surface of a reaction vessel immersed in an ice water bath and preliminarily sintered in a vacuum at 480 °C for 30 min and then 410 °C for 2 hr.

Procedure and Results. The apparatus was similar to that used in a previous work,[4] *viz.*, a conventional closed circulation system equipped with a mercury manometer and two dry ice traps on both sides of the reaction vessel. The whole apparatus was made of Pyrex glass.

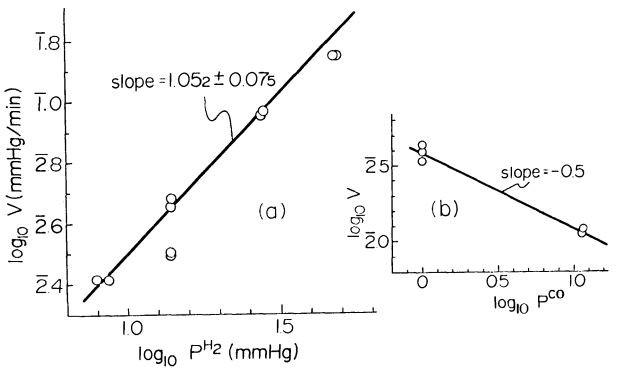

Fig. 1. Pressure dependence of the reaction rate.
(a), $\log_{10} V$ (mmHg/min) *vs.* $\log_{10} P_2$ (H_2, mmHg) at 410 °C: P_1 (CO_2)$=P_2$, P_3 (CO)$=1.0\pm0.04$ mmHg.
(b), $\log_{10} V$ *vs.* $\log_{10} P_3$ at 410 °C: $P_1=P_2=14.9\pm0.1$ mmHg.

1. Rate Equation: Rate Eq. (3) was confirmed by two series of experiments with a 1:1 mixture of CO_2 and H_2. The results of the first series are shown in Fig. 1(a) where the rate was observed at $P_3=1$ mmHg. The rate is proportional to $P_2^{1.1}$ in conformity with Eq. (3). In the second series the dependence of the rate on P_3 was examined by addition of 10 mmHg CO to a 1:1 mixture of CO_2 and H_2.

The results are shown in Fig. 1(b) which also confirms Eq. (3).

2. Kinetic Isotope Effect with Respect to Hydrogen and H_2–D_2 Equilibration: By the use of a 1:1 mixture of CO_2 and H_2 or D_2, it was found that the isotope effect on the rate was absent at temperatures 386—459 °C (Fig. 2).

In the course of reaction of a mixture of 18.2 mmHg CO_2, 18.2 mmHg H_2, and 10.8 mmHg D_2 at 410 °C, the equilibration reaction $H_2+D_2=2HD$ was completed in the first 6 minutes, whereas as little as 0.3 mmHg of the total pressure decrease had proceeded in reaction (1).

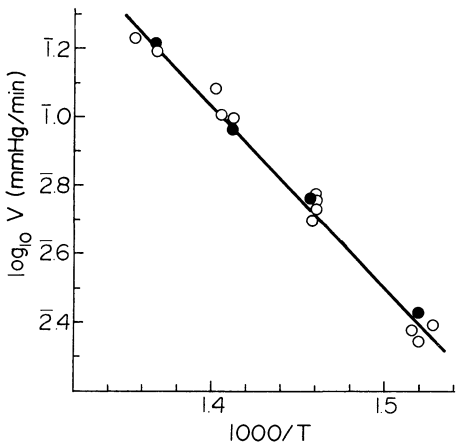

Fig. 2. Kinetic isotope effect of hydrogen:
●, reaction of CO_2 and D_2 at P_1 $(CO_2)=P_2$ $(D_2)=13.90\pm0.08$ mmHg, P_3 $(CO)=1.0\pm0.04$ mmHg; ○, reaction of CO_2 and H_2 at $P_1=P_2$ $(H_2)=13.89\pm0.11$ mmHg, $P_3=1.0\pm0.04$ mmHg.

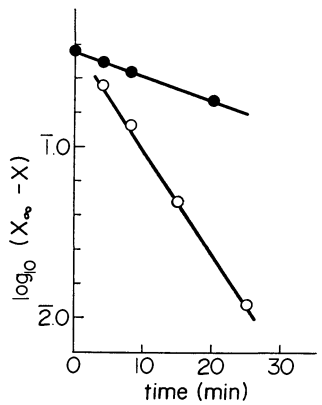

Fig. 3. The equilibration, $C^{18}O_2+CO_2=2CO^{18}O$, at 410 °C:
○, in the presence of Pt at $P_1(CO_2)=21.5\pm1$ mmHg, $P_2(H_2)=24\pm1$ mmHg, $P_3(CO)=3.5\pm0.2$ mmHg; ●, in the absence of catalyst at $P_1=19.3$ mmHg, $P_2=19.1$ mmHg, $P_3=5.5$ mmHg.

3. Equilibration of Oxygen Isotope in CO_2 Gas: Equilibration $C^{18}O_2+CO_2=2CO^{18}O$ was observed by addition of 8 mmHg ^{18}O-labelled CO_2 (79.8% $C^{18}O_2$, 19.0% $CO^{18}O$, and 1.2% CO_2) to a mixture of 25.0 mmHg H_2, 14.5 mmHg CO_2, and 3.3 mmHg CO. The result is shown in Fig. 3 where X is the mole fraction of $CO^{18}O$ in carbon dioxide and X_∞ the equilibrium value of X. The rate V_e of the equilibration was evaluated by the equation

$$N dX/dt = V_e(X_\infty - X), \qquad (4)$$

where N is the number of carbon dioxide molecules in the reaction system. This equation, being correct in the absence of reaction (1), is applicable to the present case where the decrease of P_1 was as small as 0.6 mmHg and the atomic fraction of ^{18}O in carbon dioxide was kept constant at 0.358 ± 0.001. Equilibration took place without catalyst as seen in Fig. 3 and was enhanced by the platinum catalyst by as much as 3.6×10^{17} molecules/s; the rate is far greater than that of reaction (1) which was estimated at 2.8×10^{15} molecules/s just before the introduction of ^{18}O-labelled CO_2.

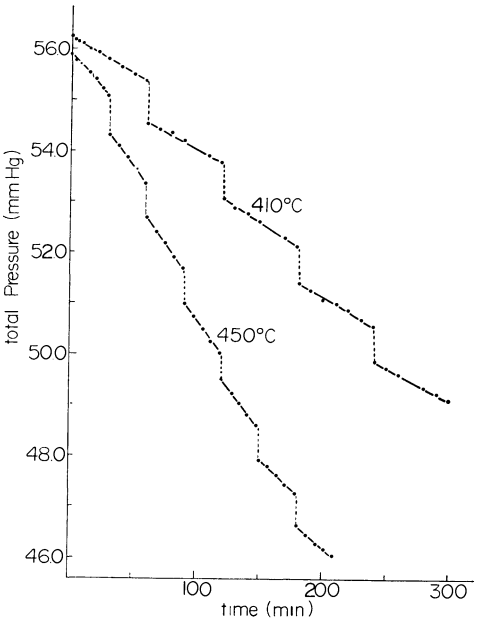

Fig. 4. Time courses of the reaction at 410 °C (runs V.6) and 450 °C (V.8).

4. Exchanges of ^{18}O and ^{13}C between CO_2 and CO: In order to see the effect of trapped water on the exchange reactions, several runs of reaction of a 1:1 mixture of normal CO_2 and H_2 were conducted at 410 °C and the formed water vapor amounting to *ca.* 9 mmHg was trapped. The exchange reaction was then observed with a mixture of 15 mmHg CO, 21 mmHg H_2, and 21 mmHg labelled CO_2. Typical time courses of the total pressure at 410 and 450 °C are shown in Fig. 4, where steep decreases of the total pressure were caused by samplings of the reacting gas. Sampled gas was analyzed mass spectrometrically for the atomic fractions of ^{18}O, (Z_1 and Z_3), and those of ^{13}C, (Y_1 and Y_3), in CO_2 and CO, respectively. In Fig. 5 Z_1 and Z_3 were plotted

against ΔP, *i.e.*, the sum of the total pressure decrements caused by the progress of reaction (1) but not by sampling. Figure 6 shows the changes of Y_1 and Y_3 with ΔP.

The exchange of ^{13}C as well as of ^{18}O between CO_2 and CO in the course of reaction (1) were followed simultaneously by the use of a mixture of ^{13}C- and ^{18}O-labelled CO_2. The results are shown in Fig. 7. In this case an equilibration, $CO+{}^{13}C^{18}O={}^{13}CO+C^{18}O$, of isotopes in CO took place additionally (Table 1), which was far slower than the equilibration of isotopes in CO_2 (Table 2).

5. Hydrogen Exchange between D_2 and H_2O: A mixture of 22.0 mmHg CO_2, 15.1 mmHg CO, and 22.1 mmHg D_2 was introduced on the catalyst successively to the runs described above. During reaction (1) which gave rise to 8.7 mmHg of the total pressure decrease, D atomic fraction of D_2 gas changed from 0.991 to 0.974, that is, dilution of D_2 by protium from condensed water was slight.

Discussion

Application of the Theory of Stoichiometric Number. The theory of stoichiometric number[6,7] assumes that all the reaction routes[8] of reaction (1) and accompanying exchanges of ^{13}C and ^{18}O are single. The stoichiometric number $\nu(s)$ of step s is the number of acts of step s necessary to complete one act of the overall reaction, *i.e.*, (1). The forward or the backward unidirectional rate of exchange is defined by the formation rate, V_{+C} or V_{-C}, of ^{13}CO or CO_2, respectively, in the reaction between pure $^{13}CO_2$ and CO, *viz.*, a particular case with $Y_1=1$ and $Y_3=0$. According to mass balance of carbon atoms irrespective of isotopic difference, it follows that

$$V = -dP_1/dt = dP_3/dt = V_{+c}-V_{-c}, \quad (5)$$

and the mass balance of ^{13}C gives

$$-d(Y_1P_1)/dt = Y_1V_{+c}-Y_3V_{-c} = d(Y_3P_3)/dt. \quad (6)$$

Solving these equations with respect to V_{+C} and V_{-C}, we have

$$V_{+c}/V_{-c} = 1 + (Y_1-Y_3)(dP_1/dY_1)/P_1 \quad (7a)$$

or

$$V_{+c}/V_{-c} = 1/[1-(Y_1-Y_3)(dP_3/dY_3)/P_3]. \quad (7b)$$

When step r in the single route of the exchange reaction is so slow as to be rate-determining for reaction (1), V_{+C} or V_{-C} might be equal to the forward or backward unidirectional rate, V_+ or V_-, of reaction (1), respectively. The stoichiometric number $\nu(r)$ of step r is then given by[6]

$$\nu(r) = -\Delta G/[RT\ln(V_+/V_-)], \quad (8)$$

where $-\Delta G$ is the affinity of reaction (1) given by

$$-\Delta G = RT\ln(K_pP_1P_2/P_3P_4). \quad (9)$$

K_p is the equilibrium constant of reaction (1) and P_4 the partial pressure of water. On the other hand, when the exchange reaction takes place without step r, V_{+C} and V_{-C} may be far larger than V_+ and V_-, and the value of V_{+C}/V_{-C} might be close to unity. Accordingly, ν_{ex} defined by

$$\nu_{ex} = -\Delta G/[RT\ln(V_{+c}/V_{-c})].$$

becomes infinitely large in this case.[9]

For the exchange of ^{18}O, similar equations are derived as

$$V = dP_3/dt = V_{+o} - V_{-o} \quad (10)$$

and

$$d(Z_3P_3)/dt = Z_1V_{+o} - Z_3V_{-o}, \quad (11)$$

where it is noteworthy that the exchange of ^{18}O between carbon monoxide and water was assumed not to take place at all. It follows from Eqs. (10) and (11) that

$$V_{+o}/V_{-o} = 1/[1-(Z_1-Z_3)(dP_3/dZ_3)/P_3]. \quad (12)$$

To evaluate the ratios of V_{+C}/V_{-C} and V_{+o}/V_{-o}, the terms dP_1/dY_1, dP_3/dY_3, and dP_3/dZ_3 in Eqs. (7a), (7b), and (12) were approximated by $-d\Delta P/dY_1$, $d\Delta P/dY_3$, and $d\Delta P/dZ_3$, respectively, which can be determined by Figs. 5, 6, and 7. The values of V_{+o}/V_{-o} given in Figs. 8 and 9 considerably fluctuate due to the large errors of estimation of terms, dP_3/dZ_3 *etc.*

(a), $\log_{10}(V_{+C}/V_{-C})$ *vs.* $-\Delta G/2.3RT$. V_{+C}/V_{-C} was evaluated according to Eq. (7a).
(b), ν_{ex} (calculated from data (a)) *vs.* $-\Delta G/2.3RT$.
(c), $\log_{10}(V_{+o}/V_{-o})$ *vs.* $-\Delta G/2.3RT$.
(d), ν_{ex} (calculated from the data (c)) *vs.* $-\Delta G/2.3RT$.

Applying the present method of analysis to the experimental result of hydrogen exchange between D_2 and H_2O, the ratio of the forward unidirectional rate V_{+H} of this exchange to the reverse one, V_{-H}, was estimated to be *ca.* 32.

Adsorption of Gaseous Components. The steps of adsorption of CO_2 and H_2 and desorption of CO and H_2O are discussed first in connection with the mechanism of reaction (1).

A large number of studies on hydrogen adsorption on platinum[10] confirm a rapid and reversible chemisorption to form adsorbed hydrogen atoms. The present results of rapid equilibration of deuterium in hydrogen gas and the fact that V was proportional to $P_2^{0.5}$ suggest that chemisorption of hydrogen is so rapid as to be nearly in equilibrium and reaction (1) is rate-determined by a surface reaction of an adsorbed hydrogen atom.

Carbon dioxide has been reported[10] to be hardly chemisorbed on platinum, but one of the authors (M.M.) observed[11] that adsorption of CO_2 on platinum film was perceptibly enhanced by the presence of equimolar hydrogen gas at temperatures above room temperature.

Adsorption of CO on platinum was found to take place reversibly and as rapidly as hydrogen[12] and, furthermore, it may be so strong as to retard reaction (1) by occupying active sites on platinum surface according to the fact that V was proportional to $P_3^{-0.5}$.

In the case where CO_2 adsorption is dissociative to form adsorbed CO, ^{13}C or ^{18}O might be exchanged between CO_2 and CO much faster than in reaction (1) on account of the rapid and reversible adsorption of CO_2 and CO and, accordingly, the ratios V_{+o}/V_{-o} and V_{+C}/V_{-C} might be close to unity against the observed results. The dissociative adsorption of CO_2 to form adsorbed CO is, thus, ruled out. The fact that the randomization of ^{18}O in CO_2 took place in the absence of platinum catalyst (Fig. 3) suggests that CO_2 adsorbed on glass surface may interact with OH groups to give an intermediate of oxygen exchange such as bicarbonate ion. However, such an intermediate is not considered to be effective for reaction (1) and isotope exchange between CO_2 and CO, since the decomposition of bicarbonate ion to CO is not plausible, and these reactions were far slower than the randomization of ^{18}O in CO_2 (Table 2).

The value of V_{+H}/V_{-H} estimated to be *ca.* 32 indicates that the step of H_2O desorption is practically irreversible in the course of reaction (1) carried out with cold traps. The adsorbed state of H_2O may be dissociative to result in the observed though slight hydrogen exchange.

Reaction Scheme and Relative Rates of Constituent Steps. According to the above discussions the water gas reaction consists of three rapid and reversible adsorption steps,

$$CO_2 \overset{1}{\longleftrightarrow} CO_2(a), \quad (13\cdot1)$$

$$H_2 \overset{2}{\longleftrightarrow} 2H(a), \quad (13\cdot2)$$

TABLE 2. REDISTRIBUTION OF ^{13}C AND ^{18}O IN CO_2

Runs	Reaction time (min)	Mole fraction of CO_2	$^{13}CO_2$	^{18}COO	$^{13}C^{18}OO$	$C^{18}O_2$	$^{13}C^{18}O_2$	Y_1	Z_1

		(0.332	0.170	0.273	0.140	0.056	0.029)		
	360	0.339	0.167	0.275	0.135	0.057	0.027	0.329	0.289
		(0.339	0.166	0.276	0.135	0.056	0.027)		
VI. 8 (450 °C)	0	0.319	0.324	0.115	0.012	0.227	0.003	0.339	0.293
		(0.330	0.169	0.274	0.140	0.057	0.029)		
	180	0.336	0.167	0.276	0.136	0.057	0.028	0.331	0.291
		(0.336	0.166	0.276	0.136	0.057	0.028)		

Values in parentheses are those in equilibrium at the observed values of Y_1 and Z_1 of CO_2.

and

$$CO \overset{3}{\longleftrightarrow} CO(a), \tag{13·3}$$

and desorption of H_2O as

$$OH(a) + H(a) \overset{4}{\longleftrightarrow} H_2O, \tag{13·4}$$

which may be practically irreversible on account of constant condensation of H_2O vapor. $CO_2(a)$ is now assumed, as the simplest case, to be directly converted into CO(a) by the step

$$CO_2(a) + H(a) \overset{5'}{\longleftrightarrow} CO(a) + OH(a). \tag{13·5'}$$

The relative rates of the above steps and the propriety of step 5′ are now discussed by applying the theory of the stoichiometric number[6] on the results of the present experiments.

The ratio V_+/V_- with respect to reaction (1) is given by

$$V_+/V_- = \prod_s (v_{+s}/v_{-s}), \quad (s=1, 2, 3, 4 \text{ and } 5') \tag{14}$$

where v_{+s} and v_{-s}, respectively, are the forward and the backward unidirectional rates of constituent steps s's. Similarly we have

$$V_{+c}/V_{-c} = \prod_s (v_{+s}/v_{-s}), \quad (s=1, 3 \text{ and } 5') \tag{15}$$

for the ^{13}C-exchange between CO_2 and CO. If ^{18}O-exchange between CO and H_2O were negligible as compared with that between CO_2 and CO, the latter exchange consists of steps 1, 3, and 5′ and it follows that

$$V_{+o}/V_{-o} = V_{+c}/V_{-c}. \tag{16}$$

However, the results given in Figs. 8 and 9 are not the case, hence ^{18}O-exchange between CO and H_2O is not negligible.

It follows from Eqs. (14) and (15) that

$$V_+/V_- = (V_{+c}/V_{-c})(v_{+2}/v_{-2})(v_{+4}/v_{-4}),$$

where

$$v_{+2}/v_{-2} \cong 1$$

on account of step 2 being nearly in equilibrium. Each act of the present five steps results in one act of reaction (1), *viz.*, $\nu(r)$ of Eq. (8) is unity, whatever the rate-determining step is. We have thus

$$-\Delta G/2.3RT = \log_{10}[(V_{+c}/V_{-c})(v_{+4}/v_{-4})] \tag{17}$$

The value of $\log_{10}(V_{+c}/V_{-c})$ varied from 0.9 to 1.3 for $-\Delta G/2.3RT$=3.2—3.6 as shown in Figs. 8 and 9 and, accordingly, it follows from Eq. (17) that

$$v_{+4}/v_{-4} \cong 10^2. \tag{18}$$

This shows the practical irreversibility of step 4 and, consequently, that the irreversible transfer of ^{18}O from CO to H_2O affects the ^{18}O-exchange between CO_2 and CO.

The propriety of step 5′ is now investigated. From Eq. (15) it follows that

$$V_{+c}/V_{-c} = v_{+5'}/v_{-5'},$$

taking account of the equilibria of steps 1 and 3, *viz.*,

$$v_{+1}/v_{-1} \cong 1 \cong v_{+3}/v_{-3}. \tag{20}$$

In reference to the steady state condition of reaction (1)

$$V = v_{+1} - v_{-1} = v_{+5'} - v_{-5'},$$

and the value 8 to 20 of V_{+c}/V_{-c}, it follows from Eqs. (19) and (20) that

$$v_{-1} \gg v_{+5'},$$

which indicates that the ^{18}O-exchange between CO and H_2O is negligibly slower than that between CO and CO_2. Consequently, Eq. (16) might contradict the observed result. The next simplest set of steps to fit the experimental results in place of step 5′ is

$$CO_2(a) + H(a) \overset{5}{\longleftrightarrow} X(a) \tag{13·5}$$

and

$$X(a) \overset{6}{\longleftrightarrow} CO(a) + OH(a), \tag{13·6}$$

where X(a) is an intermediate like formate ion in its composition. In this case the effect of the ^{18}O-exchange between CO and H_2O on the rate of that between CO and CO_2 depends on how far reaction (1) is rate-controlled by steps 5 and 6. Taking account of X(a) decomposing into CO(a)+OH(a) by a rate of v_{+6} and into $CO_2(a)$+H(a) by v_{-5}, ^{18}O transfer from CO(a) to H_2O might affect the ^{18}O-exchange between CO_2 and CO in a case where v_{+6} is not negligibly smaller than v_{-5}. Furthermore, taking account of the steady state condition

$$V = v_{+5} - v_{-5} = v_{+6} - v_{-6},$$

step 6 is concluded to be the slowest in conformity with the observed slow randomization of ^{18}O and ^{13}C in CO gas (Table 1).

The simplest scheme applicable to reaction (1) catalyzed by platinum is thus concluded to be

$$\begin{array}{l} CO_2 \overset{1}{\longleftrightarrow} CO_2(a) \\ H_2 \overset{2}{\longleftrightarrow} \begin{cases} H(a) \\ H(a) \end{cases} \end{array} \Bigg\} \overset{5}{\longleftrightarrow} X(a) \overset{6}{\longleftrightarrow} \begin{cases} CO(a) \overset{3}{\longleftrightarrow} CO \\ OH(a) \end{cases} \overset{4}{\longleftrightarrow} H_2O,$$

where steps 1, 2, and 3 are so fast as to be nearly in equilibria, step 4 is practically irreversible, and the reaction is rate-controlled by step 5 and a slower step 6.

A New Hypothesis Regarding the Surface Acidity of Binary Metal Oxides[1]

Kozo Tanabe, Takashi Sumiyoshi, Katsue Shibata,*
Tadamitsu Kiyoura,* and Jun Kitagawa*

(Received August 16, 1973)

We have proposed a new hypothesis that the acid sites on binary metal oxides are formed by an excess of a negative or positive charge in the mixed oxides and that whether the charge is excess or not, and whether it is positive or negative, are determined by the coordination numbers and valences of the positive and negative elements in the model structures pictured according to two postulates. The validity of the hypothesis is, in fact, 90% for the 31 kinds of binary oxides tested, much higher than the validity (48%) of Thomas' hypothesis. The hypothesis explains well the mechanism of the acidity generation of binary oxides and predicts whether the acid sites will be of the Brönsted or the Lewis type.

Binary metal oxides, such as SiO_2–Al_2O_3, SiO_2–MgO, SiO_2–ZrO_2, and Al_2O_3–B_2O_3, are well-known to have surface acidity and have been used as solid acid catalysts for a long time.[2] It was only very recently, though, that TiO_2–ZnO,[3] SiO_2–ZnO,[4] SiO_2–TiO_2,[5] TiO_2–ZrO_2,[6,7] ZnO–Bi_2O_3,[7] Al_2O_3–MgO[7] *etc.* have been found to show an acidic property. Thus, many other binary metal oxides may also be expected to exhibit an acidic property. However, no one can predict what kinds of binary oxides will show an acidic property. An old but popular hypothesis proposed by Thomas,[8] which gave an interpretation of the acidity generation of five species of binary oxides that were known in 1949, has been found to fail in explaining the acidity generation of recently-found binary oxides. Therefore, we have developed a new hypothesis which is well applicable to many new kinds of binary oxides.

The Hypothesis

The acidity generation of binary oxides can generally be explained by the present hypothesis that the acidity generation is caused by an excess of a negative or positive charge in a model structure of a binary oxide. The model structure is pictured according to the following two postulates:

i) The coordination number of a positive element of a metal oxide, C_1, and that of a second metal oxide, C_2, are maintained even when mixed.

ii) The coordination number of a negative element (oxygen) of a major component oxide is retained for all the oxygens in a binary oxide.

For example, the structure of TiO_2–SiO_2, where TiO_2 is the major component oxide, and that of SiO_2–TiO_2, where SiO_2 is the major component oxide, are shown in Figs. 1a and 1b. In Figs. 1a and 1b, the coordination numbers of the positive elements in the component single oxides remain 4 for Si and 6 for Ti when they are mixed, whereas those of the negative elements should be 3 and 2 respectively, according to Postulates i) and ii). In the case of Fig. 1a, the four positive charges of the silicon atom are distributed to four bonds, *i.e.*, a positive charge is distributed to each bond, while the two negative charges of oxygen atom are distributed to three bonds, *i.e.*, $-2/3$ of a valence

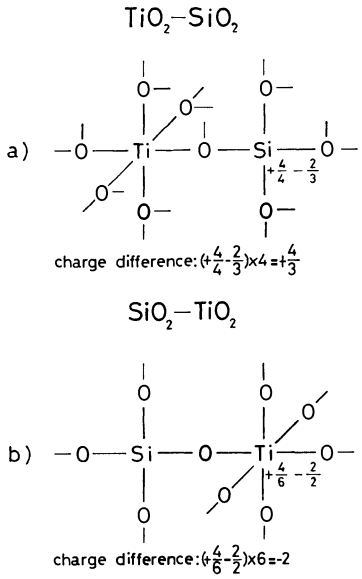

Fig. 1. Model structures of TiO_2–SiO_2 pictured according to postulates i) and ii). a): when TiO_2 is major oxide, b): when SiO_2 is major oxide.

unit is distributed to each bond. The difference in charge for one bond is $+1-2/3=+1/3$, and for all the bonds the valence unit of $+1/3\times4=+4/3$ is excess. In this case, the Lewis acidity is assumed to appear upon the presence of an excess of the positive charge. In Fig. 1b, four positive charges of the titanium atom are distributed to six bonds, *i.e.*, +4/6 of a valence unit to each bond, while two negative charges of the oxygen atom are distributed to two bonds, *i.e.*, a negative charge to each bond. The charge difference for each bond is $+4/6-1=-1/3$, and for all the bonds the valence unit of $-1/3\times6=-2$ is excess. In this case, the Brönsted acidity is assumed to appear, because two protons are considered to associate with six oxygens to keep the electric neutrality. In any case, TiO_2–SiO_2 is expected to show an acidic property because of the excess of a positive or negative charge. In fact, it exhibited a very high acidity.[5]

Let us examine another example. In ZnO–Sb_2O_3, there is no excess charge in any part of its composition according to our model structure written by Postulates

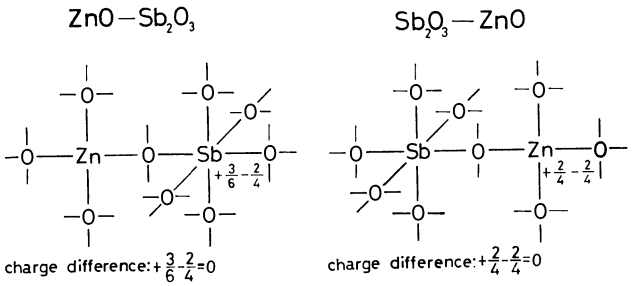

Fig. 2. Model structure of $ZnO–Sb_2O_3$ pictured according to postulates i) and ii). a): when ZnO is major oxide, b): when Sb_2O_3 is major oxide.

i) and ii), as is illustrated in Fig. 2. Therefore, the binary oxide is not expected to show any acidic property. This prediction agreed with an experimental result that $ZnO–Sb_2O_3$ did not show any acidity larger than the sum of the acidities of the component oxides.[7]

The Validity of the Hypothesis

The validity of our hypothesis was examined for 31 kinds of binary oxides. The case where the hypothesis predicts that a binary oxide should generate acidity is marked by an open circle in the fifth column of Table 1. On the other hand, the case where a binary oxide should not generate acidity is shown by a cross in the same column. The experimental results cited from the literature are shown in the next column, where open circles mark when the acid amount at a certain acid strength per unit surface area of any binary oxides is larger than the sum of the acid amounts at the same acid strength divided by the sum of the surface areas of the component single oxides, while crosses mark when no acidity is generated. The results indicate that new acid sites which differ from those of single oxides are created on the surface of 25 species of binary

Thomas' hypothesis 15/31=48%
Our hypothesis 28/31=90%

oxides. Cases where the result predicted by the hypothesis agrees with the experimental result is marked by open circles in the last column of Table 1, and cases of disagreement, by a cross. As may be seen in the table, an agreement of the prediction of our hypothesis with the experimental results was found for 28 of the 31 kinds of binary oxides. Thus, the validity of our hypothesis is 90%.

Thomas[8] proposed that the acidities of binary oxides are generated when $C_1=C_2$ and $V_1<V_2$ or when $C_1=2C_2$, where C_1 and C_2 are the coordination numbers of a positive element and a second one and where V_1 and V_2 are the valences of the respective positive elements. The validity of his hypothesis is only 48%, as is shown in Table 1. Therefore, it has been verified that our hypothesis is much better. It should also be noted that the validity of his hypothesis is low despite the fact that the coordination number of oxygen is taken as arbitrary so as to fit the experimental results.

The binary oxides which are predicted to generate surface acidity according to our hypothesis, but not according to Thomas' hypothesis, are the following thirteen species: TiO_2–CuO, TiO_2–ZnO, TiO_2–SiO_2, TiO_2–ZrO_2, TiO_2–PbO, ZnO–MgO, ZnO–ZrO_2, SiO_2–MgO, SiO_2–CaO, SiO_2–Ga_2O_3, SiO_2–Y_2O_3, SiO_2–La_2O_3, and ZrO_2–CdO. It was verified by experiments that all of the binary oxides showed a distinct acidity increase. In particular, TiO_2–SiO_2 showed a higher acidity and catalytic activity than the well-known SiO_2–Al_2O_3 catalyst.[5] TiO_2–ZnO, whose acidity was much higher than that of each component oxide, showed a surprisingly high activity for the hydration of ethylene.[3]

Though Thomas' hypothesis cannot be applied to Lewis acids,[8] our hypothesis also predicts the type of acid sites (Brönsted or Lewis), as has been mentioned above. According to our hypothesis, TiO_2–ZnO should show Brönsted acidity when TiO_2 is a major component oxide and Lewis acidity when ZnO is a major component oxide. An infrared study of pyridine adsorbed on the binary oxide revealed that TiO_2 including 5% of ZnO exhibited Brönsted acidity alone, while ZnO including 5% of TiO_2 exhibited Lewis acidity alone.[3]

Limitations of the Hypothesis

As may be seen in the model structures (Figs. 1 and 2) pictured according to Postulates i) and ii), the present hypothesis is applicable to chemically-mixed binary oxides, but not to mechanically-mixed oxides. Since the binary oxides given in Table 1 were prepared by calcining mixtures of co-precipitated hydroxides at a high temperature (500 °C), they are not mechanically-mixed oxides. The X-ray diffraction diagrams of the binary oxides showed no or weak diffraction lines, and almost all of them were assumed to be amorphous.[3,6,7,10] Thus, the structures are different from those of the component single oxides.

The present hypothesis predicts which combinations of oxides in the periodic table will generate acidity and at what compositions the Brönsted or Lewis acidity will appear, but it does not predict the acid strength. The prediction of the acid strength was reported in a foregoing paper,[7] which demonstrated a good correlation between the acid strength and the average electronegativities of metal ions of binary oxides, though the prediction is not based on any hypothesis, but on a generalization.

Properties of Ampholytic Surfactant, *N*-Alkyl-β-alanine

Takeo Okumura,* Kazuo Tajima, and Tsunetaka Sasaki

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received August 27, 1973)

Ampholytic surfactant, *N*-alkyl-β-alanine, was synthesized and its infrared absorption spectra, surface tension, isoelectric points and critical micelle concentrations of aqueous solutions were measured at various electrolyte concentrations, pH and temperature. The measurements of isoelectric points and infrared spectra confirmed a zwitterionic sructure of *N*-alkyl-β-alanine. The critical micelle concentrations determined by surface tension measurements are 1.3×10^{-2} and 9×10^{-4} mol/l respectively for the decyl and dodecyl homologs at 30 °C, the values decreasing with the increase in pH, electrolyte concentration and temperature.

Although considerable information is available concerning the properties of aqueous solutions of ionic and nonionic surfactants, little is known about those of ampholytic surfactants. Studies on *C*-alkyl betaine[1] and *N*-alkyl betaine[2-4] give information on the ampholytic surfactant. Properties of a number of other ampholytic surfactants have been investigated by Herrmann.[5] However, only a few papers have appeared on ampholytic *N*-alkyl-β-alanines.[6-8]

We have studied the effect of pH, temperature and electrolyte concentration on the critical micelle concentration (CMC) of *N*-alkyl-β-alanine by surface tension measurements. Zwitterion formation and micelle formation were discussed. A phase diagram was constructed in order to study the phase transition.

Experimental

Materials. *N*-Alkyl-β-alanine was prepared by the reaction of *n*-alkylamine with β-propiolactone in acetonitrile at 25—30 °C for one hour according to the method of Gresham *et al.*[9] The purity of *n*-alkylamine was better than 99.5% as confirmed by gas chromatography. A crude product was purified by repeated recrystallization from a mixture of acetone and ethanol (1 : 1) followed by drying in a vacuum. Thin layer chromatography confirmed the absence of unreacted materials in the purified sample. The result of elementary analysis agreed with the theoretical composition within experimental error.

Surface Tension Measurements. The surface tension was measured by a drop-weight method in a thermostated air-bath and the CMC value was determined from the surface tension *vs.* log concentration curve at different pH and temperature.

Phase Diagram. A phase diagram was constructed for the binary system consisting of surfactant and water, covering the concentration range 0—0.7 by weight fraction of the surfactant and the temperature range 0—100 °C. The transition temperature was determined by observing visually or microscopically the phase change caused by heating or cooling the sealed test-tubes containing the solutions of known concentration in a water bath.

Infrared and Proton Magnetic Resonance Spectrometry. Infrared (IR) spectra were measured with a Hitachi EPI-2 infrared spectrometer. The proton magnetic resonance (PMR) spectra in deuteriochloroform solutions were measured with a Nihon Denshi JNM PS-100 spectrometer at 100 MHz, and the chemical shifts are given by ppm, using tetramethylsilane as an external standard.

* Household Goods Research Laboratories, Kao Soap Co., Ltd., Sumida-ku, Tokyo 131.

Results and Discussion

IR and PMR Spectrometry. IR spectra of the decyl homolog in aqueous solutions are given in Table 1. The absorption bands due to COO^- and N^+H_2 in a neutral solution (pH=6) confirm the zwitterionic structure of *N*-decyl-β-alanine. The IR spectra in an acid solution (pH=1) give the absorption bands due to COOH and the characteristics of the quaternary ammonium salts. This confirms the cationic structure in an acid solution. The spectra in an alkaline medium (pH=12) lack the absorption bands due to N^+H_2 but retain the bands due to COO^-, indicating the anionic structure. Similar results have also been obtained for the dodecyl homolog.

Table 1. IR spectra of *N*-decyl-β-alanine in aqueous solutions

N-Decyl-β-alanine	COOH	COO^-	N^+H_2[a]	N^+H_2[b]
in neutral (pH 6)	—	1560 cm^{-1} 1400	2300 cm^{-1} 1650	—
in acid (pH 1)	1740 cm^{-1}	—	—	2400–2800 cm^{-1}
in alkaline (pH 12)	—	1560 cm^{-1}	—	—

a) zwitterion b) quaternary ammonium ion

The numbers of protons obtained from the measurements of PMR spectra are in agreement with those expected from the molecular structure. Thus PMR spectra also confirm the zwitterionic structure of *N*-alkyl-β-alanine.

Isoelectric Points. Isoelectric point (pH_i) of ampholytic surfactants was determined from pH titration[10] and dissociation constant measurements. The titration curves of 0.1 M hydrochloric acid solution with 0.1 M sodium hydroxide solution were plotted in the presence and also in the absence of surfactant. The common point of intersection was obtained for three such curves which gave pH_i's 7.0—7.2 and 6.8—7.0 for the decyl and dodecyl homologs, respectively.

Dissociation constant as a weak acid or base is calculated from the pH change of an acid or alkaline solution caused by the addition of a given amount of the ampholyte. The values of pK_a and pK_b thus determined for *N*-decyl-β-alanine are 3.3—3.5 and 3.1—3.2, respectively. The pH_i calculated from pK_a and pK_b for the decyl homolog is 7.0—7.2 agreeing with

Table 2. CMC values of several ampholytic surfactants in aqueous solutions

(mmol/l)

Surfactant	Decyl	Dodecyl	Reference
N-alkyl-*β*-alanine	13(30 °C)	0.9(30 °C)	Present work
C-alkyl betaine	13(30 °C)	1.3(27 °C)	1
N-alkylbetaine	18(23 °C)	1.8(23 °C)	3
trimethylamino-alkaneimide	—	1.3(25 °C)	11

those determined by pH titration.

Critical Micelle Concentrations. The CMC values determined from the plot surface tension *vs.* log concentration at 30 °C are given in Table 2 together with those of other ampholytic surfactants.[1,3,11] We see that the CMC values of *N*-alkyl-*β*-alanines are nearly equal to those of the same alkyl chain length.

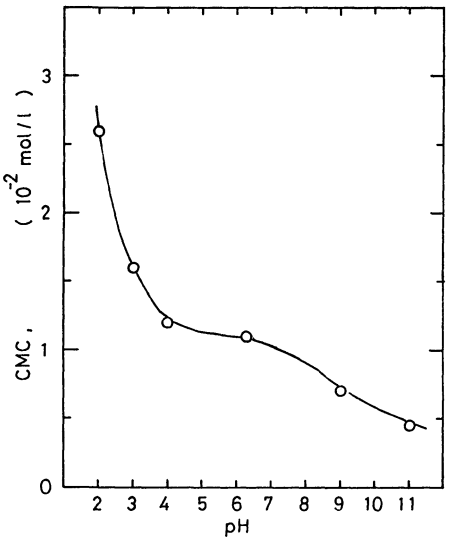

Fig. 1. Effect of pH on the CMC of *N*-alkyl-*β*-alanine at 30 °C.

The effect of pH on the CMC of *N*-decyl-*β*-alanine in 0.1 M sodium chloride solution is shown in Fig. 1. The CMC values decrease with increasing pH of the solution. The decrease is rapid in acid region, slow in alkaline side and imperceptible around pH 5—7. Corkill *et al.*[11] reported that CMC of *N,N,N*-trimethylaminododecaneimide decreased with increasing pH of the solution. This is due to the suppression of ionization of amino group, which can explain the rapid decrease of CMC of the decyl homolog in acid region but not the slow decrease of CMC in alkaline side since the enhanced dissociation of carboxyl group prevents the micelle formation. The position of the ionized group would be taken into account to explain the phenomena.

As is evident from the molecular structure, cationic ionization takes place in the inner position, while anionic ionization occurs at the end of the molecule. Thus the steric hindrance against micellization is less for the latter which acts to decrease the CMC with increasing pH. Such a steric hindrance has been studied in detail by Hartley.[12] The high CMC values in acid region show the instability of micelles in a low pH region.

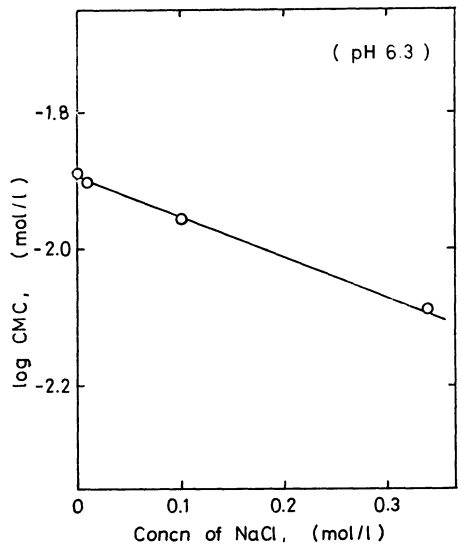

Fig. 2. Effect of electrolyte on the CMC of *N*-decyl-*β*-alanine at 30 °C.

The effect of sodium chloride on the CMC of *N*-decyl-*β*-alanine in a nearly neutral solution (pH=6.3) at 30 °C is shown in Fig. 2. The logarithm of the CMC decreases linearly with increasing concentration of added salt as in the case of nonionic surfactants.[13] In the case of ionic surfactants the plot log-log instead of that semi-log proves to be linear.[14] The difference can be explained by the zwitterionic property of *N*-alkyl-*β*-alanine in the isoelectric region where the ionic charges are neutralized in a molecule and the surfactant is considered to be nonionic.

In the plot of log CMC against $1/T$ at various pH for the decyl homolog (Fig. 3), at pH 11 the CMC increases slightly with increasing temperature in accordance with other ionic surfactants, while at pH 6.3, it decreases with increasing temperature as in the case of nonionic surfactant.[15] At pH 2, the CMC remains unchanged with temperature.

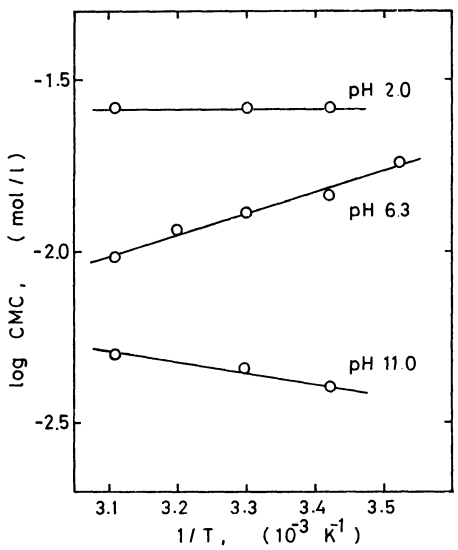

Fig. 3. Effect of temperature on the CMC of *N*-decyl-*β*-alanine

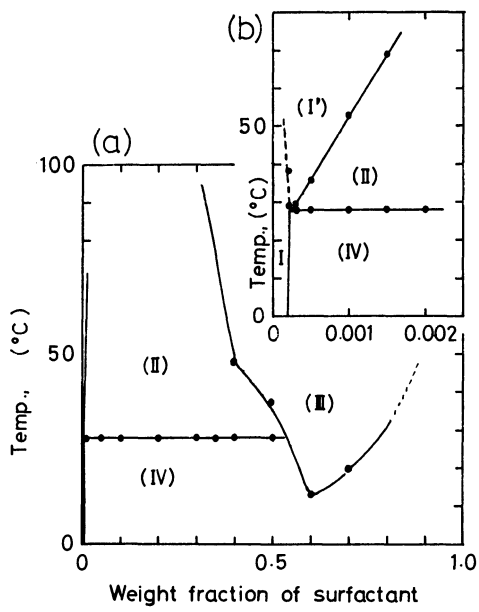

Fig. 4. Phase diagram of *N*-dodecyl-*β*-alanine/water system.
(a) system as a whole, (b) system in a dilute surfactant region; (I), (III): homogeneous region; (II), (IV): heterogeneous region.

Phase Diagram. The phase diagram of *N*-dodecyl-*β*-alanine/water system in (a) isoelectric region as a whole and (b) dilute surfactant region is shown in Fig. 4. (I) is a clear and homogeneous isotropic liquid phase consisting of surfactant monomers and water, (I') a similar phase consisting of surfactant monomers, micelles and water, (II) a region of the heterogeneous system which separates into two clear liquid phases when left standing, one rich and the other poor in surfactant, (III) a clear and homogeneous liquid phase, and (IV) a region of heterogeneous suspension consisting of a so called hydrated solid surfactant, dilute surfactant solution and (III). The line separating regions (I) and (I') shows the temperature dependence of CMC. The line separating regions (II) and (IV) is parallel to the composition axis showing the melting point of the hydrated solid surfactant determined by the differential scanning calorimetry. The cloud points usually observed in the nonionic surfactant could not be detected in the aqueous solution of *N*-decyl- and *N*-dodecyl-*β*-alanine in isoelectric region at temperatures 0—100 °C. The phase diagram for the decyl homolog and water system was also constructed for the concentrations 0—0.5 (weight fraction of surfactant) and temperatures 0—100 °C. Only one isotropic liquid phase without phase change was observed.

Mechanism of High-energy-induced Luminescence of Solid 2,3-Dimethylbutane Containing Toluene at 77 K

Tetsuo MIYAZAKI, Yoshiteru FUJITANI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received August 31, 1973)

The luminescence from 2,3-dimethylbutane (23DMB) containing a small amount of toluene (To) has been observed in the solid phase at 77 K during γ-irradiation or by ns pulse irradiation with X-rays. The emission spectrum from 23DMB–To (2 mol%) during γ-irradiation at 77 K consists of the fluorescence from the singlet-excited toluene and the phosphorescence from the triplet-excited toluene. Both the singlet- and triplet-excited toluenes are formed by the energy transfer from the irradiated 23DMB to toluene. When nitrous oxide or propylene is added to the 23DMB–To mixture, the emission spectrum is changed and becomes very similar to that from the 23DMB–To mixture during illumination with UV lights at 77 K. The spectrum, which disappears upon the addition of nitrous oxide or propylene, consists mainly of phosphorescence. It is concluded that the triplet-excited toluene may be formed by the migration of a hole and an electron. The effects of electron scavengers, such as nitrous oxide and carbon dioxide, or hole scavengers, such as propylene or tetramethylethylene, on the fluorescence have been studied by nsec-pulse irradiation. Since the fluorescence is not appreciably affected by the addition of these scavengers, the singlet-excited toluene may be formed by the excitation transfer.

We have previously studied the radiolysis of hydrocarbons in the solid phase in order to elucidate the primary process and in order to obtain information about the reaction kinetics in the solid phase. One of the most important primary processes is the migration of the short-lived entities produced by the γ-irradiation of the solid. Studies by Miyazaki *et al.* have suggested the importance of the non-ionic energy transfer in the radiolysis of solid hydrocarbons. The formation of the solvent radical and hydrogen which are formed by the fragmentation of the excited molecule is suppressed by the addition of toluene or CCl_4 in the radiolysis of solid isobutane. The phenomenon has been explained in terms of excitation transfer.[1] If toluene is an efficient acceptor of the excitation energy in the radiolysis of solid alkane, the luminescence from the excited toluene may be expected. Recently we have studied the luminescence from alkane containing a small amount of toluene during γ-irradiation at 77 K.[2] A strong emission from the excited toluene formed by the energy transfer from the irradiated alkane has been observed. The study of the luminescence gives us useful information on the energy transfer. Luminescence studies previously undertaken in radiation chemistry have been mostly concerned with the thermoluminescence or the photo-induced luminescence of γ-irradiated samples, or with the luminescence in the liquid phase during γ-irradiation.

In order to study the mechanism of the luminescence from solid 2,3-dimethylbutane containing toluene, we have here examined the effects of electron or hole scavengers on the luminescence upon irradiation with γ-rays or ns pulse X-rays.

Experimental

The 2,3-dimethylbutane(23DMB) and toluene(To) were the same as those used before.[2] They were passed through a 50 cm column packed with activated alumina and were used after distillation on a vacuum line. Nitrous oxide, carbon dioxide, and propylene, supplied by the Takachiho Shoji Co., were of a high purity and were used without further purification. The tetramethylethylene(TME), supplied by the Tokyo Kagaku Seiki Co., was more than 99.0% pure.

The errors in the measurement of the luminescence at 77 K were about 10%. Each experimental plot is an average of two or more runs.

The measurement of the luminescence during γ-irradiation was the same as that used before. The photomultiplier (Hamamatsu TV Co. R-136) can detect the light from 200 to 650 nm; its sensitivity depends upon the wavelength. It was expected that the brightness of the Shimadzu-Bausch-Lomb monochromator may depend also upon the wavelength of the lights. The sensitivity of the photomultiplier and the brightness of the monochromator were checked by using a standard tungsten lamp. The brightness of the monochromator, however, did not depend appreciably upon the wavelength of the lights. Therefore, the measured emission spectrum was corrected by considering only the sensitivity of the photomultiplier.

The pulse irradiation was done at 77 K with X-rays from Febetron 707. The maximum energy of the X-rays is 2 MeV, and the duration of a pulse is 20 ns. An apparatus for measuring the luminescence by pulse irradiation consists of a monochromator (Shimadzu GE-100), a photomultiplier (EMI-6256B), and a synchroscope (Iwatsu Electric Co., SS-112). A schematic diagram of the apparatus is given

The intensity of the fluorescence was normalized to the same peak intensity as that of 23DMB–To–N_2O (2 mol%).

intensities of the fluorescence and the phosphorescence are normalized to 10. The fluorescence was measured at 20, 60, and 180 ns after the pulse irradiation with Febetron and during γ-irradiation. The phosphorescence was measured during γ-irradiation. The fluorescences at different times show approximately the same dependence on the concentration of toluene.

The emission spectrum from 23DMB–To(2 mol%) during γ-irradiation at 77 K is shown in Fig. 3.[3] The spectrum consists of two peaks, with emission maxima near 280 and 390 nm. They are due to the fluorescence from the singlet-excited toluene and the phosphorescence from the triplet-excited toluene respectively. When nitrous oxide or propylene is added to the 23DMB–To(2 mol%), the emission spectrum is changed.

The spectrum which disappears upon the addition of nitrous oxide or propylene is obtained by subtracting

b: 23DMB–To (0.5 mol%).

the spectrum of 23DMB–To(2 mol%)–N_2O(2 mol%) or C_3H_6(2 mol%) from that of 23DMB–To(2 mol%). The intensities of the fluorescence are normalized to the same peak intensity as that of 23DMB–To(2 mol%)–N_2O(2 mol%) (Fig. 4). The emission spectrum from 23DMB–To(2 mol%) during the illumination with ultraviolet light at 77 K is also shown there.[4]

Figure 5 shows the time dependence of the fluorescence of the excited toluene formed by the ns-pulse irradiation of 23DMB containing toluene at 77 K. The rise in the fluorescence before 20 ns is due to the duration of the pulse.

Figure 6 shows the effects of electron scavengers, such as N_2O and CO_2, and hole scavengers, such as C_3H_6 and TME, on the fluorescence at 60 ns after the pulse irradiation at 77 K. Similar results are obtained also 20 and 180 ns after the pulse irradiation. The intensity of the fluorescence in the 23DMB–To(2 mol%) is taken as 10.

Discussion

Energy Transfer from Irradiated 23DMB to Toluene at 77 K. There are two possibilities with regard to the formation of the excited toluene in the irradiated 23DMB matrix. One is that it results from energy transfer from the irradiated 23DMB. The other is that it results from the direct absorption of the radiation energy by the solute toluene. The following results support the former possibility: (1) As is shown in Fig. 2, the intensity of the fluorescence increases sharply with an increase in the concentration of toluene, and then gradually increases beyond 2 mol% of toluene. The intensity of the phosphorescence increases sharply and then gradually decreases beyond 2 mol% of toluene. If the luminescence is due to the direct absorption of the radiation energy by the solute toluene, the intensity should increase linearly with an increase in the concentration of toluene.

(2) The yields of the solvent radical in the radiolysis of 23DMB at 77 K decrease upon the addition of toluene; the decrease coincides complementally with the increase in the fluorescence from toluene (Fig. 2). The results suggest that the energy which ruptures the C–H bond of the irradiated 23DMB migrates to toluene to form the excited toluene.

(3) The yields of the fluorescence from toluene in the irradiated alkanes by γ-rays or pulse X-rays at 77 K depend appreciably upon the kinds of alkanes. The yield of the fluorescence in 23DMB–To(2 mol%) is about 3—4 times as large as that in *neo*-C_5H_{12}–To(2 mol%). If the fluorescence is due to the direct absorption of the radiation energy by the solute toluene, the intensity does not depend upon the kind of alkanes, but only upon the amount of toluene.

(4) The addition of CCl_4, which is an efficient energy acceptor,[1] suppresses both the fluorescence and phosphorescence from the irradiated 23DMB–To(2 mol%) at 77 K.

(5) The intensities of the fluorescence from pure solid toluene during γ-irradiation are about 4—7 times stronger than those from 23DMB–To(2 mol%). The fluorescence due to the direct absorption of the radiation energy by toluene itself may be expected to amount to, at most, 8—15% and 3—6% of the total fluorescence from 23DMB–To(2 mol%) and –To(0.5 mol%) respectively.

The time dependence of the fluorescence from 23DMB–To(2 mol%) is similar to that from 23DMB–To(0.5 mol%) (Fig. 5). Since the fluorescence of toluene appears immediately after the ns pulse irradiation,[5] the formation of the excited toluene in the irradiated 23DMB is not due to the secondary reaction of the products, such as a trapped cation, or a trapped electron, but to the rapid energy transfer in a time period less than 10 ns.

Emission Spectrum. The rapid energy transfer in

the 23DMB matrix at 77 K cannot be ascribed to the molecular diffusion of active species, although this diffusion is the most important process in the liquid phase. A mobile entity in the solid phase is an exciton (DMB*),[6] a hole (DMB^+_m),[7] or an electron. For the formation of the excited toluene by energy transfer from the irradiated 23DMB, two processes are possible. One is that the exciton migrates to toluene. The other is that the hole and the electron encounter on the same toluene molecule, even if they travel freely through the matrix.

Figure 3 shows the effects of the addition of an electron scavenger (N_2O) or a hole scavenger (C_3H_6) on the emission spectrum of 23DMB–To during γ-irradiation at 77 K. It was found that propylene reacts efficiently with a hole by means of the following ion-molecule reaction at 77 K:[8]

$$DMB^+_m + C_3H_6 \longrightarrow C_6H_{12}{}^+ + C_3H_8 \quad (1)$$

The intensities of the phosphorescence decrease clearly upon the addition of N_2O or C_3H_6, while those of fluorescence decrease a little. The emission spectra from 23DMB–To(2 mol%)–N_2O(2 mol%) or 23DMB–To(2 mol%)–C_3H_6(2 mol%) during γ-irradiation are very similar to that from 23DMB–To(2 mol%) during the illumination with UV light (Fig. 4). The singlet-excited toluene is formed even in the presence of N_2O or C_3H_6. An excitation transfer forms a singlet-excited toluene, while an energy transfer *via* the ionic process, followed by a neutralization, favors the formation of a triplet-excited toluene. Therefore, it seems that the fluorescence may be due to the excitation transfer. This process will be discussed in more detail in connection with pulse irradiation in the next section.

On the contrary, the spectra which disappear upon the addition of N_2O or C_3H_6 are quite different from the spectrum obtained from 23DMB–To(2 mol%) during the illumination with UV light (Fig. 4). The phosphorescence is much stronger than the fluorescence in these spectra. The formation of the triplet-excited toluene is suppressed remarkably by the addition of an electron scavenger or a hole scavenger. The mechanism of the formation of the triplet-excited toluene may be represented as follows:

$$23DMB \rightsquigarrow DMB^+_m + e^- \quad (2)$$

$$DMB^+_m + To \longrightarrow 23DMB + To^+ \quad (3)$$

$$e^- + To^+ \longrightarrow To^3 \quad (4)$$

$$e^- + To \longrightarrow To^- \quad (5)$$

$$DMB^+_m + To^- \longrightarrow 23DMB + To^3 \quad (6)$$

$$To^3 \longrightarrow To + h\nu \text{ (phosphorescence)} \quad (7)$$

where To^3 represents a triplet-excited toluene. The hole and the electron produced by the irradiation (Reaction (2)) migrate to toluene (Reactions (3) and (5)). Then, the neutralization reaction (Reactions (4) and (6)) produces a triplet-excited toluene. Since N_2O may capture an electron, it disturbs Reactions (4) and (5). The suppression of Reaction (5) by the addition of N_2O was demonstrated by ESR spectroscopy in the radiolysis of 23DMB–To(2 mol%)–N_2O(2 mol%) at 77 K.[2] C_3H_6 disturbs Reactions (3) and (6) by the ion-molecule reaction with DMB^+_m (Reaction (1)). Since the amount of To^- does not correspond at all to the intensity of phosphorescence,[2] Reaction (6) may play a minor role.

Therefore, it may be concluded that the energy transfer in the 23DMB matrix consists of two processes: one forms singlet-excited toluene, and the other forms mainly triplet-excited toluene. Since the efficiencies of the emissions from the two excited states of toluene are not known in the 23DMB matrix at 77 K, the extents of the two processes cannot be determined as yet.

Effect of Scavengers on the Fluorescence. The singlet-excited toluene is formed immediately after the pulse-irradiation. Since the fluorescence in the liquid phase is suppressed by the addition of the electron scavengers (Fig. 6), ionic processes may be important in the formation of the singlet-excited toluene in the liquid phase, as has been reported previously.[9–11]

On the contrary, the fluorescence in the solid phase at 77 K is not affected appreciably by the addition of electron scavengers, such as N_2O and CO_2, or hole scavengers, such as C_3H_6 and tetramethylethylene (TME). There is a possibility that these additives may not act efficiently in the 23DMB matrix at 77 K.

In the radiolysis of 23DMB–To(2 mol%)–CO_2(2 mol%) at 77 K, CO_2 captures an electron to form CO_2^-, which is clearly detected by ESR spectroscopy, and $G(CO_2^-)$ is about 0.8.[12] When 23DMB–To(2 mol%) is γ-irradiated at 77 K, a toluene anion is formed in an appreciable amount. The formation of the toluene anion is completely suppressed by the addition of N_2O, while a toluene cation is clearly observed by ESR spectroscopy in the radiolysis of 23DMB–To(2 mol%)–N_2O(2 mol%) at 77 K. The amount of electrons captured by N_2O seems to be equal to the yield of the toluene cations (*i.e.*, $G\sim1.7$). Since the G-values of the ionization in the gas and liquid phases are about 4, there is some suspicion that the ionic reaction which is not disturbed by N_2O amounts to 2.3 G-unit. Although the yields of the ionization in the gas phase, in which a free electron and a cation are produced, and about 4 G-unit, we cannot expect that, in the crystal, the yields of holes and electrons will be 4 G-unit, for if a hole and an electron are bound by their mutual Coulomb force, they may be considered as an exciton.[6] It has been reported by several investigators that the yields of the electrons which can be captured by electron scavengers are 1.5—2.0 G-unit in the radiolysis of solid alkanes at 77 K. They used biphenyl,[13] alkyl disulfide,[14] benzene,[15] iodobenzene,[16] and nitrous oxide[16] as electron scavengers. The yields were determined by different analytical methods, such as optical or ESR spectroscopy, or gas chromatography. Therefore, the amount of electrons captured by N_2O in the 23DMB matrix ($G\sim1.7$) is near the maximum yields of electrons in the irradiated solid alkane. There is a possibility that N_2O does not directly capture a mobile electron, but that it captures an electron from a toluene anion by tunneling.[17] It can be expected from the tunneling hypothesis that the yield of the toluene cation

is not affected by the addition of N_2O. The yield of the toluene cation, however, increases remarkably upon the addition of N_2O.[2] Therefore, N_2O captures a mobile electron, disturbing the neutralization reaction between the electron and the toluene cation. TME captures a hole to produce the TME^+ cation, which is observed in the irradiated 23DMB–To(2 mol%)–TME(2 mol%) by ESR spectroscopy.[12]

Therefore, it may be considered that the reactions due to electrons or holes are suppressed by the addition of the electron scavengers (N_2O or CO_2) or the hole scavengers (C_3H_6 or TME). Figure 6 shows that the fluorescence is not appreciably affected by the addition of N_2O, CO_2, C_3H_6, or TME at 77 K. It may be concluded that the formation of the fluorescence, *i.e.*, the formation of the singlet-excited toluene, is not due to the reactions of the hole and the electron, but to a non-ionic process, such as the migration of the exciton:

$$23DMB \rightsquigarrow DMB^* \quad (8)$$

$$DMB^* + To \longrightarrow DMB^* + To^1 \quad (9)$$

$$To^1 \longrightarrow To + h\nu(\text{fluorescence}) \quad (10)$$

$$\searrow\ To^3 \quad (11)$$

$$To^3 \longrightarrow To + h\nu\ (\text{phosphorescence}) \quad (7)$$

$$DMB^* \longrightarrow C_6H_{13} + H \quad (12)$$

where To^1 represents a singlet-excited toluene. The exciton produced by irradiation migrates to the toluene, this forming the singlet-excited toluene, which emits fluorescence and phosphorescence by intersystem crossing. DMB* indicates a Frenkel exciton, a Mott-Wannier exciton, or a mobile ion-pair. Reaction (9) implies also the possibility that toluene accepts energy directly from the excited 23DMB molecule, which itself absorbs the radiation energy. It is interesting to note that the C–H bond rupture in the radiolysis of solid isobutane, whose chemical structure is similar to 23DMB, is due to the fragmentation of the excited molecule,[1] and that the formation of the singlet-excited toluene in the 23DMB–To system at 77 K competes with the formation of the solvent radical (Fig. 2).

The authors wish to thank Dr. Hiroshi Masuhara of Osaka University for his measurement of the emission during illumination with UV light. They wish also to thank Dr. Masahiro Saido of Nagoya University for his help in performing the pulse-irradiation.

3) The emission spectrum is different from the previously-reported one (Ref. 2). When the sample is irradiated, some product which absorbs the light near 280 nm may be formed, thus decreasing the emission intensity at 280 nm. Therefore, the spectra in Fig. 3 are those from a freshly-sealed sample.

4) The spectrum of 23DMB–To (2 mol%) during UV illumination with light of 250 nm at 77 K was measured by Dr. Hiroshi Masuhara.

5) The initial rise in the fluorescence before 20 ns is due to the duration of the pulse. The values at 0 ns contain larger errors than those at other times.

6) It would be useful to define the technical terms used in this paper. Such terms as "ionization", "cation", "electron", and "excited molecule" are commonly used in radiation chemistry. Though they can be clearly defined in the gas phase, where each molecule exists independently, it is difficult to do so in the crystal where the character of a molecular aggregate becomes remarkable. Since there have been very few studies of the primary process in the radiolysis of organic crystals, it is impossible to give terms suitable for the radiation chemistry in the crystal. Therefore, we adopt the terms for the mobile entities which are used in solid state physics. An electron in the conduction band and a hole can travel freely and independently through the crystal. An exciton is a neutral, excited mobile state of a crystal; an exciton can travel through the crystal, but it is electrically neutral. The exciton may be classified into two different limiting approximations. One is the Frenkel exciton, which is considered to be tightly bound, while the other is the Mott-Wannier exciton, which is weakly bound by Coulomb force, having an electron-hole interparticle distance large in comparison with the atomic radius. In this paper, we do not discriminate between the two types of excitons (*cf.* C. Kittel, "Introduction to Solid State Physics," John Wiley & Sons, New York, (1956)).

The Raman Spectra and Molecular Conformations of Surfactants in Aqueous Solution and Crystalline States

Hirofumi Okabayashi, Masataka Okuyama, Teizo Kitagawa,* and Tatsuo Miyazawa*

Department of Engineering Chemistry, Nagoya Institute of Technology, Gokiso, Nagoya 466
**Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565*

(Received September 4, 1973)

The Raman spectra were measured for sodium alkyl sulfates and potassium aliphatic carboxylates in the solid state and aqueous solutions. Vibrational assignments of Raman lines were made, and characteristic Raman lines of the alkyl sulfate ion were identified. The ethyl sulfate ion in the aqueous solution was found to exist predominantly as the *trans* form about the CH_2–O bond. For higher alkyl sulfate ions in aqueous solutions, Raman lines due to rotational isomers with *gauche* CH_2–CH_2 bonds were observed. Longitudinal accordion frequencies of the solid state and aqueous solutions were compared in order to discuss the conformations of hydrocarbon chains in solution.

The physicochemical properties of aqueous solutions of surfactants have been extensively studied. For more detailed investigations of surfactants, conformation studies of surfactant molecules in aqueous solutions are highly desirable. Laser Raman spectroscopy is useful for conformation studies of molecules, especially in aqueous solutions. However, the Raman spectra of surfactants in aqueous solutions have not been reported on.

In the Raman spectra of long-chain *n*-paraffins in the crystalline state, very strong Raman lines due to "accordion" vibrations have been observed; the frequencies of these accordion vibrations have been found to be inversely proportional to the number of carbon atoms.[1,2] Accordion vibrations of *n*-paraffins have also been observed in solution, and molecular conformations in solution have been discussed.[1,3,4]

In the present study, the Raman spectra of a homologous series of sodium alkyl sulfates and of potassium aliphatic carboxylates were measured. The characteristic Raman lines of alkyl sulfate groups were identified. Raman lines due to accordion vibrations were observed in order to study molecular conformations in aqueous solutions.

Experimental

The samples of sodium methyl sulfate (SMS), sodium dodecyl sulfate (SDS), and potassium aliphatic carboxylates ($C_{n-1}H_{2n-1}CO_2K$, $n=3$, 4, 6, 8, 10, and 12) were obtained from the Tokyo Kasei Co. and were purified by recrystallization. However, the samples of sodium ethyl sulfate (SES), sodium *n*-propyl sulfate (SPS), sodium *n*-butyl sulfate (SBS), sodium *n*-hexyl sulfate (SHS), sodium *n*-octyl sulfate (SOS), and sodium *n*-decyl sulfate (SDeS) were prepared from sulfuric acid, *n*-alkyl alcohol, and sodium hydroxide.[5]

The Raman spectra of sodium alkyl sulfates and potassium aliphatic carboxylates in the crystalline state and in an aqueous solution at room temperature were measured with a JEOL Raman spectrometer (JRS-O2AS, argon ion laser, 488.0 nm). The sodium alkyl sulfates were dissolved (30—50 wt%) in water, but the potassium aliphatic carboxylates were dissolved (30—50 wt%) in a 0.1 M KOH solution.

Results and Discussion

The Raman spectra of SDS, SDeS, SOS, SHS, SBS, and SPS in aqueous solutions are shown in Fig. 1. In the Raman spectra of surfactants (SDS, SDeS, and SOS), common Raman lines are observed at 890

Table 1. Raman frequencies (cm^{-1}), relative intensities,[a] and vibrational assignments of PMS (potassium methyl sulfate), SMS and SES in the solid state and aqueous solution and of the series from SPS to SDS in aqueous solution

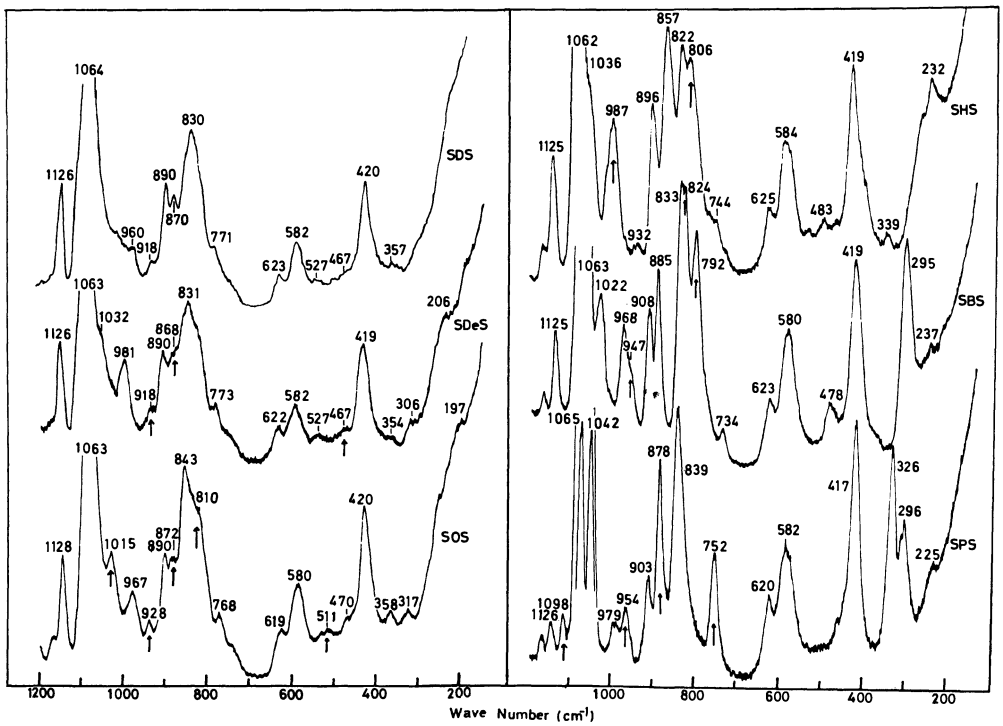

Fig. 1. Raman spectra of SDS (30 wt %), SDeS (35 wt %), SOS (40 wt %), SHS (45 wt %), SBS (50 wt %), and SPS (50 wt %) in aqueous solution at room temperature. Excited with an argon ion laser (488.0 nm). Raman lines marked with arrows are not observed in the crystalline state.

and 1131 cm^{-1}; these lines correspond to the Raman lines of long-chain *n*-paraffins[1] at about 900 and 1135 cm^{-1} and are thus assigned to the terminal-methyl rocking vibration and C–C stretching vibrations[6] respectively. For the series from SPS to SDS, common Raman lines are also observed at 417—420, 580—584, 619—625, 822—839, and 1062—1065 cm^{-1} (see Fig. 1 and Table 1). The assignment of these Raman lines was made with reference to the Raman spectra of PMS (potassium methyl sulfate)[7] and SMS.

Sodium Methyl Sulfate. The Raman frequencies of SMS in an aqueous solution are listed in Table 1, together with the Raman frequencies (and vibrational assignments) of PMS[7] in an aqueous solution. The band of PMS at 615 cm^{-1} was resolved into two components (591 and 617 cm^{-1}) in the Raman spectra of SMS. In other respects, the Raman lines of SMS closely correspond to the Raman lines of PMS; accordingly, the vibrational assignments of SMS were made following those of PMS.[7] The Raman lines due to the rocking (or asym. deform.) modes are split into two components, since there are two modes, symmetric or antisymmetric, with respect to the CH_3–O–S plane. There are two strong Raman lines at 1063 and 1004 cm^{-1}. However, the line at 1063 cm^{-1} is characteristic of alkyl sulfates; accordingly, the line at 1004 cm^{-1} is assigned to the stretching vibration of the CH_3–O bond. The weak broad line at 272 cm^{-1} can reasonably be assigned to the C–O–S deformation vibration.

The Raman line of solid SMS at about 781 cm^{-1} is split into two components. In other respects, the Raman lines of SMS in an aqueous solution closely correspond to the Raman lines in the solid state, indicating that the molecular structures of SMS in solution and in the solid state are similar.

Sodium Ethyl Sulfate. The crystal structure of SES was analyzed by the X-ray diffraction method. The ethyl sulfate ion (CH_3–CH_2–O–SO_3^-) was found to take the *trans* form in the crystalline state.[8] In solution, the *gauche* form may well be expected to appear. However, the steric repulsion between the terminal CH_3 group and oxygen atoms of the $-SO_3^-$ group possibly makes the *gauche* form much less stable than the *trans* form. In fact, the Raman spectra of the aqueous solution and the solid were found to be much the same except for the splitting of the Raman lines at about 810 and 610 cm^{-1} in the solid state, and no new lines appeared when the solid was dissolved in water. Accordingly, the ethyl sulfate ion in an aqueous solution may be concluded to exist primarily in the *trans* form.

The Raman spectra of SES were compared with those of SMS (Table 1) for vibrational assignments. The Raman lines of SES at 913 and 345 cm^{-1} were readily assigned to the CH_3–CH_2 stretching and C–C–O deformation vibrations respectively.

Sodium Propyl Sulfate. The Raman lines of SPS at 903 and 1042 cm^{-1} (Fig. 1) correspond to the infrared bands of propane at 899 and 1049 cm^{-1}, and are assigned to the methyl rocking and C–C stretching vibrations[9] respectively. The three lines of the aqueous solution at 752, 878, and 954 cm^{-1} are not observed in the solid state and are assigned to the *gauche* form about the CH_2–CH_2 bond.

Sodium Butyl Sulfate. The Raman lines of SBS

Table 2. Accordion frequencies (cm^{-1}) of sodium alkyl sulfates (SAS), potassium aliphatic carboxylates (PAC) in the solid state and aqueous solutions and of *n*-paraffins

Number of carbon atoms	SAS		PAC		*n*-Paraffin[a]	
	soln	solid	soln	solid	liquid	solid
3	326	340	496	496		
4	295	315	349	353	429	425
6	232	236	327	325	370	373
8	197	196	254	248	279	283
10	206	169	243	208	250	231
12			222	181	239	194

a) Ref. 1.

at 792 and 947 cm^{-1} disappear in the solid state. These lines closely correspond to those of the *gauche* isomer of *n*-butane at 788 and 956 cm^{-1}, and are assigned to the methylene rocking and C–C stretching vibrations[9] respectively.

Sodium Alkyl Sulfate. The Raman lines of SHS at 806 and 987 cm^{-1} disappear in the solid state; accordingly, they must be due to rotational isomers having *gauche* CH_2–CH_2 bonds. The Raman intensities of these lines relative to other lines were found to be concentration-dependent. This observation allows some detailed studies of the molecular conformations of surfactant molecules in solution (to be reported separately).

For SOS and SDeS, the Raman lines shown with arrows in Fig. 1 disappear in the solid state and are due to rotational isomers other than the all-*trans* form.

Accordion Vibrations. The accordion frequencies of sodium alkyl sulfates and potassium aliphatic carboxylates are listed in Table 2, together with those of *n*-paraffins. For the example of $n=6$, the accordion frequencies become lower in the order of: $CH_3(CH_2)_4$–CH_3 > $CH_3(CH_2)_4$–CO_2^- > $CH_3(CH_2)_4$–CH_2–OSO_3^-. These frequency differences are possibly due to the greater mass of the terminal groups of aliphatic carboxylates and alkyl sulfate ions.

For the accordion vibrations of sodium alkyl sulfate ($n \geq 4$) and potassium aliphatic carboxylate ($n \geq 6$), there are linear relations, as is shown in Fig. 2, between the reciprocal number ($1/n$) of carbon atoms and the accordion frequencies in the solid state. However,

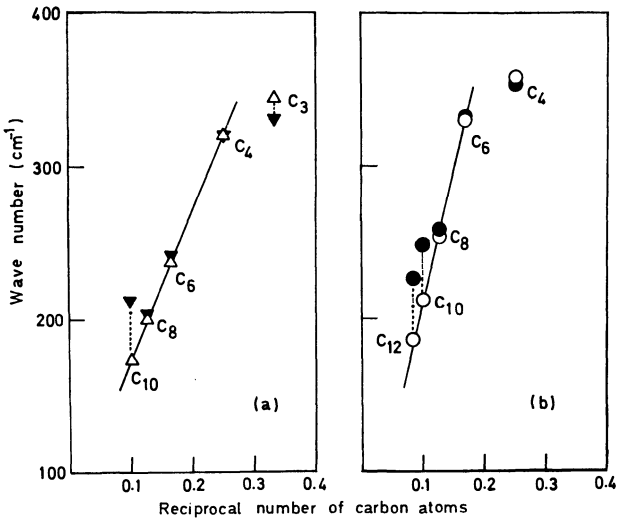

Fig. 2. Number of carbon atoms and accordion frequencies of (a) sodium *n*-alkyl sulfates (R–O–SO_3Na) and (b) potassium aliphatic carboxylates in the crystalline state (open mark) and aqueous solution (full mark).

for $n>8$, the accordion frequencies in an aqueous solution are apparently higher than those in the solid state. Similar observations were previously made of *n*-paraffins in the liquid and solid states.[3,4] Observations of these higher-frequency accordion vibrations indicate that the randomness of *n*-alkyl hydrocarbon chains is increased with the number of carbon atoms.

Electronic Excited States of the Intramolecular Exciplex and Charge-transfer Complex in (9,10-Dicyanoanthracene)-$(CH_2)_3$-(Naphthalene)

Michiya Itoh,* Tsutomu Mimura, and Toshihiko Okamoto

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received September 5, 1973)

In the previous paper two kinds of fluorescences due to the intramolecular exciplex (above ~200 K) and the charge-transfer complex (below ~160 K) were reported in a nonpolar solution of the (9,10-dicyanoanthracene)-$(CH_2)_3$-(naphthalene) systems. The fluorescence quantum yields as well as the fluorescence lifetimes of the exciplex and CT complex determined at several temperatures show a discontinuous change from room temperature to 77 K. The radiative and nonradiative decay constants of these fluorescent states suggest that the radiative decay in the exciplex is comparable with the nonradiative decay, while the nonradiative process is predominant in the excited state of the CT complex.

The binding energy of the exciplex has been attributed to the charge-transfer (CT) interaction between the electron donor and acceptor.[1] The CT character in the exciplex has been emphasized by the determination of the ($S_n \leftarrow S_1$) absorption spectra.[2,3] However, there has been no information available about the difference in the properties and relationship between the exciplex and the excited state of the CT complex. The present authors previously reported that the intramolecular exciplex fluorescence was observed in the (9,10-dicyanoanthracene)-$(CH_2)_3$-(naphthalene) systems in both polar and nonpolar solvents.[4] Only in the nonpolar solvent, the intramolecular CT-complex fluorescence (λ_{max} 540 nm) was observed below ~160 K in the wavelength region longer than the exciplex fluorescence (λ_{max} 500—510 nm). The fluorescence lifetimes of the exciplex and the CT complex at various temperatures were reported to be almost independent of the temperature, and different from each other. The appreciable differences in the fluorescence lifetimes and maxima between the exciplex and CT complex suggested that there were two different excited states in the potential energy surface of the electronic interaction between the electron-donor-acceptor moieties in this compound.

Therefore, in order to elucidate the properties of these fluorescent states of the intramolecular exciplex and CT complex, we determined the fluorescence quantum yields and the radiative and nonradiative rate constants of these excited states.

Experimental

The synthesis and purification of (9,10-dicyanoanthracene)-$(CH_2)_3$-(naphthalene) (abreviated as $\beta\alpha'$- and $\beta\beta'$-DCAN) and the determination of the absorption and fluorescence spectra were reported in a previous paper.[4] The fluorescence quantum yields were measured essentially in the way described by Parker and Rees,[5] where the solution of anthracene was used as the standard. In the determination of the quantum yields of the CT complex, the intensity of the absorption spectrum at a certain wavelength (an excitation light) corresponding to the CT complex at a certain temperature (~150—77 K) was obtained by the aid of an equilibrium constant which was estimated from a straight line of $\log \varepsilon/(\varepsilon_c-\varepsilon)$ against $1/T$ mentioned in the previous paper. The fluorescence lifetimes were determined by using a coaxial-type nitrogen gas laser as an exciting light source (30 kW peak intensity at 337 nm and 3 ns duration).[6]

Results and Discussion

The mechanism for the exciplex and CT-complex formations and decay processes can be expressed as follows:

$$\begin{array}{ccccc} D + A^* & \underset{k_4}{\overset{k_3}{\rightleftharpoons}} & (DA)^* & & (DA)_c^* \\ & k_1 \downarrow \{ k_2 & & k_5 \downarrow \{ k_6 & k_7 \downarrow \{ k_8 \\ D + A & \cdots\cdots\cdots\cdots\cdots\cdots\rightarrow & (DA)_c & & \end{array}$$

Here, D and A are the electron donor and acceptor respectively; and (DA)* and $(DA)_c$* are the exciplex and an excited state of the CT complex respectively. The CT complex in the ground state is expressed by $(DA)_c$.

Birks *et al.* made an extensive study of the rise and decay kinetics of the pyrene excimer and determined the rate constants.[7] Recently, Yoshihara *et al.* determined the rate constants of the exciplex formation and of the decay process in the exciplex of the pyrene–*N,N*-dimethylaniline system.[8] They obtained the rate constant of k_3 from the concentration dependence of the intermolecular exciplex, and also evaluated k_4 and (k_5+k_6) from an analysis of the time-dependent exciplex concentration. The value of k_4 in the literature are negligible compared with those of k_3.[1,7-9] However, no determination of the k_4 in the intramolecular exciplex has ever been reported. In this paper, it is noteworthy that the intramolecular exciplex formation is independent of the concentration. Furthermore, no rise-time of the exciplex fluorescence from which k_4 might be evaluated was observed. Therefore, k_4 was assumed to be negligible compared with k_3 in this stage, and also subsequent attempts were made to study the intramolecular exciplex formation and decay process.

The fluorescence quantum yields and lifetimes of 9,10-dicyanoanthracene as determined in several solvents are shown in Table 1. Table 1 suggests that the nonradiative rate constant, k_2, in a nonpolar solvent

Table 1. Fluorescence lifetimes and quantum yields of 9,10-dicyanoanthracene in various solvents

Solvent	τ (ns)	ϕ
MP	15.2	0.9
2-Methyl THF	15.8	0.52
Acetone	18.0	0.19
Acetonitrile	19.5	0.21

such as MP may be negligible compared with k_1. This assumption is not valid in a polar solvent, though, since the quantum yield shows a remarkable decrease in the polar solvent. In DCAN, the fluorescence quantum yield and lifetime of the 9,10-dicyanoanthracene moiety are expressed as follows:

$$\phi' = k_1(k_1+k_2+k_3)^{-1} \text{ and } \tau' = (k_1+k_2+k_3)^{-1}.$$

The results obtained here at 300 K are summarized in Table 2. If k_2 was neglected in an MP solution of DCAN, as mentioned above, the rate constant of the intramolecular exciplex formation, k_3, was directly estimated to be 1.1×10^8 s^{-1} for $\beta\alpha'$-DCAN and 1.2×10^8 s^{-1} for $\beta\beta'$-DCAN at this temperature from ϕ' and τ' respectively, both shown in Table 2. The value of k_3 can not be compared with those of the rate constants of the intermolecular exciplex formations in the literature,[8-10] because the former obeys different kinetics from those of the latter. Furthermore, the rate constants, k_3, at several temperatures were evaluated from the value of k_3 at 300 K and from the activation energy of the exciplex formation reported in previous papers,[4,11] where we assumed that there was no change in the entropy factor in this temperature region.

Table 2. Fluorescence lifetimes and quantum yields of DCAN's in MP

DCAN	DCA moiety[a]		Exciplex[a]		CT-Complex[d]	
	τ'(ns)	ϕ'	τ_e(ns)	ϕ_e[c]	τ_c(ns)	ϕ_c
$\beta\alpha'$-	8.0	0.097	63	0.25	127	0.13
$\beta\beta'$-	8.0	0.069	40.8	0.20	150	0.11

a) Determined at 300 K. b) Determined at 77 K.
c) Apparent quantum yields mentioned in the text.

The apparent fluorescence quantum yield of the exciplex, ϕ_e, can be expressed by the following equation:[8]

$$\phi_e = \phi_e'\frac{k_3\tau}{1+k_4\cdot\tau_e'}\left\{1+\frac{k_3\tau}{1+k_4\cdot\tau_e'}\right\}^{-1} = \phi_e'\cdot f.$$

Here, $\tau=(k_1+k_2)^{-1}$, $\tau_e'=(k_5+k_6)^{-1}$ and $\phi_e'=k_5\cdot\tau_e'$. Since k_4 was neglected, as has been mentioned above, f, k_5 and k_6 can be estimated by the aid of the τ, τ_e', k_3 and ϕ_e obtained in an MP solution of DCAN. These results, as determined at 300 K, are summarized in Table 3. These quantum yields, and the radiative and nonradiative rate constants of the exciplex at several temperatures, were determined in an MP solution of $\beta\beta'$-DCAN; the results are shown in Fig. 1.

On the other hand, the fluorescence quantum yields of the CT complex in an MP solution of $\beta\beta'$-DCAN at several temperatures below ~150 K were determined by the method described in the experimental section.

Table 3. Radiative and nonradiative rate constants (in units of s^{-1}), and fluorescence quantum yields in DCAN's (in MP)

DCAN	DCA moiety[a]		Exciplex[a]			CT-complex	
	$k_1\times10^{-7}$	$(k_2+k_3)\times10^{-8}$	ϕ'_e[c]	$k_5\times10^{-6}$	$k_6\times10^{-6}$	$k_7\times10^{-6}$	$k_8\times10^{-6}$
$\beta\alpha'$-	1.2	1.13	0.54	8.3	7.5	1.05	6.8
$\beta\beta'$-	0.86	1.2	0.42	10.4	14	0.7	5.9

a) Results evaluated from the data at 300 K.
b) Results evaluated from the data at 77 K.
c) Estimated quantum yields of the exciplex mentioned in the text.

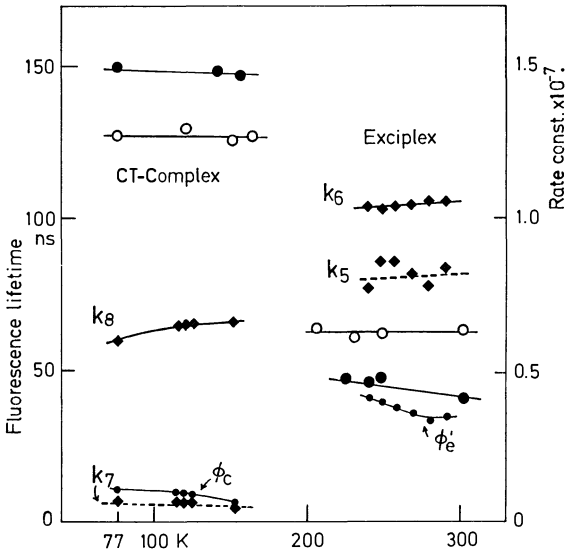

Fig. 1. Temperature dependence of the fluorescence lifetimes determined at 560 nm, —○—○— and —●—●— are $\beta\alpha'$-, and $\beta\beta'$-DCAN, respectively, and of the fluorescence quantum yields, and the radiative and nonradiative rate constants of the exciplex and the CT-complex in an MP solution. Concentrations are approximately 10^{-6}M. An unit of an ordinate for the decay rate constants is 10^7s^{-1}.

These results and the decay rate constants of the CT complex of $\beta\beta'$-DCAN at several temperatures are shown in Fig. 1. These quantum yields and the rate constants of the exciplex and the CT complex are both almost temperature-independent. It is unlikely that the quantum yield and also the rate constant can continuously change from the exciplex to the CT complex in the temperature region of ~200—160 K, as is shown in Fig. 1, where the fluorescence in the 500—550 nm region was almost quenched and was indistinguishable between the exciplex and the CT complex. This is because the solvent (MP) used here shows no steep change in viscosity in this temperature region.

Recently it has been suggested that the fluorescent state of the exciplex is identical with that of the corresponding CT complex, though no comparison of the exciplex fluorescence with that of the CT complex was made in the same electron-donor-acceptor system. Very recently, Itoh and Mimura reported experimental evidence for an identical fluorescent state of the inter-

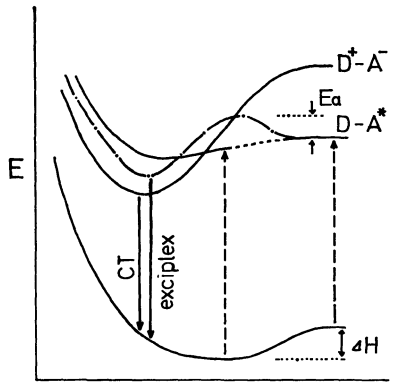

Fig. 2. The potential energy curves of the exciplex and the CT-complex.

molecular exciplex and CT complex in the 9,10-dicyanoanthracene–2-methylnaphthalene system.[12] The experimental behaviors of the intramolecular exciplex and CT complex reported here and also in the previous paper[4] demonstrate that these two fluorescences are from individual fluorescent states, as is illustrated in Fig. 2. Mataga *et al.*[13] reported the radiative and nonradiative rate constants in the exciplex of the pyrene–*N*,*N*-dimethylaniline system in the nonpolar solvent to be 2.4×10^{6} s^{-1} and 2.6×10^{6} s^{-1} respectively. Kobayashi *et al.*[14] made an extensive study of the CT complex of tetracyanobenzene and reported the radiative and nonradiative rate constants of the CT complex in a nonpolar solvent to be 10^{4-5} s^{-1} and 10^{6-7} s^{-1} respectively. As is shown in Fig. 1 and in Table 3, the radiative and nonradiative rate constants in the exciplex are comparable to each other, while the latter seems to be the main process in the CT complex. The decay constants from room temperature to 77 K obtained here are further confirmation of our arguments that the fluorescence above ~200 K is to be ascribed to the exciplex, and those below ~160 K, to the CT complex, and that there are two different fluorescent states in the intramolecular electronic interaction between the electron donor and acceptor moieties. These electronic interactions leading to the difference in the excited fluorescent states of the exciplex and the CT complex can be understood by the argument that the internal or geometrical conversion from their respective Franck-Condon excited states to the identical fluorescent state, which may be allowed in the intermolecular interaction,[12] is forbidden in these chain compounds by the steric factor concerned with the trimethylene chain.

The authors are indebted to Dr. Keitaro Yoshihara of the Institute of Physical and Chemical Research for the determination of the fluorescence lifetime and for valuable discussions.

The Crystal Structure of the 1:1 Complex of Pyromellitic Dianhydride with *trans*-Stilbene

Toshiko KODAMA and Shigekazu KUMAKURA*

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
**Department of Chemistry, Faculty of Science and Engineering, Saitama University, Shimookubo, Urawa-shi, Saitama 338*

(Received September 11, 1973)

The 1: 1 complex of pyromellitic dianhydride with *trans*-stilbene crystallizes in the space group $P2_1/c$ with two pairs of the component molecules in a unit cell with dimensions of $a=12.48$, $b=6.33$, $c=13.17$ Å, and $\beta=111.6°$. The structure was solved from a three-dimensional $|E|^2$ Patterson synthesis and refined by a block-diagonal least-squares method to a final R value of 0.12 for 1635 reflections. In the *trans*-stilbene molecule, the plane containing the central ethylene group makes an angle of 11.5° with the phenyl plane. The non-planarity of the *trans*-stilbene molecule seems to be largely due to a steric repulsion between the hydrogen atom attached to the ethylene moiety and that at the 6 and 6′ position in the phenyl group. The pyromellitic dianhydride molecule is approximately planar. The component molecules are stacked alternately in infinite columns along the a axis. The average spacing between the phenyl plane of *trans*-stilbene and the molecular plane of pyromellitic dianhydride is 3.59 Å, and these palnes make an angle of 4.8° with each other. The relative arrangement of the component molecules in the crystal differs from that observed in the crystal of the anthracene, pyrene, or perylene complex with pyromellitic dianhydride. The van der Waals forces are considered to be more important than the charge transfer force in determining the relative arrangement of the component molecules in this crystal.

The charge transfer (CT) complex of *trans*-stilbene (STB) with pyromellitic dianhydride (PMDA) crystallizes with a 1: 1 molecular ratio, whereas the CT complex of *trans*-4-methylstilbene crystallizes with a 2: 1 molecular ratio.[1] The crystal structure analysis of the former complex was carried out in order to study the molecular interaction between the donor and acceptor molecules.

Experimental

Crystals of the complex were kindly supplied by Professor Matsuo of Kyushu University. They were in the form of bright red thin plates. The cell constants were determined from zero-layer back-reflection Weissenberg photographs around the b and c axes. The crystal data are listed in Table 1. The specimens used for the intensity measurements had dimensions of $0.24\times0.24\times0.05$ mm and $0.23\times0.21\times0.05$ mm. Multiple film equi-inclination Weissenberg photographs were taken around the b axis up to the fifth layer and around the c axis up to the tenth layer. The intensities of 1635 independent reflections were estimated visually by comparison with a standard scale. The usual Lorentz, polarization, and spot-shape corrections were applied; however, no correction was made for the absorption in view of the small size of the specimens.

TABLE 1. CRYSTAL DATA

Structure Determination

A Patterson synthesis sharpened by the $\exp(B\sin^2\theta/\lambda^2)$ factor was calculated using the complete set of observed data, but it could not be interpreted satisfactorily because of the severe overlapping of peaks. The structure was, however, solved by an $|E|^2$ Patterson synthesis. From the peaks around the point of origin, the orientations of the benzene rings in the component molecules could be fixed. The molecular orientations and the relative arrangement of the component molecules were assumed so as to account for the characteristic distribution of the prominent peaks. The structure factors were calculated on the basis of the trial model thus obtained by assuming the isotropic temperature factors of all the atoms. The R value was 0.46. The atomic coordinates and isotropic temperature factors were refined by means of the block-diagonal least-squares procedures using a program written by Dr. Ashida. After five cycles of refinement, anisotropic temperature factors were introduced. The positions of the hydrogen atoms were supplied by calculation; they were not refined. The temperature factors of the hydrogen atoms were assumed to be isotropic and were given the same values as those of the atoms to which the hydrogen atoms were attached. The following weighting scheme was employed for the least squares refinement:

$$1.0 \text{ for } |F_o| \geq 5.0$$

and:

$$0.7 \text{ for } |F_o| < 5.0$$

The final R value was 0.12. The topography of the final differential synthesis was flat within the range of ±0.3eÅ^{-3}. The final atomic and thermal parameters are listed in Table 2. A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan.[2] Atomic scattering curves taken from the International Tables for X-ray Crystallography were used throughout.

TABLE 2. FINAL ATOMIC COORDINATES AND THERMAL PARAMETERS

(Estimated standard deviations are shown in parentheses ($\times 10^4$). Thermal parameters are in the form of $\exp[-(h^2\beta_{11}+k^2\beta_{22}+l^2\beta_{33}+hk\beta_{12}+hl\beta_{13}+kl\beta_{23})]$.)

Description and Discussion of the Structure

The bond lengths and angles of the PMDA and STB molecules are shown in Fig. 1 and are listed in Table 3. The standard deviations are also included in the Table. Both PMDA and STB molecules have a center of symmetry. The phenyl plane of the PMDA molecule is given by this equation:

$$0.621x - 0.452y + 0.640z = 0.000, \quad (1)$$

where x, y, and z are the coordinates in Å units referred to the a, b, and c crystal axes. The maximum deviation of the atoms from this plane is 0.010 Å. The carbonyl oxygen atoms in this molecule are significantly deviated outwards by 0.061 and 0.128 Å from this plane. The plane through C(14), O(11), C(15), and O(13) is expressed as;

$$0.723x - 0.395y + 0.567z = -0.322 \quad (2)$$

and makes an angle of 7.9° with the plane given by Eq. (1). The maximum deviation of the atoms from this plane given by Eq. (2) is 0.003 Å. Similar deviations of the carbonyl groups in the PMDA molecules were observed by Herbstein *et al.* in the complexes of PMDA with perylene[3] and pyrene.[4]

The C–C bond lengths in the benzene ring of PMDA agree with the normal value within 2σ. All the bond angles of the benzene ring deviate significantly from

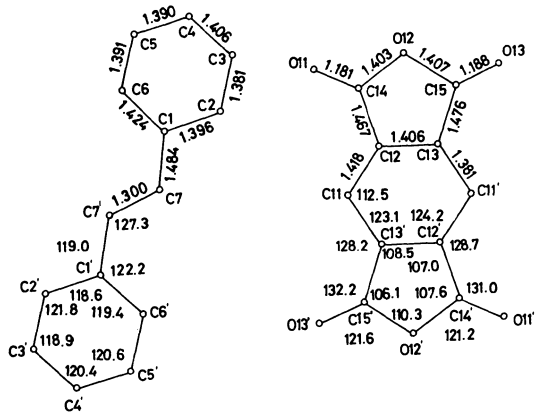

Fig. 1. Bond lengths and angles.

TABLE 3. BOND LENGTHS AND ANGLES WITH THEIR STANDARD DEVIATIONS

STB				PMDA			
C(1)–C(2)	1.396(0.012)Å	C(2)–C(1)–C(6)	118.7(0.7)°	C(11)–C(12)	1.418(0.010)Å	C(13)–C(11)–C(12)	112.6(0.4)°

C(3)–C(4)	1.406(0.013)	C(1)–C(2)–C(3)	121.9(0.6)	C(12)–C(14)	1.467(0.011)	C(13)–C(12)–C(14)	107.1(0.6)
C(4)–C(5)	1.390(0.013)	C(2)–C(3)–C(4)	119.0(0.6)	C(13)–C(15)	1.476(0.011)	C(12)–C(13)–C(11′)	123.1(0.6)
C(5)–C(6)	1.391(0.013)	C(3)–C(4)–C(5)	120.4(0.7)	C(14)–O(11)	1.181(0.009)	C(12)–C(13)–C(15)	108.6(0.5)
C(1)–C(7)	1.484(0.012)	C(4)–C(5)–C(6)	120.6(0.6)	C(14)–O(12)	1.403(0.011)	C(11′)–C(13)–C(15)	128.2(0.5)
C(7)–C(7′)	1.300(0.012)	C(1)–C(6)–C(5)	119.5(0.6)	C(15)–O(12)	1.407(0.009)	C(12)–C(14)–O(11)	131.0(0.7)
		C(1)–C(7)–C(7′)	127.4(0.5)	C(15)–O(13)	1.188(0.009)	C(12)–C(14)–O(12)	107.7(0.4)
						O(11)–C(14)–O(12)	121.3(0.7)
						C(13)–C(15)–O(12)	106.2(0.5)
						C(13)–C(15)–O(13)	132.2(0.6)
						O(12)–C(15)–O(13)	121.6(0.7)
						C(14)–O(12)–C(15)	110.4(0.5)

the normal value of 120.0°, as in the complexes with pyrene and perylene. Such strong deviations that cause the benzene ring to destroy the six-fold symmetry were not observed even in the TCNQ and the TCNB CT complexes, but are comparable with those of the *p*-nitroaniline molecule. The bond lengths and angles in the five-membered ring of this molecule are also in accordance with those of the related complexes. The STB molecule is non-planar. The ethylene reference plane and the benzene ring plane are given by the following equations:

$$0.564x - 0.213y + 0.798z = 3.521 \quad (3)$$

and:

$$0.616x - 0.375y + 0.693z = 3.591 \quad (4)$$

respectively. The maximum deviation of the atoms from the (4) plane is 0.018 Å. The planes given by Eqs. (3) and (4) make an angle of 11.5° with each other. Robertson *et al.*[5] found that the crystal of *trans*-stilbene is composed of two kinds of STB molecules, with torsional angles of about 3° and 10° formed between the ethylene and the benzene-ring planes. The torsional angle of 11.5° observed in the STB molecule in the present complex agrees with the latter value. The H(6)···H(7′) distance of 2.1 Å coincides with the usual van der Waals contact (2.2 Å). The C(6)–C(1)–C(7) angle is significantly larger than the C(2)–C(1)–C(7) angle. This might indicate that the repulsion between hydrogen atoms plays an important role in determining the torsional angle of the molecule. The C–C bond lengths in the benzene ring of STB except for C(1)–C(6) agree with the normal value within 2σ.

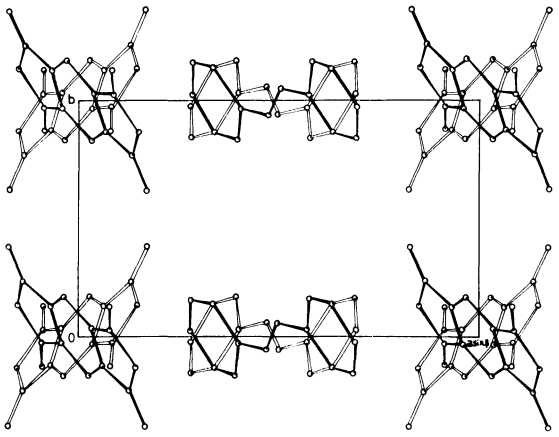

Fig. 2. The structure viewed along the c axis.

The projection of the structure viewed along the c axis is shown in Fig. 2. The crystal is composed of infinite columns in which the component molecules are alternately stacked, plane to plane, along the a axis. Each molecule is surrounded by six others in a quasi-hexagonally close-packed array. The shortest C···C, C···O, and O···O approaches between stacks are 3.64, 3.05, and 3.05 Å respectively, indicating that there are only van der Waals contacts between the stacks. In the column, one of the benzene rings of the STB molecule overlaps with the PMDA molecule related to the first by a unit translation along the *a* axis. The intermolecular contacts in the column are shown in Fig. 3. The mean plane of the PMDA molecule is given by the equation:

$$0.633x - 0.438y + 0.639z = 0.000, \quad (5)$$

and is inclined to the stack axis at an angle of 39.3°. The dihedral angle between the phenyl plane of STB and the molecular plane of PMDA is 4.8°. The average interplanar distance of 3.59 Å agrees with that observed in the crystal of the TCNB–hexamethylbenzene complex (3.54 Å)[6] and is longer than that in the crystal of graphite (3.35 Å). The shortest intermolecular contact of 3.49 Å in the stack occurs between C(4) and C(11′).

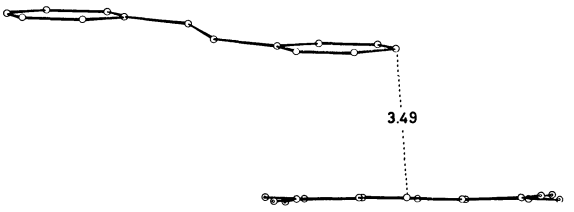

Fig. 3. Intermolecular contacts between PMDA and STB.

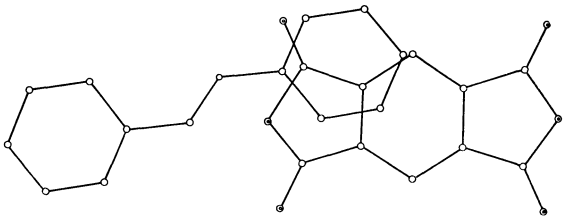

Fig. 4. The projection of STB on the molecular plane of PMDA.

A projection of the STB molecule on the molecular plane of PMDA is shown in Fig. 4. The center of the C(12′)–C(13′) bond in PMDA is superimposed on one of the C–C bonds in the phenyl group of STB adjacent to it in the stack. This relative arrangement is an interesting contrast to that observed in the crystal of the anthracene, pyrene, or perylene complexes with PMDA, in which the center of the C(12′)–C(13′) bond in PMDA is approximately superimposed on the center of the phenyl ring in the aromatic donor. The arrangements of the component molecules in these complexes seem to favor the π-π interaction between the molecules in support of the theoretical study with regard to the related complexes involving maleic anhydride as an accepter.[7] The relative arrangement observed in the present complex seems to be unfavorable for the CT interaction between the STB and the PMDA molecules. Accordingly, it may be concluded that the relative arrangment of the STB and the PMDA molecules in the crystal is mainly determined by the van der Waals interaction rather than by the CT interaction.

The authors are grateful to Professor T. Matsuo for kindly suppling the specimens. They wish also to express their sincere thanks to Professor Y. Saito, the University of Tokyo, and Professor F. Marumo, Tokyo Institute of Technology, for their helpful discussions.

The calculations were carried out on a FACOM 202 computer at the Institute for Solid State Physics and on a HITAC 5020 computer at the Computer Center of the University of Tokyo.

The Electronic Structures of Cu(II) Complexes as Determined by Means of the Configurational Interaction Method

Shunsuke KOBINATA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received September 14, 1973)

The electronic structures of Cu(II) complexes with D_{4h} effective molecular symmetry have been investigated by means of the configurational interaction method. The locally-excited configurations of the central metal ion and the charge-transfer configurations corresponding to an electron transfer from the ligand system to the central metal ion have been taken into account. A correspondence with the crystal-field treatment has been obtained using the partitioning technique of solving the secular equation. The energies of the charge-transfer configurations, the resonance integrals, and the electrostatic contribution, D_S^{ion}, were determined so as to fit the observed d-d spectra.

There have been a number of theoretical and experimental investigations of the electronic states of transition-metal complexes. The crystal-field (CF) theory has generally been successful in the spectral assignment of the low-lying d-d spectra.[1] This method is based on an electrostatic model. On the other hand, there is much experimental evidence showing the presence of covalency between the central metal ion and the ligands.[1,2] The effect of covalency on the d-d spectra has been discussed with success in terms of a semi-empirical molecular orbital treatment based on the angular overlap model.[3,4] However, few investigations by means of the configurational interaction (CI) method have been carried out.[5] The CI method is expected to give some valuable and complemental information in this respect.

In this study the electronic structures of Cu(II) complexes with D_{4h} local symmetry were treated by means of the CI method. The physical content of the CF parameters and the nature of the bonding in these Cu(II) complexes were investigated.

Method

In the treatment of the CI method, a Cu(II) complex, CuX_4Y_2, is considered to be a composite of two component groups: a copper ion and a ligand system composed of the equatorially-coordinated ligand, X_4, and the axial ligands, Y_2. The total electronic state is described as a super-position of the various configurational wave functions:[6] the ionic configurations and the charge-transfer (CT) configurations. The ionic configurations are defined as those configurations in which the copper ion has nine valence electrons, *i.e.*, Cu^{2+}. Of the various ionic configurations, we take into account only the locally-excited configurations of the Cu^{2+} ion, which arise from the rearrangement of d-electrons, because we are primarily interested in the d-d transitions.

The wave function of an ionic configuration, which belongs to an irreducible representation, Γ, of the symmetry group D_{4h}, is given as:

$$\Phi^{ion}(\Gamma) = A\Phi_L^{ion}\Phi_M^{ion}(\Gamma) \quad (1)$$

where Φ_L^{ion} and $\Phi_M^{ion}(\Gamma)$ are the determinantal wave functions of the ligand system and the Cu(II) ion. The Φ_L^{ion} is given as:

$$\Phi_L^{ion} = |(x_1\bar{x}_1\cdots x_6\bar{x}_6)(y_1\bar{y}_1\cdots y_6\bar{y}_6)(z_1\bar{z}_1\cdots z_6\bar{z}_6)| \quad (2)$$

where x_i, y_i, and z_i are the np_x, np_y, and np_z a.o.'s of the i-th coordinated atom. The numbering of atoms and the coordinated system are shown in Fig. 1. The ns a.o. of the coordinated atom was omitted for the sake of simplicity.[7] A is the antisymmetrizer for the exchange of electrons between the ligand system and the Cu(II) ion. The energies of the ionic configurations are given, measured from the center of gravity of the $^2D(d^9)$ state of the Cu(II) ion,[8] by:

$$\begin{aligned}
&\Phi^{ion}(B_{1g}):\ E^{ion}(B_{1g}) = -2D_s^{ion} - 6D_q^{ion} + D_t^{ion}\\
&\Phi^{ion}(A_{1g}):\ E^{ion}(A_{1g}) = 2D_s^{ion} - 6D_q^{ion} + 6D_t^{ion}\\
&\Phi^{ion}(B_{2g}):\ E^{ion}(B_{2g}) = -2D_s^{ion} + 4D_q^{ion} + D_t^{ion}\\
&\Phi^{ion}(E_g):\ E^{ion}(E_g) = D_s^{ion} + 4D_q^{ion} - 4D_t^{ion}
\end{aligned} \quad (3)$$

In the CF treatment, the CF parameters, D_S^{ion}, D_q^{ion}, and D_t^{ion}, are usually determined so as to fit the observed d-d spectra, independent of their physical content. Here, they are considered to be the quantities which arise only from the effect of the ionic configurations. They are given, in the point-charge model, as:[8]

$$\begin{aligned}
D_s^{ion} &= (2/7)\langle r^2\rangle(q_e/R_e^3 - q_a/R_a^3)\\
D_q^{ion} &= (1/6)\langle r^4\rangle q_e/R_e^5\\
D_t^{ion} &= (2/21)\langle r^4\rangle(q_e/R_e^5 - q_a/R_a^5)
\end{aligned} \quad (4)$$

where q_e and q_a are the charges on the equatorially and axially coordinated atoms. R_e and R_a is the

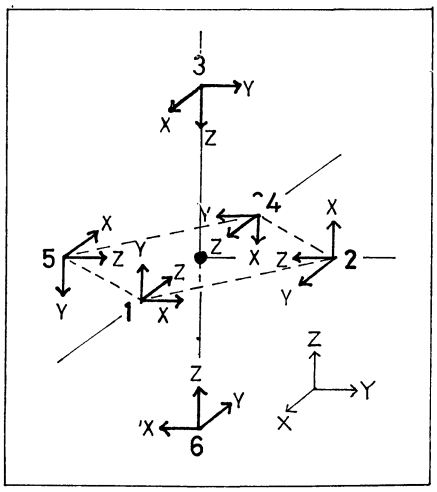

Fig. 1. Numbering and coordinate of Cu(II) complexes

distance of these atoms from the Cu(II) ion.

As to the CT configurations, we considered first those configurations which are formed by an electron transfer from the ligand system to the 3d a.o. of the Cu(II) ion (3d-CT). In these 3d-CT configurations, the copper ion has a completely filled 3d-shell. The wave function and the energy of a 3d-CT configuration, which belong to the irreducible representation of the D_{4h} symmetry group, is represented as:

$$\Phi^{CT}_{a.\delta}(\Gamma) = A\Phi^{CT}_{L.a\delta}(\Gamma)\Phi^{CT}_{M};\ E^{CT}_{a\delta}(\Gamma) \tag{5}$$

Φ^{CT}_{M} is the determinantal wave function of the copper ion of the $3d^{10}$ configuration. $\Phi^{CT}_{L.a\delta}(\Gamma)$ is the symmetry-adapted wave function of the ligand system in the 3d-CT configuration. The α and δ denote the α type of ligand and the δ type of a.o. from which an electron is transferred to the central metal ion. (α= e,a for the equatorially and axially coordinated ligand. $\delta=\sigma,\pi$ for np_z, and for np_x, np_y a.o.'s respectively) The relevant $\Phi^{CT}_{L.a\delta}(\Gamma)$'s are represented as follows:

$$\begin{aligned}
\Phi^{CT}_{L.e\sigma}(B_{1g}) &= (1/2)(z_1-z_2+z_4-z_5)\\
\Phi^{CT}_{L.a\sigma}(A_{1g}) &= (1/\sqrt{2})(z_3+z_6)\\
\Phi^{CT}_{L.e\sigma}(A_{1g}) &= (1/2)(z_1+z_2+z_4+z_5)\\
\Phi^{CT}_{L.a\pi}(E_g) &= (1/\sqrt{2})(y_3+x_6)\\
\Phi^{CT}_{L.e\pi}(E_g) &= (1/\sqrt{2})(x_2+y_5)
\end{aligned} \tag{6}$$

where z_i indicates the determinantal wave function, in which the z_i a.o. is deleted from the expression of the Φ^{ion}_{L} of Eq. (2).

The off-diagonal matrix elements between the $\Phi^{ion}_{M}(\Gamma)$ and $\Phi^{CT}_{a\delta}(\Gamma)$ are calculated by the method of Longuett-Higgins and Murrell.[6] They are expressed in terms of the diatomic resonance integrals, $\beta_{a\delta}$, between the ligand a.o. located at α position and the δ-type d-a.o. of the copper ion. They are tabulated in Table 1.

TABLE 1. OFF-DIAGONAL MATRIX ELEMENTS BETWEEN Φ^{ion} AND Φ^{CT}

$\Phi^{ion}(\Gamma)$	$\Phi^{CT}_{a\delta}(\Gamma)$	$\langle\Phi^{ion}(\Gamma)\|\mathcal{H}\|\Phi^{CT}_{a\delta}(\Gamma)\rangle$
$\Phi^{ion}(A_{1g})$	$\Phi^{CT}_{a\sigma}(A_{1g})$	$\sqrt{2}\beta_{a\sigma}$
	$\Phi^{CT}_{e\sigma}(A_{1g})$	$-\beta_{e\sigma}$
$\Phi^{ion}(B_{1g})$	$\Phi^{CT}_{e\sigma}(B_{1g})$	$\sqrt{3}\beta_{e\sigma}$
$\Phi^{ion}(B_{2g})$	$\Phi^{CT}_{e\pi}(B_{2g})$	$2\beta^{in}_{e\pi}$
$\Phi^{ion}(E_g)$	$\Phi^{CT}_{a\pi}(E_g)$	$\sqrt{2}\beta_{a\pi}$
	$\Phi^{CT}_{e\pi}(E_g)$	$\sqrt{2}\beta^{out}_{e\pi}$

The CT configurations formed by an electron transfer to 4s or 4p a.o. of the Cu(II) ion (4s-CT or 4p-CT) have the resonance interaction with all the ionic configurations of Eq. (3). It can easily be shown that these resonance interactions result in a uniform energy stabilization of the low-lying ionic configurations. Hence, these 4s-CT and 4p-CT configurations do not affect the d-a.o. splittings in a higher approximation.[5a] Therefore, we did not take the 4s-CT and 4p-CT configurations into account explicitly, for we were mainly interested in the splittings of the 3d-levels. In order to see the relationship between the CI treatment described above and the CF treatment, it is necessary first to transform the basis of the CI method (ionic and CT configurations) to the ionic configurations which appear in the CF treatment. By means of the partitioning technique,[9] the secular equation in the CI treatment is transformed to:

$$\left\{\langle\Phi^{ion}|\mathcal{H}|\Phi^{ion}\rangle - \sum_{a\delta}\frac{\langle\Phi^{ion}|\mathcal{H}|\Phi^{CT}_{a\delta}\rangle\langle\Phi^{CT}_{a\delta}|\mathcal{H}|\Phi^{ion}\rangle}{\langle\Phi^{CT}_{a\delta}|\mathcal{H}|\Phi^{CT}_{a\delta}\rangle - E(\Gamma)}\right\}c^{ion} = E(\Gamma)c^{ion} \tag{7}$$

where c^{ion} is the mixing coefficient for $\Phi^{ion}(\Gamma)$. The secular equation obtained above is different from the ordinary one in the presence of the eigenvalue, E, in the denominator. It is usually solved by an iterational procedure. When the low-lying eigenvalues, $E(\Gamma)$'s, are located in a much smaller range of energy compared with $\langle\Phi^{CT}_{a\delta}|\mathcal{H}|\Phi^{CT}_{a\delta}\rangle$, *i.e.*, when the breadth of the d-d transition energies are much smaller than the energy of the CT configurations, it can be shown that the replacement of E in the denominator of Eq. (7) by an appropriate constant, $\bar{E}$, reproduces the low-lying eigenvalues of Eq. (7) with a good accuracy. The $\bar{E}$ constant has the meaning of an averaged stabilization energy and is approximately equal to the ground-state stabilization energy. The approximation is better for larger $\bar{E}$ values, *i.e.*, for a larger covalency, if the other circumstances are same. As will be shown in the next section, the quite large value of $E^{CT}_{a\delta}-\bar{E}$ estimated by the CI treatment confirms that these conditions are fullfilled. Furthermore, the success of the CF treatment itself implies that this replacement is a good approximation.

With this replacement, the expressions of the eigenvalues are obtained as;

$$\begin{aligned}
E(B_{1g}) &= -3\gamma_{e\sigma} - 2D^{ion}_{s} - 6D^{ion}_{q} + D^{ion}_{t}\\
E(A_{1g}) &= -\gamma_{e\sigma} - 2\gamma_{a\sigma} + 2D^{ion}_{s} - 6D^{ion}_{q} + 6D^{ion}_{t}\\
E(B_{2g}) &= -4\gamma^{in}_{e\pi} - 2D^{ion}_{s} + 4D^{ion}_{q} + D^{ion}_{t}\\
E(E_g) &= -2\gamma^{out}_{e\pi} - 2\gamma_{a\pi} + D^{ion}_{s} + 4D^{ion}_{q} - 4D^{ion}_{t}
\end{aligned} \tag{8}$$

where:

$$\gamma_{a\delta} = \beta^2_{a\delta}/(E^{CT}_{a\delta}-\bar{E}) \tag{9}$$

The $\gamma^{in}_{e\pi}$ and $\gamma^{out}_{e\pi}$ are related to in-plane and out-of-plane π-bondings respectively.

When we estimate the energy splittings, a constant,

$$(4/5)\gamma_{e\sigma} + (2/5)\gamma_{a\sigma} + (4/5)\gamma^{in}_{e\pi} + (4/5)\gamma^{out}_{e\pi} + (4/5)\gamma_{a\pi} \tag{10}$$

may be added to the energy expressions of Eq. (8) so as to satisfy the center-of-gravity rule.[1b] Then, we obtain exactly the same form of energy expressions as those obtained in the CF treatment (Eq. (3)) by using the following definitions:

$$\begin{aligned}
D_s &= D^{cov}_{s} + D^{ion}_{s} = (2/7)(\gamma_{e\sigma}-\gamma_{a\sigma}) + (2/7)(2\gamma^{in}_{e\pi}-\gamma^{out}_{e\pi}-\gamma_{a\pi}) + D^{ion}_{s}\\
D_q &= D^{cov}_{q} + D^{ion}_{q} = (3/10)\gamma_{e\sigma} - (2/5)\gamma^{in}_{e\pi} + D^{ion}_{q}\\
D_t &= D^{cov}_{t} + D^{ion}_{t} = (6/35)(\gamma_{e\sigma}-\gamma_{a\sigma}) - (8/35)(2\gamma^{in}_{e\pi}-\gamma^{out}_{e\pi}-\gamma_{a\pi}) + D^{ion}_{t}
\end{aligned} \tag{11}$$

The only differences are the replacement of the D^{ion}_{s}, D^{ion}_{q}, and D^{ion}_{t} of the CF treatment by the D_q, D_s, and D_t obtained above. These differences lose all their meanings when the CF quantities are considered as parameters to be determined from the observed d-d spectra. This implies that the CF parameter treatment

gives results approximately equivalent with the CI treatment with respect to the d-d transition energies. Hence, the CF treatment is valid even in the presence of a considerable covalency.

Discussion

In the square-planar Cu(II) complexes with an *N*-coordinated ligand, such as ethylenediamine and ammonia, the effect of the axial ligand and the π-bonding of the equatorial ligand can be neglected, $\gamma_{a\sigma}=\gamma_{a\pi}=\gamma_{e\pi}^{in}=\gamma_{e\pi}^{out}=0$ in Eqs. (8) and (11). Therefore, it is apparent from Eq. (8) that $E(B_{1g})$ is the lowest energy level and $E(E_g)$ is the highest. Thus, we have obtained the same expressions of the d-d transition energies as those of Smith,[7] if $(1/5)\gamma_{e\sigma}$ in the CI treatment is replaced by the covalence parameter, σ^*, of the angular overlap model. We have studied the electronic structures of these complexes in a somewhat different manner from that of Smith.

In the case of the square-planar complexes, the $D_t^{ion}/D_q^{ion}=4/7$ and $D_t^{cov}/D_q^{cov}=4/7$ relationship hold, as may be seen from Eqs. (4) and (8) respectively. Hence, the following relationship must hold:

$$D_t/D_q = 4/7 \tag{12}$$

or, equivalently:

$$4\omega_3 = 2\omega_2 + 3\omega_1 \tag{13}$$

where ω_1, ω_2, and ω_3 are the transition frequencies from the B_{1g} ground state to the A_{1g}, B_{2g}, and E_g excited states respectively. Conversely, this relationship may be used as a criterion in the spectral assignment of the square-planar Cu(II) complexes.

In Table 2, the d-d spectra of the $Cu(NH_3)_4X_2$ and $Cu(en)_2X_2$ complexes are listed,[11] along with the D_t/D_q and D_q/D_s ratios. In these complexes the axially-ligated atom lies at a distance about 0.5—0.6 Å longer than the sum of the covalent radii of the Cu(II) ion and the ligated atom, *i.e.*, at the distance of semi-coordination.[11] However, as may be seen from Table 2, the D_t/D_q ratio for these complexes lies very near to the value, 0.57, which is expected for the square-planar complexes. This indicates that the effects of the axial covalency, $\gamma_{a\sigma}$ and $\gamma_{a\pi}$, are considerably smaller than that of the equatorial σ-bonding, $\gamma_{e\sigma}$.

To see the degree of the electrostatic and the covalent contribution to the crystal field parameters, D_s, D_q, and D_t, the D_q/D_s ratio was studied. The D_q^{ion}/D_s^{ion} ratio was estimated to be about 0.1, using in Eq. (4) the value of $\langle r^2\rangle=1.1485a_0^2$ and $\langle r^4\rangle=4.1481a_0^4$ obtained from the 3d radial function of Cu^{2+}, tabulated by Richardson *et al.*[12] The D_q^{cov}/D_s^{cov} ratio is 21/20 from Eq. (11). Hence, the D_q/D_s ratio is expected to be of the order of 0.1 or 1.05, depending on whether the electrostabic or the covalent part is the main factor in determining the values of D_q and D_s. As is shown in Table 2, the experimentally-obtained D_q/D_s ratio lies near 0.73 for *N*-coordinated complexes. This value indicates that D_s^{ion} makes a rather large contribution to D_s, because D_q^{ion} is known to be much smaller than D_q^{cov}.

CI Calculation. To make the situation clear, we investigated the $Cu(en)_2(SCN)_2$ complex as a typical example by means of the CI method. Because this complex has a rather long axial distance (R_e=2.00 Å and R_a=3.27 Å),[11] the effect of axial covalency can be neglected; *i.e.*, $\beta_{a\sigma}=\beta_{a\pi}=0$. The D_q^{ion}/D_s^{ion} and D_t^{ion}/D_q^{ion} ratios were assumed to be equal to 0.1 and 0.57 respectively, following the discussion of the preceding subsection. With these approximation, the number of the unknown CI parameters is reduced to three, $\beta_{e\sigma}$, $E_{e\sigma}^{CT}$, and D_s^{ion}. These three CI parameters were determined so as to reproduce the three observed d-d spectra. The results are shown in Table 3. As is shown in Table 3, the contribution of D_q^{ion} and D_t^{ion} to D_q and D_t is rather small. This seems reasonable because, in octahedral complexes, it is generally recognized that the CF splitting, $10D_q$, is mainly caused by the effect of the covalency.[13]

Table 3. The result of the CI calculation on $Cu(en)_2(NCS)_2$.

	Obsd	Calcd
$\omega_1(A_{1g}\leftarrow B_{1g})$	14.7 kK	14.7 kK
$\omega_2(B_{2g}\leftarrow B_{1g})$	17.2 kK	17.2 kK
$\omega_3(E_g\leftarrow B_{1g})$	20.3 kK	20.3 kK
		$\beta_{e\sigma}=-3.00$ eV
		$E_{e\sigma}^{CT}=11.17$ eV
	$D_s=2.54$ kK	$D_s^{ion}=1.12$ kK
	$D_q=1.72$	$D_q^{ion}=0.11$
	$D_t=0.91$	$D_t^{ion}=0.06$

On the other hand, the contribution of $D_s^{ion}=1.12$ kK to $D_s=2.54$ kK is large and comparable with that of $D_s^{cov}=1.42$ kK, as was expected in the preceding subsection. Smith has obtained the value of $D_s^{ion}=0.72$ for $Cu(NH_3)_4(SCN)_2$ by estimating the effective charges q_e, of Eq. (4).[7] Our method of estimation seems to be superior to that of Smith in that it does not make use of q_e.

As to the energy of the charge-transfer configuration, the value of $E_{e\sigma}^{CT}=11.17$ eV was obtained. This suggests,

TABLE 4. THE d-d TRANSITION FREQUENCIES AND THE RATIOS D_t/D_q AND D_q/D_s OF SOME *O*-COORDINATED COMPLEXES

		R_a	ω_1	ω_2	ω_3	D_t/D_q	D_q/D_s
1	$Na_2Cu(SO_4)_2 2H_2O$	O-2.41	10.3	10.3	12.7	0.59	0.57
2	$Pb_2Cu(OH)_4Cl_2$	Cl-2.75	10.9	10.9	14.6	0.47	0.52
3	$Cu(UO_2)_2(AsO_4)_2 8H_2O$	O-2.55	13.0	12.0	15.0	0.64	0.52
4	$Cu(SO_4)5H_2O$	O-2.40	10.5	10.5	13.0	0.58	0.56
5	$BaCuSi_4O_{10}$	Cu-7.56	18.8	12.9	15.8	1.00	0.41

that the CT state is the state of the strong mixing of CT and the appropriate locally-excited configurations, because the CT band can be expected at about 6—7 eV.[13]

As to the diatomic resonance integral, $\beta_{e\sigma}$, the value of −3.00 eV was obtained. In the Wolfsberg-Helmholz approximation,[18] $\beta_{e\sigma}$ is estimated to be:

$$\beta_{e\sigma} = -(1/2)F_\sigma S_{e\sigma}(I(Cu^{2+})+I(N)) \qquad (14)$$

where $S_{e\sigma}$ is the diatomic overlap integral between $3d_{x^2-y^2}$ a.o. and $2p_z$ a.o. of the ligand atom. $I(Cu^{2+})$ and $I(N)$ are the valence-state ionization potentials of the Cu^{2+} ion and nitrogen respectively. The F_σ constant is usually assumed to be 1.67.[18] Then, Eq. (14) gives $\beta_{e\sigma}=-3.54$ eV, using $S_{e\sigma}=0.0826$,[7] $I(Cu^{2+})=36.8$ eV, and $I(N)=14.5$ eV.

Using the values tabulated in Table 3 in Eq. (9), we obtain $\bar{E}=-3.44$ eV. Hence, $E_{e\sigma}^{CT}-\bar{E}$ amounts to 14.61 eV. This large value of $E_{e\sigma}^{CT}-\bar{E}$ compared with that of the d-d transition energies guarantees the validity of the replacement, $\bar{E}$, in the energy denominator to a constant, $\bar{E}$, obtained in the preceding section (Eq. (9)).

π-Bonding. In the case of Cu(II) complexes with the ligand which has a potency of the π-bonding, the treatment is complicated by the fact that we can no longer neglect $\gamma_{e\pi}^{in}$ and $\gamma_{e\pi}^{out}$ of Eqs. (8) and (11).

When the $\gamma_{e\pi}^{in}=\gamma_{e\pi}^{out}=\gamma_{e\pi}$ and $\gamma_{a\sigma}=\gamma_{a\pi}=0$ relations hold, as in $Pt(NH_3)_4CuCl_4$, Eq. (8) give same energy expressions as those of Smith by equating the covalency factors, σ* and π*, of the angular overlap model with $(1/5)\gamma_{e\sigma}$ and $(1/5)\gamma_{e\pi}$ respectively.[14] It is shown Eqs. (12) and (13) should also hold in this case. For $Pt(NH_3)_4CuCl_4$, we obtain $D_t/D_q=0.67$ and $D_q/D_s=0.43$ or $D_t/D_q=0.60$ and $D_q/D_s=0.75$, according to whether we use the assignment of Smith ($\omega_2<\omega_1<\omega_3$) or that of Hatfield and Piper ($\omega_1<\omega_2<\omega_3$)[15] respectively. The D_t/D_q ratio lies in the range of errors of Eq. (12) for both assignments. We can estimate $\gamma_{e\sigma}=(1/4)\gamma_{e\pi}$,[14] because the Wolfsberg-Helmholz relation holds approximately, as has been seen in the preceding subsection. Therefore, the D_q/D_s ratio can be expected from Eq. (11) to lie in the 0.1—0.6 range. It seems that the assignment of Smith is more reliable.

In Table 4, the d-d transition frequencies and the D_t/D_q and D_q/D_s ratios of the *O*-coordinated complexes with known crystal structures are listed. These complexes have distance longer by over 0.4 Å for the axial ligand than for the equatorial ligands.[11,16] As may be seen from Table 4, the $D_t/D_s=0.55\pm0.08$ ratios for these complexes coincide approximately with the value, 0.57, which is expected for the square-planar case, except in the case of $BaCuSi_4O_{10}$. The D_q/D_s ratio is 0.59 ± 0.08, somewhat smaller than the value for *N*-coordinated complexes, $D_q/D_s=0.73\pm0.06$. This indicates the presence of π-bonding, according to Eq. (11).

For the silicate $BaCuSi_4O_{10}$, the $D_t/D_q=1.0$ ratio was obtained following to the assignment of Clark and Burns[17] (Table 4). This high value seems unreasonable, because this complex has a complete square-planar structure ($R_e=1.91$ Å, $R_a=7.56$ Å), and because the *g*-tensor of this complex does not exhibit any abnormality compared with other complexes.[11,16] Hence, The $D_t/D_q=0.57$ ratio of square-planar complex can be expected to be fulfilled. The assignment of Clark and Burns does not seem to be very conclusive, however, because it has been made without a complete analysis of the polarized single-crystal spectrum. Another possible set of assignments which fulfills the relation of Eq. (12) is $\omega_1=15.8$ kK (or 12.9 kK), $\omega_2=12.9$ kK (or 15.8 kK), and $\omega_3=18.8$ kK. This assignment results in $D_t/D_q=0.53$ (or 0.48) and $D_q/D_s=0.42$ (or 0.70).

Mechanisms of Hydrogenation and Hydrogen Exchange of Propylene over the Electron Donor-Acceptor Complexes of Polynaphthoquinones with Potassium

Yasuhiro IWASAWA, Sadao OGASAWARA, Takaharu ONISHI,* and Kenzi TAMARU*

Department of Applied Chemistry, Yokohama National University, Ooka-cho, Minami-ku, Yokohama 233

**Department of Chemistry, the University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received September 25, 1973)

The mechanisms of the deuterium addition to propylene and the propylene-deuterium exchange reaction over the electron donor-acceptor (EDA) complex of polynaphthoquinone with potassium were investigated by means of mass and microwave spectrometry and gas chromatography in the range from room temperature to 200 °C. The hydrogenation as well as the exchange reaction proceeded *via* the half-hydrogenated state of propylene formed from the adsorbed propylene and the dissociatively-adsorbed deuterium atom on the EDA complex. However, the rate of the exchange reaction decreased upon the Fe addition to the complex, while the hydrogenation was markedly accelerated. The intermediate of the propylene-deuterium exchange reaction was determined to be the half-hydrogenated isopropyl species, whereas the deuterium addition to propylene was suggested to occur *via* another half-hydrogenated state, the *n*-propyl species.

The electron donor-acceptor (EDA) complex of the polynaphthoquinone with potassium exhibits high activities for various catalytic reactions, such as the H_2–D_2 exchange reaction, the isomerization of butene, and the synthesis of ammonia from a mixture of nitrogen and hydrogen, as was reported in a previous paper.[1] The EDA complex also readily catalyzes the hydrogen exchange of propylene with deuterium. It was concluded[1,2] by means of the microwave technique[3] that the half-hydrogenated state of propylene, the isopropyl species, is the reaction intermediate in the propylene-deuterium exchange reaction. The rate of the hydrogenation of propylene with hydrogen was expressed by the following equation: $v=k(\text{propylene})(H_2)^{1/2}$, indicating that the half-hydrogenated state may also be the reaction intermediate in the hydrogenation reaction.

However, it does not follow that the hydrogenation or deuterogenation of propylene also proceeds through the half-hydrogenated state of isopropyl species. In other words, the reaction intermediates of the hydrogenation and the exhange reaction are not necessarily the same half-hydrogenated state, even if both reactions will follow the same rate equation.

In the present experiment, the mechanisms of the deuterium addition to propylene and the exchange reaction of propylene with deuterium over the EDA complex of potassium with the polynaphthoquinone were investigated in detail, and the intermediates of the deuterium addition to propylene were examined by means of mass and microwave spectrometries and gas chromatography.

Experimental

The polynaphthoquinone employed was obtained by oxidizing 1,7-naphthalenediol with nitric acid in air, followed by treating at 350 °C for 12 hr, as was reported in a previous paper.[4] The polynaphthoquinone containing $FeCl_3$ was prepared by mixing metal-free polynaphthoquinone and $FeCl_3$ (15 wt% against polynaphthoquinone) in ethyl alcohol and then evaporating the solvent. The polynaphthoquinones thus obtained were treated at 350 °C for 6 hr *in vacuo* before use. The EDA catalysts were prepared by adding potassium vapour to the polynaphthoquinones in the absence of air. The composition of the EDA complex was found to be one potassium monomer to three naphthoquinone monomers.

The reactions were carried out over the EDA complex including 0.1 g of the polynaphthoquinone in a closed circulating system (175 cm^3). The rate of the propane formation by the hydrogenation of propylene was determined by gas chromatography, while the deuterated propylene formed by the exchange reaction of propylene with deuterium was quantatively analyzed by mass and microwave spectroscopy. The mass spectroscopy was also used for analyzing the deuterated propane.

Results and Discussion

The Mechanism of the Propylene-deuterium Exchange Reaction. The exchange reaction of propylene with deuterium over the EDA complex of potassium with the polynaphthoquinone was studied by means of the microwave technique in the range from room temperature to 200 °C. The rate of the formation of deuteriopropylene was determined by mass spectrometry. The formation of deuteriopropylene is plotted against the reaction time in Fig. 1; the figure shows that hydrogen in propylene successively exchanges with deuterium over the EDA catalyst.

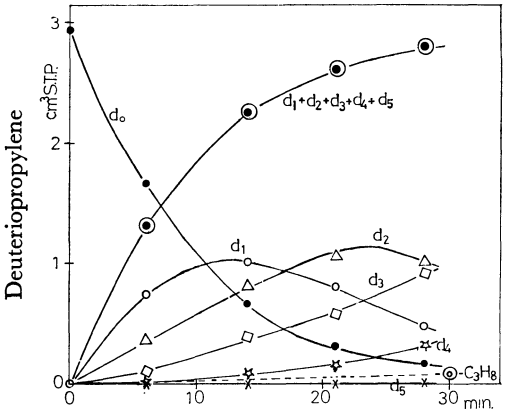

Fig. 1. Amounts of deuteriopropylenes, produced by the hydrogen exchange of propylene (1.4 cmHg) with deuterium (3.4 cmHg), against reaction time at 95 °C.

According to microwave spectrometry, three kinds of monodeuteriopropylenes, CHD=CH–CH_3(*cis*-1-d_1 and *trans*-1-d_1) and CH_2=CH–CH_2D(propylene-3-d_1), were produced in an approximate ratio of 1 : 1 : 3, and the propylene-d_2 species formed were 1,1-d_2, 3,3-d_2, and 1,3-d_2, in the approximate ratio of 1 : 3 : 6. It is concluded from these results[2] that the half-hydrogenated isopropyl species is the main reaction intermediate of the hydrogen exchange reaction over the EDA complex in the range from room temperature to 200 °C.

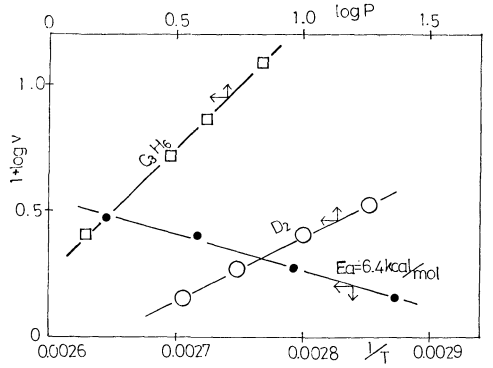

Fig. 2. Dependence of the rate of the exchange reaction upon the pressures of propylene and deuterium at 75 °C and the activation energy of the reaction.

The rate of the propylene-d_1 formation was found to be of the first-order with respect to the partial pressure of propylene and half-order with respect to the deuterium pressure as is shown in Fig. 2, where the activation energy is also given as 6.4 kcal/mol. A very small amount of propylene was reversibly adsorbed on the 1.0 g EDA complex, while the adsorption of deuterium was not appreciable under similar conditions. It was indicated in a previous paper[2] that HD in the H_2–D_2 exchange reaction was produced from hydrogen and deuterium atoms dissociated from each of the gases on the catalyst surface. The half-hydrogenated state of the isopropyl species, as the reaction intermediate, may be formed from the surface reaction of the adsorbed propylene with the deuterium atom dissociatively adsorbed on the EDA catalyst.

Consequently, the scheme of the propylene-deuterium exchange reaction may be expressed as follows;

$$C_3H_6(g) \overset{K_1}{\rightleftharpoons} C_3H_6(ad) \quad (1)$$

$$D_2(g) \overset{K_2}{\rightleftharpoons} 2D(ad) \quad (2)$$

$$C_3H_6(ad) + D(ad) \underset{k_3'}{\overset{k_3}{\rightleftharpoons}} CH_2D\text{–}\overset{*}{C}H\text{–}CH_3 \quad (3)$$

$$CH_2D\text{–}\overset{*}{C}H\text{–}CH_3 \xrightarrow{k_4} \underline{C_3H_5D}(ad) + H(ad) \quad (4)$$

where $CH_2D\text{–}\overset{*}{C}H\text{–}CH_3$ and C_3H_5D represent the half-hydrogenated state of the isopropyl species and monodeuteriopropylene(*cis*-1-d_1, *trans*-1-d_1 or 3-d_1) respectively.

The rate in the initial stage of the hydrogen exchange reaction is given as follows in the steady state according to the ordinary procedures:

provided $(C_3H_6)_{ad}=K_1(C_3H_6)_g$ and $(D)_{ad}=K_2^{1/2}(D_2)_g^{1/2}$, where $(C_3H_6)_{ad}$ and $(D)_{ad}$ were very small in amount,

$$d(CH_2D\text{–}\overset{*}{C}H\text{–}CH_3)/dt = k_3(C_3H_6)_{ad}(D)_{ad} - k_3'(CH_2D\text{–}\overset{*}{C}H\text{–}CH_3) - k_4(CH_2D\text{–}\overset{*}{C}H\text{–}CH_3) = 0,$$

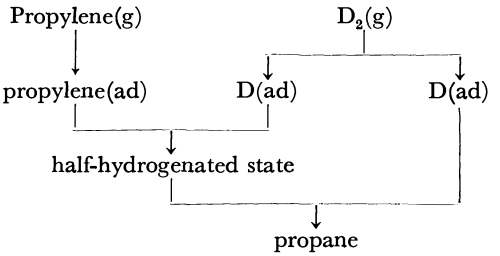
$$\therefore\ (CH_2D\text{–}\overset{*}{C}H\text{–}CH_3) = (k_3/(k_3'+k_4))(C_3H_6)_{ad}(D)_{ad},$$

$$v_{ex} = d(C_3H_5D)/dt = k_4(CH_2D\text{–}\overset{*}{C}H\text{–}CH_3) = (k_3k_4/(k_3'+k_4))(C_3H_6)_{ad}(D)_{ad} = \frac{k_3k_4}{k_3'+k_4}K_1K_2^{1/2}(C_3H_6)_g(D_2)_g^{1/2} = k_{ex}(C_3H_6)_g(D_2)_g^{1/2}.$$

The rate constant for the exchange reaction, k_{ex}, is, consequently, equal to $k_3k_4K_1K_2^{1/2}/(k_3'+k_4)$.

Therefore, the exchange reaction between propylene and deuterium may be interpreted as proceeding between the adsorbed propylene and the dissociatively-adsorbed deuterium *via* the half-hydrogenated state, the isopropyl species, as the reaction intermediate, as is shown in Steps (3) and (4).

The Mechanism and the Reaction Intermediate of the Hydrogenation of Propylene. The hydrogenation of propylene to form propane proceeded over the EDA complex of potassium with the polynaphthoquinone in the temperature range from 70 to 200 °C. As is shown in Fig. 3, the rate of the deuterogenation was found to be proportional to the partial pressure of propylene and to be half-order with respect to the deuterium pressure: $d(propane)/dt=k_d(propylene)_g(D_2)_g^{1/2}$. Accordingly, the overall reaction may be expressed as follows:



The hydrogenation of propylene to propane proceeded with hydrogen more easily by a factor of about 1.4 than with deuterium at 140 °C. The activation energy

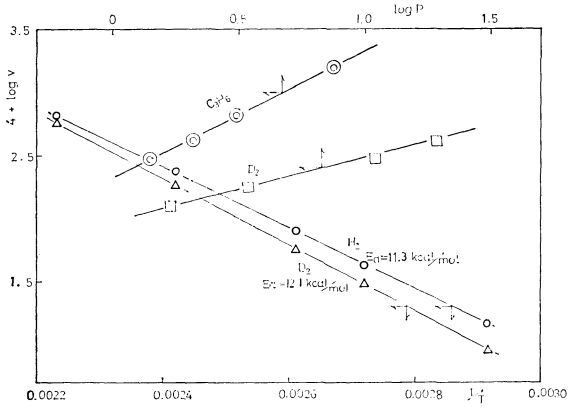


Fig. 3. Dependence of the deuterogenation upon pressures of propylene and deuterium at 140 °C and the activation energies of the reactions.

Table 1. The rates and the activation energies of reactions over the EDA catalysts

EDA catalysts[a)]	Initial rate of the monodeuterio-propylene formation (1-d_1 and 3-d_1) at 95 °C (cm^3/min)	Activation energy (kcal/mol)	Initial rate of the propane formation[c)] at 140 °C (cm^3/min)	Activation energy (kcal/mol)	Initial rate of the propylene-2-d_1 formation[c)] at 140 °C (cm^3/min)
Q–K complex	0.40	6.4	0.027	12.1	0.010
Q–$FeCl_3$–K complex	0.20	6.6	0.123	4.7	0.010

a) Q: polynaphthoquinone. b) propylene=1.4 cmHg, D_2=10 cmHg. c) propylene=1.4 cmHg, D_2=5.6 cmHg.

for the hydrogenation reaction was found to be 11.3 kcal/mol, as is given in Fig. 3.

It was confirmed in Section (1) that the half-hydrogenated state (isopropyl species) is the reaction intermediate in the hydrogen-exchange reaction of propylene with deuterium. When the deuterium addition to propylene also proceeds through the same reaction intermediate, propane will be produced by the following process (5):

$$CH_2D\text{–}\underset{*}{CH}\text{–}CH_3 + D(ad) \xrightarrow{k_5} C_3H_6D_2 \qquad (5)$$

When propane is formed by the deuterium-atom addition to the half-hydrogenated isopropyl species in Eq. (5), the rate equation in the initial stage of the reaction may be expressed as follows:

In the steady state;

$$d(CH_2D\text{–}\underset{*}{CH}\text{–}CH_3)/dt = k_3(C_3H_6)_{ad}(D)_{ad} - (k_3'+k_4)(CH_2D\text{–}\underset{*}{CH}\text{–}CH_3) - k_5(CH_2D\text{–}\underset{*}{CH}\text{–}CH_3)(D)_{ad} = 0,$$

$$(CH_2D\text{–}\underset{*}{CH}\text{–}CH_3) = \frac{k_3(C_3H_6)_{ad}(D)_{ad}}{k_3'+k_4+k_5(D)_{ad}},$$

Accordingly,

$$d(C_3H_6D_2)/dt = k_5(CH_2D\text{–}\underset{*}{CH}\text{–}CH_3)(D)_{ad} = \frac{k_3k_5(C_3H_6)_{ad}(D)_{ad}^2}{k_3'+k_4+k_5(D)_{ad}}.$$

The propylene-deuterium exchange reaction proceeded much more rapidly than the deuterogenation, as is shown in Fig. 1; that is, $k_4 \gg k_5(D)_{ad}$, or $k_3'+k_4 \gg k_5(D)_{ad}$. Accordingly, the rate of the formation of propane, $d(C_3H_6D_2)/dt$, is reduced to $(k_3k_5/(k_3'+k_4))(C_3H_6)_{ad}(D)_{ad}^2$. For $(C_3H_6)_{ad}=K_1(C_3H_6)_g$ and $(D)_{ad}=K_2^{1/2}(D_2)_g^{1/2}$, the rate is given by $(k_3k_5/(k_3'+k_4))K_1K_2(C_3H_6)_g(D_2)_g$ or, accordingly, $k'(C_3H_6)_g(D_2)_g$, where k' is equal to $(k_3k_5/(k_3'+k_4))K_1K_2$. However, the rate equation thus obtained is in disagreement with the experimental results given in Fig. 3, where the initial rate of the propane formation is first-order with respect to propylene and half-order with respect to the deuterium pressure, which excludes the mechanism of the deuterium addition through the half-hydrogenated isopropyl species in Reaction Step (5).

Though the hydrogen-exchange reaction of propylene with deuterium took place through the half-hydrogenated state, the isopropyl species, propylene-2-d_1 (CH_2=CD–CH_2) could also be observed in the temperature range higher than 70 °C. Table 1 shows the results on the EDA complexes of potassium with the polynaphthoquinone both with and without $FeCl_3$, exhibiting that another half-hydrogenated state, the normal propyl species, is present on the surface of the EDA catalyst throughout the reaction.

If the half-hydrogenated state of the normal propyl species is the reaction intermediate in the deuterogenation of propylene, the scheme of the reaction may be expressed as follows:

$$C_3H_6(ad) + D(ad) \underset{k_6'}{\overset{k_6}{\rightleftharpoons}} \underset{*}{CH_2}\text{–}CHD\text{–}CH_3 \qquad (6)$$

$$\underset{*}{CH_2}\text{–}CHD\text{–}CH_3 \xrightarrow{k_7} CH_2\text{=}CD\text{–}CH_3(ad) + H(ad) \qquad (7)$$

$$\underset{*}{CH_2}\text{–}CHD\text{–}CH_3 + D(ad) \xrightarrow{k_8} \underline{C_3H_6D_2} \qquad (8)$$

$$2\underset{*}{CH_2}\text{–}CHD\text{–}CH_3 \xrightarrow{k_9} \underline{C_3H_6D_2} + CH_2\text{=}CH\text{–}CH_3 \quad \underline{C_3H_7D} + CH_2\text{=}CD\text{–}CH_3 \qquad (9)$$

where $\underset{*}{CH_2}$–CHD–CH_3 represents the half-hydrogenated state of the normal propyl species adsorbed on the EDA catalyst. Step (8) shows that propane is produced successively from the half-hydrogenated normal propyl species and the adsorbed deuterium atom, while the propane formation by the disproportionation of the normal propyl species adsorbed on the EDA catalyst is given in Step (9).

When propane is produced successively *via* Reaction Steps (6) and (8) through the half-hydrogenated normal propyl species under the condition of a negligible hydrogen exchange, propane-d_2 ($C_3H_6D_2$) should be the only product in the deuterogenation of propylene (C_3H_6) and the formation of propane-d_1 (C_3H_7D) will not be appreciable. Propylene-d_5 (CD_2=CH–CD_3) was employed to examine clearly the deuterium content in the deuterated propane, where CD_2=CH–CD_3 remained unchanged by the rapid exchange reaction with deuterium through the isopropyl species and where the amount of the CD_2=CD–CD_3 formation through the normal propyl species was small under the present reaction conditions. The main product in the deu-

Table 2. The formation of deuterated propane in the deuterogenation of C_3HD_5 at 140 °C

EDA catalysts	The relative ratio in deuterated propane		
	$C_3H_2D_6$ (propane-d_1)	C_3HD_7 (propane-d_2)	C_3D_8 (propane-d_3)
Q–K complex	2%	81%	17%
Q–$FeCl_3$–K complex	2%	92%	6%

terium addition to CD_2=CH–CD_3(C_3HD_5) was found to be C_3HD_7, as is shown in Table 2; a small amount of C_3D_8 was also produced from the deuterium addition to CD_2=CD–CD_3, CD_2=CD–CD_3 being formed by the propylene-d_5—deuterium exchange reaction *via* the normal propyl species. Reaction Process (9) may, consequently, be excluded.

Accordingly, the initial rate of the formation of propane may be given by the following equation:

In the steady state, the *n*-propyl species on the surface stays constant,

$$\mathrm{d}(\overset{*}{\mathrm{CH_2}}\text{–CHD–}\mathrm{CH_3})/\mathrm{d}t = k_6(\mathrm{C_3H_6})_{\mathrm{ad}}(\mathrm{D})_{\mathrm{ad}} - (k_6'+k_7)(\overset{*}{\mathrm{CH_2}}\text{–CHD–}\mathrm{CH_3}) - k_8(\overset{*}{\mathrm{CH_2}}\text{–CHD–}\mathrm{CH_3})(\mathrm{D})_{\mathrm{ad}} = 0,$$

$$\therefore\ (\overset{*}{\mathrm{CH_2}}\text{–CHD–}\mathrm{CH_3}) = \frac{k_6(\mathrm{C_3H_6})_{\mathrm{ad}}(\mathrm{D})_{\mathrm{ad}}}{k_6'+k_7+k_8(\mathrm{D})_{\mathrm{ad}}},$$

$$v_{\mathrm{d}} = \mathrm{d}(\mathrm{C_3H_6D_2})/\mathrm{d}t = k_8(\overset{*}{\mathrm{CH_2}}\text{–CHD–}\mathrm{CH_3})(\mathrm{D})_{\mathrm{ad}} = \frac{k_6k_8(\mathrm{C_3H_6})_{\mathrm{ad}}(\mathrm{D})_{\mathrm{ad}}^2}{k_6'+k_7+k_8(\mathrm{D})_{\mathrm{ad}}}.$$

The rates of the deuterogenation were found to be larger than those of the propylene-2-d_1 formation by a factor of 2.7 on the Fe-free complex (Q–K complex) and by one of 12.3 over the Fe-containing complex (Q–$FeCl_3$–K complex), as is shown in Table 1. The difference in the values of k'_6 and k_7 corresponds to the isotope effect, and k_6' seems to be smaller than k_7. These observations lead to the $(k_6'+k_7)<k_8(\mathrm{D})_{\mathrm{ad}}$ relation. Accordingly, the rate equation is reduced as follows:

$$v_{\mathrm{d}} = k_6(\mathrm{C_3H_6})_{\mathrm{ad}}(\mathrm{D})_{\mathrm{ad}} = k_6K_1K_2^{1/2}(\mathrm{C_3H_6})_{\mathrm{g}}(\mathrm{D_2})_{\mathrm{g}}^{1/2},$$

$$\text{provided}\ (\mathrm{C_3H_6})_{\mathrm{ad}} = K_1(\mathrm{C_3H_6})_{\mathrm{g}}\ \text{and}\ (\mathrm{D})_{\mathrm{ad}} = K_2^{1/2}(\mathrm{D_2})_{\mathrm{g}}^{1/2}.$$

The rate equation is in agreement with the results, suggesting that the formation of propane occurs *via* the half-hydrogenated normal propyl species in Reaction Steps (6) and (8).

On the Fe-containing complex as well as over the Fe-free complex the half-hydrogenated state of propylene, the isopropyl species, was found to be the reaction intermediate of the propylene-deuterium exchange. As is given in Table 1, the activation energy of the exchange reaction was much less affected by the Fe addition to the complex. However, the activation energy of the deuterogenation markedly decreased upon the Fe addition. The value, 4.7 kcal/mol, for the deuterogenation of propylene was also smaller than that for the propylene-deuterium exchange reaction. The rate of the deuterium addition to propylene, $v_{\mathrm{d}}'=k_{\mathrm{d}}'(\mathrm{propylene})_{\mathrm{g}}(\mathrm{D_2})_{\mathrm{g}}^{1/2}$, was markedly accelerated by the Fe addition to the complex. Consequently, the difference in the effect of the Fe addition on the propylene-deuterium exchange and the deuterium addition to propylene was observed, also suggesting that the hydrogenation and the hydrogen exchange of propylene over the EDA complexes of the polynaphthoquinones proceed through different half-hydrogenated states of propylene.

Consequently, the hydrogen-exchange reaction of propylene with deuterium proceeded through the half-hydrogenated state of isopropyl species, while the half-hydrogenated state of normal propyl species was indicated to be the reaction intermediate in the hydrogenation of propylene. It is of interest to note that the half-hydrogenated state is the reaction intermediate in both the propylene-deuterium exchange and the deuterogenation of propylene over the EDA complexes of potassium with the polynaphthoquinones, but that the former reaction proceeds through the half-hydrogenated state, the isopropyl species, and the latter, through another half-hydrogenated state, the normal propyl species.

The authors wish to thank Mr. T. Kondo for his advice on and discussion of the microwave and mass spectroscopies, and Dr. K. Fukuda for his advice on the mass spectroscopy.

Polarographic Studies of Dispersed Dyes Solubilized in Surfactant Solutions. I. Kinetics of Orange OT Solubilized in Surfactant Solutions

Hajime SUZUKI, Noriko SHINOZUKA, and Shigeo HAYANO
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received October 13, 1973)

Orange OT (1-*o*-tolyl-azo-2-naphthol) dissolved in an aqueous ethanol solution and solubilized in various surfactant solutions, containing a citric acid-disodium hydrogen phosphate buffer, showed well-defined irreversible polarographic waves. The anionic, cationic, and nonionic surfactants used were sodium dodecyl sulfate (SDS) and sodium dodecylbenzenesulfonate (SDBS), dodecyltrimethylammonium chloride (DTMAC), and polyoxyethylene nonylphenyl ether (NP-$\overline{10}$) respectively. The values multiplying the transfer coefficient by the number of electrons involved in the activation step, (αn_a), were calculated from the semilogarithmic plot of the wave. The plots of αn_a against the half-wave potential of Orange OT for each solution showed that a marked surfactant electric-charge dependence of αn_a was observed with a variety of surfactant solutions; *i.e.*, the electric-charges of the surfactant molecules or micelles remarkably affected the electrode kinetics of the solubilized Orange OT. No matter what Orange OT is an uncharged species, Orange OT solubilized in the anionic surfactant solutions seemed to behave in the electrode process as if it were an anionic species, and when solubilized in the cationic and nonionic surfactant solutions it seemed to behave as a cationic species.

The electrochemistry of dispersed dyes solubilized in several surfactant solutions has been described in previous papers,[1-3] mainly with regard to the mass-transfer of the micelle. Many electrochemical studies[4-6] of surfactant solutions have been published, but in most of them the surfactant concentration has usually been below the critical micelle concentration (CMC); few papers have reported concentrations above the CMC.[1-3,7] The surfactant solution may be regarded as a new solvent taking the place of aqueous and nonaqueous solvents in the sense that it has characteristics of both in electrochemistry. The solubilized system in actuality is heterogeneous, in spite of its homogeneous appearance. An electrode process of a surfactant solution, however, involves many problems: 1) the adsorption state and equilibrium of surfactant molecules or micelles on an electrode; 2) the diffusion of an electroactive substance through bulk and adsorption phases at the electrode;[8,9] 3) an electroactive species adsorbing or not adsorbing in the adsorption phase; 4) the charge in the electric double layer affecting the electrode processes; 5) the electric-charge of a surfactant affecting the double layer, *etc.* The present paper will deal with experimental results on a few of the above problems and will discuss various possible interpretations.

The reason for using Orange OT is that this dye is water-insoluble[10] and electroactive.

Determination of αn_a, *m, and* $k^0_{f,h}$. Generally, the reaction occurring at the electrode for a totally irreversible wave may be described by the equation:

$$O + ne \longrightarrow R \qquad (1)$$

where O and R are the oxidized and reduced forms of a substance respectively. The cathodic current, i, that results from the reduction of O at any potential is described by the equation:

$$i = nFAC_o{}^0k^0_{f,h} \exp[-\alpha nF(E-E^0)/RT] \qquad (2)$$

where n is the number of electrons involved in the overall reaction; F, the Faraday constant; A, the area of the electrode; $C_O{}^0$, the concentration of O at the surface of the electrode; $k^0_{f,h}$, the heterogeneous rate constant at 0 V *vs.* N.H.E.; α, the transfer coefficient; E, the electrode potential reffered to the S.C.E.; E^0, the formal potential; R, the gas constant; and T, the absolute temperature. For couples whose formal potentials are unknown or even unmeasurable (as is the case with many totally irreversible couples), however, a convenient and interpretable potential instead of the formal potential is 0 V *vs.* N.H.E. (−0.246 V *vs.* S.C.E. at 25 °C).

Taking into account the variation in the $C_O{}^0$ with the current, Koutecký *et al.*[11] calculated the values of the $F(\chi)$ for the mean current:[12]

$$\bar{i}_{irrev} = \bar{i}_{rev}\bar{F}(\chi) \qquad (3)$$

where

$$\chi = (12/7)^{1/2}k_{f,h}t^{1/2}/D_o{}^{1/2}, \qquad (4)$$

where $k_{f,h}$ varies with the electrode potential given by:

$$k_{f,h} = k^0_{f,h} \exp[-\alpha n_a F(E+0.246)/RT] \qquad (5)$$

and where i is the mean current; t, the drop time; D_O, the diffusion coefficient of the oxidized form, and n_a, the number of electrons involved in the activation step. For a totally irreversible process, $\bar{i}_{rev}$ may be said to be equal to the mean diffusion current.

The mean current was measured instead of the instantaneous maximum current because the concentration of the solubilizable dye was very low.

Many organic compounds can generally be reduced as;[12-14]

$$O + mH^+ \rightleftharpoons O' \quad \text{(fast)} \qquad (6a)$$

$$O' + n_ae \longrightarrow I \quad \text{(rate-determining)} \qquad (6b)$$

$$I + (n-n_a)e \longrightarrow R \quad \text{(fast)} \qquad (6c)$$

where m is the number of hydrogen ions, and I, the intermediate. To describe the cathodic mean current, $\bar{i}$, resulting from the above reaction, one writes this equation:

$$\bar{i} = nF\bar{A}C^0_o k^0_{f,h} \exp[-\alpha n_a F(E+0.246)/RT] \qquad (7)$$

where A is the mean surface area of the dropping mercury electrode. If the solution is well buffered,

the combination of Eq. (7) with

$$K = C_{o'}^{0}/C_{o}^{0}C_{H^+}^{m} \quad (8)$$

for the equilibrium constant, K, of Eq. (6a) yields:

$$\bar{i} = nF\bar{A}C_{o}^{0}k_{f,h}^{0}KC_{H^+}^{m} \exp\left[-\alpha n_a F(E+0.246)/RT\right] \quad (9)$$

where C_{H^+} is the concentration of hydrogen ions at the electrode surface; the $k_{f,h}^{0}$ in Eq. (9) is the one for a first-order reaction. The essential equations, as solved by Koutecký[15] for the whole rising portion of the wave, are:

$$E = -0.246 + \frac{RT}{\alpha n_a F}\ln\frac{0.886k_{f,h}^{0}Kt^{1/2}}{D_o^{1/2}}C_{H^+}^{m} - \frac{RT}{\alpha n_a F}\ln\frac{\bar{i}}{\bar{i}_d - \bar{i}} \quad (10)$$

$$E_{1/2} = -0.246 + \frac{RT}{\alpha n_a F}\ln\frac{0.886k_{f,h}^{0}Kt^{1/2}}{D_o^{1/2}} - \frac{2.303RT}{\alpha n_a F}m(\mathrm{pH}) \quad (11)$$

$$E_{1/2}^{0} = -0.246 + \frac{RT}{\alpha n_a F}\ln\frac{0.886k_{f,h}^{0}K}{D_o^{1/2}} - \frac{2.303RT}{\alpha n_a F}m(\mathrm{pH}) \quad (12)$$

Hence,

$$\frac{dE_{1/2}^{0}}{d(\mathrm{pH})} = -\frac{2.303RT}{\alpha n_a F}m \quad (13)$$

is obtained from Eq. (12) for the estimation of m and $k_{f,h}^{0}$ at a constant value of αn_a. αn_a and m are calculated from Eqs. (10) and (13) respectively. $k_{f,h}$ is evaluated from Eq. (11) or (12) if the K value is known.

αn_a and $k_{f,h}^{0}$ are evaluated by an alternative method. By multiplying both sides of Eq. (5) by $KC_{H^+}^{m}$, we obtain:

$$\log KC_{H^+}^{m}k_{f,h} = \frac{\alpha n_a F}{2.303RT}E + \log Kk_{f,h}^{0} - m(\mathrm{pH}) - \frac{0.246\alpha n_a F}{2.303RT} \quad (14)$$

for $KC_{H^+}{}^{m}k_{f,h}$ based on Eq. (4), Eq. (8), Ilkovič's equation, and the table of χ values calculated by Weber *et al.*[11] Similarly, $Kk_{f,h}^{0}$ and αn_a are calculated from Eqs. (13) and (14).

Experimental

Materials. 1-*o*-Tolyl-azo-2-naphthol (Orange OT) was recrystallized twice from ethanol. E.P.-grade sodium dodecyl sulfate (SDS) was purified by two recrystallizations from ethanol after extraction with ethyl ether for 50 hr. A sample of sodium dodecylbenzenesulfonate (SDBS; the CMC based on the polarographic method[16] was 3.2×10^{-3} M at 30 °C), kindly supplied by Lion Oil and Fats Co. was recrystallized from petroleum ether. C.P.-grade dodecyltrimethylammonium chloride (DTMAC) was purified by recrystallization from acetone. A sample of polyoxyethylene nonylphenyl ether (NP-$\bar{1}0$) was also obtained by courtesy of the Meisei Chemical Works. Ltd., and was used without further purification. Citric acid-disodium hydrogen phosphate buffers (McIlvaine's buffer solution) were prepared from G.R.-grade reagents without purification.

Solutions. Orange OT was dissolved in 6.8 M aqueous ethanol (about 40 vol%) and solubilized in anionic, cationic, and nonionic surfactant solutions, the concentrations of which were: 2×10^{-2} M SDS, 2×10^{-2} M SDBS, 5×10^{-2} M DTMAC, and 4×10^{-2} M NP-$\bar{1}0$ respectively, buffered at various pH values. Also, the dye concentrations were 5×10^{-5} M in the aqueous ethanol, 5×10^{-5} M in the SDS, 2×10^{-5} M in the SDBS, 5×10^{-5} M in the DTMAC, and 1×10^{-4} M in the NP-$\bar{1}0$ solution.

The solutions of the solubilized dye in the surfactant solutions were prepared with shaking and warming to a desired temperature for several days and were measured by polarography after the solubilization equilibrium.

The pH was measured with a Toa Dempa Model HM-5A pH meter. In the case of aqueous ethanol solutions, the apparent pH values were measured.

Polarography. Polarographic measurements were carried out by using a PAR Model 170 (Princeton Applied Research Co.). The characteristic σ value of the dropping mercury electrode was 1.74 mg s^{-1} (the height of the mercury column h=87.15 cm) in all solutions except the DTMAC solution, in which σ=1.72 mg s^{-1} (h=87.05 cm). The potential of a polarograph was recorded against the S.C.E. The solutions were deaerated by bubbling pure nitrogen gas through them for an hour and by then allowing its overflow to cover the surfaces of the solutions during measurement. The SDBS solutions were measured at 45±0.1 °C, while the other solutions were measured at 25±0.1 °C corresponding to their Krafft points.

Results

The polarographic behavior of Orange OT has already been mentioned[3] in detail in surfactant solutions with a constant pH value. The present paper, however, will be concerned with solutions of various pH values. The relation of the limiting current to the square-root of the height of the mercury head in all the solutions shows a linear line. The lmiting current, therefore, is proved to be the diffusion-controlled current.

A maximum of the first kind in the aqueous ethanol solution containing dissolved Orange OT was appreciably observed in pH 2.78 and 5.30 solutions (it was not observed between pH 2.78 and 5.30), and it increased with an increase in the pH value.

Since the reduction wave of Orange OT solubilized in the SDS solution overlapped the reorientation wave of SDS molecules on the mercury electrode[17] at pH 4.95 and 5.88, the current of the reduction wave was not analyzed.

The potential due to the reorientation of surfactant molecules shifted unwaveringly to a negative potential with an increase in the pH in the basic solution without Orange OT, while the reorientation potential-pH relation showed a curve with a minimum at pH 4.95 in

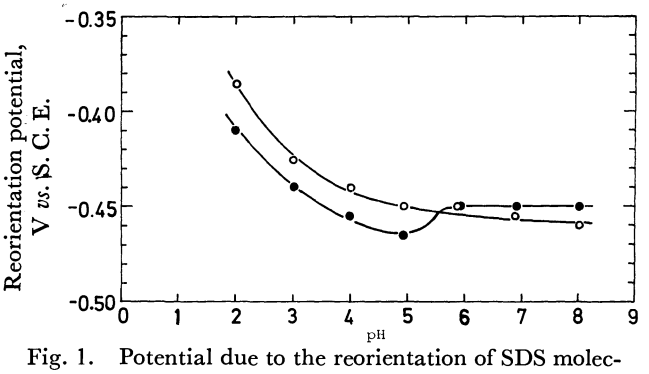

Fig. 1. Potential due to the reorientation of SDS molecules with pH: ○, SDS basic solution; ●, solution solubilizing Orange OT.

the solution solubilizing Orange OT (Fig. 1).

The reduction wave of Orange OT solubilized in the SDBS solution overlapped the tensametric wave of SDBS at pH<3.00 and could not be analyzed. The polarograph, therefore, was measured in solutions at pH>3.00.

The fine reduction wave in the DTMAC solution solubilizing Orange OT was obtained over the range of pH 1.92 to 7.99.

Two waves in the NP-$\bar{1}0$ solution solubilizing Orange OT were obtained in each pH solution. The first wave was the reduction wave of Orange OT, as the wave height linearly increased with the concentration of the dye; the second wave showed a maximum wave at −0.760 V. For a more basic solution, only the first wave shifted to the negative potential. The two waves overlapped at pH 5.88, and complicated waves were observed at pH 6.89 and 8.01 (Fig. 2).

Discussion

$E_{1/2}$—pH. The relation of the corrected half-wave potential to the pH value in each solution is shown in Fig. 3, in which the slope of each straight line is different. The equations calculated by the least-squares procedures of each relation are shown in Table 1. The slope of each straight line is different because m and αn_a are different in the variety of solutions, as will be described below. In the SDBS solution, two straight lines are obtained; they have not yet been explained.

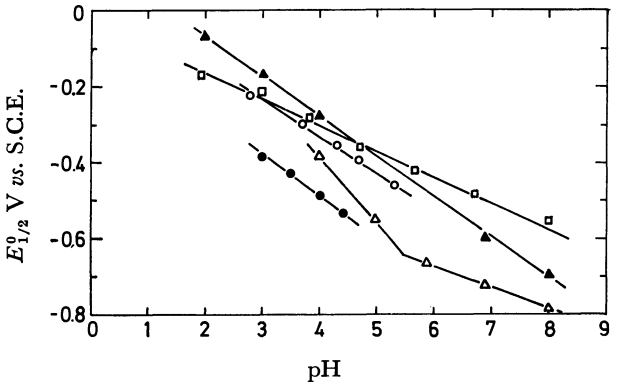

Fig. 3. $E^0_{1/2}$-pH plots: ○, aqueous ethanol; ▲, SDS, △, SDBS; □, DTMAC; and ●, NP-10 solutions.

Table 1. Relation of corrected half-wave potential against pH in each solution

Solution	Relation of $E^0_{1/2}$—pH
C_2H_5OH	$E^0_{1/2}=-0.094$ pH$+0.047$
SDS	$E^0_{1/2}=-0.107$ pH$+0.150$
SDBS	$E^0_{1/2}=-0.178$ pH$+0.329$[a]
	$E^0_{1/2}=-0.055$ pH-0.343[b]
DTMAC	$E^0_{1/2}=-0.066$ pH-0.036
NP-$\bar{1}0$	$E^0_{1/2}=-0.108$ pH-0.055

a) Left branch b) Right branch

$E_{1/2}$—log t. According to Eq. (11), the half-wave potential shifts to less negative potentials in all the solutions with an increase in the drop time. It is found that Orange OT dissolved in an aqueous ethanol solution and solubilized in each surfactant solution is an irreversible species under the conditions investigated.

The slope of $E_{1/2}$—log t in the solution of each pH value is different, mainly because of the difference in αn_a; *e.g.*, in the DTMAC solution the slopes at the pH values of pH 3.83 and 4.70 smaller than the others, which is reasonable because the (αn_a)'s of the former are larger than those of the latter (Fig. 4).

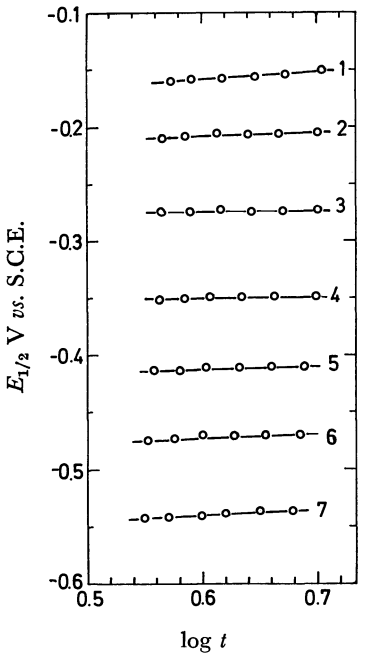

Fig. 4. $E_{1/2}$—log t plots in DTMAC solution: (1) pH 1.92; (2) 2.96; (3) 3.83; (4) 4.70; (5) 5.67; (6) 6.71; (7) 7.99.

αn_a—$E_{1/2}$. In discussing the electrode process, especially the effect of the double-layer structure on the electrode process,[18] the reaction of αn_a—$E_{1/2}$ is very important. However, the apparent value of $(\alpha n_a)_{app}$ found directly from the semilogarithmic plot of the wave, or that of the rate constant mentioned above, is markedly different from its true value.[19] The relationship between the observed value and the true value of αn_a is generally expressed by:[20,21]

$$(\alpha n_a)_{app} = \alpha n_a + (z-\alpha n_a)(\partial \Psi_1/\partial \phi)_{E_{1/2}} \quad (15)$$

where z is the electric-charge on the reacting species; Ψ_1, the potential of the outer Helmholtz plane, and

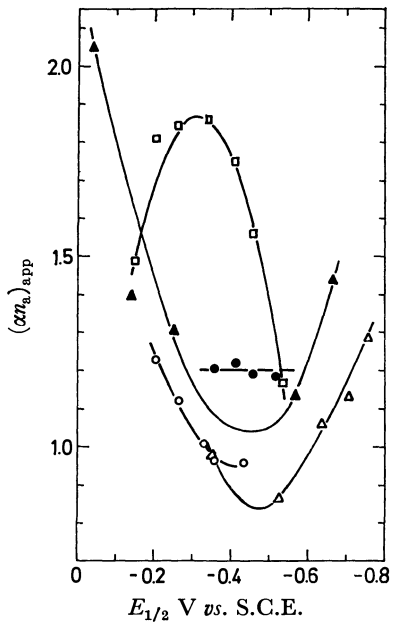

Fig. 5. Variation of $(\alpha n_a)_{app}$ with $E_{1/2}$ from semilogarithmic plot of wave: ○, aqueous ethanol; ▲, SDS; △, SDBS; □, DTMAC; and ●, NP-$\bar{1}0$ solutions.

ϕ, the potential difference between the electrode potential and the potential of the zero charge. However, most of the solutions are micellized solutions. The surfactant molecules strongly adsorb on the mercury electrode, so that the potential of zero charge can not be measured; *i.e.*, $(\partial\Psi_1/\partial\phi)_{E_{1/2}}$ can not be calculated, and the true value of αn_a can not be obtained. Therefore, only the apparent values of αn_a are shown here (Fig. 5).

In calculating $(\alpha n_a)_{app}$, the above two methods, *i.e.*, $\log i/(i_d-i)-E$ and $\log KC_H^m+k_{f,h}-E$, are applied. The difference between the values obtained by the two methods is very small.

The relation of $(\alpha n_a)_{app}$ to $E_{1/2}$ shows the curve passing through a minimum in the anionic surfactant solutions, and a maximum in the cationic surfactant solution. The $(\alpha n_a)_{app}$ in the nonionic surfactant and the aqueous ethanol solutions remains constant and decreases, respectively, with shift of the $E_{1/2}$ to the negative potential.

These results show that the electric-charge of the surfactant at the mercury electrode affects the electrode reaction of Orange OT. Though Orange OT itself is an uncharged species, when solubilized in ionic micelles it seems to behave in the electrode process as if it were an ionic species. In the cationic surfactant solution, $(z-\alpha n_a)$ becomes a positive value, judging from the fact that the plot of $\alpha n_a-E_{1/2}$ indicates a maximum; therefore, the electric-charge of the cationic surfactant micelle is not less than two.[22]

Most of the αn_a values obtained are larger than one, and the value of n_a seems to be 2 rather than one.

In the case of the aqueous ethanol and ionic surfactant solutions, the value of m is not obtained because αn_a varies with the half-wave potential and $k^0_{f,h}$ can not be calculated.

m and $Kk^0_{f,h}$ of Orange OT Solubilized in an NP-$\bar{1}0$

Table 2. Heterogeneous rate constant of Orange OT solubilized in NP-$\bar{1}0$ solution

pH	$(Kk^0_{f,h})^{a)}$ (cm l^2 mol^{-2} s^{-1})	$(Kk^0_{f,h})^{b)}$ (cm l^2 mol^{-2} s^{-1})
3.00	3.4	4.3
3.49	5.7	3.3
4.00	3.7	3.0
4.40	2.2	1.8

a) From Eq. (11). b) From Eq. (14).

Solution. In the case of Orange OT solubilized in NP-$\bar{1}0$, αn_a does not vary with the half-wave potential in the potential range. The value of m from Eq. (13) is calculated to be 2; this value is reasonable. $Kk^0_{f,h}$ is calculated from Eq. (10) or (14) as the values of αn_a and m are obtained, but K is not known. The values of $Kk^0_{f,h}$ are tabulated in Table 2.

$(z-\alpha n_a)$ in Eq. (15) becomes zero because the value of αn_a is constant in a variety of half-wave potentials. Orange OT, which is essentially an uncharged species, seems to behave as the ionic species of the unit electric-charge, because the value of αn_a is nearly equal to one.

Theoretical Calculation of the Carbon-13 Chemical Shifts of Some Normal Alkanes by the Linear Combination of Gauge Invariant Atomic Orbitals-Molecular Orbital Theory Using INDO and MINDO/2 Methods

Isao ANDO, Atsuo NISHIOKA, and Masahiro KONDO

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 7, 1973)

The ^{13}C chemical shifts of several *n*-alkanes (CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_5H_{12}, C_6H_{14}, and C_7H_{16}) were calculated using a linear combination of the gauge invariant atomic orbitals-molecular orbital theory of Pople and the INDO and MINDO/2 methods, and the results were compared with the experimental data reported by Grant *et al.* The calculated chemical-shift differences among the carbons in these molecules were found to agree with the observed data except in some cases, whereas the observed order of the chemical shift of the carbons in *n*-alkanes, which have more than two magnetically nonequivalent carbons, cannot be interpreted by means of the average excitation energy (ΔE) approximation. Histograms showing the distribution of the excitation energies from the occupied to unoccupied orbitals were obtained and compared with ΔE.

The carbon-13(^{13}C) NMR spectra of normal(*n*-) and branched alkanes were at first studied in detail by Paul and Grant.[1] These data were summarized by the so-called "Grant's empirical additivity rule". An early attempt to interpret these data theoretically was reported by Yonezawa *et al.* using the average excitation energy(ΔE) approximation for the paramagnetic term governing the ^{13}C chemical shift(σ) of *n*- and branched alkanes,[2] but their results agree only roughly with the observed data. Recently they have tried to use various values of ΔE among the individual carbons in alkanes and have suggested that the experimental data were better explained by their method than by the usual method of using a common value of ΔE for all the carbons in an alkane molecule.[3] Although the practical utility is large, this method has an ambiguity in its theoretical basis from the point of view of molecular orbital theory. Therefore it is important to consider the ΔE approximation by means of another method without this approximation. In this paper we attempt to calculate precisely the ^{13}C chemical shifts of *n*-alkanes (CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_5H_{12}, C_6H_{14}, and C_7H_{16}) in which the large molecules still have not been treated except for CH_4 and C_2H_6, by a method based on molecular orbital theory considering only the valence-electron system, in place of the ΔE approximation, and attempt to interpret theoretically the observed ^{13}C chemical shifts of large *n*-alkanes, which have not been interpreted by the ΔE approximation. For this purpose, we use Pople's consideration[4] that σ may be estimated as the sum of three terms—the diamagnetic and paramagnetic contributions, and the contribution from electrons on the other atoms in the molecule. The ^{13}C chemical shift is predominantly contributed, by the second term.[4] Pople[5] has derived the so-called linear combination of gauge invariant atomic orbitals-molecular orbital (LCGI-MO) theory for Ramsey's paramagnetic shielding tensor[6] based on a series of approximations, commonly in linear combination of atomic orbitals (LCAO-MO) theory. This approach enables us to calculate the σ values approximately for large molecules. Our calculations have been done using two different parametric self-consistent field (SCF) MO theories, that is, the MINDO/2[7] and INDO methods[8] modified for calculating the electronic excitation energies of organic compounds by Yamaguchi *et al.*[9] The major difference between these two methods is in the separation in orbital energies, which have a large effect on the ^{13}C chemical shift. As for the two MO theories, the MINDO/2 method is said to interpret better the excitation energy for π-system molecules without taking the configuration interaction (CI) into account, but for the electron density distribution, the latter may give better results than the former. Thus, in this paper the results of the two methods will be compared with each other.

Theoretical

According to Pople,[4] the chemical shielding, σ_A, of the nucleus, A, is written as;

$$\sigma_A = \sigma_d + \sigma_p + \sum_{B \neq A} \sigma_{AB} \quad (1)$$

where σ_d is the diamagnetic term, σ_p, the paramagnetic term, and σ_{AB}, the neighbour anisotropy term. The dominant factor usually governing ^{13}C chemical shielding is the paramagnetic term, whereas σ_d does not contribute predominantly. The neighbour anisotropy term can be neglected because it is unlikely to exceed a few ppm, as has been described by Pople.[10]

The diamagnetic term was calculated as:[2]

$$\sigma_d = 4.45(3.25 - 0.35(q_A - 4.0))q_A \quad (2)$$

in which q_A is the σ-electron density on the carbon, A.

According to Pople's LCGI-MO theory,[5] the paramagnetic shielding is written as:

$$\sigma_p = -2N^{-1}\chi_p^A \langle r^{-3} \rangle_{2p} \quad (3)$$

where χ_p^A is the paramagnetic contribution of the A atom to the susceptibility tensor; N, the Avogadro number, and $\langle r^{-3} \rangle_{2p}$, the mean value of r^{-3} with respect to the 2p orbital (r: the distance between the electron and nucleus). χ_p^A is written by averaging over the diagonal elements of the tensor as;

$$\chi_p^A = \frac{1}{3}\{(\chi_p^A)_{xx} + (\chi_p^A)_{yy} + (\chi_p^A)_{zz}\} \quad (4)$$

where;

$$(\chi_p^A)_{xx} = (Ne^2\hbar^2/m^2c^2)\sum_i^{occ}\sum_{k(\neq i)}^{unocc}(\Delta E_{k-i})^{-1}(c_{iy_A}c_{kz_A} - c_{iz_A}c_{ky_A}) \times \sum_B(c_{iy_B}c_{kz_B} - c_{iz_B}c_{ky_B}) \quad (5\text{-}1)$$

$$(\chi_p^A)_{yy} = (Ne^2\hbar^2/m^2c^2)\sum_i^{occ}\sum_{k(\neq i)}^{unocc}(\Delta E_{k-i})^{-1}(c_{iz_A}c_{kx_A} - c_{ix_A}c_{kz_A}) \times \sum_B(c_{iz_B}c_{kx_B} - c_{ix_B}c_{kz_B}) \quad (5\text{-}2)$$

$$(\chi_p^A)_{zz} = (Ne^2\hbar^2/m^2c^2)\sum_i^{occ}\sum_{k(\neq i)}^{unocc}(\Delta E_{k-i})^{-1}(c_{ix_A}c_{ky_A} - c_{iy_A}c_{kx_A}) \times \sum_B(c_{ix_B}c_{ky_B} - c_{iy_B}c_{kx_B}) \quad (5\text{-}3)$$

Here, c_{ixA} is the coefficient of the $2p_x$ atomic orbital on the atom of the i-th molecular orbital in the LCAO-MO theory; $\sum_i^{occ}$ and $\sum_{k(\neq i)}^{unocc}$ are the summations over the occupied and unoccoupied orbitals; $\sum_B$ runs over all the atoms in the molecule (including A), and ΔE_{k-i} is the singlet-singlet excitation energy between the i-th occupied orbital and the k-th unoccupied one. ΔE_{k-i} is expressed as follows:

$$\Delta E_{k-i} = \varepsilon_k - \varepsilon_i - J_{ki} + 2K_{ki} \quad (6)$$

where ε_k and ε_i are the unoccupied and occupied orbital energies and where J_{ki} and K_{ki} are the two-electron Coulomb and exchange integrals. $\langle r^{-3}\rangle_{2p}$ in Eq. (3) for the Slater 2p orbital of the A atom depends primarily on the local electron density on the carbon atom ($-q'_A$ e is the net charge) and is given as;[10]

$$\langle r^{-3}\rangle_{2p} = 34.33a_0^{-3}(1-0.323q_A')/24 \quad (7)$$

where a_0 is the Bohr radius. From the expressions described above, the ^{13}C chemical shieldings of n-alkanes were estimated by the INDO and MINDO/2 methods for the valence-electron system.

Here, the C–C and C–H bond lengths used are set at 1.54 and 1.10 Å respectively, and all the C–C–C, C–C–H, and H–C–H bond angles are set at 109°28′.[11]

The calculations were carried out by means of the HITAC-8800 computer of the Computer Centre of the University of Tokyo.

Results and Discussion

Before calculating the ^{13}C chemical shift of n-alkanes, it would be helpful in understanding it to discuss the electron density distributions, the orbital energies, the excitation energies, and the ionization potentials as calculated by the INDO and MINDO/2 methods. Here, although n-alkane molecules with more than three carbon atoms can take conformations containing the *gauche* form other than the *trans* form in the liquid state, only the *trans* form, which is the major conformation among the possible conformations, is involved except for n-butane and n-pentane. The total electron density and 2p electron density distributions in seven kinds of n-alkanes, as calculated by the INDO and MINDO/2 methods, are shown in Fig. 1, where the latter is given in brakets. The total and 2p electron densities on the carbon atoms as calculated by the INDO method were found to give slightly larger values than those calculated by the MINDO/2 method. Because $\langle r^{-3}\rangle_{2p}$ decreases with an increase in the total electron density, the MINDO/2 method is found to lead to a somewhat larger contribution of the paramagnetic shielding than does the INDO method. Next, let us examine the orbital energies of n-alkanes. The values calculated by both methods are shown in Fig. 2. It is found that the separations between the occupied and unoccupied orbital energies calculated by the MINDO/2 method are smaller than between those calculated by the INDO method. Therefore, the MINDO/2 method will give somewhat larger contribution to the paramagnetic shielding than will the INDO method. Further, it will become a measure of the magnitude of the paramagnetic contribution to show the histograms of the singlet-singlet transitions from occupied to unoccupied orbitals in alkanes. Therefore, they are shown in Fig. 3, where the vertical axis of the histogram indicates the number of transitions from occupied to unoccupied orbitals and where the interval of the excitation energy is 1 eV. (Such histograms for molecules with π-electrons—for example, ethylene and benzene, may not be appropriate, since the π-π^* transition of the transitions from occupied to unoccupied orbitals does not contribute to the paramagnetic shielding because of the orbital symmetry; therefore, the vertical axis of the histogram should include the weight of each transition in computing the contribution to the chemical shift. However, in the molecules considered here, a σ-electron system, such histograms may be useful in seeing the tendency of the distribution of the excitation energy of n-alkanes without the weight.) As is shown in Fig. 3, the excitation energies giving maximum values in the histograms of the transitions calculated by the MINDO/2 and INDO methods shift to higher energies with an increase in the number of carbon atoms; their exicitation energies are about 9—10 and 14—15 eV respectively, except for CH_4 and C_2H_6. Thus, the MINDO/2 method gives a value about 5 eV lower than does the INDO method. The former may be therefore expected to make a larger paramagnetic contribution than the latter.

Table 1. The calculated and observed ionization potentials of n-alkanes (eV)

	Calculated		Observed[a]
	INDO method	MINDO/2 method	
CH_4	16.71	13.15	12.95
C_2H_6	14.15	11.48	11.65
C_3H_8	12.91	10.88	11.08
C_4H_{10}	12.09	10.32	10.65
C_5H_{12}	11.52	9.96	10.33
C_6H_{14}	11.20	9.73	10.17
C_7H_{16}	10.94	9.55	10.06

a) From Ref. 12.

Before concerning with the present purpose, we will concern with the average excitation energy approximation. Our calculated results of the excitation energies showing maximum values in the histograms by the

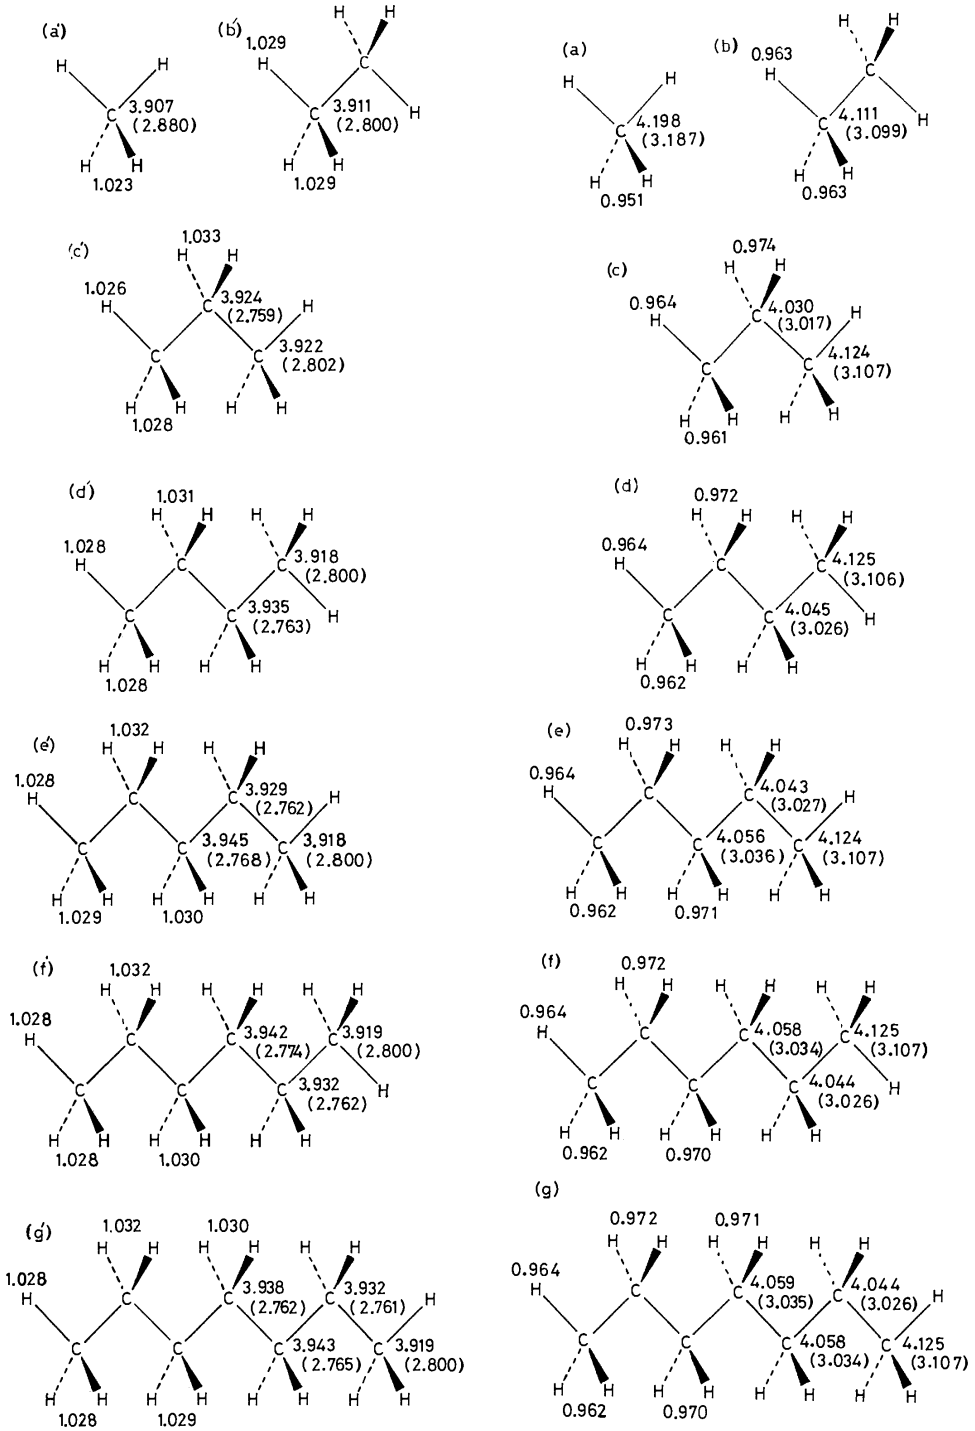

Fig. 1. Total electron density and 2p electron density (with brackets) distributions of *n*-alkanes calculated by INDO and MINDO/2 methods
a), a') CH_4; b), b') C_2H_6; c), c') C_3H_8; d), d') C_4H_{10}. e), e') C_5H_{12}; f), f') C_6H_{14}; g), g') C_7H_{16}. The prime indicates the electron density by MINDO method and other by INDO method. All the conformations are *trans* form.

MINDO/2 method are found to be near to the value of ΔE in the average excitation energy approximation, proposed by Pople[10] for the σ-system carbon atom. These may become roughly one of the measures of the value of ΔE, when the distribution of the histograms is not broad. (According to this viewpoint, the ionization potential may also become a measure of it. As for the ionization potential, the results calculated by the MINDO/2 method are somewhat lower values than those calculated by the INDO method as shown in Table 1. This corresponds to the above-obtained result for the maximum value in the histogram.) Now, let us particularly consider the large *n*-alkanes, and, as an example, let us consider *n*-pentane by the following ΔE approximation, with three magnetically non-equivalent carbon atoms:

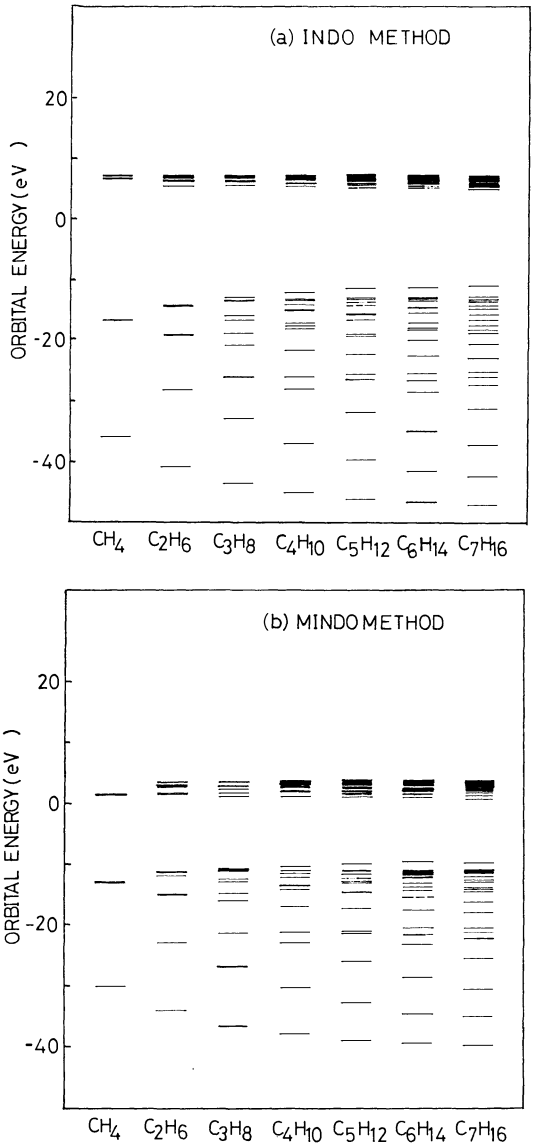

Fig. 2. Orbital energies of *n*-alkanes calculated by INDO (a) and MINDO/2 (b) methods.

$$\sigma_p = -(e^2\hbar^2/2m^2c^2\Delta E)\langle r^{-3}\rangle_{2p}\sum_{B(=A)} Q_{AB} \tag{8}$$

where;

$$Q_{AB} = \frac{3}{4}\delta_{AB}(p_{x_Ax_B}+p_{y_Ay_B}+p_{z_Az_B}) - \frac{2}{3}(p_{y_Ay_B}p_{z_Az_B}+p_{z_Az_B}p_{x_Ax_B}+p_{x_Ax_B}p_{y_Ay_B}) + \frac{2}{3}(p_{y_Az_B}p_{z_Ay_B}+p_{z_Ax_B}p_{x_Az_B}+p_{x_Ay_B}p_{y_Ax_B}) \tag{9}$$

In these formulas, $\sum_{B(=A)}$ is a summation over all the atoms; δ_{AB}, the Kronecker symbol, and p_{XAXB}, the element of the matrix for the $2p_x$ atomic orbitals on the A and B atoms. When A=B, it is the charge density in $2p_x$ on the A atom, and when A≠B, it is the bond order between the two atomic orbitals. The ^{13}C chemical shifts of *n*-pentane, as calculated by the use of the ΔE approximation using the INDO and MINDO/2 methods, are shown in Table 2, where 10 eV is used as the value of ΔE. It is shown that

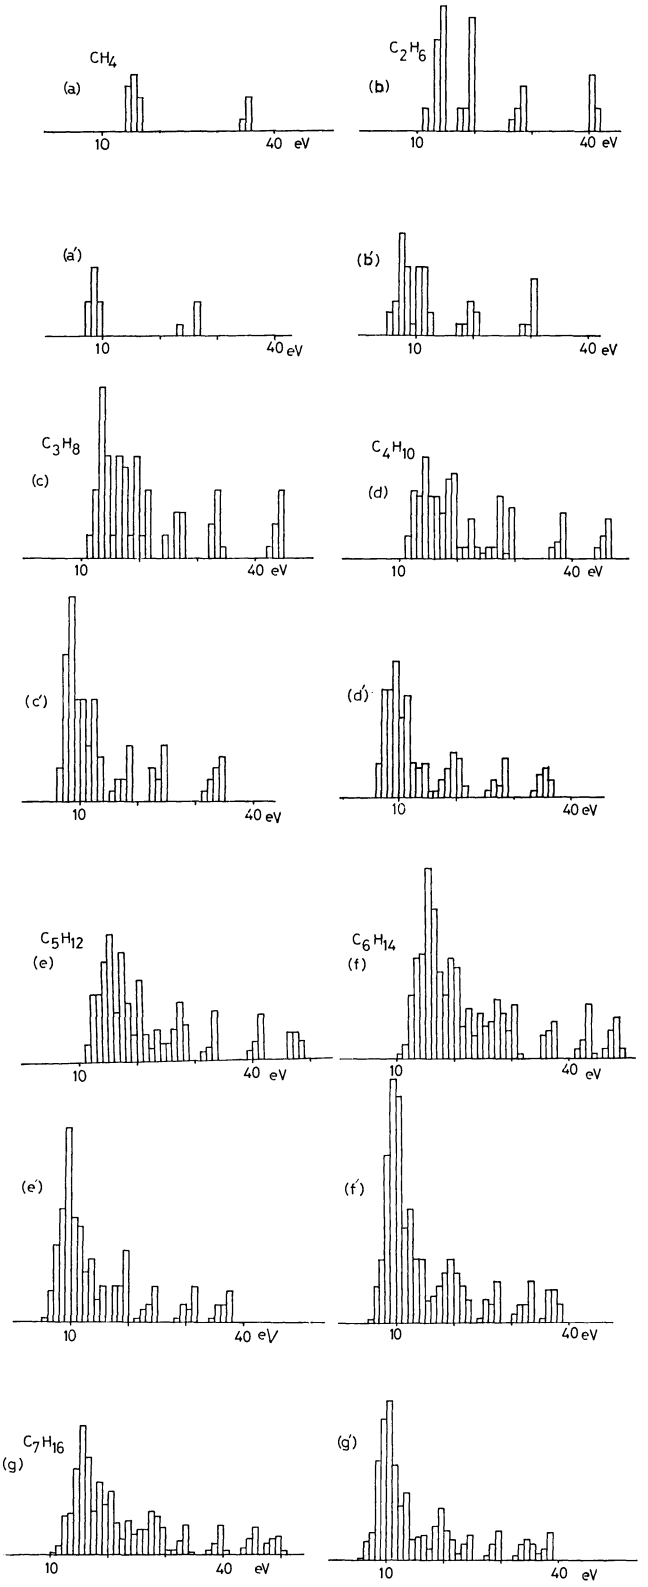

Fig. 3. Histograms of number of the excitation from occupied to unoccupied orbitals against the singlet–singlet excitation energies of *n*-alkanes calculated by INDO and MINDO/2 methods.

d) The conformation is the TT form.

the chemical-shift difference between the $CH_3(1)$ and $CH_2(2)$ carbons* agrees roughly with the experimental value, but that between the $CH_2(2)$ and central $CH_2(3)$ carbons does not agree with the experimental value (in the INDO method the order of the $CH_2(2)$ and $CH_2(3)$ carbons is opposite to that in the experimental results.) Therefore, it is difficult to interpret the ^{13}C chemical shift of long *n*-alkane by means of the ΔE approximation. When *n*-alkanes have a broad distribution of the exicitation energy, as is shown in Fig. 3, it may be seen not to be plausible to estimate the ^{13}C chemical shifts using a definite common value of ΔE.

Next, let us discuss the ^{13}C chemical shift of the *n*-alkanes calculated by means of the LCGI-MO theory using the INDO and MINDO/2 methods. The calculated results are shown in Table 3. As has been described above, the magnitudes of the paramagnetic contribution as calculated by means of the MINDO/2 method are found to give larger values than those calculated by means of the INDO method. We will first discuss the chemical shifts of the carbons in each *n*-alkane having more than two magnetically non-equivalent carbon atoms. In the case of *n*-propane calculated by the INDO and MINDO/2 methods, the order of the CH_3 and CH_2 carbons in their chemical shifts agrees qualitatively with the observed order, but for the difference between the two carbons the calculated value are too much larger than the observed value. In the case of *n*-butane, the INDO method gives a fairly good agreement with the observed results, better than the MINDO/2 method. In the case of *n*-pentane, although, as has been mentioned above, we could not interpret the observed chemical-shift difference between the $CH_2(2)$ and $CH_2(3)$ carbons when we used the ΔE approximation, the LCGI-MO theory using the MINDO/2 method gives good agreement between the calculated and observed results, while the INDO method does not give good results quantita-

* The representation of *n*-pentane is as follows; $CH_3(1)$-$CH_2(2)$-$CH_2(3)$-$CH_2(2)$-$CH_3(1)$. The representations of the other *n*-alkanes are the same as this.

tively, for the chemical-shift difference between the $CH_2(2)$ and $CH_2(3)$ carbons, although the qualitative orders of the carbons agree with each other. In the case of *n*-hexane, the MINDO/2's calculation agrees well with the observed results, but the INDO's calculation does not give good results for the chemical-shift difference between the $CH_2(2)$ and $CH_2(3)$ carbons as well as in the case of *n*-pentane. In the case of *n*-heptane, the observed four signals of the carbon atoms are assigned in order of the $CH_3(1)$, $CH_2(2)$, $CH_2(4)$, and $CH_2(3)$ carbons from the high field (the chemical-shift difference between the $CH_2(3)$ and $CH_2(4)$ is small). In the MINDO/2 method, the chemical shifts of the $CH_3(1)$, $CH_2(2)$, and $CH_2(3)$ carbons agree with the observed ones, but the $CH_2(4)$ carbon appears at a slightly lower field than the $CH_2(3)$ carbon. In the INDO method the chemical shifts of the other carbons except for the chemical-shift difference between the $CH_3(1)$ and $CH_2(2)$ carbons disagree with the observed results.

As may seen be from Table 3, the observed values of the ^{13}C chemical shifts in a molecule could be better explained by the MINDO/2 method than by the INDO method, although one of the causes of some discrepancies may be the simple *trans* planar form.

Next, with respect to *n*-butane and *n*-pentane, we will discuss the effect of possible rotational isomers on the chemical shift. Here the MINDO/2 method was used, because it gives better results than the INDO method in the TT form of *n*-pentane. The electron-density distributions and the orbital energies of the G form in *n*-butane and of the TG and GG forms in *n*-pentane are shown in Figs. 4 and 5 respectively. The latter is shown together with the *trans* forms. Histograms of the number of the excitation against

a) The $CH_3(1)$ carbon in a molecule is the reference. b) *n*-Butane: averaged over the T, G, and G′ isomers. c) *n*-Pentane: averaged over the TT, TG, TG′, GT, G′T, GG, and G′G′ isomers.

their singlet-singlet excitation energies are also shown in Fig. 6. These results do not differ greatly from those of the *trans* forms shown in Fig. 3. The difference in the electron density among the carbons in the conformation containing the *gauche* form is shown to be smaller than that in the *trans* form. On the other hand, the separation of the occupied and unoccupied orbital energy levels in the conformation containing the *gauche* form is shown to be somewhat larger than that in the *trans* form. Therefore, these results predict that the conformations containing the *gauche* form may give a smaller chemical-shift difference among the carbons than does the *trans* form. These calculated results are tabulated in Table 4. As has been predicted, in the conformations containing the *gauche* form their chemical-shift differences between the $CH_3(1)$ and $CH_2(2)$ carbons in *n*-butane, and between the $CH_2(2)$ and $CH_2(3)$ carbons in *n*-pentane, are somewhat smaller than the corresponding values in the *trans* forms. The observed results should be compared with the calculated results averaged over all the possible conformations (T, G, and G′ for *n*-butane; TT, TG, TG′, GT, G′T, GG, and G′G′ for *n*-pentane) using the following equation:[13]

$$\sigma_{AV} = \sum_i^n X_i \sigma_i \qquad (10)$$

where;

$$X_i = e^{-\Delta E_i/RT} / \sum_i^n e^{-\Delta E_i/RT}$$

in which X_i and σ_i are the fraction and the chemical shift of the *i*-th isomer respectively. R is the gas constant; T, the absolute temperature, and E_i, the energy difference between the *trans* form and the *i*-th isomer. Here, 570 cal/mol[14] is used as the value of the energy difference between the *trans* and *gauche* forms, and 300 K is used as the temperature. These results are also tabulated in Table 4, where the chemical shifts of the carbons in the G and G′ forms of *n*-butane are equal to each other; also, those of the carbons in the TG and TG′, the GT and G′T, and the GG and G′G′ forms of *n*-pentane are equal to each other. These agree relatively well with the observed results. Furthermore, from the results of the chemical-shift difference between the CH_3 and CH_2 carbons in the conformations containing the *gauche* form of *n*-butane and *n*-pentane, the difference is predicted to decrease with an increase in the temperature. However, the observed results of *n*-butane[15] and *n*-pentane[16] in neat liquid are opposite to the calculated ones. The reason for this is that the chemical-shift difference between the CH_3 and CH_2 carbons of the conformation containing the *gauche* form is too small compared with that of the *trans* form.

As has been mentioned above, the LCGI-MO theory was found to interpret well the tendencies of the chemical shift of the carbons in a molecule. However, Table 4 shows that the quantitative agreement between the calculated and observed chemical shifts of the carbons among the molecules is not satisfactory. This discrepancy arises partly from the MO theories, which do not strictly estimate the singlet-singlet excitation energies among the *n*-alkanes considered. Further, some other factors may be pointed out. A molecular orbital approximation cannot give an exact value for the energy of a molecule because it usually neglects the electron correlation due to the mutual Coulomb repulsion of the electrons. Some approximations are made for this in both the INDO and MINDO/2 treatments by the adjustment of the parameter, but there is a limit to this kind of adjustment. Thus, to improve our calculation it will be necessary to take the configuration interaction into account in the future.

(Received November 29, 1973)

A force field which reproduces satisfactorily both the observed vibrational frequencies and the elastic constants has been determined for the sodium nitrate crystal using the short-range interaction model. In addition to the short-range interactions, the long-range interactions of the vibrationally-induced dipoles were also taken into consideration on the basis of the rigid-ion model; those effective charges which explain fairly well the observed TO–LO frequency splittings were obtained. The distribution of the effective charges on each atom was examined; the best set of effective charges has been found to be $Z_{Na}=0.87\ e$, $Z_N=0.17\ e$, and $Z_O=-0.35\ e$.

The crystal vibration of soda-niter ($NaNO_3$)[2] has been extensively studied in connection with that of the isomorphic crystals having the calcite structure. However, previous investigations[2] have dealt almost exclusively with the short-range interaction model, and little attention has been paid to long-range Coulomb interactions. In the present paper, we wish to call further attention to the effect of the charge distribution on the TO–LO frequency splittings.

First, the short-range interactions are taken into consideration, and the force constants are refined so as to reproduce both the observed vibrational frequencies[2] and the elastic constants.[3] Secondly, a detailed normal coordinate treatment is performed for the optically-active crystal vibration on the basis of the rigid-ion model.[4] The basic formulation of this model was mainly established by Born and his co-workers.[4] As is implied by the name, the interactions of vibrationally-induced dipoles are taken into account as those of rigid point dipoles; any influence of the electronic polarizability of the constituent atoms is implicitly neglected. This model was first applied to the vibrational analysis of relatively simple crystals, such as alkali-halide crystals.[5] The assumptions implicit in this model are, however, considered to be untolerably drastic in a sense; as a consequence, the reproducibility of the frequency dispersion relations, in particular, is found to be poor.[6] For rather complicated crystals, even rigid-ion analyses have been scarcely performed yet because of the long and tedious procedures required, together with the experimental limitations. In the course of a survey of the vibrational properties of complex crystals,[7] in the present study the rigid-ion model is applied to the normal coordinate analysis of the optically-active vibration (wave vector $\boldsymbol{y}=\boldsymbol{0}$), regarding all the atoms as ionizable.

Method of Calculation

Crystal Structure. Sodium nitrate crystallizes in the calcite structure. As is shown in Fig. 1, this structure is most easily visualized as a sodium chloride lattice distorted by the introduction of the disk-shaped nitrate groups. Although the calcite structure is also considered to be a hexagonal lattice, the primitive unit cell is trigonal and contains two formula units of $NaNO_3$. The space group of the trigonal cell is D_{3d}^6—$R\bar{3}c$, and the cell constants[8] are found to be

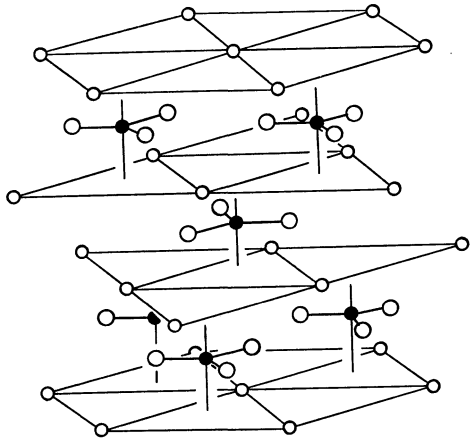

Fig. 1. Crystal structure of soda-niter.
○, Sodium; ●, Nitrogen; ◯, Oxygen.

$a_{rh}=6.3247$ Å and $\alpha=47°16'$. Each sodium atom is coordinated with six oxygen atoms of different nitrate groups, and each such oxygen atom is bound to two sodium atoms.

Normal Coordinate Treatments. In the present study, the normal coordinate treatments were performed in two steps, those based on the short-range interaction model and on the rigid-ion model.

Short-range Interaction Model: The application of Wilson's *GF*-matrix method to the analysis of the optically-active crystal vibration was previously reported by Shimanouchi *et al.*[9] In this study, the modified Urey-Bradley force field[10] was applied to the intramolecular vibrations of the nitrate groups, the correction terms of which were the bond interaction term, p, for the adjacent N–O bond pairs and the angle interaction term, n, for the adjacent O–N–O angle pairs in a single nitrate group. On the other hand, the central force field was used for the intermolecular (lattice) vibrations. With respect to the latter, only the pairs that lie within 3.5 Å were taken into consideration as effective short-range interatomic interactions. As Fig. 2 illustrates, there are six different kinds of pairs in this crystal. The corresponding interatomic distances are listed in Table 1. The dynamical matrix due to these short-range interactions will be designated as $\boldsymbol{D}^s$ hereafter.

Rigid-ion Model: In addition to the short-range interactions mentioned above, the long-range Coulomb interactions of vibrationally-induced dipoles are taken

into account in this model. The additional interactions are considered to play an important role, especially in predominantly ionic crystals, and the frequency splitting between LO- and TO-frequencies is brought about through the interactions.[4]

According to Born and Huang,[4] the Coulomb part, $\boldsymbol{D}^c$, in the dynamical matrix near the Γ point is given by:

$$D^c_{ij}(k, k'; \boldsymbol{y}\to\boldsymbol{0}) = Z_k e^2 (m_k m_{k'})^{-1/2}\{4\pi v^{-1} \lim_{\boldsymbol{y}\to 0} (y_i y_j/|\boldsymbol{y}|^2) - Z_{k'} Q_{ij}(k, k'; \boldsymbol{y}\to\boldsymbol{0}) + \delta_{kk'}\sum(k'') Z_{k''} Q_{ij}(k, k''; \boldsymbol{y}\to\boldsymbol{0})\},$$

where $\mathbf{y}$ is the wave vector; Z_k, the effective charge of the k-th atom in terms of electronic charge, e; m_k, the mass of the k-th atom, and v, the unit cell volume. The $Q_{ij}(k, k')$ is a tensor of the second rank for the wave vector zero; it is most easily visualized as the tensor representing the gradient of the Coulomb field at the k site, which is spanned by the point dipoles at the k' site over the trigonal lattice. The numerical evaluation of the tensor elements can be carried out straight-forwardly by the Ewald method.[11] The summations were performed with the PEG0 computer program.[12] The values are constant for a fixed wave vector in the same lattice; therefore, it is sufficient to calculate the sums once for each crystal.

The overall dynamical matrix of the model is now obtained by superposing the Coulomb part, $\boldsymbol{D}^c$, on the short-range part, $\boldsymbol{D}^s$, *viz.*:

$$\boldsymbol{D} = \boldsymbol{D}^s + \boldsymbol{D}^c.$$

Since this crystal contains nitrate groups, there is another serious problem to be elucidated: the distribution of the effective charges on the groups cannot be known in advance. As is shown in Fig. 3, we have inevitably assumed several trial sets of charge distribution under electrically neutral conditions in the whole crystal. In this figure, x stands for the distribution parameter and Z denotes the magnitude of the effective

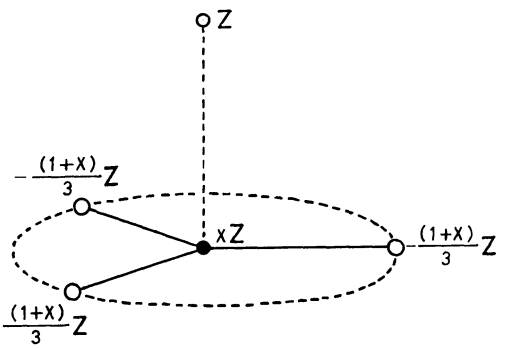

Fig. 3. Charge distribution of $NaNO_3$.
○, Oxygen; ○, Sodium; ●, Nitrogen;
z, magnitude of effective charge in terms of electronic charge e; x, distribution parameter.

charges. Supposing this distribution model, the distribution parameter, x, and the magnitude, Z, enter as independent parameters to be adjusted appropriately. Varying the parameter, x, little by little, both the magnitude, Z, and the short-range force constants were refined in order to obtain the best fit between the observed[2] and calculated frequencies, both ν_t and ν_l, by the least-squares method.[13]

If group theoretical analysis is performed on the basis of the crystal symmetry, much useful information can be obtained beforehand for the vibrational analysis. Generally, one must make the "k-group analysis" [14] based on the symmetry of the wave vector. In the case of the vibration near the center of the Brillouin zone, however, the k-group analysis is reduced to the usual factor-group analysis.[2b]

Refinement of Force Constants. As has been mentioned above, the Jacobians with respect to the frequency[13] and to the elastic constant[15] were obtained independently from the treatments of the short-range interaction model. Taking both Jacobians into consideration, the refinement of the short-range force constants was performed by the use of the following expression:

$$\Delta \boldsymbol{K} = (\tilde{\boldsymbol{J}}_h^{\nu} \boldsymbol{W}_{\nu} \boldsymbol{J}_h^{\nu} + \tilde{\boldsymbol{J}}_h^{E} \boldsymbol{W}_E \boldsymbol{J}_h^{E})^{-1} \times (\tilde{\boldsymbol{J}}_h^{\nu} \boldsymbol{W}_{\nu} \Delta \boldsymbol{\nu} + \tilde{\boldsymbol{J}}_h^{E} \boldsymbol{W}_E \Delta \boldsymbol{E}),$$

where the suffixes ν and E attached to some matrices denote those which are related to the vibrational and the elastic properties respectively. The $\boldsymbol{W}$ matrices are the relative weight matrices of the observed vibrational frequencies or elastic constants. The $\Delta\boldsymbol{\nu}$ and $\Delta\boldsymbol{E}$ are the deviation column-matrices of the calculated eigenfrequencies and elastic constants respectively from their observed values.

In the case of the rigid-ion model, both the short-range force constants and the magnitude, Z, of the effective charges were adjusted with reference to the observed ν_t and ν_l values.

The actual calculation was carried out on a TOSBAC 3400 MODEL 41 electronic computer at the Computing Center of Hiroshima University.

Results and Discussion

Optically-active Vibration. According to the rigid-ion model, certain interactions are found to be brought about between the macroscopic field and the induced dipoles if any dipole moment is induced as a whole unit cell through the vibration of fictitious charged particles. Only the A_{2u} and E_u symmetric modes of the vibration are those which give rise to the polarization. Any vibrational frequencies, ν_l, of the longitudinal wave are higher than the corresponding frequencies, ν_t, of the transverse wave. The reason for the difference in the frequencies of the longitudinal and transverse waves is obvious: in a transverse wave, the

a) Unit of $Q_{ij}(k, k')$ is Å^{-3}. In this table, $i, j = x, y$ or z, and k and k' specify the particles in the primitive cell. Atom numbering is as follows:
1 N(1/4, 1/4, 1/4); 2 N(−1/4, −1/4, −1/4); 3 O(1/3−u, 1/4, u); 4 O(u, 1/2−u, 1/4); 5 O(1/4, u, 1/2−u); 6 O(u−1/2, −1/4, −u); 7 O(−u, u−1/2, −1/4); 8 O(−1/4, −u, u−1/2); 9 Na(1/2, 1/2, 1/2); 10 Na(0, 0, 0); u=0.4901.

vibrationally-induced dipole gives rise to the direction normal to the applying macroscopic field, while in a longitudinal wave, the dipole is induced parallel to the field; therefore, this field contributes an additional restoring force. A frequency splitting between ν_l and ν_t is called a "TO-LO splitting"; the splitting width depends entirely on the long-range Coulomb interactions.

The numerical values of the diagonal elements of the dipole lattice sums were examined by the use of the following relation:

$$\sum_{1}^{3}(i)Q_{ii}(k, k'; \boldsymbol{y}\rightarrow\boldsymbol{0}) = 4\pi/v,$$

where v denotes the unit cell volume, where $i=x$, y, or z, and where k and k' specify the particles in the primitive unit cell. The calculated lattice sums are listed in Table 2. When the charges are distributed spherically or tetrahedrally, the tensor, $\boldsymbol{Q}$, becomes scalar and has the well-known value of $4\pi/3v$ (in Å^{-3}), like that of the Lorentz field.

Intramolecular Vibration: Factor-group analysis[2b] predicts that the intramolecular modes near the center of the Brillouin zone will have the irreducible representation:

$$\Gamma_n = A_{1g} + A_{2g} + 2E_g + A_{1u} + A_{2u} + 2E_u.$$

The A_{1g} and E_g branches are Raman-active, and the A_{2u} and E_u branches are infrared-active, while the A_{1u} and A_{2g} branches are optically-inactive in both infrared absorption and Raman effect.

For the short-range interaction model, the observed[2] and calculated frequencies and the tentative assignments are listed in Table 3. The results for the rigid-ion model are given in Table 4. The corresponding force constants and effective charges are also shown in Table 1. Each distribution parameter, x, is listed at the top of Table 1. Model I corresponds to the short-range interaction model, while Model II and below are based on the rigid-ion model. Apparently, the

vibrationally-induced dipoles are seen not to exert a critical effect on the intra-molecular vibration. Thus, the observed large frequency splittings between E_g and E_u symmetric N–O stretching modes were again poorly explained as in Model I. The rigid-ion model may, therefore, be considered not to be suitable for the vibration of strongly interacting systems, such as those coupled firmly with a co-valent bond. An analysis which is based on some models of a higher order might be essential for a satisfactory explanation of these experimental facts. These subjects have been discussed in part by Decius *et al.*;[16] however, apart from their background polarization model, the point dipole approximation may be unsuitable for the intramolecular vibration.

Lattice Vibration: The lattice modes of the crystal have the irreducible representation of:[2b]

$$\Gamma_l = A_{1u} + 2A_{2g} + 2A_{2u} + 2E_g + 3E_u.$$

Group theory reveals five distinct infrared-active frequencies, two of the A_{2u} symmetry and three of the E_u symmetry. There are also two Raman-active modes with the E_g symmetry. The observed[2] and calculated frequencies are given in Tables 3 and 4, together with the intramolecular ones. The contribution (%) of each

a) Notations are the same as those in Tables 1 and 3. b) t, transverse; l, longitudinal. c) Coulomb term.

potential parameter to the frequencies was calculated for Model I; the results are shown in Table 5. Similar results were obtained for the rigid-ion model; examples are given in Tables 6 and 7 for only two distribution models. Note how the Coulomb term contributes to each lattice mode. Table 4 suggests that a good agreement is obtained over a wide range of charge distributions. Unlike the intramolecular vibration, the lattice vibration is mainly concerned with the relative motion of considerably separated groups; therefore, even with the point dipole approximation the dynamical properties of the system are described satisfactorily well.

Normal coordinate treatments have been made by several groups of authors[17] using the short-range interaction model. In addition to these, both the interaction of the vibrating dipoles and the influence of the electronic polarizability were taken into account respectively as the rigid-ion model and the shell model[18]

by Plihal *et al.*[19] They regarded the nitrate group as one bulky ion, the charge of which is located at the center of the goup, and analyzed the optically-active vibrations of three crystals of the calcite structure. Their rigid-ion calculations essentially correspond to those of Model II in this study. If one assumes this charge distribution, the influence of the long-range Coulomb interactions appears mainly in the translational lattice modes, and as is illustrated in Figs. 4 and 5, the Z-dependence of the vibrational frequencies is found to be monotonic. In spite of their rather crude approximation, a good agreement was obtained between the calculated and experimental results in the same manner as in the present investigation.

As is shown in Table 1, certain short-range force constants gradually changed; however, the magnitude, Z, of the effective charges was seen to fall into the range from 0.8 e to 0.9 e, regardless of the distribution parameter, x. Though the calculated TO–LO splittings appear to depend critically on Z rather than on x under these circumstances, the x-dependence of the calculated frequencies differs slightly from model to model. Some typical behavior is illustrated in Figs. 4 and 5. As far as the present investigation is concerned, the charge distribution model of $x=+1/5$ has given the best results. In this distribution, the effective charges on the atoms are $Z_{Na}=0.87\ e$, $Z_C=0.17\ e$, and $Z_O=-0.35\ e$. Those distribution models which have

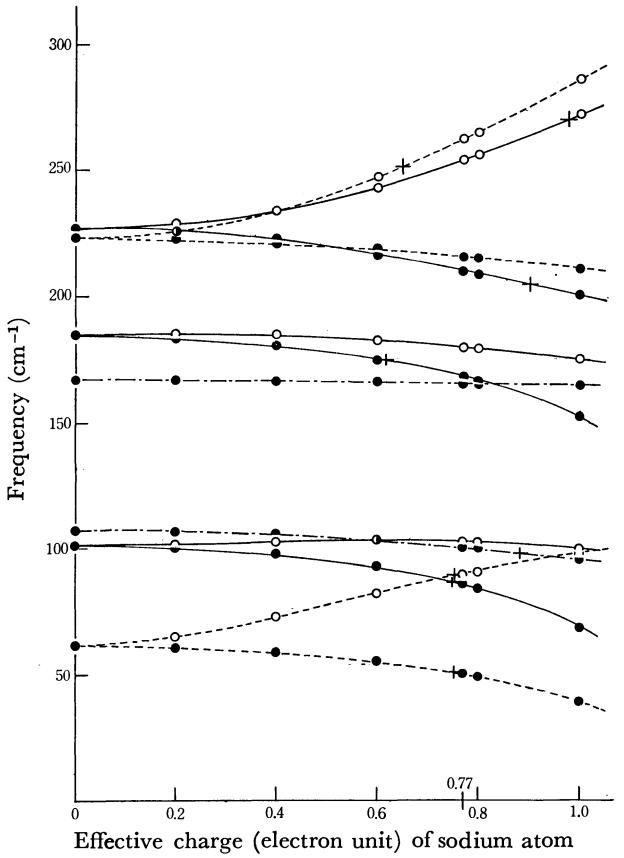

Fig. 4. Z-Dependence of optically-active lattice vibrations for $x=-1$.
(------), A_{2u}; (—·—), E_g; (——), E_u; ●, transverse mode; ○, longitudinal mode; +, observed frequency.

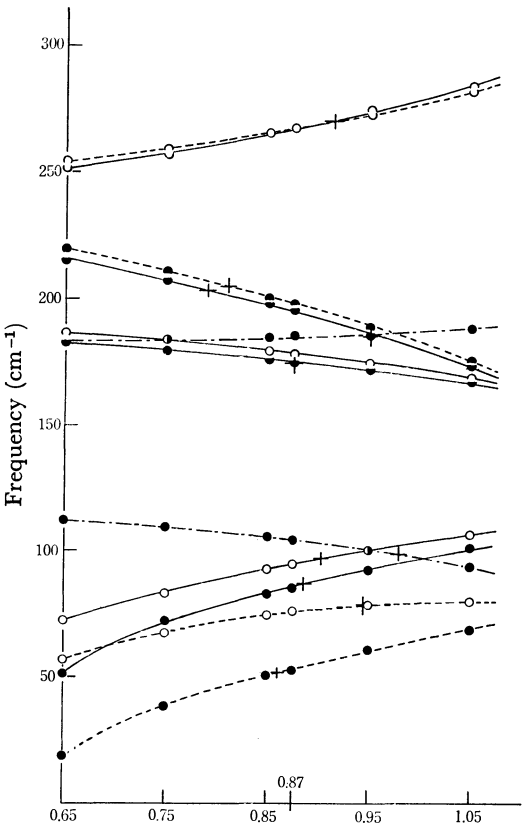

Fig. 5. Z-Dependence of optically-active lattice vibrations for $x=+1/5$. Other descriptions are the same as those in Fig. 4.

larger values of the x parameter than unity were found to give poorer results in this work. Though the above distribution is considered to be the best in this rigid-ion treatment, both the distribution parameter, x, and the magnitude, Z, might be altered in the higher-order models.

As to the short-range force constants, they have been considered in previous short-range interaction treatments to arise from the repulsive force; therefore, they must have positive values inherently. Because account was taken separately of the long-range Coulomb interactions in addition to the short-range ones, they do not necessarily have positive values. Therefore, the physical meaning of the force constants is considered to be essentially different from those in the previous treatments.

The charge distributions of various groups have been estimated from the studies of cohesive energy[20] and of electronegativity;[21] however, the results differ considerably both with the methods and with the investigators. Those obtained are, by nature, statical properties; consequently, they need not always coincide with those of the present dynamically-effective charges.

We wish to conclude this section by pointing out the following relation:

$$\sum_1^n(i)\omega_{i0}^2 = \sum_1^n(i)\omega_i^2(\boldsymbol{y}\to\boldsymbol{0}),$$

where the left and right sides are concerned with the frequencies of the equilibrium crystal field[16] and of the

rigid-ion approximation respectively, and where n is the number of the vibrational degrees of freedom.

Elastic Constant. The elastic constants of this crystal were determined long ago; the data of Bhimasenachar[3] have been most commonly referred to. Since the space group of the crystal belongs to D_{3d}^6, the independent non-zero elements are the following terms; C_{11}, C_{21}, C_{31}, C_{33}, C_{41}, and C_{44}.[22] Few attempts have been performed to make a theoretical calculation of the elastic constants of this crystal except for that by Shiro.[17c] The calculated and observed elastic constants are compared in Table 8. The contribution of the potential parameters was also calculated; it is given in Table 9. This table suggests that the predominantly contributing terms to each element are in the following manner: C_{11} and C_{21}, f_5; C_{31}, f_2; C_{33}, f_6; C_{41}, f_1 and f_2; C_{44}, f_2. It is thus verified, by the way, that weakly-interacting parts are greatly responsible for the elastic properties of the crystalline state.

Since the mode of contribution to the elastic properties is considered to be essentially independent of that to the vibrational properties, the more reliable force constants are to be obtained with reference to the two types of properties complementarily.

Finally, the resulting elastic constants are identified as the mechanical part, because all interactions except for the short-range ones were neglected in this treatment. Therefore, further work will be required to take the contributions from the other interactions[4] into consideration.

The authors wish to express their gratitude to Mr. Masaru Ohsaku of Hiroshima University for his critical reading of the preliminary manuscript and valuable suggestions, and also to Mr. Tamaki Utida of Hiroshima University for permitting them to use his program PEG0 and for his useful discussions and advice.

Radiation Chemical Studies with Cyclotron Beams. III. The Heavy-ion Radiolysis of Liquid Aliphatic Ketones

Masao MATSUI and Masashi IMAMURA

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received December 6, 1973)

The liquid-phase radiolysis of acetone, methyl ethyl ketone, and diethyl ketone with ^{4}He–, ^{12}C–, and ^{14}N–ions was carried out with the intention of discovering the specific reactions taking place in a very high LET region. The heavy ions were accelerated at various energies with an IPCR cyclotron, the LET of which was up to 80 eV/Å. The radiolytic yields of the main gaseous products, hydrogen and carbon monoxide, were found to increase appreciably with an increase in the LET and to reach the maximum values in the LET region between 50 and 70 eV/Å. The ratios of the two yields, $G(H_2)/G(CO)$, also increase substantially with an increase in the LET. These results, as well as the variations in the yields of saturated and unsaturated hydrocarbons, appear to indicate a thermal-spike effect which may bring about the thermal decomposition of free radicals, giving rise to the enhanced $G(H_2)$ and $G(CO)$ values in the high LET region.

We have been studying the radiolysis with heavy charged particles, helium, carbon, and nitrogen ions, accelerated with an IPCR 160 cm cyclotorn, the LET of which was in the range up to 80 eV/Å. In previous papers[1,2] the results of the heavy-ion radiolysis of aerated aqueous solutions of ferrous sulfate (Fricke solution) have been reported. The same procedures have also been applied to some neat organic liquids.

The aim of the present experiments is to elucidate the specific reactions induced by the interaction of energetic heavy ions with matter. Although no systematic studies of radiolysis with heavy ions have been reported, some unique results seem to reflect the specific reactions going on in the high LET region. For instance, as we[3] and other investigators[4,5] have found, the radiolytic yields of hydrogen from several organic liquids increase significantly in the high LET region, above several tens of eV/Å, irrespective of the variation in the yields in the lower LET region.[4,5]

These characteristic increases in the hydrogen yields seem not to be explainable solely on the basis of the spur-diffusion model nor the specific interaction near the end of the heavy-ion tracks.[4] Burns and his colleagues[5a] explained the increases in the decomposition yield of liquid benzene as being due to the bimolecular reaction between excited molecules which becomes important with an increase in the LET. This may be a reasonable explanation for the radiolysis in a medium LET region. On the basis of Burns' hypothesis, Voltz[6] explained a complementary correlation of the LET dependences of the radioluminescence and the radiolytic yield of liquid toluene.

In a very high LET region, the production of the energetic electrons by the knock-on collision of heavy ions may also affect the chemistry, as was suggested by Mozumder *et al.*[7] This effect has been demonstrated by us[3] to be effective in the interpretation of the discontinuities of the LET-dependence curves of $G(Fe^{3+})$ for the radiolysis of a Fricke solution with different kinds of heavy ions.

Another important effect which has been assumed, but not been definitely demonstrated, in the liquid-phase radiolysis with high LET radiations is the thermal-spike effect.[8] This effect, in fact, has occasionally been assumed in interpreting significant LET effects on the radiolysis of liquid aromatic compounds[9] and polycrystalline alkali nitrates,[10a] sodium chlorate,[10b] amino acids, and proteins.[11]

In γ radiolysis, the temperature at the center of a spur is assumed to be approximately 50—100° above the ambient temperature, and the duration of the heat may be less than 10^{-9} s, according to Magee,[12] who calculated using macroscopic parameters for the heat conductivity and the specific heat.

In a similar manner, Burns and Barker[13] estimated the temperature rise not only in a spherical spur but also in a cylindrical track, suggesting substantial thermal effects on the reactions in the very high LET region.

In this paper, we will report the results of our product analysis for the radiolysis of liquid acetone, methyl ethyl ketone, and diethyl ketone with carbon and nitrogen ions; these results suggest that the thermal-spike effect plays a role in the very high LET region.

Experimental

Materials. Reagent-grade acetone (Wako Pure Chem. Ind.), methyl ethyl ketone (Junsei Pure Chem. Co.), and diethyl ketone (Koso Chem. Co.) were dried and purified by distillation in the presence of $CaSO_4$ using a 50 cm stainless steel helix-packed column. Since a trace of water has been shown to affect the product yields,[14–16] meticulous care was taken to remove the water as completely as possible. The purified ketones were degassed thoroughly and distilled into a storage bulb through a tube filled with Molecular Sieve 4A.

Irradiation Cells. The irradiation cell shown in Fig. 1 was made of Pyrex glass and had a thin aluminum-foil (13—70 μ) window for heavy-ion irradiation which was fixed in place with a screwed brass keeper. A platinum lead was connected to the ground through a current integrator. The sample was then placed in the reservoir side of the cell by distillation *in vacuo* and was then further degassed by conventional freezing-pumping-thawing cycles before being transferred into the cell. For ^{60}Co-γ irradiation, Pyrex glass tubes (1.0 cm in O.D. and 20 cm high) were used.

Irradiation. The irradiation arrangement and the experimental procedure for the cyclotron experiments were essentially the same as those described previously.[2,3] The charged particles used were helium, carbon, and nitrogen ions accelerated with the IPCR 160 cm cyclotron. The energies of these particles entering the samples were:[17]

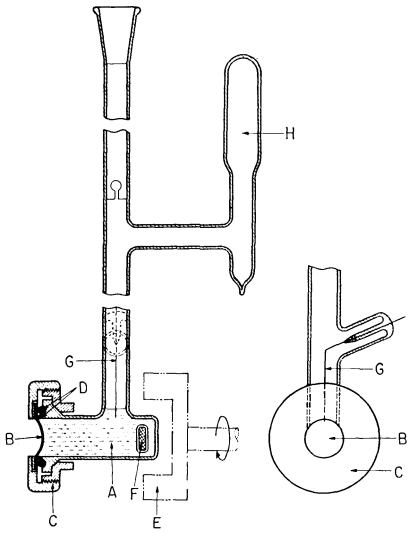

Fig. 1. Irradiation cell. A: Sample, B: Aluminum-foil window, C: Screwed brass keeper, D: Teflon rings, E: Rotating magnet, F: Stirrer, G: Platinum lead, H: Reservoir.

6.9—21.3 MeV for helium ions, 22.0—67.3 MeV for carbon ions, and 18.0—68.0 MeV for nitrogen ions, corresponding to the initial LET between 6—80 eV/Å. The current intensities were usually ~1 nA, and the total doses were in the range of $(3—10)\times10^{19}$ eV. The samples were stirred vigorously during irradiation by means of a magnetic stirrer. The ambient temperature was ~22 °C.

γ-Irradiation was carried out using a 10 kCi ^{60}Co source at a dose rate of 4.66×10^{17} eV/g min and at a total dose of up to 4.5×10^{19} eV/g.

Analysis. Gaseous products from irradiated samples were collected by using a Toepler pump. Since the hydrocarbons were found not to be degassed completely from the irradiated samples by conventional freezing-pumping-thawing cycles, we used a micro-refluxing column cooled with ice, through which the hydrocarbons were pumped out. Gas chromatographic analyses were applied to the gaseous products, H_2, CO, CH_4, C_2H_4, C_2H_6, C_3H_6, C_3H_8, and n-C_4H_{10}; analyses of the liquid products were not performed.

Energy-loss Parameter. In the present paper, the product yields are represented as a function of the energy-loss parameter, z, defined as:

$$z = \frac{1}{E}\int_0^E \left(-\frac{dE}{dx}\right) dE$$

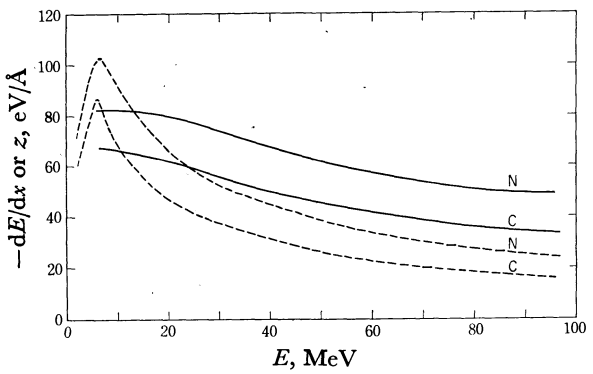

Fig. 2. Instantaneous LET (broken lines) and energy-loss parameter, z, (solid lines) for liquid acetone (20 °C) as a function of particle energy.

The values of the stopping power, $-dE/dx$, for ketones were obtained by multiplying those for water calculated by Northcliffe[18,19] by the densities of the ketones. The integration was carried out graphically; examples of z as a function of the particle energy are shown in Fig. 2.

Results

Some typical data of the product yields determined for the helium, carbon, and nitrogen ions are listed in Table 1, along with those for γ rays. The yields of the two main products, H_2 and CO, from three γ-radiolyzed ketones are reduced by 20 and 10% respectively in the presence of $I_2(10^{-2}$ M). These results, consistent with the results obtained by other workers,[15,20a] indicate that H_2 and CO are formed principally within the γ-ray spurs; therefore, in the radiolysis with carbon and nitrogen ions of high LET's, they may reasonably be assumed to be formed mostly within dense ionization tracks.

In the γ radiolysis, neither a dose nor a dose-rate

dependence was observed in the ranges under study for any ketone. A detectable dose-rate dependence was not observed at intensities between 1 and 3 nA in the heavy-ion radiolysis, either.

The γ-radiolytic yields of H_2 and CH_4 from acetone containing a small amount of water were found to be substantially higher than those for dried acetone reported here, in agreement with those obtained by Barker and Noble;[14] the detailed results over a wide LET range will be communicated elsewhere.

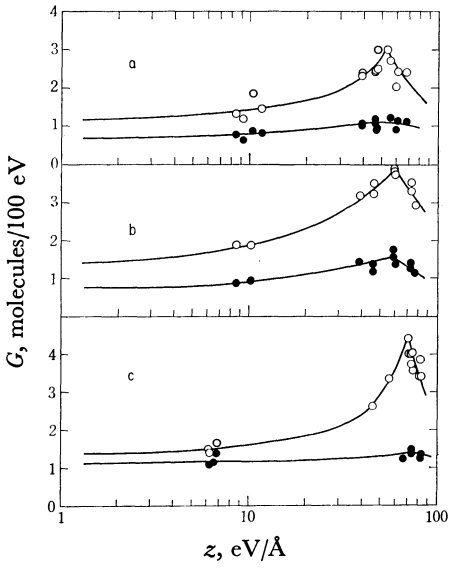

Fig. 3. Variations of $G(H_2)$ and $G(CO)$ with z. Open circles: H_2, closed circles: CO. a: acetone, b: methyl ethyl ketone, c: diethyl ketone. Yields in the vicinity of 10 eV/Å obtained with He-ions and those in the higher region with C- and N-ions.

Figure 3 shows the dependences with z of the yields of H_2 and CO for the three ketones. The yields for the γ and helim-ion radiolysis are those obtained with iodine solutions ($(3.5—7.0)\times10^{-3}$ M) in ketones; all the other yields are those with neat ketones. It should be noted that the maximum yields of H_2 and CO appear for every ketone in the very high LET region.

Discussion

Radiolysis studies of liquid acetone have been carried out by many workers,[14-16,20-25] and the ionic and the free-radical reaction mechanisms have been pointed out to be of importance. For higher ketones, one can expect reactions analogous to those of acetone.[24] Based on the reaction mechanisms proposed so far, one can reasonably assume the pathways producing hydrogen and carbon monoxide to be as follows.

A large portion of these main gaseous products are apparently formed, as may be seen from the results described above, *via* "molecular" mechanisms, even in the γ radiolysis; that is, they are formed in the spur or track region without any influence of radical scavengers. Hydrogen is presumably produced by the abstraction reaction of the hot and/or thermal hydrogen atoms which are formed by the fragmentation of the excited ketone molecules and excited ionic species resulting from the ion-molecule reactions. As will be mentioned below, hydrogen atoms are considered to be produced also by the decomposition of free radicals inside the tracks of the high LET radiations.

According to the results of photochemical studies of acetone, the excited states dissociate by these reactions:[26]

$$CH_3COCH_3^* \longrightarrow CH_3CO + CH_3 \quad (1)$$
$$CH_3COCH_3^* \longrightarrow 2CH_3 + CO \quad (2)$$
$$CH_3COCH_3^* \longrightarrow CH_2COCH_3 + H \quad (3)$$

Carbon monoxide may also be produced if acetyl radicals undergo dissociation:

$$CH_3CO \longrightarrow CH_3 + CO \quad (4)$$

Reaction (4), however, will proceed only at high temperatures because of its relatively high activation energy (13—18 kcal mol^{-1} [27,28]). Ionic reaction mechanisms producing carbon monoxide have not yet been elucidated.

As is shown in Fig. 3, both $G(H_2)$ and $G(CO)$ increase with an increase in z, reaching their maximum values at z=50, 60, and 70 eV/Å respectively for acetone, methyl ethyl ketone, and diethyl ketone. The increases in $G(H_2)$ and $G(CO)$ below the peak z's may be explained at least partly in terms of the increasing contributions of the reactions between excited ketone molecules in the dense radiation tracks, which have been proposed by Burns and his co-workers[5] for the radiolysis of benzene with high LET radiations. It should, however, be noted that, in the present study, the ratios of $G(H_2)$ to $G(CO)$ also increase from about 2(at z= 10—20 eV/Å) to about 3(at z=70—80 eV/Å) with an increase in z for the three ketones investigated. This result cannot be explained completely by the spur-diffusion model, which is based on a simple competition between the diffusion and the reaction of radicals or excited ketone molecules formed in an LET-independent step.

In order to find clues for the explanation of these significant results, the values of $G(H_2)\times z$ and $G(CO)\times z$ are plotted as a function of z in Fig. 4. The $G\times z$-value gives a measure of the number of molecules produced per 100 Å of a radiation track (G is the number of molecules produced per an absorbed energy of 100 eV). Figure 4 apparently indicates that the values of $G(CO)\times z$ almost level off above the given z's for the three ketones, whereas those of $G(H_2)\times z$ do not do so. The plateau values for $G(CO)\times z$ are estimated to be 100 ± 20.

The number of CO molecules produced should obviously not exceed the number of ketone molecules decomposed. In the γ radiolysis of liquid acetone, some oxygen-containing compounds other than carbon monoxide are produced, and their yields are greatly reduced in the presence of a radical scavenger (I_2),[15] indicating that these products are formed in the bulk. In the higher LET region, the yields of these compounds must decrease, and presumably carbon monoxide will be the main oxygen-containing product.

If this assumption is accepted, the number of CO molecules produced in the very high LET region can be said to be approximately equal to the number of

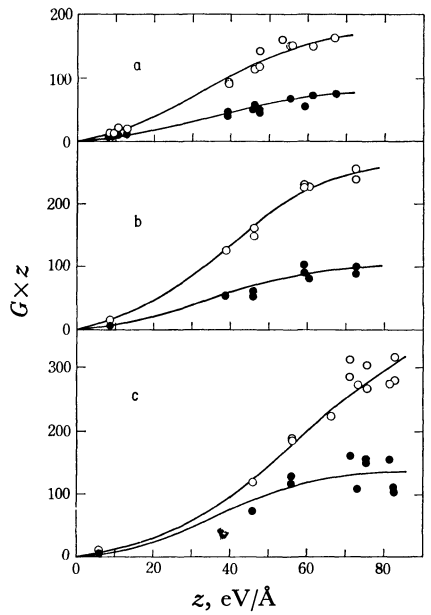

Fig. 4. Plots of $G \times z$ *vs.* z. Symbols have the same meaning as for Fig. 3.

ketone molecules decomposed. The nearly saturated curves of $G(CO) \times z$ in Fig. 4 thus indicate that the numbers of ketone molecules decomposed are limited above the given z-values: *ca.* one molecule of ketone per Å of a radiation track. The appearance of the maximum $G(CO)$ and $G(H_2)$ in Fig. 3 may be explained on the basis of such a saturation phenomenon, which has not been observed for other compounds.

The different behavior of the $G(H_2) \times z$-curves from that of $G(CO) \times z$ in Fig. 4 implies that the formation of hydrogen is still taking place more or less even after the decomposition producing carbon monoxide is "saturated." The fact that the $G(H_2)/G(CO)$ ratios increase steadily with an increase in z may support the above arguments.

Although we have not yet reached a definite conclusion, the thermal decomposition of alkyl radicals in the high temperature zones within the tracks (thermal spikes) or the formation of highly excited states of ketone molecules, thus giving rise to more hydrogen, seems to account for the increases in $G(H_2)/G(CO)$ in the high LET region.

In fact, the activation energies of the decomposition of alkyl radicals ($C_nH_{2n+1} \rightarrow C_nH_{2n}+H$) are known to be $\sim$30 kcal mol^{-1},[28] much higher than those of $C_nH_{2n+1}CO$ ($\rightarrow C_nH_{2n+1}+CO$). Therefore, the decomposition of alkyl radicals, if any, should be expected to take place only in the very high LET region where excess energies are dissipated as heat, giving rise to the formation of more hydrogen as well as that of unsaturated hydrocarbons.

The alternative explanation is the probable formation of highly (vibrationally or electronically) excited states which may form in the very high LET region and may decompose differently from the lower excited states produced in the lower LET region. The present results do not provide decisive information which can distinguish between these two proposed mechanisms; further studies are, therefore, in progress along these lines.

The authors wish to express their thanks to Dr. Takashi Karasawa for his useful suggestions throughout this study and to Messrs. Toshi Kumagaya and Yutaka Oshiro for their assistance. Thanks are also due to the members of the IPCR cyclotron operation group.

The Crystal Structure of (±)-1-Benzyl-5-phenyl-1-azacycloheptan-4-one Hydrochloride, $C_{19}H_{21}NO \cdot HCl$

Keiichi FUKUYAMA,* Shozo SHIMIZU, Setsuo KASHINO, and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received December 6, 1973)

The crystal structure of (±)-1-benzyl-5-phenyl-1-azacycloheptan-4-one hydrochloride has been determined by the heavy-atom method from three-dimensional X-ray data. The crystals are monoclinic, space group $P2_1/c$, with four formula units in a unit cell of dimensions: $a=5.967(8)$, $b=11.20(1)$, $c=25.96(2)$ Å, and $\beta=93.8(3)°$. The structure was refined by the block-diagonal least-squares method to an R index of 0.076 for 1299 independent observed reflections. The benzyl and phenyl groups are bonded equatorially to the azacycloheptanone ring which takes a chair-like conformation. The chloride ion is hydrogen-bonded to the ring nitrogen atom at a distance of 3.075(4) Å.

The title compound $C_{19}H_{21}NO \cdot HCl$ has been prepared by Morosawa[1] at this Department as an intermediate material in the course of synthetic study of seven-membered azacyclic compounds. It is of our interest to compare the conformation of the azacycloheptanone ring with that of the azacyclic six-membered rings, say, piperidine[2] and piperazine.[3] The existence of N–H···Cl hydrogen bond is of additional interest in this work.

Experimental

The crystals supplied by Dr. Shiro Morosawa were thin transparent plates having well developed {001}. Cell constants were obtained from the rotation and Weissenberg photographs taken with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å).

Crystal data:

(±)-1-Benzyl-5-phenyl-1-azacycloheptan-4-one hydrochloride $C_{19}H_{21}NO \cdot HCl$ F.W. 315.8, Mp 225 °C (decomposed)[1] Monoclinic, space group $P2_1/c$.

Systematic absences; $h0l$ when l odd, $0k0$ when k odd.

$a=5.967(8)$, $b=11.20(1)$, $c=25.96(2)$ Å, $\beta=93.8(3)°$

$V=1731$ Å^3, $Z=4$, $D_c=1.21$, $D_m=1.22$ g/cm^3 (by flotation)

μ (for Cu$K\alpha$) $=19.7$ cm^{-1}, $F(000)=672$.

The reflections were collected with Cu$K\alpha$ radiation by means of equi-inclination Weissenberg techniques for the layers from $0kl$ to $4kl$. The intensities of 1299 independent reflections were measured visually and corrected for the Lorentz and polarization factors and for spot shape. No corrections were made for absorption.

Structure Determination and Refinement

The coordinates of the chloride ion were deduced from a three-dimensional Patterson map. All the remaining non-hydrogen atoms were located in a subsequent heavy-atom Fourier map. The structure was refined by the block-diagonal least-squares method,[4] with anisotropic temperature factors for the chloride ion, to the conventional R index of 0.121. Excluding the reflections, 021, 111, 121, and 13$\bar{1}$, which were considered to suffer from extinction effect, the difference map revealed all the twenty-two hydrogen atoms.

Further least-squares refinement with anisotropic temperature factors for the non-hydrogen and with isotropic ones for the hydrogen atoms was carried out by using the weighting scheme:

$$w = 0.0 \quad \text{for } F_o < F_{min} \ (=3.6)$$

$$w = 1.0 \quad \text{for } F_{min} \leq F_o \leq F_{max} \ (=18.0)$$

and

$$w = (F_{max}/F_o)^2 \quad \text{for } F_{max} < F_o$$

The final R index was 0.076 for 1299 observed reflections.

The atomic scattering factors were taken from International Tables for X-Ray Crystallography.[5] The computations were performed on a NEAC 2200-700 computer at the Computation Center of Osaka University and on a NEAC 2200-500 computer at the Okayama University Computer Center.

Results and Discussion

The observed and calculated structure factors are given in Table 1. The final positional and thermal parameters together with their estimated standard deviations are given in Tables 2 and 3. Bond lengths and angles are shown in Fig. 1 and the stereoconfiguration drawn by the plotting program ORTEP[6] is illustrated in Fig. 2. The aromatic C–C bond lengths in the benzyl (B) and phenyl (C) groups are normal, their average values being 1.384 and 1.382 Å with maximum deviations of 0.020 and 0.038 Å, respectively. It should be noted that the bond angles of the C(sp^3) in the azacycloheptanone ring (A) range from 113.4 to 115.4° and are significantly larger than those found in piperidinium p-hydroxybenzoate (109.5 to 110.7°)[2] and in piperazinium terephthalate (110.1 to 111.0°).[3] The average C(sp^3)–C(sp^3) bond length in the ring A is 1.537 Å with maximum deviation of 0.005 Å. The C–N bond lengths, 1.494 and 1.506 Å, are close to those found in the piperidinium (1.494, 1.501 Å) and in the piperazinium (1.486, 1.494 Å) ions, but slightly differ from those in azacyclododecane hydrochloride (1.529, 1.536 Å)[7] and in 2,2,6,6-tetramethyl-4-piperidone hydrochloride (1.504, 1.533; 1.523, 1.526 Å).[8] Geometry of the carbonyl group is compared with that in some saturated cycloketones in Table 4. In the present compound, the C(4) atom deviates only by 0.02 Å from the plane through the C(3), C(5), and O(8) atoms and the C(3)–C(4)–C(5) bond angle is

2,2,6,6-Tetramethyl-4-piperidone hydrochloride[8)]	1.221	1.490	1.508	113.3
3-Bromo-2-decalone[12)]	1.25	1.48	1.52	113.4

a) This work.

$$0.5517X + 0.7942Y - 0.2546Z + 3.5414 = 0 \quad (3)$$

with maximum deviation of 0.008 Å. The ring A takes a chair-like conformation, the N(1) atom deviating by +0.682 Å, C(5) −1.119 Å and C(4) −1.135 Å from the plane (3). The N(1) and C(5) atoms are bound equatorially to the benzyl and phenyl groups, respectively. The C(9) atom of benzyl group deviates by 0.068 Å out of the plane (1).

The chloride ion is hydrogen-bonded to the N(1) atom (N(1)···Cl=3.075(4) Å) which exhibits a nearly tetrahedral hybridization, as shown in Fig. 3. Such short hydrogen bonds have also been reported for methixene hydrochloride monohydrate (3.051 Å),[15)] azacyclododecane hydrochloride (3.061 and 3.069 Å),[7)] lidocaine hydrochloride monohydrate (3.07 Å),[16)] 1-(1-phenylcyclohexyl)piperidine hydrochloride (3.088 Å),[17)] 1-methylcytosine hydrochloride (3.1 Å),[18)] and triethylammonium tetrachlorocuprate (3.11 Å).[19)]

The projection of the crystal structure viewed along the a axis is shown in Fig. 4, together with some short contacts between the molecules. The enantiomorphs occur through the medial center of symmetry. The environment around the chloride ion is shown in Fig. 5, in which the C(12^{i})···C(9^{vii}) distance 3.460 Å is the shortest C···C contact. The bulky azacycloheptanone cations and the chloride anions may be held together mainly by Coulombic interactions and hydrogen bonding to form the sheets parallel to the *ab* plane. The sheets are stacked along the *c* axis by van der Waals forces. These are in accordance with relatively high melting point and morphology of the crystal.

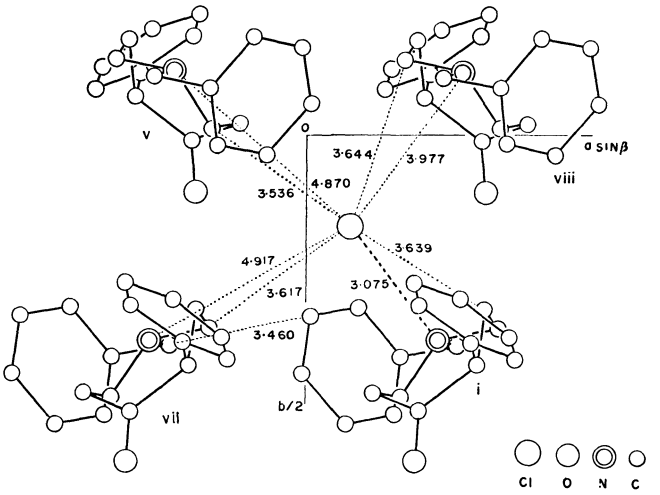

Fig. 5. The environments around the chloride ion. The estimated standard deviations of the distances are of the order of 0.005 Å.
Key to molecules. i: x, y, z. v: $-x, -1/2+y, 1/2-z$. vii: $-1+x, y, z$. viii: $1-x, -1/2+y, 1/2-z$.

Counterion Effect on the Titration Behavior of Poly(itaconic acid)

Nobuhiko MUTO

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

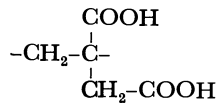
(Received November 26, 1973)

The effect of counterions on the titration behavior of poly(itaconic acid) (PIA) was studied by titrating PIA in aqueous solutions containing alkali metal salts and a tetramethylammonium salt at 25 °C. The acidity of the primary carboxylic groups of PIA increases in the order $(CH_3)_4N^+<Li^+<Na^+<K^+$, whereas that of the secondary carboxylic groups increases with the decrease in the crystallographical radii of the counterions, in the order $(CH_3)_4N^+<K^+<Na^+<Li^+$, in agreement with the results for ordinary polycarboxylic acids. The order $K^+>Na^+>Li^+$ on the binding strength to the primary carboxylate groups in the first dissociation step is interpreted in terms of the radii of the hydrated cations; it can be ascribed to the stable ring structure of the monoanion of the itaconic acid residue, resulting from the hydrogen bonding between two adjacent carboxylate groups. In apparent complete dissociation, about 80, 60, and 40% of the itaconate residues bind to Li^+, Na^+, and K^+ ions, respectively, when it is assumed that no $(CH_3)_4N^+$ ions are bound to the carboxylate groups.

The specific effect of counterions on the titration behavior of weak polyelectrolytes is of interest in connection with the selective accumulation of specific ions in biological systems. This can be ascribed to the counterion binding by the polyion with an enormously high electrostatic potential. For polycarboxylic acids, the counterion effect has been studied extensively.[1-7] Gregor and Frederick,[1] and Kagawa and Gregor[2] demonstrated that the acidity of ordinary polycarboxylic acids, *e.g.*, poly(acrylic acid) and poly(methacrylic acid), decreases with the increase in the counterion size; that is, the alkali metal ions are bound to the polyanions in the affinity order $Li^+>Na^+>K^+$. Similar phenomena have been observed with viscosity,[3] conductivity,[3,4] counterion activity,[5] counterion mobility,[6] and dilatometry[7] in alkali metal polycarboxylate systems.

Recently, some investigators[7,8] have dealt with the specific binding of the alkali metal ions with the anions of maleic acid copolymers. The counterion binding for polydicarboxylic acids, however, has not yet been clarified. From a study of the effect of the counterions on the titration behavior of poly(maleic acid), it was found that the binding strength of the alkali metal ions to the primary carboxylate groups decreases in the order $K^+>Na^+>Li^+$, whereas that to the secondary ones $Li^+>Na^+>K^+$.[9] The latter finding agrees with those for ordinary polycarboxylic acids. On the other hand, the affinity order in the first dissociation step is interpreted in terms of the radii of the hydrated cations; it can be attributed to the hydrogen-bonded ring structure of the monoanion of the maleic acid residue.[9]

The present study is concerned with poly(itaconic acid) (PIA):



The number of carbon atoms between two adjacent carboxylic groups in the itaconic acid residue is equal to that in the maleic acid group. The author has synthesized PIA and carried out potentiometric titrations in aqueous solutions containing salts. The effect of Li^+, Na^+, K^+, and tetramethylammonium ions $(CH_3)_4N^+$, on the titration behavior of PIA, in particular the binding of the alkali metal ions to the primary and secondary carboxylate groups of PIA, is reported herewith.

Experimental

Materials. The PIA sample was prepared by the procedures of Marvel and Shepherd,[10] and Sakurada *et al.*[11] as follows. Itaconic acid was recrystallized in water[12] twice before use. The itaconic acid was polymerized in a 0.5 mol/l HCl solution containing 20 wt% monomer and 0.1 wt% potassium peroxysulfate at 50 °C for 140 hr under a nitrogen atmosphere. The reaction mixture was then added slowly dropwise to acetone to precipitate the polymer. The PIA was separated by filtration, redissolved in water, reprecipitated in acetone, and dried *in vacuo* at 35 °C. white powdery product was obtained in a 20% yield. Found: C, 45.08; H, 4.86%. Calcd for $(C_5H_6O_4)_n$: C, 46.16; H, 4.65%. The polymer seems to be slightly hydrated.[10] Figure 1 shows the dependence of the reduced viscosity of aqueous PIA solutions on polymer concentration. The molecular weight of the present PIA sample may be estimated to be about 10^5, by comparison with the viscosity data of

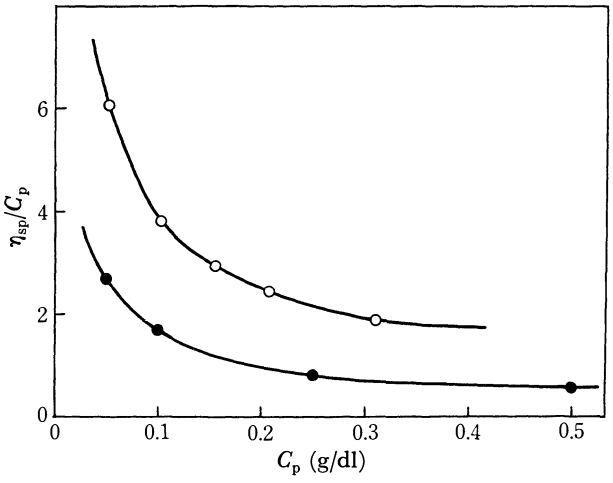


Fig. 1. The dependence of the reduced viscosity (η_{sp}/C_p) of aqueous PIA solutions on polymer concentration (C_p) at 25.0 °C. ○: present PIA and ●: PIA by Marvel and Shepherd.[10]

the PIA sample obtained by Marvel and Shepherd[10] who estimated it to be about 5×10^4. A concentrated aqueous PIA solution (*ca.* 1 wt%) was stored in a polyethylene container at 5 °C.

Carbonate-free titrants, NaOH and LiOH solutions, were prepared. The neutral salts added, $LiNO_3$, $NaNO_3$, KNO_3, and tetramethylammonium chloride, $(CH_3)_4NCl$, were thoroughly dried at 110 °C or *in vacuo* prior to weighing. All the chemicals used were of a guaranteed reagent grade. All the aqueous solutions were prepared by the use of deionized water.

Potentiometric Titrations. The pH values were measured with a Yokogawa KPH-51A pH meter equipped with Toadenpa HG-4005 glass and HC-205 calomel electrodes separated by a saturated KCl-agar salt bridge. The titrations were carried out in a special titration vessel maintained at 25.0±0.05 °C under a nitrogen atmosphere. It was found that the acid-base equilibrium was not immediately attained in the region around the half-neutralization point of PIA. The tendency was more pronounced in the case of the PIA solution without added salts. Similar phenomena have been observed in the cases of poly(maleic acid)[9] and other polyacids.[13,14] In this region, the solutions were stirred for 15 min—1 hr after each addition of a certain amount of the base until the pH readings became constant. The repeated titration curves were reproducible to within±0.01 pH unit.

Results and Discussion

pH Titration Curves. The pH titration curves of PIA with NaOH in 0.1 mol/l solutions of four kinds of 1-1 salts are shown in Fig. 2, where α' is the degree of the neutralization of the carboxylic groups of PIA (originally proportional to the gram equivalent numbers of the added base). Each titration curve has an inflection point at the same degree of neutralization ($\alpha'=1.0$), which corresponds to the equivalence point

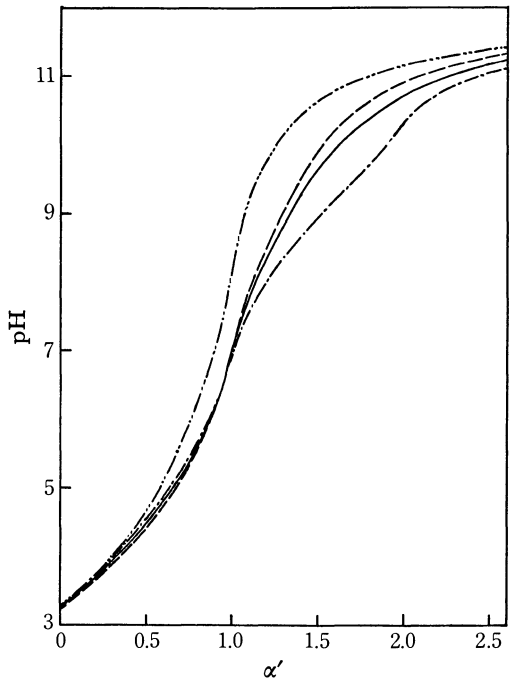

Fig. 2. The pH titration curves of 3.79×10^{-3} monomol/l PIA with NaOH in 0.1 mol/l $LiNO_3$ (·····), $NaNO_3$ (——), KNO_3 (------), and $(CH_3)_4NCl$ (-·-·-·-).

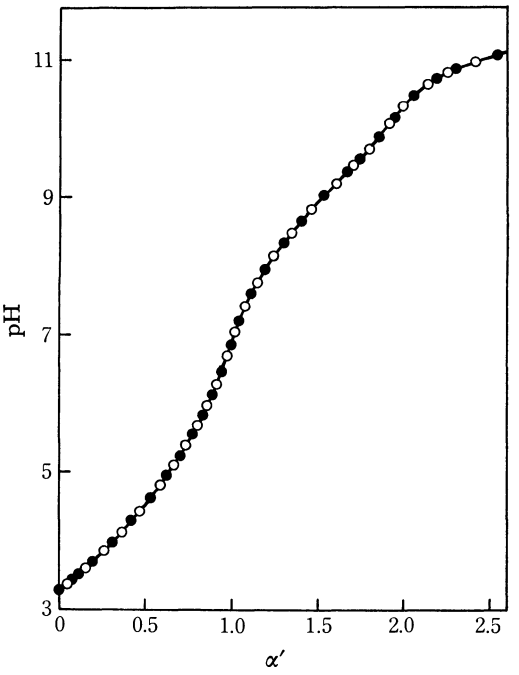

Fig. 3. The pH titration curves of 3.79×10^{-3} monomol/l PIA in 0.1 mol/l $LiNO_3$ with LiOH (○) and with NaOH (●).

of the primary carboxylic groups of PIA. The end point of the secondary ones ($\alpha'=2.0$) lies in a high pH region. Thus, no definite inflection points are observed, though a somewhat obscure inflection point is noticed in the PIA–$LiNO_3$ system (Figs. 2 and 3). It has been found that the carboxylic groups of PIA dissociate in two distinct steps,[11,15] whereas the titration curve of monomeric itaconic acid has an inflection point only at $\alpha'=2.0$.

The precise concentration of PIA, expressed in monomol/l (one monomole contains one itaconic acid residue), was determined from the gram equivalent numbers of the base added up to the first inflection point, already designated in $\alpha'=1.0$. This concentration was in fair agreement with that predicted from gravimetry of the aqueous stock solution of PIA. It has been confirmed that the PIA obtained by radical polymerization in an aqueous HCl solution has a linear chain structure consisting of repeated itaconic acid units.[10,11,16,17] Thus, in the later analysis of the dissociation behavior of PIA, it could be assumed that the amount of the secondary carboxylic groups is equal to that of the primary ones in the present PIA sample.

The added salt concentration (0.1 mol/l) is much higher than that of polyacid (*ca.* 10^{-3} monomol/l) (Fig. 2). Thus, the dissociation behavior of PIA must be substantially influenced by the cations of added salts, in spite of the use of NaOH as a titrant. For the sake of confirmation, the PIA solution in 0.1 mol/l $LiNO_3$ was titrated with LiOH as well. The titration curves with NaOH and with LiOH in 0.1 mol/l $LiNO_3$ are both in excellent agreement, as shown in Fig. 3. Such a titration procedure with NaOH in solutions containing different added salts is useful for examination of the

counterion effect, since preparing different bases so that they are carbonate-free and at approximately the same concentration is troublesome.

The effect of the four cations in the first dissociation step of PIA seems to differ from that in the second one (Fig. 2). In the second step ($\alpha' \geq 1.0$), the pH values at a given α' decrease obviously in the order $(CH_3)_4N^+ > K^+ > Na^+ > Li^+$, in agreement with the cases of ordinary polycarboxylic acids.[1,2] On the other hand, in the first step a peculiar effect of the alkali metal ions is observed; the pH values decrease in the order $(CH_3)_4N^+ > Li^+ > Na^+ > K^+$. The present findings are entirely analogous to those in the first and second dissociation steps of poly(maleic acid).[9]

Apparent Dissociation Constants. In order to characterize the counterion effect on the titration behavior of PIA, the apparent acid-dissociation constants (K_1 and K_2) of the primary and secondary carboxylic groups were calculated from the curves in Fig. 2, by the following equations:

$$pK_1 = pH + \log \frac{1-\alpha_1}{\alpha_1} \quad (1)$$

$$pK_2 = pH + \log \frac{1-\alpha_2}{\alpha_2} \quad (2)$$

where α_1 and α_2 are the degrees of dissociation of the primary and secondary carboxylic groups, respectively. The α_1 and α_2 values were determined on the basis of the electroneutrality and conservation conditions in acidic and alkaline solutions, respectively;

$$\alpha_1 = \frac{[NaOH]+[H^+]}{[A_t]} = \alpha' + \frac{[H^+]}{[A_t]} \quad (3)$$

$$\alpha_2 = \frac{[NaOH]-[A_t]-[OH^-]}{[A_t]} = \alpha' - 1 - \frac{[OH^-]}{[A_t]} \quad (4)$$

where [NaOH] is the molarity of the added titrant diluted in test solutions, and $[A_t]$ the total concentration of the itaconic acid residues, expressed in monomol/l; $[H^+]$ and $[OH^-]$ are values calculated from the measured pH values and the ionization constant of water,[18] with corrections for the activity coefficients ($y_{H^+}=0.83$ and $y_{OH^-}=0.76$ at the ionic strength of 0.1[19]). It is well-known that the apparent dissociation constants for weak polyacids continuously decrease with the increase in the degree of dissociation, that is, the increase in the charge on a polymer chain.[20]

Figures 4 and 5 show the pK_1 *vs.* α_1 and pK_2 *vs.* α_2 curves, respectively. The plots were omitted in the regions of $\alpha_1 \geq 0.9$ and $\alpha_2 \leq 0.1$ around the half-neutralization point of PIA, where Eqs. (1) and (2) hardly hold. The pK_1 values at a given α_1 are seen to decrease in the order $(CH_3)_4N^+ > Li^+ > Na^+ > K^+$, and the pK_1 curves in the presence of the alkali metal ions deviate to a greater extent from each other in the region of $0.3 \leq \alpha_1 \leq 0.6$ (Fig. 4). On the other hand, the pK_2 values at a given α_2 decrease in the order $(CH_3)_4N^+ > K^+ > Na^+ > Li^+$, the differences in the pK_2 values with the counterions being much greater than in the pK_1 values, and the effect of the alkali cations increasing with the increase in α_2 (Fig. 5).

Table 1 gives the average dissociation constants ($pK_{1,av}$ and $pK_{2,av}$) with the dffierent counterions;

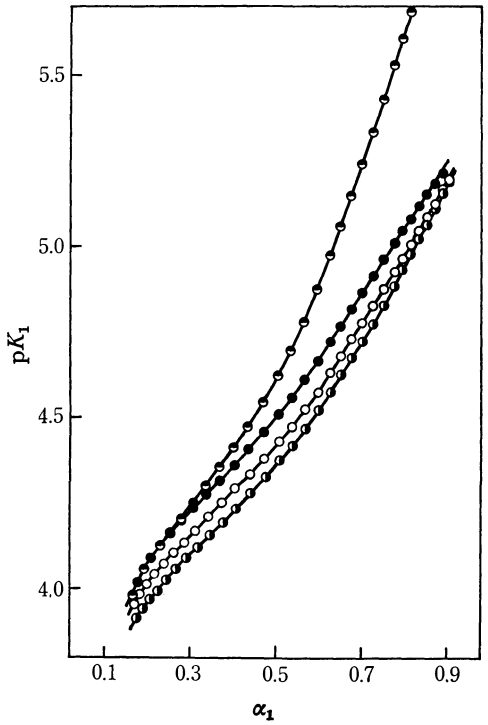

Fig. 4. The dependence of pK_1 on α_1, calculated from the curves in Fig. 2. ●: $LiNO_3$, ○: $NaNO_3$, ◑: KNO_3, and ◓: $(CH_3)_4NCl$.

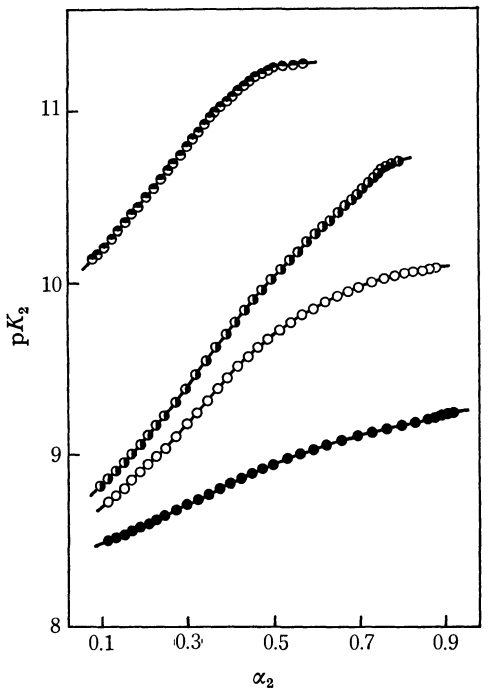

Fig. 5. The dependence of pK_2 on α_2, calculated from the curves in Fig. 2. ●: $LiNO_3$, ○: $NaNO_3$, ◑: KNO_3, and ◓: $(CH_3)_4NCl$.

the pK_1 values at $\alpha_1=0.5$ and pK_2 values at $\alpha_2=0.5$, respectively, were determined in Figs. 4 and 5. The differences in $pK_{1,av}$ with the counterions (0.06—0.12) are sufficiently larger than the estimated accuracy of pK (0.02), and hence the order of the decrease in the $pK_{1,av}$ is regarded as significant. On the other hand,

Table 1. Average dissociation constants of the primary and secondary carboxylic groups of PIA[a] in 0.1 mol/l added salts

Counterion	$pK_{1,av}$	$pK_{2,av}$
Li^+	4.50	8.95
Na^+	4.42	9.70
K^+	4.36	10.04
$(CH_3)_4N^+$	4.62	11.26

a) 3.79×10^{-3} monomol/l

such marked differences in $pK_{2,av}$ with the counterions (*e.g.*, 1.22 between K^+ and $(CH_3)_4N^+$ ions) are not known for other polycarboxylic acids. For example, the difference in pK_{av} between K^+ and $(CH_3)_4N^+$ ions for poly(acrylic acid) is 0.33 under the same conditions as the ionic strength of 0.1.[1] As for monomeric itaconic acid, the two dissociation constants have been reported to be $pK_{a,1}=3.68$ and $pK_{a,2}=5.14$ at the ionic strength of 0.1 ($NaClO_4$) at 25.0 °C.[21] Because of the increasing difficulty in the removal of protons from polyions with an enormously high electrostatic potential, the pK_{av} values of polyacids are higher than the pK_a values of the corresponding monomeric acids. Even if the effect is taken into account, the $pK_{2,av}$ values are considerably higher than the $pK_{a,2}$ of itaconic acid. Consequently, it is presumed that the protons of the secondary carboxylic groups of PIA tend to be bound to the adjacent primary carboxylate groups in each itaconic acid residue. Similar findings have been presented for poly(maleic acid).[9]

In order to support this presumption, the dependence of the titration behavior of PIA on the ionic strength in aqueous solutions was examined. Figure 6 shows the pK_1 *vs.* α_1 curves of PIA in water and in the presence of $NaNO_3$ (0.01 and 0.1 mol/l), derived from the corresponding pH titration curves according to Eqs. (1) and (3). In the cases of ordinary weak polyacids which are free from a conformational transition with the dissociation, the dependence of the apparent dissociation constant (pK) on the degree of dissociation can be represented by a second-degree polynomial.[22] The dependence in the first dissociation step, however, appears to be represented by an at least third-degree polynomial (Fig. 6). Similar findings have been presented for the primary carboxylic groups of poly(maleic acid)[23] and for poly(acrylic acid) of a relatively high molecular weight (*ca.* 10^6) without added salts.[22,24] This can be attributed to the intramolecular hydrogen bonding by the ionizable groups, in particular between the adjacent carboxylic groups.[23,24] In the absence of added salts, the portion of the pK_1 *vs.* α_1 curve in the lower α_1 region is more convex upward; hence, the structure resulting from the cooperative hydrogen bonding between two adjacent carboxylate groups in each itaconic acid residue seems to be more stable.

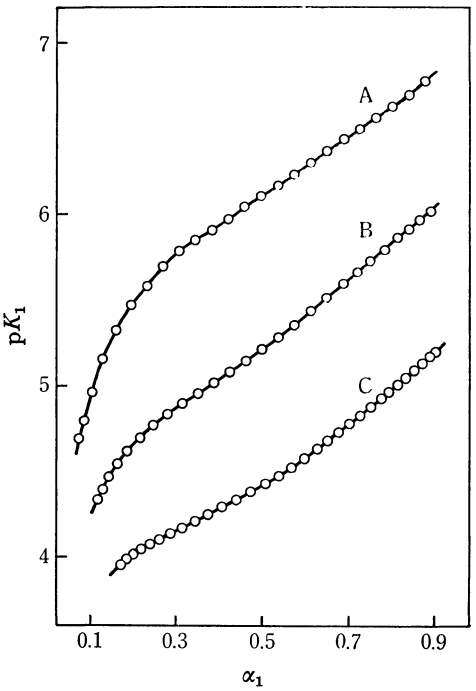

Fig. 6. The pK_1 *vs.* α_1 curves of 3.79×10^{-3} monomol/l PIA in water (curve A) and in the presence of $NaNO_3$ at 0.01 mol/l (B) and 0.1 mol/l (C).

Binding of Alkali Metal Ions. We see from Figs. 4 and 5 that the acidity of the primary carboxylic groups of PIA increases in the order $(CH_3)_4N^+<Li^+<Na^+<K^+$, and that of the secondary ones $(CH_3)_4N^+<K^+<Na^+<Li^+$. In such a case, the increment in acidity gives a measure of the interaction between carboxylic groups and counterions. Thus, the alkali metal ions are bound to the carboxylate groups of PIA in a certain way.

The carboxylic groups of PIA dissociate in the following two steps:

$$-CH_2-C(COOH)-CH_2-COOH \overset{K_1}{\rightleftharpoons} -CH_2-C(COOH)-CH_2-COO^- + H^+ \quad (5)$$

$$-CH_2-C(COOH)-CH_2-COO^- \overset{K_2}{\rightleftharpoons} -CH_2-C(COO^-)-CH_2-COO^- + H^+ \quad (6)$$

These equilibria are represented by the following simplified expressions:

$$H_2A \rightleftharpoons HA^- + H^+ \quad (7)$$

$$HA^- \rightleftharpoons A^{2-} + H^+ \quad (8)$$

On the assumption that no $(CH_3)_4N^+$ ions are bound to the carboxylate groups in the PIA–$(CH_3)_4NCl$ system, the degree of binding (θ) of the alkali metal ions (M^+) with the monoanion (HA^-) and dianion (A^{2-}) of the itaconic acid residue was calculated from the titration curves. The θ value is defined as the average number of the alkali metal ions bound to each itaconic acid residue. In the first dissociation step, MHA must be the only species of the primary carboxylate groups binding to M^+ ions. Therefore, θ can be calculated by the use of the scheme described previously.[9] In the second step, however, the scheme cannot be applied because of the presence of various species (*e.g.*, MHA, MA^-, and M_2A) as a mixture.

Thus, θ throughout the first and second steps is expressed by the equation:

$$\theta = \frac{[ML]}{[A_t]} = \frac{[L_t]-[HL]-[L^-]}{[A_t]} \quad (9)$$

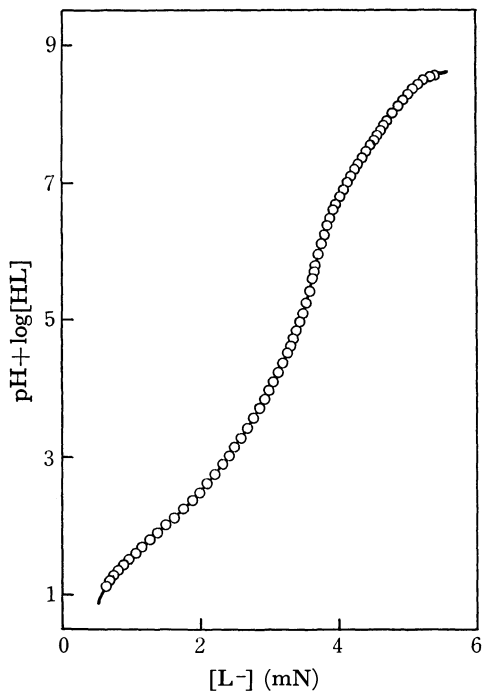

Fig. 7. The reference plot of 3.79×10^{-3} monomol/l PIA in 0.1 mol/l $(CH_3)_4NCl$, for calculation of θ.

where $[L_t]$ is the total concentration of the carboxylic groups without differentiation between the primary and secondary carboxylic groups (*i.e.*, $[L_t]=2[A_t]$), and [ML] is that of the primary and/or secondary carboxylate groups combined with M^+ ions. The [HL] related to undissociated carboxylic groups is found to be:

$$[HL] = [L_t] - [NaOH] - [H^+] + [OH^-] \qquad (10)$$

from the conservation and electroneutrality conditions. The $[L^-]$ value related to free carboxylate groups in the 0.1 mol/l MNO_3 solutions is calculated by the use of a reference plot for the 0.1 mol/l $(CH_3)_4NCl$ solution of PIA (Fig. 7).[9] After the determination of (pH+log[HL]) values for the 0.1 mol/l MNO_3 solutions of PIA, the appropriate $[L^-]$ values in the MNO_3 solutions can be found in the reference curve for the $(CH_3)_4NCl$ solution. Such a scheme with the reference plot has been devised by Mandel and Leyte.[25]

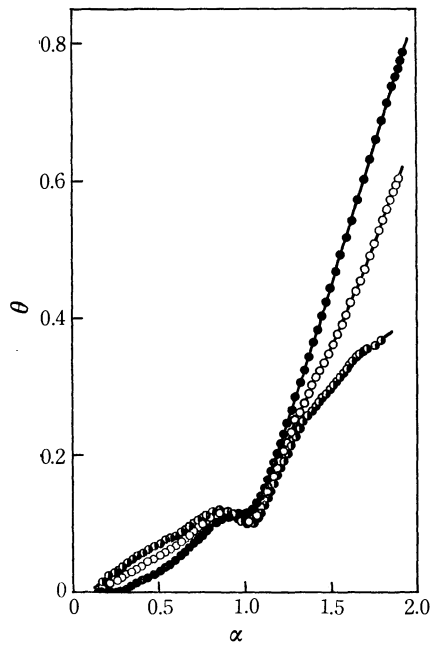

Fig. 8. The dependence of θ on α, calculated from the curves in Fig. 2. ●: Li^+, ○: Na^+, and ◑: K^+.

Figure 8 shows the dependence of θ on α, where α is the total apparent degree of dissociation of the itaconic acid groups; $\alpha=\alpha_1$ or $=1+\alpha_2$, and hence $\alpha=2$ at the apparent complete dissociation. According to the assumption on the calculation of θ, we have $\theta=0$ for $(CH_3)_4N^+$ ions over the whole α range. In the first dissociation step ($\alpha\leq1.0$), the θ values at a given α decrease in the order $K^+>Na^+>Li^+$, whereas in the second step the order of the binding strength is completely reversed. With the increase in α, the θ values in the first step gradually increase and then become practically constant (0.11—0.12) in the region near $\alpha=0.9$. The θ values in the region beyond $\alpha=1.0$ increase steeply with α, linearly for Li^+ ions. Those around $\alpha=1.0$ for Na^+ and K^+ ions appear to decrease slightly with α. However, this is not definite because of the increase in the errors inherent in the scheme with the reference plot near the half-neutralization point.

We see from Fig. 8 that when α approaches 2, about 80, 60, and 40% of the itaconic acid residues bind to Li^+, Na^+, and K^+ ions, respectively. For polyacrylate and copolymers of maleate, the binding fractions with the alkali metal ions have been evaluated from such various measurements as of counterion mobility,[6,26,27] counterion activity,[28] conductivity,[4] viscosity,[29] and apparent molal volumes[8] in the polyelectrolyte systems. The present values for polyitaconate seem to be comparable in magnitude to those for the above polycarboxylates. However, such marked differences in the θ values with the alkali cations for polyitaconate have not been found for ordinary polycarboxylates.[4,8]

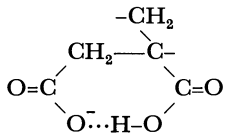
The order $Li^+>Na^+>K^+$ on binding strength in the second dissociation step of PIA agrees with the results for polymonocarboxylates[1,4] and for the second step of maleic acid polymers.[7,9] These results can be explained in terms of the crystallographical ionic radii of alkali metals;[2] the smallest Li^+ ion is bound to the largest extent. This contact binding between the alkali metal ions and the carboxylate groups in these polyelectrolyte systems resembles the so-called contact ion-pairs for weak electrolytes.

It is noteworthy that, in the first dissociation step, the binding strength of the alkali metal ions to the primary carboxylate groups is in the order $K^+>Na^+>Li^+$. This can be explained in terms of the radii of the hydrated alkali cations, which increase in the order $K^+<Na^+<Li^+$. The so-called solvent-separated ion-pairs between the hydrated cations and the carboxylate groups are predominant in the first step. The same affinity sequence of the alkali metal ions has been found for polysulfonates.[4,30] For polycarboxylates, however, it has been reported only in the case of the

primary carboxylate groups of poly(maleic acid).[9]

Interpretation on Specific Counterion Binding. A common structural feature to PIA and poly(maleic acid) is that the local density of ionizable groups along the polymer chain is much higher than that for polymonocarboxylic acids; hence, the interaction between neighboring groups must be considerable. Since the binding behavior of the counterions for PIA is quite analogous to that for poly(maleic acid),[9] a similar interpretation on the specific counterion binding in the first dissociation step is given as follows.

The monoanion of the itaconic acid residue is considered to have the structure:



involving cooperative hydrogen bonding by two adjacent carboxylate groups; hence, a single electronic charge is distributed by resonance over a wide range. Tate, who examined the titration behavior of PIA, has proposed the same structure.[15] The stability of the seven-membered ring is comparable to that of six-membered ones because of the very small volume of the hydrogen-bonded proton. Similar hydrogen-bonded seven-membered rings have been confirmed for the monoanion of maleic acid copolymers[7,31] and for the hydrogen maleate anion.[32,33] Although no sufficient evidence has been presented, it is expected that the formation of the structure leads to a rather compact conformation of the PIA chain.

Such a stable ring structure resulting from the hydrogen bonding should be effective at least in the first dissociation step. Thus, the primary carboxylate groups, which would bind to the alkali metal ions by nature, are more tightly bound to the protons of the secondary carboxylic groups. The present findings that hydrated alkali cations are more loosely bound to the primary carboxylate groups can be ascribed to such a chelation of a proton with two adjacent carboxylate groups. The intramolecular hydrogen bonding is gradually broken up with the increase in α. This results in a conformational change from a compact form to an extended form of the PIA chain. In the absence of added salts, the compact form resulting from the hydrogen-bonded structure is more stable; the pK_1 values in the lower α_1 region are fairly high (Fig. 6).

In the second dissociation step, the contact binding between the alkali metal ions and the carboxylate groups, which is much stronger than the solvent-separated binding with the hydrated cations, is predominant. Even if part of the monoanions assume the hydrogen-bonded structure, the effect should be negligible in comparison with that of the contact binding by the dianions or the carboxylate groups free from the hydrogen-bonded protons. Incidentally, the Li^+ ion is considerably smaller than the Na^+ and K^+ ions. In the high pH region, therefore, it is presumed that the Li^+ ions are more favorably located than the others in the place of the hydrogen-bonded protons. Such a chelation of a Li^+ ion with two adjacent carboxylate groups results in the higher θ values at high α. A similar structure has been proposed for the poly(maleic acid)-LiCl system in connection with the precipitation from the concentrated solution at higher α.[34]

In conclusion, we can safely say that the counterion binding for PIA is affected throughout by the interaction between the vicinal carboxylic groups.

The author wishes to thank Prof. Tsurutaro Nakagawa and Prof. Tsuyoshi Komatsu for helpful suggestions and discussion. The present work was supported in part by a Grant for Scientific Research from the Ministry of Education.

Conformations of Prolyl Residues in Oligopeptides

Tamaichi ASHIDA and Masao KAKUDO
Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received December 18, 1973)

The structures of the prolyl residues as found in the crystals of various oligopeptides were studied, and a few interesting structural features were found. (i) The C^{α}–C′–N angle of the peptide group formed by the N atom of the pyrrolidine ring and the C^{α} and C′ atoms of the preceding residue is widened to about 118° from the usual value of 114° due to the steric repulsion between the C^{α} and the two hydrogen atoms bonded to the C^{δ} atom of the pyrrolidine ring. (ii) The C^{γ} atoms of some pyrrolidine rings have some sort of disorder, and the C^{β}–C^{γ} and C^{γ}–C^{δ} bonds seem to be shortened and the C^{β}–C^{γ}–C^{δ} angles seem to be widened than usual. (iii) Almost half of the pyrrolidine rings have an approximate C_2 (half-chair) symmetry, the twofold axis passing through the N atom and the midpoint of the C^{β}–C^{γ} bond. The others have an approximate C_s (envelope) symmetry, the mirror plane passing through either the C^{β} or C^{γ} atom with equal probabilities. In this case the $NC^{\alpha}C^{\gamma}C^{\delta}$ or $NC^{\alpha}C^{\beta}C^{\delta}$ groups are almost planar, respectively. (iv) The conformation of C^{γ}-*exo* against the C′ atom bonded to the C^{α} atom is mainly found in the residues having the α-helix type torsion angles, while the C^{γ}-*endo* is in those having the collagen type torsion angles.

Proline is a unique imino acid which imposes a certain restriction on the conformations of proteins. The restriction is due to the formation of the pyrrolidine ring, and also to the bulky methylene group linked to the imino nitrogen atom, to which only a hydrogen atom is linked in all the other amino acids. The conformations of the pyrrolidine rings as observed in crystal structures were reviewed by Balasubramanian *et al.*,[1] however, they could include in the review only five examples of the prolyl residues in peptides. Recently, the structures of seven prolyl residues in three oligopeptides were established in our laboratory. The present paper deals with the conformations and the dimensions of ten prolyl and one hydroxyprolyl residues in six crystals.

Residues **1′** *and* **1″**: Pyrrolidine rings of C(4) C(5) C(6′) C(7) N(2) and C(4) C(5) C(6″) C(7) N(2) of L-Leu-L-Pro-Gly, numbering as in the original report.[2] R=12.9, mean e.s.d. of the bond distances σ=0.015 Å.

Residues **2** *and* **3**: Pro and Hyp of tosyl-L-Pro-L-Hyp.[3] R=9.3, σ=0.016 Å.

Residue **4**: Pro of *p*-bromo-Z-Gly-L-Pro-L-Leu-Gly.[4,5] R=4.3, σ=0.02 Å.

Residues **5** *and* **6**: Pro(1) and (2) of *o*-bromo-Z-Gly-L-Pro(1)-L-Leu-Gly-L-Pro(2).[6] R=11.6, σ=0.03 Å.

Residues **7** *and* **8**: Pro(1) and (2) of Z-Gly-L-Pro(1)-L-Leu-Gly-L-Pro(2).[7] R=5.8, σ=0.008 Å.

Residues **9**, **10**, *and* **11**: Pro(1), (2), and (3) of Aoc-L-Pro(1)-L-Pro(2)-L-Pro(3).[8] R=6.0, σ=0.008 Å.

Bond Lengths and Angles

The nomenclature and the definition of the atoms, bonds and torsion angles[9] are given in Fig. 1, and the bond lengths and angles are summarized in Table 1. In Fig. 2 their mean values of the peptide groups are compared with the standard values for the usual peptide groups given by Corey and Pauling[10] and by Marsh and Donohue.[11] The torsion angles of the peptide main chain are listed in Table 2. All these values were recalculated from the published coordinates of the crystal structures.

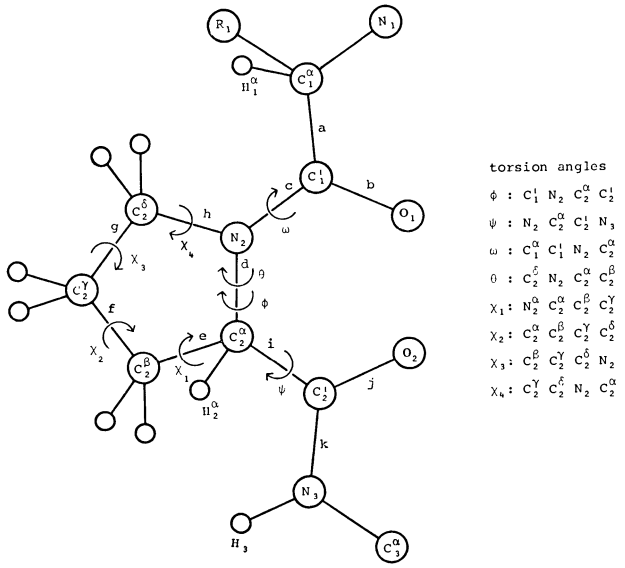

Fig. 1. The nomenclature and the definition of the atoms, bonds and torsion angles. The convention given by IUPAC-IUB Commission on Biochemical Nomenclature[9] is adopted.

Peptide Groups. The mean C^{α}–C′–N angle (ac) of 118° is significantly larger than 114° given by Corey and Pauling[10] and 116° by Marsh and Donohue.[11] While the O–C′–N (bc) of 120.5° is less than 125° or 123.5°, respectively. This is certainly due to the steric repulsion between the C^{α} atom of the preceding residue and the bulky C^{δ} methylene group of the pyrrolidine ring, in particular two hydrogen atoms bonded to the C^{δ} atom. In the cases of **4** to **8** the preceding residues are glycines, but the same tendency is observed. Thus this discrepancy from the standard values is not affected by the sizes of the side groups of the preceding residues.

A similar tendency is also found in the bond angles of C^{α}–C′–N (ik) and O–C′–N (jk) of the peptide groups between the prolyl and the following residues. However, if the residues **2**, **9**, and **10**, which are followed by prolyl residues, are not taken into account, the mean value of the C^{α}–C′–N angles of 116° is quite close to the standard value. Thus the presence of the pyr-

1′ and **1″** now discussed in this paper. On the other hand in *p*-bromo-Z–Gly–Pro–Leu–Gly,[5] Z–Gly–Pro–Leu–Gly–Pro,[7] and Aoc–$(Pro)_3$,[8] the C^γ atoms of the residues **4**, **7**, and **10** gave unusually large vibrational amplitudes in the direction perpendicular to the pyrrolidine planes, but no anomalies were found in the vicinities of the C^γ sites in the difference electron density maps. Although the possibilities of the disordered structure as postulated for Leu–Pro–Gly should be taken into account, the refinements employing usual anisotropic temperature factors seemed to be reasonably converged. The models thus obtained give the shorter bond lengths of C^β–C^γ and C^γ–C^δ and the wider C^β–C^γ–C^δ angles than the true values. DL-Proline HCl shows also a similar tendency.[12]

Puckering of Pyrrolidine Ring

The torsion angles of all the five bonds of the pyrrolidine ring are listed in Table 3. Balasubramanian *et al.* classified the proline ring structures into two classes, A and B.[1] Conformation A is characterized by negative χ_1, and C′ and C^γ are on opposite side of the roughly planar $NC^\alpha C^\beta C^\gamma$ plane (C^γ-*exo*), while conformation B has positive χ_1, and the two atoms are on the same side of the plane (C^γ-*endo*).

Among newly determined structures of the pyrrolidine rings in peptides, several residues, such as **5**, **9**, and **10**, are reported to have more planar $NC^\alpha C^\gamma C^\delta$ groups rather than $NC^\alpha C^\beta C^\delta$. Also in two of four rings in tetra-proline[13] the C^β atoms are displaced mostly from the ring planes. Therefore, a further study of the puckering of the rings is made from a slightly different viewpoint from that of Balasubramanian *et al.*[1]

The structures viewed along the C′–N bonds of the peptide linkages, more strictly, along the bisectors of the C^α–N–C^δ angles are presented in Fig. 3. It is clearly shown that almost half of the structures have roughly a C_2 (half-chair) symmetry[14] with the twofold axis passing through the N atom and the midpoint of the C^β–C^γ bond. In this structure neither the $NC^\alpha C^\beta C^\delta$ nor $NC^\alpha C^\gamma C^\delta$ groups are planar. This structure may be designated as C_2-C^γ-*exo* (C^β-*endo*) or C_2-C^γ-*endo* (C^β-*exo*) depending on whether C^γ is displaced on the same side as C′ or on the opposite side of the $NC^\alpha C^\delta$ plane. Both of these structures have been actually found so far. The others have an approximate C_s (envelope) symmetry, the mirror plane passing through either the

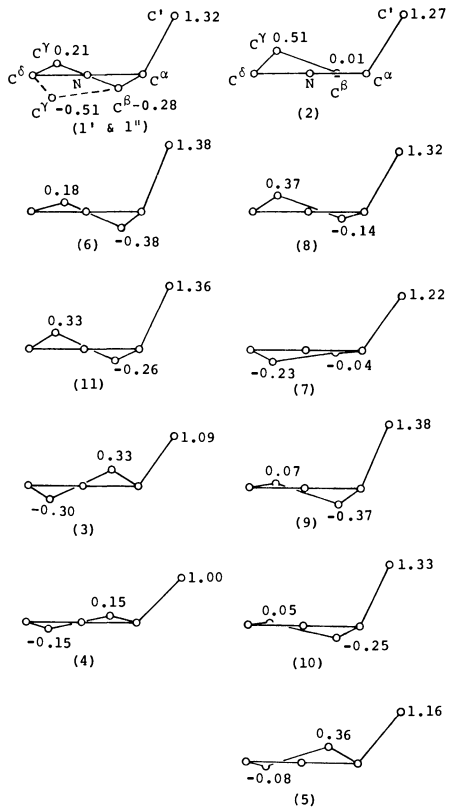

Fig. 3. The conformations of the pyrrolidine rings viewed along the bisectors of the $C^\alpha NC^\delta$ angles. The displacements of the atoms from the $NC^\alpha C^\delta$ planes are shown in Å unit. *left*: the rings of approximate C_2 symmetry, *right*: the rings of approximate C_s symmetry.

Table 3. The conformations of the pyrrolidine rings in the oligopeptides

Residue	Conformation	Shift (Å) from $NC^\alpha C^\delta$-plane			Torsion angles (degrees)				
		C^β	C^γ	C′	θ	χ_1	χ_2	χ_3	χ_4
	C^β-*endo*, C^γ-*exo*, (C^δ-*endo*) (conformation A)								
1″	C_s-C^δ-*endo*	−0.28	−0.51	1.32	−11	−3	16	−22	21
3	C_2-C^γ-*exo*	0.33	−0.30	1.09	13	−31	37	−30	12
4	C_2-C^γ-*exo*	0.15	−0.15	1.00	6	−16	21	−17	6
5	C_s-C^β-*endo*	0.36	−0.08	1.16	13	−24	27	−19	3
7	C_s-C^γ-*exo*	−0.04	−0.23	1.22	−2	−7	14	−14	9
	C^β-*exo*, C^γ-*endo* (conformation B)								
1′	C_2-C^γ-*endo*	−0.28	0.21	1.32	−11	26	−31	24	−8
2	C_s-C^γ-*endo*	0.01	0.51	1.27	0	21	−32	31	−20
6	C_2-C^γ-*endo*	−0.38	0.18	1.38	−15	32	−38	27	−7
8	C_s-C^γ-*endo*	−0.14	0.37	1.32	−5	24	−33	29	−14
9	C_s-C^β-*exo*	−0.37	0.07	1.38	−14	25	−27	19	−3
10	C_s-C^β-*exo*	−0.25	0.05	1.33	−10	17	−20	14	−2
11	C_2-C^γ-*endo*	−0.26	0.33	1.36	−10	29	−38	31	−13

The conformation of **6** is an intermediate of C_2-C^γ-*endo* and C_s-C^β-*exo*.
The conformation of **8** is an intermediate of C_s-C^γ-*endo* and C_2-C^γ-*endo*.

C^β or C^γ atoms. If the mirror plane passes through C^β, χ_4 is close to zero and the atoms $C^\alpha C^\gamma C^\delta N$ are coplanar. This structure may be designated as C_s-C^β-*endo* or C_s-C^β-*exo* depending on the direction of the displacement of the C^β atom from the $NC^\alpha C^\gamma C^\delta$ plane. If the C^γ atom is on the mirror plane, θ is close to zero, the four atoms $C^\alpha C^\beta C^\delta N$ are coplanar, and the structure may well be characterized by C_s-C^γ-*exo* or C_s-C^γ-*endo*. All the four C_s structures have also been found so far. In Fig. 3 it is clearly shown that notwithstanding the approximate symmetry the displacement of the C′ atom from the $NC^\alpha C^\delta$ plane is larger for C^γ-*endo* (C^β-*exo*) than for C^γ-*exo* (C^β-*endo*) due to a steric requirement.

The above discussion shows that the displacement alone of the C^γ atom from the $NC^\alpha C^\beta C^\delta$ plane is not necessarily appropriate to describe the conformation of the pyrrolidine ring. The five torsion angles or the displacements of the C^β and C^γ atoms from the $NC^\alpha C^\delta$ plane are the necessary informations to describe the structure. The notation suggested in this report, such as C_2-C^γ-*endo*, gives more directly an approximate picture of the prolyl ring. The conformations of the prolyl residues in peptides classified on these lines are summarized in Table 3, where the displacements of the C^β and C^γ atoms and the five torsion angles are also listed. Among these examples residue **6** is an intermediate of C_2-C^γ-*endo* and C_s-C^β-*exo*, and residue **8** is an intermediate of C_s-C^γ-*endo* and C_2-C^γ-*endo*. Residue **1″** cannot be classified into anyone of these structures, but is a unique example of C_s-C^δ-*endo*. According to the classification by Balasubramanian *et al.*,[1] conformation A includes C^β-*endo* and/or C^γ-*exo* irrespective of the symmetry of the ring, and B includes C^β-*exo* and/or C^γ-*endo*.

The pyrrolidine rings in crystals of amino acids are also classified in this way; L-proline[15] is C_2-C^γ-*endo*, L-hydroxyproline[16] and proline in copper DL-proline dihydrate[17] are C_s-C^γ-*exo*, and the pyrrolidine ring in acetyl-L-proline-*N*-methylamide[18] is an intermediate of C_2-C^γ-*endo* and C_s-C^γ-*endo*. The pyrrolidine ring of DL-proline HCl[12] might be termed C_s-C^α-*exo*, really a rare example.

A theoretical treatment of the conformations of the pyrrolidine rings by a potential energy calculation showed that C^γ-*endo* is somewhat stabler than C^γ-*exo*, but the energy difference between the two conformations is only marginal, and may not be so decisive in determining the conformations.[19,20] Among 12 examples, 7 are C^γ-*endo*, while 5 are C^γ-*exo*.

In such discussions the rotation of the C^α–C′ bond should be taken into consideration.[21] The prolyl residues are classified into two groups according to the rotation angle ϕ as shown in Table 2. One is the collagen type with large positive ϕ (residues **1**, **2**, **9**, **10**), and the other is the α-helix type with small negative ϕ (residues **4**, **5**, **7**). A model building shows easily that in the α-helix type the NH group of the following residue is in contact with the H atoms bonded to the C^γ and C^δ atoms of the ring, and the contact may be too close if the C^γ atom is in *endo* against the C′ atom. Each of the three residues of this type is C^γ-*exo* (conformation A). While in collagen type, since all the four residues are C^γ-*endo* or C^β-*exo*, the O atom of the following peptide group may be in appropriate nonbonding (van der Waals) contact with the ring atoms of conformation B. Thus, although the number of examples may not be large enough, it may be concluded that the α-helix type residues take conformation A while the collagen type residues take conformation B. The relation, however, may not be so explicit, since a simple molecule of acetyl-L-proline-*N*-methylamide[18] is an α-helix type with $\phi = -16°$, but C^γ is in the *endo* position. The intermolecular interactions may play a key role in this structure rather than the intramolecular interactions mentioned above.

The last point is that the disordered C^γ atom mentioned earlier has another effect on the shape of the pyrrolidine ring, that is, the ring having a disordered C^γ atom, such as residues **4**, **7**, and **10**, is significantly more planar than the others. All the torsion angles of the bonds of the ring are close to zero, and the displacements of the C^β and C^γ atoms from the $NC^\alpha C^\delta$ plane are smaller than the others. The C^γ atom has usually two stereochemically possible sites on each side of the ring, if the rest of the ring is fixed. For instance, in residue **10** the distance between the two possible sites is about 0.8 Å. The actually located site of the C^γ atom in this residue is on the midway of the line joining the two possible sites, 0.2 Å to the closer site and 0.6 Å to the other. Thus, the actually located site is significantly closer to the plane of the pyrrolidine ring than the stereochemically ideal one.

Vibration-Rotation Spectrum of Methyl Fluoride II. Analysis of $\nu_3+\nu_6$ Band

Jun NAKAGAWA, Isao SUZUKI,* Takehiko SHIMANOUCHI, and Tsunetake FUJIYAMA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

**Educational Computer Centre, The University of Tokyo, Bunkyo-ku, Tokyo 113*

***Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158*

(Received December 28, 1973)

The $\nu_3+\nu_6$ band of methyl fluoride has been measured with a high-resolution infrared spectrometer. The molecular constants are obtained with the least-squares method. The effect of the x,y-type Coriolis interaction is discussed and the theoretical spectra are compared with the observed spectrum.

In a previous paper[1] (hereafter referred to as I), we have reported the analysis of the $2\nu_3$ band of CH_3F under high resolution. As mentioned in I, the $2\nu_3$ band is expected to have the x,y-type Coriolis interaction with the $\nu_3+\nu_6$ band similar to that observed in the ν_3 and ν_6 fundamentals.[2,3] The effect of this interaction may be seen more clearly in the weaker $\nu_3+\nu_6$ band and the result of the analysis is reported in the present paper.

Since the vibration-rotation energy levels for both the $2\nu_3$ and $\nu_3+\nu_6$ bands have been accurately determined, more precise scheme may be drawn for the x,y-type Coriolis interaction between the two levels. As mentioned in I, the band centers of these two bands are separated by about 140 cm^{-1}; the shifts of vibration-rotation levels are relatively small and may be treated in the conventional way. The effect of the perturbation would be more profound in the intensity of the $\nu_3+\nu_6$ band. The $\nu_3+\nu_6$ band may further couple with the $(2\nu_6)^0$ and $(2\nu_6)^2$ bands through the same ζ^y_{36} term. These bands occur at higher frequency side of the $\nu_3+\nu_6$ band and are extremely weak, and their effects on the $\nu_3+\nu_6$ band are negligible for the intensity wise.

Experimental

The sample was purchased from PCR Inc. of USA with the stated purity of 99% and used without further purification.

The spectra were measured with a 2500 mm focal length Littrow-McCubbin type instrument at the University of Tokyo,[1,4] in the 12th and 13th orders of a 31.6 lines/mm grating. An InSb detector was used at liquid nitrogen temperature. A White type long-path cell was used and its path length was kept 6 m. The sample pressure was *ca.* 45 mmHg and the resolving power was better than 0.06 cm^{-1}.

The frequencies of the observed lines were calibrated against the standard lines of CO.[5] In the region where the CO lines overlap with CH_3F lines, the suitable lines of $D^{35}Cl$ and $D^{37}Cl$ were used as the secondary standard, the frequencies of which had been calibrated against the CO lines. The standard deviation of the fitted lines was 0.007 cm^{-1} and, therefore, the accuracy of the observed lines was believed to be better than $\pm$0.01 cm^{-1}.

Spectral Features and Assignment of the Observed Bands

The rapidly scanned spectra ($\Delta\nu\simeq$0.10 cm^{-1}) of P- and R-branch sides are shown in Figs. 1 and 2, the 12th and 13th orders of grating being used respectively. Since each Q-branch is resolved into its J-components, the Q-branches cannot be distinguished from P- and R-branches. Near the band center, however, the Q-branches appear fairly clearly, because there is no overlapping with the strong ^RR- and ^PP-branches. Many of the P- and R-branch lines in the subbands are seen to be resolved into the individual components. Furthermore, the spectrum of R-branch side shows the clear series of the ^RR-branches which begin by about 2270 and 2291 cm^{-1}, while no obvious series are found in the P-branch side.

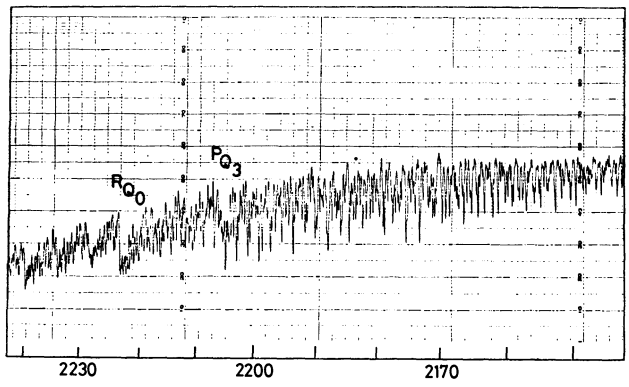

Fig. 1. The rapid scan spectrum of the $\nu_3+\nu_6$ band of CH_3F. P-branch side. Grating order=12th. Path length=6 m. Pressure=45 mmHg. Resolution=0.10 cm^{-1}.

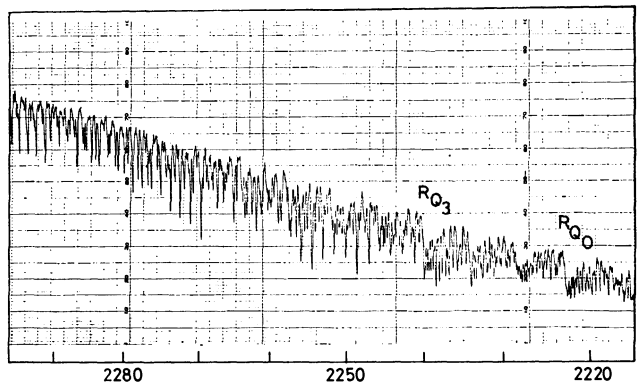

Fig. 2. The rapid scan spectrum of the $\nu_3+\nu_6$ band of CH_3F. R-branch side. Grating order=13th. Path length=6 m. Pressure=45 mmHg. Resolution=0.10 cm^{-1}.

Although the assignment of the observed lines is complicated by the fact that the Q-branches are resolved into its J-components, we can assign the lines by the following way.

(1) Since no strong ^{R}R-branch and ^{P}P-branch lines occur near the band center, the most prominent Q-branch line can be assigned to the $^{R}Q_0$. (2) The lines of the $^{R}Q_1$, $^{R}Q_2$, $^{R}Q_3$, $^{P}Q_1$, $^{P}Q_2$, and $^{P}Q_3$ branches are easily identified, because they show usual intensity alternation due to the three fold symmetry. The J-components of each Q-branch are determined graphically. (3) ^{R}R-branches are assigned in consideration of the statistical weights and the missing lines ($J \geqq K$).

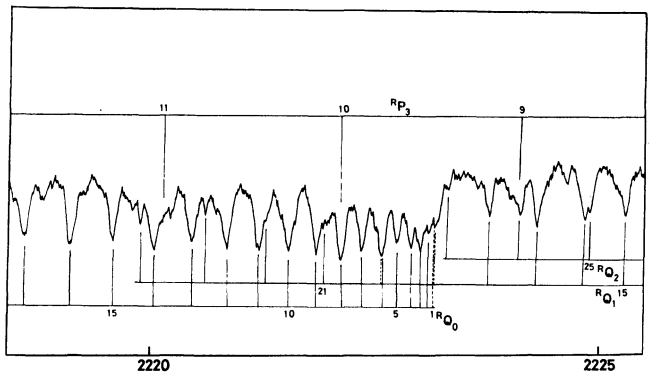

Fig. 3. The band center of the $\nu_3+\nu_6$ band. The $^{R}Q_0$-branch is mainly seen. Resolution=0.06 cm^{-1}.

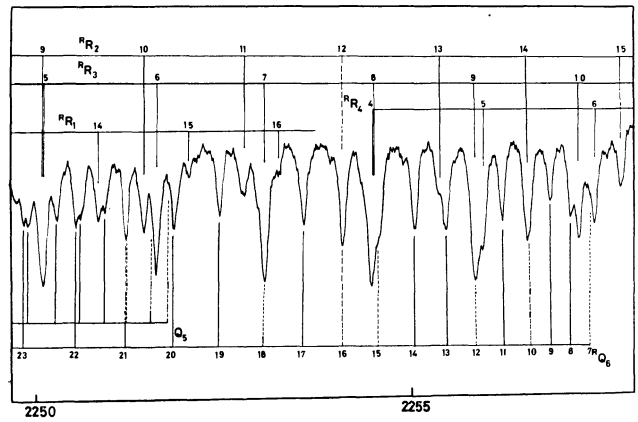

Fig. 4. The $^{P}Q_6$-branch of the $\nu_3+\nu_6$ band. Unassigned stronger bands are mainly from $^{P}P_1$- and $^{P}P_2$-branches.

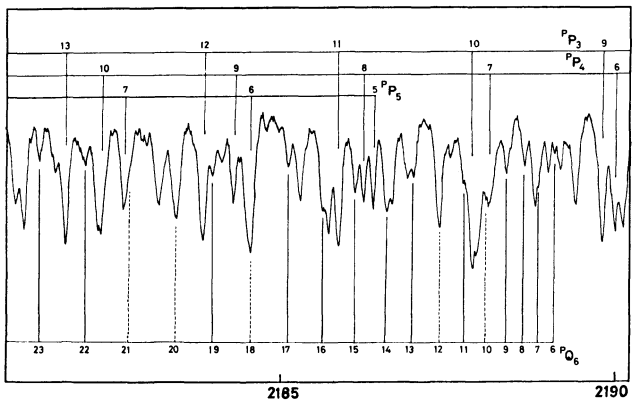

Fig. 5. The $^{R}Q_6$-branch of the $\nu_3+\nu_6$ band.

(4) The assignments of the ^{P}P-branches are made by the use of the parameters obtained from the analysis of the ^{R}R-branches and from the microwave study.[6] A few of the ^{R}P- and ^{P}R-branches are observed.

In Fig. 3 the spectrum of $^{R}Q_0$ branch is shown with the assignment of several lines. The spectra near the $^{P}Q_6$- and $^{R}Q_6$-branches are shown in Figs. 4 and 5, respectively; the P-branch side is more complex and less intense.

Determination of the Molecular Constants

The vibration-rotation energy of a symmetric top in an E-vibrational state can be written in the form

$$\begin{aligned} T_{v,l}(J,k) = {} & G(v,l) + B_v J(J+1) + (A_v - B_v)k^2 \\ & - 2A_v\zeta_v kl - D_J^v[J(J+1)]^2 \\ & - D_{JK}^v J(J+1)k^2 - D_K^v \cdot k^4 \\ & + \eta_J^v J(J+1)kl + \mu_K^v k^3 l, \end{aligned} \quad (1)$$

where $G(v,l)$ is the vibrational energy, A_v and B_v are the rotational constants, and D_J^v, D_{JK}^v, D_K^v, η_J^v, and η_K^v are the centrifugal distorsion constants and ζ_v is Coriolis coupling constant.

From the selection rules for a perpendicular band ($\Delta k=+1$, $\Delta l=+1$, and $\Delta J=0$, ± 1, or $\Delta k=-1$, $\Delta l=-1$, and $\Delta J=0$, ± 1), the transition frequencies can be calculated as the differences between the energy levels of the upper and lower states. Some of the parameters, however, cannot be determined from the analysis of this band alone. The A'' value is obtained from the ζ-sum rule,[2] the D_k'' value is calculated from the harmonic force field,[7] and the D_{JK}'' value is obtained by the microwave study.[6] The molecular constants which are obtained from the least-squares method are listed in Table 1 together with the microwave values. A part of the observed frequencies are listed in Table 2 with their assignments and the calculated frequencies.[8] The lines which are not fully resolved are given zero or smaller weights.

x,y-Type Coriolis Interaction

As mentioned earlier, the $\nu_3+\nu_6$ band has Coriolis interaction with $2\nu_3$, $(2\nu_6)^0$ and $(2\nu_6)^2$ bands. In this section, the influence of this interaction to the $\nu_3+\nu_6$ band will be discussed.

Since the selection rules for this type of interaction is $\Delta J=0$, $\Delta k=+1$, and $\Delta l=+1$ or $\Delta J=0$, $\Delta k=-1$, and $\Delta l=-1$, the analyses of the $2\nu_3$ and $\nu_3+\nu_6$ bands show that the levels which interact with each other are closest at $k=26$ or 27 and the effects are hardly observed for the levels of relatively small k values. In this work, assignment can be done to the $k=12$ lines for R-branch and the $k=10$ lines for P-branch. If there is any strong local interaction, the effect will be seen as the difference of the effective rotational constant B'_{eff} for each subband. In Fig. 6, the B'_{eff} values are plotted against the upper state quantum numbers $k'l'$. These B'_{eff} values agree each other within the experimental errors and no systematic variations are found. This means the interaction does not affect any particular rotational levels strongly, but the contribution of the interaction will be included as a whole in the parameters of Eq. (1).

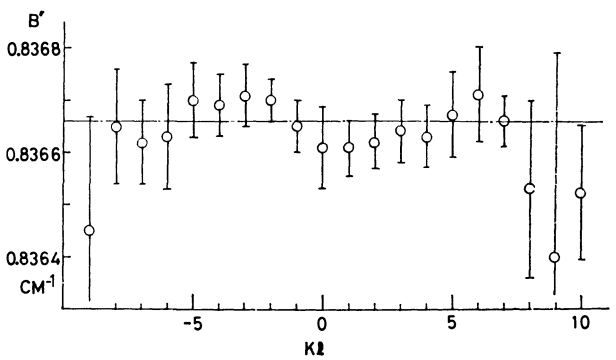

Fig. 6. The effective rotational constants plotted against the upper state quantum number $k'l'$.

The influence to the intensity is qualitatively shown in the fact that the R-branch structure is much simpler than that of the P-branch and the series of lines can be seen more clearly in the R-branch. The maximum J-values which we can assign are about 35 for the P-branch and 25 for the R-branch. For Q-branches, the ^{R}Q-branch is stronger than the ^{P}Q-branch. If the influence of the x,y-type Coriolis interaction is only seen as the anomaly of the intensity, the contribution from the weak $2\nu_6$ band can safely be neglected. Then we consider only the interaction between the $2\nu_3$ and $\nu_3+\nu_6$ bands.

The calculation of the intensity perturbation was given by di Lauro and Mills[3] in detail, the Hamiltonian matrix of this interaction can be written as

$$\begin{array}{l} |1,1^{+1};J,k+1\rangle \quad |2,0;J,k\rangle \quad\quad |1,1^{-1};J,k-1\rangle \\ \begin{bmatrix} \nu_{36}+F'(J,k,l) & +2B_e\Omega\zeta^y_{36}f(J,k) & 0 \\ & \nu_{33}+F''(J,k) & -2B_e\Omega\zeta^y_{36}f(J,k-1) \\ \text{(Hermitian)} & & \nu_{36}+F'(J,k-1,-l) \end{bmatrix} \end{array} \tag{2}$$

where ν_{36} and ν_{33} denote the vibrational energies of the $\nu_3+\nu_6$ and $2\nu_3$ levels, respectively. $F'(J,k,l)$ and $F''(J,k)$ are the rotational energy levels $T_{v,l}(J,k)-G(v,l)$ in Eq. (1),

$$\Omega = \frac{1}{2}[(\omega_3/\omega_6)^{1/2}+(\omega_6/\omega_3)^{1/2}]$$

and
$$f(J,k) = [J(J+1)-k(k+1)]^{1/2} \tag{3}$$

Perturbed energy can be obtained by diagonalizing the Hamiltonian matrix (2). Perturbed line intensities depend upon the mixing of the wave functions and the vibrational transition moments of these two bands, M_{33} and M_{36}. According to the calculations of di Lauro and Mills,[3] the enhancement or the depletion of the particular line intensity depends upon the sign of the product of $M_{33}\times M_{36}\times\zeta^y_{36}$. If this sign is positive, ^{P}P-, ^{R}P-, and ^{R}Q-branches of $\nu_3+\nu_6$ band are enhanced and ^{R}R-, ^{P}R-, and ^{R}Q-branches are depleted. This is called as 'positive' perturbation. The situation is reversed when the sign of the above product is negative.

If the unperturbed energy of the interaction levels, the intensity ratio M_{33}/M_{36}, and the Coriolis coupling constant, ζ^y_{36} are known, the theoretical spectrum can be calculated. A computer program for x,y-Coriolis interaction is written in Fortran IV for a HITAC 8800/8700 system in the University of Tokyo, and simulated spectra may be obtained with the aid of a Calcomp x,y-plotter. This program is used to judge whether the perturbation is 'positive' or 'negative'.

Discussion

The analysis of the ν_6 fundamental band[2] gave the Coriolis coupling constant ζ_6^z as 0.284, which agrees fairly well with our present result, 0.274. The vibration-rotation constants for this band are given as $(B_0-B_{36})=0.0151$ and $(A_0-A_{36})=-0.0069$ cm^{-1}. From the preceding analyses, the vibration-rotation constants of the fundamental bands have been obtained as $\alpha_3^B=0.01134$,[2] $\alpha_6^B=0.0043$,[2] $\alpha_3^A=0.00977$,[1] and $\alpha_6^A=-0.013$ cm^{-1}.[2] From these constants, the rotational constants of $\nu_3+\nu_6$ band are expected to be $(B_0-B_{36})=0.0156$ and $(A_0-A_{36})=-0.0033$ cm^{-1}. The constant for B agrees well with the observed value, while for A the agreement is poor. This is almost certainly due to the rather large experimental error of the α_6^A constant, since the unresolved ^PP-branches and the ambiguities of the J-values of Q-branch maxima make the subband origins of the ν_6 band uncertain. We believe that the value of the $2\nu_3$ and $\nu_3+\nu_6$ bands is more reliable. Since the ^RR-branches were fully resolved, the α_6^B value was obtained with smaller experimental errors.

Table 3. 'Corrected' molecular constants of $2\nu_3$ and $\nu_3+\nu_6$ bands of CH_3F (in cm^{-1} except ζ)

	$2\nu_3$ band	$\nu_3+\nu_6$ band	Ground state[6]
ν_0	2081.382	2221.705	
A	5.06170	5.08779	5.081[b]
B	0.83553	0.83369	0.851794
D_J	1.96×10^{-6}	1.82×10^{-6}	1.997×10^{-6}
D_{JK}	1.0×10^{-5}	2.26×10^{-5}	1.47×10^{-5}
D_K	8.2×10^{-5}	7.91×10^{-5}	8.0×10^{-5} [a]
ζ		0.274	
η_J		1.34×10^{-4}	
η_K		1.0×10^{-5}	
	$\lvert\zeta_{36}^y\rvert=0.38$[a]		
	$[M_{36}/M_{33}]^2=0.05$.[b]		

a) Calculated from the Harmonic force field.[7]
b) Assumed.

Since the vibration-rotation levels of both the $2\nu_3$ and $\nu_3+\nu_6$ bands are known, we can estimate the rotational and centrifugal distortion constants corrected for the perturbation between these two levels. If the value of $|\zeta_{36}^y|$ is fixed to 0.38 which has been obtained from the harmonic force field in Ref. 7, we obtain the 'corrected' constants listed in Table 3. Recently Betrencourt[9] reported the analysis of the $2\nu_3$ band which is consistent with our previous results (I). He also gave the unperturbed constants for the $2\nu_3$ level which are slightly different from ours. The differences arise mainly from the fact that somewhat different values are used for the energy levels of the $\nu_3+\nu_6$ band and for ζ_{36}^y.

If the ratio of the transition moments, M_{36}/M_{33}, is further assumed, the simulated spectra can be drawn by the program mentioned earlier. In Fig. 7, the calculated spectra are shown for the cases of the positive and negative perturbations. From the comparison with the observed spectrum, the Coriolis perturbation between the $2\nu_3$ and $\nu_3+\nu_6$ bands is concluded to be 'positive'.

So far we have ignored the effect of the $(2\nu_6)^0$ or $(2\nu_6)^2$ band. The consideration of these two bands would hardly affect the spectroscopic constants in the $2\nu_3$ band from which they are apart by about 280 cm^{-1}, but the effect may be significant on the $\nu_3+\nu_6$ band. It was shown[3] that the x,y-Coriolis interaction affects in different way on the $^RQ_0$-branch, on $^RR_0$- and $^RP_0$-branches, and on the remaining other branches, and that there are three effective rotational constants B'_{eff}. In our measurement, the effective rotational constant which is obtained from $^RQ_0$-branch is 0.83672 ± 0.00007 and the constant obtained from $^RR_0$- and $^RP_0$-branches is 0.83661 ± 0.00005, while the constant obtained from the remaining branches is 0.83667 ± 0.00002 cm^{-1}. In these calculations, the ground state constants are fixed to the microwave values, and for the calculation of $^RQ_0$- and $^RR,P_0$-branches, the upper state constants except B' and D_J' are assumed to be the same as the values obtained from

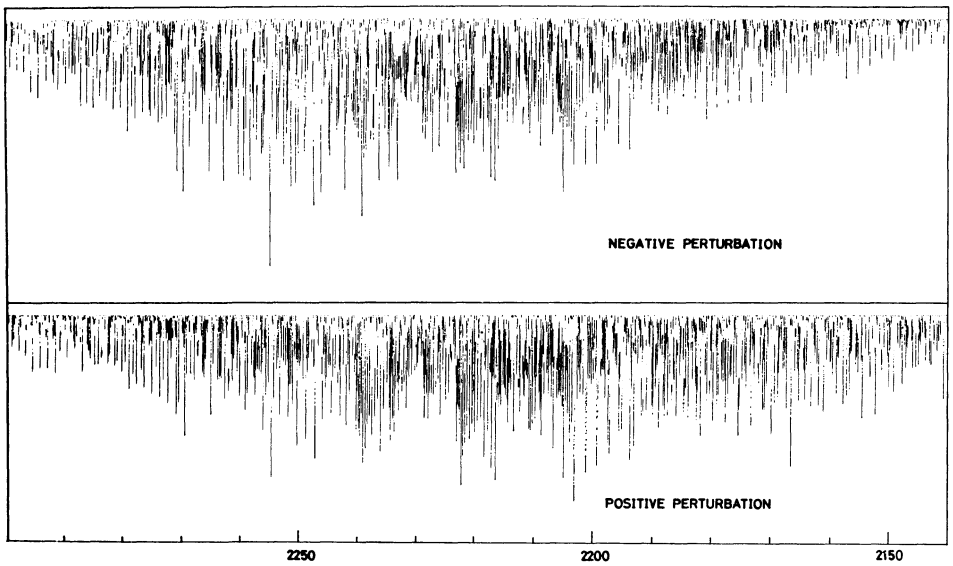

Fig. 7. Simulated spectra of the $\nu_3+\nu_6$ band.

all the other data.

If we consider the four way Coriolis interaction among the $2\nu_3$, $\nu_3+\nu_6$, $(2\nu_6)^0$, and $(2\nu_6)^2$ bands as well as the l-type doubling, the effective rotational constants of the $\nu_3+\nu_6$ band are given as

$$B'_{\text{eff}} = B'_{\text{unp}} - 4B_e^2\zeta^2\Omega^2/\Delta E'' - q/2 \quad (\text{for } {}^{R}Q_0\text{-branch}) \tag{4}$$

$$B'_{\text{eff}} = B'_{\text{unp}} + 8B_e^2\zeta^2\Omega^2/\Delta E - 4B_e^2\zeta^2\Omega^2/\Delta E' - 4B_e^2\zeta^2\Omega^2/\Delta E'' + q/2 \quad (\text{for } {}^{R}R,P_0\text{-branches}) \tag{5}$$

$$B'_{\text{eff}} = B'_{\text{unp}} + 4B_e^2\zeta^2\Omega^2/\Delta E - 2B_e^2\zeta^2\Omega^2/\Delta E' - 4B_e^2\zeta^2\Omega^2/\Delta E'' \quad (\text{for other branches}) \tag{6}$$

where $\Delta E=(\nu_3+\nu_6)-2\nu_3$, $\Delta E'=(2\nu_6)^0-(\nu_3+\nu_6)$, $\Delta E''=(2\nu_6)^2-(\nu_3+\nu_6)$, and q denotes the l-type doubling constant. The above equations are further reduced, if we assume $\Delta E=\Delta E'=\Delta E''$.

$$B'_{\text{eff}} = B'_{\text{unp}} - 4B_e^2\zeta^2\Omega^2/\Delta E - q/2 \quad (\text{for } {}^{R}Q_0\text{-branch}) \tag{7}$$

$$B'_{\text{eff}} = B'_{\text{unp}} + q/2 \quad (\text{for } {}^{R}R,P_0\text{-branches}) \tag{8}$$

$$B'_{\text{eff}} = B'_{\text{unp}} - 2B_e^2\zeta^2\Omega^2/\Delta E \quad (\text{for other branches}) \tag{9}$$

It is interesting to note that B'_{eff} for the ${}^{R}R_0$- and ${}^{R}P_0$-branches is *unperturbed* in contrast to the case of the two way Coriolis interaction originally treated by di Lauro and Mills.[3] If we use $|\zeta_{36}^{y}|=0.38$, $B_e=0.8518\ \text{cm}^{-1}$, and $\Delta E=140\ \text{cm}^{-1}$, these corrections are calculated as -0.00298, 0, and $-0.00149\ \text{cm}^{-1}$ for the above three kinds of branches. From the experimental value, l-type doubling constant can be roughly estimated as $-0.003\ \text{cm}^{-1}$.

Electrical Properties of Ferric Oxyhydroxides

Katsumi KANEKO and Katsuya INOUYE

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 280

(Received January 9, 1974)

The electrical conductivity of α-FeOOH, β-FeOOH, and γ-FeOOH was measured in dry air at room temperature in the frequency range of dc to 10 MHz under various pressures of 9—150 kg/cm². The logarithm of conductivity, log σ, shows a linear relationship with the ratio of true density to apparent density, d_0/d', of the samples compressed at different pressures. σ_1 at 7 MHz, determined by extrapolating the log σ *vs.* d_0/d' plots to unity of d_0/d', is proportional to the number of the nearest iron atoms with identical spin. The conductivity increases with increasing frequency f. The ac conductivity σ_{ac} which equals σ minus σ_{dc}, where σ_{dc} is the dc conductivity, is proportional to f^s ($0.6<s<0.8$) in the lower frequencies than 1 MHz. This behavior is presumed to be due to the hopping of a *d*-electron in the t_{2g}-orbital of Fe^{2+} to the t_{2g}-orbital of adjacent Fe^{3+}, through a slight overlapping of t_{2g}-orbitals of Fe^{2+} and Fe^{3+}.

The oxide film formed on transition metal surfaces in atmospheric environments consists of minute crystals of particular oxides and oxyhydroxides together with some amorphous polynuclear complexes. The mechanism of oxide formation under ambient atmospheric conditions has not been sufficiently established. The corrosion process of iron could be better understood if one investigates the correlation between the structure and the physico-chemical properties of the constituent substances of the oxide film. Information on the electrical conductivity of these oxides and oxyhydroxides is desirable, since it is apparent that the transport of electrons and ions plays an important role in the formation of oxide film. Although the electrical conductivity of pure iron oxides such as α-Fe_2O_3, Fe_3O_4, and FeO has been studied to a certain extent, the study on ferric oxyhydroxides (iron hydroxide oxides) is insufficient, possibly because of the difficulty to eliminate the contact resistance between oxyhydroxide crystals by means of sintering at a high temperature, since ferric oxyhydroxides unavoidably decompose around 300 °C.[1] Okamoto, Furuich, and Sato[2] measured the electrical conductivity of hydrous ferric oxides, so-called ferric hydroxides, by compressing at 1 kg/cm² with the dc-method, but not that of pure ferric oxyhydroxides, which is necessary.

In the preceding paper[3] the frequency dependence of the conductivity of unignited fine crystals of α-Fe_2O_3 was reported in the frequency range of dc to 30 MHz under various pressures of 9—150 kg/cm², and the results were discussed from the viewpoint that the electrical conductivity variations with respect to pressure and frequency reflect the intrinsic structure and imperfection of α-Fe_2O_3. The experimental procedures proposed appear to enable elimination of the contact resistance between fine crystals in general.

The same method has been applied to three forms of ferric oxyhydroxide known, α-FeOOH, β-FeOOH, and γ-FeOOH, which occur widely in the atmospheric corrosion products of iron. The relationship between structure and electrical conductivity of these three types of ferric oxyhydroxide is discussed.

Experimental

Samples. α-FeOOH was prepared by hydrolyzing 0.6 M ferric sulfate solution at 50 °C for 30 hr, the pH being adjusted to 13.6 with 0.1 M KOH solution. α-FeOOH filtered was washed with water until no sulfate ion was detected and dried at 100 °C for 3 hr.[4] β-FeOOH was prepared by the following procedure. One liter of 0.1 M $FeCl_3$ containing 60 g urea was heated to 98 °C within 1 hr and kept at this temperature for additional 5 hr. The filtered precipitates were washed with water until no Cl^- was detected and dried at 100 °C for 3 hr.[5] γ-FeOOH was obtained by warming at 60 °C for 50 min a mixed solution of 500 ml 0.2 M $FeCl_2$, 100 ml 2 M hexamethylenetetramine, 13.5 ml concentrated HCl, and 100 ml 1 M sodium nitrite. Preparation of γ-FeOOH was performed in a stream of nitrogen. The precipitates obtained were washed with water until no Cl^- was detected and dried at 60 °C for about 10 hr.[6]

Examination of Samples. The X-ray diffraction patterns were obtained by the powder method with an automatic diffractometer (Geigerflex 2001, Rigaku Denki Co.) by use of Mn-filtered FeK_α (30 kV, 10 mA). The BET surface-area was determined with a Shibata Surafce-area meter using N_2 adsorption at liquid nitrogen temperature.

The ferrous ion content was determined by titration with 0.005 N cerium sulfate solution in the presence of ferroin as an indicator, after the samples had been dissolved in hydrochloric acid by heating in a stream of carbon dioxide. The total iron content in β-FeOOH was determined by titration with 0.05 N $K_2Cr_2O_7$ solution. The chlorine content in β-FeOOH was determined by the Volhard method. The amount of cation impurities was determined by emission spectroscopy.

Electrical Measurements. Electrical conductivity in the frequency range of dc to 10 MHz under various pressures 9—150 kg/cm² at room temperature was measured by the method described in the preceding paper[3] in air dried with silica gel. Samples were dried at 100 °C for 1 hr prior to conductivity determination. The conductivity change with the adsorption of water on α-FeOOH and γ-FeOOH was negligible during the measurements but an increase of approximately 10% in conductivity was observed for β-FeOOH. The conduction was found to be approximately ohmic with applied voltage in the range ~200—~4000 V/cm.

The sign of Seebeck voltage of compressed samples dried at 100 °C for 1 hr was measured in air with a μV-meter (Oyo Denki Co.) in order to determine the sign of the predominant charge carrier.

Results

Properties of Samples. Each sample prepared gave X-ray diffraction patterns of crystalline α-FeOOH,

β-FeOOH, and γ-FeOOH, structures of which have been reported elsewhere.[7-9] In Table 1 are given the crystallite size calculated by the Scherrer formula for the half-value width of the principal lines, the specific surface area (S_{N_2}) and the ratio of iron atoms exposed to crystal surface to the total iron atoms, which was estimated by assuming that only the developed face area of crystals contributes to the specific surface area. The instrumental broadening in diffraction lines was subtracted by use of patterns of magnetite crystals. The ratio of chlorine to iron for β-FeOOH was found to be 9.5 atomic%. The content of cation impurities is given in Table 2. The amount of ferrous iron, providing the carrier, was found to be 0.06 wt% for all samples. The Fe^{2+}/Fe ratio was hence calculated as approximately 0.1 atomic%.

Electrical Conductivity and Compression of Powder Sample. The logarithm of electrical conductivity log σ and the ratio of the true density to the apparent density d_0/d' of the compressed specimen show linear relationships as in the case of α-Fe_2O_3.[3] The relationships for α-FeOOH, β-FeOOH, and γ-FeOOH at different measuring frequencies are shown in Figs. 1 and 2.

The values of σ_i at dc and 7 MHz, determined by extrapolating the linear relationship between log σ and d_0/d', are shown in Table 3. The density values found in literature were used for the calculation: α-FeOOH, 4.28;[10] β-FeOOH, 3.0;[8] and γ-FeOOH, 4.07.[9]

Frequency Dependence. The frequency dependence of conductivity and dielectric constant of α-FeOOH as the representative of three forms of oxyhydroxide is shown in Fig. 3. β-FeOOH and γ-FeOOH gave a frequency dependence similar to that of α-FeOOH. The frequency dependence of σ_i is also shown in Fig. 3. The dielectric constant decreases with the frequency below 10 kHz and becomes constant above 10 kHz. It increases slightly with pressure in the whole frequency range. The electrical conductivity increases with fre-

σ_i at 7 MHz $\Omega^{-1}cm^{-1}$	8×10^{-7}	1.5×10^{-6}	2.3×10^{-6}
z	2	4	6

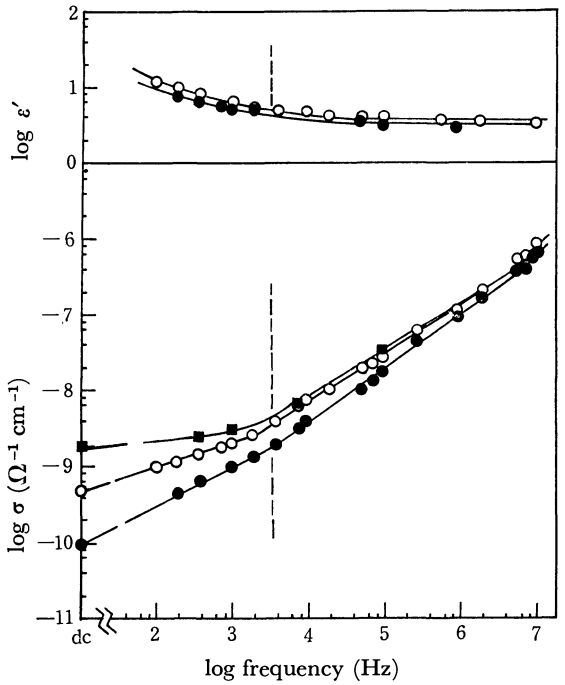

Fig. 3. Frequency dependence of conductivity σ and dielectric constant ε' for α-FeOOH compressed at 9 kg/cm² (●) and 150 kg/cm² (○). The frequency dependence of σ_i is denoted by ■.

quency in the frequency range below 10 kHz and more steeply above 10 kHz. The dispersion of electrical conductivity in the lower frequency range becomes less recognizable with the increase of pressure and is influenced by humidity. On the other hand, the dispersion in the higher frequency range is slightly affected by compression.

In the frequency range below 1 MHz, the ac conductivity (σ_{ac}) which equals σ minus σ_{dc}, where σ_{dc} is the dc conductivity, has the relation with frequency (f) as given by,

$$\sigma_{ac} \propto f^s. \quad (1)$$

The exponents s range from 0.6 to 0.8 and are almost independent of the pressure (Table 4).

The steepest increase of conductivity was observed with the frequency above 1 MHz.

Table 4. Exponents (s)

	At 9 kg/cm²	At 150 kg/cm²	σ_i
α-FeOOH	0.7	0.7	0.7
β-FeOOH	—	~ 1k 0.5	—
		2k ~ 1M 0.8	
γ-FeOOH	0.7	0.6	0.7

Sign of Carriers. The sign of carriers in both α-FeOOH and γ-FeOOH is presumed to be negative, judging from the sign of the cold probe due to the Seebeck voltage observed in the preliminary experiments. The adsorption of water molecules on crystals made it difficult to conclude the exact carrier sign for β-FeOOH, but it appears to be also negative.

Discussion

Frequency Dependence. The frequency dependence of electrical conductivity in the lower frequency range greatly depends on the pressure. The dispersion observed in the lower frequency range seems to be ascribed to the heterogeneity in the specimen, namely the intergranular gaps. The frequency dependence of dielectric constant agrees with that of the two-layer condenser which consists of two admittances in series.[11] Each layer consists of a resistance and a capacitance in parallel. The conductivity above 10 kHz does not become constant but exhibits a pronounced dispersion, though the two-layer condenser consisting of the frequency-independent admittance of crystals and that of gaps suggests that the conductivity of the system should be invariable with respect to the frequency in the frequency range above 10 kHz where the dielectric constant is unchangeable. The dispersion of conductivity occurs in both cases of 150 kg/cm² and σ_i. The dispersion seems to be due to the frequency-dependent conductivity of crystals. The two-layer condenser model could be extended to the inhomogeneous system consisting of the crystals with frequency-dependent conductivity and of the intergranular gaps as in the case of α-Fe_2O_3.[3] The frequency-dependent conductivity in the frequency range above 10 kHz is much higher than σ_{dc} and almost equals σ_{ac}. The ac conductivity given by Eq. (1), in which s is 0.8, was obtained by Pollack and Geballe[12] for the impurity conduction due to hopping processes in doped silicon at low temperature. The chemical analysis indicates that all ferric oxyhydroxides examined are non-stoichiometric having a general composition of $Fe^{II}_{3\delta}$ $Fe^{III}_{1-2\delta}$ OOH where δ is much smaller than 1. In view of the fact that the sign of carriers by the Seebeck voltage measurement is negative, the electrical conduction in ferric oxyhydroxides is attributed to the hopping of excessive d-electrons in Fe^{2+} to Fe^{3+} rather than to that of protons. Fe^{2+} ions are randomly distributed spatially and have an energy differing by about kT. The hopping occurs mainly between a pair of Fe^{2+} and the adjacent Fe^{3+}. Thus the electrical conductivity of ferric oxyhydroxides exhibits a frequency-dependence similar to the impurity conduction at low

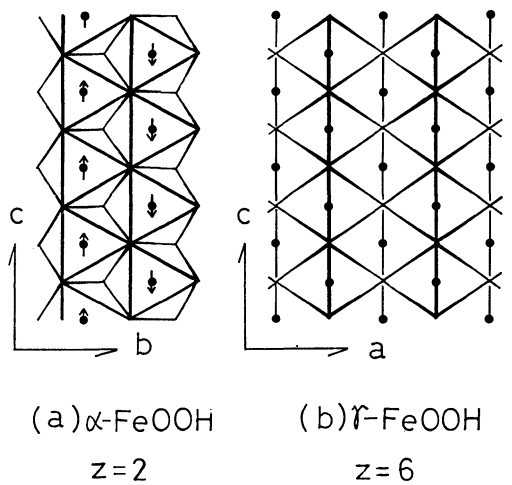

Fig. 4. Crystal structure of α-FeOOH (a) and γ-FeOOH (b). Filled circles denote iron ions and arrows the spin direction of iron ions. O and OH ions are located at the corners of octahedrons.

temperature.

The increase of conductivity with the frequency observed above 1 MHz may be due to the hopping processes with the different mechanism from the above-mentioned processes.

Structure and Hopping Conduction. In ferric oxyhydroxides, Fe^{3+} ions are surrounded octahedrally by six oxygen atoms. These octahedral units form a binuclear complex by sharing edges. In α-FeOOH[13,14] and β-FeOOH,[8,15] the dimers are stacked parallel to the c-axis and the strings are further joined by sharing corners and by hydrogen bonds, as illustrated in Fig. 4(a). In γ-FeOOH, on the other hand, the dimers form layers parallel to the ac-plane by sharing edges (Fig. 4(b)) and each layer links together with hydrogen bonds.[9] It is characteristic of β-FeOOH to embrace chlorine in tunnels parallel to c-axis. The Fe–Fe distance between the nearest neighbors is about 3 Å for each form of oxyhydroxides and there seems no appreciable interaction among iron atoms except nearest neighbors. The distortion at the surface of fine crystals is so predominant as to disturb the periodic potential and to give more localized d-electrons, since much surface Fe exists as shown in Table 1. The state of d-electrons in ferric oxyhydroxide crystals may be regarded approximately as that of "octahedral complex molecules." The d-electron level of a central metal splits into t_{2g} having a small contribution of the $2p_\pi$ orbital of oxygen and e_g having a small contribution of the sp-hybrid orbital of oxygen in molecular orbital of an octahedral complex.[16]

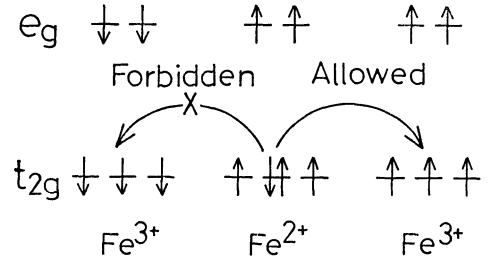

Fig. 5. Electron configurations on the occasion of the hopping of a d-electron in Fe^{2+} to Fe^{3+}.

A charge transfer occurs by the mechanism where a d-electron in the t_{2g}-orbital of Fe^{2+} hops to the adjacent site, t_{2g}-orbital of Fe^{3+}, through a slight overlapping of t_{2g}-orbitals of Fe^{2+} and Fe^{3+}. So long as no magnetic perturbation is present, the spin state of an electron before hopping must be in accord with that of an electron after hopping[17] (Fig. 5). Consequently the transfer probability is proportional to the number z of the nearest iron atoms in the same spin state. In the case of slight interactions among the partners, the transfer probability under an oriented electric field would also be proportional to z for the powdery crystals in various directions. It is noteworthy that the value of σ_i at 7 MHz is proportional to that of z at room temperature (Table 3). The preceding paper[3] showed that the σ_i at 7 MHz reflects the inner structure. This proportionality seems to be caused by the difference in the number of the nearest hopping-partners, since the amount of Fe^{2+} for each form of oxyhydroxide is equal.

All oxyhydroxides are antiferromagnetic and their Néel temperatures T_N found in previous works are as follows: β-FeOOH, 270 K;[18] γ-FeOOH, 50 K[18] or 70 K.[19] For α-FeOOH, different values ranging from 330 to 403 K have been reported.[14,20] The value of z at room temperature (Table 3) was estimated on the assumption that spins can be converted freely above T_N.

State of Chlorine in β-FeOOH. The sample of β-FeOOH examined in this work contains 9.5 atomic % chlorine which cannot be removed by washing with abundant distilled water until no Cl^- was detected with $AgNO_3$ solution. The presence of free chlorine ions would result generally in an increase of conductivity. The results obtained, however, indicate that the influence of chlorine is not remarkable and that chlorine may be immobile and does not seriously distort the electronic structure of iron. For a more definitive discussion on the chlorine effect the β-FeOOH samples with different contents of chlorine should be examined.

The authors express hearty thanks to Dr. R. Matsumoto (Fundamental Res. Inst., Nippon Steel Corp.) for emission spectroscopic analyses.

This research was partly supported by the Science Research Fund of the Ministry of Education.

Brillouin Scattering and Elastic Constants of Tetragonal Pentaerythritol

Hiroatsu MATSUURA* and Tatsuo MIYAZAWA**

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received January 17, 1974)

The Brillouin scattering from tetragonal pentaerythritol crystals was measured by using a helium–neon laser and a pressure-scanned Fabry-Perot interferometer. The Brillouin components from the longitudinal acoustic mode and the transverse acoustic mode polarized parallel to the scattering plane were observed for various crystal directions with the scattering vector in the (001) and (010) planes. From the observed Brillouin shifts, the frequencies and velocities of sound waves with the wavelength of 290 nm were obtained, and the elastic constants were determined, in units of 10^{11} dyn/cm^2, as $C_{11}=3.94\pm0.01$, $C_{13}=0.76\pm0.03$, $C_{16}=0.00\pm0.05$, $C_{33}=1.33\pm0.02$, $C_{44}=0.44\pm0.03$, and $2C_{66}+C_{12}=5.13\pm0.03$. The present hypersonic values of the elastic constants were compared with previous values by the ultrasonic technique.

Brillouin scattering is one of the experimental techniques for determining elastic constants of solid materials. This method has become particularly useful since the development of lasers as monochromatic light sources and of high-resolution interferometers. In Brillouin-scattering measurements, velocities of thermally excited sound waves are observed and accordingly no external acoustic excitation is necessary. Furthermore, only one crystal specimen suffices for determining elastic constants, unlike the ultrasonic technique which generally requires many crystal specimens with particular faces.

In our previous study,[1] the Brillouin scattering from a cubic crystal of potassium bromide was measured and the three elastic constants were determined. The Brillouin measurement was extended, in the present study, to a molecular crystal of tetragonal pentaerythritol $C(CH_2OH)_4$, and the elastic constants were compared with previous results of an ultrasonic study on this crystal.[2]

Experimental

The experimental arrangement for the observation of Brillouin scattering was essentially the same as that was used in our previous study.[1] The light source was a helium–neon gas laser in the fundamental transverse mode, giving radiation at 632.8 nm with an output of about 50 mW. The light scattered from the sample at 90° away from the incident-beam direction was analyzed by a pressure-scanned Fabry-Perot interferometer. In the present measurements, the incident laser beam was focused by a lens inserted just before the sample, so that the beam in the crystal had an appropriately narrow width which allowed the efficient collection of the scattered light. This light-focusing system is particularly important for measuring Brillouin scattering from small crystal specimens. The spacer between the interferometer etalons had a thickness of 6.075 mm, giving the free spectral range of 24.674 GHz.

Crystal specimens of pentaerythritol were generously supplied to us by Dr. H. Yamada.[3] The crystal with dimensions of $5\times3.5\times2.5$ mm^3 was immersed in liquid anethole, which had nearly the same refractive index as that of pentaerythritol. This technique was found to be useful in reducing a large amount of unwanted light scattered from rough crystal surfaces. The sample was supported by a rotatable holder, the same apparatus that was used in the previous study on potassium bromide,[1] which allowed the crystal to be rotated about an axis perpendicular to the scattering plane. Accordingly, any direction in a crystal plane parallel to the scattering plane could be chosen as the direction of the scattering vector. The Brillouin scattering was measured for the scattering vector in two crystal planes, the (001) and (010) planes. The measurements were made at 23 ± 1°C at least five times for each orientation of the crystal. For certain crystal directions, Brillouin shifts were expected to be larger than the half of the free spectral range with the spacer of ~6 mm. Accordingly, auxiliary measurements were also made with a spacer of the 3 mm thickness so that the free spectral range was made as large as ~50 GHz.

The crystal structure of pentaerythritol at room temperature belongs to the tetragonal system with the space group of S^2_4–$I\bar{4}$.[4] The c axis was readily identified, since the crystal was cleaved very easily perpendicular to this axis. This axis was determined by the X-ray diffraction technique.

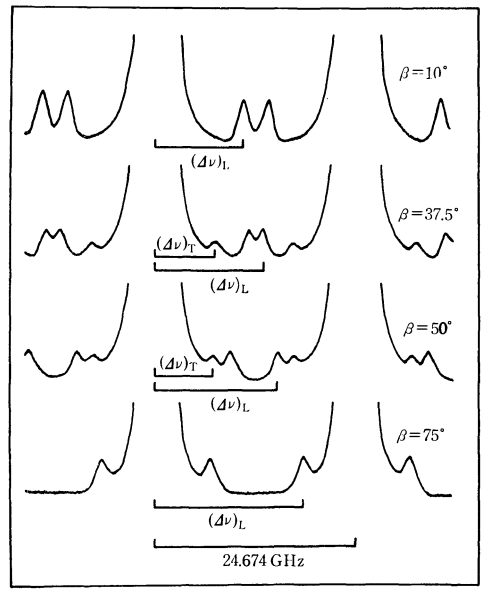

Fig. 1. Brillouin spectra of tetragonal pentaerythritol in Measurement II. $(\Delta\nu)_L$ and $(\Delta\nu)_T$ are the longitudinal and in-plane transverse Brillouin shifts, respectively.

Some typical examples of the observed Brillouin spectra are shown in Fig. 1, and the observed frequency shifts and sound velocities are listed in Tables 1 and 2.

Analysis of Brillouin Spectra

The frequency shift in Brillouin scattering, $\Delta\nu$, is related to the velocity of elastic waves in the medium, v, by[5]

$$\Delta\nu/\nu_i = \pm(v/c)(n_i^2+n_s^2-2n_in_s\cos\theta)^{1/2}, \quad (1)$$

where ν_i is the frequency of the incident light wave, c is the velocity of light in vacuum, n_i and n_s are the refractive indices of the medium for the incident and scattered directions, and θ is the angle of scattering. In a crystal, there are three modes of elastic waves, one longitudinal and two transverse modes, propagating with different velocities.[6] Accordingly, observation of three pairs of Brillouin components with different frequency shifts is expected for any crystal, unless double refraction is taken into account. However, the Brillouin scattering from one of the transverse modes polarized perpendicular to the scattering plane (out-of-plane transverse mode) is usually not observable, since this mode gives in general much weaker Brillouin intensities than the longitudinal mode or the other transverse mode polarized parallel to the scattering plane (in-plane transverse mode). The longitudinal and in-plane transverse modes are mixed with each other for general crystal directions.

The tetragonal pentaerythritol crystal is uniaxial, and accordingly has the optical property of double refraction. In uniaxial crystals, two refractive indices of n' and n'' for ordinary and extraordinary rays, respectively, are related, by the following equations, to the principal refractive indices of $n_a=n_b$ and n_c, where the suffixes represent the principal crystal axes,

$$n' = n_a \quad (2)$$

and

$$n'' = n_an_c/(n_a^2\sin^2\phi+n_c^2\cos^2\phi)^{1/2}, \quad (3)$$

where ϕ is the angle between the c axis and the direction of the wave vector of light. In the present measurements, the Brillouin scattering was observed for the scattering vector in the (001) plane (Measurement I) and the (010) plane (Measurement II). Since the crystal was rotated about an axis perpendicular to the scattering plane, the incident and scattered lights were also in the (001) plane or the (010) plane. For Measurement I, $\phi=90°$ for both incident and scattered lights, and accordingly the refractive indices of the ordinary and extraordinary rays are given by

$$n_i' = n_s' = n_a \quad (4)$$

and

$$n_i'' = n_s'' = n_c. \quad (5)$$

For Measurement II,

$$n_i' = n_s' = n_a, \quad (6)$$

$$n_i'' = n_an_c/(n_a^2\sin^2\phi_i+n_c^2\cos^2\phi_i)^{1/2}, \quad (7)$$

and

$$n_s'' = n_an_c/(n_a^2\sin^2\phi_s+n_c^2\cos^2\phi_s)^{1/2}. \quad (8)$$

The ordinary and extraordinary rays are polarized lights whose electric vectors are perpendicular and parallel, respectively, to the plane determined by the wave vector of light and the optical axis of the crystal

(c axis in tetragonal crystals). Hence, it may be more convenient to give the refractive indices according to the polarization of the incident and scattered lights. The refractive indices for the incident light with the vertical (V) and horizontal (H) electric vectors and for the scattered light with the vertical (v) and horizontal (h) electric vectors (the scattering plane being horizontal) are given by; for Measurement I

$$n_V = n_v = n_c \text{ (extraordinary ray)} \quad (9)$$

and

$$n_H = n_h = n_a; \text{ (ordinary ray)} \quad (10)$$

and for Measurement II

$$n_V = n_v = n_a, \text{ (ordinary ray)} \quad (11)$$

$$n_H = n_a n_c/(n_a^2 \sin^2 \phi_i + n_c^2 \cos^2 \phi_i)^{1/2}, \text{ (extraordinary ray)} \quad (12)$$

and

$$n_h = n_a n_c/(n_a^2 \sin^2 \phi_s + n_c^2 \cos^2 \phi_s)^{1/2}. \text{ (extraordinary ray)} \quad (13)$$

The Brillouin measurements were attempted in the present study with the incident laser beam with vertical (V) and horizontal (H) electric vectors. The vertically polarized light gave a pair of Brillouin components in Measurements I and II, with an additional pair for certain crystal directions in Measurement II, but the horizontally polarized light gave no detectable Brillouin components. The Brillouin spectra reported here are, accordingly, those observed by the incident light with a vertical polarization (V). The polarization of the observed scattered light was found to be vertical (v). Hence, the refractive indices for Measurement I are $n_V=n_v=n_c$, and for Measurement II, $n_V=n_v=n_a$. Equation (1) is now reduced, under the present experimental condition, to the following equations; for Measurement I

$$\Delta\nu/\nu_i = \pm 2(v/c)n_c \sin(\theta/2), \quad (14)$$

and for Measurement II

$$\Delta\nu/\nu_i = \pm 2(v/c)n_a \sin(\theta/2). \quad (15)$$

The refractive-index values of $n_a=1.5537$ and $n_c=1.5109$ (for 659 nm)[7] were used in the present analysis of Brillouin spectra of tetragonal pentaerythritol. From the polarization of the incident and scattered lights and the intensities, the observed Brillouin components were assigned to the acoustic mode almost entirely longitudinal with admixture of the transverse mode. The additional weaker components observed in Measurement II were assigned to the mode primarily in-plane transverse mixed with the longitudinal mode. The polarization of the acoustic waves were confirmed by examining eigenvectors of the Christoffel-equation matrix as will be mentioned later.

Since the Brillouin-scattering measurements were made for the scattering angle $\theta=90°$, the wavelength of the scattering sound wave, λ_s, is given by; for Measurement I

$$\lambda_s = \lambda_i/(\sqrt{2}\, n_c), \quad (16)$$

and for Measurement II

$$\lambda_s = \lambda_i/(\sqrt{2}\, n_a), \quad (17)$$

where λ_i is the wavelength of the incident light in a vacuum. By substituting $\lambda_i=632.8$ nm for a helium–neon laser, the wavelength of the sound wave is obtained as $\lambda_s=296.2$ nm for Measurement I and $\lambda_s=288.0$ nm for Measurement II.

The crystallographic a axis was determined by the X-ray diffraction technique with experimental error less than $\pm 1°$. The observed sound velocities were obtained by Eqs. (14) and (15), and are listed in Tables 1 and 2. The direction of the scattering vector, which is equivalent to the propagation direction of the sound wave responsible for Brillouin scattering, is described in Table 1 by the angles α and β for Measurements I and II, respectively. α is the angle between the scattering vector and the [100] direction in the (001) plane, and β is the angle between the scattering vector and the [001] direction in the (010) plane.

Calculation of Elastic Constants

The crystal structure of pentaerythritol at room temperature belongs to the tetragonal system with the space group of S_4^2–$I\bar{4}$.[4] Accordingly, the number of independent elastic constants is reduced to seven; namely $C_{11}=C_{22}$, C_{33}, $C_{44}=C_{55}$, C_{66}, C_{12}, $C_{13}=C_{23}$, and $C_{16}=-C_{26}$ (other elastic constants vanish by symmetry). Hence, the Christoffel equation,[8] which relates the elastic constants and elastic-wave velocities, v, is given for this crystal by

$$\begin{vmatrix} \lambda_{11}-\rho v^2 & \lambda_{12} & \lambda_{13} \\ \lambda_{12} & \lambda_{22}-\rho v^2 & \lambda_{23} \\ \lambda_{13} & \lambda_{23} & \lambda_{33}-\rho v^2 \end{vmatrix} = 0, \quad (18)$$

where $\lambda_{11}=l^2C_{11}+m^2C_{66}+n^2C_{44}+2lmC_{16}$, $\lambda_{22}=l^2C_{66}+m^2C_{11}+n^2C_{44}-2lmC_{16}$, $\lambda_{33}=(l^2+m^2)C_{44}+n^2C_{33}$, $\lambda_{12}=(l^2-m^2)C_{16}+lm(C_{66}+C_{12})$, $\lambda_{13}=nl(C_{44}+C_{13})$, $\lambda_{23}=mn(C_{44}+C_{13})$, l, m, and n are the direction cosines of the propagation direction of the sound waves, and ρ is the mass density. It is more convenient to express λ's in terms of the angle α or β. For Measurement I ($l=\cos\alpha$, $m=\sin\alpha$, and $n=0$), $\lambda_{11}=C_{11}\cos^2\alpha+C_{66}\sin^2\alpha+2C_{16}\cos\alpha\sin\alpha$, $\lambda_{22}=C_{11}\sin^2\alpha+C_{66}\cos^2\alpha-2C_{16}\cos\alpha\sin\alpha$, $\lambda_{33}=C_{44}$, $\lambda_{12}=(C_{12}+C_{66})\cos\alpha\sin\alpha+C_{16}(\cos^2\alpha-\sin^2\alpha)$, and $\lambda_{13}=\lambda_{23}=0$, and for Measurement II ($l=\sin\beta$, $m=0$ and $n=\cos\beta$), $\lambda_{11}=C_{11}\sin^2\beta+C_{44}\cos^2\beta$, $\lambda_{22}=C_{66}\sin^2\beta+C_{44}\cos^2\beta$, $\lambda_{33}=C_{33}\cos^2\beta+C_{44}\sin^2\beta$, $\lambda_{12}=C_{16}\sin^2\beta$, $\lambda_{13}=(C_{44}+C_{13})\cos\beta\sin\beta$, and $\lambda_{23}=0$.

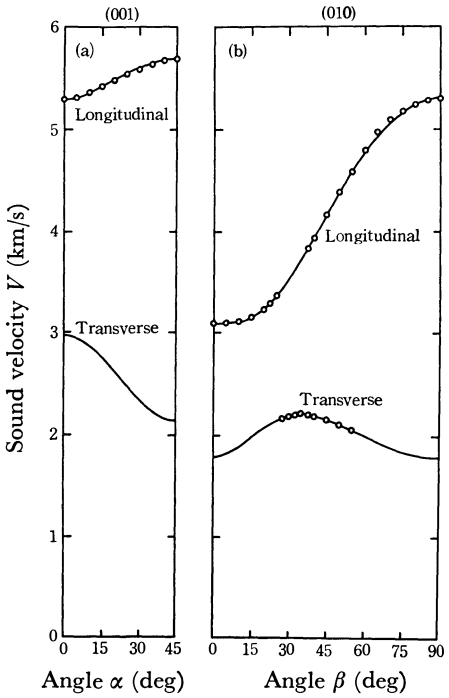

Fig. 2. Sound velocity of the longitudinal and in-plane transverse modes in tetragonal pentaerythritol, in Measurement I (a) and Measurement II (b). The sound velocity of the in-plane transverse mode in Measurement I was calculated by assuming $C_{12}=2.66\times10^{11}$ and $C_{66}=1.24\times10^{11}$ dyn/cm^2. ○: observed value; ——: calculated value.

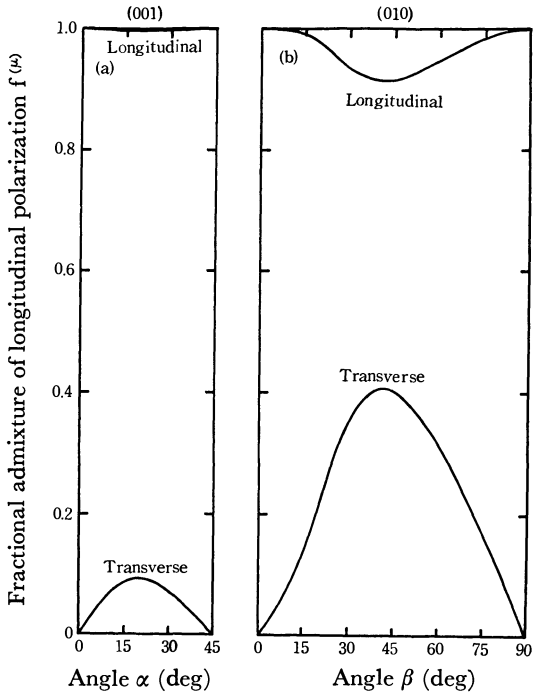

Fig. 3. Fractional admixture of longitudinal polarization for the longitudinal and in-plane transverse modes in tetragonal pentaerythritol, in Measurement I (a) and Measurement II (b).

The elastic constants of tetragonal pentaerythritol were determined, by solving Eq. (18), from 38 observed values for the sound velocity by the least-squares method. The mass density[2] of $\rho=1.398$ g/cm^3 was used in the calculations. In the least-squares adjustment of the elastic constants, the values of C_{12} and C_{66} were hardly settled, but a combination of $2C_{66}+C_{12}$ was determined fairly accurately. The determined values of the elastic constants are listed in Table 3, in comparison with values obtained previously by the ultrasonic technique.[2] The observed and calculated sound velocities are shown in Fig. 2. Figure 3 shows the fractional admixture of longitudinal polarization $f^{(\mu)}$ for the longitudinal and in-plane transverse modes, defined by

$$f^{(\mu)} = \boldsymbol{e}_{\mathrm{pol}}^{(\mu)}\cdot\boldsymbol{e}_{\mathrm{prop}}, \tag{19}$$

where μ is an index for the acoustic modes, $\boldsymbol{e}_{\mathrm{pol}}^{(\mu)}$ is a unit vector in the polarization direction of the mode μ of the sound wave [corresponding to the eigenvector of Eq. (18) for the mode μ], and $\boldsymbol{e}_{\mathrm{prop}}$ is a unit vector in the propagation direction of the sound wave [corresponding to the direction cosines l, m, and n appearing in Eq. (18)].

Discussion

The elastic constants of tetragonal pentaerythritol determined in the present study may be compared with values obtained by the ultrasonic pulse technique with a frequency of 5 MHz.[2] The Brillouin values of C_{11} and C_{33} are in excellent agreement with the ultrasonic values. Also, the agreement for C_{13} and C_{44} is almost satisfactory, considering experimental errors involved. The discrepancy in values of elastic constants may also be attributable in part to the dispersion of the sound velocities for the hypersonic and ultrasonic regions. However, the Brillouin value of $2C_{66}+C_{12}$ is much larger than the ultrasonic value. Indeterminacy of separate values for C_{12} and C_{66} in the present study does not allow further discussion on this discrepancy. The C_{11} value of pentaerythritol (3.9×10^{11} dyn/cm^2) is very close to the values of the corresponding constant for alkali halides [$(3—4)\times10^{11}$ dyn/cm^2].[1,9] The intermolecular hydrogen bonds formed in planes parallel to the (001) plane are, at least in part, responsible for the C_{11} value comparable to those of ionic crystals.

In the present study, the longitudinal Brillouin components were observed in both Measurements I and II, but the in-plane transverse components were observed only for $\beta=27.5—55°$ in Measurement II. It is evident from Fig. 3 that the appreciable mixing with the longitudinal mode allowed the observation of the transverse Brillouin components for these crystal directions. On the contrary, in Measurement I, the mixing is too small to enhance the transverse Brillouin intensities.

In Brillouin-scattering measurements, only one crystal specimen suffices for determining elastic constants, unlike the ultrasonic technique which generally requires many crystal specimens with particular faces. Accordingly, the Brillouin scattering technique is free from experimental errors arising in the process of cutting and polishing crystal specimens. This is one of the

advantages of the Brillouin-scattering method over the ultrasonic method. Also, in the Brillouin scattering, measurements of sound velocities are possible for any desired crystal direction, once the crystallographic axes are determined. However, the Brillouin scattering from the three acoustic modes, one longitudinal and two transverse modes, are generally not all observed in the spectra. This disadvantage is compensated in part by measuring sound velocities of the observable modes for many crystal directions. However, this experimental limitation sometimes makes it difficult to determine all of independent elastic constants. In the present study, separate values for C_{12} and C_{66} could not be determined uniquely because of the lack of experimental sound velocities for the in-plane transverse mode in Measurement I. The present study has nevertheless indicated that the Brillouin-scattering technique, using a laser and a high-resolution interferometer, is useful in determining elastic constants of crystals. So far only a few molecular crystals have been reported,[10-12] whose elastic constants were determined by this method, but it is expected that an increasing number of crystals will be studied by the Brillouin-scattering technique.

Numerical calculations in the present study were carried out with a NEAC 2200-700 computer at the Computer Center of Osaka University. The authors wish to thank Dr. Haruka Yamada of Kwansei Gakuin University for supplying them with crystal specimens of pentaerythritol, and Professor Masao Kakudo and Dr. Nobuo Tanaka of Osaka University for measuring X-ray diffraction of the sample.

Temperature Dependence of the Lattice Vibrations of Triglycine Sulfate

Norio KANEKO, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, School of Science and Engineering, Waseda University, Tokyo 160

(Received January 18, 1974)

Far infrared spectra from 400 to 30 cm^{-1} of triglycine sulfate and its deuterated analogue were measured and the bands due to the librational modes of glycine molecules were identified. Polarized Raman spectra below 300 cm^{-1} of triglycine sulfate single crystals were measured and the symmetry species of the observed lattice vibrations were determined. Temperature dependence of the lattice vibrations was examined. Significant changes were detected in both infrared and Raman spectra on crossing the Curie temperature, indicating a flipping motion of glycine I in the paraelectric phase and suggesting the ferroelectric transition in triglycine sulfate to be of an order-disorder type.

Triglycine sulfate (TGS) is one of the few crystals which exhibit ferroelectricity at room temperature. Since its discovery in 1956 by Matthias *et al.*,[1] the crystal structure as well as ferroelectric transition have been extensively studied.

A detailed crystal structure was reported by Hoshino *et al.*[2] and recently by Itoh and Mitsui.[3] Hoshino *et al.* proposed an order-disorder type theory of the ferroelectric transition based on their X-ray diffraction data. They explained the dipole switching mechanism in the ferroelectric phase in terms of the flipping of the $NH_3^+CH_2COOH$ glycinium ion (glycine I) between two equivalent orientations in the crystal, plus the tunneling of the hydrogen bonded proton between the $NH_3^+CH_2COO^-$ zwitter-ion (glycine II) and the other $NH_3^+CH_2COOH$ ion (glycine III).

The theory was supported by critical X-ray scattering study.[4] However, deuteron magnetic resonance studies[5,6] cast some doubt about the proposed dipole reversal mechanism and the order-disorder nature of the ferroelectric transition.

Infrared and Raman studies on TGS have been carried out by several investigators. Dodd[7] measured polarized infrared spectra from 4000 to 625 cm^{-1} and concluded that TGS, unlike crystalline glycine, was not in the zwitter-ion form. She further reported that heating the crystal above the Curie temperature (48 °C) produced no appreciable changes in the infrared spectra. Khanna *et al.*[8] investigated the infrared spectra of TGS and its deuterated analogue at room temperature and liquid N_2 temperature and found the bands due to the zwitter-ion as well as glycinium ion. Recent investigation by Raman spectra[9] supported the presence of the zwitter-ion in TGS crystals.

Barker and Tinkham[10] measured polarized infrared reflection spectra down to 14 cm^{-1}, but no soft mode was observed. Sato[11] measured infrared spectra at various temperatures and found that the band at 575 cm^{-1} markedly decreased in intensity with temperature rise of the crystal, disappearing above the Curie temperature. Quilichini *et al.*[12] measured polarized Raman spectra below 200 cm^{-1} at various temperatures, but failed to reveal significant spectral changes due to ferroelectric transition.

The purpose of this paper is two-fold; to determine symmetry species of the lattice vibrations by polarized Raman spectra, and to detect changes in the infrared and Raman spectra by temperature variation and thereby giving additional information on the mechanism of the ferroelectric transition in TGS.

Experimental

Single crystals of TGS were grown from an aqueous solution containing glycine and sulfuric acid in proper molar proportions. The composition of the crystals were checked by titrating a small amount of the sample with a standard NaOH solution. The crystals were in the form of thick plates (about 7 mm × 7 mm × 3 mm) with a broad face parallel to the b-axis (two-fold axis) and a cleavage plane perpendicular to the b-axis.

The far infrared spectra (400—30 cm^{-1}) of TGS and its *N*-deuterated powder suspended in Nujol were recorded with a Hitachi FIS-3 spectrophotometer. The *N*-deuterated analogue was prepared by recrystallizing the sample several times from heavy water solutions.

The Raman spectra were recorded with a Shimadzu R-2D double monochrometer. The 5145 Å line of an Ar^+ laser was used as the excitation wave-length with 700 mW power output. For the polarized Raman spectra, single crystals with three facets each respectively parallel to the cleavage plane (010), the optic plane ($\bar{1}02$) and the plane perpendicular to both planes was used. The third facet was almost parallel to the (100) plane, the angle between them being less than 3°. A polarization scrambler, a quartz wedge, was placed between the analyser and slit to correct preferential sensitivity of the monochrometer to the polarization of the scattered light. The spectra were recorded by photon counting detection and the wave numbers of the Raman bands were calibrated using spontaneous emission lines from the laser.

The temperature variation of the infrared and Raman-spectra were measured using high and low temperature cells. For the infrared spectra a double chopping method was employed to eliminate the effect of the radiation from the sample and the reference. The temperature of the crystal was measured and controlled within ±1°C by means of a copper-constantan thermocouple in the range −190 −25 °C and an alumel-chromel thermocouple in the range above 25 °C.

Results and Discussion

The crystal structure of TGS is monoclinic; the space group is C_2^2–$P2_1$ in the ferroelectric phase and C_{2h}^2–$P2_1/m$ in the paraelectric phase.[2,13] In either phase, the Bravais unit cell contains two units of the formula $NH_3^+CH_2COO^-(NH_3^+CH_2COOH)_2SO_4^{2-}$. The crys-

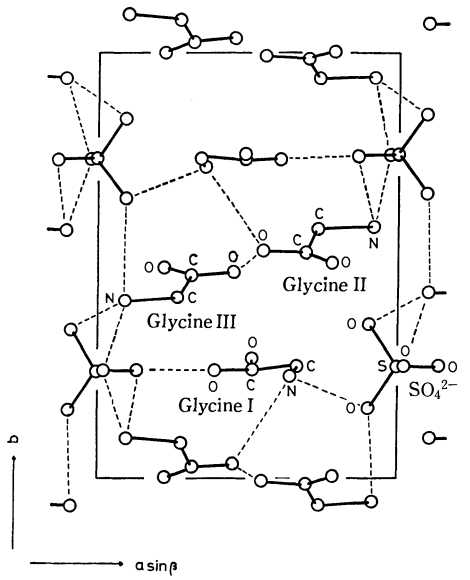

Fig. 1. Projection of the crystal structure of TGS on the ab-plane (ferroelectric phase). Positions of hydrogen atoms are not given. Hydrogen bonds are indicated by dotted lines.

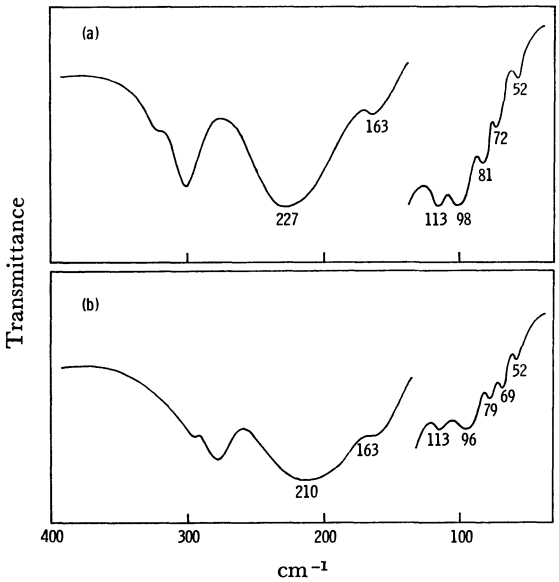

Fig. 2. Far infrared spectra of TGS and its deuterated powder suspended in Nujol.
(a) $NH_3^+CH_2COO^-(NH_3^+CH_2COOH)_2SO_4^{2-}$
(b) $ND_3^+CH_2COO^-(ND_3^+CH_2COOD)_2SO_4^{2-}$

tal structure in the ferroelectric phase is shown in Fig. 1. The lattice constants are: $a=9.417$, $b=12.643$, $c=5.735$ Å, and $\beta=110°23'$. The monoprotonated glycinium ions are denoted by glycine I and III, and the zwitter-ion by glycine II. The molecular plane of glycine I is tilted 12.5° with respect to the ac-plane. The transition from the ferroelectric to the paraelectric phase might be due to a statistical disorder in the orientation of the glycine I ions with respect to the ac-plane (y=1/4 and 3/4), *i.e.* above the Curie point, these planes become the mirror planes in a statistical sense.[3)]

Assignment of Lattice Vibrations. The 45 optically active lattice modes can be classified by the usual group theoretical method as 23A+22B in the ferroelectric phase and $12A_g+12B_g+11A_u+10B_u$ in the paraelectric phase. Classification of the lattice vibrations is given in Table 1 together with the activities in the infrared and Raman spectra.

Table 1. Classification of lattice vibrations of TGS

	(1) Ferroelectric Phase (C_2^2–$P2_1$)			
	Trans	Lib.	IR	Raman
A	11	12(3)	M_z	α_{xx} α_{yy} α_{zz} α_{xy}
B	10	12(3)	M_x M_y	α_{xz} α_{yz}

	(2) Paraelectric Phase (C_{2h}^2–$P2_1/m$)			
	Trans	Lib.	IR	Raman
A_g	6	6(1)	ia	α_{xx} α_{yy} α_{zz} α_{xy}
B_g	6	6(2)	ia	α_{xz} α_{yz}
A_u	5	6(2)	M_z	ia
B_u	4	6(1)	M_x M_y	ia

Figures in parentheses donate the number of librational modes of SO_4^{2-}.

The far infrared spectra from 400 to 30 cm^{-1} of TGS and its deuterated analogue are given in Fig. 2. Lattice vibrations are observed at 52, 72, 81, 98, 113, 163, and 227 cm^{-1}. The bands at 72, 81, 98, and 227 cm^{-1} shift respectively to 69, 79, 96, and 210 cm^{-1} by deuteration of the NH_3^+ group, while those at 52, 113, and 163 cm^{-1} remain unchanged. Accordingly, the bands at 72, 81, and 98 cm^{-1} can be assigned to the librational modes of the glycine molecules, and the band at 227 cm^{-1} being atrributable to the lattice mode associated with hydrogen bonds. The shift of the band at 227 cm^{-1} is slightly greater than that expected from the change of the moment of inertia. However, this band is undoubtedly overlapped by more than one band and its peak shift can not be determined accurately. The bands at 52, 113, and 163 cm^{-1} could be assigned either to librational modes of SO_4^{2-} or to translational modes.

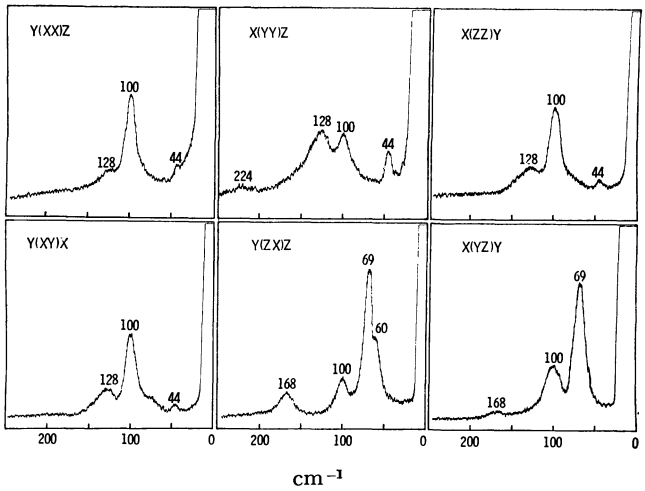

Fig. 3. Polarized Raman spectra of TGS single crystals. The Raman tensor components are expressed according to Porto's notation.

The polarized Raman spectra of TGS single crystals are shown in Fig. 3. The Raman tensor components are expressed in terms of the notation of Damen *et al.*[14] The lattice vibrations are detected at 44, 60, 69, 100, 128, 168, and 224 cm^{-1}. The frequencies agree with the values in literatures.[15-17] We see from Fig. 3 that the bands at 44, 128, and 224 cm^{-1} belong to symmetry species A and those at 60, 69, and 168 cm^{-1} to species B. The band at 100 cm^{-1} is overlapped by lattice modes belonging to species A and B. In the spectrum at liquid N_2 temperature, the band splits into three bands at 93, 101, and 111 cm^{-1}.

TABLE 2. FREQUENCIES (cm^{-1}) OF LATTICE VIBRATIONS OF TGS AND ASSIGNMENTS

IR (powder)	Raman (single crystal)	Symmetry species	Assignment
	44	A	
52			
	60	B	
72	69	B	Lib.(glycine)
81			Lib.(glycine)
98	100	A+B	Lib.(glycine)
113			
	128	A	
163	168	B	
227	224	A	H-bonds[a]

a) A lattice mode associated with hydrogen bonds.

The frequencies of the lattice modes observed in the infrared and Raman spectra are summarized in Table 2 along with some of their general assignments. The Raman spectra of TGS crystals cut at 45° to the b-axis were also measured in order to identify the longitudinal modes. However, no TO–LO splitting was observed.

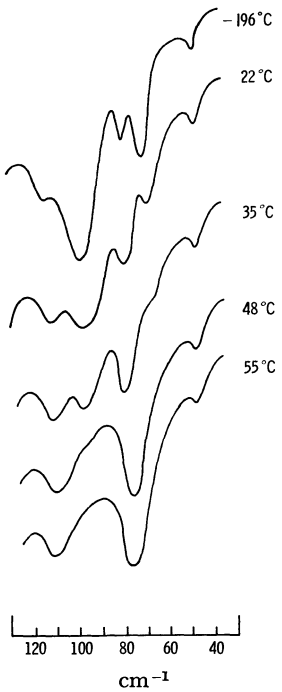

Fig. 4. Temperature dependence of the infrared bands of TGS powder.

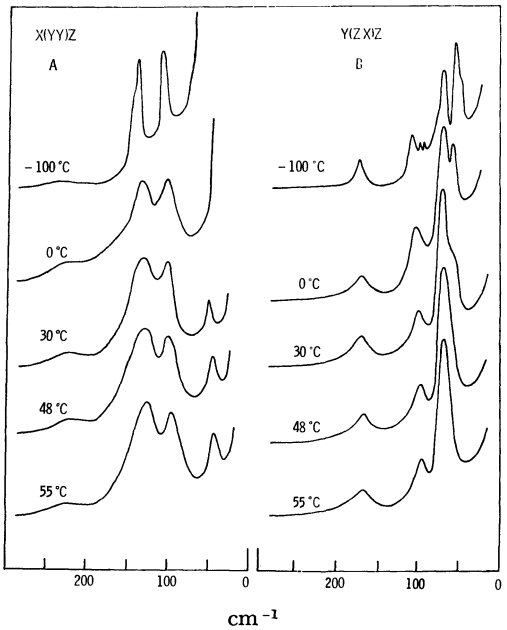

Fig. 5. Temperature dependence of the Raman bands of TGS single crystals.

Temperature Variation. The far infrared spectra from 130 to 30 cm^{-1} at liquid N_2 temperature and elevated temperatures are shown in Fig. 4. The band at 98 cm^{-1} gradually decreases in intensity with the rise in temperature of the crystal disappearing completely in the paraelectric phase (above 48 °C). The band at 72 cm^{-1} also seems to disappear above the Curie temperature, although it is probably masked by the near-by band at 81 cm^{-1} which gradually shifts to lower frequencies and become more intense and broad with the rise in temperature. The polarized Raman spectra below 250 cm^{-1} at various temperatures are reproduced in Fig. 5. It is seen that the band at 60 cm^{-1} which belongs to B symmetry species gradually decreases in intensity as the temperature rises and fades away above the Curie temperature.

As the crystal changes from non-centrosymmetric structure C_2^2 to centrosymmetric structure C_{2h}^2 at the Curie point when the crystal is heated, it is possible that the disappearance of the infrared and Raman bands is caused by the difference in the selection rule. If this is the case, the lattice vibration corresponding to the infrared band at 98 cm^{-1} should become a "gerade" mode in the paraelectric phase, intensity enhancement of the Raman band arising from this lattice mode thus being expected. Further, the lattice vibration corresponding to the Raman band at 60 cm^{-1} should be an "ungerade" mode in the paraelectric phase, giving rise to a strong band in the infrared spectrum. However, the Raman band at 100 cm^{-1} does not seem to exhibit appreciable intensity changes by temperature variation, and the band corresponding to the Raman band at 60 cm^{-1} can not be detected in the infrared spectrum.

The disappearance of the infrared band at 98 cm^{-1} and the Raman band at 60 cm^{-1} can be explained satisfactorily if we assume that these bands arise from

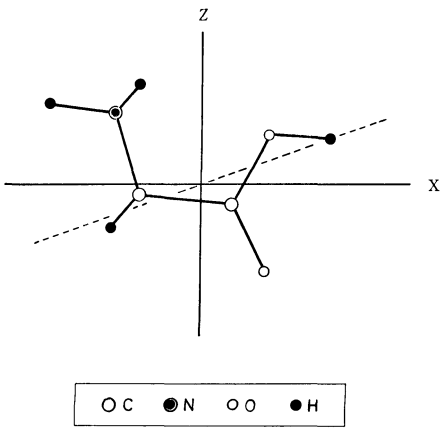

Fig. 6. Principal axes of the monoprotonated glycinium ion. The direction of the dipole moment is also shown by a dotted line.

the librational mode around the z axis of glycine I (Fig. 6). According to the crystal structure proposed by Hoshino *et al.*,[2] the molecular plane of glycine I makes an angle of 12.5° with the ac-plane in the ferroelectric phase, while in the paraelectric phase, glycine I performs a flipping motion between the two equivalent tilted positions with respect to the ac-plane. Because of this flipping motion, the infrared and Raman bands due to the librational modes of glycine I ions around the z axis might be smeared over the spectrum and their peaks would not be detected above the Curie temperature (48 °C). We see from Figs. 4 and 5 that the intensity decrease of the bands at 98 and 60 cm^{-1} starts at a temperature much lower than the Curie point. This is probably because the flipping motion of glycine I in the ferroelectric phase does not abruptly 'freeze in' at the Curie point but persists to some extent in the ferroelectric phase.

It is interesting to see that the intensity of the infrared band at 81 cm^{-1} gradually increases as the temperature of the crystal increases. The band can be assigned to the librational mode in which glycines II and III librate out-of-phase. In the paraelectric phase, TGS crystals have a center of symmetry between glycines II and III and hence glycines II and III must be in the same configuration, implying that one proton tunnels between them. Thus, the dipole moment of these two molecules in the paraelectric phase might differ from that in the ferroelectric phase and the intensity enhancement of the infrared band at 81 cm^{-1} is attributable to the change in the dipole moment.

Savatinova and Simova[18] carried out temperature variation of the low frequency Raman spectra of TGS powder using a mercury lamp as the exciting source and concluded that the frequency of the band at 70 cm^{-1} decreases to zero near the temperature of the phase transition. However, their conclusion is inconclusive since this band is heavily overlapped by the band at 60 cm^{-1} and moreover, these two bands are masked by the exciting line of the mercury lamp and the behavior of the band in their experiment is not clear in detail. We see in Fig. 5 that the band at 69 cm^{-1} in fact shifts somewhat to lower frequencies as the temperature rises. However, the frequency of this band does not go to zero even in the paraelectric phase.

Expenses incurred in the experiments were defrayed from the Kawakami Foundation.

(Received January 24, 1974)

Proton donor-acceptor interactions in excited states were studied by measuring mainly time-resolved fluorescence spectra for β-naphthol–TEA in toluene and in acetonitrile, and for β-naphthylamine–TEA in nonpolar mixed solvents. The Stern-Volmer relation was found to be satisfied for β-naphthol–TEA in toluene. The rate constant and activation energy of hydrogen bond formation in the excited state of this system were obtained to be 2.2×10^9 M^{-1} s^{-1} at 30 °C and 1.6 kcal/mol, respectively, indicating that the process is diffusion-controlled. The time dependences of the intensities of the fluorescence bands due to the free and complexed β-naphthol were measured with the solutions containing various concentrations of triethylamine in acetonitrile. From the analysis of the result, it is shown that this system is led to the ion-pair formation *via* the hydrogen-bonded species in the excited state. For β-naphthylamine–TEA in nonpolar mixed solvents, the bands due to hydrogen-bonded species in the ground and excited states were observed at 370 and ~390 nm in the absorption and fluorescence spectra, respectively.

One of the present authors (S.N.) and Gouterman[1] studied the hydrogen bonding effect upon the electronic absorption spectra of α- and β-naphthols and obtained the results that the hydrogen bonding has the chargetransfer character to some extent. Förster[2] found ion-pair formation in the excited states of β-naphthol and other compounds through proton transfer. Weller *et al.*[3–5] and Stryer[6] have studied the proton-transfer reaction in the excited state of β-naphthol in aqueous solution by measuring its fluorescence and have determined several kinetic and thermodynamic constants. Mataga *et al.*[7–9] measured the fluorescence spectra of ternary solutions containing β-naphthol or other proton donors and acceptors in organic solvents. They showed that a hydrogen-bonded complex and an ion-pair exist in the excited state of the system containing β-naphthol and triethylamine in benzene. Baba *et al.*[10,11] measured fluorescence and excitation-polarization spectra with some hydrogen bonding systems including α-naphthol as proton donor and discussed the nature of their lowest excited singlet states. Hirota[12] investigated the behaviors of 3-hydroxy-2-naphthoic acid and its derivatives in their excited states by measuring relative fluorescence intensities of the free and hydrogen-bonded species as a function of temperature.

The above-mentioned studies have been made by measuring mainly fluorescence spectra, excitation polarization spectra, and quantum yields. In other words, they have been done under steady-state conditions. Recently, however, the fast transient technique has been applied to the study of proton transfer in the excited state. Ware[13] studied the intramolecular proton transfer of 2-hydroxy-3-naphthoic acid in the excited state by measuring the fluorescence decay. Furthermore, Ofran and Feitelson[14] studied the proton dissociation of β-naphthol in the excited state with the aid of fluorescence decay measurements.

In the present study, we have undertaken to study the interaction of β-naphthol or β-naphthylamine in the excited state with triethylamine by measuring nanosecond time-resolved fluorescence spectra and by analyzing the decays of fluorescence bands due to the free and complexed proton donors.

Experimental

β-Naphthol and β-naphthylamine were purified by vacuum sublimation after repeated recrystallizations from water. Triethylamine (TEA) was refluxed with acetic anhydride and thereafter distilled under reduced pressure. The purified TEA was degassed and stored in a refrigerator. Spectrograde toluene was distilled from sodium. Methylcyclohexane and isopentane were distilled after passing through a 1 m silica gel column. Acetonitrile was distilled from phosphorus pentoxide and thereafter from calcium hydride.

Samples used for fluorescence measurements were degassed by the freeze-thaw method. In order to protect them from moisture, they were prepared in a dry-box filled with dry nitrogen gas.

Absorption spectra were measured with a Cary recording spectrophotometer model 14. Fluorescence spectra were measured with a Spex 0.75 m grating monochromator, excitation being effected by an Ushio USH-102D high pressure mercury lamp and an EMI 9558QB photomultiplier being used as a detector. β-Naphthol and β-naphthylamine were excited at 313 nm by using an aqueous solution of $NiSO_4\cdot6H_2O$–$CoSO_4\cdot7H_2O$ as a solution-filter. The monochromator was used with a slit width of $\lesssim$0.5 mm. Fluorescence lifetimes and nanosecond time-resolved spectra were measured by the method described previously[15] which used a coaxial nitrogen gas laser as an excitation source.

Results and Discussion

Hydrogen Bond Formation between β-Naphthol and TEA in Toluene. Time-resolved fluorescence spectra observed with the β-naphthol–TEA–toluene system are shown in Fig. 1. The steady-excitation fluorescence spectrum of β-naphthol in toluene is also shown in this figure for the purpose of comparison. The time-resolved fluorescence spectrum measured with the ternary system immediately after excitation ($t=0$) has a new band at 410 nm in addition to the band due to the free β-naphthol molecule at 355 nm. The former corresponds to the band found in the steady-excitation fluorescence spectrum of the β-naphthol–TEA–benzene system and ascribed to the ion-pair by Mataga and

temperature coefficient of the viscosity.[18]

The k_3 value obtained by the present authors is very close to that obtained by Weller *et al.*[4,5] ($k_3=2\sim3\times10^9$ M^{-1} s^{-1}) for the systems containing β-naphthol and several carboxylate ions from the analysis of the fluorescence quantum yield. Furthermore, the value obtained is reasonable in view of the fact that k_3 is calculated to be $3\sim8\times10^9$ M^{-1} s^{-1} with the help of Smoluchowski's equation:[19,20]

$$k_3=\frac{4\pi R_0(D_A+D_B)}{R_0\int_{R_0}^{\infty}e^{U(r)/kT}\frac{dr}{r^2}}\frac{N_A}{1000}=4\pi R_0(D_A+D_B)\left(\frac{N_A}{1000}\right) \quad [M^{-1}\ s^{-1}] \qquad (4)$$

Here, R_0, the sum of collision radii is taken to be 3 Å,[21] D_A and D_B are individual diffusion coefficients, N_A is Avogadro's number, and $U(r)$ is the interaction energy between the reactants. The k_3 value was evaluated to be $3\sim8\times10^9$ M^{-1} s^{-1} by taking $U(r)$ to be zero or $-kT$.

Here let us turn to the time dependence of fluorescence of the hydrogen-bonded species measured at 410 nm for the β-naphthol–TEA–toluene system. The rise process was not observed since the rise time is too fast to be observed by the present detecting system. The decay process is almost single exponential and the fluorescence decay time of the hydrogen-bonding system decreases from ~6 to ~4 ns with the increasing concentration of TEA from 10^{-2} to 10^{-1} M.

Judging from the K_{eq} value, which is 60 M^{-1} in benzene at room temperature,[7] the concentrations of D and (DA) are almost equal to each other in the ground state for the concentrations used. Therefore the direct excitation of (DA) to (DA)* must be taken into account in addition to the process D*+A→(DA)*. In this case, the time dependence of the fluorescence due to (DA)* is represented by Eq. (5).

$$[(DA)^*]=\frac{k_3[A][D^*]_0}{(k_5+k_6)-(k_1+k_2+k_3[A])}\left(e^{-(k_1+k_2+k_3[A])t}-e^{-(k_5+k_6)t}\right)+[(DA)^*]_0e^{-(k_5+k_6)t}. \qquad (5)$$

Here, $[(DA)^*]$ and $[(DA)^*]_0$ represent the concentrations of the complexed species in the excited state at $t=t$ and $t=0$, respectively. As is expected from the experimental results, the pre-exponential factor of the first term on the right-hand side of Eq. (5) is positive. Therefore, Eq. (5) shows that the decay lifetime of (DA)* is determined by the two terms $1/(k_5+k_6)$ and $1/(k_1+k_2+k_3[A])$. This is a reason why the observed decay lifetime is slightly dependent on [A].

Hydrogen Bond Formation between β-Naphthol and TEA in Acetonitrile. The absorption spectra were measured for acetonitrile solutions containing a fixed concentration of β-naphthol and various concentrations of TEA, with the result shown in Fig. 4. The equilibrium constant, K_{eq}, in the ground state at 25 °C was obtained to be 19 M^{-1} by analyzing the dependence of the absorption intensity at a fixed wavelength upon the TEA concentration.[1]

Figure 5 shows the fluorescence spectra measured for an acetonitrile solution containing β-naphthol and TEA with steady-state excitation, the intensities of which are normalized at 340 nm. From this figure, it is revealed

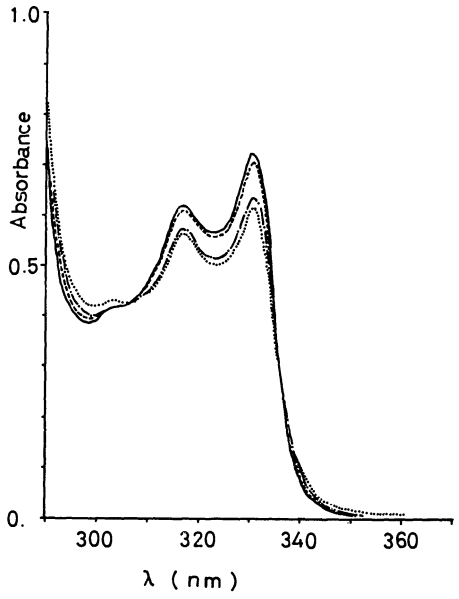

Fig. 4. Absorption spectra of the β-naphthol–TEA system in acetonitrile at 25 °C. The concentrations of TEA are 0, 0.705×10^{-2}, 2.11×10^{-2}, and 2.82×10^{-2}M for curves ——, ------, -·-·, and ·····, respectively. The concentrations of β-naphthol are commonly 3.46×10^{-4}M.

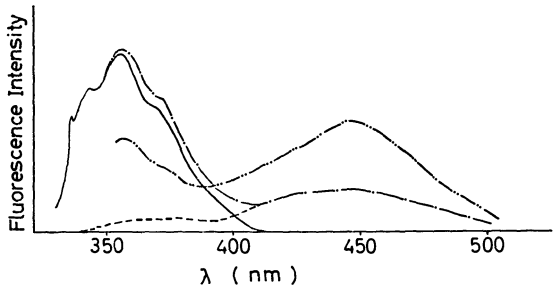

Fig. 5. The fluorescence spectra of the β-naphthol-TEA system in acetonitrile at 25 °C. The concentrations of TEA are 0, 0.705×10^{-2}, and 3.52×10^{-2}M for curves ——, -·-, and -··-, respectively. Curve —— is a difference between curves —— and -·- normalized at 340 nm. The scattering of the excitation light prevented us from measuring the spectrum for the solution containing 3.52×10^{-2}M TEA below 355 nm.

that, besides the fluorescence band at 355 nm due to the free β-naphthol molecule, two bands appear at ~370 and ~450 nm and increase their intensities with the increasing concentration of TEA, though the latter two bands are weak compared with the former band. The band at ~370 nm can be ascribed to hydrogen bonded β-naphthol[8] and the largely redshifted band at 450 nm to either of the ion pair or the β-naphtholate ion.

The above-mentioned spectral data show the existence of two different kinds of hydrogen-bonded or complexed species, $(DA)^*_{CN}$ and $(DA)^{**}_{CN}$, in the excited state of the system involving β-naphthol and TEA in acetonitrile. Therefore the following scheme may be applied to this system:

$$\begin{array}{ccccc} D^* + A & \underset{k_4}{\overset{k_3}{\rightleftharpoons}} & (DA)^*_{CN} & \underset{k_8}{\overset{k_7}{\rightleftharpoons}} & (DA)^{**}_{CN} \\ I_D \uparrow k_1 \downarrow \{k_2 & & I_{DA} \uparrow\downarrow k_5 \{k_6 & & k_9 \downarrow \{k_{10} \\ D + A & \underset{}{\overset{K_{eq}}{\rightleftharpoons}} & (DA) & & \end{array}$$

Scheme 2.

According to Scheme (2), the following equations can be obtained:

$$\frac{d[D^*]}{dt} = -(k_1+k_2+k_3[A])[D^*] + k_4[(DA)^*_{CN}] \quad (6.1)$$

$$\frac{d[(DA)^*_{CN}]}{dt} = k_3[A][D^*] - (k_4+k_5+k_6+k_7)[(DA)^*_{CN}] + k_8[(DA)^{**}_{CN}] \quad (6.2)$$

$$\frac{d[(DA)^{**}_{CN}]}{dt} = k_7[(DA)^*_{CN}] - (k_8+k_9+k_{10})[(DA)^{**}_{CN}] \quad (6.3)$$

These equations are solved as follows:

$$[D^*] = \sum_{i=1}^{3} a_i e^{-\mu_i t} \quad (7.1)$$

$$[(DA)^*_{CN}] = \sum_{i=1}^{3} b_i e^{-\mu_i t} \quad (7.2)$$

$$[(DA)^{**}_{CN}] = \sum_{i=1}^{3} c_i e^{-\mu_i t} \quad (7.3)$$

The pre-exponential factors are related with each other by

$$a_i = \frac{k_4}{K_1-\mu_i} b_i \quad (8.1)$$

$$c_i = \frac{k_7}{K_3-\mu_i} b_i \quad (8.2)$$

$-\mu_i$'s (i=1,2,3) are roots of the following cubic equation:

$$\mu^3 + \alpha\mu^2 + \beta\mu + \gamma = 0 \quad (9)$$

where

$$\alpha = K_1 + K_2 + K_3 \quad (10.1)$$

$$\beta = K_1K_2 + K_2K_3 + K_3K_1 - k_3k_4[A] - k_7k_8 \quad (10.2)$$

$$\gamma = K_1K_2K_3 - k_3k_4[A]K_3 - k_7k_8K_1 \quad (10.3)$$

$$K_1 = k_1 + k_2 + k_3[A] \quad (11.1)$$

$$K_2 = k_4 + k_5 + k_6 + k_7 \quad (11.2)$$

$$K_3 = k_8 + k_9 + k_{10} \quad (11.3).$$

According to the above scheme, the time dependences of [D*], $[(DA)^*_{CN}]$, and $[(DA)^{**}_{CN}]$ can be represented by the sum of three exponential terms with time constants of $\tau_1=1/\mu_1$, $\tau_2=1/\mu_2$, and $\tau_3=1/\mu_3$.

In order to check experimentally the above consideration, the fluorescence lifetimes of free β-naphthol and $(DA)^{**}_{CN}$ were measured at 360 and 450 nm, respectively. The measurement of the lifetime for $(DA)^*_{CN}$ was complicated by the overlapping of the fluorescence band of D*. Furthermore, it was found that the Stern-Volmer relation concerning the effect of the TEA concentration upon the fluorescence lifetime of free β-naphthol was not satisfied. This means that the dissociation reaction of the hydrogen-bonded species $(DA)^*_{CN}$ into free β-naphthol and TEA must be taken into account for this system.

The decay curves observed at 450 nm for the systems

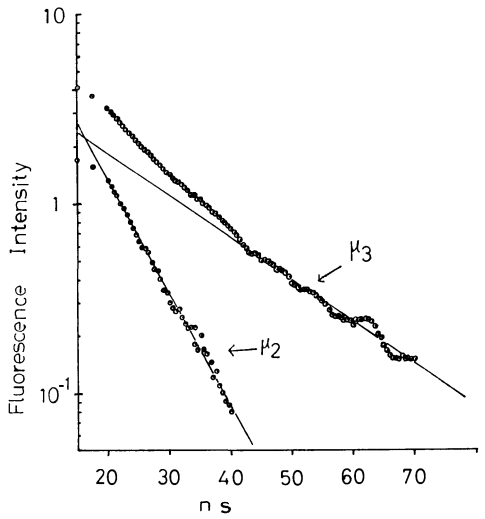

Fig. 6. Semilogarithmic plot of fluorescence intensity $I(t)$ observed at 450 nm *vs.* time for the system containing 3.46×10^{-4}M β-naphthol and 3.52×10^{-2}M TEA in acetonitrile. N_2 gas laser pulse starts at time t=0.

with various concentrations of TEA consists of two singlet exponential curves, as is clearly seen in Fig. 6 which shows an example of the observed curves. This may be explained by considering that the exponential component with the greatest μ_i, say μ_1, rises too fast to be observed. Thus the greater and smaller decay components observed at 450 nm correspond to μ_2 and μ_3, respectively.

Let us turn to the fluorescence decay at 360 nm. The decay curve at 360 nm observed for each solution is separated into two components which are assigned to μ_1 and μ_3, or μ_2 and μ_3.[22] Thus the μ_1, μ_2, and μ_3 values were obtained from the decay curves observed

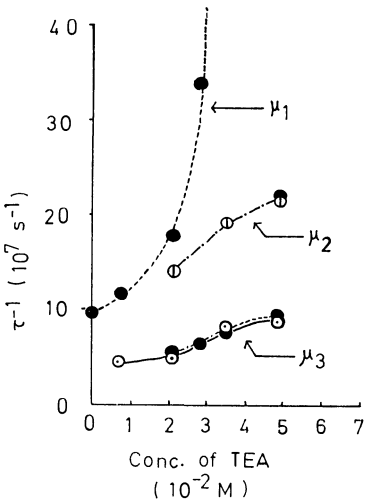

Fig. 7. Plots of the decay rates observed at 360 and 450 nm *vs.* the concentration of TEA for the β-naphthol–TEA system in acetonitrile at 30 °C. The concentration of β-naphthol is 3.45×10^{-4}M. ●, observed at 360 nm; ⊙ and ◑ are the faster and slower decay rates, respectively, observed at 450 nm. The μ_1 value at 2.8×10^{-2}M TEA was measured with the single photon counting method.[22]

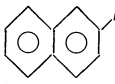
at 450 and 360 nm for the solutions containing a fixed concentration of β-naphthol and various concentrations of TEA. The results are summarized in Fig. 7.

Figure 7 shows that the μ_2 or μ_3 values obtained at both wavelengths agree well with each other for the respective solutions and therefore the decay curve observed with each of the solutions consists of the three exponential components. This gives experimental evidence for the validity of Eq. (7) and therefore an experimental support for the reaction mechanism shown by scheme (2) that $(DA)^{**}_{CN}$ is produced *via* $(DA)^{*}_{CN}$.[23]

The fluorescence peak of $(DA)^{**}_{CN}$ appears at 450 nm and is far removed from that of D* (355 nm). This indicates that $(DA)^{**}_{CN}$ is an ion-pair



or a solvated β-naphtholate ion. In view of the fact that process 8 in reaction scheme (2), namely, the back reaction from $(DA)^{*}_{CN}$ to $(DA)^{**}_{CN}$, can not be disregarded,[24] $(DA)^{*}_{CN}$ is regarded as the ion-pair. This is because the process from the solvated β-naphtholate ion to $(DA)^{*}_{CN}$ is too slow to occur within the lifetime of $(DA)^{**}_{CN}$.[25]

Hydrogen Bond Formation between β-Naphthylamine and TEA. The hydrogen bond formation was studied for the solution containing β-naphthylamine and TEA in the 1:1 mixed solvent of isopentane and methylcyclohexane (PM). The absorption spectra observed with the system at room temperature changed only slightly with an increase in the concentration of TEA. At −30 °C, as is seen in Fig. 8, the absorption spectra change somewhat remarkably owing to the hydrogen bond formation and exhibit an isosbestic point. From the observed spectra, the equilibrium constant was found to be 7 M^{-1} at −30 °C. Thus it is obvious that at low temperature a hydrogen bond is formed between β-naphthylamine and TEA in the mixed solvent. At room temperature the spectrum of β-naphthylamine is not changed by the addition of TEA and hydrogen bond formation is negligibly small.

Fluorescence spectra observed with the β-naphthylamine–TEA system at 25 °C and −50 °C are shown in Fig. 9. They are insensitive to the concentration of TEA until it becomes 0.0705 M at which condition a remarkable change occurs in the spectra. This implies that, at this concentration of TEA, k_3[A] is comparable with the intrinsic decay rate constant of excited β-naphthylamine and hydrogen bond formation occurs within its lifetime. From this consideration, the order of magnitude of k_3 was obtained to be 10^9 M^{-1} s^{-1} by taking the critical value of [A] to be 0.1 M. This k_3 value seems to be reasonable.

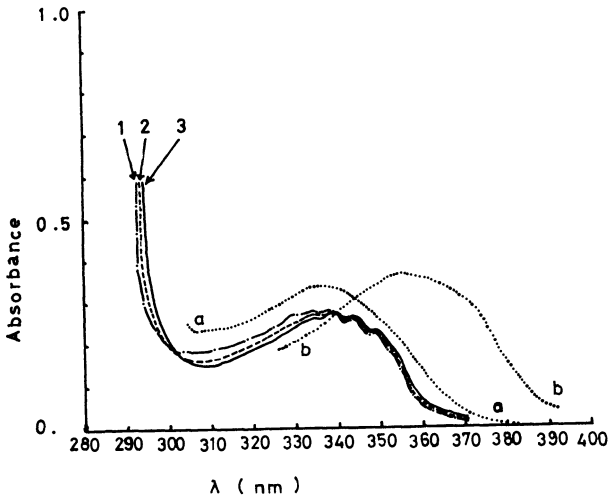


Fig. 8. Absorption spectra of β-naphthylamine in a 1:1 mixed solvent of methylcyclohexane and isopentane. Curves 1, 2, and 3 were measured at −30 °C, for solutions with the TEA concentrations of 0, 0.705×10^{-1}, and 1.41×10^{-1}M, respectively. Curves a and b were measured at 77 K for solutions with the TEA concentrations of 0 and 0.705×10^{-1}M, respectively. The concentrations of β-naphthylamine are 1.04×10^{-4}M and 0.92×10^{-4}M for curves 1∼3 and curves a∼b, respectively.

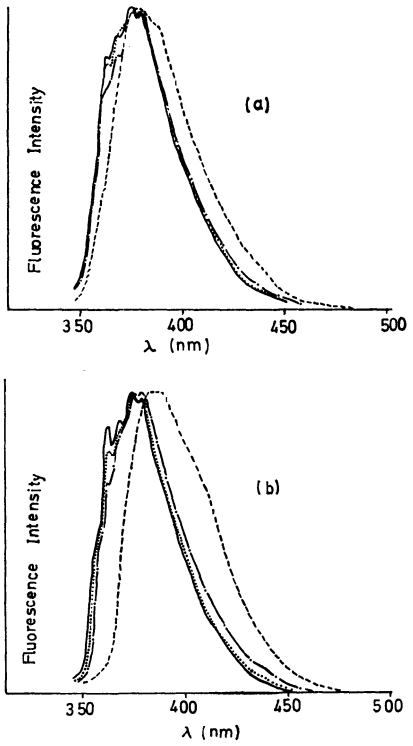

Fig. 9. Fluorescence spectra of β-naphthylamine in the 1:1 mixed solvent of methylcyclohexane and isopentane. The concentrations of TEA are 0, 0.705×10^{-4}, 0.705×10^{-2}, and 0.705×10^{-1}M for curves (1) ——, (2) ·····, (3) -·-·, and (4) ------, respectively. The concentration of β-naphthylamine is 0.92×10^{-4}M. (a) at 25 °C, (b) at −50 °C.

Fluorescence decay curves were measured at room temperature for the β-naphthylamine solutions containing various concentrations of TEA and single exponential curves were obtained. The lifetimes obtained at 360 and 420 nm are 15∼14 ns for the solutions containing $0\sim0.7\times10^{-1}$ M TEA. Hence they are almost independent of the concentration of TEA. One of the reasons for this is that the ratio of the hydrogen-bonded β-naphthylamine molecule in the excited state to the total excited molecules is small, as revealed from the observed fluorescence spectra shown in Fig. 9.

We should like to express their thanks to Professor E. Lippert, Technical University of Berlin, Professor Ichiro Hanazaki, Osaka University and Dr. Takayoshi Kobayashi, The Institute of Physical and Chemical Research for their helpful discussions.

23) Another possible mechanism for the formation of $(DA)^*_{CN}$ and $(DA)^{**}_{CN}$ is the following competitive one:

$$(DA)^{**}_{CN} \underset{k_7}{\overset{k_8}{\rightleftharpoons}} D^* + A \underset{k_4}{\overset{k_3}{\rightleftharpoons}} (DA)^*_{CN}$$
$$k_9 \downarrow \lessgtr k_{10} \qquad k_1 \downarrow \lessgtr k_2 \qquad k_5 \downarrow \lessgtr k_6$$

Scheme 3.

This process can be disregarded from the concentration of the observed dependence of μ_i's upon the concentration of TEA.

As is seen in Fig. 7, the observed rises and decays are represented by $\sum_{i=1}^{3} a_i e^{-\mu_i t}$ and $\sum_{i=1}^{3} c_i e^{-\mu_i t}$ for D* and $(DA)^{**}_{CN}$, respectively. The pre-exponential factors a_1, a_3, and a_2 successively become more predominant with the increasing concentration of TEA. From this observation the following relation is obtained:

$$\Delta a_2 > \Delta a_3 > \Delta a_1 \qquad \text{relation (1)}$$

A similar relation is obtained concerning the pre-exponential factors c_i's; among these c_1 is the factor for the rise component:

$$\Delta c_2 > \Delta c_3 \qquad \text{relation (2)}$$

Here, Δ means the increment of the corresponding quantity due to the increase in the concentration of TEA. Furthermore, the relation, $\Delta\mu_1 > \Delta K_1 \gtrsim \Delta\mu_2 > \Delta\mu_3$ can be obtained from the experimental result shown in Fig. 7 and Eq. (11.1). From this relation and initial conditions of Eq. (6), say

$$\sum_{i=1}^{3} a_i = [D^*]_0, \sum_{i=1}^{3} b_i = [(DA)^*_{CN}]_0 \sim 0, \text{ and } \sum_{i=1}^{3} c_i = [(DA)^{**}_{CN}]_0 \sim 0,$$

the following relation concerning b_i's can be derived for scheme (2):

$$\Delta b_1 < \Delta b_2 < \Delta b_3 \qquad \text{relation (3)}$$

Similarly, relation (3) is also obtained for scheme (3).

According to the process shown by scheme (2), the pre-exponential factors for the decay and rise components are expressed by Eq. (8). Since a_1, a_2, a_3, b_2, b_3, c_2, and c_3 are positive and b_1 and c_1 are negative, the relation $\mu_3 < \mu_2 < K_1 < \mu_1 < K_3$ is obtained, and Δa_i's are represented by $\Delta a_1 = \{1/\Delta(\mu_1 - K_1)\} \times (-\Delta b_1)$, $\Delta a_2 = \{1/\Delta(K_1 - \mu_2)\} \times (\Delta b_2)$, and $\Delta a_3 = \{1/\Delta(K_1 - \mu_3)\} \times (\Delta b_3)$. Therefore, relation (3) is consistent with relations (1) and (2) only for the case of $1/\Delta(K_1 - \mu_2) > 1/\Delta(K_1 - \mu_3)$ and $1/\Delta(K_3 - \mu_2) > 1/\Delta(K_3 - \mu_3)$, respectively. These relations on $\Delta\mu_i$'s and ΔK_1 are satisfied. Thus, the observed dependence of the pre-exponential factors on the concentration of TEA can be explained in term of Scheme (2).

According to Scheme (3), the pre-exponential factors are expressed as follows:

$$a_i = \frac{k_4(c-\mu_i)}{(a-\mu_i)(c-\mu_i) - k_7 k_8 [A]} b_i, \text{ and}$$

$$c_i = \frac{k_7 k_8 [A]}{(a-\mu_i)(c-\mu_i) - k_7 k_8 [A]} b_i,$$

where $\mu_1 > c > \mu_2 > \mu_3$ or $\mu_1 > a > \mu_2 > \mu_3$ in this case. Furthermore, $\Delta a_1 = (\Delta Q_1) \times (-\Delta b_1)$ and $\Delta a_{2,3} = (-\Delta Q_{2,3}) \times (\Delta b_{2,3})$, and $\Delta c_{2,3} = (\Delta R_{2,3}) \times (\Delta b_{2,3})$ For this case, relation (3) is consistent with relations (1) and (2) only when $\Delta Q_2 > \Delta Q_3$ and $\Delta R_2 > \Delta R_3$ hold. In actuality, however, the examination of $\Delta\mu_i$'s and Δa_i shows that the reverse is the case. Thus, scheme (3) can safely be disregarded.

24) On the assumption of disregarding process 8, the fluorescense of D* and $(DA)^{**}_{CN}$ are to be represented by decay curves with the two time constants of λ_1^{-1} and λ_2^{-1} and of λ_2^{-1} and $(k_9+k_{10})^{-1}$, respectively, where $\lambda_{1,2} = 1/2\{(K_1+K_2) \pm \sqrt{(K_1-K_2)^2 + 4k_3k_4[A]}\}$. The expectation conflicts with the findings that the fluorescence decay of D* is repesented by three time constants and that the two decay constants obtained for $(DA)^{**}_{CN}$ are dependent on the concentration of TEA.

25) From the rate constant of the association between solvated ions, $10^{10}\ M^{-1}s^{-1}$, and the concentration of proton ($<10^{-4}$M), it is revealed that the association reaction between the solvated β-naphtholate ion and triethylammonium ion possibly proceeds with a rate smaller than $10^6\ s^{-1}$ and is too slow to occur within the intrinsic lifetime of a solvated β-naphtholate ion (*e.g.* $10^8\ s^{-1}$ in aqueous solution).[4,14]

X-Ray Photoelectron Spectroscopy of *p*-Benzoquinone, Hydroquinone and Their Halogen-Substituted Derivatives

Toshiaki OHTA, Masamichi YAMADA, and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received February 6, 1974)

X-Ray photoelectron spectra of *p*-benzoquinone, chloranil, bromanil, iodanil, hydroquinone, tetrachlorohydroquinone and chloranilic acid were observed by using the samples freshly deposited in the high vacuum of the spectrometer. The chemical shifts of C ls and O ls levels determined from the XPS spectra are compared with the chemical shifts predicted according to the electrostatic potential model by use of the charge distributions calculated by CNDO/2 method. The charge distributions in the quinone derivatives are successfully estimated by using the observed binding energies of C ls and O ls levels.

X-Ray photoelectron spectroscopy (XPS) shows promise as a tool to investigate the electronic structures of molecules. From XPS spectra, we can determine the binding energies of core-electron levels, which are known to vary more or less depending on the chemical bonds. This chemical shift of a core-electron level exhibits a rather simple correlation with the charge distribution in the molecule. It was shown by Siegbahn and his collaborators[1] that the chemical shifts of C ls levels determined from the gas-phase XPS spectra of simple organic molecules can be successfully predicted from the charge distributions obtained by CNDO calculations, by using the electrostatic potential model.

For investigating the electronic structure of molecule, it is naturally desirable to observe the gas-phase XPS spectrum. However, this is not easy to do in the case of the organic compound which is a solid of low vapor pressure at room temperature. In such a case, the XPS spectrum is usually measured with a powder specimen, but the C ls and O ls spectra thus obtained are often affected significantly by the presence of chemical species containing carbon and/or oxygen, adsorbed on the sample surface.

This paper reports the XPS spectra of *p*-benzoquinone, hydroquinone and their halogen-substituted derivatives, which were observed with the films freshly deposited in the high vacuum of the spectrometer to avoid the contamination effects. The purpose of this study is to elucidate the effect of halogen substitution on the binding energies of C ls and O ls levels.

Experimental

The XPS spectra were measured with McPherson ESCA 36 electron spectrometer by employing AlK_α (1486.6 eV). The sample was deposited on the surface of the variable-temperature sample holder which was kept at about −50 °C by using dry ice–acetone mixture, in the 10^{-6} Torr vacuum of the spectrometer. Only in the case of iodanil, we carried out both the preparation of the film and the measurement of XPS spectra at the room temperature, since its vapor pressure is sufficiently low. For calibrating binding energies, we deposited a small amount of gold onto the sample surface, and used Au $4f_{7/2}$ (84.0 eV) as the reference,[2] the core levels of halogen being used as subsidiary references. With this method, binding energies were obtained with the accuracy better than ±0.2 eV.

All the compounds except bromanil and iodanil were commercially obtained and purified by sublimation *in vacuo*. The crystal of chloranilic acid usually contains water of crystallization but the powder which we obtained by sublimation, was found to be the water-free modification. Bromanil and iodanil were synthesized in our laboratory, and purified by sublimation.

Results

The C ls spectra of chloranil, bromanil and iodanil are shown in Fig. 1. Each of them exhibits a C ls spectrum with a shoulder in the high binding-energy side of the main peak, indicating clearly that the spectrum is composed of two bands, namely, a strong band at lower energy and a weak band at higher energy. In each case, we resolved the observed C ls spectrum into two components by means of the following procedure. First, we determined the standard profile of a single band by examining the shape of Au $4f_{7/2}$ spectrum of an evaporated gold film and that of F ls spectrum of Teflon. Then, assuming this standard profile for each constituent band, we adjusted the splitting and intensities so that the composite spectrum well reproduced the observed spectrum. The results are shown in Fig. 1 by solid lines. In these cases, we were able

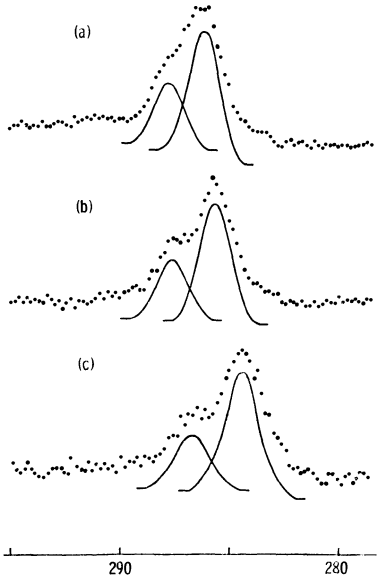

Fig. 1. Carbon 1s spectra.
(a): chloranil, (b): bromanil, (c): iodanil.

to resolve the observed C ls spectrum into two components with the intensity ratio nearly 2: 1.

The situation was slightly complicated in the case of *p*-benzoquinone, where it was not possible to obtain the C ls spectrum completely free from the contamination effect. Figure 2 shows the spectra measured respectively 10 and 20 min after preparation of the evaporated film. We can see that the profile of the spectrum appreciably changed with time. It is not clear why such phenomenon occurred only in the case of *p*-benzoquinone. Possibly it is connected in some way with the relatively high vapor pressure of this compound. As shown in Fig. 2, we can resolve the C ls spectrum of *p*-benzoquinone into three components, of which binding energies are respectively 283.4, 284.3, and 286.0 eV. Among them, we can attribute the one at 284.3 eV to the C ls band associated with the contamination carbon.

Like quinone derivatives, hydroquinone exhibited the C ls spectrum with a shoulder, which was able to be resolved into two components with intensity ratio 2: 1 as shown in Fig. 3. However, the C ls spectrum of tetrachlorohydroquinone exhibits no shoulder. Seemingly, the splitting is quite small in this case. It should be noted that there is an extra band separated by 6—7 eV from the main peak in the C ls spectrum of hydroquinone as well as in that of tetrachlorohydroquinone. The corresponding extra bands were observed very weakly also in their O ls spectra. It is most likely that these extra bands are the shake-up satellites associated with the excitations of valence electrons.[3]

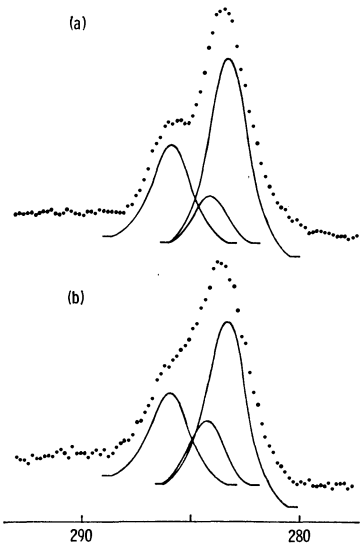

Fig. 2. Carbon 1s spectra of *p*-benzoquinone measured respectively (a) 10 min and (b) 20 min after preparation of the evaporated film.

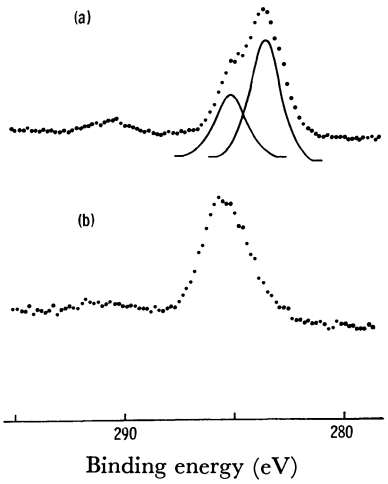

Fig. 3. Carbon 1s spectra.
(a): hydroquinone, (b): tetrachlorohydroquinone.

In the case of chloranilic acid, the O ls spectrum appeared as a very broad band with a width of about 3 eV. This spectrum was able to be resolved into two components of equal intensity. Although we can expect that the C ls spectrum of this compound is composed of three components, we could not resolve the observed C ls spectrum to the corresponding bands.

The binding energies of core levels determined from the XPS spectra are summarized in Table 1.

Table 1. Binding energies of core levels (unit; eV)

Compound	C ls		O ls	
	C_1	C_2		
Chloranil	287.7	286.1	531.5	
Bromanil	287.5	285.6	531.4	
Iodanil	286.7	284.4	531.0	
p-Benzoquinone	286.0	283.4	530.8	
Hydroquinone	285.1	283.5	532.2	
Tetrachlorohydroquinone	285.5		532.5	
Chloranilic acid	286.2		533.1	531.7

Compound	Cl 2p	Cl 2s	Br $3p_{3/2}$	Br 3d	I $3d_{5/2}$	I 4s	I 4p	I 4d
Chloranil	200.2	270.9						
Tetrachlorohydroquinone	200.0	270.7						
Chloranilic acid	200.1	271.2						
Bromanil			183.4	70.1				
Iodanil					619.8	187.2	123.0	50.1

Discussion

Chemical Shifts in C 1s and O 1s Levels. According to the electrostatic potential model, the binding energy of a core level can be correlated with the charge distribution in the molecule by Eq. (1);

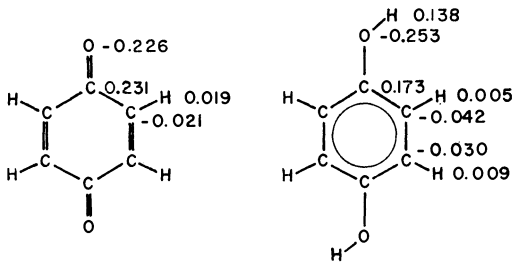
$$E_i = E_A^0 + k_A q_i + \sum_j q_j/R_{ij} \quad (1)$$

where q_i is the charge on the i-th atom, q_j is that on the j-th atom, R_{ij} is the interatomic distance given in atomic units, and E_A^0 and k_A are the empirical constants characteristic of the kind of atom. This relation was originally proposed by Siegbahn *et al.*[4] on the basis of classical electrostatic theory. For the charge densities calculated by CNDO method, they gave the k_A values as follows; k_C=21.9 for C ls and k_O=25.8 for O ls (unit; eV/unit charge).[1] The quantum mechanical meaning of Eq. (1) was critically discussed by Schwartz, Switalski, and Stronski,[5] who gave theoretically the following k_A values; k_C=22.108 and k_O=30.951 (eV/unit charge).

When we are interested only in the chemical shift, we can use the energy change expression given as follows;

$$\Delta E_i = k_A q_i + \sum_j q_j/R_{ij} \quad (2)$$

We carried out CNDO/2 calculations on *p*-benzoquinone, hydroquinone, chloranil, tetrachlorohydroquinone and chloranilic acid, assuming the molecular geometries based on the crystal structure data.[6] Figure 4 shows the charge densities of the first two compounds. Due to the molecular symmetry, we can classify the six carbon atoms into two groups, namely the two carbon atoms forming bond with oxygen and the other four carbon atoms. We will denote these two types of carbon atom as C_1 and C_2, respectively. Since the charge density is considerably different between these two kinds of carbon atom, we can expect a splitting between their C ls levels.



(a) *p*-Benzoquinone (b) Hydroquinone

Fig. 4. Charge densities obtained from CNDO/2 calculations.

From the charge densities obtained by CNDO/2 calculations, we calculated ΔE according to Eq. (2) with the assumption that k_C=21.9 eV/(unit charge). The results are given in Table 2. These results suggest that, in the cases of *p*-benzoquinone, hydroquinone and chloranil, the C ls spectrum will split into two bands separated by 1—2 eV. Since the intensity of each band is to be proportional to the number of atoms

Table 2. Calculated chemical shifts, ΔE (unit; eV)

Compound	C ls		O ls
	C_1	C_2	
p-Benzoquinone	2.5	0.9	−3.0
Chloranil	4.1	2.6	−1.6
Hydroquinone[a]	1.5	0.1, 0.2	−3.0
Tetrachlorohydroquinone	3.3	2.1, 2.1	−1.6

Compound	C ls			O ls	
	C_1	C_2	C_3	O_1	O_2
Chloranilic acid[b]	3.4	3.5	1.2	−2.4	−1.1

a) The C ls levels of C_2 carbons split into two depending on the orientation of OH group. b) C_1, C_2, and C_3 correspond to C(=O), C(–OH), C(–Cl) respectively, and O_1 and O_2 to (C=O, O(–H) respectively.

responsible for it, the intensity of the low-energy band will be twice of that of the high-energy band. This is in accord with the observations, consequently, we can assign without ambiguity the two bands obtained by resolving the C ls spectrum of each of these compounds to the two levels predicted by the above calculations. In the case of chloranilic acid, the calculation predicts the presence of three C ls bands of equal intensity, but we were not able to resolve its C ls spectrum to the components corresponding to these predicted bands.

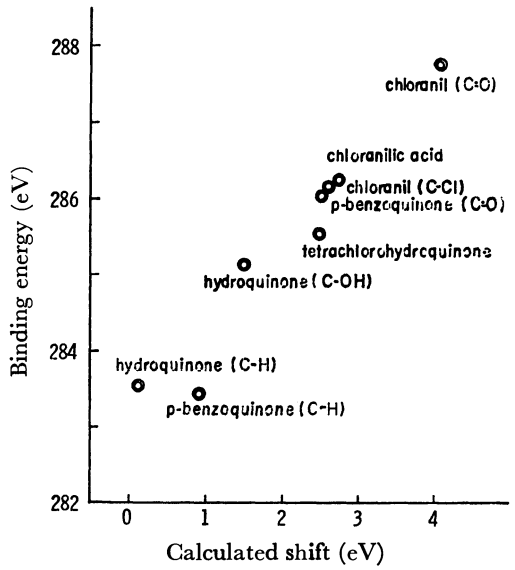


Fig. 5. Measured binding energy shifts of carbon 1s electrons versus shifts calculated with the electrostatic potential model.

Figure 5 demonstrates the good correlation between the observed binding energies of C ls level and the calculated values of ΔE. The data well fit on a straight line which makes an angle of 45 degree with the abscissa.

The correlation between the observed and calculated chemical shifts of O ls level is shown in Fig. 6, where we assumed that k_O=25.8 eV/(unit charge). The correlation is less satisfactory in this case as compared with the case of C ls level.

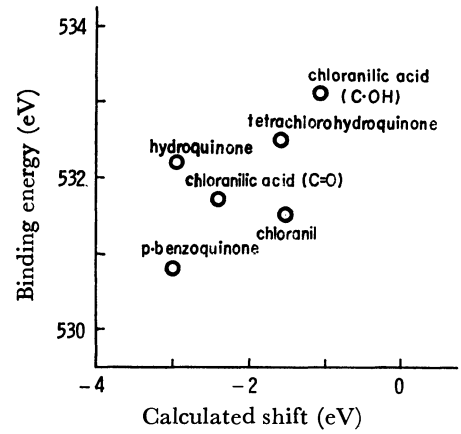

Fig. 6. Measured binding energy shifts of oxygen 1s electrons *versus* shifts calculated with the electrostatic potential model.

We can rewrite Eq. (1) in the following form:

$$E_i - \sum_j (q_j/R_{ij}) = E_A^0 + k_A q_i \quad (3)$$

Thus, if we plot $E_i - \sum_j (q_j/R_{ij})$ against q_i, we will obtain a straight line, and we can determine k_A from its inclination and E_A^0 by extrapolating it to $q_i=0$. Since the data were limited, we were not able to determine the k_A value with sufficient accuracy. Therefore, we assumed the k_A values proposed by Siegbahn *et al.*, and determined E_A^0 by the extrapolation. By this way, we found the $E_C^0=283.3\pm0.2$ eV for $k_C=21.9$ eV/(unit charge) and $E_O^0=534.0\pm0.5$ eV for $k_O=25.8$ eV/(unit charge).[7]

Charge Distributions in the Quinone Derivatives. As we can see in Table 1, the C 1s and O 1s levels of the halogen-substituted quinones are systematically shifted with the electronegativity of halogen. In these molecules, we need to know only four quantities in order to specify the charge distribution. Those are the charge densities on oxygen, halogen and two non-equivalent carbon atoms, C_1 and C_2, which we will denote as q_O, q_X, q_{C_1}, and q_{C_2}, respectively. These quantities must satisfy the condition of the electrical neutrality of molecule, consequently, one of them can be derived from other three quantities. By using the relation given by Eq. (1) for the O 1s level and the C 1s levels of the two kinds of carbon atom, we obtain three equations relating the observed binding energies to the charge densities. We solved such equations for the E_A and k_A values which we have determined in the preceeding section. The results are given in Table 3.

Table 3. Charge densities estimated from XPS spectra of quinone derivatives

Compound	C_1	C_2	O	X
Chloranil	0.29_5	0.05_3	-0.24_4	-0.07_9
Bromanil	0.29_8	0.02_8	-0.24_3	-0.05_6
Iodanil	0.29_2	-0.02_0	-0.24_6	-0.00_2
p-Benzoquinone	0.28_7	-0.08_4	-0.24_5	0.06_3

The validity of the above procedure could be questioned when we consider the approximate nature of Eq. (1), and the limited reliability of the empirical values of E_A^0 and k_A. Nevertheless, the results given in Table 3 seem to be quite satisfactory. The charge densities on carbon and oxygen atoms in C=O group are little affected by the substituted halogen. The charge density on the carbon atom directly bounded with halogen and that on the halogen atom systematically change with the electronegativity of the substituted halogen. These are in accord with the chemical intuitions.

The Decomposition of Hydrogen Peroxide with Metal Complexes. I. The Catalytic Decomposition of Hydrogen Peroxide by the Ammine-Copper(II) Complex Ions in an Aqueous Solution

Katumitu HAYAKAWA and Sumio NAKAMURA

Department of Chemistry, Faculty of Science, Kagoshima University, Kamoike-cho, Kagoshima 890

(Received July 23, 1973)

The catalytic decomposition of hydrogen peroxide by the ammine-copper(II) complex ions has been studied using kinetic measurements, UV and visible spectroscopy, electron-spin resonance spectroscopy, and polarography. It was found that there were two reaction paths in the catalytic decomposition of hydrogen peroxide. In the first case, a linear part was observed in the plot of the amount of oxygen evolved *vs.* time. In this case, a brown intermediate was formed which was later found to be a diamagnetic peroxo-copper complex and to contain some of the stable oxygen anion radical just after the mixing of the reactants. The activation energy of the reaction was found to be 23 ± 1 kcal mol^{-1}. In the second case, no linear part was observed in the kinetic curve. In this case, the reaction had a reaction order in hydrogen peroxide varying from the first- to the second-order depending on the initial concentrations of the reactants. The nature of the brown compound and the active species of the reaction is discussed.

Since it was learned that the transition metal-ammine complexes have an enzyme-like activity in the decomposition of hydrogen peroxide,[1] many kinetic studies of the catalytic decomposition of hydrogen peroxide have been made for many transition-metal complexes.[2-10] On the other hand, electron spin resonance (ESR) studies have clarified the formation of complexed radical species in the reactions of the Ti^{III}–H_2O_2 system,[11-13] the Ce^{IV}–H_2O_2 system,[14] and the VO^{2+}–H_2O_2 system.[15] However, in the catalytic decomposition of hydrogen peroxide by the ammine-copper(II) complex ions, there is little information regarding such a radical intermediate and the rate of the reaction.[8,10]

The object of this paper is to clarify the nature and role of the brown intermediate formed in the catalytic decomposition of hydrogen peroxide by the ammine-copper(II) complex ions and to report a new reaction path without the brown intermediate. The active species of the ammine-copper(II) complex ions in the decomposition of hydrogen peroxide and the composition of the brown intermediate are discussed.

Experimental

Materials. Stabilized 30% hydrogen peroxide (GR) obtained from the Mitsubishi Gas Kagaku Co. was purified by distillation under reduced pressure. A solution of hydrogen peroxide was titrated with standard potassium permanganate just before use. The ammonia solution (28%, GR) was purified by distillation and was titrated with standard hydrochloric acid. The copper(II) sulfate (GR) was purified by recrystallization, after which the solution was titrated with standard ethylenediaminetetraacetic acid. The other chemicals (all GR) were used without further purification.

Measurements. The rates were determined by measuring the volume of oxygen evolved by the decomposition of hydrogen peroxide with a gas buret. The volume of the evolved oxygen agreed with the calculated volume from the initial concentration of hydrogen peroxide within an error of 2%. In order to clarify the composition of the brown compound formed during the reaction, the brown precipitate was prepared by the use of the reactants on a large scale without stirring and was analyzed after the decomposition of the precipitate by 3 M H_2SO_4. The absorption spectra of the reaction mixtures were recorded using a Shimadzu SV-50 Spectrophotometer. Polarograms of the reaction mixtures were recorded using a Yanagimoto PS-52 Polarograph and a PR-2 Polarorecorder. The potassium chloride was used as a supporting salt in the reaction mixtures. The ESR spectra were recorded using an X-band spectrometer with a 455 kHz field modulation. To obtain the ESR signal in the reaction mixture, a continuous-flow technique and a quenching technique were used.[13] The luminol test[16] was made using a solution of luminol (100 mg) in a 7 M ammonia solution (100 ml).

Results and Discussion

Kinetics. The effect of the concentration of ammonia is shown in Fig. 1. In the cases of 1, 2, and

a) 10^3 M min^{-1} for the reaction through Path A and M^{1-n} min^{-1} for the n-th-order reaction.

3 in Fig. 1, the reaction solution became brown and a linear part was observed in the kinetic curves (the plot of the amount of oxygen evolved *vs.* time). This is termed Path A (the solid line). In the cases of 4 and 5 in Fig. 1, no linear part is observed (termed Path B, the broken line). As the concentration of ammonia or the ammonium salt increases to some extent, the rate increases. The reaction path changes from Path A to Path B with the increase in the ammonia. With a further increase in the concentration of ammonia or the ammonium salt, the rate decreases and the reaction has an induction period. Path A appears at a high concentration of hydrogen peroxide and at low concentrations of the ammonia and the ammonium salt.

In Path A, the rate in the linear part, k_0, increased with an increase in the initial concentration of ammonia or the copper(II) ion and decreased with an increase in the initial concentration of hydrogen peroxide (Table 2). However, no simple relationship between the rate and the initial concentrations of three components was found. The rate was independent of the concentration of the brown intermediate, which was estimated by the optical density at 360 nm

Table 2. The rates of linear part, k_0, *versus* the optical density at 360 nm
Temperature 30 °C

The initial concentrations of			$D_{360\ nm}$	k_0 (10^3M min^{-1})

(Table 2). The activation energy, which was obtained from the dependence of k_0 on the temperature (15—45 °C) at $[H_2O_2]_0$=0.04—0.09 M, $[CuSO_4]_0$=0.25—0.44 mM, and $[NH_3]_0$=0.13—0.045 M, was found to be 23±1 kcal mol^{-1}.

Path B had an order of reaction in hydrogen per-

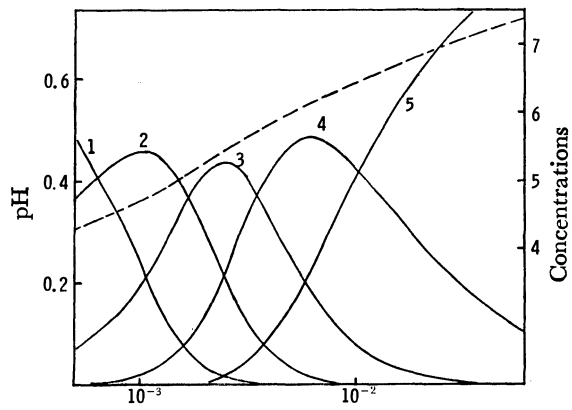

Fig. 2. The distribution of the ammine-copper(II) complex ions at the concentrations of 0.49 mM $CuSO_4$ and 1.5 M $(NH_4)_2SO_4$; 1. aquo-complex ion, 2. mono-ammine-, 3. diammine-, 4. triammine-, 5. tetra-ammine-complex ion. The broken line indicates the pH. This distribution was calculated by use of the formation constants of the ammine-copper(II) complex ions (L. G. Sillén and A. E. Martell, "Stability Constants of Metal-Ion Complexes," The Chemical Society, London (1964), p. 152).

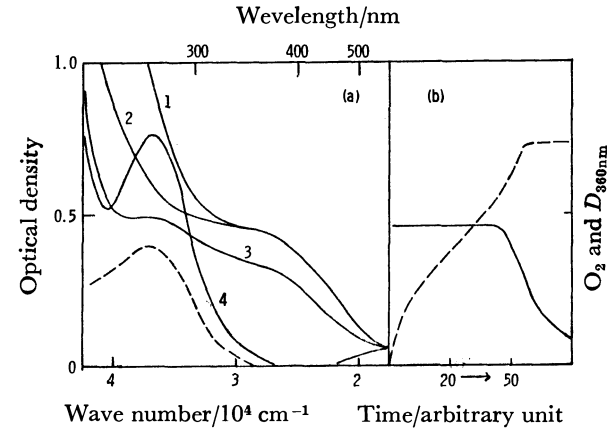

Fig. 3. (a) Spectra of the reaction mixtures: 1. 1 min, 2. 35 min, 3. 48 min, 4. 217 min. The broken line indicates a spectrum of the supernatant solution of the copper(II) sulfate-dilute ammonia mixture. (b) Schematic diagram of the relationship between the optical density at 360 nm (solid line) and the kinetic curve in the case of Path A (broken line).

oxide varying from the first- to the second-order, depending on the initial concentrations of the four components (Table 1). The order was determined by adjusting n to get an optimum linear plot of $[H_2O_2]^{-n+1}$ *vs.* time. The latter fourteen runs, given in Table 1, had a linear part in the plot of $[H_2O_2]^{-n+1}$ *vs.* time, at least in the region of an extent of reaction between 15 and 90% for each kinetic run.

For the 1.5 M ammonium sulfate, the maximum rate was observed (the 23rd row in Table 1) when the concentrations of the triammine- and tetraammine-copper(II) complex ions were much larger than those of the other ammine-copper(II) complex ions (Fig. 2). When the concentration of ammonia increases further, the concentration of $[Cu(NH_3)_4]^{2+}$ increases and the rate decreases. The maximum rate is observed when the pH is higher than that at which the concentration of the triammine-copper(II) complex ion is at its maximum (the broken line in Fig. 2). Therefore, it may be supposed that the active species is the hydroxo-triammine-copper(II) complex ion. It has been reported that the hydroxo-type complex is the active species in the catalytic decomposition of hydrogen peroxide by the triethylenetetramineiron(III) complex ion,[3,17] the citrato-copper(II) complex ion,[18] and the ammine-copper(II) complex ion.[10] The activation energy was found to be 15 ± 1 kcal mol^{-1} in one of the reactions through Path B (1.4-order rate constant), in which $[H_2O_2]_0$ is 0.04 M, $[CuSO_4]_0$ is 0.3 mM, and $[NH_3]_0$ is 0.27 M.

The Brown Compound. The brown solution has a broad absorption band in the region from 500 nm to UV (1 and 2 in Fig. 3-a), and the optical density at 360 nm was constant until the final period of the reaction (Fig. 3-b). The band with a peak at 267 nm after the termination of the reaction (4 in Fig. 3-a) is considered to be caused by the hydroxo-copper(II) complex because of the agreement with the absorption band of the supernatant solution of the mixture between the copper(II) ion and the dilute ammonia solution (the broken line). At high concentrations of the ammonium salt or ammonia, the brown compound was not observed. From the easy formation of the brown compound at a high pH and/or at a low concentration of ammonia and ammonium ion, and from the appearance of the hydroxo-copper(II) complex ion after the decomposition of the brown compound, it is supposed that the brown compound is formed from a hydroxo-copper(II) complex.

To characterize the brown compound formed in the reaction mixture, the brown precipitate was prepared by the use of the reactants on a large scale without stirring and was then separated from the reaction mixture. We could not obtain the spectrum of the solid because it was bulky like the hydroxide. The visible spectrum of the aqueous solution of the solid agreed with that of the brown intermediate. The

Table 3. Analysis of the brown precipitate

Time of reaction	Ratio of moles

120 min[a]	0.81	0.00	0.81

a) The sample was separated from the solution in which the reaction was undergoing. b) ( ) self-decomposition.

peroxide and copper in the precipitate were analyzed, and the volume of the oxygen gas, which was liberated by the decomposition of the precipitate by acid or on standing for 12 hr, was measured by means of a gas buret (Table 3). When the precipitate was decomposed by acid immediately after separation from the reaction solution and washing, *ca.* 10^{-5} mol of oxygen gas evolved. Therefore, it may be supposed that a part of the oxygen which was adsorbed on the precipitate after the self-decomposition was liberated by the acid treatment. The fact that the molar ratio of $(H_2O_2+2O_2)/Cu$ in the case of decomposition by the acid treatment agreed with the molar ratio of $2O_2/Cu$ in the case of the self-decomposition (shown in the fourth column in Table 3) indicates that the hydrogen peroxide coordinates to the copper ion with a molar ratio of 1 : 1. Ammonia was detected in the brown precipitate, but the quantity was too small for us to obtain the NH_3/Cu ratio.

Thus, the brown compound is found to be a peroxo-copper complex and to decompose with the evolution of oxygen on standing. The brown peroxo-copper complex changed to a green compound on standing for several hours and to a sky-blue compound on standing for several days.

ESR. The ESR signal obtained using a quenching technique and the ESR signal of the free O_2^- radical obtained by the UV irradiation of an alkaline hydrogen peroxide aqueous solution are shown in Figs. 4-a and 4-b respectively (measured at 77 K). The S_1 signal in Fig. 4-a is assigned to the O_2^- radical. The S_2 signal is consistent with the perpendicular component of the anisotropic signal of the tetraammine-copper(II) complex ion, as is shown in Fig. 4-c. The copper(II) complex ion is considered to be present in a very small amount because of the weak intensity of the signal as compared with the signal of the copper(II) ion of the original concentration.

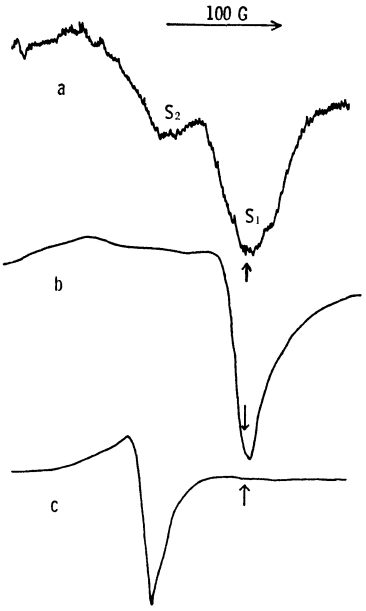

Fig. 4. ESR spectra of the quenched sample of the reaction mixture (a), the oxygen anion radical, O_2^-, (b), and the ammine-copper(II) complex ions (c) measured at 77 K.

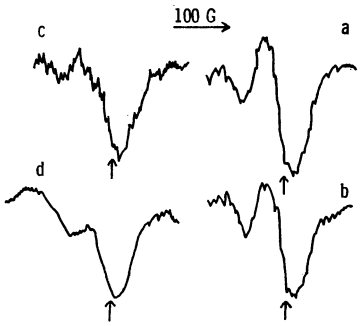

Fig. 5. Dependence of the signal of the quenched sample on the temperature: a. 108 K, b. 149 K, c. 217 K, and d. 77 K after the melting treatment for two minutes.

The dependence of the S_1 signal on the temperature is shown in Fig. 5. The S_1 signal was observed at 232 K and was also observable at 77 K after the melting treatment of the quenched sample for two minutes at *ca.* 0 °C. The signal of the free O_2^- radical obtained by the UV irradiation was not as stable as the S_1 signal; *e.g.*, it had already disappeared at 194 K.

Sometimes no signal was observed in the range of the magnetic field between 0 and 4300 gauss at 77 K in the brown quenched sample at a high concentration of hydrogen peroxide or a small rate of mixing; therefore, it may be concluded that the copper ion in the brown intermediate is a diamagnetic species.

From these facts, the increased stability of the O_2^- radical, and the lack of the copper(II) ion, the O_2^- radical which coordinates to any diamagnetic copper complex ion can be tentatively proposed as the origin of S_1, even without any direct evidence such as the hyperfine structure due to the copper nucleus. It may be supposed that the observation of the resolved hyperfine structure in the sample of the polycrystalline state is fairly difficult as compared with the case of the Ti^{III}–H_2O_2 system[19] or the VO^{2+}–H_2O_2 system,[15,20] where the ESR signal was detected by means of a flow technique.

It is known that the free radical resulting from hydrogen peroxide coordinates with the oxidized form of the metal ion in the reactions of the Ti^{III}–H_2O_2 system[11-13,21] and the VO^{2+}–H_2O_2 system[15,21] and with the reduced from of the metal ion in the reaction of the Ce^{IV}–H_2O_2 system.[14,21] The free radical is stabilized by the coordination with the metal ion.

The diamagnetic copper(III) ion in the D_{4h} symmetry has a vacant $d(x^2-y^2)$ orbital which does not overlap with the π^*-orbital of the O_2^- radical. Therefore, the electron transfer from the unpaired π^*-orbital to the vacant $d(x^2-y^2)$ orbital is difficult. For this reason, it is considered that the free radical coordinated to the copper(III) ion is stabilized. The complexed radical compound has been considered to be formed in a by-path of the catalytic decomposition of hydrogen peroxide because of the increased stability of the compound compared to that of the original free radical.[12,13,21]

About the copper(III) compound, it has been re-

ported that a colloidal copper(III) oxide is formed in the reaction between hydrogen peroxide and the ammine-copper(II) complex.[22,23]

Luminol Test. When an alkaline luminol reagent was added to a mixture of hydrogen peroxide and hemin, a chemiluminescence was observed.[24] The ammoniacal luminol reagent was here added to the brown precipitate, a mixture of hydrogen peroxide and the copper(II) ion, a hydrogen peroxide solution, and a copper(II) sulfate solution. Chemiluminescence was observed in the brown precipitate and the mixture of hydrogen peroxide and the copper(II) ion. This fact suggests that the decomposition of hydrogen peroxide by the ammine-copper(II) complex ions and that of the brown compound by the ammonia solution proceeds with the formation of a free radical, because the chemiluminescence is observed in the reaction between the luminol reagent and the free radical resulting from hydrogen peroxide.[16]

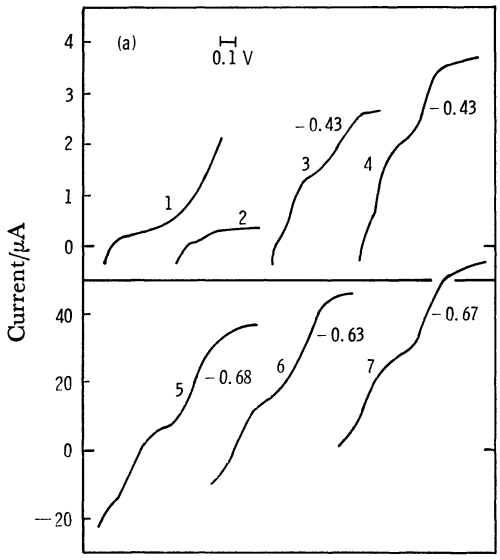

Fig. 6. Polarograms of the reaction mixture (a) and the copper(I) chloride-ammonia mixture (b); 1. 40 min, 2. 130 min, 3. 300 min, 4. 310 min after mixing of the reactants; 5. 10 min, 6. 22 min, 7. 45 min after mixing of copper(I) chloride and ammonia. The 1 M KCl and 1.5 M ammonium sulfate were used for (a) and (b) as the supporting salt respectively. The fractional values in this figure indicate a half-wave potential *vs.* SCE.

Polarography. Polarograms of the reaction mixture and the mixture of the copper(I) ion and ammonia are shown in Fig. 6. In the reaction mixture, the wave-height of the mixture of the ammine-copper(II) complex ions (3 and 4 in Fig. 6-a, the two-step wave) increased with the decrease in the brown intermediate after the disappearance of the wave of hydrogen peroxide (1 and 2 in Fig. 6-a). In the mixture of the copper(I) ion and ammonia, the first wave (*ca.* −0.25 volt *vs.* SCE) resulting from Cu(II)⇌Cu(I) shifted from a negative current to a positive current with the increase in the copper(II) ion by air-oxidation (Fig. 6-b). The shift was also observed in a mixture of a reductant and an oxidant.[25] The difference in the half-wave potential between the reaction mixture and the mixture of the copper(I) ion and ammonia is a result of the difference in the concentrations of ammonia and the supporting salt (1 M KCl for the reaction mixture and 1.5 M $(NH_4)_2SO_4$ for the mixture of the copper(I) ion and ammonia). The rate of the formation of the ammine-copper(II) complex ions by the addition of concd ammonia to the brown compound was very rapid as compared with that by the addition of concd ammonia to the copper(I) chloride, which was tested by the rate of blue coloration. These facts suggest that the copper ion in the brown intermediate is not a univalent ion.

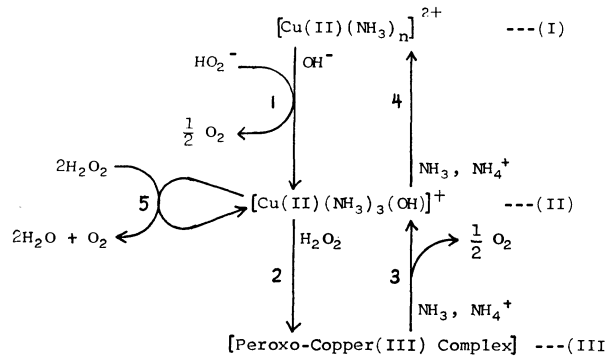

Fig. 7. Reaction scheme of the catalytic decomposition of hydrogen peroxide by the ammine-copper(II) complex ions.

Reaction Scheme. From the preceding discussions, it may be assumed that the path of the catalytic decomposition of hydrogen peroxide by the ammine-copper(II) complex ions is as is shown schematically in Fig. 7. In the reaction scheme, Reaction 1 is very slow compared with the other reactions. Reaction 2 depends on the concentrations of hydrogen peroxide and the hydroxide ion. Reaction 3 depends on the concentration of ammonia or the ammonium ion. The rate of the evolution of oxygen in Reaction 5 is much larger than that in Reaction 3.

In Path A, the rate of Reaction 2 is much larger than that of Reaction 3, so the copper compound in the reaction mixture is almost entirely Compound III (brown intermediate) during the reaction. The rate of the evolution of oxygen is the sum of the rates of Reactions 3 and 5. In the initial stage of Path A, Reaction 5 is predominant, so the rate of the evolution of oxygen is large (see the solid lines in Fig. 1). In the final stage of Path A, the concentration of Compound II increases because of the small rate of Reaction 2 resulting from the low concentration of hydrogen peroxide, so the rate of the evolution of oxygen increases because of the increase in Reaction 5 (2 and 3 in Fig. 1). The linear part can be attributed to the steady concentration of Compounds III and II. Also, the fact that the rate in the linear part is not proportional to the concentration of the brown Compound III suggests that the rate is determined by the concentrations of ammonia and Compounds II and III.

In Path B, the rate of Reaction 2 is very small compared with the rates of Reactions 3 and 4, so Com-

pound III is not observed. The increase in the ammonia or the ammonium salt decreases the active species, II, and the rate of the decomposition of hydrogen peroxide. The induction period is caused by Reaction 1. The mechanism of Reaction 5 was not found owing to the complicated rate equation.

The difference in the activation energy between the two reaction paths, A and B, suggests that their mechanisms of the evolution of oxygen gas are different.

The authors wish to express their thanks to Professor Keiji Kuwata and Professor Kozo Hirota, Osaka University, for kindly putting the ESR spectrometer at their disposal and for their valuable advice.

Change from Metastable Cubic to Stable Tetragonal Form of Submicron Barium Titanate

Shigeharu NAKA, Fumihiko NAKAKITA, Yoshiko SUWA, and Michio INAGAKI

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received September 27, 1973)

The change from metastable cubic to stable tetragonal form was investigated on the submicron $BaTiO_3$ which was prepared by the hydrolysis of titanium tetraisopropoxide in barium hydroxide solution and by crystallization in the glass of BaO–TiO_2–SiO_2–Al_2O_3 system. The precipitated $BaTiO_3$ was found to be the aggregates of minute grains of about 100 Å, to have large amount of strain and to absorb about 6% of OH and alcoholic radicals, some of them absorbed chemically. It is in a metastable cubic form. After the heating above 800 °C, it changed to stable tetragonal form in association with weight loss and decrease in lattice strain. The samples heated at 800—900 °C did not show the Curie point on the DTA curve although they were tetragonal. The samples heated at 1300 °C had the Curie point about 122 °C. The glass-devitrified $BaTiO_3$ was also cubic and had large lattice strain. In order to change to tetragonal form, the heating above 1000 °C was needed. The metastable cubic form of submicron $BaTiO_3$ seemed to be stabilized by the absorbants on the surface which balanced with large amount of strain in the lattice.

As the raw materials for the preparation of high-density sintered ceramic bodies, as the catalysts and as the filler materials, high-purity submicron oxide powders have been studied. On these oxide powders, some structural anomalies have been observed. For example, ZrO_2 prepared from zirconium tetra-tertiary butoxide by thermal decomposition was found to have cubic form,[1] and that precipitated from alkaline aqueous solution and calcined at low temperature was tetragonal,[2] although the monoclinic form was stable at room temperature. $BaTiO_3$, of which stable form at room temperature was tetragonal, was cubic when it was prepared by pyrolysis of barium titanyl oxalate or by simultaneous hydrolysis of barium bis-isopropoxide and titanium tetrakis-tertiary amyloxide.[3,4] The appearance of these metastable forms of oxides were discussed mainly in relation to their small crystallite sizes.

On the $BaTiO_3$ ceramics, the dependence of dielectric constant on particle size has been studied in detail. The ceramics with fine particle size of about 1 μ was found to have very different temperature dependence of dielectric constant from that with coarse particles (about 50 μ), the latter having a similar behavior to the single crystal, and the former showing very diffuse transition from tetragonal to cubic form and having large dielectric constant at room temperature.[5,6] The maximum of dielectric constant at the particle size of about 1 μ was reported on the $BaTiO_3$ which was crystallized in the glass.[7] The decrease of dielectric constant with the decrease of particle size was also shown on the pure, unsintered and pressed $BaTiO_3$.[8] These experimental results were discussed on the basis of internal strain of the crystallite, many faults in the lattice or nonferroelectric surface layer of the particle.

In the present work, the change of $BaTiO_3$ from the metastable cubic to the stable tetragonal form was investigated, in relation to lattice strain, on the submicron $BaTiO_3$ powders.

Experimental

Preparation of Submicron $BaTiO_3$ Powder. The submicron $BaTiO_3$ powders were prepared in the same way as Kiss *et al.*[3] In the 0.41—0.48 N aqueous solution of barium hydroxide (reagent grade) with pH of 11—13, the isopropyl-alcohol solution of the equivalent molar weight of titanium tetra-isopropoxide (CP grade) was hydrolyzed and the precipitates were obtained. During the reaction, the solution was stirred violently and kept at 90 °C in the N_2 atmosphere. After aging the precipitates in the solution at 90 °C, it was filtered, washed by water and then dried in a vacuum. The stoichiometry of the prepared samples was known by the fact that any additional phases, such as Ba_2TiO_4, $BaTi_2O_5$, and TiO_2, were not identified by X-ray after the heating at 1100 °C. The non-stoichiometry of the precipitates occurred from the lowering of pH during the reaction could be avoided by the addition of KOH in the $Ba(OH)_2$ solution to keep the pH-value constant.

The samples thus prepared were heated at various temperatures from 120 °C to 1300 °C in air and studied by X-ray diffraction techniques, electron microscopy, thermal analyses (DTA and TGA), and infrared absorption spectra.

Crystallization of $BaTiO_3$ in the Glass. The crystallization of $BaTiO_3$ in the glass was performed according to Herczog.[7] The glass was prepared from the mixture of 42.9 mol% $BaCO_3$, 35.8% TiO_2, 14.2% SiO_2, and 7.1% Al_2O_3 by melting at 1480 °C for 2 hr, after 1200 °C pre-heating, in the platinum crucible and quenched into water.

The glass samples thus prepared were heated at 800 °—1200 °C in air and the precipitated microcrystalline $BaTiO_3$ was studied by X-ray.

Results and Discussion

X-Ray Diffraction Studies. X-Ray diffraction patterns of submicron $BaTiO_3$ are shown in Fig. 1. After heating at 120 °C for 24 hr, X-ray pattern of the sample is indexed by the cubic system, which have to be the high-temperature modification of $BaTiO_3$. After heating at 1300 °C for 5 hr, however, the sample is tetragonal, of which X-ray pattern is not differentiated from the crystal prepared by solid state reaction.

In the BaO–TiO_2–SiO_2–Al_2O_3 system glass, $BaTiO_3$ crystals were precipitated by the heating above 800 °C. The crystals precipitated after heating at 800 °C for 5 hr were also cubic and those after heating at 1200 °C were tetragonal, which coexisted with small amount of hexagonal feldspar $BaAl_2Si_2O_8$.

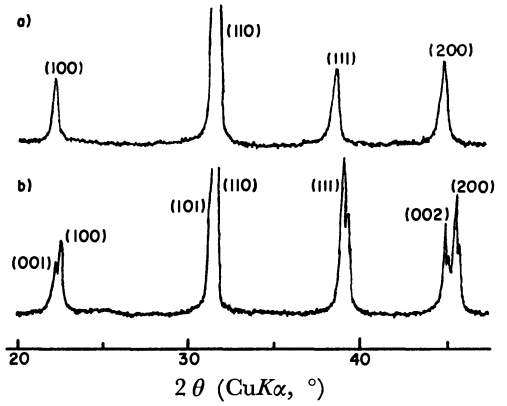

Fig. 1. X-ray diffraction patterns of submicron $BaTiO_3$ heated at 120 °C for 24 hr (a) and at 1300 °C for 5 hr (b)

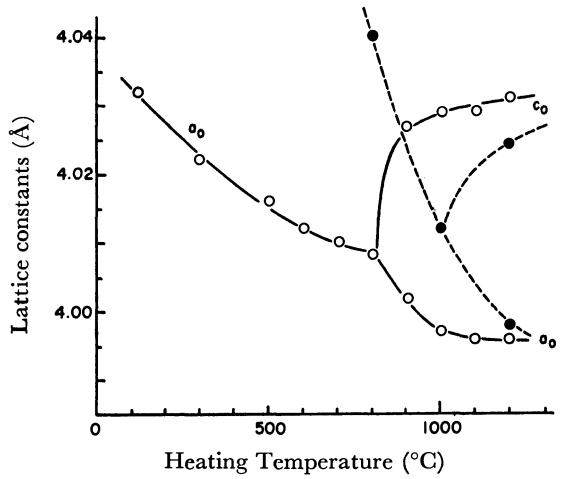

Fig. 2. Changes of lattice constants a_0 and c_0 with heating temperature for the constant heating time of 5 hr
○: precipitated, ●: glass-devitrified

On both precipitated and glass-devitrified $BaTiO_3$ samples, the changes of lattice constants a_0 and c_0, which are determined by using (111), (002), and (200) diffraction lines, with heating temperature are shown in Fig. 2. The transition temperature from the metastable cubic to the stable tetragonal form is at about 800 °C for the precipitated sample and at about 1000 °C for the glass-devitrified. At low heating temperature, the unit cell of the samples is relatively large. This might suggest the existence of large amounts and many kinds of lattice defects.

In Fig. 3, the half widths of (111) and (002) diffraction line profiles are plotted as a function of heating temperature on the precipitated $BaTiO_3$ heated at each temperature for 5 hr. The half width of (111) line decreases with the increase in heating temperature and this corresponds to the crystallite growth and the decrease in strain. However, the observed half width of (002) line shows an increase above 700 °C. This is caused from splitting of the cubic (002) line to the tetragonal (002) and (200) lines and shows consistency with the changes of lattice constants.

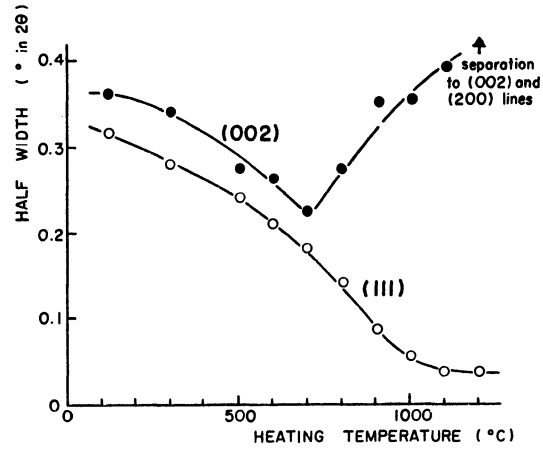

Fig. 3. Changes of half width of (111) and (002) diffraction lines with heating temperature for the constant heating time of 5 hr.

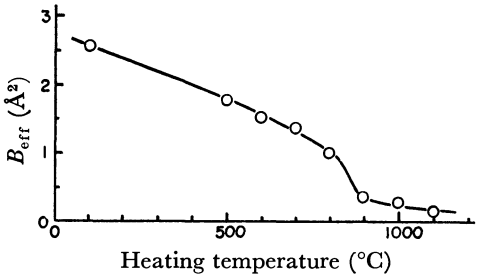

Fig. 4. Change of effective Debye parameter B_{eff} with heating temperature for the constant heating time of 5 hr.

On the same precipitated samples, the effective Debye parameter B_{eff} was measured, which was a measure of lattice strain in the powders.[9] The change of B_{eff} with heating temperature is shown in Fig. 4. With the increase of heating temperature, the value of B_{eff}, that is, lattice strain, decreases rapidly. The step-wise decrease between 800 and 900 °C corresponds to the structural change from cubic to tetragonal form.

On the metastable cubic $BaTiO_3$ devitrified in the glass, large value of B_{eff}, that is, large amount of lattice strain, was observed.

Electron Microscopic Observations. The precipitates heated at 120 °C for 24 hr, consisted of the polyhedral

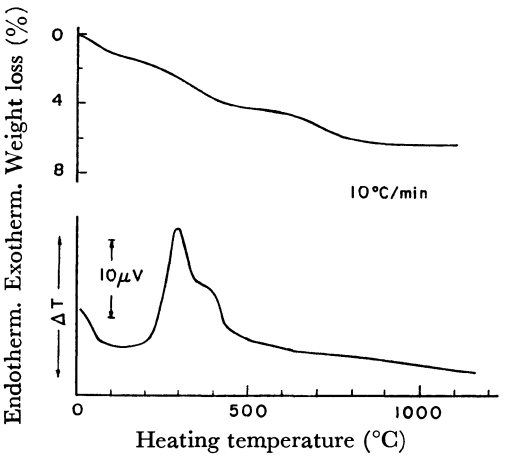

Fig. 5. TGA and DTA curves for the precipitated $BaTiO_3$.

particles with the apparent dimension of about 500 Å and these polyhedra seemed to be the aggregates of minute grains of about 100 Å. These particles grew up with the increase in heating temperature, to 0.1—1 μ in dimension after the heating at 1100 °C for 5 hr.

Thermal Analysis Studies. The results of thermogravimetric and differential thermal analyses (TGA and DTA) are shown in Fig. 5 on the precipitates heated at 120 °C for 24 hr. At 290 and 375 °C, two exothermic peaks are observed on the DTA curve. However, the weight loss occurs in two steps, though very diffuse, up to about 450 °C and to about 800 °C. The first step of weight loss corresponds to the exothermic peaks. The chemical species which cause the weight loss are supposed to be the absorbed OH and isopropoxy groups from the infrared absorption spectra for the samples quenched from different temperatures. Most of the absorbants which have been absorbed on the surfaces of submicron $BaTiO_3$ particles during their preparation, are desorbed up to 450 °C and are responsible to the exothermic peaks. Some of the absorbants remained above 450 °C and desorbed gradually up to about 800 °C. The experimental fact that one of the absorbants on the $BaTiO_3$ surfaces is OH groups, may be due to the basic nature of barium.[10]

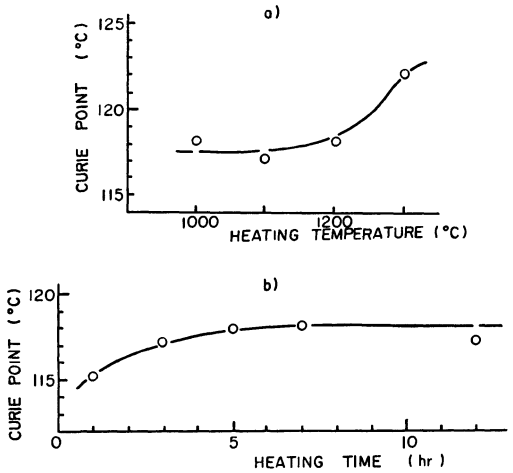

Fig. 6. Changes of Curie point with heating temperature for the constant heating time of 5 hr (a) and with heating time at 1000 °C (b)

On the precipitated $BaTiO_3$ heated above 1000 °C and transformed to the tetragonal form, the Curie point, the reversible transition point from tetragonal to cubic, was measured with DTA. In Fig. 6a, the relation between the Curie point and heating temperature for a constant heating time of 5 hr is shown. The observed Curie point is plotted as a function of heating time at 1000 °C, in Fig. 6b. With the increase of heating temperature, the Curie point increases to 122 °C. This Curie point corresponds to the value of 123 °C for the $BaTiO_3$ ceramics with coarse grain (—100 μ) reported by Jonker.[5] At 1000 °C, however, the lattice strain in the precipitates seems not to be annealed out and consequently the Curie point observed is about 118 °C even after the annealing for 12 hr. The sample heated at 900 °C was tetragonal, but Curie point was difficult to be detected on their DTA curves.

On the precipitated $BaTiO_3$ heated below 900 °C, the Curie point was not detected at low temperatures down to the liquid nitrogen temperature. This fact suggests that the Curie point disappears, not shifts to low temperatures, probably because of the presence of strain.

The measurement of dielectric constant was carried out on the pressed specimens of the precipitated $BaTiO_3$. However, the reliable value of dielectric constant was difficult to obtain because of the lack of the sufficiently dense specimens.

On the Formation of Metastable Cubic Form. The submicron $BaTiO_3$, precipitated from titanium-alkoxide and barium hydroxide solution, and precipitated in the glass matrix, had the cubic form which was metastable thermodynamically. This metastable cubic form changed to the stable tetragonal form only after heating above 800 °C for the precipitated and above 1000 °C for the glass-devitrified $BaTiO_3$. The latter needed higher temperature than the former, which might be caused from the clamping effect[11] of glass matrix. The decrease of lattice strain with heating corresponded to the change from the metastable cubic to the stable tetragonal form. Phenomenological similarity was found between the present results and the irradiation-induced transition,[12] in which the introduction of defects by irradiation resulted in the change from the tetragonal to cubic form. An amount of lattice strain remained in the tetragonal submicron $BaTiO_3$ and it caused the disappearance of the Curie point. The Curie point of $BaTiO_3$ was reported to be smeared out by grinding and compression[13] and also to disappear by the irradiation in the amount of 2.1×10^{20} nvt.[14]

As shown in the TGA and DTA curves, the submicron precipitates absorbed OH and isopropoxy groups on their surfaces, some amount of radicals being absorbed chemically. The space charge layer, which has been supposed to be present on the surface of ferroelectric solids,[15] did not appeared to exist in the present submicron $BaTiO_3$ because the charges, if they existed, might be diverged or cancelled out by the absorption of OH and alcoholic radicals. The cubic form was assumed to be stabilized, though metastably, by the absorbants which might balance with large strain in the metastable lattice structure. Above 800 °C at which almost all absorbants disappear, the submicron $BaTiO_3$ transformed to tetragonal form. On ZrO_2, the tetragonal form (hightemperature form) has been known to appear metastably at room temperature by bonding the small amounts of OH groups.[16]

The large lattice strain of the metastable cubic form of $BaTiO_3$ seemed to be related to the small particle size. According to Goswami,[8] the strained surface layer of $BaTiO_3$ particles is non-ferroelectric. The particle size of the present submicron $BaTiO_3$ is much smaller than the reported values of surface layer thickness.[8] In other words, all of the submicron particles have the characteristics of the surface layer, large strain and non-ferroelectric.

Polarographic Studies of the Associated Ion-pairs of Polyphosphate with the Hexaamminecobalt(III) Ion

Niro MATSUURA, Kisaburo UMEMOTO, Masao TAKIZAWA,* and Yukio Sasaki*

Department of Pure and Applied Science, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

**Tokyo Institute of Photographic Technology, Iiyama, Atsugi, Kanagawa 243-02*

(Received October 2, 1973)

The polarographic behavior of the hexaamminecobalt(III) ion was studied in solutions of polyphosphate with different numbers of chains. The decrease in the diffusion current, i_d, with an increase in the phosphate (C_p)-to-hexaamminecobalt(III) (C_{Co}) mole ratio was found to be proportional to 1/4 the power of the molecular weight, M, of the $Co(NH_3)_6^{3+}$-polyphosphate. This fact shows the associated ions between $Co(NH_3)_6^{3+}$ ions and polyphosphate anions are transported to the electrode by diffusion at a rate depending on the square root of the molecular weight of the diffusion depolarizer. From the shift of the half-wave potential in the presence of excess polyphosphate, the chemical compositions of the associated ion-pairs were determined as a function of log C_p/C_{Co}.

The association of hexaamminecobalt(III) ions with sulfate, iodide, and several other halide ions has been evidenced by the spectrophotometric studies in aqueous media.[1-4] Hexaamminecobalt(III) ($Co(NH_3)_6^{3+}$) cations form precipitates with pyrophosphate and polyphosphate anions, but the precipitate of $Co(NH_3)_6^{3+}$-polyphosphate dissolves in an excess of polyphosphate. Laitinen *et al.*[5,6] reported the amperometric determination of pyrophosphate and triphosphate, with hexaamminecobalt(III) or tris-ethylenediamminecobalt(III) as the titrant. For completing the precipitation of $Co(NH_3)_6^{3+}$-triphosphate, the addition of some alcohol is indispensable. Since $Co(NH_3)_6^{3+}$ is highly stable and inert to ligand substitution, it is interesting to study in detail the type and the strength of the interaction exerted between $Co(NH_3)_6^{3+}$ ions and polyphosphate ions. The present work will deal with the diffusion currents and the half-wave potentials of $Co(NH_3)_6^{3+}$ in solutions of the polyphosphate with different numbers of chains.

Experimental

Apparatus. A Yanagimoto polarograph of the P8-D was employed for recording the DC polarograms. The potential was calibrated by means of potentiometer to within 1 mV. For the measurement, an H-type cell was used, the SCE being isolated from the solution by a bridge of saturated KCl with ultrafine sintered-glass membranes. The internal resistance was about 3 kΩ. The capillary used had an m value of 2.355 mg/s and a drop time of 3.57 s at a mercury height of 78.8 cm in distilled water at open circuit and at 25 °C.

Reagents. For obtaining sodium triphosphate of a high purity, a commercial triphosphate product containing more than 80% of triphosphate was used as the starting material. The purification was carried out by recrystallization, and the recrystallization was carried out by the use of 20% ethanol. When recrystallization was repeated five times, the product was the hydrate crystal of $Na_5P_3O_{10}\cdot 6H_2O$ (99.9% purity, according to our anion-exchange chromatographic analysis).[7] For preparing polyphosphate, the sodium dihydrogenphosphate (NaH_2PO_4) of the guaranteed reagent was dehydrated and melted at 800 °C for 3 hr. Vitreous oligomer phosphate with an average number of 100 chains was obtained by pouring the molten salt on a cold brass plate. The hexaamminecobalt(III) chloride was prepared according to the method described in the literature,[8] recrystallization from 60% alcohol and a 0.5 M hydrochloric acid solution was repeated two times. For the polarographic measurements, polyacrylamide was used as the maximum suppressor. All the other reagents used were guaranteed reagents. Triply-distilled water was used for test solutions throughout the experiments.

Results and Discussion

Precipitation. Hexaamminecobalt(III)-oligomer phosphate, including pyrophosphate, was precipitated either from a 0.1 M $NaClO_4$ solution of pH 5.95 or from a 0.1 M $NH_3\cdot NH_4Cl$ buffer solution of pH 9.98. The precipitate of hexaamminecobalt(III) pyrophosphate was not dissolved by increasing the pyrophosphate concentration. The precipitate of hexaamminecobalt(III) polyphosphate was formed within a C_p/C_{Co} mole ratio of about 10; the precipitate dissolved again in excess of polyphosphate. Polarograms of $Co(NH_3)_6^{3+}$ upon the addition of polyphosphate are shown in Fig. 1. The precipitate formation of hexaamminecobalt(III) polyphosphate results in a sharp decrease in the diffusion currents, as is shown in Fig. 2. Curves a and b in Fig. 2 correspond to the precipitations

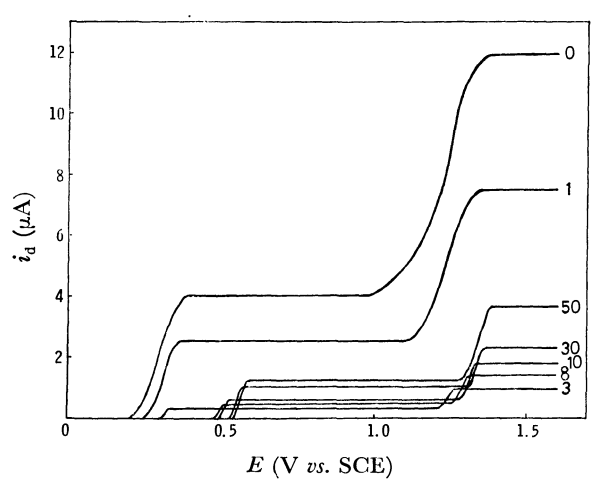

Fig. 1. Polarograms of $Co(NH_3)_6^{3+}$ with addition of polyphosphate. The numerical values show the C_p/C_{Co} mole ratio.

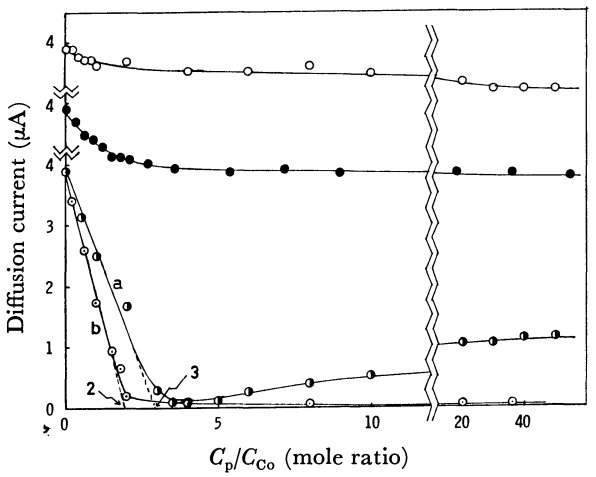

Fig. 2. Diffusion currents for reduction of 1×10^{-3} M $Co(NH_3)_6^{3+}$ ion (first wave) in 0.1 M $NaClO_4$ with 0.007% polyacrylamide.
(○) orthophosphate (◉) pyrophosphate
(●) triphosphate (◑) polyphosphate

of polyphosphate and pyrophosphate respectively. Curve a has a minimum at a C_p/C_{Co} mole ratio of about 3, which could be estimated by the extrapolation of the straight line a to the intercept on the abscissa. The diffusion current attains a constant value at a polyphosphate concentration of about 2×10^{-2} M, equal to a C_p/C_{Co} ratio of about 20. Curve b in Fig. 2 show an equivalent point, C_p/C_{Co}, equal to 2 on the abscissa, which agrees with the precipitation of hexaamminecobalt(III) pyrophosphate in a one-to-one mole ratio with respect to the concentrations of pyrophosphate and hexaamminecobalt(III). If one mole of $Co(NH_3)_6^{3+}$ and one mole of $P_2O_7^{4-}$ precipitate, then one mole of the univalent cation is required to neutralize the excess charge. From flame photometric analysis of the sodium content in the precipitate of hexaamminecobalt(III) pyrophosphate, the C_{Na}/C_{Co} mole ratio was found to be unity. From these finding, the composition of the hexaamminecobalt(III) pyrophosphate precipitate is shown to be $Na[Co(NH_3)_6]$-P_2O_7, in agreement with the formula proposed by Laitinen and McCune.[5,6] Curve a in Fig. 3 shows the decrease in the diffusion current for $Co(NH_3)_6^{3+}$ in presence of polyphosphate at various C_p/C_{Co} mole ratio. Curve b in Fig. 3 is the result of the unprecipitated phosphate concentration obtained by the molybdenum-blue method of colorimetric analysis for the phosphate after the polyphosphate form has been converted into the monomer form by acid hydrolysis.[9] Curves a and b in Fig. 3 show the equivalent point at C_p/C_{Co} mole ratio of 3 corresponding to the concentrations of 7.78×10^{-4} M and 2×10^{-4} M for $Co(NH_3)_6^{3+}$ and phosphate respectively. From these data, the apparent solubility product, K'_{sp}, can be calculated by:

$$K'_{sp} = (7.78\times10^{-4}) \times (2\times10^{-4})^3 = 6.22 \times 10^{-15}$$

for the precipitation reaction expressed by (1):

$$Co(NH_3)_6^{3+} + 3(PO_3^-) = Co(NH_3)_6(PO_3)_3 \quad (1)$$

The polyphosphate anion, $(PO_3^-)_n$, is a linear-chain oligomer with an average number of chains of about 100 and has a single negative charge per chain-like molecule, PO_3. A single PO_3^- unit produces an ionic bond with one-third of the trivalent hexaamminecobalt-(III) ion. The precipitation reaction (1) is a reasonable assumption when the PO_3^- unit in the polymer chain behaves like a monomer free ion.

Diffusion Current. The curves in Fig. 2 show that the diffusion currents due to the reduction of Co(III) to Co(II) for a fixed $Co(NH_3)_6^{3+}$ concentration of 1×10^{-3} M in a concentration range of a large C_p/C_{Co} ratio such as 20: 1 are 3.35, 2.85, and 1.05 μA for orthophosphate, triphosphate, and oligomer phosphate with an average number of chains of 100 respectively. It appears likely that the diffusion current depends on the polyphosphate species. In this respect, synthetic oligomer phosphates with numbers of chains of 6, 10, and 20 are employed for measuring the diffusion currents at the C_p/C_{Co} ratio of 50. The results are represented in Fig. 4 by plotting log i_d against log M

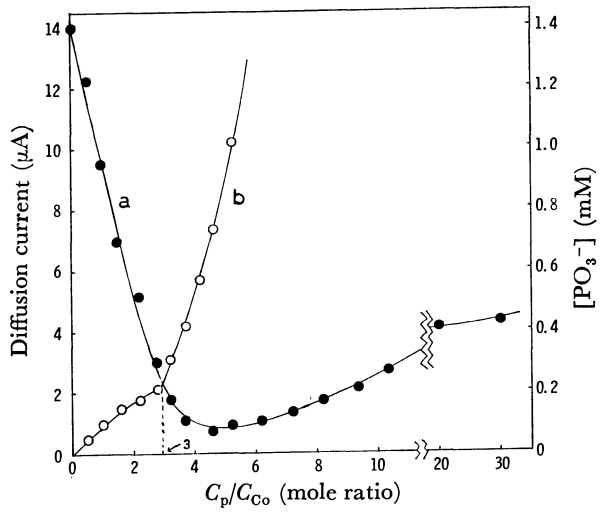

Fig. 3. Variation of diffusion current with $Co(NH_3)_6^{3+}$ concentration of 3.6×10^{-3} M (curve a) and phosphate ion concentration (curve b) with increasing C_p/C_{Co} mole ratio.

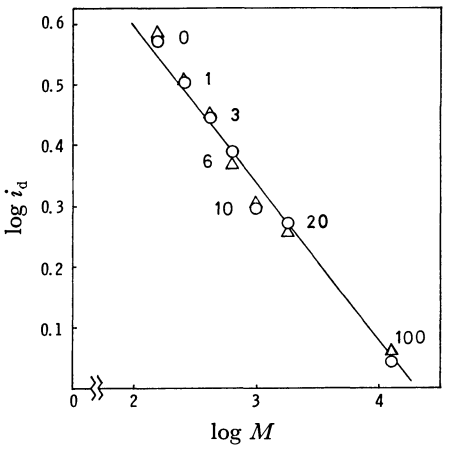

Fig. 4. The relationship between log i_d for the first wave and log M. The numerical values show the number of chains.

in order to establish a quantitative relation between the diffusion current, i_d, and the molecular weight, M, of the $Co(NH_3)_6^{3+}$-oligomer phosphate. Since the influence of the viscosity was observed only when there were 100 chains, the corrected value of i_d was used for that. The straight line drawn for $\log i_d - \log M$ plots in Fig. 4 has a slope approximately equal to $-1/4$. This fact can be explained as follows. Since the diffusion current, i_d, is proportional to the square root of the diffusion coefficient, D, in the relation known as the Ilkovic equation, and since the diffusion coefficient, D, is inversely proportional to the square root of the molecular weight, M, of the diffusion species,[10] the diffusion current, i_d, is inversely proportional to 1/4 the power of the molecular weight, M, of $Co(NH_3)_6^{3+}$ polyphosphate. This is a reasonable assumption for associated ion-pairs with respect to $Co(NH_3)_6^{3+}$ polyphosphate when the decrease in the diffusion current is due to the diffusion coefficient. The constancy of $i_d \times M^{1/4}$ holds well for all the oligomer phosphates with different numbers of chains, as is shown in Table 1. It is worthwhile noting this application of the $i_d \times M^{1/4}$ rule that the molecular weight of an oligomer phosphate can be determined by measuring the diffusion current of the reduction containing an excess amount of the oligomer phosphate in question.

Half-wave Potential. The variation in the half-wave potentials with the increasing C_p/C_{Co} ratio is illustrated in Fig. 5 for the hexaamminecobalt(III)

polyphosphate system in two media with different pH values. The influence of the adsorption on the electrode surface of polyphosphate was checked by measuring the electrocapillary curve; this influence is rarely observed. The negative shifts of the half-wave potentials observed in the range of C_p/C_{Co} ratios from 3 to 6 are larger than the shifts observed at C_p/C_{Co} ratios beyond 6. This fact indicates that the soluble and stable ion-pairs were formed in the vicinity of C_p/C_{Co} ratios of about 6. The maximum value of the potential shift amounts to some hundred millivolts on the negative side at the C_p/C_{Co} ratio of 50. In Fig. 6 similar curves for the variation in half-wave potentials are illustrated for orthophosphate, pyrophosphate, and triphosphate respectively. The negative shifts of their potentials are not so large as compared with the shifts caused by the higher-oligomer phosphate. It can be seen that the larger the number of chains of phosphate, the more the negative shifts of the half-wave potentials. The final values of the half-wave potentials at the C_p/C_{Co} ratio of 50 are represented in Table 2, where all the electrochemically active species of hexaamminecobalt(III) are presented in the form of ion-pairs produced between $Co(NH_3)_6^{3+}$ and oligomer phosphate anions. The transfer coefficients, α, shown in the third column of Table 2 were obtained from the plots of $\log[i/(i_d-i)]$ against E at the C_p/C_{Co} ratio of 50.

Synergism in the Liquid-Liquid Extraction and the Extraction Chromatography of Manganese(II), Cobalt(II), and Zinc(II) in the Thenoyltrifluoroacetone-Trioctylphosphine Oxide-Cyclohexane Extraction System

Takaharu Honjo, Masanobu Horiuchi, and Toshiyasu Kiba

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920

(Received October 15, 1973)

The synergism appearing in the liquid-liquid extraction and the extraction chromatography of trace amounts of manganese(II), cobalt(II), and zinc(II) has been investigated with TTA (thenoyltrifluoroacetone) in various solvents with or without TOPO (tri-*n*-octylphosphine oxide). For example, the $pH_{1/2}$ of the extraction of Co(TTA)$_2$ differed with the solvent used; it was, for example, 4.1 for nitrobenzene, 4.6 for cyclohexane, and 5.2 for benzene, when examined with 0.1 M TTA. When 0.01 M TOPO was present under the same conditions, the above values became 3.3, 2.4, and 3.1 respectively. The synergism was thus found to become more effective as a less polar solvent was used. The extraction constants of the three metals with only 0.1 M TTA–cyclohexane increases in the order of Mn(II)–Zn(II)–Co(II); however, when 0.001 or 0.01 M TOPO was present, all the extraction curves of the three metals became identical, even in the acidic region of pH 1—4. The overall stability constants of the adducts, M(TTA)$_2$–(TOPO)$_n$, increased in the order of Zn(II)–Co(II)–Mn(II), unlike the case of M(TTA)$_2$. The adducts were found to have two TOPO for Mn(II) and Co(II), but only one for Zn(II). The extraction equilibria were found to be attained within two minutes. Unlike as in the batch extraction, the column-extraction chromatography gave a dissimilar order of the extractability of three metals (Zn(II)–Mn(II)–Co(II)) when 0.1 M TTA–cyclohexane was the stationary phase on Kel-F in the presence of TOPO. The mutual separation could not be achieved among these metals in the presence of TOPO, and the synergism was found to be rather unfavorable for the separation of metals. The relation between the batch extraction and the extraction chromatography was also discussed briefly on the basis of the distribution data obtained.

The synergistic effect has been known to bring about a considerable enhancement of the extractability of metals in the liquid-liquid extraction of metal-β-diketonates in the presence of TOPO (tri-*n*-octylphosphine oxide); this effect can be attributed to the adduct formation between the metal chelates and TOPO.[1-5] Under the synergism, metal ions can usually be extracted quantitatively even in a lower pH region, but the distribution ratios of individual ions become so close to each other that the attempt of the mutual separation of metals by the batch extraction ends in failure. The extraction chromatography of inorganic compounds involving the metal chelates has recently been developed as a powerful separation technique,[6-8] in it the extraction and the back-extraction are repeated many times on so-called theoretical plates. A delicate separation can be expected through the use of this process. Taking advantage of this technique, Cvjetićanin studied the synergism appearing in the reversed-phase partition (extraction) chromatography of Am(III), Ce(III), and La(III) on paper treated with TTA and TOPO;[9] he found the adduct formation of M(TTA)$_3$(TOPO)$_2$, which appeared also in the liquid-liquid extraction of the same metal-chelate-solvent system. Aly and Raieh investigated the synergism in the extraction chromatography of the TTA-DBDECP-(Celite) system and clarified the factors affecting the column performance for separating Eu(III) from Sm(III) and Cm from Cf.[10] Since the same extraction process is generally used in both batch and column extractions, the extraction mechanism can be elucidated from both of the above techniques, as has been described by the present authors in connection with the system of Zn(II), Hg(II), and Co(II)–STTA–cyclohexane-(Kel-F),[11] and that of Ag(I), Bi(III), Cd(II), and Zn(II)–TOA–carbon tetrachloride(Kel-F).[12]

In the present paper we will describe the behavior of trace amounts of Mn(II), Co(II), and Zn(II) in the liquid-liquid extraction as well as in the extraction chromatography with TTA in the presence or the absence of TOPO, and will compare the results obtained by the two methods. The utility of the synergism in the extraction chromatography, the mutual separation of the metals, and the mechanism of the adduct formation will then be discussed further.

Experimental

Apparatus. Hitachi-Horiba M-3 and M-4 pH meters; a shaking machine, Type V-S, of the Iwaki Co.; a centrifuge machine of the Kubota Co.; a well-type scintillation counter of the Kobe Kogyo Co.; a 200-channel pulse-height analyzer, type EDS-34208A, of the same company; a chromatographic glass tube, 10×300 mm, with a fritted glass filter; a fraction collector, Toyo SF-200 A.

Materials. The radioisotopes, ^{54}Mn, ^{60}Co, and ^{65}Zn as chloride in a hydrochloric acid solution, were supplied by the New England Nuclear Corp. and the Radio Chemical Center, and were used as the tracers. The purity of each tracer was checked from its γ-spectra (^{60}Co: 1.17, 1.33; ^{65}Zn: 1.12; ^{54}Mn: 0.85 MeV) by the 200-channel pulse-height analyzer. TTA (thenoyltrifluoroacetone) and TOPO (tri-*n*-octylphosphine oxide), GR-grade reagents, were purchased from the Dojindo Co. Kel-F 300 moulding powder, the trade name of polytrifluorochloroethylene, was obtained from the Daikin Kogyo Co. The cyclohexane, benzene, and nitrobenzene were all purified by distillation. All the other reagents were of a GR grade and were employed without further purification.

Extraction and Back Extraction. The experimental procedure was the same as has previously been described.[2-5,11,12]

To a 10 ml portion of an aqueous solution containing a few ppm of metals, sodium acetate (0.1 M) (for the acidic region) or boric acid (0.1 M) (for the basic region) were added, after which the pH of the solution was adjusted to a desired value. A 10 or 30 ml portions of an organic solvent containing TTA (0.1 M) and varying amounts of TOPO were then added. Both phases were placed in a 50 ml glass-stoppered centrifuge tube and agitated by the shaking machine for from one to three hours at 20 °C. After centrifugation a 2 ml portion of each phase was pipetted out into a test tube, and the γ-activity of each portion was measured with the NaI(Tl) well-type scintillation counter. The distribution ratio of the metals was calculated from the counting rate of both phases. The pH of the aqueous phase was checked again after the extraction. The back extraction was carried out by shaking a 5 ml or 10 ml portions of the organic phase containing the extracted metal chelates with an aqueous solution of the desired acidity. Then a 1 or 3 ml portion was pipetted out of both phases into a test tube and the back distribution ratio was determined as in the case of the extraction.

Extraction Chromatography. All the aqueous solutions and organic solvents containing TTA should be pre-equilibrated before use. A 150 ml portion of 0.1 M sodium acetate solution which had been adjusted to pH 4.5 was shaken with a 20—30 ml portion of 0.1 M TTA–TOPO–cyclohexane for an hour. After discarding the organic solution, a 20 ml portion of the aqueous solution was taken out and was agitated with 30 ml of a new 0.1 M TTA–TOPO–cyclohexane solution for an hour. Then 20 ml of the organic solution was taken out, poured onto 5 g Kel-F powder (42—80 mesh), and allowed to stand for two hours. On the other hand, 200—250 ml of a 0.1 M sodium acetate solution, adjusted to the desired pH, was agitated with 30—40 ml of 0.1 M TTA–TOPO–cyclohexane for an hour to prepare the eluting solution. The procedure for preparing the column was the same as has previously been described.[11,12] A buffer solution of pH 4.5 was placed in the column tube, and 1—2 ml of the 0.1 M TTA–TOPO–cyclohexane was poured in. A slurry of TTA–TOPO–cyclohexane–Kel-F powder was then dropped into the tube in small portions. After every addition the slurry in the column tube was stirred with a sharp-pointed glass rod and gently pressed with the other, flat end of the same rod under a slow flow of the eluting solution. The stop-cock was then closed, and the column was filled again with the eluting solution. This operation was repeated about ten times until all the slurry made from 5 g Kel-F had been poured into the tube. Thereafter, a separating funnel was fitted at the top of the column tube; from it 100 ml of a buffer solution of pH 4.5 was passed through to wash down the excess unabsorbed organic solvent through the completely opened cock at the bottom of the tube.

The column bed thus prepared was 10×200 mm. The fraction collector was placed below the column tube and operated so as to collect each 10 ml portion of the eluate.

When the liquid surface came to the upper surface of the column bed, 1 ml of the sample solution was poured onto the bed. The sample solution containing a radioactive tracer had been buffered to pH 4.5. Then, 2—3 ml of the buffer solution was repeatedly poured onto the column and flowed through the column. By this treatment, all the metal ions could be completely retained on the column. A separating funnel containing a buffer solution with pH 4.5 was fitted on the column tube, and the column was washed with 100 ml of the solution. The eluting solution was then passed through from another separating funnel newly-fitted on the tube at the rate of 0.5 ml/min. From each 10 ml fraction of the eluate, a 3 ml portion was pipetted out in a test tube and the radioactivity was measured by means of the well-type scintillation.

Theoretical

Liquid-Liquid Extraction. The extraction constant of a metal chelate, K; the pH of the half extraction, $pH_{1/2}$, and the stability constant of the metal chelate adduct, β_n, can be calculated from the data obtained by the following equations:

$$D = (MR_2)_0/(M^{2+}) \quad (1)$$

$$K = (MR_2)_0(H^+)^2/(M^{2+})(HR)_0^2 \quad (2)$$

$$\log K = \log D - 2\log (HR)_0 - 2pH \quad (3)$$

$$pH_{1/2} = -\log K/2 - \log (HR)_0 \quad (4)$$

$$D^* = \{(MR_2)_0 + \sum_1^n (MR_2L_n)_0\}/(M^{2+}) \quad (5)$$

$$\beta_n = (MR_2L_n)_0/(MR_2)_0(L)_0^n \quad (6)$$

$$\log D^*/D = \log (1+\beta_n(L)_0^n) \quad (7)$$

where D and D^* are the distribution ratios in the absence and in the presence of the organic base, TOPO; M stands for metal, HR for β-diketone, and L for TOPO; the parentheses designate the concentration of the chemical species in the aqueous phase and in the organic phase with the suffix 0.

Extraction Chromatography. The distribution of metals can be derived from the data obtained by the column-extraction chromatography by employing the following equations:

$$D = (V_m - V^*)/V \quad (8)$$

$$D^* = (V_m^* - V^*)/V \quad (9)$$

$$\log D^*/D = \log (V_m^* - V^*)/(V_m - V^*) \quad (10)$$

where V_m and V_m^* are the volumes of the effluent necessary to reach the maximum concentration of the eluted metal ion in the absence and in the presence of TOPO; V^* is the volume of the mobile phase in the column, and V that of the stationary phase.

Results and Discussion

Liquid-Liquid Extraction in the TTA–TOPO–Solvent System. The liquid-liquid extraction was carried out for a trace amount of Co(II) with 0.1 M TTA in various solvents *i.e.* cyclohexane, benzene, and nitrobenzene, in the presence of 0.01 M TOPO as well as in the absence of the base. The results are shown in Fig. 1.

From the figure it can be seen that the $pH_{1/2}$ of cobalt extraction differs among the solvents, from 4.1 for nitrobenzene, and 4.6 for cyclohexane to 5.2 for benzene. All the straight lines with a slope of about 2 also show that the extractions proceed almost ideally, but a slight deviation from the integer suggests the formation of some water-soluble complexes in the extraction process.

On the other hand, when the same extraction was carried out in the presence of 0.01 M TOPO, the extractability of the metals is remarkably enhanced by the adduct formation and the $pH_{1/2}$ shifts lower with

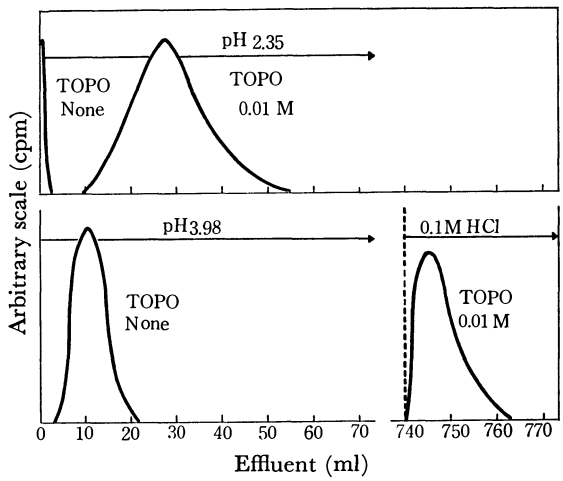

Fig. 4. Chromatograms of a trace amount of Co(II) on 0.1 M TTA–cyclohexane (Kel-F) column in the presence and in the absence of 0.01 M TOPO.

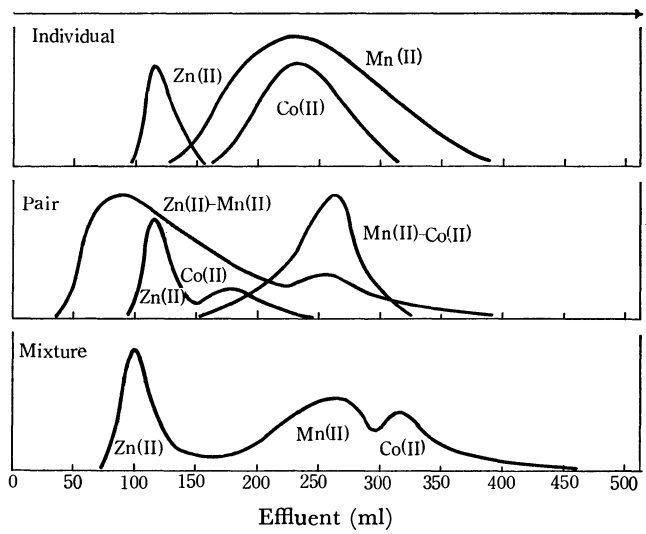

Fig. 5. Chromatograms of a trace amount of Mn(II), Co(II), and Zn(II) on 0.1 M TTA–cyclohexane (Kel-F) column in the presence of 0.01 M TOPO. pH=3.6.

on Kel-F was washed down by passing 20—30 ml of acetone through the column; the washings were received in a 200 ml measuring flask, 50—60 ml of distilled water was added, and the content was shaken by hand. After standing for a day, the separated cyclohexane solution was transferred into a graduated cylinder, and its volume was measured after every experiment. 5.8 ml was obtained as the mean value of the stationary-phase volume. The volume of the mobile phase on the column was determined as follows: one drop of 0.1 M hydrochloric acid containing a ^{60}Co tracer (20000 cpm/ml) was put on the top of the column bed and much water pre-equilibrated with a TTA–TOPO–cyclohexane solution was passed through the column at the flow rate of 0.5 ml/min; each 0.31 ml fraction of the effluent was taken in a test tube, and the γ-activity was counted; the elution curve was prepared for the counting rate against the effluent volume; the volume required to reach the maximum counting rate was estimated as the volume of the mobile phase (2.7 ml was obtained in this case). In order to investigate how to make the synergistic effect appear in extraction chromatography, the Co(II)–TTA–cyclohexane system was first tested with and without TOPO, since the synergistic effect had been known to depend on the concentration of the organic base.[1] The results are shown in Fig. 4 as the elution curves from the 0.1 M TTA–cyclohexane(Kel-F) column as well as from the 0.1 M TTA–0.01 M TOPO–cyclohexane(Kel-F) column, with eluting solutions of various pH's. When a sample solution of pH 4.5 was passed through the column, the Co(II) was retained completely on the column in both cases and was then eluted by eluting solutions. Without TOPO, Co(II) could be eluted instantly with the eluting solution of pH 2.35 into the first fraction of 2.3 ml; nevertheless, with the eluting solution of pH 4.0 it was eluted somewhat later, as its elution peak appeared around 10 ml of the effluent. On the other hand, with TOPO the elution feature changed remarkably, as the elution peak with the eluting solution of pH 2.35 appeared around 30 ml of the effluent, while with the eluting solution of pH 4.0 Co(II) did not appear in the effluent after as much as 740 ml of the eluting solution had been passed through the column.

Therefore, Co(II) had to be released from the column by passing 0.1 M hydrochloric acid through. The extraction chromatography was examined with a column of 0.1 M TTA–0.01 M TOPO–cyclohexane–(Kel-F) for Mn(II), Co(II), and Zn(II) individually, and also for mixtures of them. After the metals had been retained on the column by passing through sample solutions of pH 4.5, the metals were eluted with the eluting solution of pH 3.6. In Fig. 5, the chromatograms of the individual metal ions, of the mixtures of two ions, and of a mixture of three ions are illustrated. As some overlap of the elution curves can be seen for Mn(II) and Co(II), even in the case of the independent tests, the separation of each metal ion seems to be difficult except for that of Zn(II) from the mixture.

Table 2. Comparison of the distribution ratio, D^*, obtained by batch and chromatographic extraction

Ions		D*	
		Extraction chromatography	Batch extraction
	Mn	40.9 (98.9)	499 (99.8)
	Co	40.9 (98.9)	322 (99.7)
	Zn	15.9 (97.2)	81 (98.8)
Mn–Co	Mn	44.4 (99.0)	
	Co	44.4 (99.0)	
Mn–Zn	Mn	40.1 (98.9)	
	Zn	15.1 (97.0)	
Co–Zn	Co	29.7 (98.5)	
	Zn	19.4 (97.7)	
Mn–Co–Zn			
	Mn	45.2 (99.0)	
	Co	54.7 (99.2)	
	Zn	17.6 (97.4)	

The values in the blacket are the percent extraction, % E, of metals.

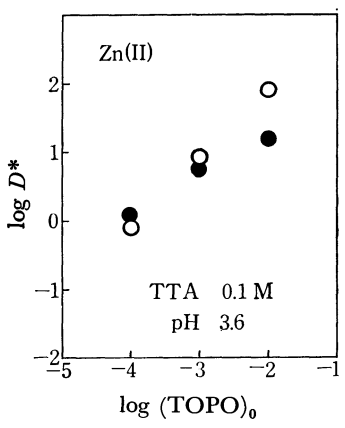

Fig. 6. Distribution ratio of a trace amount of Zn(II) with 0.1 M TTA in cyclohexane as a function of TOPO concentration obtained by batch and chromatographic extraction.
Batch extraction: —○—
Extraction chromatography: —●—

Moreover, it can also be seen that the elution peaks of the ions do not always coincide, especially when there is a wide gap between the individual ion-peak and that obtained in the mixture of two ions. The delayed appearance of the peaks of Mn(II) and Co(II) from the mixture of the three metals seems to be due to the competition of the chelate formation among metals or to some kinetic disposition of each chelate. In coclution, the synergistic effect is not favorable to the separation of metals.

Relation between Extraction Chromatography and the Liquid-Liquid Extraction. The distribution ratios of the three metals are summarized in Table 2 in the case of both the batch extraction and the extraction chromatography; some discrepancy can be noticed. The effect of the TOPO concentration on the Zn(II)–TTA–TOPO–cyclohexane system is shown in Fig. 6, in which the distribution is found to increase with the concentration of TOPO; the values are in quite good agreement with each other, whether they are determined by batch extraction or by extraction chromatography. If some discrepancy seems to exist between them, it might be caused by the difference in the process between the batch extraction and the chromatography; in the former the equilibrium could be reached after shaking the two phases, but in the chromatography the contact time of the two phases and the kinetic properties of the complex formation, as well as the rate of the release from the organic phase, back-extraction, might be an important factors in providing an elution curve.

Classification of Polarographic Current-Potential Curves of Inorganic Anions as a Function of Reduction Potentials

Yoshio UMEZAWA, Michio HIROTA, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 12, 1973)

DC polarographic behaviors of a variety of inorganic anions are examined systematically. Irrespective of chemical species, the shapes of current-potential curves are classified into three groups as a function of reduction potentials: i) $E_{1/2}>0$ V(SCE); The so-called minima cannot be observed beyond the ecm potentials. ii) 0 V$>E_{1/2}>$ecm; The minima can be observed. iii) $E_{1/2}<$ecm; The distortion at the rising portion of the DC polarograms can always be observed. These results suggest that whether the minima can be observed or not is due to the difference in the relative position of half-wave potentials with respect to the ecm potential. Furthermore, it is likely that the distortion at the rising portion of the DC polarogram of Group iii) is similar in origin to that of the minima of Group ii). The present results are discussed in terms of the electron density and electronic energy level of electrons in the metal electrode. The discussion based on the phenomenological equation of Butler was also given for the sake of comparison to explain the observed phenomena.

The electrochemical method is one of the most important techniques for the study of electron transfer reactions in solution. The characteristic features of the electrode reaction are i) electronic energy level of one of the reactants, *i.e.*, the electrode, is varied artificially by means of applied potentials—"quantum mechanical effect",[1,2] and ii) due to the large charge density of the double layer, electrostatic interaction between the electrode and the charged depolarizer may be much larger than that of the other types of redox reactions—"electrostatic effect".[3]

The purpose of this paper is to demonstrate experimentally the contribution of the above two effects separately in polarography. Polarographic behaviors of a variety of inorganic anions are examined systematically. It is shown that the pattern of the DC polarogram of inorganic anions is classified into three types as a function of reduction potentials. The results are discussed in terms of the quantum mechanical and electrostatic effects as mentioned above. The results of the present study will be useful to clarify the structure of the double layer and to understand the mechanism of the electrode reaction.

Experimental

DC polarograms were taken with a Yanagimoto Model P-8 Polarograph. A Yanagimoto Model MRP was used as the reference electrode (SCE). Capillaries with drop times of 3—4 s in 1 M KCl solution at a mercury height of 70 cm (open circuit) were used. Sample solutions in the cell were deaerated by bubbling purified nitrogen gas before and throughout the measurements. Gelatin was added to the sample solutions as maximum suppressor. All chemicals used were of analytical reagent grade and metal complexes used were prepared according to the usual methods. Half-wave potentials were evaluated directly from the polarograms.

Results

It is found that the shapes of DC polarograms of a variety of anion depolarizers are roughly divided into three groups A, B, C, in the decreasing order of reduction potentials. The results are cited schematically in Fig. 1. Typical DC polarograms which belong to these groups are shown in Figs. 2 and 3. For the systems of Group A, the half-wave potentials, $E_{1/2}$, are relatively more positive than those of Group B. For the system of Group C, $E_{1/2}$ is situated more negative than the electrocapillary maximum (ecm) potential.

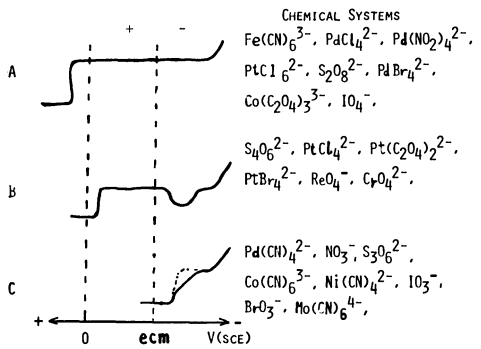

Fig. 1. Typical DC polarographic pattern of inorganic anions as a function of reduction potentials, $E_{1/2}$.
A: $E_{1/2}>0$, B: $0>E_{1/2}>$ecm potential, C: $E_{1/2}<$ecm potential, Supporting electrolyte: 0.1—1 M alkali halide (KCl), Without surface-active substances.

Dependence on Chemical Systems. As shown in Fig. 1, the chemical systems are classified into two types

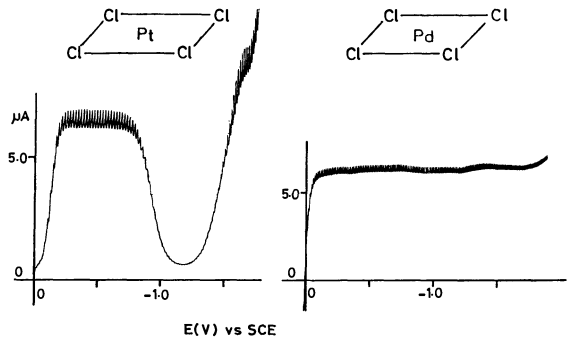

Fig. 2. Typical examples of DC polarograms which belong to Group A and B in Fig. 1.
Right: 1 mM $PdCl_4^{2-}$, 1.0 M KCl, 0.01% gelatin (Group A).
Left: 1 mM $PtCl_4^{2-}$, 1.0 M KCl, 0.01% gelatin (Group B).

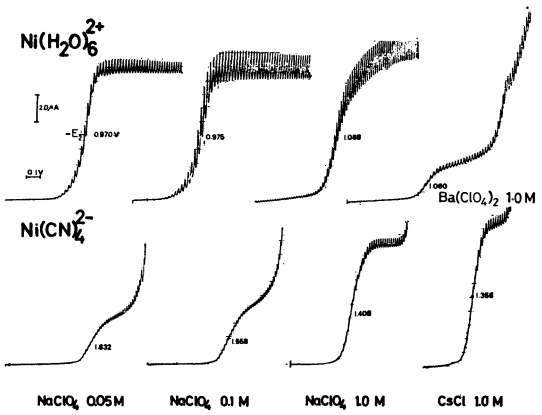

Fig. 3. Typical examples of DC polarograms which belong to Group C in Fig. 1.
Systems: 1 mM $Ni(CN)_4^{2-}$ with different kinds of supporting electrolytes, where polarograms of $Ni(H_2O)_6^{2+}$ with the same kinds of supporting electrolytes are also cited for comparison.

according to whether they do (B) or do not show (A) the decrease in the limiting diffusion current (the minimum) beyond the ecm. This classification is non-specific for the type of chemical species such as metal complexes, metal oxides, and oxo acids of halogens, but is only attributed to the difference of the relative position of the half-wave potentials between the two groups.

Effect of Supporting Electrolyte. For the systems of Group A, the decrease in the limiting diffusion current beyond the ecm (the minimum) can be observed in the absence of supporting electrolyte, but it is completely eliminated by suitable amount of supporting electrolyte. The minimum of Group B does not disappear on addition of supporting electrolyte; it merely decreases and becomes narrower in the order of $Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$ and $CN^- > I^- > Cl^- > ClO_4^-$, for the cation and the anion of the supporting electrolyte, respectively. In the case of Group C, the rising portion of the DC polarogram is distorted, which is recovered by added salts in the similar way as the minimum of Group B (Fig. 3).

Effect of Surface-active Substances. The effect of surface-active substances on the shapes of the current-potential curves are also examined systematically. For Group A upon adding suitable amount of gelatin, the decrease in the limiting diffusion current beyond the ecm can be observed even in the presence of supporting electrolyte. This is shown in Fig. 4 taking $Pd(NO_2)_4^{2-}$ ion as an example. Similarly, the minimum of Group B and the distortion of the polarogram of Group C are much pronounced by the addition of gelatin. These situations are represented schematically in Fig. 5.

Discussion

Electrostatic Effect. It has been well-accepted[3,4] that the electrostatic repulsion of anion depolarizers from negatively charged electrode is the dominant origin of the minimum phenomena. However, quite different behavior between Groups A and B in Fig. 1 cannot be elucidated solely by the simple electrostatic model.[4] The distortion of the DC polarogram of Group C (see Figs. 1 and 3) is generally referred to as the irreversible wave.[3] Results of Fig. 1 imply that the irreversible wave of Group C is similar in origin to that of the minimum of Group B.

At a negative potential E_n beyond the ecm, all the anions are more or less subject to electrostatic repulsion from the negatively charged electrode surface, which

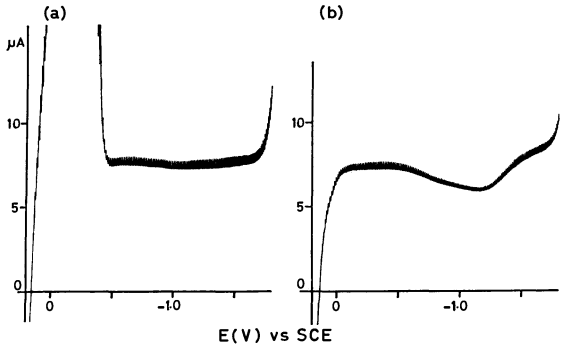

Fig. 4. Effect of surface-active substances on the i—E curve of Group A in Fig. 1.
System: 1 mM $Pd(NO_2)_4^{2-}$ in 0.1 M KNO_2
(a) without gelatin (b) 0.01% gelatin added

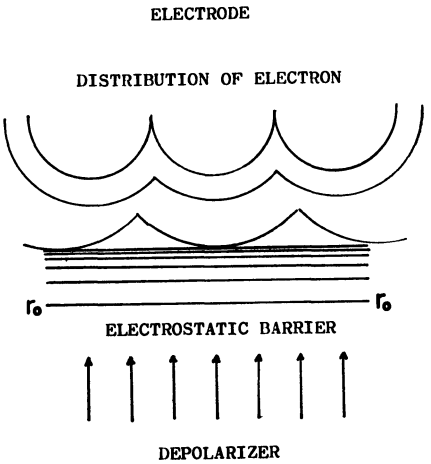

Fig. 6. Distribution of electron cloud of the metal electrode at the interface (See Text)

is non-specific for Group A, B, or C. Because the electron in the metal electrode is represented by a wave function, it will not vanish at the surface of the metal, but will die away exponentially into the remote from the electrode.[1] In Fig. 6 is drawn the distribution of the electron density of the metal electrode at the interface, where r_0 denotes the mean distance of the nearest approach of an anion against the coulombic field at the potential E_n. In the presence of the electrostatic repulsion, the anion cannot go within r_0 resulting in the small probability of electron transfer at r_0 in comparison with that at the surface of the metal. This is probably the important origin of the minimum for the systems of Groups A and B, and the distortion at the rising portion of the polarogram for the systems of Group C.

Electronic Level of the Electrode. The highest occupied electronic energy level of the metal electrode can be represented as:[1,5]

$$\phi = E_F + V \quad (1)$$

where E_F is the Fermi level of the metal electrode in contact with the electrolyte solution at open circuit, V the applied potential *vs.* the SCE. Because the current density at the dropping mercury cathode is small in polarography, the potential of the anode is made constant by the SCE. Equation (1) indicates that the effect of an electrode potential of 1 V is to raise the highest occupied level at the cathode, ϕ, by 1 eV. This situation is shown in Fig. 7. It is also seen in Fig. 7 that the number of electrons (electron density)

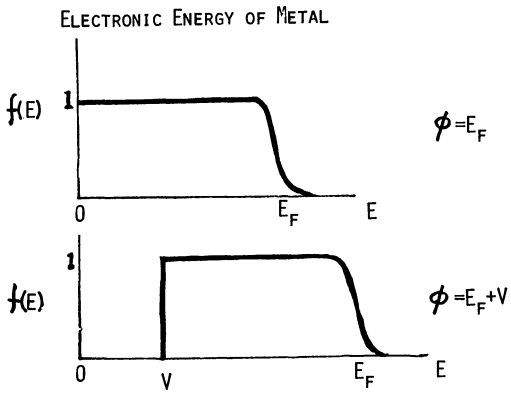

Fig. 7. Electronic energy level of the metal cathode as a function of applied potential, V.
ϕ: Highest occupied level of the metal cathode in contact with the electrolyte solution
E_F: Fermi level of the electrode in contact with the electrolyte solution
$f(E)$: Fermi distribution function

in the metal cathode whose energy is higher than any given value is increased with increasing applied negative potentials. Among a great number of electrons in the metal cathode, only the electrons that have any energy higher than the half-wave potential of depolarizers can participate in the electrochemical reduction process. As shown in Fig. 1, the half-wave potential of the system of Group B, $(E_{1/2})_b$, is always more negative than that of Group A, $(E_{1/2})_a$,

$$(E_{1/2})_a > (E_{1/2})_b > E_n \quad (2)$$

where E_n is a negative potential beyond the ecm, where the minima appear. From the above considerations, it may be concluded that in the metal cathode at the potential E_n, numbers of electrons which can participate in the electrochemical reduction for Group A is greater than that for Group B. Therefore, it appears that the different behavior of the minimum between Groups A and B is due to the difference in the numbers of electrons as mentioned above, resulting from the difference in the half-wave potential between two Groups.

In the case of the minimum of Group B, the increase of the current at rather negative potentials can be observed (Figs. 1 and 2). Furthermore, in the case of Group C, the distortion of the polarogram at the rising portion is recovered with increasing applied negative potentials until the limiting diffusion current is attained (Figs. 1 and 3). These two phenomena can also be explained in terms of the increase with increasing applied negative potentials in the numbers of electrons which can participate in the electrochemical reduction.

The effect of gelatin in Figs. 4 and 5 can be explained as being due to the enhancement by gelatin of repulsion of anions from the electrode surface (see Fig. 6).

Phenomenological Equation. According to the phenomenological equation of the irreversible electrode reaction, the current much smaller than the limiting diffusion current can be written as:[3]

$$i = nFqk_e^0[Me^{n+}]_s \exp\left\{-\frac{\alpha nF(E-E^0)-W}{RT}\right\} \quad (3)$$

$$[Me^{n+}]_s = [Me^{n+}] \exp(-zFW/RT) \quad (4)$$

where n, F, q, and R are as usual, k_e^0 the heterogeneous rate constant at the standard potential E^0, α the transfer coefficient, W the mean electrostatic potential at the distance of an ionic radius from the surface of the electrode, $[Me^{n+}]_s$ the surface concentration of depolarizers. In the above equations, it is assumed that the electrode process involves only ions in direct contact with the electrode and that electron transfer to more distant ion is hardly likely.[3] The increment of applied negative potentials beyond the ecm influences upon the observed current intensity through different two terms in Eq. (3), *i.e.*, i) $[Me^{n+}]_s$ and ii) the exponential term. Of these two, $[Me^{n+}]_s$ decreases in a similar way both in Groups A and B, which is due to the electrostatic repulsion of anions from the negatively charged electrode surface. As shown in Fig. 1 the half-wave potential of Groups A is always more positive than that of Group B. Therefore, it appears that in the case of Group A appreciable increase beyond the ecm potential in the exponential term of Eq. (3) prevents the appearance of the minima. This conclusion is to be compared with the discussion given in the previous section (*Electronic Level of the Electrode*).

Stereochemical Studies of *N*-Methyl-(*S*)-alaninatocobalt(III) Complexes with Chiral Tetramines. II.[1] Cobalt(III)-*N*-Methyl-(*S*)- and (*R*)-alaninate-*N*,*N*′-Bis(β-aminoethyl)-1(*R*), 2(*R*)-diaminocyclohexane Systems

Masahiko SABURI and Sadao YOSHIKAWA

(Received January 9, 1974)

The preparation and structural assignments of *N*-methyl-(*S*)- and -(*R*)-alaninatocobalt(III) complexes with *N*,*N*′-bis(β-aminoethyl)-1(*R*),2(*R*)-diaminocyclohexane (abbreviated as (*R*)-baetchxn) are described. The *Λ*-β_2-(*SSR*) isomer has been obtained for Co(*N*-Me-(*S*)-ala)((*R*)-baetchxn)$^{2+}$ ion. The two isomers, which have been found for the Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion under equilibrium condition at pH 7, are assigned as the *Λ*-β_2(*SSR*) and *Λ*-β_2(*SSS*) configurations, taking into account the stereospecific coordination of the (*R*)-baetchxn. The stereoisomerism of *Δ*-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion is also discussed. The structures of two species observed in the PMR measurements of Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion and assigned to *Λ*-β_2(*SSR*) and *Λ*-β_2-(*SSS*) configurations, respectively, are determined, based on the chemical shifts of α-methine protons of *N*-methyl-alaninate moieties.

The presence of three diastereoisomers has been proved for the β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion (*N*-Me-(*S*)-ala=*N*-methyl-(*S*)-alaninate ion). These isomers were assigned to the *Λ*-β_2(*SSR*) *Δ*-β_2(*RRS*), and *Δ*-β_2-(*RSS*) configurations by Buckingham and coworkers.[2,3] In a previous report, we examined the adequacy of these assignments by the use of 5(*S*)-methyl-1,4,7,10-tetraazadecane (abbreviated as 5(*S*)-metrien) in place of trien. The 5(*S*)-metrien, one of chiral trien derivatives, coordinates stereospecifically with the *Δ-cis-β*(*RR*) configuration.

The two diastereoisomers of the *Δ*-β_2-Co(*N*-Me-(*S*)-ala)(5(*S*)-metrien)$^{2+}$ ion detected by the proton magnetic resonance (PMR) measurements were assigned to the *Δ*-β_2(*RRS*) and *Δ*-β_2(*RRR*) configurations. Further, the remarkable similarities observed between the PMR and circular dichroism (CD) behaviors of the *Δ*-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ and *Δ*-β_2-Co(*N*-Me(*S*)-ala)(5-(*S*)-metrien)$^{2+}$ isomers in equilibria in neutral aqueous solution (pH 6.5—7.0) led to the conclusion that one of the *Δ*-β_2 isomers of the trien complex has the (*RRR*) configuration, instead of the (*RSS*) configuration.[1] This conclusion interpreted consistently the difference of stabilities between the *Δ*-β_2(*RRS*) and *Δ*-β_2-(*RSS*) configurations of Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion expected from a strain energy minimization study (the former is 3.2 kcal/mol in favor of the latter).[2]

However, it is difficult to neglect completely the possibility of the inversion at the "planar" secondary N atom for the 5(*S*)-metrien complexes. *N*,*N*′-Bis(β-aminoethyl)-1(*R*),2(*R*)-diaminocyclohexane (abbreviated as (*R*)-baetchxn) is one of chiral trien derivatives, which has been demonstrated to adopt stereospecifically the *Λ-cis-β*(*SS*) configuration upon coordination. Further, it is significant that for the coordinated (*R*)-baetchxn there is no possibility of conformational inversion with respect to the central diamine linkage, since the 1(*R*),2(*R*)-diaminocyclohexane moiety takes solely the λ conformation due to its cyclic structure. The conformational inversion at the central diamine linkage is necessary for the isomerization from the *Λ-β*(*SS*) to *Λ-β*(*SR*) configuration. In order to confirm the conclusions on the *Δ*-β_2-Co(*N*-Me-(*S*)-ala)(5(*S*)-metrien)$^{2+}$ complexes, *N*-Me-(*S*)- and *N*-Me-(*R*)-ala (*N*-Me-(*R*)-ala=*N*-methyl-(*R*)-alaninate ion) complexes with (*R*)-baetchxn have been examined, the results of which will be reported in this paper.

Experimental

N-Methyl-(*S*)-alanine and *N*-Methyl-(*R*)-alanine were prepared by the method of Quitt, Hellerbach, and Vogler,[5] using (*S*)- and (*R*)-alanine, respectively, as the starting amino acids. Commercially available 1,2-diaminocyclohexane (Tokyo Kasei Kogyo) was resolved with *d*-tartaric acid, according to the method of Asperger and Liu.[6] *N*,*N*′-Bis(β-aminoethyl)-1(*R*),2(*R*)-diaminocyclohexane was prepared as follows.

N,N′-*Bis(chloroacetyl)-1*(R),*2*(R)-*diaminocyclohexane.* 1(*R*),2(*R*)-diaminocyclohexane dihydrochloride (14.0) was dissolved in 150 ml of water, containing 18 g of sodium hydroxide. Tothis solution cooled in an ice bath to 10°C was added a solution of chloroacetyl chloride (22.6 g) in benzene (80 ml) drop by drop with vigorous stirring by means of a blender. After the addition had been completed, the stirring was continued for 10 more min. The resultant white solid mass was filtered off, and washed with water. Yield, 28 g. The crude product was recrystallized from methanol by adding ether. Found: C, 44.71; H, 5.98; N, 11.11%. Calcd for $C_{10}H_{16}N_2O_2Cl_2$: C, 44.29; H, 5.95; N, 10.33%.

N,N′-*Bis(glycyl)-1*(R),*2*(R)-*diaminocyclohexane Dihydrochloride.* *N*,*N*′-Bis(chloroacetyl)-1(*R*),2(*R*)-diaminocyclohexane (14.0 g) dissolved in 200 ml of hot methanol was mixed with 300 ml of aqueous ammonia (28%) and ammonium carbonate (50 g). The mixture was left to stand at room temperature for 7 days, and the resultant solution was evaporated to dryness on a rotary evaporator under reduced pressure. The white precipitates, which remained, were collected, washed with ethanol and ether, and dried under vaccuum. Yield, 12.0 g. The crude product was recrystallized from methanol–ethanol mixture (1:2). Found: C, 39.83; H, 7.24; N, 18.73%. Calcd for $C_{10}H_{22}N_4O_2Cl_2$: C, 39.35; H, 7.27; N, 18.36%.

N,N′-*Bis(β-aminoethyl)-1*(R),*2*(R)-*diaminocyclohexane Tetrahydrochloride.* To a suspension of lithium aluminium

hydride (10.8 g) in anhydrous tetrahydrofuran (250 ml) was added *N,N'*-bis(glycyl)-1(*R*),2(*R*)-diaminocyclohexane dihydrochloride (14.0 g) in small portions. The mixture was then stirred and heated under reflux for 24 hr, and cooled to room temperature. The subsequent treatments were the same as those described in a previous paper.[4]

Δ-cis-*β*-*Dichloro(*N,N'-*bis(β-aminoethyl)-1*(R),*2*(R)-*diaminocyclohexane)cobalt(III) Chloride Hemihydrate* (*Δ*-cis-*β*-[$CoCl_2$(R)-*baetchxn*)]$Cl \cdot 0.5H_2O$) was also prepared according to the method reported previously.[4]

Δ-β_2(SSR)-[*Co*(N-*Me*-(S)-*ala*)(R)-*baetchxn*)]$(ClO_4)_2$. *Δ*-*cis*-*β*-[$CoCl_2$((*R*)-baetchxn)]$Cl \cdot 0.5H_2O$ (1.15 g) was dissolved in 5 ml of water, followed by 0.126 g of $LiOH \cdot H_2O$. To the solution were added 0.31 g of *N*-methyl-(*S*)-alanine and 0.5 g of active charcoal, successively. The solution was then warmed to 70 °C on a water bath for 30 min. The active charcoal was filtered off and washed with a small volume of water. The filtrate and washings were combined and concentrated to a volume of 2 ml on a water bath below 70 °C. Then, 1.5 g of solid $LiClO_4$ were added, and cooled in an ice bath for 2 hr. The orange-red crystals, which separated, were collected, washed with cold water and ethanol, and air-dried. Yield, 1.30 g. The product was recrystallized from hot water. Found: C, 27.83; H, 5.80; N, 12.77%. Calcd for $[Co(C_{10}H_{24}N_4)(C_4H_8NO_2)](ClO_4)_2$: C, 27.42; H, 5.98; N, 12.97%.

Δ-β_2-[*Co*(N-*Me*-(R)-*ala*)((R)-*baetchxn*)]I_2, *A Mixture of Δ*-β_2(SSR) *and Δ*-β_2(SSS) *Isomeres.* *Δ*-*cis*-*β*-[$CoCl_2$((*R*)-baetchxn)]$Cl \cdot 0.5H_2O$ (0.57 g) was dissolved in 5 ml of water, followed by 0.063 g of $LiOH \cdot H_2O$. The solution was warmed to 70 °C on a water bath, and 0.155 g of *N*-methyl-(*R*)-alanine and 0.2 g of active charcoal were added, successively. The resultant solution was warmed to 70°C for 15 min. The active charcoal was then filtered off, and washed with a small volume of water. The filtrate and washings were combined and concentrated to a volume of 3 ml on a water bath below 60 °C. To the solution were added 0.7 g of NaI dissolved in a minimum volume of water, and cooled in an ice bath overnight. The red crystals, which separated, were collected, washed with dilute NaI solution and ethanol, and air-dried. Yield, 0.52 g. Found: C, 27.85; H, 5.38; N, 10.83%. Calcd for $[Co(C_{10}H_{24}N_4)(C_4H_8NO_2)]I_2$: C, 27.33; H, 5.24; N, 11.39%.

Δ-β_2(SSR)-[*Co*(N-*Me*-(R)-*ala*)((R)-*baetchxn*)]$(ZnCl_4)$. The filtrate obtained after the removal of active charcoal as described above was concentrated to a volume of 7 ml on a water bath below 60 °C. The solution was, then, diluted with 20 ml of ethanol, and 1.5 g of NaI dissolved in a minimum volume of water was added. The solution was cooled in an ice bath overnight, and the orange-rad crystals, which appeared, were filtered off, washed with ethanol, and air-dried. Yield, 1.27 g. This compound, which contains the ethanol of crystallization, was added in 10 ml of 0.1 M HCl, containing an excess amounts of freshly prepared AgCl. All the contents were mixed thoroughly until the complexes dissolved completely. Silver salts were filtered off, and washed well with water. The filtrate and washings were combined, and zinc chloride (1.4 g) was added, followed by 1 ml of concentrated HCl. The resultant solution was cooled in a refrigerator overnight, and the orange crystals, which appeared, were collected, washed with cold water and ethanol, and air-dried. Yield, 0.65 g. A further crop of crystals was obtained from the filtrate after the concentration. Found: C, 28.72; H, 5.58; N, 12.05%. Calcd for $[Co(C_4H_8NO_2)(C_{10}H_{24}N_4)](ZnCl_4)$: C, 29.57; H, 5.67: N, 12.32%.

Measurements. Visible absorption spectra were measured with a Shimadzu MPS-50L recording spectrophotometer. Circular dichroism curves were obtained with a JASCO J-20 automatic recording spectropolarimeter. 100-MHz proton magnetic resonance spectra were obtained using a JEOL PS-100 spectrometer using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an internal standard reference. For the PMR measurements, perchlorate salt (about 50 mg sample) suspended in the solvent (0.01 M DCl or D_2O, 0.5—0.7 ml) was treated with twice the molar amounts of tetraphenylarsonium chloride. The white precipitates were removed by filtration, and the filtrate was employed for PMR measurement. Iodide salts (about 60 mg samples) suspended in the solvent (0.5—0.7 ml) were treated with twice the molar amounts of silver nitrate. The precipitated AgI were removed by filtration, and the PMR spectra of the filtrates were recorded.

60 MHz PMR spectra were obtained with a Hitachi R-20B spectrometer.

Results and Discussion

The 100 MHz PMR spectra of the Co(*N*-Me-(*S*)-ala)((*R*)-baetchxn)$^{2+}$ ion, obtained in 0.01N DCl and D_2O solutions, are shown in Fig. 1(a) and (b), respectively. In 0.01 M DCl, the deuterium exchange of *N*-bonded protons is retarded sufficiently so that the *N*-methyl proton signal is observed as the doublet at 2.58 ppm (standard, DSS). In D_2O solution, the *N*-bonded protons have exchanged with solvent D_2O, and the *N*-methyl signal has collapsed to a singlet. In both spectra ((a) and (b)), the C-methyl signals were observed as the single doublet at 1.50 ppm. It is apparent from these observations that the Co(*N*-Me-(*S*)-ala)((*R*)-baetchxn)$^{2+}$ ion is composed of the single species. Further, the PMR spectrum obtained in 0.01N DCl (Fig. 1(a)) corresponds well to that of the *Δ*-β_2(*SSR*)-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion reported earlier,[2] except that complicated broad peaks are found in 1.0—2.0 and 2.0—2.5 ppm regions for the (*R*)-baetchxn complex. These broad peaks should be ascribed to the signals for protons of the cyclohexane ring of (*R*)-baetchxn.

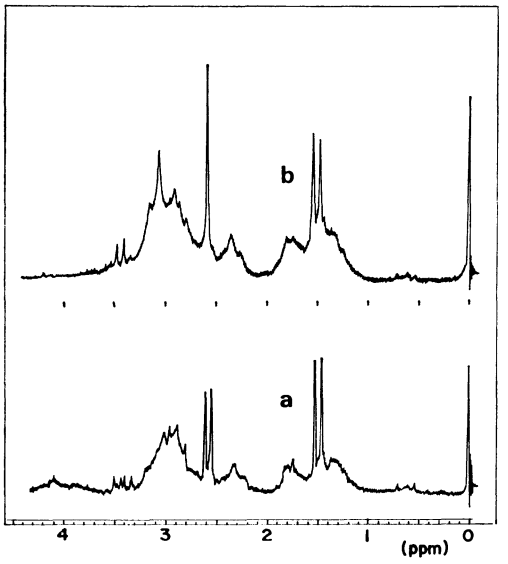

Fig. 1. 100 MHz PMR spectra of *Δ*-β_2-(*SSR*)-[Co(*N*-Me-(*S*)-ala)((*R*)-baetchxn)]$^{2+}$ ion; (a) in 0.01 M DCl, and (b) in D_2O.

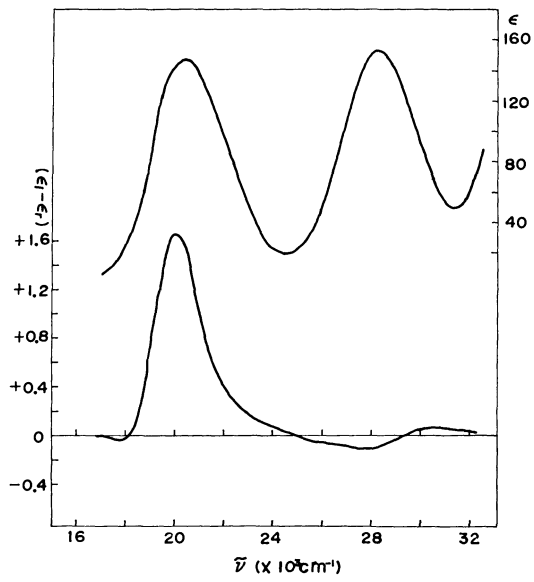

Fig. 2. Visible absorption and CD spectra of Λ-β_2-(*SSR*)-[Co(*N*-Me-(*S*)-ala) ((*R*)-baetchxn)]$^{2+}$ ion.

The Co(*N*-Me-(*S*)-ala)((R)-baetchxn)$^{2+}$ ion shows the visible absorption and CD spectra shown in Fig. 2. These curves resembles closely to the corresponding curves of the Λ-β_2(*SSR*) isomers of Co(*N*-Me-(*S*)-ala)-(trien)$^{2+}$ and Co(*N*-Me-(*S*)-ala)(5(*R*)-metrien)$^{2+}$ ions. Therefore, the present (*R*)-baetchxn complex can be assigned to the Λ-β_2(*SSR*)(*S*)[3] configuration.

It was found previously that the Δ-β_2-Co(*N*-Me-(*S*)-ala)(5(*S*)-metrien)$^{2+}$ complex arised in the single species as the iodide, whereas the same complex ion gave rise to a mixture of two isomeric forms as the perchlorate.[1] Similarly, the Δ-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion could be isolated in the pure state as the iodide form.[2] On these bases, we tried to obtain the Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion, which should appear in the Λ-β_2 configuration and in the enantiomeric relation to the above Λ-β_2 isomers with *N*-Me-(*S*)-ala group, as the iodide form.

However, [Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)]I_2 isolated from an aqueous solution, was found to be an isomeric mixture of two species, though the complex ions had the Λ absolute configuration as expected. The PMR spectra of this complex obtained in 0.01 M DCl and D_2O solutions are shown in Fig. 3(a) and (b), respectively. The spectrum in 0.01 M DCl shows two *N*-methyl doublets at 2.40 and 2.57 ppm, indicating the presence of two isomers in the crystalline state. The *C*-methyl signals, which appeared as three peaks in the vicinity of 1.5 ppm, can be regarded as an overlap of two doublets.

It was found unexpectedly that one of the isomers of Λ-β_2-Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion crystallized out from an aqueous ethanol in the single isomeric form. The PMR spectrum of this orange-red needle-like crystals measured in 0.01 M DCl is shown in Fig. 3(c). This spectrum exhibits only one doublet for the *N*-methyl signal (2.40 ppm). The *C*-methyl signal is also observed as the single double (1.43 ppm). These findings indicate that the present complex is largely composed of the single species. Furthermore, the presence of ethanol in the crystal is obviously demonstrated by the triplet and quartet centered at 1.14 and 3.60 ppm, respectively. However, the elemental analysis data for this complex could not provide any sufficient results. Hence, we turned this compound to the tetrachlorozincate salt, which gave the consistent analysis data.

The PMR spectrum of the above complex obtained in 0.01 M DCl (Fig. 3(d)) was found to be identical with that shown in Fig. 3(c), except for the signals of ethanol appeared additionally in the latter case. The spectrum of this complex obtained in D_2O was also identical with that of Fig. 3(b). The PMR spectral changes caused by the variation of the pH of solvent

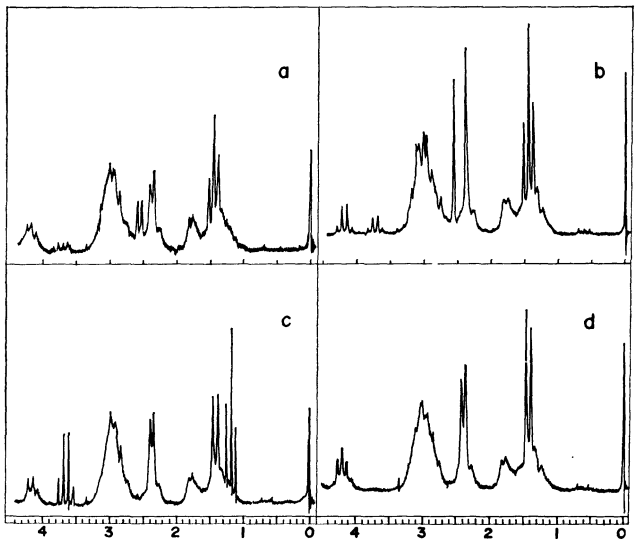

Fig. 3. 100 MHz PMR spectra of Λ-β_2-[Co(*N*-Me-(*R*)-ala) ((*R*) baetchxn)]$^{2+}$ ion; (a) Λ-β_2-(*SSR*)+Λ-β_2-(*SSS*) in 0.01 M DCl, (b) Λ-β_2-(*SSR*)+Λ-β_2-(*SSS*) in D_2O (pD=6.8), (c) Λ-β_2-(*SSR*) containing ethanol in 0.01M DCl, (d) Λ-β_2-(*SSR*), ($ZnCl_4$) salt in 0.01 M DCl.

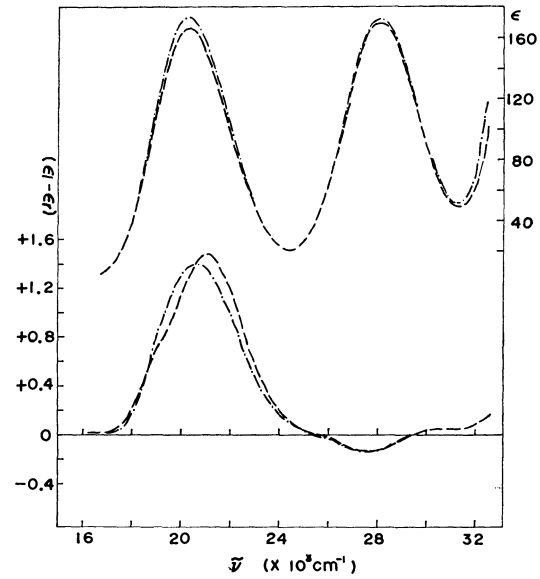

Fig. 4. Visible absorption and CD spectra of Λ-β_2-[Co-(*N*-Me-(*R*)-ala)-((*R*)-baetchxn)] ($ZnCl_4$) in 0.1 M $HClO_4$ (----), and in H_2O (pH 7) (-·-·).

are analogous to those observed for the Δ-β_2-[Co(*N*-Me-(*S*)-ala)(trien)]I_2[2] and for the Δ-β_2-[Co(*N*-Me-(*S*)-ala)(5(*S*)-metrien)]I_2. Corresponding to these PMR changes, the visible absorption and CD spectral changes were noticed for the trien and 5(*S*)-metrien complexes in acidic and neutral aqueous solutions. The CD and visible absorption curves of Λ-β_2-[Co(*N*-Me-(*R*)-ala)-((*R*)-baetchxn)]($ZnCl_4$) also changed in a similar way through the variation of the solvents, as shown in Fig. 4.

Buckingham and coworkers have supposed that the isomerization of the isolated Δ-β_2-Co(*N*-Me-(*S*)-ala)-(trien)$^{2+}$ ion at pH 6.5—7.0 may be caused by the inversion at an asymmetric secondary N center, and that two possibilities exist for scuh isomerization; inversion at the *N*-methyl group or at the "planar" secondary N center of β-trien skeleton. The latter possibility has been adopted by Buckingham *et al.*, and the equilibrium between the Δ-β_2-(*RRS*)(*S*) and Δ-β_2-(*RSS*)(*S*) configurations has been postulated.[2]

In the case of (*R*)-baetchxn complex with Λ-β configuration, the possibility of the conformational inversion of the central chelate ring can be thoroughly excluded, since the conformation of the 1(*R*),2(*R*)-diaminocyclohexane chelate ring is solely restricted in the *λ-gauche* form. Hence, the possibility of the inversion at the "planar" secondary N center which must accompany the conformational inversion of the central chelate ring can also be ruled out for the (*R*)-baetchxn complex. Therefore, the two isomers observed for the Λ-β_2-Co(*N*-Me(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion should be arisen from a source of asymmetry other than the "planar" secondary N center of trien moiety. The inversion at the *N*-methyl group can be regarded as the relevant origin of the isomerization mentioned above. Consequently, the two species detected in the PMR spectrum (Fig. 3(b)) should be assigned to the Λ-β_2(*SSR*)(*R*) and Λ-β_2(*SSS*)(*R*) configurations.

The complex ions, Λ-β_2-Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ and Δ-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$, are in the enantiomeric relation with regard to every chiral center: the absolute configuration around the Co(III) ion, those of the secondary N centers of trien skeleton and of *N*-methyl groups, and those of the asymmetric α-C atom of *N*-methylalanine moiety. Therefore, the stereoisomerism noticed for the restricted Λ-β(*SS*) framework of (*R*)-baetchxn complexes must be applicable to the Δ-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion, even though the possibility of the inversion at the "planar" secondary N center would be retained for the trien complex.

The PMR spectrum of Λ-β_2-Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion (Fig. 3(b)) indicates that the relative intensities of *N*-methyl signals of the Λ-β_2(*SSR*)(*R*) fand Λ-β_2(*SSS*)(*R*) isomers are approximately equal. This means that these isomers have the comparable stabilities with each other. The Δ-β_2(*RRS*) and Δ-β_2(*RRR*) isomers of Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion must also have the nearly equal stabilities, even if the other isomer, Δ-β_2(*RSS*) form, would be sufficiently stable in comparison with the Δ-β_2(*RRS*) form, as expected by Buckingham *et al.*[2] In practice, however, only two species have been detected in the PMR spectrum of the Δ-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion equilibrated at pH 7.[2] Further, the PMR spectral features of these isomers are entirely analogous to those of the Λ-β_2-Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion, especially in the regions of the *N*-methyl and *C*-methyl signals. Accordingly, the two detectable species of Δ-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion should be assigned as the (*RRS*) and (*RRR*) isomers, instead of the (*RSS*) isomer. This conclusion is in accordance with that obtained in a previous paper, using the 5(*S*)-metrien.[1]

It has been considered to be difficult to make individual structural assignments for the two isomers of Δ-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ ion.[2] We have tentatively assigned these isomers to the Δ-β_2(*RRS*) and Δ-β_2-(*RRR*) configurations, respectively, on the ground of the chemical shifts of *N*-methyl groups of the two isomers. To make sure these assignments, we have examined the PMR spectra of Λ-β_2-Co(*N*-Me-(*R*)-ala)-((*R*)-baetchxn)$^{2+}$ isomers, and obtained interesting findings.

In the spectrum of Fig. 3(b), two small quartets are observed at 3.73 and 4.19 ppm. These signals can be assigned to the methine protons of *N*-Me-(*R*)-ala moieties of the Λ-β_2(*SSR*) and Λ-β_2(*SSS*) isomers, respectively. For the corresponding *N*-Me-(*S*)-ala complex ion, the methine quartet is detected at 3.44 ppm in the spectrum of Fig. 1(b), though the same signal can not be recognized in Fig. 1(a) due probably to the overlap of N–H resonance. Similarly, it is rather difficult to find definitely the methine quartet in the spectrum of Fig. 3(a) because of the appearance of broad N–H peaks in the region of 4.0—4.5 ppm.

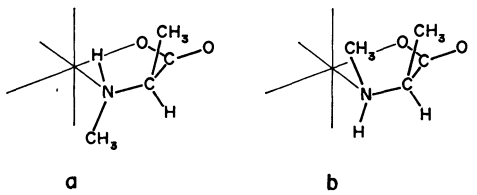

Fig. 5. Structures of coordinated *N*-Me-(*R*)-ala moiety; (a) *trans* and (b) *cis*.

The relative orientations of the *N*-methyl and C-methyl groups should be the most significant structural factor which affects the chemical shift of the methine proton of *N*-methylalaninate group. As illustrated for the *N*-Me-(*R*)-ala chelate rings in Fig. 5, the two adjacent methyl groups are *trans* (Fig. 5(a)) or *cis* (Fig. 5(b)) to each other. In the *trans* form, the *N*-methyl is *cis* with respect to the methine proton, and, therefore, the methine should be strongly affected by the magnetic anisotropy of the C–N bond of the *N*-methyl group. It is anticipated that the C–N bond anisotropy will appear in a similar manner as that for the C–C single bond, and that the methine proton in the *trans* form (Fig. 5(a)) will show the high-field shift compared to the methine in the *cis* form (Fig. 5(b)), because the C–N bond anisotropy should no longer have any significant effects to the methine proton in the latter case.

The *N*- and *C*-methyl groups are in the *trans* con-

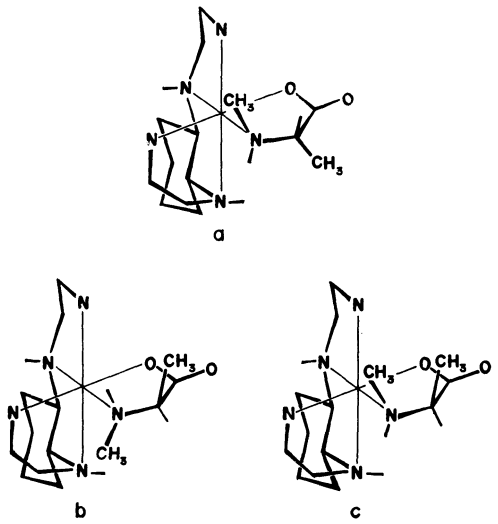

Fig. 6. Structures of (*R*)-baetchxn complexes: (a) *Λ*-β_2-(*SSR*)(*S*), (b) *Λ*-β_2-(*SSS*)(*R*), and (c) *Λ*-β_2-(*SSR*)(*R*).

figuration for the *Λ*-β_2(*SSR*)(*S*) and *Λ*-β_2(*SSS*)(*R*) isomers, while these are *cis* in the *Λ*-β_2(*SSR*)(*R*) isomer of the (*R*)-baetchxn complexs, as shown in Fig. 6(a)—(c). The methine resonance of *Λ*-β_2(*SSR*)(*S*) isomer, with the *trans* configuration, is found at 3.44 ppm as described previously. Taking account of the C–N bond anisotropy, the quartets observed at 3.73 and 4.19 ppm in Fig. 3(b) should be assigned to the *trans* and the *cis* configuration, or to the *Λ*-β_2(*SSS*)(*R*) and the *Λ*-β_2-(*SSR*)(*R*) configuration, respectively.

It was found that the *Λ*-Co((*S*)-ala)$(en)_2^{2+}$ and -Co-((*R*)-ala)$(en)_2^{2+}$ ions ((*S*)-ala and (*R*)-ala=(*S*)- and (*R*)-alaninate) show their methine quartets at about 3.98 and 4.15 ppm, respectively.[7,8] Both these complexes are free from the C–N bond anisotropy under consideration. It is interesting to note that the chemical shifts of methine protons of the (*R*)-ala complex coincide well with that of the *Λ*-β_2(*SSR*)-Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion (4.19 ppm), in which there are no influences of the C–N anisotropy. The difference of the chemical shifts (0.17 ppm) between the above (*S*)- and (*R*)-alanine complexes should be ascribed to the difference of the absolute configuration of the α-C atom of alaniate group. The methine signal of the *Λ*-β_2-(*SSS*)(*R*) isomer, having the *trans* configuration with respect to the *N*- and C-methyl groups, appeared in the higher field relative to that of the *Λ*-β_2(*SSR*)(*R*) isomer with the *cis* configuration, but in the lower field than that of the *Λ*-β_2(*SSR*)(*S*) isomer with the *trans* configuration. The difference in the chemical shifts of the methine signals between the (*SSR*)(*S*) and (*SSS*)(*R*) isomers (0.29 ppm), both of which take the *trans* configuration with regard to the *C*- and *N*-methyl groups, seem to be analogous to that found in the above alanine complexes.[7,8]

The determination of the *C*-methyl groups of *Λ*-β_2-(*SSR*) and *Λ*-β_2(*SSS*) isomers of Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion has been achieved by the spin-decoupling method. Since a 60 MHz spectrometer has been employed for these measurements, the two *C*-methyl signals have appeared separately as two doublets

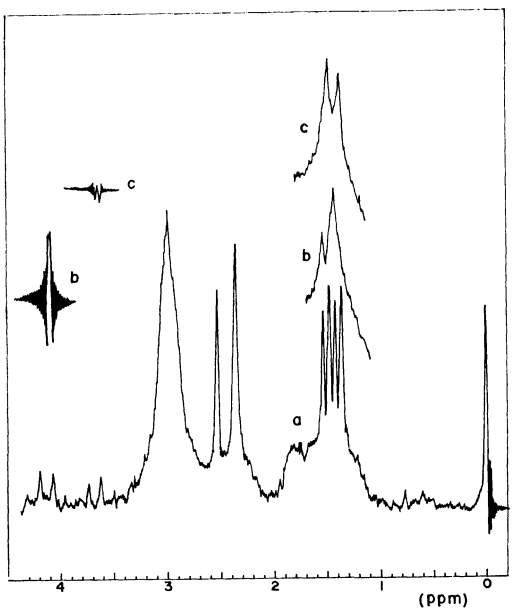

Fig. 7. 60 MHz PMR spectra of mixture of *Λ*-β_2-(*SSR*)- and *Λ*-β_2-(*SSS*)-[Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)]$^{2+}$ ion; (a) in D_2O, (b) the spectrum irradiated at 4.19 ppm, (c) the spectrum irradiated at 3.73 ppm.

as shown in Fig. 7. The irradiation of the quartet at 4.19 ppm has caused the collapse of the doublet in the higher field (1.43 ppm) to the singlet, and the irradiation of the quartet at 3.73 ppm has produced the collapse of the doublet at 1.51 ppm to the singlet, as indicated in Fig. 7. From these results, the isolated isomer of the *Λ*-β_2-Co(*N*-Me-(*R*)-ala)((*R*)-baetchxn)$^{2+}$ ion which shows the *C*-methyl doublet at 1.43 ppm (Fig. 3(d)) can be decided as the (*SSR*)(*R*) configuration. The PMR spectral data of the (*R*)-baetchxn and related complexes are summarized in Table 1.

Table 1. Assignments of proton resonance shifts[a] of *N*-methylalanine moieties

	C–CH_3	N–CH_3	C–H
Λ-β_2(*SSR*)-Co(*N*-Me-(*S*)-ala)-((*R*)-baetchxn)$^{2+}$	1.50	2.58	3.44
Λ-β_2(*SSR*)-Co(*N*-Me-(*R*)-ala)-((*R*)-baetchxn)$^{2+}$	1.43	2.40	4.19
Λ-β_2(*SSS*)-Co(*N*-Me-(*R*)-ala)-((*R*)-baetchxn)$^{2+}$	1.51	2.57	3.73
Λ-β_2(*SSR*)-Co(*N*-Me-(*S*)-ala)-(5(*R*)-metrien)$^{2+}$	1.53	2.61	3.52[b]
Λ-β_2(*RRS*)-Co(*N*-Me-(*S*)-ala)-(5-(*S*)-metrien)$^{2+}$	1.42	2.38	4.06
Λ-β_2(*RRR*)-Co(*N*-Me-(*S*)-ala)-(5(*S*)-metrien)$^{2+}$	1.50	2.58	3.80[b]
Co(*N*-Me-(*S*)-laa)$(NH_3)_4^{2+}$	1.48	2.48	3.54
Λ-Co(*N*-Me-(*S*)-ala)$(en)_2^{2+}$	1.49	2.53	3.55

a) ppm from DSS. b) Determined by the spin decoupling method, using a 60 MHz spectrometer.

No attention has been turned to the methine signals of the *N*-methylalanine group in former studies.[1,2] This may be due to the fact that the complicated methylene (and methine) proton signals of trien,[2] 5(*R*)- or 5(*S*)-metrien,[1] which appear in the region of 3.3—

3.8 ppm, obscure the methine quartets in question. However, one of the methine quartets is clearly noticed at 4.06 ppm in the PMR spectrum of the Δ-β_2-Co(*N*-Me-(*S*)-ala)(5(*S*)-metrien)$^{2+}$ isomers in D_2O.[1] The corresponding quartet can be acknowledged in the PMR spectrum of the Δ-β_2-Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ isomers reported by Buckingham *et al.*[2] We have sought the hidden methine signals of 5(*R*)- and 5(*S*)-metrien complexes by the decoupling method. The most appropriate position of the irradiation which produces the collapse of the *C*-methyl doublet to a singlet has been determined as the center of the methine signal. The data are given in Table 1. The assignments of the two isomers of Δ-β_2-Co(*N*-Me-(*S*)-ala)-(5(*S*)-metrien)$^{2+}$ ion is consistent with those made from the chemical shifts of the *N*-methyl group in a previous paper.[1] The same arguments should be applicable to the Co(*N*-Me-(*S*)-ala)(trien)$^{2+}$ system, though the adequecy has not been examined in this study.

Studies on Amino-hexoses. XVIII. A Simplified Method of Preparing 2-Amino-3-*O*-(D-1′-carboxyethyl)-2-deoxy-D-glucose 6-(Dihydrogen Phosphate) (Muramic Acid 6-Phosphate)

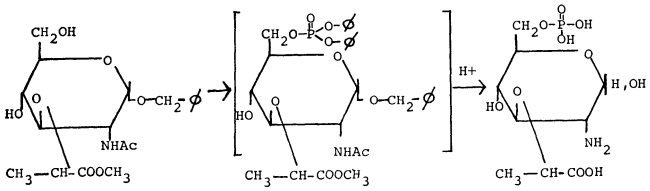
Sumihiro HASE and Yoshio MATSUSHIMA

The Department of Chemistry, Osaka University College of Science, Toyonaka 560

(Received July 23, 1973)

Muramic acid 6-phosphate was prepared from benzyl 2-acetamido-2-deoxy-3-*O*-[D-1′(methoxycarbonyl)-ethyl]-α-D-glucopyranoside *via* two reaction stages: diphenylphosphorylation under restricted conditions, followed by hydrolysis. When the reaction mixture was chromatographed on a Dowex 1×8 (formate form) column, the product was obtained as fine needles. Among the periodate oxidation products of the compound, glycolaldehyde phosphate was detected, while formaldehyde was not. Equimolar amounts of muramic acid and inorganic phosphate were produced by an alkaline phosphatase. The physical data are consistent with those of authentic muramic acid 6-phosphate.

The first synthetic muramic acid 6-phosphate was reported by Konami, Osawa, and Jeanloz[1] to be identical with the muramic acid phosphate obtained from bacterial cell walls, thus establishing the structure of the natural compound. We tried more or less to simplify the preparation of the compound and the estimation of a phosphate group at the 6 position of muramic acid. The route of the reactions is shown in Scheme 1. We simplified the synthesis of muramic acid 6-phosphate in a better yield (25%) to two reaction stages; selective phosphorylation and acid hydrolysis, whereas the previously reported method used 6 reaction stages. The physical constants of the synthesized compound (mp, $[\alpha]_D$, infrared spectrum, and R_{GlcNAc}) are consistent with those reported.[1] It has been reported that[2] a primary hydroxyl could be phosphorylated preferentially with a limiting amount of the reagent. For example, D-glucosamine 6-phosphate[3] was synthesized by selective diphenylphosphorylation under restricted conditions. In addition, the introduction of the bulky diphenylphosphate group at the C-4 hydroxyl of the muramic acid derivative seemed to be interfered by the lactyl group on C-3. The resulting compound was hydrolyzed with strong acid to remove the blocking groups. It seemed that phosphate migration did not occur, because a phosphate group on C-6 was more stable than that on C-4, as it was reported that D-glucosamine 4-phosphate was converted to D-glucosamine 6-phosphate during acid hydrolysis.[4] The hydrolysate of the diphenylphosphate of the muramic acid derivative showed, besides muramic acid and its 6-phosphate (main product), two minor spots on tlc. The main peak was isolated by Dowex 1×4 (formate form) column chromatography. The physical data were identical with those of the authentic compound, so the phosphate group might be at C-6. In the course of the reactions, hydrolysis by strong acid was used; therfore, the possibility of the migration of the phosphate group could not be excluded. The position of the phosphate group at muramic acid was thus estimated in the following way. Periodate oxidation study was performed by the previously reported method.[5] The periodate oxidation products of muramic acid 6-phosphate or muramicitol 6-phosphate gave a peak of glycolaldehyde phosphate which was positive for organic phosphate and diphenylamine reactions (Fig. 1). This fact indicates the 6-phosphate of muramic acid. The absorbtion spectrum of the fraction developed by diphenylamine was the same as that obtained from the reference compounds (Fig. 2). Formaldehyde was not detected in the periodate oxidation products; this is further evidence of the presence of the phosphate group at C-6 (Table 3). The infrared spectrum of the muramic acid-6-phosphate synthesized agreed well with the reported data.



Scheme 1.

Experimental

Abbreviations used: Glc, glucose; Mur, muramic acid; Mur 6-P, muramic acid 6-(dihydrogen phosphate); GlcN, glucosamine; GlcNAc, N-acetyl-glucosamine.

The diphenylphosphorochloridate was purchased from Merck Co. and was used without purification. The muramic acid was synthesized by the reported method.[6] The glucosamine 6-phosphate sodium salt and α-DL-glycerophosphate disodium salt were commercial specimens from the Sigma Chem. Co. Avicel SF (microcrystalline cellulose) was purchased from the Funacoshi, Co. Ltd., and the Kiesel Gel F_{254} from the Merck Co. The calf mucosa alkaline phosphatase (grade II, 10 mg/ml) [EC 3.1.3.1] was purchased from Boehringer Mannheim.

2-Amino-3-O-(D-1′-carboxyethyl)-2-deoxy-D-glucose 6-(Dihydrogen Phosphate). Benzyl 2-acetamido-2-deoxy-3-*O*-[D-1′-(methoxycarbonyl)ethyl]-α-D-glucopyranoside[7] (1.0 g) was dissolved in 30 ml of pyridine, after which the solution was cooled in a dry ice-acetone bath. To this solution was added 0.65 ml of diphenylphosphorochloridate. After the reaction mixture had been maintained at −20 °C for 16 hr, 1.0 ml of water was added to this solution. The solution was then allowed to stand for 30 min and was concentrated. The residue was dissolved in chloroform. The solution was washed with water, concentrated, and placed on a silicic acid column. The conditions were as follows: a column (2.5×20 cm; 52 g

silicic acid activated overnight at 150 °C) was eluted with ethyl acetate: toluene (5:2 v/v) and 8 ml fractions were collected. The main peak appeared at the 14—21 fractions. The main fraction was concentrated to give a colorless sirup which gave a single spot on a thin-layer chromatogram (Merck Kiesel Gel F_{254}, ethyl acetate: toluene=5:2 v/v, R_f=0.37).

To the sirup we then added 20 ml of 3 M hydrochloric acid, and the solution was heated for 6 hr at 100 °C.[1] The water-soluble fraction of the hydrolysate was concentrated and placed on a Dowex 1×4 column (100—200 mesh, formate form), which was then eluted with 0.5 M formic acid.[8] Ten-ml fractions were collected, and the main peak appeared at tubes number 10—16. The main fraction was concentrated, and the residue gave fine needles in ethanol-water in a refrigerator. Yield, 230 mg (25% of theory). mp 170.5—171.5 °C (dec.); reported mp 170—172 °C (dec.).[1] Found: C, 31.29; H, 6.20; N, 4.10; P, 9.11%. Calcd for $C_9H_{18}O_{10}NP\cdot H_2O$: C, 30.95; H, 5.77; N, 4.01; P, 8.87%. Mol wt. 349.2. $[\alpha]_D^{22}$ +107.7°→+104.1° (8 min)→+90.2° (3 hr)→+90.2±7.5° (at equilibrium; *c* 0.194, water). Reported $[\alpha]_D$ +106° (8 min)→+79° (at equilibrium).[1]

Table 1. Paper and thin layer chromatography of muramic acid 6-phosphate

Relative mobilities to glucosamine or *N*-acetyl-glucosamine were shown.

Solvent	GlcN	GlcNAc	Mur	Mur 6-P
Ethylacetate: Acetic acid: Pyridine: Water (5:1:5:3) (Whatman No. 1)[a]	—	1.00	0.60	0.15
Butanol: Acetic acid: Water (5:3:2) (Whatman No. 1)[a]	—	1.00	1.13	0.67
Butanol: Acetic acid: Water (2:1:1) (Avicel SF)[b]	1.00	—	1.84	1.22
Butanol: Acetic acid: Water (2:1:1) (Kiesel Gel F_{254})[c]	1.00	—	1.12	0.45

Spots were detected. a) by silver nitrate reagent[9]. b) by ninhydrin reagent. c) by sulfuric acid.

Analyses of Muramic Acid 6-Phosphate Synthesized. The compound gave one spot on paper and thin-layer chromatograms. The results are summarized in Table 1. On a paper electrophoretogram the compound gave a single spot with $M_{\text{gluconic acid}}$=1.0 at 700 V/15 cm for 35 min in an acetic acid pyridine buffer (pH 3.5).

Periodate Oxidation of Muramic Acid 6-Phosphate. As a reference, α-DL-glycerophosphate or D-glucosamine 6-phosphate (4.1 and 5.0 μmol each) in 0.5 ml of water was treated with 9.5 μmoles of sodium periodate in 0.5 ml at pH 5. The reaction mixture was allowed to stand at 25 °C for 48 hr in the dark. It was then placed on a Dowex 1×4 column (200—400 mesh, chloride form, 0.9×10 cm); the column was eluted first with 20 ml of 0.052 M hydrochloric acid and then with 0.05 M hydrochloric acid.[5] One and a half-ml fractions were collected and the aliquots were analyzed for organic phosphate[10] and diphenylamine-positive substances[11] (Fig. 1, A, B). Muramic acid 6-phosphate (4.9 μmol) was treated in the same way, and the oxidation was continued for 62 hr (Fig. 1, C). Muramic acid 6-phosphate was reduced with sodium borohydride and then treated in the same way (Fig. 1, D). The absorbtion spectra of the color developed by diphenylamine[5] with peak fractions at tubes number 24—26 are shown in Fig. 2.

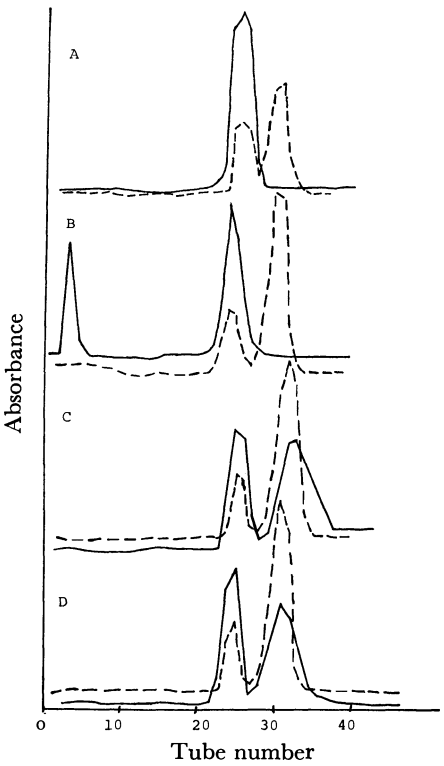


Fig. 1. Column chromatography of the periodate oxidation products of muramic acid 6-phosphate and standard samples.

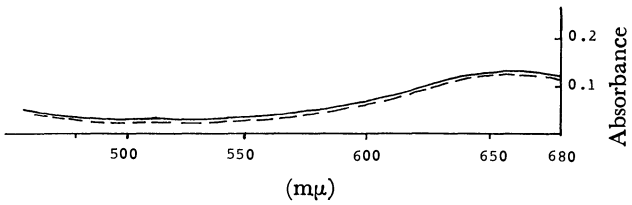

Fig. 2. Absorbtion spectra of the color developed by diphenylamine with peak fractions appeared at tube number 24—26 shown in Fig. 1.
Muramic acid 6-phosphate or reduced muramic acid 6-phosphate ----; glucosamine 6-phosphate or α-glycerophosphate ——.

Table 2. Analyses by the alkaline phosphatase of muramic acid 6-phosphate

	Recovery		
	with the enzyme	without the enzyme	incubation time (hr)
Mur 6-P	<1.0%	83%	4
Mur produced from Mur 6-P	103%	<2.5%	4
Inorganic phosphate	101%	<1%	1

Analyses by Alkaline Phosphatase. To a 0.2 ml solution of 0.40 μmole of muramic acid 6-phosphate, was added 0.4 ml of water and 0.2 ml of a 0.1 M ethanolamine–HCl buffer (pH 9.5, containing 0.005 M $MgCl_2$). To this solution 2 μl of the enzyme solution was added, after which the mixture was incubated at 37 °C.[12] Aliquots were analyzed for inorganic phosphate, and aminosugars were determined by means of an automatic amino acid analyzer (Hitachi KLA 3B). The results are shown in Table 2.

Detection of Formaldehyde in Periodate Oxidation Products. The pH of a sample solution (0.8 μmol in 0.08 ml of water) was adjusted to 5 if necessary. The oxidation was carried out with 4.3 μmol of sodium periodate in 0.02 ml at 25 °C for 48 hr. The excess periodate was decomposed with arsenite, and chromotropic acid was used for the determination of formaldehyde.[13] When glucose was used as an standard, 0.04 mol of formaldehyde was detected from one mole of muramic acid 6-phosphate, and 0.91 mol from one mol of muramic acid.

The Formation of Ethers from Borneol and Isoborneol in the Presence of Boron Trifluoride Etherate

Kimiko NAGAI, Mitsuru NAKAYAMA, Akihiko MATSUO, Shizuko EGUCHI, and Shûichi HAYASHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received August 25, 1973)

dl-Borneol and *dl*-isoborneol, when separately submitted to the action of boron trifluoride etherate at room temperature, gave different ethers; the one from borneol was characterized as bornyl isobornyl ether, and the other from isoborneol, as diisobornyl ether. The ethers were also obtained from borneol and isoborneol in the reaction with zinc chloride. When *d*-borneol was used, an optically-active bornyl isobornyl ether was obtained.

In connection with a previous communication on the formation of cyclodiethers from 6-methyl-5-hepten-2-ol and citronellol,[1] the action of boron trifluoride etherate on borneol and isoborneol was examined in the present work; two kinds of ethers were obtained, whose structures were characterized as bornyl isobornyl and diisobornyl ethers.

Long years ago Ikeda obtained a condensation product in the reaction of borneol with zinc chloride; he described it as dibornyl ether. However, he did not attempt the reaction of isoborneol with zinc chloride, for this alcohol was more sensitive than borneol. Besides, in his work the structural characterization was not thoroughgoing enough; indeed, no consideration has yet been made[2] of the formation mechanism. In the present work, then, the reactions of borneol and isoborneol with zinc chloride were reexamined, and the reaction of borneol with camphene was examined in the presence of boron trifluoride etherate.

Results and Discussion

Reactions of dl-*Borneol and* dl-*Isoborneol with Boron Trifluoride Etherate.* *dl*-Borneol (I) and *dl*-isoborneol (II) were separately submitted to the action of boron trifluoride etherate under such conditions as are shown in Table 1. The reaction mixtures were subjected to fractional distillation followed by elution chromatography to separate individual components, which were characterized as tricyclene (III), camphene (IV), and C_{20}-hydrocarbons, together with the following two ethers.

dl-*Bornyl Isobornyl Ether (V)*: In the reaction of *dl*-borneol with boron trifluoride etherate (Experiment 3), the compound was isolated as feather-like crystals (mp 42.5—43.5 °C, $[\alpha]_D^{20}$ ±0° ($CHCl_3$)) in a 14% yield. The molecular formula of this compound was determined to be $C_{20}H_{34}O$ from the molecular ion, *m/e* 290, and the molecular weight, 288, as taken by the Rast method. The IR spectrum showed characteristic ether bands at 1117, 1087, and 1078 cm^{-1}, while the NMR spectrum revealed the presence of two oxygen-carrying methine groups on the proton signals at δ 3.18 (1H, t) and 3.50 (1H, dq), but there was no indication of the presence of unsaturated bonds; the mass spectrum with characteristic ions at *m/e* 153 (8%, $C_{10}H_{17}O$), 152 (23, $C_{10}H_{16}O$), and 137 (base, $C_{10}H_{17}$) were reasonably explained as that of a di-monoterpene ether. Accordingly, the compound may be thought to be an ether consisting of two saturated bicyclic monoterpenes.

Together with the above signals, the NMR spectrum taken in a $CDCl_3$ solution showed methyl signals at δ 0.80, 0.90, 1.01 (each 3H, s) and 0.85 (9H, s). Among these, the first three were close to the separating methyl signals in the NMR spectrum of isoborneol (δ 0.81, 0.91 and 1.02; each 3H, s), while the last agreed with a combined methyl signal seen in the spectrum of borneol (δ 0.85, 9H, s). Regarding the NMR spectrum taken in a C_5D_5N solution, also, the methyl signals (δ 0.85, 9H, s; 0.95, 0.98, 1.09, each 3H, s) could be connected with those of borneol (δ 0.87, 6H, s; 0.98, 3H, s) and isoborneol (δ 0.85, 1.07, 1.28, each 3H, s), although the methyl signals to be assigned to the isobornyl moiety of the ether showed field shifts slightly higher than those of free isoborneol. These facts indicate that the compound is bornyl isobornyl ether.

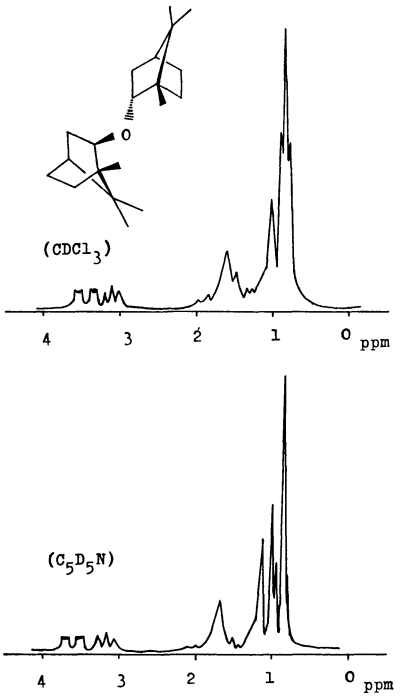

Fig. 1. NMR spectra of bornyl isobornyl ether (V).

This characterization of the ether was further supported by the signal patterns of the oxygen-carrying methine groups: according to Flautt[3] and Tori,[4] who have investigated in detail the NMR spectra of 2-substituted bornane derivatives, the α-methine proton of

the *endo*-substituted isomer (proton *exo*) appears as a quartet of two characteristic spacings split by a much smaller spacing, whereas that of the *exo*-substituted isomer (proton *endo*) appears as a triplet or a near triplet without any additional splitting; this difference gives a good test for the identification of the *exo* and *endo* isomers. The NMR spectrum taken in $CDCl_3$ showed two signals attributable to α-methine protons. That is, the one appeared as a quartet (δ 3.50) with a small splitting, and the other, as a triplet (δ 3.18). When the NMR spectrum taken in a C_5D_5N solution was compared with that in $CDCl_3$, both the α-methine signals were retained with nearly the same patterns, although the chemical shifts showed a slight down-field shift.

Thus, it is certain that the compound is optically-inactive bornyl isobornyl ether.

dl-*Diisobornyl Ether (VI)*: The compound was obtained as feather-like crystals (mp 87—88 °C, $[\alpha]_D^{20}$ ±0° ($CHCl_3$)) in a 21% yield by the reaction of *dl*-isoborneol with boron trifluoride etherate at room temperature (Experiment 10). The molecular formula, $C_{20}H_{34}O$, was the same as that of bornyl isobornyl ether (V) discussed above, and the IR and mass spectra of the two compounds were nearly superimposable upon each other. In addition, the NMR spectrum was constituted of methyl, methylene, and α-methine signals with the same relative intensity as that of the above bornyl isobornyl ether, although these proton signals differed fairly much in pattern. Accordingly, this evidence seems to indicate that the compound is a stereo-isomer of bornyl isobornyl ether (V).

The proton signals of the two α-methine groups were overlapped as a triplet centering at δ 3.18 in a $CDCl_3$ solution, and as a near triplet centering at δ 3.20 in a C_5D_5N solution. Besides, the chemical shifts of the α-methine signals were in agreement with those in $CDCl_3$ and C_5D_5N solutions respectively of the α-methine proton belonging to the isobornyl moiety of bornyl isobornyl ether (V). Such proton signals of the α-methine group indicate that the ether-linkage of this compound is in the *exo-exo* conformation. Thus, the ether was characterized as diisobornyl ether (VI).

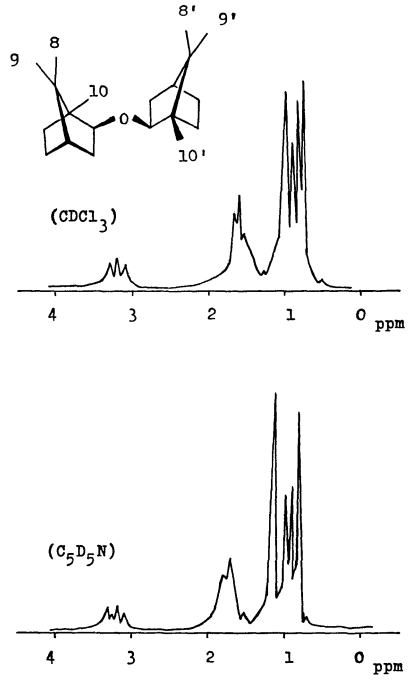

Fig. 2. NMR spectra of diisobornyl ether (VI).

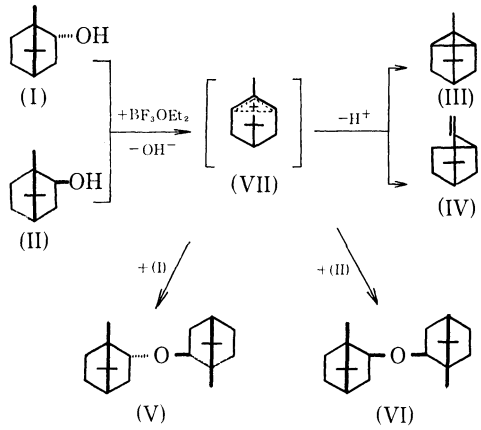
The methyl signals in $CDCl_3$ and C_5D_5N solutions of the ether were also reasonably connected with those of diisobornyl ether in comparison with the methyl signals of isoborneol[4] and the isobornyl moiety of bornyl isobornyl ether; besides, according to Tori's assignments for isoborneol, the methyl signals of δ 0.85 (6H, s, $C_{(9)}$ and $C_{(9')}$) and 1.02 (6H, s, $C_{(8)}$ and $C_{(8')}$) in $CDCl_3$ and of δ 0.81 (6H, s, $C_{(9)}$ and $C_{(9')}$) and 1.09 (6H, s, $C_{(8)}$ and $C_{(8')}$) in C_5D_5N were assigned to the two gem-dimethyls, and the methyl signals of δ 0.90 and 0.95 (each 3H, s) in $CDCl_3$ and of δ 0.91 and 0.95 (each 3H, s) in C_5D_5N, to $C_{(10)}$- and $C_{(10')}$-methyls.

Reactions of Borneol and Isoborneol with Zinc Chloride. When the structural elucidation was carried out on the products of the reaction with boron trifluoride etherate, we were especially interested in a *d*-dibornyl ether which had been obtained by Ikeda in the reaction of *d*-borneol with zinc chloride,[2] for its melting point agreed with that of our bornyl isobornyl ether and dibornyl ether was not obtained in our experiment.

The reaction of *dl*-borneol with zinc chloride was thus traced, and feather-like crystals whose melting point agreed with that reported by Ikeda were obtained. This compound, however, was identical with our *dl*-bornyl isobornyl ether in the IR, NMR, and mass spectra and in a gas-chromatographic comparison. Therefore, it was confirmed that Ikeda's ether was not dibornyl ether, but bornyl isobornyl ether.

Ikeda did not examine the reaction of isoborneol with zinc chloride. We tried this reaction under similar conditions and obtained diisobornyl ether. Thus, zinc chloride also acts similarly on borneol and isoborneol as boron trifluoride etherate.

Formation Mechanism of Bornyl Isobornyl and Diisobornyl Ethers. As has been mentioned above, camphene and tricyclene were detected in the monoterpene fraction of each reaction product in the reaction of borneol and isoborneol with boron trifluoride etherate. These compounds are thought to be produced *via* a non-



Scheme 1.

classical carbonium ion (VII): a molecule of borneol or isoborneol undergoes the elimination of the hydroxyl group, followed by deprotonation, to give camphene or tricyclene.

The formation of the bornyl isobornyl and diisobornyl ethers mentioned above may be explained in terms of the nucleophilic attack of each molecule of borneol and isoborneol on the common carbonium ion (VII), in which the alcohol molecule approaches stereospecifically from the *exo*-side because of the steric hindrance and the asymmetric influence of the molecule. By the formation mechanism, the following experimental results can also be explained. When the *d*-borneol was submitted to the action of boron trifluoride etherate, we obtained optically-active bornyl isobornyl ether, $[\alpha]_D^{20}$ +53.8° ($CHCl_3$). Next, the reaction of *dl*-borneol or *d*-borneol with *d*-camphene was attempted in the presence of boron trifluoride etherate, because it has been established that camphene produces the carbonium ion in the acid-catalyzed reaction; from the reaction of *dl*-borneol and *d*-camphene, *dl*-bornyl isobornyl ether was obtained, while from that of *d*-borneol with *d*-camphene, we obtained optically-active bornyl isobornyl ether, $[\alpha]_D^{20}$ +54.6° ($CHCl_3$), whose specific rotation was equal to that of the above optically-active ether obtained in the reaction of *d*-borneol itself.

Experimental

Apparatus. For the analyses and preparative glc of monoterpenic hydrocarbons, a Shimadzu glc-apparatus was used: column temperature, 100 °C; stainless-steel separating column (3 m×3 mm) packed with Carbowax 6000 (30%) on Celite 545 (60—80 mesh); flow rate of the helium carrier, 60 ml/min. The mass spectra were taken on a Hitachi RMS-4 spectrometer at an ionization voltage of 80 eV, an ion-accelerating voltage of 1800 eV, and an ionization chamber temperature of 150 °C, or on a Hitachi-7L high-resolution spectrometer under the same conditions.

Materials. Commercial *dl*- and *d*-borneol and *dl*-isoborneol[5] were purified through repeated recrystallizations from benzene. They each showed one peak in glc; *dl*-Borneol mp 210 °C, $[\alpha]_D^{25}$ ±0° ($CHCl_3$); *d*-borneol: mp 205—206 °C, $[\alpha]_D^{22}$ +21.4° ($CHCl_3$). *dl*-Isoborneol: mp 212.0—212.3 °C, $[\alpha]_D^{25}$ ±0° ($CHCl_3$).

Commercial *d*-camphene was purified: mp 48.5—49.5 °C, $[\alpha]_D^{20}$ +5.3° ($CHCl_3$).

The chemical grade of boron trifluoride etherate (BF_3 47%) was used without any purification.

The zinc chloride was freshly dehydrated by fusion just before the experiment.

Reactions of Borneol and Isoborneol with Boron Trifluoride Etherate. To *dl*-borneol or *dl*-isoborneol, boron trifluoride etherate was added, drop by drop, in ether or with no solvent, as is shown in Table 1; the mixtures were then allowed to stand for a period from 7 min to 10 day at temperatures from 25 °C to 80 °C. The reaction mixtures were washed with a saturated aqueous solution of sodium carbonate and then with water, dried over anhydrous sodium sulfate, and fractionated under reduced pressure into a lower-boiling (bp 30—100 °C/4 mmHg) fraction, a higher-boiling (bp 100—150 °C/4 mmHg) fraction, and a residue.

Characterization of Monoterpene Compounds. The lower-boiling fractions from Experiments (1)—(5) and (7)—(10) showed two components except for the reactant in tlc using silica gel and hexane (R_f 0.91 and 0.78) and in glc (T_R 11.7 and 16.8). The components were isolated by means of preparative glc.

Tricyclene: The compound showing one peak with T_R 11.7 in glc and one spot with R_f 0.91 in tlc was isolated as colorless and pleasant odor crystals; mp 67.3—67.9 °C. The IR,[6] mass[7] spectra and gas chromatographic behavior coincided with those of tricyclene.

dl-*Camphene*: The compound showing one peak with T_R 16.8 in glc and one spot with R_f 0.78 on tlc was isolated as colorless and camphor-like-smelling crystals; mp 51.0—51.5 °C (lit,[8] 49—51 °C), $[\alpha]_D^{20}$ ±0° ($CHCl_3$). The IR[6] and mass spectra[7,9] with those of camphene, and the compound was gas-chromatographically identical with the authentic specimen.

Characterization of Dimerized Compounds. The higher-boiling fractions of the reaction products from borneol showed one or two components with T_R 10.9 and 18.8 on glc with the SE-30 column, while those from isoborneol showed such components with T_R 10.5 and 18.1. These components were isolated through elution chromatography with silica gel–benzene and then characterized.

C_{20}-*Hydrocarbon from* dl-*Borneol*: A colorless, viscous oil showing one peak with T_R 10.9 was isolated from the reaction mixture of *dl*-borneol. From the molecular ion (*m/e* 272) and the molecular weight (275) taken by the Rast method, the molecular formula of this compound was determined as $C_{20}H_{32}$. Although the mass spectrum showed abundant ions at *m/e*

a) Five grams of the alcohol were used in each experiment. b) Relative amounts of reaction products were determined with the aid of gas chromatography.

257 (M^+-15, 4%), 229 (M^+-43, 10), 109 (31), 95 (base), 81 (57), and 41 (56), no further structural information was obtained from any of the mass, IR, or NMR spectra.

C_{20}-Hydrocarbon from dl-*Isoborneol*: The compound (T_R 10.5) was isolated from the reaction mixture of *dl*-isoborneol as a colorless, viscous oil. The hydrocarbon was determined to have the same molecular formula, $C_{20}H_{32}$, as that from the reaction mixture of borneol, and it had the same molecular ion (*m/e* 272) and the same molecular weight (270, Rast method), but a difference was observed between the IR and NMR spectra of the two hydrocarbons. The mass spectrum showed abundant ions at *m/e* 257 (M^+-15, 12%), 229 (M^+-43, 23), 162 (M^+-110, base), 147 (42), 109 (55), and 95 (66).

dl-*Bornyl Isobornyl Ether from* dl-*Borneol*: Colorless feather-like crystals, mp 42.5—43.5 °C, $[\alpha]_D^{20}$ ±0° ($CHCl_3$), showing a peak with T_R 18.8 was obtained in a yield of 14% from a reaction mixture of *dl*-borneol. Found: C, 82.94; H, 11.92%. Calcd for $C_{20}H_{34}O$: C, 82.69; H, 11.80%. The mass spectrum showed ions at *m/e* 290 (M^+, 4%), 272 (M^+-18, 10), 153 ($C_{10}H_{17}O$, 8), 152 ($C_{10}H_{16}O$, 13), 137 ($C_{10}H_{17}$, base), 95 (C_7H_{11}, 29), 81 (C_6H_9, 90), 69 (27), 67 (30), 55 (28), and 41 (42).

d-*Bornyl Isobornyl Ether from* d-*Borneol*: *d*-Borneol was subjected to a reaction with boron trifluoride etherate under the same conditions as in Experiment (3) to give *d*-bornyl isobornyl ether as colorless feather-like crystals; mp 42.0—42.8 °C, $[\alpha]_D^{20}$ +53.8° ($CHCl_3$). The IR, NMR, and mass spectra were in good agreement with those of *dl*-bornyl isobornyl ether, and the compound was confirmed to be identical with the *dl*-ether in gas chromatography.

dl-*Diisobornyl Ether from* dl-*Isoborneol*: A crystalline portion of the reaction mixture from isoborneol was dried on a porous plate to separate colorless feather-like crystals in a yield of 21%, mp 87—88 °C, $[\alpha]_D^{20}$ ±0° ($CHCl_3$). Found: C, 82.93; H, 11.91%. Calcd for $C_{20}H_{34}O$: C, 82.69; H, 11.80%. The IR and mass spectra were nearly superimposable on those of *dl*-bornyl isobornyl ether, but the NMR spectra were different between the two ethers.

Reactions of Borneol and Isoborneol with Zinc Chloride. dl-*Bornyl Isobornyl Ether*: *dl*-Borneol was submitted to a reaction with zinc chloride under conditions similar to those in Ikeda's report,[2] that is, 5 g of borneol were mixed with 2.5 g of zinc chloride in dried benzene (4 ml), and the mixture was boiled for 3 hr. The reaction mixture was then washed with 2M hydrochloric acid and water, dried over anhydrous sodium sulfate, and then chromatographed over a silica-gel column with a mixed solvent of hexane and ethyl acetate (95: 5) to isolate colorless crystals in a 25% yield; mp 42.5—53.0 °C, $[\alpha]_D^{20}$ ±0° ($CHCl_3$). The IR, NMR, and mass spectra were superimposable on those of the *dl*-bornyl isobornyl ether obtained from the reaction of *dl*-borneol with boron trifluoride etherate, and their mixed-melting-point determination showed no depression.

d-*Bornyl Isobornyl Ether*: *d*-Borneol was also subjected to the reaction; we thus obtained *d*-bornyl isobornyl ether, which was identified by comparison with *d*-bornyl isobornyl ether obtained in the reaction of *d*-borneol with boron trifluoride etherate.

dl-*Diisobornyl Ether*: *dl*-Isoborneol was mixed with zinc chloride in dried benzene in the same ratio as in the case of borneol, and the mixture was then boiled for 50 min. Colorless crystals were obtained in a 16% yield; mp 87—88 °C, $[\alpha]_D^{20}$ ±0° ($CHCl_3$). This compound was identical in melting point and in the IR and NMR spectra with the *dl*-diisobornyl ether obtained from *dl*-isoborneol in the presence of boron trifluoride etherate.

Reaction of Borneol with Camphene in the Presence of Boron Trifluoride Etherate. dl-*Bornyl Isobornyl Ether*: To a mixed solution of *dl*-borneol (5 g) and *d*-camphene (5 g) in dried ether (20 ml), boron trifluoride etherate (2.5 ml) was added, drop by drop; the mixture was then allowed to stand at room temperature for 24 hr. The reaction mixture was treated with the usual procedure to give colorless crystals in a 30% yield; mp 42.5—43.5 °C; $[\alpha]_D^{20}$ ±0° ($CHCl_3$). This compound was identical with the ether drived by the above-described method.

d-*Bornyl Isobornyl Ether*: A mixed solution of *d*-borneol and *d*-camphene was treated with boron trifluoride etherate as has been described above; a colorless crystalline product was thus obtained; mp 42.0—42.8 °C, $[\alpha]_D^{20}$ +54.6° ($CHCl_3$). This compound was identical with the ether obtained in the reaction of *d*-borneol with boron trifluoride etherate.

Synthetic Studies of Carbohydrate Derivatives with Photochemical Reactions. X.[1] An Unusual Photo-induced Addition of Lactonitrile to Some Enoses

Kazuo MATSUURA, Kazuo SENNA, Younosuke ARAKI, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received September 7, 1973)

The photochemical addition of lactonitrile to 3,4,6-tri-*O*-acetyl-D-glucal, 2,3,4,6-tetra-*O*-acetyl-2-hydroxy-D-glucal, methyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside, and methyl 5-deoxy-2,3-*O*-isorpopylidene-β-D-*erythro*-pent-4-enofuranoside afforded 1′-cyanoethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-(**6a**) and -β-D-*erythro*-hex-2-enopyranoside(**6b**), 1′-cyanoethyl 2,4,6-tri-*O*-acetyl-3-deoxy-α- and -β-D-*erythro*-hex-2-enopyranoside, **6a** and **6b**, and 1′-cyanoethyl [methyl (4*R*)-5-deoxy-2,3-*O*-isopropylidene-β-D-*erythro*-pentofuranosid]-4-uloside respectively, all in good yields. These facts can be explained by assuming the catalytic effect of a certain acidic species which might extricated from lactonitrile during the irradiation.

As part of this series of investigations, the photochemical addition of secondary alcohols to enoses has been reported briefly; in it the corresponding tertiary alcohols were obtained through the addition of α-*C*-radicals of secondary alcohols to enoses.[2] On the other hand, in contrast with the case of these secondary alcohols, the photochemical behavior of lactonitrile(**1**) was found to be unusual in such reaction; it gives the corresponding adducts, which have the 1′-cyanoethyl ether structure.[3] In this article, the detailed results of an investigation of the unusual photo-induced reaction of **1** with 3,4,6-tri-*O*-acetyl-D-glucal(**2**), 2,3,4,6-tetra-*O*-acetyl-2-hydroxy-D-glucal(**3**), methyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside(**4**), and methyl 5-deoxy-2,3-*O*-isopropylidene-β-D-*erythro*-pent-4-enofuranoside(**5**) will be described.

Results and Discussion

The irradiation of a solution of **2** in **1** was carried out by the use of a low-pressure mercury lamp under a nitrogen atmosphere at room temperature. The resultant reaction mixture was, after concentration *in vacuo* to a sirup, subjected to chromatographic separation to afford 1′-cyanoethyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside(**6a**) and the corresponding β-anomer(**6b**) in 37 and 47% yields[4] respectively. Moreover, 1′-cyanoethyl 2,4,6-tri-*O*-acetyl-3-deoxy-α-D-*erythro*-hex-2-enopyranoside(**7a**) and its β-anomer(**7b**) were similarly obtained from **1** and **3** in 40 and 40% yields respectively. The structural assignment of these products was successfully accomplished by the use of the NMR and mass spectroscopic data (Table 1 and Fig. 1 respectively). The signals of the anomeric protons of 2,3-dideoxy- and 3-deoxy-α-D-*erythro*-hex-2-enopyranosides have been shown by Ferrier *et al.*[5,6]

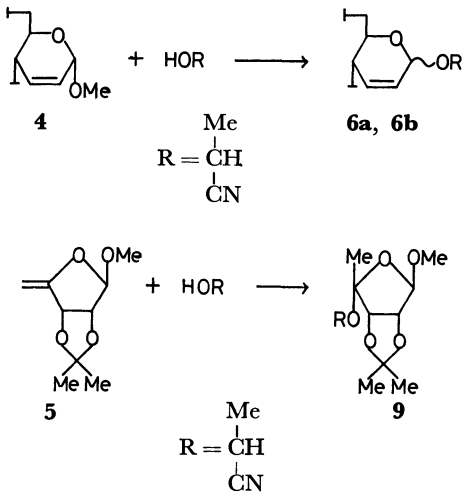
All the chemical shifts in this table are expressed by δ value in ppm, and the coupling constants are expressed in Hz.

to appear at a field higher than those of the corresponding β-anomers. The signals of **6a**, **6b**, **7a**, and **7b** were observed at δ 5.23, 5.34, 5.30, and 5.34 ppm respectively; those products were thus concluded to occupy the α-, β-, α-, and β-anomeric configurations respectively. Incidentally, the chromatographic behavior of **6a** and **6b** in glc, tlc, and column chromatography was in full accordance with that of **7a** and **7b** respectively. A further comparison of their NMR data with those[5a] of 2-enopyranosides led us to the conclusion that all the D-*erythro*-hex-2-enopyranosides described herein adopted the H1 conformation(**8**) with the $J_{3,4}$ and $J_{4,5}$ values of *ca.* 2 and *ca.* 10 Hz respectively, indicative of the quasi-axial and axial protons at *C*-4 and *C*-5 respectively. Moreover, the mass spectra of **6a** and **6b** showed the same spectral pattern and supported the expected structures; such typical fragment peaks as *m/e* 213, 181, and 139 were apparently detected in their spectra, and were found to agree with the results of Ferrier *et al.*[7]

The present reaction was thus confirmed to afford neither sugar derivatives with the tertiary alcohol substituents, in contrast with the reactions of ordinary secondary alcohols to enoses,[2] nor those with an ether linkage at *C*-2, but the 2-enopyranosides.

The irradiation of a solution of **4** in **1**, followed by



chromatographic separation, was subsequently carried out; it was found to involve a transglycosidation reaction giving **6a** and **6b** in 40 and 47% yields respectively.

Subsequently, the addition of **1** to 4-enofuranosyl derivatives such as **5**, which have an exocyclic double bond, was studied in the expectation that their higher reactivity could be proved in comparison with those having an endocyclic double bond.[1] 1′-Cyanoethyl

TABLE 2. NMR DATA OF **9**

[methyl (4*R*)-5-deoxy-2,3-*O*-isopropylidene-β-D-*erythro*-pentofuranosid]-4-uloside(**9**) was afforded in a 60% yield by the irradiation of **5** in **1**, followed by chromatographic separation. The NMR evidence for its structural determination is presented in Table 2. Two new *C*-methyl signals appeared at δ 1.61 (Me-4) and 1.47 (doublet, J_{CH-CH_3}=7.0 Hz, Me-1′) ppm besides those of the isopropylidene group. Moreover, 12% of the NOE was observed in the *H*-3 signal (δ 4.45 ppm) on irradiation at the methyl signal at δ 1.61 ppm.[8] From these data, the chirality at *C*-4 was thus established to be *R*. In the mass spectrum of this product, the peaks of *m/e* 242 (M^+-CH_3) and 226 (M^+-OCH_3) were observed as well as that of *m/e* 54 ($NC-C^+H-CH_3$), although no molecular ion peak was observed.

In order to elucidate the mechanism of these unusual photochemical reactions, the following examinations were carried out by the use of **3** as the model compound of the enoses to **1**. Each 10 mg portion of **3** was dissolved in **1** (0.5 ml) and treated under the following conditions, after which it was analyzed by glc. The dark reaction of the solution afforded no product, but resulted in a quantitative recovery of **3**. However, the treatment of **3** under dark conditions in **1**, which had previously been irradiated with a low-pressure mercury lamp for 30 hr afforded **7a** and **7b**, whose peaks were apparently observed in the glc of this reaction mixture in the same ratio as has been presented before. The peak of neither **3** nor of any other product could be detected in the chromatogram. An examination of the separately-photoirradiated **1** by ESR proved it to involve no radical species; however, the dark reaction with **3** in this **1** still afforded **7a** and **7b**. It is of interest, on the other hand, that the addition of an appropriate amount of liquid hydrogen cyanide to the system of the dark reaction resulted in the same results as were obtained in the photoinduced reaction of **3** in **1**. In view of the results reported by Ferrier *et al.*,[5a,9] boron trifluoride was also used in the above dark reaction in place of liquid hydrogen cyanide. It was, however, found to be too effective to give a mixture of the above products and a considerable amount of by-products, in spite of a short reaction period such as within 10 min.[10] In any case, the photochemical process conceivably takes place in the process of liberating a certain acidic species such as hydrogen cyanide from **1**, in considering that **1** is known to be equilibrated with a system of acetaldehyde and hydrogen cyanide in an aqueous solution.[11] Therefore, these reactions can be explained as the acid-catalyzed reactions of the enoses with **1**. The acid-catalyzed reaction of **2** or **3** with alcohols has already been shown to give the corresponding 2-enopyranosides.[5a,9] Either the formations of **6a** and **6b** or of **7a** and **7b** are thus conceivably brought about by a similar reaction process, and **4** may be interpreted to give **6a** and **6b** in terms of an acid-catalyzed *trans*-glycosidation reaction. Moreover, **5** can also be explained to afford **9** by such an acid-catalyzed reaction selectively; the sole formation of **9** can be assumed to arise from the stereochemical requirement of the carbonium ion, which was produced by the protonation on *C*-5 of **5**, which has a slightly pyramidal conformation of its quasi-*ribo* structure because of the potential repulsion with the endo-methyl group of the isopropylidene ring.

Experimental

Irradiations were carried out with a low-pressure mercury lamp (30 W) of the Riko Kagaku Co., Ltd. in a quartz-glass test tube at a distance of about 5 cm. Tlc's were carried out by the use of Wakogel B-5 and the solvent system of benzene–methanol (9: 1 v/v) for the development. The NMR spectra were taken with a Varian XL-100 appratus in deuterochloroform, using tetramethylsilane (TMS) as the internal standard. Glc was carried out with a Hitachi K-53 apparatus; column: 10% SE-30 on Chromosorb W (60—80 mesh); carrier gas: nitrogen under 1.5 Atm unless otherwise noticed; oven temperature: 200 °C, and injection temperature: 300 °C. The mass spectra were taken with a Hitachi RMU-6E appratus. The ESR spectrum was taken with a JOEL JEP-1X EPR spectrometer.

*1′-Cyanoethyl 4,6-Di-O-acetyl-2,3-dideoxy-α-(***6a***) and -β-*D-erythro-*hex-2-enopyranoside (***6b***).* *A*) A solution of 3,4,6-tri-*O*-acetyl-D-glucal (**2**) (1.00 g) in lactonitrile (**1**) (12 ml) was irradiated with the UV lamp under a nitrogen atmosphere at room temperature for 27 hr, after which the volatiles were evaporated *in vacuo*. The residue was subsequently chromatographed on a silica gel (Mallinckrodt Silica Gel, 100 mesh) column, using benzene–acetone (49: 1 v/v) as an eluting solvent system; **6b** (485 mg, 47%) and **6a** (380 mg, 37%) were in turn eluted out separately. The retention volumes of **2**, **6b**, and **6a** in glc were, respectively, 1 (=1.1 min), 1.7, and 2.1. Specific rotations: **6a**: $[\alpha]_D^{22}$ +49.4° (*c* 1.0, Me_2CO), **6b**: $[\alpha]_D^{22}$ +78.2° (*c* 1.0, Me_2CO). Found: C, 54.87 (**6a**) and 55.32 (**6b**); H, 5.81 (**6a**) and 6.18 (**6b**); N, 4.98 (**6a**) and 4.73 (**6b**) %. Calcd for $C_{13}H_{17}O_6N$: C, 55.12; H, 6.05; N, 4.95%. The NMR data of **6a** and **6b** are presented in Table 1. Their mass spectral data are presented in Fig 1.

B) A solution of methyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (**4**) (1.00 g) in **1** (12 ml) was irradiated with the UV lamp under the same conditions as have been described above for 27 hr; the resultant solution was treated as in the previous experiment to afford **4** (30 mg, 3% recovery), **6b** (560 mg, 47%) and **6a** (480 mg, 40%).

*1′-Cyanoethyl 2,4,6-Tri-O-acetyl-3-deoxy-α-(***7a***) and -β-*D-erythro-*hex-2-enopyranoside (***7b***).* A solution of 2,3,4,6-tetra-*O*-acetyl-2-hydroxy-D-glucal (**3**) (500 mg) in **1** (12 ml) was irradiated with the UV lamp under the same conditions for 27 hr, and the resultant solution was evaporated *in vacuo*.

The residual sirup was subjected to chromatographic separation in the way described previously to afford **7b** (205 mg, 40%) and **7a** (205 mg, 40%). The retention volumes of **3**, **7b**, and **7a** in glc were, respectively, 2.1, 4.7, and 4.8. Specific rotations; **7a**: $[\alpha]_D^{22}$ +95.2° (*c* 1.0, Me_2CO) and **7b**: $[\alpha]_D^{22}$ +25.0° (*c* 1.0, Me_2CO). Found: C, 52.50 (**7a**) and 52.80 (**7b**); H, 5.91 (**7a**) and 5.40 (**7b**); N, 3.86 (**7a**) and 4.27 (**7b**) %. Calcd for $C_{15}H_{19}O_8N$: C, 52.78; H, 5.61; N, 4.10%.

The NMR spectral data of **7a** and **7b** are presented in Table 1.

*1′-Cyanoethyl [Methyl (4*R*)-5-Deoxy-2,3-*O*-isopropylidene-β-*D-erythro-*pentofuranosid]-4-uloside (***9***).* A solution of methyl 5-deoxy-2,3-*O*-isopropylidene-β-D-*erythro*-pent-4-enofuranoside (**5**) (1.00 g) in **1** (15 ml) was irradiated with the UV lamp under a nitrogen atmosphere at room temperature for 41 hr; the resultant solution was then subjected to column chromatography after its concentration *in vacuo* to give **9** (840 mg, 60%). Its retention volume in glc was 2.5 with reference to that of **5**

(1.0) under 0.8 Atm of nitrogen gas. $[\alpha]_D^{22}$ +24.0° (*c* 1.0, Me_2CO). Found: C, 55.55; H, 7.42; N, 5.29%. Calcd for $C_{12}H_{19}O_5N$: C, 56.02; H, 7.44; N, 5.44%. The NMR spectral data of this product are presented in Table 2. Mass spectral data of this product: *m/e* 242 (M^+–Me), 226 (M^+–OMe), 187 (M^+–OCH(Me)CN), 54 (C^+H(Me)CN), and so on.

Reactions of 2,3,4,6-Tetra-O-acetyl-2-hydroxy-D-glucal (3) with Lactonitrile (1) under Dark Conditions. *A*) A solution of **3** (10 mg) in **1** (0.5 ml) was allowed to stand for 100 hr at room temperature in the dark under a nitrogen atmosphere.

In the gas chromatogram of the resultant mixture, there are no detectable peaks except that of **3**.

B) Lactonitrile (**1**) (0.5 ml) was irradiated with the UV lamp for 30 hr at room temperature under a nitrogen atmosphere, and then **3** (10 mg) was dissolved in this **1**. The solution was allowed to stand for 30 hr under the same conditions as in the previous Experiment A. In the gas chromatogram of the resultant mixture, there are two peaks of the **7a** and **7b** products, but no peak of **3**.

C) Lactonitrile (**1**) (5 ml) was irradiated with the UV lamp much as has been described in the previous Experiment B, and then the resultant **1** was examined by ESR spectrometry.

No radical species were detected in variable measurements, even with the sensitivity of 10^{13} molecules. After these examinations, **3** (10 mg) was added to 0.5 ml of the recovered **1** and the solution was allowed to stand for 30 hr under the same conditions as in Experiment A. The gas chromatogram of the resultant mixture has the same pattern as that of Experiment B.

D) A solution of **3** (10 mg) in **1** (0.5 ml) containing a drop of liquid hydrogen cyanide was allowed to stand for 10 hr under the same conditions as above. In the gas chromatogram of the resultant mixture, there are two peaks of **7a** and **7b**, and a small peak of **3**. In another experiment involving three drops of liquid hydrogen cyanide, its gas chromatogram has only the peaks of **7a** and **7b** in the same reaction time.

E) A solution of **3** (10 mg) in **1** (0.5 ml) containing a drop of trifluoroboron-diethyl etherate (BF_3: OEt_2) was allowed to stand for 10 min under the same conditions as above. In the gas chromatogram of the resultant mixture, there are two peaks of by-products, two peaks of **7a** and **7b**, and no peak of **3**. In a reaction time of 1 hr, only the peaks of the by-products were detected. The retention volumes of the by-products in glc were 1.1 and crossed soon after (*cf.* **3**=2.1, **7a**=4.8, and **7b**=4.7). The conversion of **7a** and **7b** into the by-products was also confirmed by adding a drop of BF_3: OEt_2 to the solution of **7a** and **7b** in **1** (those substances had been obtained in Experiment B) and by then allowing the mixture to stand for 1 hr under the same conditions.

The authors are grateful to Dr. Masatsune Kainosho, Ajinomoto Co., Inc., and Mr. Katsuhiko Kushida, Nippon Electric Varian, for the measurement and analysis of the NMR spectra, and to Mr. Asao Murai, Ajinomoto Co., Inc., for the measurement of the mass spectra. They are also grateful to Associate Professor Shin Sato, Tokyo Institute of Technology, for the measurement of the ESR spectrum and its analysis, and to the members of the Laboratory of Organic Analysis, Tokyo Institute of Technology, for the elemental analysis.

Dehydrogenation of 2-(1-Cyclohexenyl)cyclohexanone with Palladium Catalyst

Kimiaki IMAFUKU, Junko ODA,* Kenshi ITOH,** and Hisashi MATSUMURA

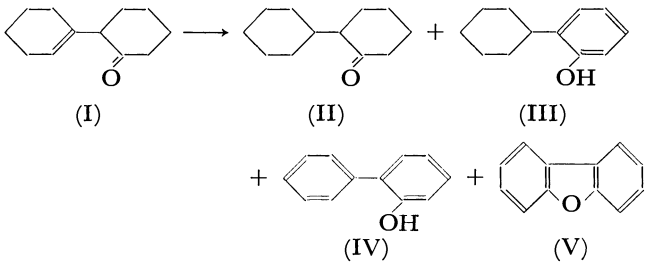
Department of Chemistry, Faculty of Science, Kumamoto University, 2–39–1, Kurokami, Kumamoto 860

(Received September 10, 1973)

The dehydrogenation reaction of 2-(1-cyclohexenyl)cyclohexanone was carried out in the presence of 5% palladium-on-charcoal at temperatures 280, 300, and 320 °C, the reaction time being 1/2—8 hr. *o*-Cyclohexylphenol and *o*-phenylphenol were obtained as dehydrogenation products, and dibenzofuran as the cyclization product *via* *o*-phenylphenol. In a short reaction time, 2-cyclohexylcyclohexanone was formed together with the dehydrogenation products. The compound disappeared, the amount of two phenols and dibenzofuran increasing with reaction time. The dehydrogenation process is discussed.

Many investigations have been made on the dehydrogenation of alicyclic compounds. In order to obtain *o*-phenylphenol, we carried out the dehydrogenation of *o*-cyclohexylphenol with palladium-on-charcoal and found that various rearranged products were obtained together with the desired *o*-phenylphenol.[1]

The present communication deals with the dehydrogenation of 2-(1-cyclohexenyl)cyclohexanone (I), which was unknown up to now, in the presence of the same catalyst under various conditions. Four products obtained in this procedure were confirmed to be 2-Cyclohexylcyclohexanone (II), *o*-cyclohexylphenol (III), *o*-phenylphenol (IV), and dibenzofuran (V).



(I) (II) (III) (IV) (V)

Experimental

Materials. *5% Palladium-on-charcoal*: The palladium catalyst was prepared by the method of Mozingo.[2]

2-(1-Cyclohexenyl)cyclohexanone (I): 2-(1-Cyclohexenyl)-cyclohexanone (I) was prepared[3] by the self-condensation of cyclohexanone with phosphorus pentoxide, and was purified by distillation: bp 103—104 °C/1 mmHg [bp 114—116 °C/3.5 mmHg[4]]; oxime: mp 157—159 °C [mp 155 °C[5]].

2-Cyclohexylcyclohexanone(II): 2-Cyclohexylcyclohexanone (II) was obtained by catalytic hydrogenation of I in the presence of palladium chloride in methanol,[6] and was distilled; bp 145—147 °C/19 mmHg [bp 135 °C/11 mmHg[6]]; oxime: mp 100—102 °C [mp 102 °C[7]]; semicarbazone: mp 176—178 °C [mp 174—177 °C[8]].

Others: *o*-Cyclohexylphenol (III) and *o*-phenylphenol (IV) were supplied by Sanko Chemical Co. Ltd. Commercial dibenzofuran (V) (Tokyo Kasei Kogyo Co. Ltd.) was used.

Dehydrogenation of 2-(1-Cyclohexenyl)cyclohexanone. A mixture of I (2 g) and 5% palladium catalyst (400 mg) was heated at 280, 300, 320 °C under nitrogen atmosphere. At appropriate intervals of time, aliquots taken from the reaction mixtures were dissolved in benzene, and the catalyst was filtered off. The filtrates were analyzed gas chromatographically for determination of the reaction products.

Determination of Products. Quantitative determination of the products was performed gas chromatographically on a Shimadzu Model GC-1C gas chromatograph (column: 3% XE-60/Chromosorb W, 3 mmϕ × 150 cm; temperature 180 °C).

Measurements of Spectra. The IR spectra were recorded on a JASCO Model IRA-1 spectrophotometer in chloroform. The NMR spectra were taken on a Hitachi-Perkin-Elmer Model R-24 (60 MHz) spectrometer, using carbon tetrachloride and tetramethylsilane as the solvent and internal reference, respectively.

Results and Discussion

Dehydrogenation Products. 2-(1-Cyclohexenyl)-cyclohexanone (I) was treated with 5% palladium catalyst at 300 °C for 4 hr under nitrogen atmosphere. The gas chromatogram of the reaction mixture is shown

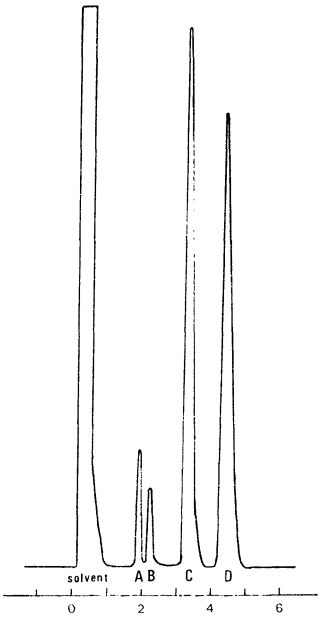


Fig. 1. Gas chromatogram of dehydrogenation products (300 °C, 4 hr).
Column: 3% XE-60/Chromosorb W, 3 mmϕ × 150 cm
temperature: 180 °C, carrier: H_2 32.1 ml/min

* Present address: Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860.

** Present address: Nihon Shokuhin Kako Co., Ltd., Mishima-shi, Shizuoka.

in Fig. 1. The mixture was found to contain four components. It was found that components B, C, and D are identical with dibenzofuran (V), *o*-phenylphenol (IV), and *o*-cyclohexylphenol (III), respectively, in comparison with authentic materials. V was also obtained in the dehydrogenation of III with the same catalyst.[1]

Component A was separated gas chromatographically (column: 3% XE-60/chromosorb W, 10 mmϕ × 75 cm, 150 °C); semicarbazone: mp 175—177 °C. The spectral data for this compound are given in Table 1, together with those of I and II, which were obtained[6] by catalytic hydrogenation of I.

Table 1. Spectral data

Compound	Mp of semicarbazone (°C)	IR (cm^{-1}) $\nu_{C=O}$	IR (cm^{-1}) δ_{CH_2}	NMR δ(ppm)
I	185—187	1734	1450	1.3—3.0 5.28
II	176—178	1730	1450	0.6—2.9
A	175—177	1730	1450	0.6—2.8

Thus, component A was confirmed to be 2-cyclohexylcyclohexanone.

A similar compound, 2,6-dicyclohexylcyclohexanone, was obtained in the dehydrogenation of 2,6-di(1-cyclohexenyl)cyclohexanone.[9,10]

Effects of Reaction Time and Temperature. The dehydrogenation of I was investigated in detail in the presence of 5% palladium-on-charcoal at temperatures 280, 300, and 320 °C for reaction time 1/2—8 hr. The changes in the amount of products obtained at temperatures 300 and 320 °C are shown in Figs. 2 and 3, respectively.

In all cases, increase in the reaction time caused a decrease in the yield of II and an increase in the amount of the phenols (III and IV). The change was remarkable at higher temperature. In particular, at 320 °C, II disappeared rapidly and V increased (47.3% after 8 hr).

Reaction Process. Since II hydrogenated was produced together with III and IV within 30 min, it is thought that dehydrogenation and hydrogenation take place competitively in an initial stage. Subsequently, II was dehydrogenated into III and IV.* The dehydrogenation occurs more readily in the cyclohexanone ring than in the cyclohexene ring.

III was also dehydrogenated into IV. This process has been reported.[1] It is thought that V was formed *via* IV, since it was produced in the dehydrogenation of III and in the cyclization of IV in the presence of palladium catalyst.[1]

* The dehydrogenation of 2-cyclohexylcyclohexanone is in progress. The process was found to give *o*-cyclohexylphenol, *o*-phenylphenol, and dibenzofuran.

Catalytic Hydrogenation of Cyclic Olefins on Nickel Catalysts*

Masatsugu KAJITANI, Yoshiaki SASAKI, Junko OKADA, Kazuo OHMURA, Akira SUGIMORI, and (the late) Yoshiyuki URUSHIBARA

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received October 23, 1973)

The catalytic hydrogenation of cyclic olefins was investigated over various nickel catalysts. The hydrogenation of cyclohexene was promoted by basic reaction conditions and depressed by acidic ones, the hydrogenation of cyclooctene being only slightly influenced by the acidity. The results of competitive hydrogenation indicate that cyclooctene is adsorbed more strongly on nickel catalysts than cyclohexene. The external olefinic bond is preferentially hydrogenated to the internal olefinic bond.

Cycloalkenes show different reactivities in catalytic hydrogenation, depending on the ring size. Jardine and McQuillin found that, over a Pd-charcoal catalyst, the rate of hydrogenation is linear with respect to the heat of hydrogenation, the rates of hydrogenation being of the order: cyclohexene>cyclopentene>cyclooctene.[1] In the case of nickel catalysts, Brown[2] and Brown and Brown[3] reported the order to be: cyclopentene>cyclohexene>cyclooctene (over R-Ni catalyst), cyclopentene>cyclooctene>cyclohexene (over P-1 Nickel Boride catalyst, abbreviated to P-1 Ni_2B).

We have investigated the hydrogenation of cycloalkenes with Urushibara type nickel catalysts, the preparation conditions of which are widely variable. We also studied the effects of added alkali and acid, and the competitive hydrogenation of cycloalkenes. The results were compared with those of other nickel catalysts.

They might provide some insight into the nature of catalysts and the behavior of cycloalkenes in catalytic hydrogenation.

Experimental

Materials. Commercial cyclohexene (Tokyo Kasei, Reagent Grade) and cyclooctene (Wako Pure Chemical Industry, Reagent Grade) were distilled at 83.5 °C and 63 °C/62 mmHg. Reagent Grade cyclopentene, 4-vinylcyclohexene, 1-methylcyclohexene, 3-methylcyclohexene, and 4-methylcyclohexene (Wako Pure Chemical Industry) were used without further purification.

The samples were proved to be pure by gas-chromatography. Trace amounts of methylcyclohexene contaminants were detected by gas-chromatography.

Commercial ethanol was carefully distilled and used as the solvent of hydrogenation.

Catalysts. Urushibara type nickel catalysts were prepared by simplified methods[4] Ppt-Ni was easily prepared by adding 4.04 g of powdered nickel chloride ($NiCl_2 \cdot 6H_2O$) to 10 g of zinc dust suspended in 4 ml of distilled water under vigorous stirring. This was filtered off, washed with about 200 ml of hot distilled water previously degassed by boiling and then with EtOH.

U-Ni-N catalyst was prepared by refluxing ppt-Ni with 30 ml of isopropyl alcohol for two hours under stirring.[5]

Urushibara type nickel catalysts prepared by simplified methods are usually distinguished from ordinary catalysts by the bracketed letter (s) [U-Ni-A (s) or U-Ni-B (s)].[4,6] However, (s) has been omitted in this paper.

R-Ni(W-7 type) catalyst was prepared by the method of Adkins and Billica.[7]

Nickel Boride catalyst (Ni_2B) was prepared as reported by Paul *et al.*, by reducing nickel chloride with sodium borohydride in aqueous solution.[8]

After these catalysts had been subjected to hydrogenation, they were washed throughly with distilled water to completely remove alkali or acid, and several times with ethanol to remove contamination in the water. In particular, U-Ni-B, R-Ni and Ni_2B were sufficiently washed with water until the washings were neutral to phenolphthalein.

The catalysts thus prepared contain about 1 g of Ni.

Hydrogenation. The substrate (0.01 mol) was hydrogenated with various nickel catalysts in 20 ml of ethanol at 30 °C and atmospheric pressure in a glass bottle shaker at 300—350 strokes per minute.

Addition of alkali or acid was carried out before the catalyst was saturated with hydrogen gas. The amounts of alkali and acid added were 0.3 ml of 10% NaOH and 0.5 ml of 13% CH_3COOH, respectively. The amount of alkali added to U-Ni-A was so chosen as to make the solution faintly alkaline to phenolphthalein, as reported by Nishimura.[9]

The rate of hydrogenation was expressed in terms of the initial rate of hydrogen uptake in the region of 0 to about 20% hydrogenation, in which the hydrogen uptake curve was approximately linear.

Analysis of Reaction Mixture. The reaction mixture resulting from the competitive hydrogenation of a mixture of cyclohexene (0.01 mol) and cyclooctene (0.01 mol) was collected at about 100 ml of hydrogen uptake, and subjected to gas-chromatographic analysis as soon as possible. A column of 20% PEG 20M on Celite 545 (column temperature: 56 °C) was used.

Results and Discussion

Effect of Ring Size. In order to investigate the characteristics of nickel catalysts prepared by various methods, the hydrogenation of cyclopentene, cyclohexene, and cyclooctene was carried out at 30 °C under atmospheric pressure. The results are summarized in Table 1. The activities of the catalysts used were compared in terms of the initial rate of hydrogen uptake.

The rates of hydrogenation with U-Ni-A, U-Ni-B, and ppt-Ni were found to be in the order: cyclopentene>cyclohexene>cyclooctene (Nos. 1, 4, and 6,

* A part of the present work was presented at the 27th Annual Meeting of the Chemical Society of Japan, Nagoya, October 12th, 1972. Abstract of Paper, Vol. 2, p. 359.

12	Ni_2B+B[c]		49	44	1.1

a) r_1=(rate of cyclohexene/rate of cyclooctene). b) A: 0.5 ml of 13% CH_3COOH. c) B: 0.3 ml of 10% NaOH. d) Prepared by refluxing ppt-Ni with *i*-PrOH (30 ml) for 2 hr.

Table 1). The order is the same as that with Raney nickel catalyst.[2,3] However, the relative reactivities varied depending on the method of preparation. When the hydrogenation is performed over U-Ni-B, the difference in reactivities is the greatest, while hydrogenation over ppt-Ni gives a rate of hydrogenation of cyclohexene similar to that of cyclopentene.

This could be explained by the change of the catalyst surface by acid and alkali. U-Ni-A catalyst can be subjected to hydrogenation under practically neutral conditions since acetic acid adsorbed on U-Ni-A can be removed easily by washing. On the other hand, sodium hydroxide adsorbed on U-Ni-B cannot be removed completely by washing with water, even if washing is repeated as often as necessary until the washings are no longer alkaline to phenolphthalein.

In order to confirm the role of acid and alkali, the effects of added alkali or acid on the rates of hydrogenation of cyclohexene and cyclooctene were investigated in detail. It was found that the rate of hydrogenation of cyclohexene is remarkably influenced by added acid or alkali, while the hydrogenation of cyclooctene is influenced to a lesser extent (Nos. 2 and 3, Talbe 1). U-Ni-B of basic character exhibited higher activity for cyclohexene than U-Ni-A of neutral character. On the other hand, cyclooctene was hydrogenated by U-Ni-A and U-Ni-B at a comparable rate.

The ratio of the rate of hydrogenation of cyclohexene to that of cyclooctene over U-Ni-A added alkali (abbreviated to U-Ni-A+B) is 3.3, and the value is similar to that of U-Ni-B. This suggests that the behavior of the U-Ni-B catalyst is due to the presence of sodium hydroxide used as the digesting agent. In the case of U-Ni-A added acid (abbreviated to U-Ni-A+A), cyclooctene was hydrogenated more easily than cyclohexene (an inversion in reactivity). Ppt-Ni, the precursor of the Urushibara nickel catalyst, behaves similarly to U-Ni-B. The U-Ni-N catalyst prepared by refluxing ppt-Ni with *i*-PrOH exhibited also a high reactivity to cyclohexene.[5]

R-Ni(W-7 type), which was well washed until the washings were no longer alkaline to phenolphthalein, behaved similarly to U-Ni-A. With R-Ni, the effect of added alkali was similar to that with U-Ni-A catalyst.

Nickel boride catalyst (Ni_2B), prepared according to Paul *et al.*[8] by reducing nickel chloride with sodium borohydride in aqueous solution and then washing until the washings were no longer alkaline to phenolphthalein, exhibited approximately the same catalytic activity in the hydrogenation of cyclohexene and cyclooctene.

It was confirmed that the effects of alkali or acid on the rate of hydrogenation of cyclohexene and cyclooctene were the same for Ni_2B as for the U-Ni-A catalyst.

As regards hydrogenation performed over various types of nickel catalysts, the activity for hydrogenation of cyclohexene is promoted by alkali and inhibited by acid, while the hydrogenation of cyclooctene is influenced slightly by alkali or acid.

Apparent Activation Energy. The rates of hydrogenation of cyclohexene and cyclooctene (Table 1) are comparable with the apparent activation energies of the hydrogenation of cyclohexene and cyclooctene in the presence of U-Ni-A, U-Ni-B, and ppt-Ni (Table 2).

TABLE 2. APPARENT ACTIVATION ENERGIES OF HYDROGENATION OF CYCLOHEXENE AND CYCLOOCTENE

Cyclohexene; 0.01 mol, cyclooctene; 0.01 mol, solvent; EtOH 20 ml, Ni content of catalysts; U-Ni-A and U-Ni-B 1 g, ppt-Ni 2 g, hydrogenation temperature; 30—50 °C

8	Ni_2B	16.3	43.8	0.37	0.38
9	Ni_2B+A[d]	4.8	38.1	0.13	0.35
10	Ni_2B+B[e]	18.4	33.2	0.55	0.50

a) yield of hydrogenation products at about 20% of hydrogen uptake. b) r_2=(yield of cyclohexane/yield of cyclooctane). c) [product ratio (r_2)/rate ratio (r_1)]. d) A: 0.5 ml of 13% CH_3-COOH. e) B: 0.3 ml of 10% NaOH. f) prepared by refluxing ppt-Ni with *i*-PrOH (30ml) for 1 hr.

ppt-Ni, cyclooctene gave a greater activation energy than cyclohexene. In the case of U-Ni-B, the presence of a small amount of alkali can lower the activation energy of the hydrogenation of cyclohexene. U-Ni-B and U-Ni-N have a similar behavior toward cyclohexene and cyclooctene as regards the rate and activation energy. This suggests a resemblance in the surface character of the catalysts.

Competitive Hydrogenation. The competitive hydrogenation of a mixture of cyclohexene and cyclooctene with various nickel catalysts was carried out in order to obtain further information on the selectivities of catalysts.

Competitive hydrogenation has been reported on olefins[11] and nitrobenzenes,[12] the results of which give information on the selectivity in adsorption.

The selectivity in the competitive reaction was obtained by comparing the product ratio (r_2), that is, yield of cyclohexane/yield of cyclooctane, at about 20% of hydrogen uptake,[13] with the rate ratio (r_1) obtained in individual hydrogenation. The value (product ratio/rate ratio; r_2/r_1) is used as a measure for the strength of adsorption. The results are summarized in Table 3.

We see that cyclooctene is more slowly hydrogenated than cyclohexene (No. 1, Table 1). However, in competitive hydrogenation, cyclooctene which is more strongly adsorbed on the catalyst is preferentially hydrogenated.

Though the rates of hydrogenation of cyclohexene and cyclooctene are dependent upon the catalysts and the addition of acid or alkali, it was found that the values (r_2/r_1) in the adsorption of cyclohexene and cyclooctene is approximately equal in all cases except U-Ni-N. Cyclooctene is twice as strongly adsorbed as cyclohexene. The character of U-Ni-N, which exhibits a different selectivity of adsorption from other catalysts, showed lower double bond migration in the hydrogenation of 1-octene.[5]

Hydrogenation of Methylcyclohexenes. The hydrogenation of methylcyclohexenes was studied in some detail (Table 4).

Table 4. Hydrogenation of methylcyclohexenes (0.01 mol) at 30 °C under atmospheric pressure

Solvent: EtOH 20 ml, Ni content of catalyst: 1 g

	Initial rate of H_2 uptake (ml/min)			
	(Cyclohexene)	4-Me	3-Me	1-Me
U-Ni-A	27	12	8	2
U-Ni-A+A[a]	7	5	3	1
U-Ni-A+B[b]	32	21	20	2
U-Ni-B	55	36		4

a) 0.5 ml of 13% CH_3COOH. b) 0.3 ml of 10% NaOH.

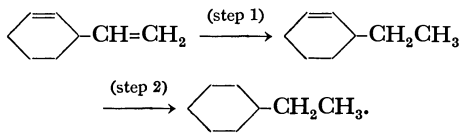
The rate of hydrogenation of cyclohexene was depressed by introducing methyl groups. The effect was in the order: 4-methyl<3-methyl≪1-methyl. 1-Methylcyclohexene could be hydrogenated only at a very small rate. This is probably explained by steric hindrance in the adsorption.

It was found that the rates of hydrogenation of 4-methylcyclohexene and 3-methylcyclohexene are accelerated by added alkali and inhibited strongly by added acid.

Hydrogenation of 4-Vinylcyclohexene (Fig. 1). The difference in reactivity between the internal olefin (cyclohexene ring) and the external olefin (vinyl group) was investigated in the hydrogenation of 4-vinylcyclohexene.

The hydrogen uptake curves at 30 °C under atmospheric pressure are shown in Fig. 1.

Hydrogenation of 4-vinylcyclohexene proceeds stepwise as follows:



The hydrogen uptake curve exhibits a break at an

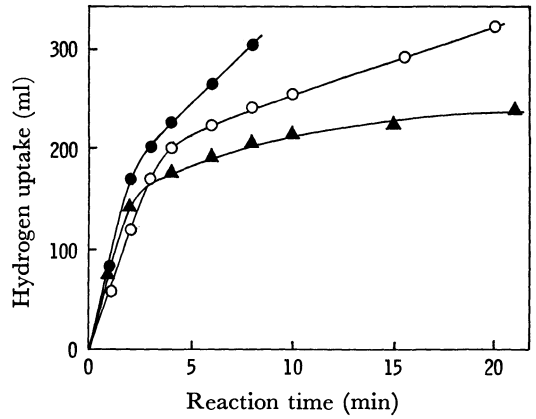


Fig. 1. Hydrogenation of 4-vinylcyclohexene (1 ml) over Urushibara type catalysts in EtOH (20 ml) at 30 °C under atmospheric pressure. Ni content of catalysts: 1 g ●: U-Ni-B, ▲: U-Ni-A, ○: ppt-Ni

uptake of 1.0 mol of hydrogen. After the uptake of 1.0 mol of hydrogen, glc analysis showed that the vinyl group had been almost completely hydrogenated. Brown has reported that the selective hydrogenation of 4-vinylcyclohexene takes palce with the P-1 Ni_2B catalyst.[2)]

The rates of hydrogenation at each step are as follows: step 1, U-Ni-B>U-Ni-A>ppt-Ni; step 2, U-Ni-B>ppt-Ni>U-Ni-A.

It is noted that ppt-Ni catalyst differs from U-Ni-A catalyst in the rate of hydrogenation at step 2, *viz.*, at the hydrogenation of cyclohexene ring. The above facts suggest that ppt-Ni exhibits characteristics similar to those of U-Ni-B which exhibits a high activity for cyclohexene owing to its basic character, as is expected from the results of cyclohexene hydrogenation and the apparent activation energy.

The authors wish to thank Dr. Shigeo Nishimura, Tokyo University of Agriculture and Technology, for his valuable suggestions.

Regio- and Stereo-selectivities in the Epoxidations of Limonene, *endo*-Dicyclopentadiene, and *exo*-Dicyclopentadiene

Tadashi SATO and Eigoro MURAYAMA

Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo 160

(Received November 2, 1973)

The regio- and stereo-selectivities were observed in the radical and peracid epoxidations of limonene, *endo*-, and *exo*-dicyclopentadienes. The observations were considered in view of the proposed mechanisms for these reactions.

It has been believed that the epoxidation by molecular oxygen of olefin induced by a radical initiator proceeds through a peroxy-radical attack to open the double bond,[1] while the epoxidation by peracid proceeds through an electrophilic attack of the peracid oxygen to make a three-membered cyclic transition state.[2] In our experiments connected with studies of the unsensitized photooxidations of limonene and dicyclopentadienes,[3] we observed substantial regio- and stereo-selectivities in the radical and peracid epoxidations. These observations were then considered in the light of the proposed mechanisms.

Results

Limonene (**1**), *endo*-dicyclopentadiene (**2**), and *exo*-dicyclopentadiene (**3**) were oxidized with molecular oxygen at 40—60 °C (Ox I) and with peracid (Ox II). The epoxides **4**—**10** were isolated in pure states by preparative gas chromatography, and the product identification was carried out spectroscopically (see Experimental Section). The ratios of the regioisomers in each case were calculated; they are shown in Table 1.

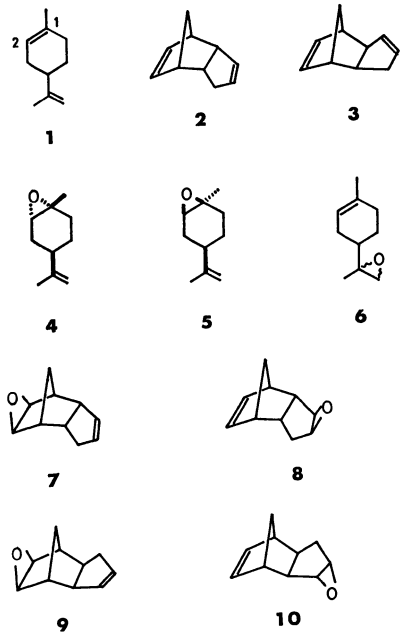

Table 1. Product ratios in the epoxidations of **1**–**3**

	(4+5)/6	7/8	9/10
Ox I	4.8	7.0	7.4
Ox II	14.0	1.3	3.7

Discussion

It was found that the 1,2-epoxidation of **1** by the radical-initiated oxidation proceeds in quite a stereoselective manner, affording mainly the *trans*-isomer **4**.* This result should be contrasted with that of the peracid epoxidation, where a 1 : 1 mixture of *trans*- and *cis*-isomers (**4** and **5**) has been obtained.[6] This observation can now be interpreted in terms of the general pattern of radical attack on 4-substituted cyclohexene.[7]

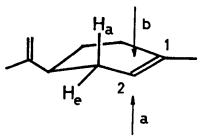

Fig. 1.

Presumably, the initial attack of the peroxy radical occurs at C-2 rather than at C-1 in view of Markownikov's principle (Fig. 1). The a-attack (*trans* to isopropenyl) at C-2 would be preferable to the alternative b-attack, since the b-attack creates a larger energy by its interference with the neighboring quasi-axial hydrogen (H_a), thus leading to the more unfavorable twisted-boat transition state. This type of attack can reasonably be said to lead to the preferential formation of **4** over **5**, as has actually been observed.

As is revealed by Table 1, the relative reactivity of each double bond in **1**—**3** was characteristic of the oxidation method. With **1**, the regioselectivity was observed in Ox II, while with **2** and **3**, the selectivity was observed to a larger extent in Ox I. These observations can be explained by the following consideration. The epoxidation with peracid has been interpreted as proceeding by an electrophilic attack of peracid oxygen on the double bond, thus producing a three-membered cyclic transition state.[2] It has generally been accepted that, in the reactions proceeding through a four-, five-, or six-membered cyclic transition state, the reactivity of a strained double bond is greatly enhanced as compared with that of a strain-free double bond, because a great deal of strain-energy release is expected in the transition state, while in the reaction proceeding through a three-membered cyclic transition state, scarcely any strain-energy release is expected in the transition state, and the strain present in the double bond can not play a very important role

* A previous experiment dealing with this problem has not led to any definite result.[4] A non-stereospecific radical epoxidation has, however, been reported with α-terpineol.[5]

in the reactivity.[8] Evidently, each double bond in **1** is characterized mostly by its electron density rather than by its strain energy, while the situation is reversed with **2** and **3**, since the double bond in the norbornene moiety is confined under strained circumstances. In the Ox II of **1**, where the reactivity of the double bond is determined mostly by the electron density, three-substituted olefin would be epoxidized preferentially over the two-substituted olefin, and a high selectivity should result. The selectivity would be reduced with Ox I, since there is little difference in strain energy between the two double bonds in **1**. The minor preference for the formation of **4** and **5** over **6** is probably a reflection of the electrophilic nature of the radical reaction.[9]

Contrary to the results with **1**, we observed a substantial regio selectivity in Ox I with **2** and **3**. Evidently the radical epoxidation *via* double-bond opening proceeds much faster with a double bond of strained norbornene. In Ox II, however, there was little selectivity between the two double bonds. A slight preference in the reactivity of norbornene double bond, particularly with **3**, induces us to picturize the transition state as involving a *loose* three-membered cyclic ring, thus affording an additional, although small, energy of strain release. The extreme low **7**/**8** ratio with **2** may be considered as a consequence of π-interaction through the space between the two double bonds in **2**, which interaction is evidently lacking in **3**.[10]

Experimental

Only experiments which do not overlap with those reported in our previous paper[3] are described here.

Starting Material. **3**: Prepared according to the method reported by Bartlett.[11]

Peracid Oxidation. Olefin (0.5 g) and perbenzoic acid (0.5 g) were dissolved in chloroform (6 ml) and stirred for 12 hr at 0 °C.

Product Identification. **5**: IR; Identical with the reported.[6] NMR; δ 1.25 (3H, s), 1.67 (3H, s), 2.85 (1H, d), and 4.65 (2H, s). **9**: IR; 1620 and 850 cm^{-1}. NMR; δ: 1.75 (2H, ABq, *endo*-methylene with an anisotropic effect by the epoxy ring), 2.96 (2H, s), and 5.43 (2H, m). **10**: IR; 1572 and 840 cm^{-1}. NMR; δ 1.40 (2H, b.s, *endo*-methylene), 3.10 (1H, d), 3.43 (1H, t), and 6.06 (2H, b.s).

The Photo-Fries Rearrangement of Aryloxy-1,3,5-triazines

Yukio OHTO, Haruo SHIZUKA, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received November 2, 1973)

Aryloxy-*s*-triazines gave *o*- and/or *p*-hydroxyaryl-*s*-triazines upon irradiation; however, from arylamino- and arylthio-*s*-triazines, no photo-rearrangement product was obtained. The *p*-CH_3, *p*-Cl, and *p*-OCH_3 groups in the phenoxy moiety did not prevent the photoreaction of aryloxy-*s*-triazines; however, the *p*-CHO, *p*-$COCH_3$, *p*-$COOC_2H_5$, and *p*-NO_2 groups prevented the photoreaction. As to substituents in the *s*-triazine moiety, such groups as –Cl, $-OCH_3$, $-OC_6H_5$, and $-CH_3$ did not prevent the photoreaction; however, C_6H_5 and amino groups prevented the reaction. In the photolysis of 2,4-dimethoxy-6-(1-naphthyloxy)-*s*-triazine, 1-hydroxy-2-naphthyl- and 4-hydroxy-1-naphthyl-*s*-triazines were obtained, with the preferential formation of the former. On the other hand, from 2,4-dimethoxy-6-(2-naphthyloxy)-*s*-triazine, 2-hydroxy-1-naphthyl-*s*-triazine was obtained upon irradiation. In a similar manner, 2- and 4-acetyl-1-naphthols were obtained from 1-naphthyl acetate, and 1-acetyl-2-naphthol was isolated from 2-naphthyl acetate.

The photo-Fries rearrangement has been extensively investigated; the mechanism of the reaction and some of the substituent effects have been revealed with the reactions of *O*-acyl-phenols and *N*-acyl-anilines.

Recently, we have reported that aryloxy-dimethoxy-*s*-triazines rearrange photochemically to give the corresponding *o*- and/or *p*-hydroxyaryl-*s*-triazines.[1] The reaction had been found to proceed *via* a radical process. However, the characteristics of the *s*-triazinyl moiety as a migrating group and the relations between the chemical constitutions and the photoreactivities have not been revealed. In addition, aryloxy-*s*-triazines containing various substituents in the aryloxy and *s*-triazine moieties are readily available by the condensation of aryloxy-halo-*s*-triazines with nucleophiles or by the reaction of halo-*s*-triazines with phenolates. Therefore, if the photo-Fries rearrangement of aryloxy-*s*-triazines takes place regardless of substituents in the aryloxy and *s*-triazine moieties, this photoreaction may provide a useful and convenient route for the syntheses of various hydroxyaryl-*s*-triazines. This paper will report the substituent effects on the photo-Fries rearrangement of phenoxy-*s*-traizines and naphthyloxy-*s*-triazines; the function of the *s*-triazinyl group for the reaction will also be discussed.

Experimental

Materials. Aryloxy-*s*-triazines were prepared by the condensation of phenolates with cyanuric chloride in the usual way,[2] followed by treatment with nucleophiles. The compounds thus obtained are listed in Table 1.

The experimental procedure and solvents were almost the same as those previously described.[1] A low-pressure mercury lamp was used as the 254 nm radiation source. After long irradiation at 254 nm, the reaction mixture was concentrated and the photo-products were separated and purified by column chromatography.

The identification of the photo-products was performed by means of their NMR, IR, UV, and MS spectra, by elemental analyses, and by studying the solubility in an alkaline solution.

Results and Discussion

Scope of the Photo-Fries Rearrangement of s-*Triazine Derivatives.* It is well known that not only *O*-acyl-phenols,[3] but also *N*-acyl-anilines,[4] rearrange photochemically to yield the corresponding ketones. Thus, in the cases of *s*-triazine derivatives, the photolysis was investigated not only with aryloxy-*s*-triazines, but also with arylamino- and arylthio-*s*-triazines. However, such an attempt with arylamino-*s*-triazines was unsuccessful, regardless of the substituents in the *s*-triazine and aniline moieties; ordinary arylamino-*s*-triazines are stable on irradiation with UV light. On the other hand, dimethoxy-phenylthio-*s*-triazine showed a complex spectral change on irradiation, and it had no isosbestic point. Thus, it may be said that, among the arylamino-, aryloxy-, and arylthio-*s*-triazines, the aryloxy derivative is the sole *s*-triazine compound capable of yielding photo-rearrangement products.

*Effects of Substituents on the Photo-Fries Rearrangement of Phenoxy-*s*-triazines.* As preliminary experiments, the reactivities for the photoreaction of all the phenoxy-*s*-triazines listed in Table 1 were checked by measuring their spectral change with the lapse of time at 254 nm in cyclohexane and ethanol. As a result, the progress of the photoreaction of aryloxy-*s*-triazines was found to depend significantly upon the substituents in the aryloxy and *s*-triazinyl groups.[5] The *p*-CH_3, *p*-Cl, and *p*-OCH_3 groups in the phenoxy moiety did not prevent the progress of the photoreaction; however, when electron-withdrawing groups such as *p*-CHO, *p*-$COCH_3$, *p*-$COOC_2H_5$, and *p*-NO_2 were introduced into the phenoxy moiety, the photoreaction did not take place.

As for substituents in the *s*-triazine nucleus, although the overall effect varied with the combination of two substituents, such substituents as –Cl, $-OCH_3$, $-OC_6H_5$, and $-CH_3$ did not prevent the photoreaction. Thus, any aryloxy-*s*-triazines containing any two of these substituents underwent the photo-rearrangement readily. It is known[6] that the derivatives of halo-*s*-triazine dissociate into the halogen atom and the *s*-triazinyl radical in benzene to give *s*-triazinylbenzene on irradiation. However, *s*-triazine derivatives containing both chloro and aryloxy substituents are preferentially rearranged photochemically to give hydroxyaryl-chloro-*s*-triazines. On the other hand, the phenyl group and such substituents as $-NH_2$, $-NHCH_3$, $-N(CH_3)_2$, and $-NHC_6H_5$ prevented the reaction very much.

In order to make clear the effects of the substituents

in the *s*-triazine nucleus quantitatively, the quantum yields for the product formation were measured with several aryloxy-*s*-triazines. The results are shown in Table 2. From Table 2 it is obvious that the introduction of amino groups into the *s*-triazine nucleus hinders the photoreaction; in the experimental results it can be seen that, regardless of the substituents, the more positive the $\sigma_mX+\sigma_mY$ value in Table 2 becomes, the larger the quantum yield for the product formation becomes. These facts indicate that the progress of the photo-rearrangement depends mainly upon the electron-attracting ability of the *s*-triazine moiety. However, this apparent relation does not hold in every case; aryloxy-phenyl-*s*-triazine did not rearrange photochemically even though the phenyl group ($\sigma_m=+0.06$) is an electron-attractive substituent. If the reaction mechanism of the photo-Fries rearrangement is kept in mind, the question of the substituent effects may be solved. In general, the photo-Fries rearrangement occurs *via* the predissociation originated from $S_1(\pi\pi^*)$ $^1B_2$ (or ^1L_b), involving the β-bond fission of benzene derivatives.[1,7] The photochemical primary process of aryloxy-*s*-triazine originates from the lowest excited singlet state, $^1B_2$, which corresponds to the $^1B_{2u}$ state of benzene.[1] The reactivity in the photo-Fries rearrangement is dependent upon the electronic character of the lowest excited singlet state in a benzene derivative. The absorption spectrum of aryloxy-phenyl-*s*-triazine is very close to that of 2,4-dimethoxy-6-phenyl-*s*-triazine. Thus, the lowest absorption band of the molecule may be assigned to $^1L_a\leftarrow{}^1A$ (not to $^1L_b\leftarrow{}^1A$), considering the structureless band at 255 nm with $\varepsilon=2.25\times10^4$, just like that of biphenyl.[8] This band ($^1L_a\leftarrow{}^1A$) masks the photoreactive band ($^1B_2\leftarrow{}^1A_1$), and the $^1B_2$ state is not the lowest $\pi\rightarrow\pi^*$ singlet state, resulting in the significant decrease in the β-bond fission.

The introduction of electron-donating substituents such as amino groups into the *s*-triazine nucleus results in a bathochromic shift of the $\pi\rightarrow\pi^*$ band in *s*-triazine and a slight hypsochromic shift of the $n\rightarrow\pi^*$ band.[9a] The amino substituent increases the intensity of the lowest singlet $\pi\rightarrow\pi^*$ band in *s*-triazine, whose transition is symmetry-forbidden.[9b] Furthermore, the $^1A_1\leftarrow{}^1A_1$ band in aryloxy-*s*-triazine, with an amino group in the *s*-triazine nucleus, is assumed to be large enough to overlap the $^1B_2\leftarrow{}^1A_1$ band of the aryloxy group.[5] In fact, the vibrational structure in the $^1B_2\leftarrow{}^1A_1$ band disappears, in contrast to that of 2,4-dimethoxy-6-

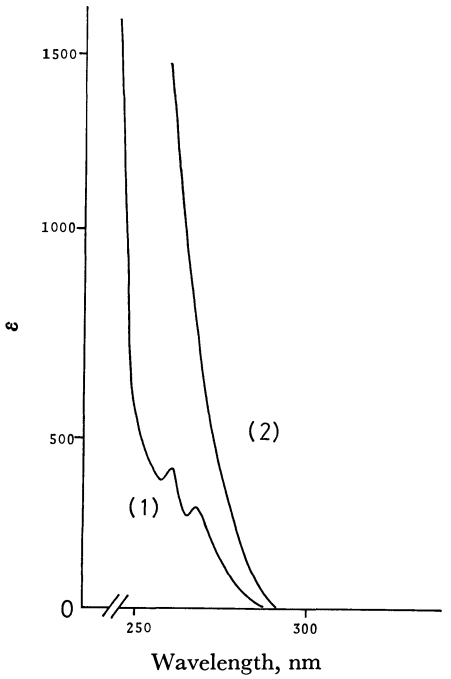

Fig. 1. UV spectra of 2,4-dimethoxy-6-phenoxy-*s*-triazine (1) and 2,4-bis(dimethylamine)-6-phenoxy-*s*-triazine (2).

phenoxy-*s*-triazine, as is shown in Fig. 1. Thus, the amino substituent in the *s*-triazine nucleus considerably lowers the quantum yield, as is shown in Table 2.

As has been mentioned above, the presence of an electron-withdrawing group such as *p*-NO_2, *p*-$COCH_3$, *p*-CHO, or *p*-$COOC_2H_5$, in the phenoxy moiety prevented the photo-rearrangement almost completely; it may be said that the predissociation at a β-band is difficult, because the $n\pi^*$ singlet state, which corresponds to the excitation from the non-bonding orbital in these substituents to the π^* molecular orbital, is the lowest excited singlet state in these cases (except for *p*-$COOC_2H_5$).

When more than two aryloxy groups are present in an *s*-triazine nucleus, the reaction stops at the stage of the rearrangement of one of the aryloxy groups, as in the photoreaction of tris(*p*-tolyloxy)-*s*-triazine to give 2-(5-methyl-2-hydroxyphenyl)-4,6-bis(*p*-tolyloxy)-*s*-triazine; *o*-hydroxyaryl-*s*-triazines are generally very stable on irradiation,[10] and *s*-triazine derivatives containing more than two *o*-hydroxyaryl groups could not be obtained by this photo-reaction.

Since *o*- and/or *p*-hydroxyaryl-chloro-*s*-triazines can be obtained in good yields by the photolysis of aryloxy-chloro-*s*-triazines, from these compounds a number of *o*- and *p*-hydroxyaryl-*s*-triazines including compounds which can not be obtained by the direct photolysis of the corresponding aryloxy-*s*-triazines were prepared by treatment with nucleophiles. There are several methods for the preparation of *o*- and *p*-hydroxyaryl-*s*-triazines.[10] Among these methods, the Friedel-Crafts *s*-triazinylation of phenols is assumed to be the most convenient; however, there are some limitations. For example, by the reaction with halo-*s*-triazines in the presence of aluminium chloride, only phenols with high reactivities towards electrophiles condense to give the desired products.[11] Therefore, the photo-Fries rearrangement of aryloxy-chloro-*s*-triazines, followed by treatment with nucleophiles, may be a novel and general convenient method for the preparation of various hydroxyaryl-*s*-triazines. Table 3 lists the *o*- and *p*-hydroxyaryl-*s*-triazines prepared directly or indirectly by the photo-Fries rearrangement.

Photo-rearrangements of Naphthyloxy-s-triazines. From the standpoint of studying the effect of the aryloxy moiety on the photo-rearrangement of aryloxy-*s*-triazines, some photo-reactions of naphthyloxy-*s*-triazines have been carried out. There have been many studies

of the Fries-rearrangement of *O*-acyl-naphthols;[12] however, little is known about their photo-reactions. Recently, the photolysis of 2-naphthyl ester with a high-pressure mercury lamp to give 2-naphthol[13] and the γ-radiolysis of 2-naphthyl acetate to give 1-, 6-, and 8-acetyl-2-naphthols and 2-naphthol[14] have been reported. However, no photo-Fries rearrangement of *O*-*s*-triazinyl-naphthols has been reported.

In the photolysis of 2,4-dimethoxy-6-(1-naphthyloxy)-*s*-triazine at 254 nm in ethanol, 2,4-dimethoxy-6-(1-hydroxy-2-naphthyl)-*s*-triazine, 2,4-dimethoxy-6-(4-hydroxy-1-naphthyl)-*s*-triazine, and α-naphthol were obtained, while only 2,4-dimethoxy-6-(2-hydroxy-1-naphthyl)-*s*-triazine was obtained as a rearrangement product, together with β-naphthol, from 2,4-dimethoxy-6-(2-naphthyloxy)-*s*-triazine, as is shown in Tables 4 and 5.

As has been mentioned in a previous paper,[1] in the photo-Fries rearrangement of 2,4-dimethoxy-6-phenoxy-*s*-triazine the quantum yields for the product formation are parallel to the odd π electron densities of the phenoxy radical, as is shown below, where Φ_o and Φ_p denote the quantum yields for the formation of *o*- and *p*-hydroxyphenyl derivatives and where ρ_o and ρ_p denote the odd π electron densities on the *ortho* and *para* positions in the phenoxy radical

$$0.5\Phi_o/\Phi_p = \rho_o/\rho_p \approx 0.5$$

The values of ρ_p and ρ_o are 0.125 and 0.25 respectively, as reported by Muller *et al.*[15]

In Fig. 2 are shown the calculated values of the odd π electron densities of the 1- and 2-naphthyloxy radicals

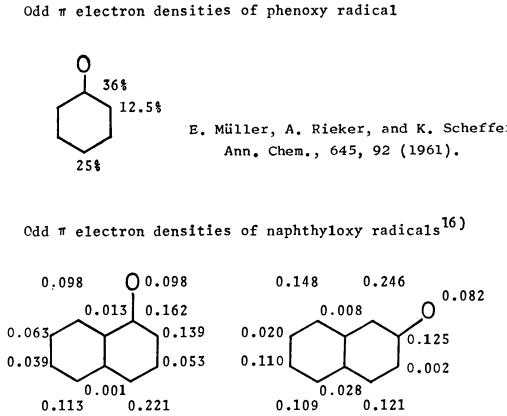

Fig. 2. Odd π electron densities of phenoxy radical and odd π electron densities of naphthyloxy radicals.[16]

obtained using the semi-empirical SCF-MO method.[16] From these values, the formation of 2-, 4-, and 5-*s*-triazinyl derivatives from 1-naphthyloxy-*s*-triazine and the formation of 1-, 6-, and 8-*s*-triazinyl derivatives from 2-naphthyloxy-*s*-triazine may be expected. However, the photoproducts from 1-naphthyloxy-*s*-triazine were the 2- and 4-*s*-triazinyl derivatives, while in the case of the 2-naphthyloxy derivative, 1-*s*-triazinyl derivative was obtained as the sole photo-rearrangement product. The result of these reactions tempted us to check the photoreaction of ordinary naphthyl esters. In a similar manner, in the photoreactions of 1-naphthyl acetate, 2- and 4-acetyl-1-naphthols were obtained, while 1-acetyl-2-naphthol was isolated from 2-naphthyl acetate. Thus, in the cases of naphthyloxy-*s*-triazines and naphthyl esters, the experimental results on isomer distribution did not agree with the calculated values of the odd π electron densities of naphthyloxy radicals; in addition, no acyl or *s*-triazinyl derivative of the adjacent aromatic nucleus was obtained, unlike the case of the ordinary Fries rearrangement of *O*-acetyl-2-naphthol to give 1- and 6-acetyl-2-naphthols.[17] When the 1-position of *O*-*s*-triazinyl-2-naphthol was occupied by another substituent, such as the methyl group, only a small amount of 1-methyl-2-naphthol was formed upon irradiation; most of the starting material was recovered, in spite of the expectation that *s*-triazinylated products at remote positions of high odd π electron densities of 2-naphthol would be formed.

1-Hydroxy-2-acetylnaphthalene (*o*-)	41	1.5
4-Hydroxy-1-acetylnaphthalene (*p*-)	27	
(1-Naphthol)	18	
2-Naphthyl acetate	—	
2-Hydroxy-1-acetylnaphthalene	67	
(2-Naphtol)	20	

In Table 4 the quantum yields for the product formation in the reactions of naphthyloxy-*s*-triazines are listed. From these results, it is obvious that, in the photoreaction of 1-naphthyloxy-*s*-triazine, the ratio

of the quantum yields for the *ortho* and *para* rearrangements [Φ_O/Φ_P (1.3)] differs considerably from that of the odd π electron densities of the 1-naphthyloxy radical [ρ_O/ρ_P (0.63)]; in the case of the 1-naphthyloxy radical, even though the calculated value of the odd π electron density at the 4-position is larger than that at the 2-position, the quantum yield for the rearrangement to the latter was larger than that to the former. A similar relation was also observed in the photoreaction of *O*-acetyl-1-naphthol, suggesting that the preferential formation of the *ortho* isomer generally holds in the photo-rearrangement of derivatives of the *O*-acyl-1-naphthol type. The preferential formation of the *ortho* isomer in these cases is of interest from the viewpoint of the synthesis of the 2-isomer, because, in the ordinary electrophilic reactions of 1-naphthol in the dark, the formation of the 4-isomer always predominates and the yield of the 2-isomer is quite low.

Thus, in the photo-rearrangement of *O*-acyl or *O*-*s*-triazinyl-naphthols the distance of the migration is considered to be also important, although the acyl or *s*-triazinyl group migrated to the positions of the high odd π electron densities; the migration of the acyl or *s*-triazinyl group to an adjacent position occurred readily, as in the cases of phenol derivatives, but it was difficult for any migration to a remote position to take place. These facts are consistent with the findings that the viscosity of a solvent scarcely affects the *ortho*-rearrangement, but does affect the *para*-rearrangement considerably.[1] A similar difficulty of the rearrangement to a remote position is also observed in the ordinary Fries rearrangement of *O*-acyl-1-naphthols. In this case, with an increase in the size of the acyl group, the rate of the formation of the 4-acyl-1-naphthols falls off to such an extent that the method is of little value in their preparation.[18] Generally, *s*-triazinyl group is a bulky substituent; therfore, in the cases of *O*-*s*-triazinyl-1-naphthols, the steric hindrance caused by the adjacent benzene nucleus, which is assumed to be the reason for the difficulty of the rearrangement to the 4-position, may be more significant than in the cases of ordinary acyl derivatives. However, the difference in steric hindrance between the *s*-triazinyl and acetyl groups seems to be small, as may be seen from a comparison of the values of the *o*/*p* ratio in these cases. On the other hand, in the photoreactions of naphthol derivatives, the formation of considerable quantities of naphthols was observed as compared with the cases of phenol derivatives. This difference between phenol and naphthol derivatives may be explained by a difference in the odd π electron densities at the oxygen atoms of the phenoxy and naphthyloxy radicals. Because of the low odd π electron densities at the oxygen atoms of naphthyloxy radicals, the probabilities of the back reactions with *s*-triazinyl radical to give the starting materials may be low, and naphthyloxy radicals are assumed to escape relatively readily from the solvent cage and to abstract a hydrogen atom from the solvent molecule to yield the respective naphthols in fairly good yields.

Addition of Methanesulfenyl Chloride and Sulfur Chloride to 1,4-Dimethyl-3,6-dimethylene-2,5-piperazinedione and Substitution of the Adducts

Juji Yoshimura, Yuichi Sugiyama, Kenji Matsunari,* and Hiroshi Nakamura

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology Ookayama, Meguro-ku, Tokyo 152

(Received November 5, 1973)

Addition of methanesulfenyl chloride or sulfur chloride to 3,6-dimethylene-(**1a**) and 3,6-dibenzylidene-1,4-dimethyl-2,5-piperazinediones (**1b**) gave the Markownikoff products. The addition of methanesulfenyl chloride to **1a** proceeded stepwise within 1 hr, and gave a mixture of (*Z,Z*)-, (*Z,E*)-, and (*E,E*)-isomers of the corresponding 3,6-bis(methylthiomethylene) derivative, accompanied by gradual elimination of hydrogen chloride. 3,6-Dichloro groups of the adduct were substituted with water, ethanethiol and ethanol to give the corresponding hydroxy, ethylthio, and ethoxy derivatives, respectively. A similar substitution with ethanedithiol and hydrogen sulfide followed by aeration gave 7,9-dimethyl-1,6-bis(methylthiomethyl)-8,10-dioxo-2,5-dithia-7,9-diazabicyclo[4,2,2]-decane and the corresponding 3,6-epitetrathio derivative, respectively. The same mode of reaction of sulfur chloride with **1a** and **1b** gave a few 1,6-disubstituted-7,9-dimethyl-8,10-dioxo-3,4-dithia-7,9-diazabicyclo[4,2,2]-decanes. Mass fragmentations of new compounds were also described.

It was found that bromination of 1,3,4,6-tetramethyl-2,5-piperazinedione with bromine was accompanied by elimination of hydrogen bromide and re-addition of bromine gave the corresponding 3,6-dibromo-3,6-bis-(bromomethyl) derivative, and that tetrabromide was successfully substituted with water or methanol to give the corresponding 3,6-disubstituted derivatives, while that substituted with sulfur-containing nucleophiles gave only 1,4-dimethyl-3,6-dimethylene-2,5-piperazinedione (**1a**) and sulfur.[1] The latter elimination seems to proceed through the formation of the spiro-thiiranium ion of the substitued compounds, in participation with the bromine atom of bromomethyl groups. In order to extend the synthetic pathway of 3,6-epidithio-2,5-piperazinediones by substitution of 3,6-dihalogeno groups with mercapto groups and the subsequent oxidative disulfide-ring formation,[2] addition of methanesulfenyl chloride to **1a** was examined. Schmidt and Csizmadia[3] reported that the relative amount of Markownikoff and anti-Markownikoff adducts formed in the addition of 4-chlorobenzenesulfenyl chloride to *cis*- and *trans*-1-phenylpropene are strongly dependent upon the solvent and reaction temperature. Concurrent anti-Markownikoff addition of sulfur chloride to two olefinic functions of **1a** and 3,6-dibenzylidene-1,4-dimethyl-2,5-piperazinedione (**1b**)[4] was also examined with the expectation that it would give directly the 3,6-epidithio derivative. In both additions, only Markownikoff adduct was formed.

Results and Discussion

NMR analysis of the addition of methanesulfenyl chloride[5] to **1a** in chloroform (Fig. 1) showed that the first (b) and second (c) additions proceed stepwise during 10 min and 1 hr, respectively, followed by gradual elimination of hydrogen chloride (d) when the reaction mixture was kept at room temperature for a week. The elimination was accelerated by refluxing the reaction mixture for several hours to give the corresponding 3,6-bis(methylthiomethylene) derivative (**2**) in a good yield. This indicates that the addition occurs in the Markownikoff mode, and the adduct

does not turn into the spiro-thiiranium ion, as was observed previously.[1] Separation of **2** on tlc gave the possible three isomers in the ratio 4(**2a**): 3(**2b**): 1(**2c**). From the chemical shifts of vinyl protons (Table 1), their configurations were assigned to (*Z,Z*), (*Z,E*), and (*E,E*), respectively, the vinyl proton in *Z*-configuration being deshielded about 0.55 ppm by the neighboring carbonyl group.[6] It is worth noting that irradiation of (*E,E*)-isomer in chloroform with high-pressure mercury light for 20 hr gave a mixture of **2a**, **2b**, and **2c** in the ratio 1 : 2 : 1.

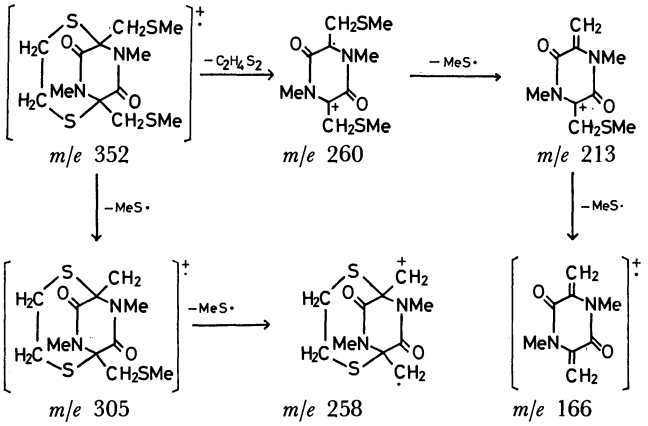
2c	6.15	3.23	2.34

Since the Markownikoff adduct was fairly stable, though it could not be isolated in a pure state, substitution of its 3,6-dichloro groups was attempted. Treatment of the adduct, obtained by evaporating the reaction mixture, with dioxane–water at room temperature overnight gave 3,6-dihydroxy-1,4-dimethyl-3,6-bis(methylthiomethyl)-2,5-piperazinedione (**3a**) in 42% yield. 3,6-Bis(ethylthio) (**3b**) and 3,6-diethoxy (**3c**) derivatives were obtained similarly by treatment with excess ethanethiol and ethanol in chloroform, respectively. A similar substitution with ethanedithiol in a dilute solution gave the bicyclic compound; 7,9-dimethyl-1,6-bis(methylthiomethyl)-8,10-dioxo-2,5-dithia-7,9-diazabicyclo[4,2,2]decane (**4**) in 18% yield. However, treatment of the adduct with sodium thioacetate or sodium tetrasulfide induced the elimination reaction to give **2** as the predominant product, even at lower temperatures with less than stoichiometric amount of nucleophiles, while that with hydrogen sulfide gave the corresponding epitetrathio derivative (**5**). In the latter case, another product which seemed to be the corresponding dimercapto derivative was detected on tlc. However, the compound polymerized easily to give an intractable sirup, compound **5** being isolated in 34% yield by aeration of the reaction mixture in a large amount of chloroform. Hydrogenation of **5** with sodium borohydride again gave the unstable dimercapto derivative, though it could not be isolated in a pure state.

Though the steric configuration of **3** could not be determined, the NMR spectra indicated that **3b** is composed of a *ca.* 1 : 3 mixture of *cis* and *trans* isomers, and the others only of one isomer. In general, mass spectra of these new compounds show intense fragment peaks of $(M-SCH_3)^+$ and $(M-CH_2SCH_3)^+$; for example, the base peak of **3a** at *m/e* 233 $(M-CH_2SCH_3)^+$ strongly supports the structure. In the case of **5**, the parent peak could not be observed, but the first fragmentation stage $M^{\ddagger}\rightarrow(M-4S)^{\ddagger}$ was deduced from a metastable ion peak, *m/e* 174.5. In the fragmentation pattern of **4** (Fig. 2) deduced from metastable ion peaks (*m/e* 221, 192, 186, 174.5, and 129.5), the *m/e* 260 $(M-C_2H_4S_2)^{\ddagger}$ peak shows the structure unambiguously.



m/e 352 *m/e* 260 *m/e* 213

m/e 305 *m/e* 258 *m/e* 166

Fig. 2. The major fragmentation pathways of **4**.

NMR analysis of the addition reaction of sulfur chloride to **1a** gave similar information to that for methanesulfenyl chloride. However, isolation of the adduct was very difficult in high concentration of reactants, since its bifunctionality causes polymerization due to the intermolecular addition reaction. Examination of the effect of concentration on the relative amount of polymeric and monomeric adducts (Fig. 3) indicates that 0.0125 M solution was the best for the formation of the monomeric adduct, which was isolated as 1,6-dihydroxy-7,9-dimethyl-8,10-dioxo-3,4-dithia-7,9-diazabicyclo[4,2,2]decane (**6a**) by treatment of the reaction mixture with water. In the mass fragmentation pattern of **6a** (Fig. 4; metastable ion peaks, *m/e* 143.3, 136, 120.5, and 115.5), the peak at *m/e* 218 $(M-CH_2S)^{\ddagger}$ proves its characteristic structure. Formation of **6a** also indicates that the addition proceeded in the Markownikoff mode. Addition of sulfur chloride to **1b** proceeds very slowly in dioxane in the presence of zinc chloride, and does not proceed in tetrahydrofuran or chloroform. Consequently, the addition in dioxane

was easily subjected to side-reactions such as elimination, polymerization, and disproportionation of sulfur, making the yield of monomeric adduct (**6b**) very low. Acetylation of **6a** with acetic anhydride in pyridine gave the corresponding diacetate (**6c**).

Addition of sulfur chloride to 1,2,3,4-tetrahydro-2-methyl-3-methylene-1,4-dioxopyrazino[1,2-*a*]indole[7] gave only intractable products. However, the prevention of side-reactions by fixation of the terminal chlorodithio group of the corresponding adduct with ethanethiol gave 3-ethyldithiomethylene (**7a**) and 3-ethyltrithiomethylene derivative (**7b**) in 11% and 13% yield, respectivly.

Experimental

All the melting points are uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 60 °C. The infrared spectra were measured in KBr disks, and the NMR spectra were obtained at 100 MHz with a JNM-100H spectrometer in deuteriochloroform unless otherwise stated, using TMS as an internal reference. The mass spectra were obtained on a GEOL JNS-01S mass spectrometer, using a direct inlet and an ionization energy of 70 eV. Chemical shifts and coupling constants were recorded in δ and Hz units, respectively, and frequencies in cm^{-1}.

1,4-Dimethyl-3,6-bis(methylthiomethylene)-2,5-piperazinedione (2a, 2b, and 2c). To a solution of 1,4-dimethyl-3,6-dimethylene-2,5-piperazinedione (0.2 g, 1.2 mmol) in chloroform (20 ml) was added dropwise methanesulfenyl chloride (0.6 g, 7.2 mmol), and the resulting solution was evaporated, after being left to stand for 1 hr at room temperature. A solution of the residual sirup in chloroform (20 ml) was refluxed for 8 hr, and evaporated to give crystals (0.17 g, 56%) from ether, which were separated into three isomers (R_f= a; 0.38, b; 0.25, c; 0.2) on a preparative tlc, using benzene–ethyl acetate (5: 1) as the developing solvent. **4a**: mp 138—139 °C; yield, 0.08 g (26%), **4b**: mp 172—174 °C; yield, 0.06 g (19%), **4c**: mp 275 °C (sublime); yield, 0.02 g (6.4%).

Found: **4a**: C, 46.69; H, 5.51; N, 10.86; S, 24.58%. **4b**: C, 46.67; H, 5.46; N, 10.72; S, 24.61%. **4c**: C, 46.37; H, 5.25; N, 10.71; S, 24.72%. Calcd for $C_{12}H_{22}N_2O_2S_2$: C, 46.49; H, 5.46; N, 10.84; S, 24.82%.

These compounds show the characteristic olefinic double bond absorption at *ca.* 1570 cm^{-1}.

3,6-Dihydroxy-1,4-dimethyl-3,6-bis(methylthiomethyl)-2,5-piperazinedione (3a). Methanesulfenyl chloride (0.6 g, 7.2 mmol) was added to a solution of 1,4-dimethyl-3,6-dimethylene-2,5-piperazinedione (0.2 g, 1.2 mmol) in dry chloroform (10 ml). The mixture was allowed to stand at room temperature for 1 hr, and then evaporated to give a sirup. A solution of the sirup in dioxane–water was left to stand at room temperature overnight and evaporated to give amorphous solid (200 mg) which was recrystallized from acetone. Yield, 180 mg (42%). Mp 193—195 °C, IR: 3260 (OH), 1625 (amide); NMR (DMSO): 6.80 (OH), 3.13 and 2.95 (SCH_2; ABq, J=13.8), 2.78 (NMe), 1.92 (SMe).

Found: C, 40.99; H, 5.69; N, 9.46%. Calcd for $C_{10}H_{18}N_2O_4S_2$: C, 40.79; H, 6.16; N, 9.51%.

3,6-Bis(ethylthio)-1,4-dimethyl-3,6-bis(methylthiomethyl)-2,5-piperazinedione (3b). Excess ethanethiol (20 ml) was added to a solution of the same addition product in chloroform as for **3a** and the mixture was evaporated, after being left to stand overnight at room temperature. The sirup obtained was purified on a preparative tlc, using benzene–ethyl acetate (5: 1) as the developing solvent. The portion of R_f=0.75 (0.2 g, 43%) was collected, and recrystallized from petroleum ether. Mp 72—73 °C; IR: 1640 (amide); NMR of the main isomer in the mixture of 3: 1: 3.65 and 3.09 (CH_2S; ABq, J=15), 3.07 (NMe), 2.17 (SMe), 2.65—3.00 (CH_2S; q), 1.20 (CH_3; t, J=7.5).

Found: C, 43.64; H, 6.45; N, 7.18; S, 33.55%. Calcd for $C_{14}H_{26}N_2O_2S_4$: C, 43.97; H, 6.85; N, 7.33; S, 33.48%.

3,6-Diethoxy-1,4-dimethyl-3,6-bis(methylthiomethyl)-2,5-piperazinedione (3c). Ethanol (20 ml) was added to a solution of the same addition product in chloroform (40 ml) as for **3b**, and the resulting solution was left to stand at room temperature overnight. Evaporation of the reaction mixture gave a sirup which was purified on a preparative tlc, using benzene–ethyl acetate (10: 1) as the developing solvent. The portion of R_f=0.42 was recrystallized from ether. Mp 135—136 °C, yield, 100 mg (23%); IR: 1645 (amide), 1045 (C–O–C). NMR: 3.60 (OCH_2; q), 3.35 and 3.05 (CH_2S; ABq, J=14), 2.98 (NMe), 2.07 (SMe), 1.19 (CH_3; t, J=7.5).

Found: C, 47.99; H, 7.49; N, 8.05; S, 18.21%. Calcd for $C_{14}H_{26}N_2O_4S_2$: C, 47.99; H, 7.48; N, 8.00; S, 18.27%.

7,9-Dimethyl-1,6-bis(methylthiomethyl)-8,10-dioxo-2,5-dithia-7,9-diazabicyclo[4,2,2]decane (4). Ethanedithiol (113 mg, 1.2

mmol) was added to a solution of the same addition product in dioxane (30 ml) as for **3c**, and the resulting solution was then evaporated, after being left to stand overnight at room temperature. The residual sirup was purified on a preparative tlc, using benzene–ethyl acetate (5: 1) as the developing solvent (R_f=0.35) to give crystals which were recrystallized from methanol. Mp 170—171 °C, yield, 80 mg (18%), IR: 1650 (amide); NMR: 3.63 and 2.99 (CH_2; ABq, J=14), 3.14 (NMe), 2.14 (SMe), 1.55 (SCH_2CH_2S; s).

Found: C, 40.92; H, 5.87; N, 7.89; S, 36.41%. Calcd for $C_{12}H_{20}N_2O_2S_4$: C, 40.92; H, 5.72; N, 7.95; S, 36.38%.

1,4-Dimethyl-3,6-bis(methylthiomethyl)-3,6-epitetrathio-2,5-piperazinedione (5). To a solution of excess hydrogen sulfide in chloroform (30 ml) was added a solution of the same addition product in chloroform (20 ml) as for **4**, and the resulting solution was left to stand at room temperature overnight, and then evaporated. The solution of the residual sirup in chloroform (300 ml) was oxidized by airing for 1 day and evaporated. The residue was purified on a preparative tlc using benzene–ethyl acetate (5: 1) as the developing soluent (R_f= 0.7), to give crystals (160 mg, 34%) which were recrystallized from methanol. Mp 183—184 °C; IR: 1650 (amide); NMR: 3.63 and 3.13 (CH_2; ABq, J=14), 3.08 (NMe), 2.18 (SMe).

1,6-Dihydroxy-7,9-dimethyl-2,5-diphenyl-8,10-dioxo-3,4-dithia-7,9-diazabicyclo[4,2,2]decane (6b). A solution of 3,6-dibenzylidene-1,4-dimethyl-2,5-piperazinedione (630 mg, 1.9 mmol), sulfur chloride (370 mg, 2.7 mmol) and a small amount of zinc chloride in dioxane (20 ml) was allowed to stand for 48 hr at room temperature. The reaction mixture was extracted with chloroform (100 ml), and the extract was washed twice with water (100 ml), and evaporated to give a white powder which was recrystallized from chloroform to give white crystals (20 mg, 2.5%). Mp 229 °C (decomp.). IR: 3350 (OH), 1640 (amide).

Found: C, 75.72; H, 4.60; N, 6.37; S, 15.61%. Calcd for $C_{20}H_{20}N_2O_4S_2$: C, 57.67; H, 4.84; N, 6.73; S, 15.40%.

1,6-Diacetoxy-7,9-dimethyl-8,10-dioxo-3,4-dithia-7,9-diazabicyclo-[4,2,2]decane (6c). A solution of **6a** (50 mg, 0.19 mmol) in pyridine (10 ml) and acetic anhydride (5 ml) was allowed to stand at room temperature for 3 hr, evaporated, and the residue was treated with chloroform–ethanol to give white crystals (34 mg, 52%) which were recrystallized from chloroform–ethanol. Mp 268—271 °C. IR: 1760 (OAc), 1670 (amide). NMR: 3.85 and 3.15 (CH_2; ABq, J=15), 2.88 (NMe), 2.13 (OAc).

Found: C, 41.78; H, 4.61; N, 8.12%. Calcd. for $C_{12}H_{16}N_2O_6S_2$: C, 41.37; H, 4.63; N, 8.04%.

3-Ethyldithiomethylene- (7a) and 3-Ethyltrithiomethylene-1,2,3,4-tetrahydro-2-methyl-1,4-dioxopyrazino[1,2-a]-indole (7b). A solution of 1,2,3,4-tetrahydro-2-methyl-3-methylene-1,4-dioxopyrazino[1,2-*a*]indole (0.4 g, 1.8 mmol), sulfur chloride (2.0 g, 15 mmol) and a small amount of zinc chloride in dioxane (16 ml) was allowed to stand for 20 min. A solution of ethanethiol (4.4 g, 71 mmol) in chloroform (100 ml) was added to the reaction mixture which was left to stand for 20 min. The solution was washed with water, evaporated, and the residue was fractionated on a C-200 silicic acid column, using benzene and benzene–ethyl acetate (6: 1) as an effluent. The latter fraction was evaporated, and then the residue was again fractionated on a C-200 silicic acid column, being eluted with benzene–ethyl acetate (20: 1) to give **7b** (80 mg, 13%) and **7a** (60 mg, 11%). They were recrystallized from chloroform–ligroin to give orange and yellow needles, respectively Mp **7a**; 136 °C, **7b**; 148 °C. IR: **7a**; 1660 (amide), **7b**; 1650 (amide). NMR: **7a**; 1.40 and 2.94 (SEt; J=7.5), 3.43 (NCH_3), 7.0 (=CHSS), 8.51 (H_6: $J_{6,7}$=7.5), **7b**; 1.42 and 2.97 (SC_2H_5; J=7.5), 3.43 (NCH_3), 7.07 (=CHSSS), 8.41 (H_6; $J_{6,7}$=7.5).

7a: Found: C, 56.38; H, 4.20; N, 8.60%. Calcd for $C_{15}H_{14}N_2O_2S_2$: C, 56.58; H, 4.43; N, 8.80%.

7b: Found: C, 51.47; H, 3.74; N, 7.76%. Calcd for $C_{15}H_{14}N_2O_2S_3$: C, 51.40; H, 4.03; N, 7.99%.

Aminosugars. XXII. Syntheses and Properties of 6-Deoxy-6- and 3-Deoxy-3-guanidino-D-hexoses[1]

Juji YOSHIMURA, Tetsuo SEKIYA, and Yoshio OGURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology Ookayama, Meguro-ku, Tokyo 152

(Received November 9, 1973)

Methyl 6-deoxy-6-guanidino-α-D-glucopyranoside, 6-deoxy-6-guanidino-D-galactose, 3-deoxy-3-guanidino-D-allose (**7**), and 3-deoxy-3-guanidino-D-glucose were synthesized by guanidination of the corresponding aminosugars. The acetate of **7** was proved to exist in a bicyclic structure; 2′,4′,6′-tri-*O*-acetyl-D-allopyrano[1′,2′,3′;4,5,6]-2-acetylimino-1,3-diacetyl-perhydropyrimidine, whereas others exist as the usual pyranoses. Properties of the new compounds and the synthetic methods were examined.

During the last decade, the syntheses and properties of aldoses having an amino or a mercapto group at *C*-4, *C*-5, or *C*-6 position have been extensively studied. It was clarified that the former two exist in various tautomeric mixtures involving five- and six-membered hemiacetal formation with functional groups at *C*-4 and *C*-5 positions, while the latter involve the corresponding septanose and bicyclic 1,6-anhydrosugar, in addition to the usual pyranose.[2] In a previous paper of this series,[3] we disclosed that 2-deoxy-2-guanidino-D-glucose exists mainly in a new bicyclic structure, α-D-glucofurano[1′,2′;4,5]-2-imino-imidazolidine, under acidic conditions, which isomerizes into 2-amino-4-(D-*arabino*-tetrahydroxybutyl)imidazole *via* the corresponding 2-imino-imidazoline-4 structure in an alkaline solution. The results stimulated us to examine the structure of 6-deoxy-6- and 3-deoxy-3-guanidino-hexoses.

Syntheses of guanidino-sugars have not been studied extensively. However, 6-deoxy-guanidino-1,2-*O*-isopropylidene-α-D-glucofuranose[4] and methyl 3-deoxy-4,6-*O*-benzylidene-3-nitroguanidino-α-D-allopyranoside[5] were synthesized by the cyanamide method. Formation of 2-deoxy-2-guanidino-D-glucopyranosyl thiol and -D-galactopyranosyl thiol through the S→N migration of amidino group in the corresponding 1-thiopseudourea derivatives was indicated by Wolfrom *et al.*[6] Glycosylguanidines could not be obtained in a pure state by direct condensation of aldoses with free guanidine,[7] but they were synthesized through glycosylisothioureas.[8] 2-Deoxy-2-guanidino-α-D-altropyranoside was obtained by the reaction of the corresponding 2,3-epoxide with guanidine, but substitution of 3-*O*- or 6-*O*-tosyl-hexoside with guanidine was unsuccessful.[9]

In this paper the syntheses and properties of several 6-deoxy-6- and 3-deoxy-3-guanidino-D-hexoses are reported.

Results and Discussion

6-Deoxy-6-guanidino-D-hexoses. Reaction of methyl 6-amino-6-deoxy-α-D-glucopyranoside[10] with 1.5 equivalent of cyanamide in water at 60 °C with an adjusted pH of 8.2—8.6 gave the corresponding 6-guanidino derivative (**1**) as crystalline flavianate, in 26 and 50% yield for 9 hr and 1 day, respectively. When the pH of the reaction mixture was not adjusted, it increased beyond 10 with the progress of guanidination, a di-*O*-carbamoyl-mono-*O*-amidino derivative (**2**) of **1** being obtained in 73% yield based on cyanamide. The compound showed characteristic absorptions of carbamoyl (1742 and 1588 cm^{-1}) and guanidino groups (1680 and 1615 cm^{-1}) in the IR spectrum, and ring proton signals of α-D-glucopyranose in the NMR spectrum. The position of three *O*-substituents was not determined definitely. However, the *C*-2 position was considered to be the most reasonable for the *O*-amidino group, since 3- and 4-*O*-amidino groups once formed seem to be hydrolyzed to *O*-carbamoyl groups by the intramolecular catalytic action of 6-guanidino group. Acetylation of **1** with acetic anhydride in pyridine gave methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-diacetylguanidino-α-D-glucopyranoside (**3**) in 31% yield, together with 6-monoacetylguanidino derivative. The former showed characteristic absorptions of diacetylguanidino group [λ_{max}^{EtOH} (nm), 221 (ε 8.35×10^3), 255 (ε 1.58×10^4); ν_{max} 1698, 1620, and 1555 cm^{-1}]. It is worth noting that *N*-acetyl groups in diacetylguanidino moiety of **3** are very labile,[11] whereas *O*-glycosidic linkage in **1** strongly resisted acid hydrolysis. De-*O*-acetylation of **3** in methanol with a small amount of sodium methoxide at room temperature caused the shift of λ_{max}^{EtOH} to 234 nm, indicating the elimination of one *N*-acetyl group. **3** was easily converted into **1** only by refluxing in methanol for 14 hr. This means that the alkalinity of 6-guanidino group arose from diacetylguanidino group[12] catalyzed de-*O*-acetylation by the ester-exchange reaction. Treatment of **1** with 6 M hydrochloric acid at 80 °C for 1 day gave no hydrolyzed product, indicating that the protonation of 6-guanidino group prevents the approach of other protons to *C*-1 position, as was observed in the case of 2-amino-2-deoxy-hexosides.[13]

For comparison of synthetic methods, synthesis of **1** by the *S*-methylisothiourea method in ammonia solution[14] was examined. This method gave nearly the same yield as the former (Table 1), but the use of hydrochloride of the aminosugar and diluted ammonia within 10% gave a better yield. This indicates that a suitable buffer action is desirable in this reaction, and that highly concentrated ammonia may consume *S*-methylisothiourea by its conversion into free guanidine.

In order to obtain a 6-guanidino derivative having no protecting group at *C*-1, 6-amino-6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactose[15] was treated with *S*-methylisothiourea under the best conditions (Table 1), to give 6-guanidino derivative (**4**) as flavianate in

35% yield. Hydrolysis of **4** with flavianic acid gave de-*O*-isopropylidenated product (**5**) as flavianate in 65% yield, which was also obtained in 59% yield by successive guanidination and hydrolysis without isolation of **4**. An attempted substitution of 1,2;3,4-di-*O*-isopropylidene-6-*O*-tosyl-α-D-galactose[16] with guanidine in butanol or in dimethylformamide gave unsuccessful results, similarly to those reported by Danilov and Lishanskii.[9] Acetylation of **5** with acetic anhydride in pyridine gave a sirupy hexaacetate (**6**) in 28% yield, which showed characteristic absorptions of diacetylguanidines. Ring-proton signals of the NMR spectrum of **6** (Fig. 1) confirmed by simulation proved completely its structure to be 1,2,3,4-tetra-*O*-acetyl-6-deoxy-6-diacetylguanidino-β-D-galactopyranose.

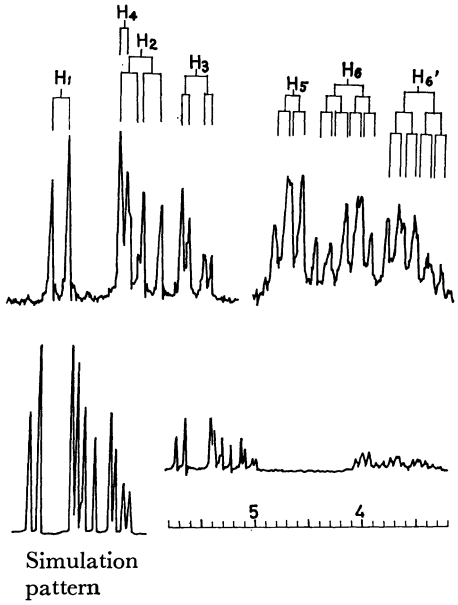

Fig. 1. Ring-proton signals in the NMR spectrum of **6**.

Although the 6-guanidino group in **1** clearly showed the electrostatic effect on the *C*-1 position, the fact that **5** showed positive Sakaguchi reaction after removal of flavianic acid, and that it was converted into **6** suggests that the nucleophilicity of guanidino group is not so strong as to make the septanose or an additional seven-membered aminal ring by surmounting new non-bonded interactions, which will arise by change of the conformation.

*3-Deoxy-3-guanidino-*D*-hexoses.* Guanidination of 3-amino-3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose[17] by *S*-methylisothiourea method was unsuccessful, and that with cyanamide in water gave a Sakaguchi-reaction positive product. However, it could not be isolated in a pure state. The fusion method[18] of the aminosugar hydrochloride with 1.5 equivalent of cyanamide at 130 °C for 40 min gave the de-5,6-*O*-isopropylidenated 3-guanidino derivative (**7**) as crystalline picrate in 57% yield. When the free aminosugar was used cyanamide dimerized rapidly to biguanide, no product being obtained. Hydrolysis of **7** with 2 M hydrochloric acid gave 3-deoxy-3-guanidino-D-allose as a hygroscopic sirup which is negative to both the Sakaguchi and Fehling reactions. Acetylation of this sirup with acetic anhydride in pyridine gave a sirupy hexaacetate (**8**), UV absorption of which (λ_{max}^{EtOH} 217 nm) differs from that of **3** and **6**. NMR spectrum of **8** (Fig. 2) showed the presence of α-D-allopyranose ring from the long-range coupling between H_1 and H_3 (J=1.9 Hz) and a *trans*-diaxial coupling ($J_{4,5}$=10.6 Hz). Although 1,2,4,6-tetra-*O*-acetyl-3-deoxy-3-diacetylguanidino-α-D-allopyranose structure is possible, **8** was determined to be 2′,4′,6′-tri-*O*-acetyl-α-D-allopyrano[1′,2′,3′;4,5,6]-2-acetylimino-1,3-diacetyl-perhydropyrimidine from the absence of diacetylguanidino moiety in UV spectrum, negative Sakaguchi and Fehling reaction of 3-deoxy-3-guanidino-D-allose, and the presence of lower-shifted acetylimino proton signal (δ 2.52) in the NMR spectrum, as observed in that of 3′,5′,6′-tri-*O*-acetyl-α-D-glucofurano[1′,2′;4,5]-2-acetyl-

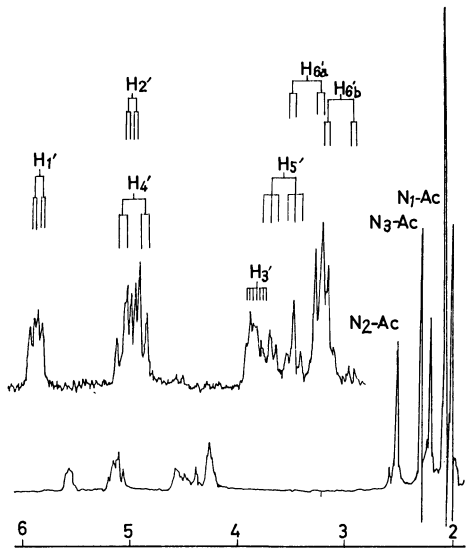

Fig. 2. The NMR spectrum of **8**.

imino-1,3-diacetylimidazolidine.[3]

For the sake of comparison, synthesis of **7** by indirect guanidination was attempted. Reaction of 3-amino-3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose with cyanogen bromide or with potassium cyanate gave the corresponding 3-cyanamido (**9**) and 3-ureido derivative (**10**) in 89 and 73% yields, respectively. Dehydration of **10** with methanesulfonyl chloride gave **9** in 50% yield. Reaction of **9** with methanolic ammonia at 90 °C in a sealed tube or with hydrogen sulfide in pyridine gave **8** or the corresponding 3-thioureido derivative (**11**) in 26 and 20% yields, respectively. Direct conversion of the aminosugar into **11** by the reaction with potassium thiocyanate gave only the de-5,6-*O*-isopropylidenated product, which was confirmed as the corresponding 5,6-di-*O*-acetyl derivative.[19] These results indicate that the fusion method is the best for synthesis of **7**.

In order to examine whether 3-deoxy-3-guanidino-D-glucose can make an additional aminal-ring, synthesis was carried out as follows. Though the reason is not clear, guanidination of 3-amino-3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose[20] with cyanamide by the fusion method was unsuccessful. Thus an indirect method was adopted. Reaction of the aminosugar with cyanogen bromide in ether gave the corresponding 3-cyanamide as a sirup, which was then treated with methanolic ammonia in a sealed tube at 80—90 °C for 20 hr to give the corresponding 3-guanidino derivative (**12**) as the crystalline flavianate. Hydrolysis of **12** with flavianic acid gave 3-deoxy-3-guanidino-D-glucose (**13**) also as crystalline flavianate, which is positive to the Sakaguchi and Fehling tests. Base-catalyzed acetylation of **13** gave a sirup containing three products, from which a hexaacetate (**14**) was isolated with a preparative tlc.

The NMR spectrum of **14** indicated that it is composed of α- (H_1: δ 6.31, $J_{1,2}$=3.5 Hz) and β-anomers (H_1: δ 5.71, $J_{1,2}$=8.0 Hz) in the ratio 3:1. The relative amount of the α-anomer increased with reaction time, but both anomers could not be separated. Chemical shifts of ring-protons were different only in that of H_1 and H_2, and irradiation of amino-proton (δ 8.11, $J_{N,3}$=9.0 Hz) caused H_3 proton signal from quartet to triplet (δ 4.79, $J_{2,3}$=$J_{3,4}$=9.7 Hz). Consequently, **14** was determined to be 1,2,4,6-tetra-*O*-acetyl-3-deoxy-3-diacetylguanidino-α,β-D-gluco-pyranose.

The result suggests again that **13** could not make additional intramolecular aminal-ring, probably due to strong nonbonded interactions for the inversion of the conformation from *C*1 to 1*C*, as observed in the case of **6**.

Experimental

All melting points are uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 45 °C. Specific rotations were measured in a 0.5 dm tube, with a Carl Zeiss LEP-Al Polarimeter. The IR spectra were recorded in KBr discs with a Hitachi Model EPI-GS grating IR spectrophotomeser. The NMR spectra were taken with a JMN-4H-100 MHz Spectrometer in deuteriochloroform unless otherwise stated, using tetramethylsilane as an internal standard. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

Methyl 6-Deoxy-6-guanidino-α-D-glucopyranoside (1) Dihydrochloride. i) Cyanamide Method: a) A solution of methyl 6-amino-6-deoxy-α-D-glucopyranoside hydrochloride[10] (1.15 g, 5 mmol), cyanamide (0.32 g, 7.5 mmol) and 1 M sodium hydroxide (1 ml, 1 mmol) in water (10 ml) was kept at 80 °C for 17 hr. The pH of the solution which changed to 10.0 was adjusted with 2 M hydrogen chloride to 5.0, and the solution was evaporated to give a sirup. The sirup was dissolved in ethanol (20 ml), filtered, and the filtrate was left to stand overnight in a refrigerator after addition of acetone, to give white crystals (**2**) (0.6 g, 73% based on cyanamide). Mp 183 °C, $[\alpha]_D^{23}$ +69.8° (*c* 1.0, H_2O); IR: 1742 and 1588 (urethane), 1680 and 1665 (guanidino group), 1615 (guanyl).

Found: C, 30.73; H, 6.27; N, 23.71; Cl, 17.42%. Calcd. for $C_{11}H_{23}N_7O_7Cl_2$: C, 30.28; H, 5.81; N, 23.48; Cl, 17.25%.

b) In a reaction similar to the above experiment, the pH of the solution was adjusted to 8.2 at the beginning and maintained at 8.0—8.6 during the course of reaction at 60 °C. The reaction mixture was treated with Amberlite IRA-410 (3 ml), and filtered. The solute was absorbed on a column of Amberlite CG-50 (15 ml), and the column was washed successively with deionized water (200 ml), 5% aqueous ammonia (200 ml), and water (200 ml), and then eluted with 0.5 M hydrogen chloride. The neutral effluent was evaporated, and the residue was extracted with ethanol. The extract was evaporated, and the residual sirup was dissolved in water (20 ml), deionized with Amberlite IRA-410 (3 ml), and the solution was evaporated to give a sirup. From a mixed solution of the sirup in water (0.5 ml) and flavianic acid (1.5 g) in ethanol (10 ml), yellow flavianate (**1**, 1.045 g) was obtained as crystals. The second crop (0.245 g) was obtained from the mother liquor. Yield, 1.29 g (50%); mp 155 °C (dec.); $[\alpha]_D^{23}$ +43.5° (*c* 2.0, H_2O); IR: 1673 and 1655 (sh) (mono substituted guanidine).

Found: C, 38.62; H, 4.38; N, 12.58; S, 6.02%. Calcd for $C_{18}H_{23}N_5O_{13}S$: C, 38.60; H, 4.14; N, 12.52; S, 5.73%.

ii) S-Methylisothiourea Method: A solution of methyl 6-amino-6-deoxy-α-D-glucopyranoside[10] (0.69 g, 3 mmol) and *S*-methylisothiourea sulfate (0.62 g, 4.5 mmol) in ammonia (10%, 10 ml) was left to stand at room temperature for 4 days, treated with Amberlite IRA-410 (3 ml) to remove sulfate ion, and then filtered. The filtrate was passed through an Amber-

lite CG-50-I column, and treated as above to give **1** in 51% (0.86 g) yield.

Methyl 2,3,4-Tri-O-acetyl-6-deoxy-6-diacetylguanidino-α-D-glucopyranoside (3). To a cold solution of **1** (8.34 g, 15 mmol) in pyridine (5 ml) was added dropwise acetic anhydride (15 ml, 150 mmol) for 30 min with stirring. The resulting solution was kept at room temperature for 2 day, poured into ice-water (200 ml), and then extracted with chloroform (50 ml ×4). The extract was successively washed with 2 M hydrochloric acid (40 ml×4), saturated sodium bicarbonate (40 ml ×4) and water, dried, and evaporated. The residue was fractionated on a silica-gel column (Kiesel Gel 60) with methanol–benzene (0.5—1.0% methanol), into **3** (2.04 g, 31%) and a mixture of methyl 6-monoacetylguanidino-6-deoxy-2,3,4-tri-*O*-acetyl-α-D-glucopyranoside and another unknown compound (0.62 g). $[\alpha]_D^{23}$ +71.5° (*c* 1.98, $CHCl_3$), +86.9° (*c* 0.84, EtOH); IR: 1750 (OAc), 1705, 1616, and 1555 (diacetylguanidine); λ_{max}^{EtOH} (nm) 221 (ε 8.35×10^3) and 254.7 (1.58×10^4); NMR: 4.97 (H_1: d, $J_{1,2}$=3.2), 4.87 (H_2; q, $J_{2,3}$=9.5), 5.49 (H_3; t, $J_{3,4}$=9.5), 3.95 (H_5; m, $J_{5,6}$=7.0, $J_{5,6'}$=3.4), 3.55—3.80 (H_6 and H_6'), 3.44 (OMe), 2.21, 2.12, 2.09 and 2.02 (5×Ac).

Found: C, 48.13; H, 5.90; N, 9.53%. Calcd for $C_{18}H_{27}N_3O_{10}$: C, 48.54; H, 6.11; N, 9.44%.

When a solution of **3** (305 mg, 0.69 mmol) in ethanol (20 ml) was refluxed for 14 hr, it became positive to the Sakaguchi reaction, and showed one spot on paper chromatography (Toyoroshi No. 50), using ethyl acetate–pyridine–acetic acid–water (5: 5: 1: 3) as developing solvent, of which R_f value (0.36) consists with that of **1**. Addition of flavianic acid (288 mg) in ethanol (5 ml) to the product gave the flavianate of **1**. Yield, 260 mg (69%).

6-Deoxy-6-guanidino-1,2; 3,4-di-O-isopropylidene-α-D-galactopyranose (4) Flavianate. A solution of 6-amino-6-deoxy-1,2; 3,4-di-*O*-isopropylidene-α-D-galactopyranose[15] (1.56 g, 6 mmol) and *S*-methylisothiourea sulfate (1.25 g, 9 mmol) in 10% ammonia (15 ml) was left to stand at room temperature for 4 day and then evaporated. The residue was dissolved in water (8 ml). The solution was treated with Amberlite IRA-410, and the solute was absorbed on an Amberlite CG-50-I (15 ml) column. The column was eluted with deionized water, aqueous ammonia (5%, 200 ml), and then 0.5 M hydrochloric acid. The last effluent was evaporated, and the residue was extracted with ethanol (20 ml). The ethanol solution was diluted with water (20 ml), treated with Amberlite IRA-410 (4 ml), and then evaporated to give a sirup (0.8 g). A solution of the sirup and flavianic acid (1.05 g) in ethanol (20 ml) was left to stand in a refrigerator for one day to give yellow crystals. Yield, 1.29 g (35%); mp 135 °C; $[\alpha]_D^{23}$ −20.6° (*c* 1.0, EtOH): IR: 1668 and 1650 (monosubstituted guanidine).

Found: C, 44.51; H, 4.85; N, 10.89; S, 5.38%. Calcd for $C_{23}H_{29}N_5O_{13}S$: C, 44.87; H, 4.75; N, 11.38; S, 5.21%.

6-Deoxy-6-guanidino-D-galactose (5) Flavianate. a) A solution of the flavianate of **4** (123 mg, 0.2 mmol) and flavianic acid (35 mg, 0.1 mmol) in water (5 ml) was kept at 65 °C for 2 hr, and then evaporated. From the residue, excess flavianic acid was removed with ethanol to give yellow crystals. Yield, 70 mg (65%); mp 200 °C (dec.); $[\alpha]_D^{23}$ +14.3°⟶+18.5° (*c* 0.7, H_2O); IR: 1675 and 1645 (monosubstituted guanidine).

Found: C, 38.61; H, 4.30; N, 12.79; S, 5.97%. Calcd for $C_{17}H_{21}N_5O_{13}S$: C, 38.13; H, 3.95; N, 13.08; S, 5.99%.

This compound was positive to the Fehling test, and to the Sakaguchi reaction after removal of flavianic acid with IRA-410.

b) A solution of 6-amino-6-deoxy-1,2; 3,4-di-*O*-isopropylidene-α-D-galactopyranose (1.30 g, 5 mmol) and *S*-methylisothiourea sulfate (1.04 g, 7.5 mmol) in aqueous ammonia (10%, 8 ml) was treated as above, without isolation of **4**. Yellow crystals (**5**). identical with those described above, were obtained in 59% (1.58 g) yield.

1,2,3,4-Tetra-O-acetyl-6-deoxy-6-diacetylguanidino-β-D-galactopyranose (6). To a cold solution of the flavianate of **5** (5.36 g, 0.01 mmol) in pyridine (30 ml) was added dropwise acetic anhydride (10 ml, 100 mmol), and the resulting solution was left to stand at room temperature for 2 day, and then poured into ice–water (500 ml). The aqueous solution was extracted with chloroform (100 ml×5), and the extract was washed 2 M hydrochloric acid, saturated bicarbonate and water. with Evaporation of the extract gave a sirup (3.4 g) which was fractionated on a silica-gel column (Kiesel Gel 60), using benzene–acetone (5: 1) as effluent. The first fraction gave a pure sirupy hexaacetate (1.2 g, 27.3%). $[\alpha]_D^{23}$ +16.5° (*c* 1.17, EtOH); IR: 1745 (OAc), 1694, 1600, and 1555 (diacetylguanidine); λ_{max}^{EtOH} (nm) 254 (ε 1.73×10^4), 221 (8.94×10^3); NMR: 13.04 and 9.15 (2×NH), 5.69 (H_1; d, $J_{1,2}$=7.9), 5.33 (H_2; q, $J_{2,3}$=10.0), 5.07 (H_3; q, $J_{3,4}$=3.7), 5.40 (H_4; q, $J_{4,5}$=0.5), 4.00 (H_5; q, $J_{5,6}$=8.0, $J_{5,6'}$=5.0), 3.74 (H_6; dq, $J_{6,6'}$=14.0, $J_{6,NH}$=8.0), 3.41 ($H_{6'}$; dq, $J_{6',NH}$=5.0), 1.95, 2.00, 2.09, 2.13, and 2.15 (6×Ac).

Found: C, 47.82; H, 5.66; N, 8.75%. Calcd for $C_{19}H_{27}N_3O_{11}$: C, 48.18; H, 5.75; N, 8.88%.

3-Deoxy-3-guanidino-1,2-O-isopropylidene-α-D-allofuranose (7) picrate. a) A homogeneous solution of 3-amino-3-deoxy-1,2; 5,6-di-*O*-isopropylidene-α-D-allofuranose hydrochloride[17] (296 mg, 1 mmol) and cyanamide (64 mg, 1.5 mmol) in water (10 ml) was evaporated and the residue was heated at 130—133 °C for 40 min on a silicone-oil bath. The cooled reaction mixture was dissolved in water (6 ml), treated with Amberlite IRA-410 (3 ml), and evaporated to one-third volume. Addition of picric acid (276 mg) in methanol (4 ml) to the remaining solution gave yellow crystals (295 mg, 56.6%) which were recrystallized from water. Mp 193—193.5 °C, $[\alpha]_D^{23}$ +47.9° (*c* 1.09, MeOH), IR: 1645 (monosubstituted guanidine), the Sakaguchi reaction; positive.

Found: C, 37.41; H, 4.51; N, 17.02%. Calcd for $C_{16}H_{22}N_6O_{12}$–H_2O: C, 37.21; H, 4.76; N, 16.52%.

b) A solution of **9** (100 mg, 0.35 mmol) in saturated methanolic ammonia (15 ml) was heated in a sealed tube at 80 °C for 15 hr, and then evaporated to give a sirup. From the sirup and picric acid (100 mg) in methanol–water (4 ml, 50%), yellow crystals, identical with **7**, were obtained (46 mg, 26%).

2′,4′,6′-Tri-O-acetyl-α-D-allopyrano[1′,2′,3′; 4,5,6]-2-acetylimino-1,3-diacetyl-perhydropyrimidine (8). A solution of **7** (254 mg, 0.5 mmol) in 2 M hydrochloric acid was heated at 70 °C for 6 hr, and picric acid deposited was filtered off. The water layer was extracted with ether (10 ml×5) and then evaporated to give a sirup (135 mg). The sirup was acetylated with acetic anhydride (0.5 ml) in pyridine (2 ml), and the reaction mixture was poured into ice–water and extracted with chloroform (20 ml×5). The extract was successively washed with 2 M hydrochloric acid, saturated sodium bicarbonate and water, and then evaporated to give a sirup (165 mg). This sirup showed three spots on tlc (MeOH: pyridine=9: 1), and was fractionated into a mixture (122 mg) of spot I and spot II (main), and spot III (46 mg). From the mixture, sirupy spot II (35 mg, 15%) was obtained in a pure state by fractionation on a silica-gel column (Wakogel C-200) using benzene–ethyl acetate (4: 1) as effluent, which was crystallized from ether. Mp 134 °C, $[\alpha]_D^{23}$ +188° (*c* 0.235, EtOH), IR: 1725 (OAc), 1700 (=NAc), 1635 (NAc). λ_{max}^{EtOH} 216 nm, NMR: 5.57 ($H_{1'}$; q, $J_{1',2'}$=3.4, $J_{1',3'}$=1.9), 5.17 ($H_{2'}$; q, $J_{2',3'}$=2.5), 5.12 ($H_{4'}$; q, $J_{4',5'}$=10.6), 4.59

($H_{3'}$; m, $J_{3',4'}=3.9$), 4.46 ($H_{5'}$; sex, $J_{5',6'_a}=3.5$, $J_{5',6'_b}=3.0$), 4.34 ($H_{6'_a}$; q, $J_{6'_a,6'_b}=12.0$), 4.24 ($H_{6'_b}$; q), 2.52 (=NAc), 2.30 and 2.22 (NAc), 2.09 and 2.02 (3×OAc).

Found: C, 49.51; H, 5.51; N, 9.21%. Calcd for $C_{19}H_{25}N_3O_{10}$: C, 50.11; H, 5.53; N, 9.23%.

3-Cyanamido-3-deoxy-1,2; 5,6-di-O-isopropylidene-α-D-allofuranose (9). a) To a solution of 3-amino-3-deoxy-1,2; 5,6-di-*O*-isopropylidene-α-D-allofuranose[17] (130 mg, 0.5 mmol) in ether (5 ml) was added portionwise cyanogen bromide (27 mg, 0.25 mmol) in ether (3 ml) with stirring, and the resulting solution was left to stand at room temperature for 4 hr. A white precipitate (67 mg) deposited was filtered off, and the filtrate was evaporated. The residue was extracted with benzene, and the extract was again evaporated to give colorless sirup (62.3 mg, 89%) which was purified on a silica-gel column. This sirup crystallized on standing. Mp 83—84 °C, $[\alpha]_D^{23}$ +76.1° (*c* 1.80, EtOH), IR: 2220 (CN).

Found: C, 54.89; H, 7.07; N, 9.56%. Calcd for $C_{13}H_{20}N_2O_5$: C, 54.92; H, 7.09; N, 9.85%.

b) A solution of **10** (151 mg, 0.5 mmol) and methanesulfonyl chloride (58 ml, 0.75 mmol) in pyridine (4 ml) was left to stand at room temperature for one day, poured into ice-water (30 ml), and then extracted to give a sirup (112 mg, 79%) which was purified on a silica-gel column as above. Yield, 96 mg (68%).

3-Deoxy-1,2; 5,6-di-O-isopropylidene-3-ureido-α-D-allofuranose (10). A solution of 3-amino-3-deoxy-1,2; 5,6-di-*O*-isopropylidene-α-D-allofuranose (259 mg, 1 mmol), potassium cyanate (122 mg, 1.5 mmol), and acetic acid (0.06 ml, 1 mmol) in water (5 ml) was heated at 100 °C for 90 min, and treated with Amberlite IRA-410 (2 ml) for one day and then with Amberlite CG-50-I to remove potassium ion and unreacted starting material. The effluent was evaporated to give a sirup (258 mg, 85.5%) which crystallized from ether. Yield, 220 mg (73%), mp 164 °C, $[\alpha]_D^{23}$ +87.4° (*c* 1.0, EtOH), IR: 1675 (ureido).

Found: C, 51.18; H, 7.27; N, 9.52%. Calcd for $C_{13}H_{22}N_2O_6$: C, 51.64; H, 7.34; N, 9.27%.

3-Deoxy-1,2; 5,6-di-O-isopropylidene-3-thioureido-α-D-allofuranose (11). To a solution of **9** (177 mg, 0.62 mmol) in pyridine (5 ml) was passed hydrogen sulfide at room temperature for 5 hr. The solution was then evaporated to give a sirup which crystallized from ethanol (40 mg, 20%). Recrystallization from methanol gave fine needles. Mp 219—220 °C, $[\alpha]_D^{23}$ +108.4° (*c* 0.5, EtOH), IR: 3430, 3360, and 3330 (NH), 1532 (thioureido).

Found: C, 48.64; H, 7.00, N, 9.00; S, 9.83%. Calcd for $C_{13}H_{22}N_2O_5S$: C, 49.04; H, 6.97; N, 8.79; S, 10.07%.

3-Deoxy-3-guanidino-1,2; 5,6-di-O-isopropylidene-α-D-glucofuranose (12) Flavianate. To a cold solution of 3-amino-3-deoxy-1,2; 5,6-di-*O*-isopropylidene-α-D-glucofuranose[20] (2.5 g, 9.7 mmol) in ether (60 ml) was added with stirring 0.5 equivalent of cyanogen bromide in ether (40 ml), and the resulting solution was left to stand at room temperature for 6 hr, the hydrobromide of the aminosugar then being filtered. The sirupy product obtained by evaporation of the filtrate was purified on a silica-gel column with benzene–ethyl acetate (8: 1) as effluent. The cyanamido derivative (1.11 g, 81.5% based on cyanogen bromide) showed the characteristic absorption of nitrile (2200 cm^{-1}) in IR spectrum. A solution of the cyanamide in methanol (50 ml) saturated with ammonia was heated in a sealed tube at 80—90 °C for 20 hr, and then evaporated. Addition of flavianic acid (1.4 g, 3.8 mmol) in ethanol to a suspension of the resulting sirup in a small amount of water gave the flavianate of **12** as yellow crystals, which were recrystallized from aqueous acetone. Mp 185—190 °C (decomp.), yield, 39% based on the cyanamide; $[\alpha]_D^{23}$ −22.4° (*c* 1.0, pyridine).

Found: C, 44.77; H, 4.73; N, 11.47; S, 5.58%. Calcd for $C_{23}H_{29}N_5O_{13}S$: C, 44.87; H, 4.74; N, 11.37; S, 5.21%.

3-Deoxy-3-guanidino-D-glucose (13) Flavianate. A suspension of the flavianate of **12** (500 mg, 0.81 mmol) and flavianic acid (200 mg, 0.51 mmol) in water (60 ml) was heated at 80 °C for 4 hr to give a homogeneous solution, and the solution was then evaporated. The residue was washed with ethanol to give **13** quantitatively as flavianate. For elemental analyses. a portion of it was recrystallized from methanol. Mp 210 °C (decomp.); $[\alpha]_D^{23}$ +17.2→+23.8° (in H_2O, after 48 hr).

Found: C, 38.65; H, 4.01; N, 13.41%. Calcd for $C_{17}H_{21}N_5O_{13}S$: C, 38.13; H, 3.95; N, 13.08%.

This compound was positive in the Sakaguchi and Fehling reactions.

1,2,3,4-Tetra-O-acetyl-3-deoxy-3-diacetylguanidino-α,β-D-glucopyranose (14). Acetylation of **13** (300 mg, 0.56 mmol) with acetic anhydride (620 mg, 6.08 mmol) in pyridine gave sirupy product which showed three spots (R_f=0.66, 0.52 and 0.12) on a preparative tlc with benzene–ethyl acetate (1: 1) as developing solvent. The portion R_f=0.52 was extracted with acetone to give **14** (50 mg, 19%) as a sirup. $[\alpha]_D^{23}$ +35.8° (*c* 1.21, $CHCl_3$); λ_{max}^{EtOH} 256 and 220 nm.

Found: C, 48.52; H, 5.82; N, 8.32%. Calcd for $C_{19}H_{27}N_3O_{11}$: C, 48.19; H, 5.74; N, 8.87%.

The authors are greatful to Mr. H. Matsumoto for measurement of NMR spectra, and to members of the Laboratory of Organic Analysis for elemental analysis.

Solvent Effects in Diazo-coupling Reactions

Yōji HASHIDA, Hiroki ISHIDA, Shizen SEKIGUCHI, and Kohji MATSUI
Department of Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma 376
(Received November 26, 1973)

The kinetics of the diazo-coupling reactions of benzenediazonium fluoroborates with 1,3,5-trimethoxybenzene and 2-naphthol have been studied in non-aqueous media including both protic and dipolar aprotic solvents. In the case of the reaction with 1,3,5-trimethoxybenzene, no significant solvent effect on the reaction rate was observed. However, in the case of the reaction with 2-naphthol, the reaction rate was affected markedly by the solvent; in dipolar aprotic solvents, the reaction proceeded much faster than in protic solvents. The observed results are interpreted in terms of the difference in solvation toward the naphtholate ion.

Generally, diazo-coupling reactions are carried out in an aqueous medium. The mechanisms of these reactions and the reactivities of the reactants have been extensively studied kinetically.[1] However, little is known about the solvent effects on the reaction rate. Recently, a kinetic study of the coupling reactions of *N,N*-dimethylaniline in several dipolar aprotic solvents (nitromethane, acetonitrile, and sulfolane) has been reported by Penton *et al.*,[2] who showed that no significant solvent effect was observed.

In this paper, we wish to report the solvent effects on the reactions of diazonium salts with 1,3,5-trimethoxybenzene and 2-naphthol.

Experimental

Reagents. Commerical 1,3,5-trimethoxybenzene and 2-naphthol were recrystallized from ethanol and water respectively. *m*-Nitrobenzenediazonium fluoroborate and benzenediazonium fluoroborate were prepared by the usual method[3] and dried under a vacuum over phosphorus pentoxide in the dark.

Solvents. The methanol was dried with calcium oxide and fractionally distilled. The formic acid was twice fractionally distilled. The acetic acid was purified according to the method of MacInnes *et al.*[4] The propionic acid was dried over anhydrous sodium sulfate and fractionally distilled. The nitromethane and acetonitrile were purified by drying over phosphorus pentoxide and fractionally distilled. The dimethyl sulfoxide was purified by distillation on sodium hydroxide. The dimethylformamide was purified according to the method of Clare.[5]

Kinetic Measurements. The rates were measured by following the increase in the optical density of the azo compound formed with the lapse of time using a Hitachi 124-type spectrophotometer thermostated at 20 °C. As a large excess of the substrate was always present, the reactions followed a pseudo-first-order relationship (1):

$$k't = \ln \frac{E_\infty}{E_\infty - E_t} \quad (1)$$

where E_∞ and E_t denote the optical densities at an infinite time and at time t respectively. The rate constants thus obtained were constant up to more than 80% of the reaction.

Reaction with 1,3,5-Trimethoxybenzeme: To 100 ml of a solution of 1,3,5-trimethoxybenzene (2×10^{-3}M), was added 1 ml of a solution of *m*-nitrobenzenediazonium salt (4×10^{-3}M). Aliquots of the reaction mixture were pipetted into a thermostated spectrophotometric cell at 20 °C, and the optical density was measured at the absorption maximum of the azo compound.

Reaction with 2-Naphthol: Because of the dependence of the apparent rate constant (k') on the solvent acidity, all the kinetic measurements were carried out in appropriate buffer solutions. A reaction mixture containing 2-naphthol ($1—5\times10^{-3}$M) and appropriate buffer reagents was divided into two parts. One of the parts was used for the kinetic measurement in a manner similar to that described in the reaction of 1,3,5-trimethoxybenzene. The 475 mμ wavelength was monitored for an increase in the optical density of the azo compound. The other part was used for the measurement of the acidity function (H_-) using Eq. (2), by adding an appropriate indicator; the ionization ratio of an indicator was measured spectrophotometrically.

$$H_- = \mathrm{p}K_a + \log \mathrm{R} \quad (2)$$

$\mathrm{p}K_a$: Ionization constant of an indicator in a given solvent
R: Ionization ratio for an indicator in a given solvent

Table 1 lists the indicators employed and their $\mathrm{p}K_a$ values. The kinetic results are summarized in Tables 2, 3, 4, and 5.

In an aqueous medium, the rates were measured as follows: bacause of the low solubility of the azo compound, 10 ml portions of the sample solution were withdrawn from the reaction mixture at definite time intervals and added to 5 ml of a 2 M HCl solution in order to stop the reaction. The solution was then diluted to 25 ml with methanol, and the extinction was measured.

$\mathrm{p}K_a$ *Measurements.* The $\mathrm{p}K_a$ values of 2-naphthol in organic solvent were determined by the indicator method using Eq. (3);[6] the ratio of the acidic to the basic form of an indicator and 2-naphthol was determined spectrophotometrically.

$$\mathrm{p}K_a = \mathrm{p}K_I + \log \frac{C_{Ib}\times C_{Na}}{C_{Ia}\times C_{Nb}} \quad (3)$$

$\mathrm{p}K_a$: $\mathrm{p}K_a$ value of 2-naphthol

Table 1. $\mathrm{p}K_a$ VALUES OF INDICATORS

pK_I: pK_a value of an indicator

C_{Ia}, C_{Ib}: Concentrations of the acidic and basic forms of an indicator respectively.

C_{Na}, C_{Nb}: Concentrations of the acidic and dissociated forms of naphthol respectively

The results obtained are summarized in Table 6.

As a check of the method described above, the pK_a value of phenol was also measured. As is evident from Table 6, there is no disagreement between the pK_a values of phenol in the present work and the reference.

Results and Discussion

Reaction with 1,3,5-Trimethoxybenzene. The first-order dependence of the reaction rate on the concentration of a diazonium salt may be apparent from the applicability of Eq. (1) to this reaction; the reaction rate (k') also showed a first-order dependence on the substrate concentration. Thus, the reaction rate can be expressed by Eq. (6), showing that this is a reaction

between a cation and an uncharged molecule:

$$\text{Rate} = k_2(\text{Ar}-\overset{+}{\text{N}}_2)\left(\begin{array}{l}\text{MeO}\\ \\ \text{MeO}\end{array}\!\!\!

must be small, because this reaction is a cation-anion combination reaction and in the transition state the charge is considered to have almost disappeared.[1] Therefore, the rate change shown in Table 9 is considered to depend mainly on the difference in solvation energy toward the naphtholate ion.

It is well known that an anion is solvated in protic solvents by the general hydrogen-bonding interaction;[7] consequently, the substrate is stabilized and the rate is slow in the hydroxylic solvents, as can be seen in Table 9. The increase in the rate on transfer from water to methanol may be understood from the difference in the hydrogen-bonding capacity of these solvents.[12] On the other hand, the fact that anions are poorly solvated in dipolar aprotic solvents[7] is considered to be responsible for the rapid reactions in these solvents.

It is interesting that, despite the similar physical properties of dimethyl sulfoxide and acetonitrile, a large difference was observed between the rate constants of the reactions in these solvents; the reactivity sequence in Table 9 is in accord with the order of the pK_a values of naphthol (Table 6) in these solvents. The results suggest that a naphthol generates a reactive naphtholate ion in a solvent in which it indicates a high pK_a value. However, a detailed discussion of these results must wait until later.

Oxytocin Analogues Containing No Disulfide Bond. III. The Synthesis of Three Analogues of 1,6-Aminosuberic Acid-Oxytocin

Tsutomu YAMANAKA* and Shumpei SAKAKIBARA**
Peptide Institute, Protein Research Foundation, Ina, Minoh, Osaka 562
(Received November 26, 1973)

[Asu^{1,6}]-oxytocin, an analogue of deamino-oxytocin in which the disulfide bond is replaced by an ethylene linkage, is completely resistant to deterioration during storage under concentrated conditions. In the present study, three new analogues of this material, [Phe^3, Asu^{1,6}]-oxytocin, [Val^4, Asu^{1,6}]-oxytocin, and [Gly^7, Asu^{1,6}]-oxytocin, were synthesized to find out a hormonal compound possessing a specifically higher uterotonic activity. Among them, the [Gly^7]-analogue was found to be the most promising compound; it showed a relatively higher uterotonic activity (245 IU/mg) in the rat, with a faint antidiuretic activity (0.02 IU/mg) and a weak depressor activity.

Deamino-oxytocin, which has a β-mercaptopropionyl residue in place of the cysteinyl residue in the 1 position of oxytocin, exhibits a higher oxytocic activity than the original oxytocin.[2] This fact indicates that the free amino group of oxytocin is not essential for the hormonal function. One or both sulfur atoms of the disulfide bridge in the deamino-oxytocin can also be replaced by one or two methylene groups respectively without any conspicuous loss of the hormonal activities.[3–5] In the first paper of this series,[5] we introduced an efficient procedure for the synthesis of such an analogue of deamino-oxytocin, [Asu^{1,6}]-oxytocin, in which the disulfide bond is replaced by an ethylene linkage, as is shown in Fig. 1.[5] The compound synthesized by the new procedure showed a much higher oxytocic potency than the reported value[4] for the compound. Then, the procedure was applied to the syntheses of [Asu^{1,6}]-vasopressins and vasotocins. These new derivatives were also confirmed to be biologically active, as had been expected.[6–8] Thus, it was concluded that the disulfide bridge itself in neurohypophyseal hormones in not required, in general, for the exhibition of their hormonal activities.[8] Later, the [Asu^{1,6}]-oxytocin synthesized by our procedure was found to be crystallized from water,[9] and the crystallized compound showed a higher uterotonic activity (160 IU/mg) than the highest value (134 IU/mg),[9] so far reported for the amorphous compounds.

Both natural and synthetic neurohypophyseal hormones are known to be reduced in their potency in the course of such common procedures for isolation as concentration and lyophilization. The Asu-derivatives, however, are completely resistant to inactivation during those procedures, even in the presence of triethylamine.[8,9]

Therefore, if we can find an analog of the Asu-oxytocin, which has a sufficiently higher potency in oxytocic activity, with negligibly lower potencies in pressor and antidiuretic activities, the use of such a compound as a drug for labor induction should be much more advantageous than that of natural oxytocin.

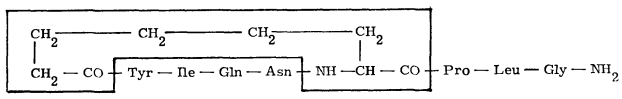

Fig. 1. Structure of [Asu^{1,6}]-Oxytocin.

In the present study, we have synthesized three new analogues of the Asu-oxytocin, [Phe^3, Asu^{1,6}]-oxytocin, [Val^4, Asu^{1,6}]-oxytocin, and [Gly^7, Asu^{1,6}]-oxytocin, and their hormonal activities have been compared in order to find a promising compound for use as an oxytocic hormone. Their parent compounds, [Phe^3]-oxytocin,[10] [Val^4]-oxytocin,[11] and [Gly^7]-oxytocin,[12] are already known to exhibit specific spectra in their biological activities (See Table 1).

The syntheses were carried out by the stepwise elongation technique,[13] as is shown in Charts 1, 2, and 3. Two different procedures, which had previously

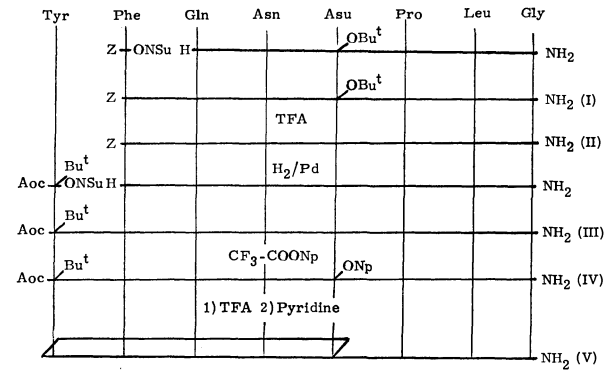

Chart 1. Synthesis of [Phe^3, Asu^{1,6}]-Oxytocin.

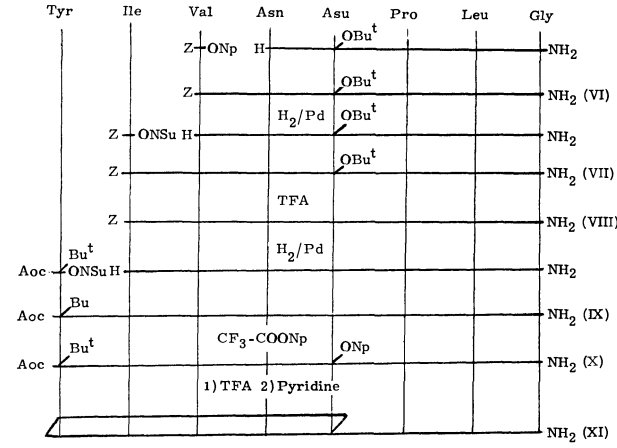

Chart 2. Synthesis of [Val^4, Asu^{1,6}]-Oxytocin.

been used for the synthesis of Asu-oxytocin[5] and Asu-vasopressins,[8] were applied to the cyclization of these linear peptides in order to compare the efficiency of the respective procedures. Consequently, no particular difference was found between these two procedures in terms of the yield.

The biological activities of the products were determined by the Yoshitomi Pharmaceutical Industry; the data are shown in Table 1. For comparison, the reported values for the original compounds are also included in the Table. In the cases of Phe- and Val-analogues, no significant changes were observed in their biological activities. However, the Gly-analogue was considered to be one of the promising compounds as an oxytocic hormone; its uterotonic activity was much more potent than that of the original Asu-oxytocin, and the ratios of the pressor and antidiuretic activity to the uterotonic activity were both sufficiently lower than those of the original compounds.

Experimental[14]

All the melting points were determined by the capillary method, and are given as uncorrected values. The products were dried over phosphorus pentoxide *in vacuo* at room temperature, unless otherwise noted. The solvent systems used for chromatography were: I, Chloroform: methanol: acetic acid (95: 5: 3 v/v); II, *n*-butanol: acetic acid: water (4: 1: 1 v/v); III, *n*-butanol: pyridine: water (4: 1: 1 v/v).

General Procedure for the Removal of Benzyloxycarbonyl or Benzyl Groups by Catalytic Hydrogenolysis. Hydrogen was gently bubbled through a solution or suspension of a benzyloxycarbonyl or benzyl derivative at room temperature, in which palladium black or palladium charcoal had previously been added as the catalyst. The progress of the reaction was monitored by thin-layer chromatography using Merck's Silica-gel G. After the completion of the reaction had been confirmed by thin-layer chromatography, the catalyst was removed by filtration, the filtrate was concentrated under reduced pressure, and the residue was subjected to the next step.

Benzyloxycarbonyl-L-phenylalanyl-L-glutaminyl-L-asparaginyl-ω-t-butyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (I).

Benzyloxycarbonyl-L-glutaminyl-L-asparaginyl-ω-*t*-butyl-L-α-aminosubery-L-prolyl-L-leucylglycine amide[5] (4.0 g, 4.41 mmol) was subjected to catalytic hydrogenolysis in a mixture of dioxane–water (3: 1 v/v, 80 ml), and the product was dissolved in DMF (20 ml). The benzyloxycarbonyl-L-phenylalanine *N*-hydroxysuccinimide ester[15] (2.8 g, 7.06 mmol) was then added to the solution, and the mixture was allowed to react for 3 days at room temperature. Ethyl acetate was added to the reaction mixture to precipitate the product, which was collected by filtration and recrystallized from 90% aqueous ethanol; wt. 3.79 g (81.5%); mp 184—186 °C, $[\alpha]_D^{17}$ −42.7° (*c* 0.95, DMF).

Found: C, 57.95; H, 7.28; N, 13.47%. Calcd for $C_{51}H_{74}O_{13}N_{10}\cdot H_2O$: C, 58.16; H, 7.27; N, 13.30%.

Benzyloxycarbonyl-L-phenylalanyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (II). Compound I (3.71 g, 3.5 mmol) was dissolved in TFA (50 ml), and the solution was kept for an hour at room temperature. Then, the TFA was removed under reduced pressure and the oily residue was solidified by trituration with ether. The product was reprecipitated from 90% ethanol, washed with ethanol, and dried; wt. 2.85 g (80.7%); mp 182.5—185 °C (decomp.), $[\alpha]_D^{18}$ −45.9° (*c* 0.91, DMF).

Found: C, 56.14; H, 6.90; N, 13.57%. Calcd for $C_{47}H_{66}O_{13}N_{10}\cdot 1.5H_2O$: C, 56.10; H, 6.91; N, 13.92%.

t-Amyloxycarbonyl-O-t-butyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (III). Compound II (4.5 g, 4.4 mmol) was subjected to catalytic hydrogenolysis in a mixture of dioxane–water (4: 1 v/v, 100 ml). Then the heptapeptide amide thus formed was treated with the *t*-amyloxycarbonyl-*O*-*t*-butyl-L-tyrosine *N*-hydroxysuccinimide ester[8] (4.0 g, 8.9 mmol) in DMF (20 ml) at room temperature for 24 hr. The product was precipitated by the addition of ethyl acetate, and the precipitates were collected by filtration, washed well with hot ethyl acetate, and then reprecipitated from 33% aqueous ethanol; wt. 2.17 g (41.3%); mp 197.5—198.5 °C (decomp.), $[\alpha]_D^{23}$ −37.7° (*c* 1.0, DMF).

Found: C, 58.09; H, 7.40; N, 12.74%. Calcd for $C_{58}H_{87}O_{15}N_{11}\cdot H_2O$: C, 58.22; H, 7.50; N, 12.88%.

t-Amyloxycarbonyl-O-t-butyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparaginyl-ω-p-nitrophenyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (IV). Compound III (1.33 g, 1.11 mmol) was treated with *p*-nitrophenyl trifluoroacetate[5,16] (2.8 g, 11.9 mmol) in a mixture of DMF (25 ml) and pyridine (6.2 ml) for 3 hr at 50 °C. The product was precipitated with ether, collected by filtration, and washed well with ether. The washed material was reprecipitated from 40% aqueous ethanol; wt. 1.08 g (74%); mp 198—199 °C (decomp.), $[\alpha]_D^{23}$ −32.9° (*c* 0.75, DMF).

Found: C, 58.34; H, 7.19; N, 12.42%. Calcd for $C_{64}H_{90}O_{17}N_{12}\cdot H_2O$: C, 58.34; H, 7.04; N, 12.76%.

Lactam of L-Tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (V): [Phe³, Asu¹,⁶]-Oxytocin. Compound IV (616 mg, 0.47 mmol) was dissolved in TFA (6 ml), and the solution was allowed to react for 1.5 hr at room temperature. Then, the TFA was evaporated out under reduced pressure, and the residue was dissolved in DMF (10 ml). The solution was stirred into pyridine (300 ml), drop by drop, at 40 °C. After the addition, the mixture was kept overnight at room temperature, and then concentrated to a residue under reduced pressure, and the residue was treated with ether to obtain the product as a powder. The powdered material was dissolved in a minimum amount of methanol and charged on the top of a column of Sephadex LH-20 (1.5×45.5 cm). The column was eluted with methanol, 1.5 g fractions were collected, and peptides were detected by means of the UV absorption at 280 nm. The effluents in tubes No. 21 to 27 were pooled and concentrated. The product was applied to 7 thin-layer plates of Silica-gel GF 254 (5×16 cm each) and developed by the solvent system II. The locations of the separated materials were detected by UV-irradiation, and the major band on each plate was collected by scraping. The material adsorbed on the pooled silica-gel was extracted with methanol and further applied to a column of CM-Sephadex C-25 (H^+ form) (1.5×27 cm). The column was eluted with 50% aqueous methanol, and 3 g fractions were collected. The effluents in tubes No. 15 to 24 were pooled and concentrated, and the residue was lyophilized from water; wt. 47 mg (overall 18%), $[\alpha]_D^{17}$ −68.1° (*c* 0.36, methanol).

Ratio of amino acids in an acid hydrolyzate (6 M HCl, 48 hr at 105 °C): Tyr, 1.00; Phe, 1.00; Glu, 1.03; Asp, 1.00; Asu, 0.97; Pro, 0.94; Leu, 0.97; Gly, 0.97. The average recovery was 93%.

Found: C, 51.58; H, 7.01; N, 13.08%. Calcd for $C_{45}H_{67}O_{12}N_{11}\cdot 7H_2O$: C, 51.65; H, 7.31; N, 13.08%.

This material was confirmed to be homogeneous by thin-layer chromatography (Silica-gel G, Solvent II) and by paper electrophoresis (Toyo, No. 514, pH 4.8 pyridine-acetic acid buffer). The R_f-values on paper chromatography (Toyo, No. 51) were 0.74 for Solvent II and 0.55 for Solvent III. These chromatograms were located with Pauly's reagent.

Benzyloxycarbonyl-L-valyl-L-asparaginyl-ω-t-butyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (VI). Benzyloxycarbonyl-L-asparaginyl-*ω*-*t*-butyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine amide[5] (3.5 g, 4.6 mmol) was subjected to catalytic hydrogenolysis in a dioxane–water mixture (3: 1 v/v, 80 ml), and the resulting material was allowed to react with the benzyloxycarbonyl-L-valine *p*-nitrophenyl ester[17] (2.25 g, 6.0 mmol) in DMF (16 ml) for 2 days at room temperature. Excess ethyl acetate was added to the reaction mixture to precipitate the product, which was then collected by filtration and washed with ethyl acetate. The filtrate was recrystallized from 90% aqueous ethanol; wt. 3.4 g (86%); mp 222—223 °C (decomp.), $[\alpha]_D^{26}$ −46.5° (*c* 0.79, DMF).

Found: C, 59.02; H, 7.94; N, 12.61%. Calcd for $C_{42}H_{66}O_{11}N_8$: C, 58.72; H, 7.75; N, 13.02%.

Benzyloxycarbonyl-L-valyl-L-asparaginyl-ω-t-butyl-L-α-aminosuberyl-L-leucylglycine Amide (VII). Compound VI (3.15 g, 3.67 mmol) was suspended in a mixture of dioxane and water (2: 1 v/v, 75 ml), and the mixture was subjected to catalytic hydrogenolysis as has been shown above. During the course of the hydrogenolysis, the insoluble material went into a solution. After the removal of the catalyst, the solution was concentrated under reduced pressure, the residue was dissolved in 30 ml of DMF, and then the benzyloxycarbonyl-L-isoleucine *N*-hydroxysuccinimide ester[15] (2.0 g, 5.5 mmol) was added to the solution. The mixture was allowed to react for one day at room temperature. Then, ethyl acetate was added to the reaction mixture, the precipitated product was collected by filtration, and it was reprecipitated from 90% aqueous ethanol; wt. 2.45 g (67.5%); mp 240—240.5 °C (decomp.), $[\alpha]_D^{17}$ −40.6° (*c* 0.85, DMF).

Found: C, 58.18; H, 8.06; N, 12.48%. Calcd for $C_{48}H_{77}O_{12}N_9\cdot H_2O$: C, 58.22; H, 8.04; N, 12.73%.

Benzyloxycarbonyl-L-isoleucyl-L-valyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (VIII). Compound (VII) (2.17 g, 2.16 mmol) was dissolved in TFA (25 ml) and the solution was kept for one hour at room temperature. Then, the TFA was removed under reduced pressure, and an oily residue was solidified by trituration with ether. The product was reprecipitated from 90% aqueous ethanol, collected by filtration, washed with ethanol, and dried; wt. 1.63 g (80.1%); mp 224—226 °C (sintered) and 236—238 °C (decomp.), $[\alpha]_D^{23}$ −44.9° (*c* 0.84, DMF).

Found: C, 55.88; H, 7.46; N, 13.08%. Calcd for $C_{44}H_{59}O_{12}N_9\cdot 1.5H_2O$: C, 56.03; H, 7.70; N, 13.37%.

t-Amyloxycarbonyl-O-t-butyl-L-tyrosyl-L-isoleucyl-L-valyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (IX).

Compound VIII (1.57 g, 1.68 mmol) was subjected to catalytic hydrogenolysis in dioxane–water (3: 1 v/v) as has been described above. The catalyst was filtered off, the filtrate was concentrated under reduced pressure, and the resulting peptide amide was dissolved in DMF (60 ml). The *t*-amyloxycarbonyl-*O*-*t*-butyl-L-tyrosine *N*-hydroxysuccinimide ester[8] (1.29 g, 2.88 mmol) was then added to the solution, and the mixture was allowed to react for 2 days at room temperature; the pH of the solution was kept at 7—8 throughout the period using *N*-ethylmorpholine. Then, the product was precipitated by the addition of ethyl acetate, collected by filtration, and washed well with ethyl acetate. Finally, the washed product was reprecipitated from 90% aqueous ethanol; wt. 0.93 g (49%); mp 229—230 °C (decomp.), $[\alpha]_D^{25}$ −43.1° (*c* 0.77, DMF). Ratio of amino acids in an acid hydrolyzate (6 M HCl, 48 hr at 105 °C): Tyr, 1.29; Ile+Asu, 2.17; Val, 0.84; Asp, 0.97; Pro, 1.00; Leu, 1.19;

Gly, 0.97.

Found: C, 58.27; H, 8.36; N, 12.08%. Calcd for $C_{55}H_{90}O_{14}N_{10}\cdot H_2O$: C, 58.28; H, 8.18; N, 12.36%.

t-Amyloxycarbonyl-O-t-butyl-L-tyrosyl-L-isoleucyl-L-valyl-L-asparaginyl-ω-p-nitrophenyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (X). The protected octapeptide amide (IX) (871.7 mg, 0.77 mmol) was treated with *p*-nitrophenyl trifluoroacetate[5,16] (2.8 g, 11.9 mmol) for 3 hr at 50 °C in a mixture of DMF (25 ml) and pyridine (6.2 ml). Then, the product was precipitated with ether, collected by filtration, and washed well with ether. The product was purified by reprecipitation from DMF–ether; wt. 0.60 g (62%); mp 251—252 °C (decomp.), $[\alpha]_D^{27}$ −37.0° (*c* 0.73, DMF).

Found: C, 58.67; H, 7.78; N, 12.09%. Calcd for $C_{61}H_{93}O_{16}N_{11}\cdot H_2O$: C, 58.40; H, 7.63; N, 12.28%.

Lactam of L-Tyrosyl-L-isoleucyl-L-valyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (XI): [Val⁴, Asu¹·⁶]-Oxytocin. Compound X (0.67 g, 0.53 mmol) was dissolved in TFA (6 ml), and the mixture was allowed to react for 1.5 hr at room temperature. Then, the TFA was evaporated out under reduced pressure and the residue was dissolved in DMF (10 ml). The solution was stirred into pyridine (300 ml), drop by drop, at 40 °C. After standing overnight at room temperature, the pyridine solution was concentrated to a residue under reduced pressure, the residue was triturated with ether, and the separated material was collected. The product was dissolved in water (15 ml), and the solution was passed through a column of Amberlite IR-45 (OH^- form, 1×10 cm) and a column of CM-Sephadex C-25 (H^+ form, 1×10 cm) successively. The effluents were monitored by means of the UV absorption at 280 nm, and the fractions containing a major peak were pooled and lyophilized to obtain the final product; wt. 99.5 mg (24.8%); $[\alpha]_D^{20}$ −101° (*c* 0.47, water). The homogeneity of the product was confirmed by thin-layer chromatography on Silica gel G using the solvent system II (single spot, with R_f 0.58 as located by exposure to iodine vapor) and by paper electrophoresis (Toyo No. 514), using a pyridine–acetic acid buffer pH 4.8 (50V/cm, 60 min, located by a Pauly reagent). Ratio of amino acids in an acid hydrolyzate (6 M HCl, 48 hr at 105 °C): Tyr, 0.95; Ile, 1.00; Val, 0.98; Asp, 1.04; Asu, 1.05; Pro, 1.04; Leu, 1.03; Gly, 0.98. The average recovery was 85%.

Found: C, 53.89; H, 8.00; N, 13.86%. Calcd for $C_{45}H_{70}O_{11}N_{10}\cdot 4H_2O$: C, 54.09; H, 7.87; N, 14.02%.

Benzyloxycarbonyl-glycyl-L-leucylglycine Amide (XII). Benzyloxycarbonyl-glycyl-L-leucylglycine ethyl ester[18] (26.0 g) was dissolved in methanol (340 ml), and the solution was saturated with ammonia at 0 °C. After having been kept for 72 hr at room temperature, the solution was concentrated under reduced pressure and the residue was recrystallized from ethanol –*n*-hexane; wt. 19.6 g (81.3%); mp 123—125 °C, $[\alpha]_D^{16}$ −15.2° (*c* 1.1, DMF). lit[12], mp 113—115°C, $[\alpha]_D^{28}$ −15.3° (*c* 1, DMF).

Found: C, 56.49; H, 7.11; N, 14.69%. Calcd for $C_{18}H_{26}O_5N_4\cdot 1/4H_2O$: C, 56.46; H, 6.98; N, 1D.63%.

Benzyloxycarbonyl-ω-t-butyl-L-α-aminosuberyglycyl-L-leucylglycine Amide (XIII). Compound XII (8.2 g, 22 mmol), was subjected to catalytic hydrogenolysis in ethanol, and the glycyl-L-leucylglycine amide thus obtained was coupled with the benzyloxycarbonyl-ω-*t*-butyl-L-α-aminosuberic acid α-*p*-nitrophenyl ester[5] (8.4 g, 16.8 mmol) in DMF (12 ml) for 24 hr at room temperature. Water was added to the reaction mixture to precipitate the product, which was then taken up with ethyl acetate. The solution was washed thoroughly with 1 M aqueous ammonia until no yellow color was detectable in the washing; then the solution was washed once with 0.6 M hydrochloric acid and dried over sodium sulfate. The dried solution was concentrated under reduced pressure, and the residue was recrystallized from ethyl acetate–ethanol; wt. 9.1 g (88.1%); mp 144—146 °C, $[\alpha]_D^{22}$ −10.8° (*c* 0.98, DMF).

Found: C, 59.01; H, 8.13; N, 11.11%. Calcd for $C_{30}H_{47}O_8N_5\cdot 1/4H_2O$: C, 59.04; H, 7.85; N, 11.48%.

Benzyloxycarbonyl-L-asparaginyl-ω-t-butyl-L-α-aminosuberyglycyl-L-leucylglycine Amide (XIV). Compound XIII (9.3 g, 15.4 mmol) was subjected to hydrogenolysis in ethanol, and the product was allowed to react with the benzyloxycarbonyl-L-asparagine *p*-nitrophenyl ester[13] (6.3 g, 16.2 mmol) in DMF (20 ml) for 2 days at room temperature. The product was precipitated by dilution with ethyl acetate and collected by filtration; the collected material was washed with ethyl acetate and acetone, and recrystallized from 90% aqueous ethanol; wt. 9.8 g (86.3%); mp 223—224.5 °C (decomp.), $[\alpha]_D^{22}$ −13.1° (*c* 0.96, DMF).

Found: C, 55.59; H, 7.52; N, 13.09%. Calcd for $C_{34}H_{53}O_{10}N_7\cdot H_2O$: C, 55.34; H, 7.51; N, 13.29%.

Benzyloxycarbonyl-L-glutaminyl-L-asparaginyl-ω-t-butyl-L-α-aminosuberylglycyl-L-leucylglycine Amide (XV). The benzyloxycarbonyl group of Compound XIV (9.8 g, 13.3 mmol) was removed by catalytic hydrogenolysis, and the product was coupled with the benzyloxycarbonyl-L-glutamine *p*-nitrophenyl ester[13] (5.6 g, 14 mmol) as above. The product was precipitated from the reaction mixture, collected by filtration, and boiled in 90% aqueous ethanol to extract the soluble materials. The remaining insoluble material was collected by filtration and dried; wt. 9.8 g (85.9%); mp 244.5—245 °C (decomp.), $[\alpha]_D^{25}$ −30.7° (*c* 0.75, acetic acid). Ratio of amino acids in an acid hydrolyzate (6 M HCl, 48 hr at 105 °C): Glu, 1.08; Asp, 1.00; Asu, 0.94; Gly, 2.03; Leu, 1.00; The average recovery was 97%.

Found: C, 54.76; H, 7.35; N, 14.92%. Calcd for $C_{39}H_{61}O_{12}N_9\cdot 1/2H_2O$: C, 54.66; H, 7.29; N, 14.71%.

Benzyloxycarbonyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-ω-t-butyl-L-α-aminosuberylglycyl-L-leucylglycine Amide (XVI). The benzyloxycarbonyl group of Compound XV (9.8 g, 11.4 mmol) was removed by catalytic hydrogenolysis, and the product was coupled with the benzyloxycarbonyl-L-isoleucine *N*-hydroxysuccinimide ester[15] (5.5 g, 15.2 mmol) in DMF (90 ml), as in the case of Compound VII. Ethyl acetate was added to the reaction mixture, and the precipitate was reprecipitated from DMF–ethyl acetate; wt. 8.1 g (73.3%); mp 248—249 °C (decomp.), $[\alpha]_D^{25}$ −39.4° (*c* 0.83, acetic acid).

Found: C, 55.69; H, 7.72; N, 14.50%. Calcd for $C_{45}H_{72}O_{13}H_{10}\cdot 1/2H_2O$: C, 55.71; H, 7.58; N, 14.44%.

Benzyloxycarbonyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberylglycyl-L-leucylglycine Amide (XVII). Compound XVI (7.9 g, 8.14 mmol) was treated with TFA (80 ml) as in the case of the synthesis of compound VIII. The product was reprecipitated from 90% aqueous ethanol; wt. 7.55 g (98.6%); mp 239—240 °C (decomp.), $[\alpha]_D^{23}$ −33.3° (*c* 1.0, acetic acid).

Found: C, 52.57; H, 7.22; N, 14.88%. Calcd for $C_{41}H_{64}O_{13}N_{10}\cdot 2H_2O$: C, 52.33; H, 7.28; N, 14.89%.

Benzyloxycarbonyl-O-benzyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberylglycyl-L-leucylglycine Amide (XVIII). Compound XVII (7.45 g, 7.9 mmol) was subjected to hydrogenolysis in an ethanol–water–acetic acid mixture (5: 5: 2 v/v, 100 ml), and the free heptapeptide amide thus obtained was treated with the benzyloxycarbonyl-*O*-benzyl-L-tyrosine *N*-hydroxysuccinimide ester[19] (7.0 g, 13.9 mmol) in a mixture of dimethyl sulfoxide (250 ml) and DMF (50 ml) for 2 days at room temperature. The reaction mixture was kept at pH 6—7 with *N*-ethylmorpholine throughout the period. Excess ethyl acetate was added to the reaction mixture, and the precipitate was collected by filtration and boiled in 80%

aqueous ethanol (400 ml). The remaining material was collected by filtration at room temperature and washed well with ethanol; wt. 8.0 g, (86.5%); mp 251—252 °C (decomp.), $[\alpha]_D^{25}$ −15.2° (*c* 0.63, dimethylsulfoxide). Ratio of amino acids in an acid hydrolyzate (6 M HCl, 48 hr at 105 °C): Tyr, 0.90; Ile, 1.10; Glu, 1.00; Asp, 0.98; Asu, 1.03; Gly, 1.90; Leu, 0.98. The average recovery was 98%.

Found: C, 58.67; H, 6.97; N, 13.15%. Calcd for $C_{57}H_{79}O_{15}N_{11}\cdot 1/2H_2O$: C, 58.65; H, 6.91; N, 13.20%.

Benzyloxycarbonyl-O-benzyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-ω-2,4,5-trichlorophenyl-L-α-aminosuberylglycyl-L-leucylglycine Amide (XIX). Compound XVIII (4.3 g, 3.68 mmol) was suspended as a fine powder in a mixture of DMF (80 ml) and pyridine (29 ml), and 2,4,5-trichlorophenyl trifluoroacetate[5,16] (10.7 g, 36.4 mmol) was added to the suspension. The mixture was stirred for 7 hr at 50 °C, and then the product was precipitated by the addition of ether, collected by filtration, and dried; wt. 4.64 g (93.7%); mp 253—254 °C (decomp.), $[\alpha]_D^{25}$ −21.4° (*c* 0.42, dimethyl sulfoxide).

Found: C, 56.20; H, 6.37; N, 11.63; Cl, 8.37%. Calcd for $C_{63}H_{80}O_{15}N_{11}Cl_3\cdot 1/2H_2O$: C, 56.18; H, 6.06; N, 11.44; Cl, 7.90%.

Lactam of L-Tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberylglycyl-L-leucylglycine Amide (XX): [Gly,[7] Asu[1,6]]-Oxytocin. a) Compound XIX (1.31 g, 0.97 mmol) was subjected to catalytic hydrogenolysis using palladium black in DMF (350 ml). After 40 hr at room temperature, the catalyst was removed by filtration and the filtrate was concentrated under reduced pressure. The residue was triturated with ether to obtain a hygroscopic powder, which was then extracted with water (15 ml×2). The extract was passed through a column of Amberlite IR-45 (OH^- form, 3×11.5 cm), which was then eluted with water. The fractions of the effluents which showed an optical density of >2.0 at 280 nm were collected and passed through another column of CM-Sephadex C-25 (H^+ form, 3×12.5 cm). The effluent and washing of the latter column were pooled and lyophilized to obtain a crude product; wt. 504 mg (52.5%). A portion (240 mg) of this material was further purified by silica-gel column chromatography (Merck's Silica-gel for column chro matography, 70—325 mesh, 2.0×22.5 cm) using the solvent system. II Fractions of 6 g were collected, and the presence of peptides was monitored by means of the UV absorption at 280 nm. The effluents in tubes No. 57 to 63 were collected and concentrated under reduced pressure. The residue was passed through a column of CM-Sephadex C-25 (H^+ form, 3×8.5 cm). The effluents in fractions corresponding to the volume from 75 to 110 ml were pooled and lyophilized to obtain the final product; wt. 164 mg (recovery 68.3%); $[\alpha]_D^{25}$ −44.0° (*c* 0.55, water). The homogeneity of the purified product was confirmed by thin-layer chromatography, as in the case of compound XI. The R_f-values on paper chromatography (Toyo No. 51) were 0.65 for the solvent system II, 0.59 for the solvent system, III and 0.76 for a solvent system of *n*-butanol: acetic acid: pyridine: water (15: 3: 10: 6 v/v). This peptide was Pauly-positive and ninhydrin-negative. Ratio of amino acids in an acid hydrolyzate (6 M HCl, 48 hr at 105 °C): Tyr, 1.00; Ile+Asu, 2.00; Glu, 1.02; Asp, 1.00; Gly, 1.98; Leu, 0.96. The average recovery was almost quantitative.

Found: C, 51.22; H, 7.31; N, 15.31%. Calcd for $C_{42}H_{65}O_{12}N_{11}\cdot 4H_2O$: C, 51.05; H, 7.45; N, 15.60%.

b) Compound XIX (20.0 g, 14.8 mmol) was dissolved in TFA (150 ml) together with anisole (50 ml), and HBr gas was introduced gently into the solution for 90 min at room temperature. Then, the mixture was concentrated under reduced pressure, and the residue was washed with ether and dried. The dried compound was dissolved in 150 ml of DMF, and the solution was stirred into pyridine (31), drop by drop, at 50 °C over a 4 hr period. After standing overnight at room temperature, the solution was concentrated under reduced pressures (lower than 45 °C), the residue was treated with columns of Amberlite IR-45 and CM-Sephadex C-25 successively, as in the case of a), and the crude lactam was obtained as an amorphous powder; wt. 3.0 g (21%). This material was subjected to further purification as has been shown above to obtain the final product; wt. 2.2 g (recovery 73%).

The authors wish to express their thanks to Dr. Tadao Okada of the Yoshitomi Pharmaceutical Ind. for determining the biological activities of the synthetic peptides.

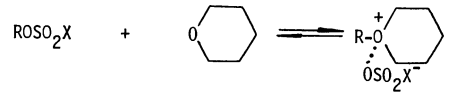
Superacids and Their Derivatives. III.[1] Kinetics of the Oxonium Ion Formation from Superacid Esters and Tetrahydropyran. Oxonium-Ester Equilibria

Shiro KOBAYASHI, Tadashi ASHIDA, and Takeo SAEGUSA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto, 606

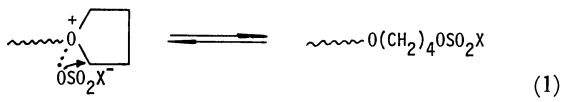
(Received December 20, 1973)

Kinetic studies on the oxonium formation reaction between superacid esters ($ROSO_2X$) and tetrahydropyran (THP) were carried out by means of NMR spectroscopy. The reaction was found to be an equilibrium process.



The rate constant (k) of S_N2 reaction and the equilibrium constant ($1/K=k/k'$) were determined. The solvent effect was examined and k was found to be in the order: nitrobenzene>chlorobenzene≈CH_2Cl_2>liquid SO_2. The effects of R and X in $ROSO_2X$ were studied. Relative reactivities of primary alkyl series in the reaction of $ROSO_2Cl$ with THP were: Me: Et: *n*-Pr=4.63: 1.0: 0.294 in CH_2Cl_2 and Me: Et: *n*-Pr=3.19: 1.0: 0.452 in nitrobenzene. The effect of X on k was in the order Cl≈CF_3>F, the $1/K$ value being also extremely low when X=F. The result was discussed in relation to the kinetics of the polymerization of tetrahydrofuran (THF) by $ROSO_2X$.

We have found that superacid esters[2] and anhydrides[1] are very effective initiators for the cationic ring-opening polymerization of tetrahydrofuran (THF). Kinetic studies on the THF polymerization with a superacid ester initiator revealed that the propagating species was predominanantly a cyclic oxonium one (**1**), and that the concentration of ester type species (**2**) was very small although the latter might be in equilibration with the former species under the polymerization conditions as shown in the following. In fact, **2** could not be detected during the THF polymerization in CH_2Cl_2 by means of high resolution NMR spec-



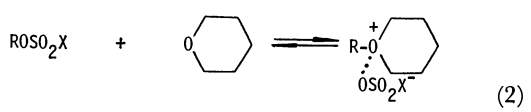
(1)

1 2

(X=Cl, F, CF_3)

troscopy.[2] Thus it is importantto examine the oxonium-ester equilibrium in more detail by independent reactions. Although it is known that a superacid ester such as ethyl fluorosulfate ($EtOSO_2F$) reacts with ether to form an oxonium ion,[3] no quantitative study on the oxonium formation reactions from superacid esters has been carried out so far.[4]

In the present study reactions of superacid esters with tetrahydropyran (THP) were examined as a model system, as shown in the following. Superacid esters examined were primary alkyl esters of chlorosulfonic ($ROSO_2Cl$), fluorosulfonic ($ROSO_2F$) and trifluoromethanesulfonic ($ROSO_2CF_3$) acids.



(2)

R=primary alkyl THP

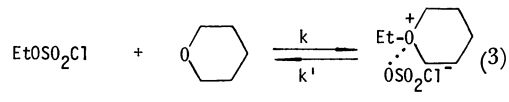
X=Cl, F, CF_3

THP was employed as an ether component since THP is an ether of high basicity[5] and has no ring-opening polymerizability.[6] The reaction corresponds to the initiation of the cyclic ether polymerizations by superacid ester initiators.[2] Kinetic analysis was carried out by direct determination of the instantaneous concentrations of THP and the product oxonium ion by means of NMR spectroscopy. Thus, the reaction was found to be characterized by a reversible reaction, *i.e.*, the ester and oxonium species are in equilibration. We have also studied the effects of the nature of R and X in $ROSO_2X$ as well as those of solvents on the reaction rate (k) and equilibrium constant ($1/K$).

Results and Discussion

Determination of Reaction Rates. Figure 1 shows an NMR spectrum of the reaction system of $EtOSO_2Cl$ with THP in CH_2Cl_2 at a reaction time of 124 min at 35 °C. Signal assignments are given in Table 1.

The following relationships are given for the concentration of the respective component:



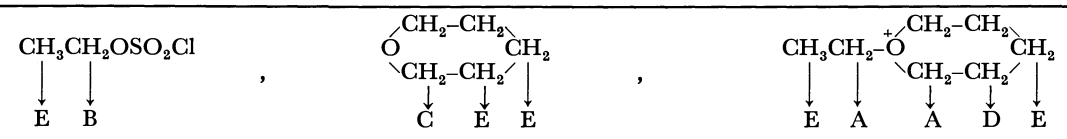
(3)

3

at time 0	$[E]_0$	$[T]_0$	—
at time t	$[E]_0-[Ox]$	$[T]_0-[Ox]$	$[Ox]$

where $[E]_0$ and $[T]_0$ denote the initial concentrations of $EtOSO_2Cl$ and THP, respectively, [Ox] denotes the concentration of the product, cyclic oxonium, and k and k' denote the rate constants of the oxonium formation reaction and the reverse reaction, respectively. The stoichiometry of (3) was shown to be valid by the areas of the respective peaks on the basis of that of the internal standard $CHCl_3$ (Table 1). From the signal (peak D) of the β-methylene protons of the cylic oxonium, the [Ox] *vs.* time relationship was obtained (Fig. 2). The rate equation of the oxonium formation of (3) is given by

TABLE 1. SIGNAL ASSIGNMENTS IN THE REACTION OF $EtOSO_2Cl$ WITH THP IN CH_2Cl_2 AT 35 °C AND INTEGRAL VALUES



Signal	Chemical shifts in ppm[a)]	Integral value
A	4.9—4.7 (m)	$6Ox+2(E_0-Ox)=2E_0+4Ox$
B	4.60 (q)	
C	3.6 (m)	$4(T_0-Ox)=4T_0-4Ox$
D	2.0 (m)	$4Ox$
E	1.8—1.3 (m)	$3(E_0-Ox)+6(T_0-Ox)+5Ox=3E_0+6T_0-4Ox$
$CHCl_3$	7.30 (s)	S_0

a) Calculated from the chemical shift of $CHCl_3$ as δ 7.30. Multiplicity: m=multiplet, q=quartet and s=singlet

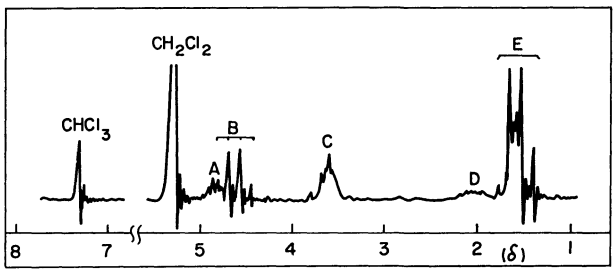


Fig. 1. NMR spectrum of the reaction system of $EtOSO_2Cl$ with THP in CH_2Cl_2 after 124 min at 35 °C. $[E]_0=0.822$ mol/l, $[T]_0=0.835$ mol/l, $CHCl_3$: an internal standard.

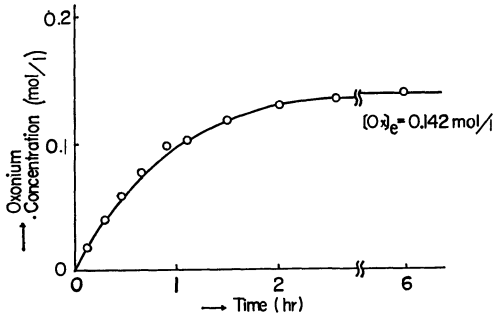

Fig. 2. Time-conversion curve of the reaction of $EtOSO_2Cl$ with THP at 35 °C in CH_2Cl_2. $[E]_0=0.822$ mol/l, $[T]_0=0.835$ mol/l.

$$\frac{d[Ox]}{dt} = k([E]_0-[Ox])([T]_0-[Ox]) - k'[Ox], \quad (4)$$

and the equilibrium constant of (3), $1/K$, is defined by

$$\frac{1}{K} = \frac{k}{k'} = \frac{[Ox]_e}{([E]_0-[Ox]_e)([T]_0-[Ox]_e)} \quad (5)$$

where $[Ox]_e$ is the concentration of the cyclic oxonium at equilibrium which can be obtained from Fig. 2. Equation (4) is then transformed by using Eq. (5) into

$$\frac{d[Ox]}{dt} = k\{[Ox]^2-(K+[E]_0+[T]_0)[Ox]+[E]_0[T]_0\} \quad (6)$$

By introducing α and β, which are two roots of the equation $X^2-(K+[E]_0+[T]_0)X+[E]_0[T]_0=0$, Eq. (6) becomes

$$\frac{d[Ox]}{dt} = k([Ox]-\alpha)([Ox]-\beta) \quad (7)$$

where

$$\alpha = \frac{1}{2}\left\{K+[E]_0+[T]_0+\sqrt{(K+[E]_0+[T]_0)^2-4[E]_0[T]_0}\right\}$$
$$\beta = \frac{1}{2}\left\{K+[E]_0+[T]_0-\sqrt{(K+[E]_0+[T]_0)^2-4[E]_0[T]_0}\right\} \quad (8)$$

Integrating (7) from t_1 to t_2 and $[Ox]_1$ to $[Ox]_2$, we have

$$k = \frac{2.303}{(\alpha-\beta)(t_2-t_1)} \log \frac{(\beta-[Ox]_1)(\alpha-[Ox]_2)}{(\alpha-[Ox]_1)(\beta-[Ox]_2)} \quad (9)$$

The $1/K$ value could be obtained from $[Ox]_e$ value (Fig. 2) according to Eq. (5). Thus the values of α and β of Eq. (8) were calculated. In the $EtOSO_2Cl$–THP system at 35 °C in CH_2Cl_2, $1/K$ value was 0.301 l/mol, and k was then obtained by Eq. (9): $k=7.80\times10^{-5}$ l/mol·s at 35 °C in CH_2Cl_2.

Similarly, kinetic analysis was carried out with other superacid esters in CH_2Cl_2 and liquid sulfur dioxide (SO_2) solvents. In nitrobenzene and chlorobenzene solvents, however, no internal standard was used; instead, these solvents were used as standards for integration. The reactions in these four solvents were homogeneous throughout the kinetic runs. Kinetic runs were carried out at 35 °C and dataare summarized in Table 2.

Reaction Mechanism. The reaction of THP with superacid esters (Eq. (2)) is a dipole-dipole reaction to produce an onium salt. It is interesting to compare Eq. (2) with the Menschutkin reaction, which is also a dipole-dipole reaction between amine and alkyl halide to produce an ammonium salt (Eq. (10)).

$$RY + R_3'N \longrightarrow RR_3'\overset{+}{N}\overset{-}{Y} \quad (10)$$

Since the Menschutkin reaction is not reversible[9] the present reaction of (2) is characterized by equilibrium process.

Kinetic runs of the $EtOSO_2Cl$–THP reaction (3) were carried out in CH_2Cl_2 and nitrobenzene at various temperatures. Arrhenius plots were linear in both cases, and activation parameters were obtained (Table 3). The reaction was faster in nitrobenzene than in CH_2Cl_2. ΔH^* values 14.4 and 15.2 kcal/mol are relatively low for a bimolecular reaction (favorable for k), whereas ΔS^* values, −31 and −26 e.u., are also low (unfavorable for k). It is typical for a dipole-dipole reaction to form ionic species. These values of activation

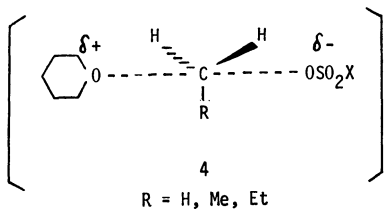
	5.56 ($1/K$=0.476, 30 °C)	10.9 ($1/K$=1.60, 29 °C)
	7.80 ($1/K$=0.301, 35 °C)	24.8 ($1/K$=1.40, 35 °C)
	17.0 ($1/K$=0.175, 42 °C)	55.9 ($1/K$=1.08, 44 °C)
$\Delta H^{\ddagger}$ (kcal/mol)	14.4	15.2
$\Delta S^{\ddagger}$ (e.u.)	−31	−26

a) $1/K$ in l/mol.

parameters are very close to those of the Menschutkin reaction, *e.g.*, $\Delta H^{\ddagger}$=13.0 kcal/mol and $\Delta S^{\ddagger}$=−29 e.u. in the reaction of pyridine with methyl iodide in nitrobenzene.[10]

(11)

Thus the transition state of Eq. (2) may be formulated in a similar way to the Menschutkin reaction.[9]



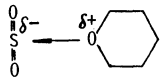
4

R = H, Me, Et

In the reaction of $EtOSO_2Cl$ with THP, $1/K<1$ in CH_2Cl_2 but $1/K<1$ in nitrobenzene in the temperature range examined (Table 3). The temperature rise led to a decrease in $1/K$ values, *i.e.*, oxonium formation is thermodynamically favored at lower temperatures. It should be added that no side reactions were observed in all the kinetic runs.

Solvent Effects. As seen from Tables 2 and 3 the rates (k) were in the order nitrobenzene>chlorobenzene≈CH_2Cl_2>liquid SO_2. This order can not be simply explained by the solvent polarity because it is not in line with the order of dielectric constants (Table 2): nitrobenzene>liquid SO_2>CH_2Cl_2>chlorobenzene. Since the solvents are of different character they may have complicated effects. It can be said that the reaction is faster in more polar solvents as in the case of the Menschutkin reaction.[7] In aromatic solvents, k in nitrobenzene is 2.6 times as high as that in chlorobenzene at 35 °C. This can be compared with the reactivity in the Menschutkin reaction of Eq. (11), in which the rate was 9.3 times as high as that in chlorobenzene.[10]

In liquid SO_2 at 20 °C, k was 5.3 times smaller than in nitrobenzene (calculated value of $k=6.50\times10^{-5}$ l/mol·s at 20 °C). A similar observation was also noted in the above Menschutkin reaction.[11] A decreased reactivity in liquid SO_2 may be attributed to the solvation of THP at the initial state (**5**) as an interaction of amine with liquid SO_2.[11] The complex formation of **5** is not unreasonable, because it is known that equilibrium constants are significantly large in the formation of complexes between SO_2 and alcohol.[12]



5

It may be significant to compare activation parameters of the $EtOSO_2Cl$–THP reaction in CH_2Cl_2 and in nitrobenzene. Although k was larger in nitrobenzene, the $\Delta H^{\ddagger}$ value was also larger in it, *i.e.*, an increased reactivity is ascribed to the more favorable entropy factor in nitrobenzene. A similar result was observed in the Menschutkin reaction of Eq. (11), in

TABLE 4. SOLVENT EFFECTS ON Eqs. (2) AND (11)

Solvent	$10^5 \cdot k$ (l/mol·s)	$\Delta H^{\ddagger}$ (kcal/mol)	$\Delta S^{\ddagger}$(e.u.)

C_6H_5Cl	398[b]	13.2	−33
$C_6H_5OCH_3$	676[b]	12.5	−34
$C_6H_5NO_2$	3720[b]	13.0	−29

a) Present work of the reaction of Eq. (2). Data at 35 °C. b) Taken from Ref. 10. Data at 100 °C in the Menschutkin reaction of Eq. (11).

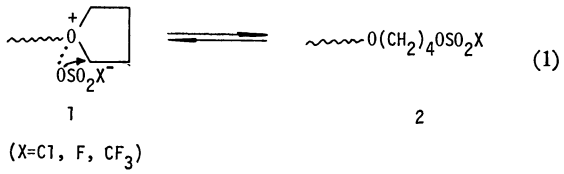
which an entropy factor ($\Delta S^{\ddagger}$) determines the reaction rate in various solvents irrespective of a slight change in $\Delta H^{\ddagger}$ values.[10] These solvent effects are compared and summarized in Table 4.

As to $1/K$ values of Eq. (2) the order of magnitude is roughly proportional to that of dielectric constants. The product oxonium ion is highly stabilized in solvents of high polarity. Among the solvents examined, liquid SO_2 is probably unique in the sense that it stabilizes the oxonium ion by electrophilic solvation of the counter-anion.[11]

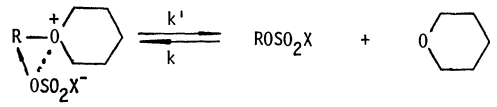
Effects of R and X in $ROSO_2X$. The rate of Eq. (2) depends upon the nature of R in $ROSO_2X$ (Table 2). The order of reactivities is Me>Et>*n*-Pr as seen in the other series of S_N2 reactions.[13] This order agrees with that of $1/K$ values in both CH_2Cl_2 and nitrobenzene.

Table 5 shows relative rates (Et=1.0) in several S_N2 reactions of dipole-dipole reactions (Nos. 1—5) like Eq. (2) and dipole-ion reactions (Nos. 6 and 7). The change of solvent (CH_2Cl_2 and nitrobenzene) had little effect on the relative reactivities (Nos. 1 and 2). A close resemblance of the relative rates, especially between reactions of Nos. 1, 2, 3, and 7, seems to indicate that the reactions proceed *via* a similar mechanism. The nature of X in $ROSO_2X$ also affects the rate. In the $EtOSO_2X$–THP reaction at 35 °C the order of reactivities is Cl≈CF_3>F in both CH_2Cl_2 and nitrobenzene solvents (Table 2). It should be noted that $1/K$ values are extremely low in the case of $ROSO_2F$.

Comparison of Eq. (2) with the THF Polymerization. It would be worth while to compare the reaction (2) with the THF polymerization initiated by superacid esters.[2] The equilibrium of Eq. (1) resembles rather the reverse reaction of Eq. (2) as given by Eq. (12).

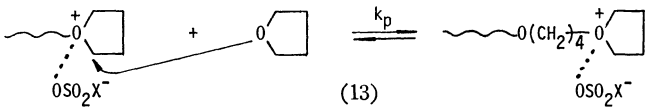


(1)



(12)

Both processes Eqs. (1) and (12) are intramolecular ones to produce ester type species. The products, however, are entirely different. In Eq. (1), the counter-anion of OSO_2X^- attacks the α-carbon of THF ring in the oxonium **1** to cause the ring-opening of THF. On the other hand, in Eq. (12) the counter-anion attacks alkyl group rather than α-carbon of the THP ring. In the propagation process of the THF polymerization (Eq. (13)), THF monomer attacks intermolecularly the α-carbon of THF ring in **1** instead of the intramolecular attack of the counter-anion of OSO_2X^-.



(13)

The existence of the oxonium-ester type equilibrium of Eq. (2) (or Eq. (12)) strongly suggests that the same type of equilibration (Eq. (1)) actually takes place during the course of THF polymerization. Such equilibration is very likely dependent upon the solvent since the present results of the solvent effect show remarkable changes of k and $1/K$ values of Eq. (2).

In a very recent presentation by Matyjaszewski *et al.*[19] the oxonium-ester equilibrium (Eq. (1)) has been discussed in the kinetic study of the THF polymerization by $EtOSO_2CF_3$ initiator. With a variation of polymerization solvents a wide range of apparent k_p values ($2.0—23.0 \times 10^{-3}$ l/mol·s, at 25 °C) have been obtained. They claimed that low apparent k_p values in non-polar solvents were due to a larger fraction of

the ester type **2** concentrations. However, no concentrations of oxonium **1** and ester **2** were determined in their kinetics.[19] For a quantitative argument further study of the oxonium-ester equilibria in detail is required.

Experimental

Materials. All the reagents were distilled under nitrogen. Methyl ($MeOSO_2Cl$), ethyl ($EtOSO_2Cl$) and *n*-propyl (*n*-$PrOSO_2Cl$) chlorosulfates were prepared by the reactions of sulfuryl chloride with the corresponding alcohols,[14] bp, $MeOSO_2Cl$, 51—52 °C/25 mmHg (lit.[14] 40 °C/14 mmHg), $EtOSO_2Cl$, 58 °C/25 mmHg (lit.[14] 42 °C/10 mmHg) and *n*-$PrOSO_2Cl$, 61 °C/20 mmHg (lit.[14] 52 °C/10 mmHg). $EtOSO_2F$ and $EtOSO_2CF_3$ were obtained in the same manner as reported.[2] $MeOSO_2F$ was prepared by the reaction of dimethyl sulfate with FSO_3H,[2] bp 92—94 °C. THP was dried on sodium metal and distilled. This procedure was repeated twice. Purification of CH_2Cl_2 was carried out in the same way as in the previous work.[2] Nitrobenzene was dried on phosphorus pentoxide and distilled *in vacuo*.[7] Chlorobenzene and $CHCl_3$ (an internal standard) were dried on Molecular Seives and distilled before use. Liquid SO_2 was obtained by condensation of gaseous SO_2 (Seitetsu Kagaku Co., Ltd).

Kinetic Procedures. Kinetic reactions were carried out under nitrogen. A typical run is as follows. Into an NMR sample tube containing 0.752 ml of CH_2Cl_2, 0.088 ml (0.822 mmol) of $EtOSO_2Cl$, 0.081 ml (0.835 mmol) of THP, and 0.080 ml (1.00 mmol) of $CHCl_3$ were introduced with a microsyringe, giving the initial concentrations of $[E]_0=0.822$ mol/l and $[T]_0=0.835$ mol/l. During the sample preparation the NMR sample tube was cooled in a Dry Ice–acetone bath. The tube was sealed, and inserted into the probe of the NMR spectrometer (Hitachi R-20B). Up to this step the extent of the reaction was negligible. The reaction was then followed by taking spectra several time at the desired temperature. For the determination of equilibrium concentration, the sample tube was kept at the same temperature until the reaction no longer proceeded. The NMR spectrum was then recorded. The oxonium concentration of the spectrum was taken to be an $[Ox]_e$ value. The reaction temperature was kept constant within ± 1 °C and the experimental error of the integration was within $\pm 2\%$.

A Macrocyclic Enzyme Model System. Acyl Transfer from *p*-Nitrophenyl Carboxylates to Paracyclophane Oxime[1]

Yukito MURAKAMI, Junzo SUNAMOTO,* and Koji KANO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received January 8, 1974)

The deacylation reactions of *p*-nitrophenyl carboxylates by 10-hydroxy-11-hydroxyimino[20]paracyclophane (Oxime-I) have been investigated in an alkaline aqueous acetone. Oxime-I was acylated by *p*-nitrophenyl laurate (PNPL) and decanoate (PNPD), but was not affected by *p*-nitrophenyl acetate (PNPA) and hexanoate (PNPH). Meanwhile, 2-hydroxycyclodecanone oxime (Oxime-II) and acetoxime (Oxime-III) did not undergo any reaction with all of the present carboxylic esters under the same conditions. These results suggest that the acylation reactions of Oxime-I with PNPD and PNPL proceed primarily through incorporation of the substrates into the cyclic oxime cavity. The formation of an intra-complex was also suggested by an evidence that the copper(II) ion markedly retarded the reaction rate of PNPL with Oxime-I below the catalyst-absence level. The binding constant for PNPL with Oxime-I was considerably large in comparison with the usual micelle-substrate or synthetic polymer-substrate complexes. On the basis of thermodynamic parameters for the binding and the subsequent acylation, the driving force for the incorporation and the geometry of the intra-complex have been discussed.

The three kinds of esterase model systems have been widely developed to establish some new catalytic systems for organic synthesis as well as to understand the enzymatic mechanisms from the bioorganic viewpoints: these are micellar surfactants,[2] synthetic polymers,[3] and macrocyclic compounds.[4] Micellar surfactants and synthetic polymers have been known to construct the hydrophobic field through micelle formation and aggregation, respectively. The hydrophobic interaction between these enzyme models and substrates resulted in the formation of intra-complexes to provide the proximity effects due to plausible orientation and to raise the local concentrations of the attacking nucleophiles. The formation of hydrophobic binding sites in these cases is, however, in dynamic equilibria with the bulk phase and subject to the external medium effects consequently.[5] Thus, these mobile structures may provide a limited substrate specificity. On the other hand, macrocyclic compounds may exhibit several novel and unique characters primarily due to the following effects.

1) The macrocyclic cavity provides a steady binding site due to a characteristic ring conformation of hydrophobic nature. This binding site can be little affected by the external factors such as temperature, hydrogen ion concentration, ionic strength, dielectric constant, and other medium properties.

2) A high substrate specificity can be brought about by the geometric requirements for binding of substrates into these macrocyclic cavities as well as by spatial geometries of substrate molecules incorporated into these cavities on the other. Utilization of cycloamyloses,[4a] cyclic peptides,[4b] and cyclic *N*-methylhydroxamic acid[4c] have provided much fruitful results though they need to be further investigated.

In this work, we prepared a sizable cyclic compound, 10-hydroxy-11-hydroxyimino[20]paracyclophane (Oxime-I), and studied the acyl transfer from *p*-nitrophenyl carboxylates to the cyclic oxime. Oxime-I provides an appropriate hydrophobic binding site with the paracyclophane skeleton and one nucleophilic function with the oxime group. In reference to the Stuart molecular models shown in Fig. 1, Oxime-I has an inner diameter of about 6.5 Å and a depth of about 4.5 Å. 2-Hydroxycyclodecanone oxime (Oxime-II) and

Oxime-I Oxime-II

* Present address: Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Nagasaki 852.

acetoxime were also used in order to characterize the catalytic ability of Oxime-I.

Experimental

Spectroscopic measurements were run on a JASCO DS-403G grating IR spectrophotometer, a Varian A60 NMR spectrometer, a JEOL JMS-01SG mass spectrometer, and a Hitachi EPS-2 recording spectrophotometer. pH measurements were carried out with a TOA HM-9A pH-meter equipped with a Metrohm EA-125 combined electrode.

Acetoxime of reagent grade was commercially obtained (Nakarai) and used without further purification.

p-Nitrophenyl Carboxylates. *p*-Nitrophenyl acetate (PNPA), hexanoate (PNPH), decanoate (PNPD), and laurate (PNPL) were respectively prepared by the reaction of the corresponding carbonyl chlorides with *p*-nitrophenol in ether in the presence of pyridine. The crude esters were further purified and identified by elemental analyses and spectroscopic measurements before use.

The synthetic steps for Oxime-I are shown in Scheme 1.

Ethyl ω-Phenyldecanoate (1). Ethyl ω-phenyldecanoate was prepared by the esterification of ω-phenyldecanoic acid, which was synthesized according to the procedures described in the literature,[6] and purified by distillation *in vacuo*: bp 140—142 °C/0.075 mmHg, yield 82.3%.

1-(9-Carbethoxynonanyl)-4-(9-carbethoxy-1-oxononanyl) benzene (2). In a 100-ml three-necked flask was placed a mixture of 2.76 g (0.01 mol) of **1**, 4.0 g (0.03 mol) of anhydrous aluminum chloride, and 20 ml of carbon disulfide and the reaction flask was cooled in an ice bath with vigorous stirring. Then, 2.48 g (0.01 mol) of ω-carbethoxypelargonoyl chloride was added dropwise into the mixture in about 15 min. The reaction mixture was stirred for 30 min at room temperature and 3 hr under reflux, and then allowed to stand overnight at room temperature. The red oil obtained was treated with hydrochloric acid at ice-cooled temperature and extracted with carbon disulfide. The organic layer was separated, washed with water, and dried over sodium sulfate. After removal of the solvent, the pale yellow residue was recrystallized from petroleum ether (bp 30—70 °C): mp 56—58.5 °C, yield 2.4 g (49%).

Found: C, 73.74; H, 9.87%. Calcd for $C_{30}H_{18}O_5$: C, 73.73; H, 9.90%.

p-Bis(9-carboxynonanyl)benzene (3). A mixture of 6.0 g (0.012 mol) of **2**, 8.4 g (0.15 mol) of potassium hydroxide, 9.0 g (0.13 mol) of hydrazine hydrate, and 50 ml of diethylene glycol was heated under reflux for 3 hr. After removal of hydrazine and water, the mixture was refluxed for additional 10 hr. Into the resulting solution cooled to room temperature was added about 250 ml of water. This solution was neutralized with hydrochloric acid. The precipitates were recovered, washed with water, and recrystallized from methanol: mp 124—128.5 °C, yield 3.2 g (64%).

Found: C, 74.35; H, 10.16%. Calcd for $C_{26}H_{42}O_4$: C, 74.58; H, 10.13%.

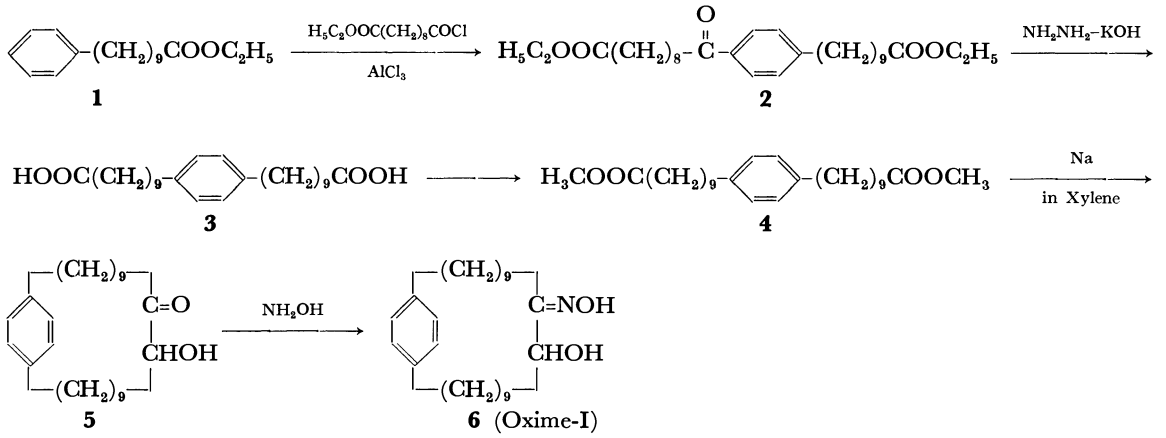
p-Bis(9-carbomethoxynonanyl)benzene (4). A mixture of 4.5 g (0.011 mol) of **3**, 5 ml of concentrated sulfuric acid, and 150 ml of methanol was heated under reflux for 12 hr. A half volume of methanol was distilled off. The residue was diluted with water and extracted with ether. The ethereal solution was washed with water and dried over sodium sulfate. After removal of ether, the crude material was recrystallized from methanol: mp 61—66.4 °C, yield 3.5 g (71.2%). NMR (CCl_4, TMS as an internal reference): δ 1.27—2.63 (36H, m, methylene envelope), 3.58 (6H, s, $-C\underline{H}_3$), and 6.96 (4H, br., $-C_6\underline{H}_4-$).

Found: C, 75.35; H, 10.31%. Calcd for $C_{28}H_{46}O_4$: C, 75.27; H, 10.39%.

10-Hydroxy-11-oxo[20]paracyclophane (5). A 3-liter creased flask of three-necked round-bottom was equipped with a mechanical vacuum stirrer of stainless steel and a reflux condenser, the top of which was connected to a dropping funnel furnished with a needle valve. In the flask were placed 500 ml of xylene and 1.0 g (0.043 g atom) of crust-free sodium metal. It was refluxed for 15 min with vigorous stirring under nitrogen atmosphere. Gaseous nitrogen was streamed throughout the apparatus during the course of reaction. Then, 3.0 g (6.7 mmol) of **4** dissolved in 250 ml of xylene was added dropwise for a period of 20 hr. Reflux was continued for additional 30 min after the complete addition of **4**. The reaction flask was then cooled in an ice bath. Glacial acetic acid (4 ml) dissolved in 6 ml of xylene was added dropwise in about 30 min while cooling and stirring were continued. The resulting mixture was transferred into a 2-liter separatory funnel together with 25 ml of water. The xylene layer was separated, washed with water, and dried over active calcium sulfate. After rapid removal of xylene, the crude material was recrystallized from *n*-pentane as white granular crystals: mp 46—51 °C, yield 1.4 g (53.7%). IR (KBr disk): ν_{OH}, 3400; $\nu_{C=O}$, 1704 cm^{-1}.

Found: C, 81.57; H, 11.48%; M^+, 386. Calcd for $C_{26}H_{42}O_2$: C, 80.75; H, 10.97%; mol wt, 386.68.

10-Hydroxy-11-hydroxyimino[20]paracyclophane (Oxime-I). Into a mixture of 500 mg (1.29 mmol) of **5**, 300 mg (4.32 mmol) of hydroxylamine hydrochloride, and 10 ml of methanol



Scheme 1. Synthesis of Oxime-I.

containing a small amount of water was added gradually 530 mg (13 mmol) of sodium hydroxide powder. The mixture was heated under reflux for 10 min, neutralized with dilute aqueous hydrochloric acid, and then extracted with about 200 ml of *n*-pentane. The organic layer was separated, washed with water, and dried over sodium sulfate. After a half volume of *n*-pentane was distilled off, the residue was cooled to about −10 °C. The colorless needles were recovered: mp 91.5—93 °C, yield 440 mg (84.8%). IR (KBr disk): ν_{OH}, 3300; $\nu_{C=N}$, 1650 cm^{-1}.

Found: C, 77.70; H, 11.28; N, 3.20%; M^+, 401. Calcd for $C_{26}H_{43}NO_2$: C, 77.73; H, 10.81; N, 3.49%; mol wt, 401.70.

2-Hydroxycyclodecanone (sebacoin). 2-Hydroxycyclodecanone was prepared according to the procedures described in the literature:[7] mp 36.5—39 °C (lit,[7] 38—39 °C), yield 47.3%.

2-Hydroxycyclodecanone Oxime (Oxime-II). Sebacoin oxime was prepared by a method similar to that used for the preparation of Oxime-I. The crude Oxime-II (mp 86—96 °C) was purified by means of column chromatographic technique with the combination of active alumina and absolute methanol: mp 101—103 °C, yield 1.2 g (50%). IR (KBr disk): ν_{OH}, 3220; $\nu_{C=N}$, 1650 cm^{-1}.

Found: C, 64.92; H, 10.58; N, 7.30%; M^+, 185. Calcd for $C_{10}H_{19}NO_2$: C, 64.81; H, 10.36; N, 7.56%; mol wt, 185.30.

Kinetic Measurements. The rate of formation of *p*-nitrophenoxide ion was measured at 400 nm. Reactions were initiated by the addition of 30 μl of 1×10^{-3}M *p*-nitrophenyl carboxylate in acetone to 3.0 ml of a reaction solution which was pre-equilibrated at an appropriate temperature in the thermostatted cell set in a Hitachi 124 recording spectrophotometer. The reaction solution was prepared in a 10 ml volumetric flask by placing 1.0 ml of $1-7\times10^{-4}$M Oxime-I in acetone–water (1: 1 by volume), 0.5 ml of acetone, 0.9 ml of 1.0 M aqueous potassium chloride, and an appropriate amount of 0.1 M sodium hydroxide to adjust the pH-value of medium in this order, and subsequently by filling up with distilled and deioninized water to the mark. The overall concentrations of *p*-nitrophenyl esters and the oxime in the reaction mixture were 1×10^{-5}M and $2-15\times10^{-6}$M, respectively. The acetone content in the above reaction mixture was about 10% of the total volume, and also varied in a 10—30% (v/v) range. The temperature of a reaction mixture was maintained constant with an accuracy of ±0.1 °C. A buffer system, sodium carbonate–sodium borate, was used for reactions at pH 10.

Product Analysis. *p*-Nitrophenyl laurate (82.9 mg, 0.26 mmol) underwent reaction at 20 °C with Oxime-I (98.8 mg, 0.24 mmol) in 50 ml of acetone–water (1: 5 by volume) containing 2.6 ml of 0.1 M sodium hydroxide. After the complete decomposition of the ester, the reaction mixture was extracted with *n*-hexane. The aqueous alkaline layer remained was carefully neutralized with dilute hydrochloric acid and extracted with ether. Upon evaporation of the ethereal layer, *p*-nitrophenol and lauric acid were detected by tlc as well as by UV and IR spectroscopy. On the other hand, tlc of the mixture obtained from *n*-hexane extracts showed the existence of three components. Two of them were identified as the unreacted Oxime-I and its hydrolyzate, 10-hydroxy-11-oxo[20]paracyclophane (**5**), though both were only in a trace amount. The third component, which was isolated from the mixture, showed a strong IR absorption band at 1710 cm^{-1} ($\nu_{C=O}$) and a UV spectrum having absorption maxima at 213, 220, 260, 267, and 274 nm in methanol. These results indicate that Oxime-I was acylated by *p*-nitrophenyl laurate (Eq. (1)) in a manner as seen for the acylation of aryl-oxime with *p*-nitrophenyl carboxylates.[8]

$$\text{>C=N-OH} + \text{Ph-O-C(O)-R} \longrightarrow \text{>C=N-O-C(O)-R} + \text{Ph-OH} \quad (1)$$

Meanwhile, Oxime-I was hydrolyzed to give the parent ketocyclophane (**5**) to an insignificant extent under the same reaction conditions. In addition, the degradation of Oxime-I did not show any meaningful effect on the reaction kinetics.

Results and Discussion

In the alkaline hydrolyses of PNPD and PNPL, pseudo-first-order plots deviated positively after 25—30% conversion of the esters. This phenomenon has been attributed to the self-aggregation of the substrates.[9] Meanwhile, in the presence of Oxime-I the rate of *p*-nitrophenol release from the esters started to deviate gradually downward from the first-order plot in the same conversion range. Therefore, a pseudo-first-order rate constant k_{obs} was obtained from the linear portion at the initial stage of reaction. Oxime-I did not, however, provide any effect on the *p*-nitrophenol release from esters of smaller alkyl chains, PNPA and PNPH (Table 1). Similarly, smaller cyclic oxime (Oxime-II) as well as acetoxime also did not show any effect on the reaction rate of all the substrates studied (Table 1). In the reaction of Oxime-I either with PNPD or PNPL, the usual saturation-type kinetics have been observed as illustrated for the PNPL–Oxime-I system in Fig. 2. These kinetic evidences and the product analysis suggest that there proceed two competetive reactions, the hydrolysis of an uncomplexed substrate and the acyl transfer reaction *via* an intra-complex formed between Oxime-I and either PNPD or PNPL, as shown by Eq. (2).

$$\begin{array}{ccc} S + \text{Oxime-I} & \overset{K}{\rightleftharpoons} & \text{S-Oxime-I} \\ \downarrow k_{hyd} & & \downarrow k_{acyl} \\ P_1 & & P_2 \end{array} \quad (2)$$

where k_{hyd} and k_{acyl} stand respectively for the rate

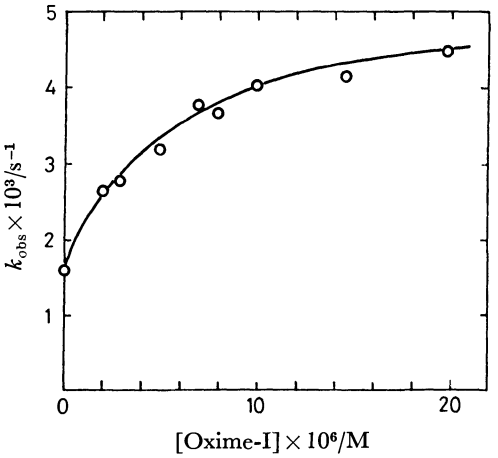


Fig. 2. Saturation-type kinetics for the reaction of PNPL (9.90×10^{-6}M) with Oxime-I in 10.9% (v/v) aqueous acetone at 34.1 °C, μ=0.10 (KCl), and pH 12.3 (1.00×10^{-2}M sodium hydroxide).

a) Total initial concentration: PNPD, 1.03×10^{-5}M; PNPL, 9.90×10^{-6}M. b) Total initial concentration of Oxime-I: with PNPD, $6.03-48.2\times10^{-6}$M; with PNPL, $1.98-19.80\times10^{-6}$M.

constant of hydrolysis in the bulk phase and that of acylation due to the intra-complex; S and S–Oxime-I represent the substrate and the substrate—Oxime-I complex, respectively, and K is the binding constant. The observed pseudo-first-order rate constant k_{obs} is given by Eq. (3)

$$k_{obs} = (k_{hyd}+k_{acyl}K[\text{Oxime-I}])/(1+K[\text{Oxime-I}]) \quad (3)$$

which can be rearranged to

$$1/(k_{hyd}-k_{obs}) = 1/(k_{hyd}-k_{acyl}) + 1/(k_{hyd}-k_{acyl})K[\text{Oxime-I}] \quad (4)$$

A good linear relationship has been obtained by plotting the left-hand side of Eq. (4) against the reciprocal concentration of Oxime-I, as typically seen in Fig. 3. We calculated the rate constant for acylation and the binding constant from the intercept and the slope, respectively. Kinetic results are summarized in Table 2.

It is interesting to examine the difference in reactivity in terms of the correlations between the ring size of

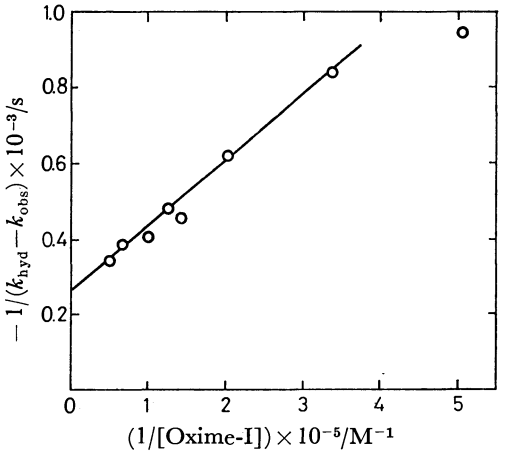

Fig. 3. Analysis of kinetic data (given in Fig. 2) for the decomposition of PNPL in the presence of Oxime-I by means of Eq. (4).

cyclic oximes and the molecular size (or geometry) of substrates. Table 1 shows that Oxime-I was acylated only by the esters having a long alkyl chain residue and not by the smaller esters such as PNPA or PNPH, while Oxime-II and acetoxime could not be acylated even by longer esters. It may be, therefore, reasonable to assume that the present acyl transfer reactions from PNPL and PNPD to Oxime-I must proceed through the intra-complex formation, which would be caused by an incorporation of a substrate into the cyclic cavity of Oxime-I and not by a simple hydrophobic entanglement.

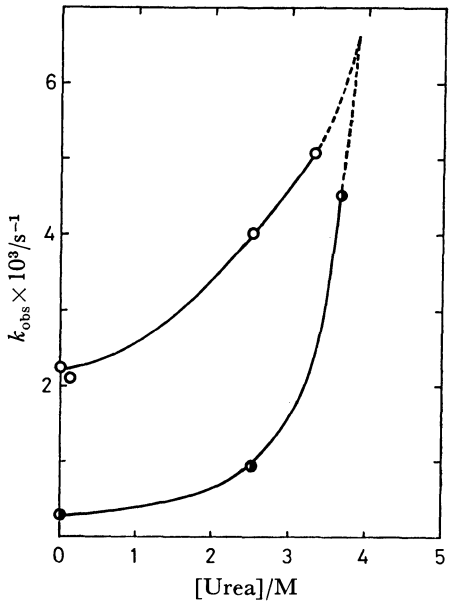

Fig. 4. Effects of added urea on the decomposition of PNPL (9.90×10^{-6}M) in 10.9% (v/v) aqueous acetone at 20.0 °C, μ=0.10 (KCl), and pH 12.3 (1.00×10^{-2}M sodium hydroxide): ○, with Oxime-I (9.90×10^{-6}M); ◑, without Oxime-I.

Driving Force for Incorporation. The increase in concentration of acetone appeared to decrease the incorporation of the substrate into the cyclic cavity of Oxime-I significantly (Table 2). Similar results have been obtained for the cycloamylose—phenyl acetate system,[4a] where the effect of acetonitrile content was examined. Moreover, Fig. 4 shows that the addition of urea to the reaction system also reduces the incorporation: as the concentration of urea increases, the overall pseudo-first-order rate constant (k_{obs}) and the rate constant for spontaneous hydrolysis increase and finally both become equal. Consequently, a driving force for the incorporation of a substrate into the cavity of Oxime-I should be attributed to the hydrophobicity of a substrate and the oxime as well. These results suggest that the self-aggregation of the substrate acts in favor of the incorporation but the resulting hindered nucleophilic center provides a steric effect against attacking hydroxide ion. The Stuart molecular model shows, in fact, that the folded substrate molecule can be inserted tightly into the Oxime-I cavity. If the elongated substrate molecule could be incorporated, PNPA and PNPH, having molecular head and tail similar to PNPD and PNPL, would also undergo the acyl transfer reaction with Oxime-I. It should be noted in the present study that urea or an organic solvent perturbs the hydrophobicity of the substrate esters only and not the cyclic oxime cavity.

Effect of the Copper(II) Ion. Oxime-I has three donor atoms, one nitrogen and two oxygens. It is expected that an appropriate metal ion may show somewhat a unique effect on the reactivity of Oxime-I. The copper(II) ion, which was used as nitrate, did not give any effect on the reaction of PNPL in the absence of Oxime-I, while it profoundly retarded the *p*-nitrophenol release in the presence of the oxime. Upon addition of over equimolar amount of copper ion relative to the ester and the oxime, the reaction rate was reduced below the Oxime-I absence level (Fig. 5). These results suggest that Oxime-I deactivated by the coordination of the copper(II) ion still holds a large ability of substrate-incorporation and consequently the ester decomposition becomes largely decelerated. Thus, we can say that the effect of copper(II) provides another evidence for the incorporation. Hershfield and Bender investigated the hydrolysis of PNPL catalyzed by a macrocyclic hydroxamic acid. Although the reaction rate was markedly accelerated upon addition of copper(II), they did not give any plausible elucidation for the catalytic mechanism.[4c] The copper-concerned reactions in both cases apparently proceed through somewhat different mechanisms.

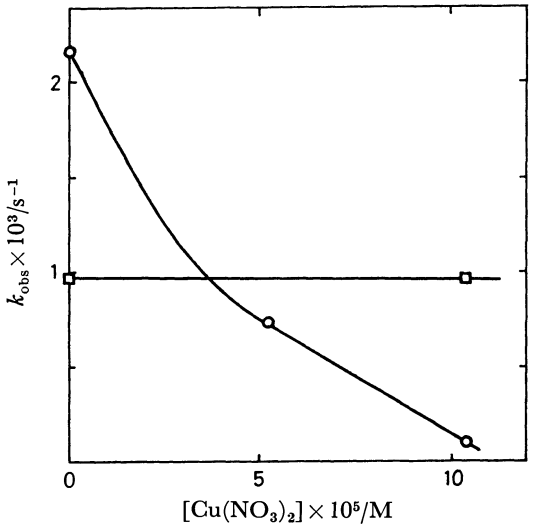

Fig. 5. Effects of added copper(II) ion on the decomposition of PNPL (4.76×10^{-5}M) in 26.7% (v/v) aqueous acetone at 20.0 °C and pH 12.3 (1.00×10^{-2}M sodium hydroxide): ○, with Oxime-I (4.76×10^{-5}M); □, without Oxime-I.

Catalytic Effect and Substrate Specificity. Oxime-II and acetoxime did not show any meaningful effect on the decomposition of PNPD and PNPL. This means that these two oximes undergo no acyl transfer reaction at least under the present conditions. It has been well known that acetoxime (pK_a 12.4) shows exceedingly large nucleophilicity due to α-effect.[10] Our present cyclic oximes, Oxime-I and -II, must have approximately the same nucleophilicity as that of acetoxime as

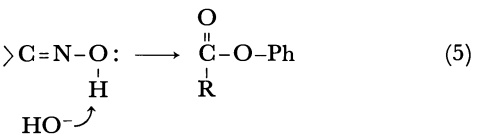
far as the oxime moiety concerns. The large reactivity of Oxime-I, therefore, can be attributed to the incorporation which brings about the proximity effect for the reaction. This effect is analogous to the cases of intramolecular catalysis. The inertness of Oxime-II, on the other hand, seems to be ascribed to its small ring size which inhibits such an incorporation.

Table 3. Catalytic specificity of oxime-I in the reactions with *p*-nitrophenyl carboxylates

Carboxylate	$k_{obs(Oxime-I)}/k_{obs(Oxime-II)}$	k_{acyl}/k_{hyd}
PNPA	*ca.* 1[a]	—
PNPH	*ca.* 1[a]	—
PNPD	0.7[b]; 1.2[c]	2.4[c]
PNPL	2.3[b]; 7.4[c]	14.7[c]

a) At 25.0 °C in 30% (v/v) aqueous acetone with pH 11.5. b) At 19.6 °C in 26.7% (v/v) aqueous acetone with pH 12. c) At 20.0 °C in 10.9% (v/v) aqueous acetone with pH 10.

Clearly from the preceding comments, the overall rate constant in the presence of Oxime-II, $k_{obs(Oxime-II)}$, is nearly equal to the rate constant for spontaneous hydrolysis of esters. We define the catalysis specificity of Oxime-I in terms of either $k_{obs(Oxime-I)}/k_{obs(Oxime-II)}$ or $k_{obs(Oxime-I)}/k_{hyd}$, each rate constant being obtained under the same conditions. These are listed in Table 3, along with the specific rate ratio, k_{acyl}/k_{hyd}. The specificity of Oxime-I further increased at lower pH region where the nucleophilicity of the oxime group must become smaller. This fact, as well as the product analysis, suggests that the acyl transfer reaction in the intra-complex may proceed through the direct nucleophilic attack of the oxime to the carbonyl carbon, not through the general base catalysis. In addition, the acylation exhibits the linear dependence on pH in a 9—12 pH range (Fig. 6). This is consistent with a mechanism shown by Eq. (5). Deceleration of the decomposition rate of PNPD in the presence of Oxime-I at higher pH (Table 3) is not clear at



(5)

present. However, this is predictive of the presence of substrate specificity for Oxime-I. Our results are, therefore, apparently different from those obtained by Hershfield and Bender,[4c] in which the rate enhancement was gained only by the extension of alkyl-chain length without substrate specificity. They did not indicate clearly which effect, simple entanglement or

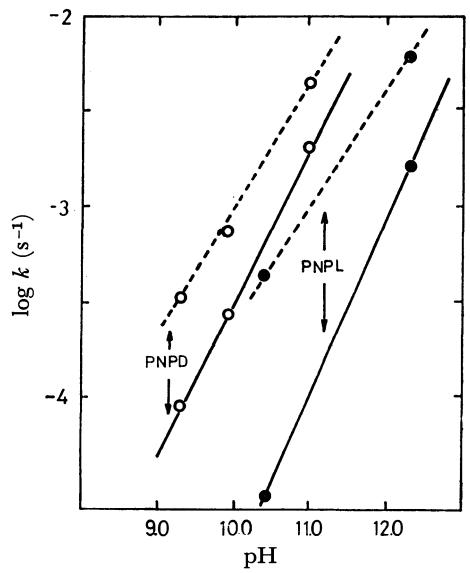


Fig. 6. pH-rate correlations for alkaline hydrolyses (solid lines) of PNPD (1.00×10^{-5}M, ○) in 10.0% (v/v) aqueous acetone with μ=0.10 (KCl) at 30.0 °C and PNPL (9.90×10^{-6}M, ●) in 10.9% (v/v) aqueous acetone with μ=0.10 (KCl) at 33.9 °C; and acyl transfer reactions of these carboxylates (broken lines) with an equimolar concentration of Oxime-I under the same conditions employed for the corresponding alkaline hydrolyses.

incorporation, contributed to the interaction of the cyclic compound with substrates.

Binding Property. Table 2 shows that the binding constants for the incorporation of PNPD and PNPL into Oxime-I are considerably larger ($K\approx10^5$ M^{-1}) than those for phenyl acetates into cycloamyloses ($K\approx10^3$ M^{-1}).[11] In the present study, it became clear that large hydrophobic guest molecules lead to the formation of relatively stable inclusion complexes and the interior of the cyclic oxime provides a better hydrophobic binding site. In order to understand the nature of incorporation, the temperature dependency of binding constant for PNPL–Oxime-I was examined using kinetic method. Thermodynamic parameters were obtained from a plot of $\ln K$ *vs.* $1/T$(K) by the least-squares method: $\Delta G°$(307.3 K) = −7.2 kcal mol^{-1}, $\Delta H°$ = −9.4 kcal mol^{-1}, and $\Delta S°$ = −7.3 e.u. at pH 12 in 10.9 vol% aqueous acetone. The binding constant is comparatively temperature dependent in a similar trend as observed for the combination of *m*-ethylphenyl acetate and cyclohexaamylose.[11a] The thermodynamic data apparently show that the stabilization due to binding is mostly caused by a favorable enthalpy change. Bender and his co-workers have proposed

Table 4. Activation parameters for alkaline hydrolysis and acylation reaction of PNPL[a]

Reaction	E_a kcal mol^{-1}	$\Delta S^{\ddagger}$ e.u.	$\Delta H^{\ddagger}$ kcal mol^{-1}	$\Delta G^{\ddagger}$ kcal mol^{-1}
Hydrolysis	18.5±0.7	−13.2±2.3	17.9±0.7	22.0±1.5
Acylation	14.9±0.3	−22.5±0.8	14.3±0.3	21.3±0.6

a) Experimental conditions: pH, 12.3; μ, 0.10 (KCl); temp., 307.3 K; medium, 10.9% (v/v) acetone–water.

that the sizable enthalpy change in the formation of cycloamylose complex was brought about by liberating water molecules, which were loosely bound to the cycloamylose cavity through hydrogen bonding, upon inclusion of a guest molecule.[11a] In the paracyclophane cavity, however, the van der Waals forces would provide such a favorable enthalpy effect. Further investigation is in progress in our laboratories.

Activation Parameters for Hydrolysis and Acyl Transfer Reactions. Activation parameters for the hydrolysis of PNPL and the acylation of Oxime-I with the same ester are listed in Table 4. A decrease of activation enthalpy ($\Delta\Delta H^{\ddagger}=4$ kcal mol^{-1}), which plays the major role in the stabilization of transition state, may be caused by the difference in nucleophilicity between hydroxide ion and oximate. Furthermore, the proximity effect brought about by the intra-complex formation seems to be responsible for such a smaller activation enthalpy. A much larger loss of activation entropy ($\Delta\Delta S^{\ddagger}=-10$ e.u.) for the acyl transfer reaction would be rather unexpected: the intramolecular catalysis is entropically favored.[12] This fact suggests that the base-catalyzed nucleophilic reaction results in the formation of a polar transition state and consequently the hydrophobic interaction is partly destroyed.

Conclusion

The sizable paracyclophane oxime demonstrated several unique behaviors as expected. An appropriate cavity size can give out the substrate specificity: this is associated with bulkiness, geometry, and molecular volume of a substrate as well as hydrophobicity of both substrate and paracyclophane. Most significantly, the incorporation of a substrate, having an appropriate geometrical character, into the cyclic cavity was confirmed by the kinetic method. It has been also shown that Oxime-I has a large binding ability toward *p*-nitrophenyl decanoate and laurate, as can be compared to some native enzyme systems.[13] The present study provides a rare and unique example among the enzyme model systems so far studied,[2-5] and may be predictive of the possibility for preparation of a more reactive esterase models. Upon substitution with appropriate functional groups, the paracyclophane skeleton may be modified to yield higher deacylation ability.

Thanks are due to Miss Chieko Gondo for her assistance in part of the rate measurements, and also to the Research Institute of Yoshitomi Pharmaceutical Co., Ltd. for the mass spectral measurements.

2-Hydroxynicotinamide. Found: C, 50.14; H, 4.56; N, 19.43%.

Photo-products from the UV-irradiation in Acidic Ethanol Solutions: Ethylated nicotinic acid and its derivatives were identified mainly on the basis of NMR-spectra (Table 1). 4-Ethylnicotinic acid (mp 137—138 °C), λ_{max} 268 nm. Found: C, 61.85; H, 5.82; N, 9.15%.

Photo-ethylation product from 3-cyanopyridine was a mixture consisted of 6-ethyl- and 4,6-diethyl-3-cyanopyridines. These compounds could not be separated by column chromatography. Identification was made only on the basis of NMR-spectra.

Photo-products from the UV-irradiation of Nicotinic Acid in Aqueous Solutions: UV-irradiation of nicotinic acid in aqueous solution (without adding acid or alkali) brought about the increase in absorption at 284 nm. The photo-product (mp 229—230 °C, decomp.) was identified as 2-(3-pyridyl)pyridine-5-carboxylic acid from the following ground. Equivalent as an acid (by titration with sodium hydroxide), 188; Calcd,

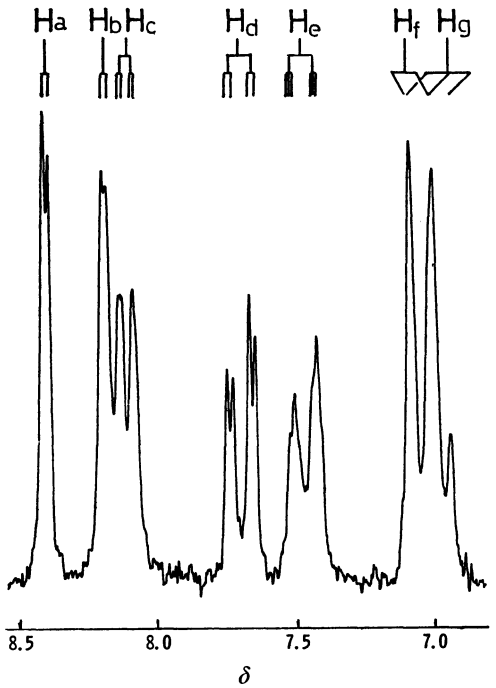

Fig. 1. NMR spectrum of 2-(3-pyridyl)pyridine-5-carboxylic acid

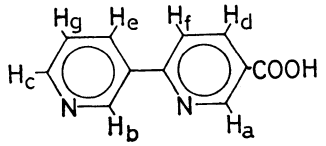

200. The NMR-spectrum was assigned as shown in Fig. 1. The assignment was confirmed by double resonance technique.

Found: C, 65.32; H, 3.87; N, 13.96%. Calcd for $C_{11}H_8N_2O_2$: C, 65.99; H, 4.03; N, 13.99%.

Photo-products from the UV-irradiation in Ethanol Solutions: 3-Cyano-6-(1-hydroxyethyl)pyridine (liquid) and ethyl 6-(1-hydroxyethyl)nicotinate (liquid) were identified on the basis of UV, IR, and NMR spectra.

3-Cyano-6-(1-hydroxyethyl)pyridine: UV; λ_{max}, 268 nm; IR, 3400 (OH), 2980 (aliph. CH), 1480, 1380 (CH_3) and 2240 cm^{-1} (CN). The assignment of NMR-spectra is shown in Table 2.

Ethyl 6-(1-hydroxyethyl)nicotinate: UV; λ_{max}, 266 nm; IR, 3340 (OH), 1720 (C=O), 2960, 1470 and 1370 cm^{-1} (aliph. CH); NMR, Table 2.

Table 2. NMR-spectra of (1-hydroxyethyl)-nicotinic acid derivatives
(Expressed in δ-value)

	Ethyl 6-(1-hydroxy-ethyl)nicotinate	3-Cyano-6-(1-hydroxy-ethyl)pyridine

Photo-products from the UV-irradiation in Alkaline Ethanol Solution: The photo-product in the irradiation of nicotinic acid in alkaline ethanol solution was not trapped by anion exchange resin. The UV spectra (λ_{max}, 266 and 251 nm) and the effects of acid and alkali on UV spectra agreed with those of pyridine. They were different from those of ethylpyridine, another candidate of the photo-product.

Results and Discussion

Photoreactions in Acidic Solutions. Nicotinic acid and its derivatives show a similar UV spectral change on irradiation with 254 nm light in acidic aqueous solutions. An example of nicotinic acid is shown in Fig. 2. The absorption at ~320 nm brought about by UV irradiation corresponds to the introduction of hydroxyl group at the 2-position of pyridine nucleus. This type of UV spectral change was also observed in the irradiation of 3-cyanopyridine and nicotinamide in acidic aqueous solutions. The results of the product

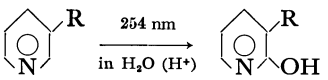
analysis are shown in Table 3. 2-Hydroxynicotinamide was identified in the photo-product from nicotinamide, but the rate of its formation was much smaller compared with 2-hydroxy-3-cyanopyridine and 2-hydroxynicotinic acid.



R=COOH, CN, $CONH_2$

The photo-hydroxylation of nicotinic acid was quenched by oxygen. Oxygen not only inhibited the formation of 2-hydroxynicotinic acid, but also diminished remarkably the transformation of nicotinic acid. This indicates that the photoreaction is ascribed to the triplet state.

In order to obtain further information on the photo-hydroxylation, the pH dependence of the reaction was investigated on nicotinic acid and 3-cyanopyridine (Figs. 3 and 4). In addition, is shown the pH dependence of either λ_{max} of UV-absorption (for nicotinic acid) or the molecular extinction coefficient (for 3-cyanopyridine) of the starting materials. They inform of the form of the substances in solutions. In both

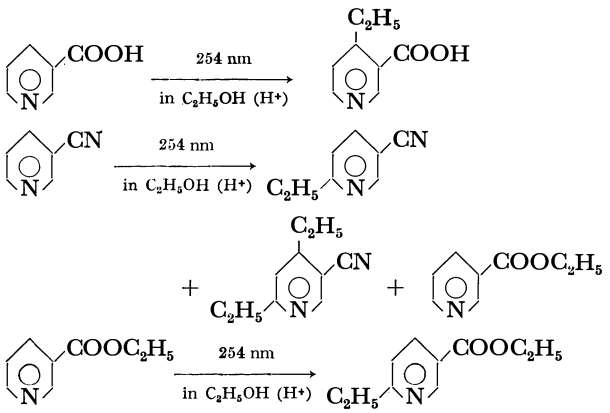
a) LP: Low pressure mercury lamp

cases, the change of chemical form correlates well to that of photoreactivity. Since pK_a value of the protonated nicotinic acid is 2.07, photo-hydroxylation is considered to occur in pyridinium form.

It has been reported that in several pyridine derivatives such as quinoline and acridine, the basicity of the lowest singlet excited state differes by 10^5 from that of the ground state, whereas the basicity of the lowest triplet state is similar to that of the ground state.[8,9] If the photo-hydroxylation derives from the excited singlet state and the lifetime of the excited state is long enough to permit the proton transfer before reaction, the pH range for the photo-hydroxylation should be much wider than our results indicate. This fact also supports that the triplet state is responsible for the photo-hydroxylation. The photo-hydroxylation is thus characteristic for the triplet state of the cationic form of nicotinic acid and its derivatives.

For photo-hydroxylation, the electron attracting group at the pyridine nucleus is essential. Pyridine and the zwitterion form of 3-carboxy-1-methylpyridinium do not undergo photo-hydroxylation.[2] 2-Pyridinecarboxylic acid also shows similar photoreactivity.[1a]

The photoreaction of nicotinic acid and its derivatives in acidic ethanol solutions are summarized in Table 4. The dominant photoreaction of the cationic form of nicotinic acid and its derivatives is the substitution on the pyridine nucleus introducing an ethyl group.



The position of substitution is dependent on the functional group attached to the pyridine nucleus. Nicotinic acid gives 4-ethylnicotinic acid, while ethyl nicotinate is ethylated at 6-position. The UV-irradiation of 3-cyanopyridine yields 6-ethyl- and 4,6-diethyl-3-cyanopyridines. In the photo-ethylation of 3-cyanopyridine, ethylation at 6-position is the initial photoreaction, because at lower conversion, 6-ethyl-3-cyanopyridine was the dominant ethylation product. In the prolonged UV-irradiation of nicotinic acid in acidic methanol, 4-methyl- and 4,6-dimethylnicotinic acids were obtained.

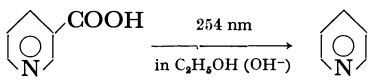
Photo-ethanolysis of nitrile was observed in 3-cyanopyridine. In our reaction condition, ethyl nicotinate was not formed without UV-irradiation.

Photo-alkylation has been reported for several *N*-heteroaromatic compounds such as pyridine,[10] quinoline,[11,12] phenanthridine,[13] and pyrimidine.[14] Similarly to other *N*-heteroaromatic compounds, photo-ethylation of nicotinic acid and its derivatives would be initiated by the hydrogen abstraction from ethanol by N atom of the π-π^* excited state of nicotinic acid, followed by the combination of monohydrogenated nicotinic acid and 1-hydroxyethyl radicals and finally dehydration by acid.

In neutral ethanol solution, 3-cyanopyridine and ethyl nicotinate gave 6-(1-hydroxyethyl) derivative in UV-irradiation, but in lower yield, in comparison with in photo-ethylation in acidic solution. Natsume *et al.* obtained only addition product in UV-irradiation in methanol.[3] We identified the aromatized product. This behavior is similar to that of quinoline reported by Stermitz *et al.*[12]

Photoreactions in Alkaline Solutions. The high photo-stability of nicotinic acid and its derivatives in strongly alkaline aqueous solutions is remarkable. Nicotinic acid and nicotinamide were satisfactorily recovered after comparatively long irradiation (Table 6). 3-Cyanopyridine is also resistant to UV-irradiation, but a part of it is hydrolyzed thermally to nicotinamide.

In contrast to the behavior in aqueous solutions, nocitinic acid undergoes photo-decarboxylation in basic ethanol solution.



The corresponding photoreaction in aqueous solution would be the decarboxylative bipyridyl formation accompanying the formation of a trace of pyridine in

Table 5. Photoreactions of nicotinic acid derivatives in ethanol solutions

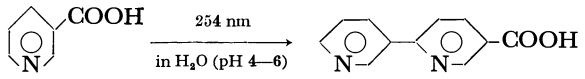
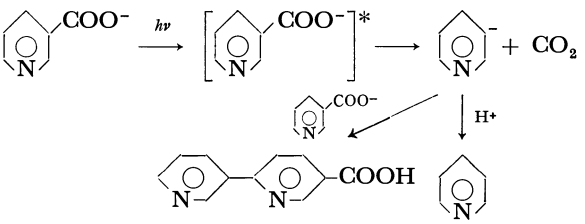
the comparatively small pH range from 4 to 6 (Fig. 3).



The pH dependence of the photochemical bipyridyl formation indicates that the reaction is initiated by the excitation of the anionic form of nicotinic acid (pK_a value of nicotinic acid is 4.81 at 25 °C). This photoreaction involves probably the attack of pyridyl carbanions formed by the decarboxylation of nicotinate ions to the positively charged 6-position of the ground state nicotinate ions.



CNDO/2 Considerations of the Photoreactivity. Some of the photoreactivities of nicotinic acid can be reasoned on the basis of CNDO/2 consideration.

Electronic State of the Cationic Form of Nicotinic Acid. The electronic configurations of π-orbitals near highest occupied and lowest vacant levels as well as the total electron density of π-π^* state of the cationic form of nicotinic acid are shown in Fig. 5. Photo-hydroxylation occurs at 2-position with the greatest positive charge in π-π^* state. This suggests that the photosubstitution proceeds *via* nucleophilic attack of water toward the positively charged 2-position of excited nicotinic acid, although the mechanism of photohydroxylation has not yet been elucidated.

Photo-ethylation is considered to be initiated by the

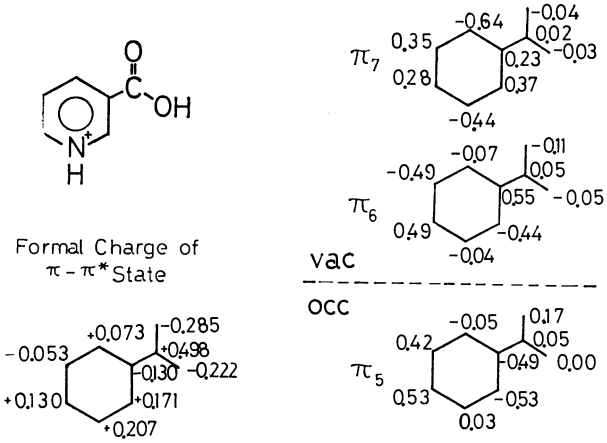


Fig. 5. Electronic states of nicotinic acid in pyridinium form

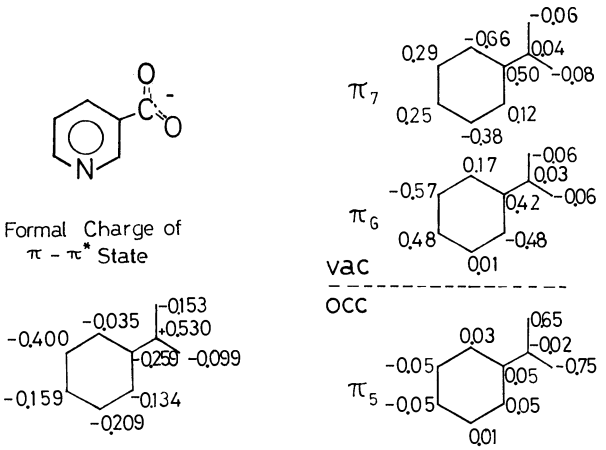

Fig. 6. Electronic states of nicotinic acid in anionic form

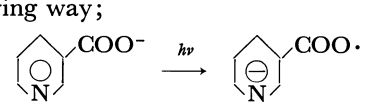
hydrogen abstraction by the N atom of excited nicotinic acid. This behavior can not be reasoned by the CNDO/2 calculation, because the free valence of nicotinic acid cation at N atom is not large.[15]

Electronic State of Anionic Form of Nicotinic Acid. The electronic configurations of π-orbitals (π_5, π_6, and π_7) are shown in Fig. 6. In this case, it is remarkable that one electron localized at carboxylate group in highest occupied level is promoted to π_7, where the electron is localized only in the pyridine ring. This electronic promotion could be schematically expressed in the following way;



In analogy with benzoyloxy radicals, the excited

nicotinate anion would be easily decarboxylated.

The photo-decarboxylation of nicotinic acid in alkaline ethanol solution and the decarboxylative bipyridyl formation can be interpreted well in terms of CNDO/2 calculation.

Concerning the photoreactivity of the excited nicotinate anion, the following problems remain unsolved:

i) Why does the excited nicotinate anion become photo-resistant in strongly alkaline aqueous solution?

ii) Why does the excited nicotinate anion give bipyridyl derivative instead of pyridine in aqueous solution, in which the protonation of pyridyl carbanion is more favorable than in ethanol solution?

The authors wish to thank Mr. Humitaka Miyazawa and Miss Harumi Nakazawa for their experimental assistance. They are grateful to Prof. Shigeo Nishimura and Mrs. Michiko Tsuchimoto for the measurement of NMR spectra and to Nihon Denshi Co. for the careful measurement of double resonance spectra.

15) The contribution of π_7 state to the character of excited nicotinic acid (in pyridinium form) can explain the photoreactivity of nicotinic acid both in aqueous and in ethanol solutions. In π_7 state, the electron density at 2-position is low and the partial free valence at N is large.

Photochemistry of Heterocyclic Compounds. VI. The Photochemical Behavior of Phenazine in Hydroxylic Solvents[1]

Shigeo WAKE, Yoshio OTSUJI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received January 21, 1974)

The photochemical behavior of phenazine in acidified hydroxylic solvents varied with the concentration of acids present in the solutions. Irradiation of phenazine in an aqueous phosphoric acid afforded a 1 : 1 mixture of phenazinium and 1-hydroxyphenazinium cation radicals which were converted to a mixture of phenazine and 1-hydroxyphenazine. Irradiation in moderately strongly acidified alcohols (0.1—1.0 M HCl in alcohols) or in acetic acid containing 0.1 M *p*-toluenesulfonic acid yielded a 1 : 1 mixture of phenazine and the corresponding 1-alkoxyphenazines or 1-acetoxyphenazine after work-up of the reaction mixture. On the other hand, irradiation in a very strongly acidified methanol (5.6—9.6 M HCl in methanol) gave only the phenazinium cation radical. Mechanistic studies revealed that in the moderately strongly acidified media the reaction proceeds through a solvent-addition to the excited singlet phenazinium monocation, and in the very strongly acidified methanol the reaction proceeds through an electron transfer from the solvent to the excited singlet phenazinium dication.

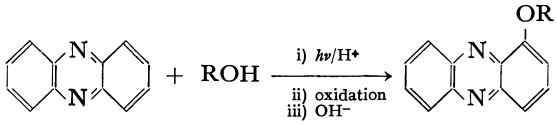
The photochemistry of phenazine has received considerable attention. Toromanoff[2] has shown that irradiation of phenazine in deaerated alcohols gives 5,10-dihydrophenazine. Koizumi and co-workers[3] have proposed that the photoreduction of phenazine in alcohols occurs through a hydrogen abstraction from the higher n, π^* triplet state. However, Davis and co-workers[4] have presented evidence that a reactive state of the photoreduction is the n, π^* singlet state.

Recently, Bailey, Roe, and Hercules[5] have studied the photochemistry of phenazine in acidified methanol. They have concluded on the basis of spectroscopic evidence that in very weakly acidified media (acetate buffers in methanol), phenazine is reduced to 5,10-dihydrophenazine through the lowest n, π^* singlet state. They have also shown that in moderately strongly acidified media (0.1—1.0 M HCl in methanol), phenazine gives the green phenazinium cation radical, which is produced by the reaction of 5,10-dihydrophenazine with phenazinium cation, through the lowest excited singlet state. However, the structure of the photoproducts was deduced only from electronic and ESR spectra of the reaction mixtures, and no unequivocal evidence for the structures was given in their investigation.

We have recently investigated the photochemistry of phenazine in detail and have found that the photochemical behavior of phenazine in hydroxylic solvents is strongly dependent on the concentration of acids present in the solutions. For example, we obtained a mixture of phenazinium and 1-methoxyphenazinium cation radicals upon irradiation of phenazine in moderately strongly acidified methanol (0.1—1.0 M HCl in methanol). However, in the photoreaction in very strongly acidified methanol (5.6—9.7 M HCl in methanol), the photoreduction took place to give the phenazinium cation radical. In this paper, the results accumulated so for are summarized and the mechanisms are proposed on the basis of informations obtained from kinetic studies of these photochemical reactions.

Results

Photoreactions in Moderately Strongly Acidified Solutions. When a 2.8×10^{-3} M solution of phenazine (I) in 2 M aqueous phosphoric acid was irradiated with a high-pressure mercury lamp under nitrogen atmosphere, a green solution containing green precipitates was produced. Oxidation of the green reaction mixture with air or other oxidizing agents, followed by neutralization of the resulting solution, gave 1-hydroxyphenazine (IIa) accompanied by the starting material. Irradiation of I in various alcohols acidified with 0.1 M *p*-toluenesulfonic acid and similar work-up of the reaction mixture afforded a mixture of I and the corresponding 1-alkoxyphenazines (IIb—IId). Similarly, the photoreaction of I in acetic acid containing *p*-toluenesulfonic acid yielded 1-acetoxyphenazine (IIe). These photochemical solvent-addition reactions were not observed upon irradiation in the absence of acids. The results are summarized in Table 1.



IIa, R=H
b, R=CH_3
c, R=C_2H_5
d, R=i-C_3H_7
e, R=CH_3CO

The structure of the photoproducts was confirmed by comparison with the respective authentic samples or by the spectroscopic data.

Quantitative studies of these photoreactions were then preformed. When I was irradiated in 2 M phosphoric acid, the yield of IIa increased with increasing irradiation time.

However, the molar ratio of IIa to I in the reaction mixture reached a plateau, which was very close to unity, upon prolonged irradiation under nitrogen atmosphere as shown in Table 1. Irradiation under air brought about a decrease in the recovery of I (14%) and an increase in the yield of IIa (81%). IIa was surprisingly stable under the reaction conditions; ir-

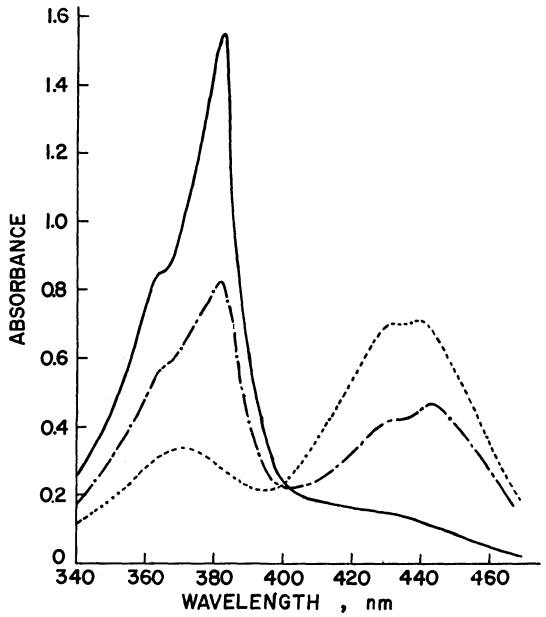

Fig. 1. Spectral change during irradiation of 7.0×10^{-5}M solution of phenazine in 2 M H_3PO_4: ——, before irradiation; ·····, irradiation for 20 min; ------, irradiation for 1.5 hr.

radiation of IIa in 2 M phosphoric acid for 7 hr under air resulted in the recovery of the starting material in a quantitative yield.

The change in the absorption spectrum during the photoreaction was also examined. A solution of I in 2 M phosphoric acid in a quartz cell was irradiated after degassing by a freeze-pump-thaw cycle method. The result is shown in Fig. 1. The spectral change almost ceased after irradiation for 1.5 hr. The spectrum recorded after irradiation for 1.5 hr was identical in shape with that of phenazinium cation radical (III) prepared by the method similar to that of Fellion and Uebersfeld.[6] Furthermore, the green precipitates obtained by the photoreaction displayed the same IR and electronic spectra as those of the green species which was produced by treatment of a mixture of I and IIa in dioxane containing 2 M phosphoric acid with an aqueous solution of sodium hydrosulfite (the green species produced by this treatment in the dark gave a mixture of I and IIa after oxidation and neutralization).

The ESR spectrum of the green precipitate obtained by the photoreaction exhibited the same *g*-value (2.003) as that of the known ESR spectrum of III previously reported.[7]

These observations strongly suggest that the product primarily formed by the photoreaction of I in 2 M phosphoric acid consists of a 1:1 mixture of III and 1-hydroxyphenazinium cation radical (IV), which affords I and IIa upon oxidation and neutralization. The green species, the primary products, obtained by the photoreactions of I in solvents other than water are therefore supposed to be a 1:1 mixture of III and the respective 1-alkoxyphenazinium cation radicals (V) or 1-acetoxyphenazinium cation radical (VI).

Photoreactions in Very Strongly Acidified Solutions. When I was irradiated in HCl-saturated methanol, the green solution was obtained. The absorption spectrum of this green solution was very similar to that obtained by the photoreaction of I in 0.1 M HCl–methanol. However, work-up of this green solution resulted in a complete recovery of the starting material and no IIb could be detected. These results indicate that in HCl-saturated methanol, the photoreduction of I to give III takes place preferentially over the photochemical solvent-addition reaction.

Mechanistic Studies. Deoxygenated solutions of I in water or methanol containing various concentrations of acids in a 1 cm optical cell were irradiated with a high-pressure mercury lamp fitted with a cut-off filter which transmitted >310 nm light. At appropriate time intervals, the spectra of the solutions were recorded.

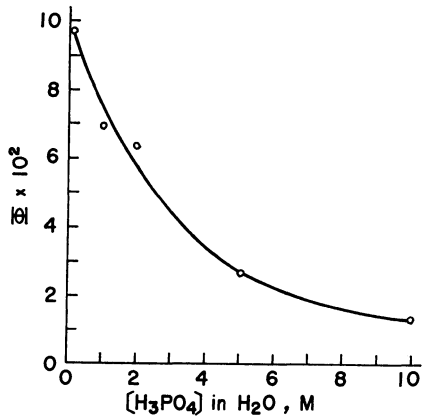

Fig. 2. Quantum yields for the formation of a 1:1 mixture of III and IV as a function of the acid concentrations upon irradiation of I in aqueous phosphoric acid. Initial concentrations of I were 7.22×10^{-5}—6.07×10^{-5}M. The quantum yield at 7.0×10^{-5}M of I in 0.1 M H_3PO_4 was estimated by using the relationship of Eq. (9), coupled with the quantum yields in Table 2 (Φ=0.08 at 4.21×10^{-5}M of I and Φ=0.071 at 3.25×10^{-5}M of I).

For each reaction the 380 nm band of I decayed with production of the 430 nm band as has been shown in Fig. 1. For calculations of the rates of formations of the products, it was considered that the 430 nm band was of a mixture of the cation radicals (III+IV or III+V) or of the single phenazinium cation radical (III) depending on the concentration of acids. The rates were then converted to the quantum yields by use of the potassium ferrioxalate actinometer.[8]

Photoreactions in Aqueous Media. Variation of the quantum yields for the formation of a mixture of the cation radicals III and IV with the concentrations of phosphoric acid was investigated. The quantum yields decreased with increase of the concentrations of acid in a fashion depicted in Fig. 2. Dependence of the quantum yields on the concentrations of I in 2 M phosphoric acid was also studied. The results are summarized in Table 2. A plot of reciprocal quantum yields *vs.* reciprocal concentrations of I gave a straight

a manner that a minimum is produced at an intermediate concentration of the acid. Furthermore, the quantum yields for the formation of III at the high concentration of the acid (5.6 M HCl in methanol) decreased with increase of the concentrations of I as shown in Table 3. This result is in sharp contrast with the result of the photoreactions in 2 M phosphoric acid, where the photoproduct was the mixed cation radicals and the quantum yields for their formation increased with increase of the concentrations of I.

Quenching experiments employing 1,2-dibromoethane as a quencher were also performed. Essentially no quenching was observed as recognized from the results shown in Table 3.

Discussion

Phenazine (I) undergoes the solvent-addition reaction or the reduction reaction, depending on the concentration of acids, upon irradiation in acidified hydroxylic solvents.

$$P + H^+ \xrightarrow{h\nu,\ k_1} {}^1PH^{+*} \text{ (excitation and protonation)} \quad (1)$$

Scheme 1.

Photoreactions in Moderately Strongly Acidified Media. The pathway represented in Scheme 1 is proposed for the photochemical solvent-addition reactions which occur upon irradiation of I in moderately strongly acidified hydroxylic solvents (in Scheme 1, all the intersystem crossing and radiationless deactivation processes of excited species, which have no immediate relation to the chemical reactions, are omitted).

The pK_a of the ground state of I has been reported to be 1.23 in water[10] and to be 4.5 in methanol.[5] Thus, in aqueous phosphoric acid (the first pK_a of phosphoric acid in water is 1.04 at 18 °C), I exists either in the neutral form or in the form of monoprotonated phenazinium cation (PH^+). In acidified methanol containing HCl more than 0.1 M, I exists almost exclusively in the form of PH^+.

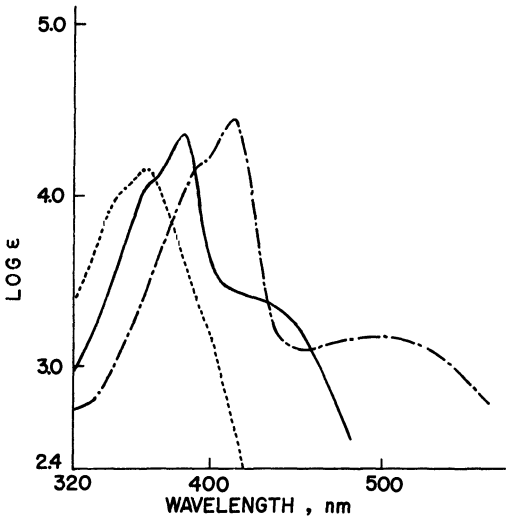

Fig. 5. Absorption spectra of phenazine: ------, in methanol; ——, in aqueous 10 M phosphoric acid; -·-·-, in concentrated sulfuric acid.

The pK_a^* of the lowest excited singlet state of I is expected to be much higher than the corresponding ground state pK_a judging from the fact that the absorption spectrum of I shifts to longer wavelength in acidified media than in neutral media as shown in Fig. 5. It is therefore reasonable to suppose that in the excited singlet state I exists predominantly in the form of phenazinium cation even in relatively weakly acidified media.[11]

We thus propose that the excited monoprotonated phenazinium cation (PH^{+*}) is a reactive species for the photochemical solvent-addition reactions to I. This proposal was derived further from the following arguments.

Firstly, the nonprotonated species is immediately disqualified as a reactive species from the fact that the solvent-addition reactions did not take place in neutral media. Secondly, let's consider variation of proportion of PH^{+*} as a function of the acid concentration. The proportion of PH^{+*} will decrease with increasing the proportion of the excited diprotonated species (PH_2^{2+*}) which would presumably be produced in the presence of the higher concentrations of acids (see also later). Therefore, if PH^{+*} is the reactive species, the quantum

yield for the formation of a mixture of the cation radicals, $PHOR^{+}\cdot$ and $PH_2^{+}\cdot$, is expected to decrease at such higher concentrations of acids as to bring the formation of $PH_2^{2+}*$ predominant. This is exactly the results shown in Figs. 2 and 4. Quenching experiments performed by employing 1,2-dibromoethane and air as quenchers (Tables 2 and 3) suggest that the excited singlet is the reactive state, which is consistent with the conclusion reached by Bailey and co-workers[5] for the photoreactions of I in acidified methanol. An application of the steady state assumption regarding the transient species, $^1PH^{*1}$, $^1PH_2^{2+*}$, PHOR, $PH\cdot$, and $POR\cdot$, in Scheme 1 leads to the relationship of Eq. (9) under the conditions where the concentration of acids is constant:

$$1/\Phi = A/[P] + B \quad (9)$$

where [P] is the concentration of I present in the reaction mixture, which will be roughly equal to the concentration of I initially added, and the coefficients, A and B, are of constant values. The relationship depicted in Fig. 3 is in accordance with this equation.

Photoreactions in Very Strongly Acidified Media. The photoreaction of I in methanol containing HCl more than 5.6 M gave only phenazinium cation radical, $PH_2^{+}\cdot$. A proposed mechanism for this photoreduction is shown in Scheme 2 (in this scheme, all the intersystem crossing and deactivation processes of the excited species, which have no immediate relation to the chemical reactions, are also omitted, as does in Scheme 1).

$$PH^{+} \xrightarrow{h\nu,\, k_1} {}^1PH^{+}* \text{ (excitation)} \quad (2)$$

$$^1PH^{+}* + H^{+} \xrightarrow{k_3} {}^1PH_2^{2+}* \text{ (excited state protonation)} \quad (3)$$

$$^1PH_2^{2+}* + PH^{+} \xrightarrow{k_{10}} 2PH^{+} + H^{+}$$
(quenching of the excited protonated species) (10)

$$^1PH_2^{2+}* + CH_3OH \xrightarrow{k_{11}} PH_2^{+}\cdot + CH_3OH^{+}\cdot$$
(photoreaction; electron transfer) (11)

where all symbols are the same as those in Scheme 1.

Scheme 2.

The absorption spectrum of I in methanol containing 9.7 M HCl indicated that a predominant form of I in its ground state in this medium was PH^{+}. But the pK_a* for the second protonation at the excited singlet state to form the excited diprotonated phenazinium dication ($PH_2^{2+}*$) is again expected to be much higher than the corresponding second pK_a at the ground state judging from the magnitude of the spectral shift observed in the concentrated sulfuric acid (see Fig. 5). Therefore, the excited phenazine may possibly exist in the form of $PH_2^{2+}*$ at higher concentrations of acids.

The electron transfer reaction to $PH_2^{2+}*$ from solvent would produce phenazinium cation radical ($PH_2^{+}\cdot$) as represented in the reaction (11) of Scheme 1. The observation that in the presence of higher concentrations of acids, $PH_2^{+}\cdot$ was produced only in methanol but not in water strongly supports this electron transfer mechanism; the electron transfer from water to the substrate would be unfavorable under the reaction conditions. Noteworthy is in this connection the behavior of diazaheteroaromatic diquaternary salts. Curphey[13] has reported that 1,4-diethylpyrazinium difluoroborate is converted to its cation radical upon dissolving in ethanol. This observation implies that dications of diazaheteroaromatic compounds possess enough ability to abstract an electron from an alcohol even in the dark owing to their high electron deficiency caused by an accumulation of two positive charges.

The result that the quantum yields for the formation of $PH_2^{+}\cdot$ increased with decrease of the initial concentrations of I suggests that $PH_2^{2+}*$ may effectively be quenched by PH^{+}.

Lack of quenching by 1,2-dibromoethane again suggests that the excited singlet state ($^1PH_2^{2+}*$) is a reactive state for the photochemical reduction of I in very strongly acidified methanol.

Experimental

Unless otherwise indicated, irradiations were carried out with a Taika 100 W high-pressure immersion mercury lamp at room temperature.

Materials. Phenazine (I) was prepared by the method of Wohl and Aue.[14] Purification was performed by column chromatography on acidic alumina using benzene as an eluent, followed by recrystallization from EtOH, mp 171—172 °C.

All other chemicals were of commercial origin and were usually used after purification by distillation or recrystallization. Water was purified by redistillation of deionized water.

Preparation of the Authentic Samples. 1-Hydroxyphenazine (IIa), mp 156—158 °C, and 1-methoxyphenazine (IIb), mp 166—167 °C, were prepared by the method of Surrey.[15] 1-Acetoxyphenazine (IIe) was prepared by the reaction of IIa and acetic anhydride in pyridine, and purified by recrystallization from MeOH, mp 119—120 °C; NMR ($CDCl_3$) δ 2.58 (s, 3H, $-CH_3$), 7.50—8.38 (m, 7H, aromatic H).

The structure of the photoproducts was identified by the mixed melting point test and by the comparison of IR spectra of the products with those of the corresponding authentic samples unless otherwise indicated.

Irradiation of I in Aqueous 2 M H_3PO_4 Solution. I (100 mg, 0.56 mmol) in aqueous 2 M H_3PO_4 solution (200 ml) was placed in a quartz vessel and N_2 was bubbled for 20 min. Irradiation was then carried out for 7 hr with bubbling N_2. Green solid (A) deposited was collected by filtration. The filtrate was allowed to stand overnight under air, while the color of the solution turned from green to red. The solution was then neutralized with Na_2CO_3 and extracted with ether. The ether solution was extracted with 10% NaOH until no more purple color moved to aqueous layer, and then the ether layer was dried over Na_2SO_4. Distillation of the ether gave 17 mg of the unchanged I. The combined aqueous extracts were made faintly acid with dilute HCl, and again extracted with ether. The ether extract was dried over Na_2SO_4, and then concentrated by distillation to give 34 mg of IIa which was recrystallized from EtOH–H_2O, mp 156—158 °C. The green solid A was dispersed in aqueous EtOH and oxidized with $K_3Fe(CN)_6$. Work-up of the resulting solution by the procedure similar to that described above gave 35 mg of I and 15 mg of IIa.

Irradiation of I in Acidified Methanol. A mixture of I (100 mg, 0.56 mmol) and *p*-toluenesulfonic acid monohydrate

(1 g, 5.3 mmol) in dry MeOH (50 ml) was placed in a quartz vessel, and N_2 was bubbled for 20 min. After irradiation for 7 hr under N_2, $K_3Fe(CN)_6$ in H_2O was added until the solution turned into yellow. The solution was evaporated to dryness under reduced pressure. The residue was neutralized with 5% Na_2CO_3 and then extracted with ether. The extract was dried over Na_2SO_4, and the ether was removed by distillation The residue was chromatographed on alumina. Elution with benzene yielded 65 mg (65%) of unchanged I. Elution with benzene–EtOH (10: 1) yielded 30 mg (26%) of IIb, which was recrystallized from EtOH–H_2O to give the analytical sample, mp 166—167.5 °C.

I (100 mg, 0.56 mmol) in dry MeOH (50 ml) containing 0.1 M HCl was also irradiated for 7 hr under air. Similar work-up of the reaction mixture gave 57 mg (57%) of I and 37 mg (32%) of IIb.

Irradiation of I in Acidified Ethanol. A mixture of I (100 mg, 0.56 mmol) and *p*-toluenesulfonic acid monohydrate (1 g, 5.3 mmol) in dry EtOH (50 ml) was irradiated under N_2 for 7 hr. Work-up of the reaction mixture by the method similar to that described above gave 70 mg (70%) of I and 20 mg (16%) of 1-ethoxyphenazine (IIc) which was recrystallized from EtOH–H_2O to give the analytical sample, mp 126—127 °C (lit,[16] mp 130 °C); picrate, mp 188—190 °C (lit,[16] mp 195 °C). Found: C, 75.10; H, 5.32; N, 12.57%. Calcd for $C_{14}H_{12}N_2O$: C, 74.99; H, 5.38; N, 12.49%.

Irradiation of I in Acidified 2-Propanol. A mixture of I (100 mg, 0.56 mmol) and *p*-toluenesulfonic acid monohydrate (2 g, 10.6 mmol) in dry i-PrOH (100 ml) was irradiated under N_2 for 7 hr. Work-up of the reaction mixture similar to that described above gave 82 mg (82%) of I and 5 mg (4%) of 1-isopropoxyphenazine (IId) which was recrystallized from EtOH–H_2O to give the analytical sample, mp 83—85 °C; NMR (CCl_4) δ 1.58 (d, 6H, J=6 Hz, $-CH_3$), 4.70—5.30 (m, 1H, $>CH$), 7.72—8.58 (m, 7H, aromatic H); mass spectrum (80 eV) *m/e* 238, 223, 196, 180, 168. Found: C, 75.42; H, 5.70; N, 11.56%. Calcd for $C_{15}H_{14}N_2O$: C, 75.60; H, 5.92; N, 11.76.

Irradiation of I in Acetic Acid. A mixture of I (100 mg, 0.56 mmol) and *p*-toluenesulfonic acid monohydrate (1 g, 5.3 mmol) in dry AcOH (50 ml) was irradiated under N_2 for 7 hr. After irradiation, $FeCl_3$ was added to the reaction mixture until the solution turned into yellow. The solution was then evaporated to dryness under reduced pressure, and an aqueous Na_2CO_3 was added to the residue until the neutralized solution was obtained. The neutralized solution was extracted with ether. After the ether extracts were dried over Na_2SO_4, the ether was removed by distillation. The residue was subjected to tlc (silica gel, DMF: AcOH: H_2O= 10: 1: 1). The upper spot was extracted with $CHCl_3$, then the solvent was evaporated to dryness. IR and NMR spectra of the residue were identical with those of the authentic sample of IIe. Quantitative analyses of I and IIe were performed by converting IIe to IIa by treatment with an aqueous NaOH: the residue obtained upon irradiation was dissolved in a mixture of EtOH (5 ml) and 10% NaOH solution (5 ml), and the mixture was kept at 40 °C for 1 hr. A 10% NaOH solution (20 ml) was added to the mixture, and the alkaline solution thus obtained was extracted with ether. Work-up of the ether and aqueous layers gave 75 mg (75%) of I and 20 mg (19%) of IIa.

Irradiation of IIa in 2 M H_3PO_4 Solution. IIa (100 mg, 0.51 mmol) in aqueous 2 M H_3PO_4 (80 ml) was irradiated under air for 7 hr. The solution was neutralized with Na_2CO_3 and extracted with ether. Work-up of the ether extracts resulted in a quantitative recovery of IIa.

Quantum Yield Determinations. A 5 ml of reactant solution was degassed under vacuum by four freeze-pump-thaw cycles in a side arm through which a 1 cm quartz cell was connected. Then the quartz cell and the side arm were closed under vacuum and the solution was transfered into the quartz cell. The absorption spectrum of the reactant solution was recorded, and irradiation was then started. During the course of the photoreactions, additional complete spectra (6—8 times) were taken. Optical densities at 380 nm band of the reactant and at 430 nm band of the product were monitored and the simultaneous equations were used to determine the amount of product formed. A plot of the amount of the product formed *vs.* total quanta absorbed was prepared, and the quantum yield was determined from the slope of the straight line. The photoreaction was never carried out beyond the point where 20% of I has been photolyzed. All studies were made at room temperature. After the photoreaction was ceased, the solution was oxidized by exposing it to air, and the analysis of IIa or IIb was performed by taking absorption spectrum.

A Toshiba SHL-100 UV high-pressure mercury lamp was used as a light source. Light was filtered through a Toshiba UV 31 filter glass. The filter glass permitted to pass the light with the following wavelength distribution: 3% 3130 Å, 18% 3660 Å, 16% 4045 Å, 28% 4358 Å, 28% 5461 Å, 6% 5780 Å. Potassium ferrioxalate actinometer[8] was used for measuring the light intensity. Reproducible output rates of 8.7×10^{16} quanta min^{-1} were recorded.

Photochemistry of Heterocyclic Compounds. VII. The Photochemical Behavior of Phthalazine and Quinoxaline in Acidified Alcohols

Shigeo WAKE, Yuichi TAKAYAMA, Yoshio OTSUJI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received January 23, 1974)

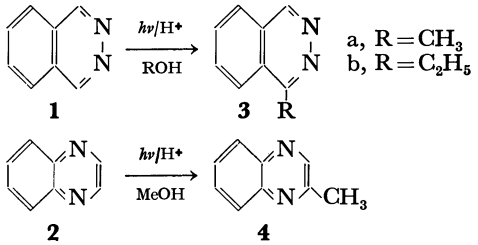
Irradiation of phthalazine (**1**) and quinoxaline (**2**) in acidified methanol yielded 1-methylphthalazine (**3a**) and 2-methylquinoxaline (**4**), respectively. The quantum yields for the formation of 1-alkylphthalazines, which were obtained upon irradiation of **1** in acidified alcohols, varied with the sort of alcohols used and decreased in the order of methanol>ethanol≫2-propanol. When a mixture of **1** and 2,6-di-*t*-butylphenol (**6**) was irradiated in benzene containing trifluoroacetic acid under evacuated conditions, the oxidation of **6** occurred to form 3,5,3′,5′-tetra-*t*-butyldiphenoquinone (**7**) without destruction of **1**. Detailed mechanistic studies suggest that the photoalkylations of **1** and **2** in acidified alcohols proceed through an electron-transfer from solvents to an excited state of the protonated diazines.

In the previous communication,[1] we have reported that phenazine undergoes an ionic solvent-addition reaction to form 1-hydroxy- or 1-alkoxyphenazines upon irradiation in water or alcohols in the presence of protic acids. However, other studies on the photoreactions of nitrogen heteroaromatic compounds in acidified alcohols have indicated that the photoalkylation, rather than the solvent-addition, appears to be a general reaction for this class of compounds.[2-3] These two distinct observations led us to study the photochemical behaviors of phthalazine and quinoxaline, both of which belong to the class of diazine similar to phenazine.

In contrast to phenazine, phthalazine and quinoxaline underwent the photoalkylation reaction upon irradiation in acidified alcohols. Detailed mechanistic studies on the photoreaction of phthalazine suggested that the photoalkylation proceeded through the pathway involving an electron-transfer from alcohols to the excited protonated phthalazine. The details are presented in this paper.

Results

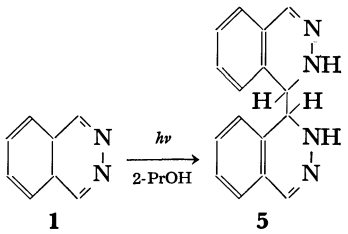
Photo-products. Irradiation of dilute solutions of phthalazine (**1**) in methanol and ethanol containing HCl with a low-pressure Hg lamp under nitrogen atmosphere afforded 1-methyl and 1-ethylphthalazines (**3a** and **3b**), respectively. Irradiation of quinoxaline (**2**) in acidified methanol under similar conditions gave 2-methylquinoxaline (**4**). The results are summarized in Table 1. *p*-Toluenesulfonic acid was also effective as an acid-catalyst for these photoalkylations. On the other hand, when a 0.01 M solution of **1** in methanol was irradiated for 3 hr in the absence of acid, **3a** was not obtained. However, treatment of the resulting reaction mixture with HCl gave **3a** in an 11% yield.



Reaction temperature influenced remarkably on the yields of the products, *i.e.*, irradiation of the solutions of **1** and **2** in acidified methanol at their reflux temperatures raised the yields of the products as shown in Table 1. No reactions took place upon irradiation of aqueous solutions of **1** and **2** both in the presence and absence of acids.

In contrast to the above photoreactions, irradiation of **1** in 2-propanol containing *p*-toluenesulfonic acid gave only a small amount of tarry material. Vpc analysis of the reaction mixture did not show any indication for the presence of the photoalkylation products. Vpc analysis also showed that the rate of disappearance of **1** was faster in methanol than in 2-propanol. Thus, irradiation of **1** in 2-propanol containing 0.1 M *p*-toluenesulfonic acid for 3 hr resulted in a 77% recovery of **1**, while a similar irradiation of **1** in methanol resulted in a 51% recovery of the starting material (see Table 1).

Irradiation of **1** in 2-propanol without added acid afforded a reductive dimerization product (**5**). The structure of **5** was established by a combination of the elemental analysis and spectral data (see Experimental section). The dimer was not obtained by the irradiation in methanol.



Photoreaction of 2,6-Di-t-butylphenol (6) in the Presence of 1 in an Acidic Medium. When irradiation of an equimolar mixture of **1** and **6** in benzene containing trifluoroacetic acid was carried out under evacuated conditions, 3,5,3′,5′-tetra-*t*-butyldiphenoquinone (**7**) was obtained together with a small amount of unidentified tarry material. The yield of **7** increased with increase of irradiation time, and in every case **1** was recovered

TABLE 1. PHOTOREACTIONS OF **1** AND **2**

Compd.[a]	Solvent	Irrad. conditions		Recovered starting material, %	Product

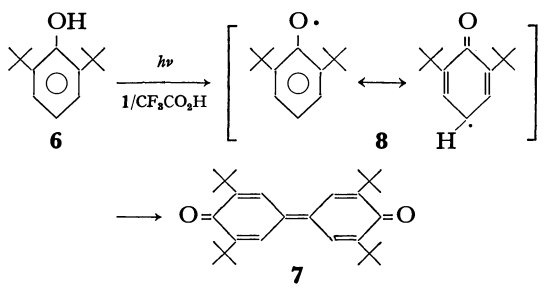
a) A mixture of 0.5 mmol of **1** and 0.5 mmol of **6** in 50 ml of benzene containing trifluoroacetic acid (0.1 M) was irradiated under evacuated conditions.
b) The yields of **7** were calculated on the basis of the amount of **6** used.

in a high yield. The results are shown in Table 2. However, **7** could not be detected in the reaction mixture when the irradiation was conducted without added acid or in the absence of **1**. In these cases, the starting materials were recovered unchanged. No reaction also took place without irradiation.



Quantum Yields. The quantum yields for the formation of alkylated products obtained by irradiation of **1** in various acidified alcohols were measured. The results are shown in Table 3. The quantum

TABLE 3. THE QUANTUM YIELDS FOR THE FORMATION OF 1-ALKYLPHTHALAZINES[a]

Solvent	Product	Φ
MeOH, 0.1 M HCl	**3a**	0.026
EtOH, 0.1 M HCl	**3b**	0.0055
2-PrOH, 0.1 M HCl	—[b]	0

a) The 0.01 M solutions of **1** in acidified alcohols were irradiated for 4 hr, and then the products were analyzed to determine the quantum yields.
b) No alkylated product was detected in the reaction mixture.

yields decreased in the order of methylation>ethylation≫propylation.

The quantum yields for the formation of **3a** from **1** were also determined in the presence of various amounts of HCl. The results are depicted in Fig. 1. The

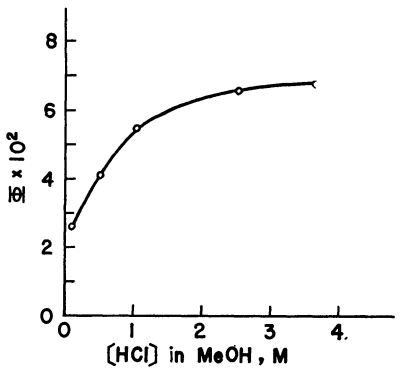


Fig. 1. Effect of HCl concentrations on the quantum yields for the formation of **3** upon irradiation of **1** in acidified methanol. A 0.01 M solution of **1** was irradiated.

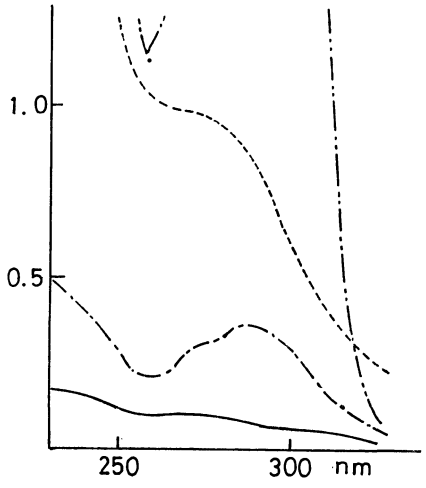

Fig. 2. UV spectra of acidified alcohols: ——, methanol containing of 1 M HCl; ------, methanol containing 5 M HCl; -·-·-, ethanol containing 1 M HCl; —·—, ethanol containing 5 M HCl.

quantum yields increased with increase of the concentration of the acid present. However, when the irradiation was carried out in the presence of 7.2 M HCl, it was found that the quantum yield for the formation of **3a** decreased to a half of the value that was obtained upon irradiation in the presence of 3.6 M HCl. However, spectral examination (Fig. 2) demonstrated that in the presence of higher concentrations of acids, methanol itself absorbed much of the light at 245 nm which was also a main effective light for the photoreaction. Therefore, decrease in the quantum yield for the formation of **3a** in the presence of 7.2 M HCl does not necessarily mean that the quantum efficiency for the reaction decreases at higher concentrations of the acid, but it may merely due to the decrease in number of quanta absorbed by **1**.

To evaluate effects of air on the quantum efficiency of the photoreaction, irradiation of **1** in 0.1 M HCl–MeOH was carried out under evacuated conditions. Quenching experiment employing 1,2-dibromoethane as a quencher was also performed. The results are summarized in Table 4.

Table 4. Irradiation of **1** in acidified methanol[a)]

Quencher	Quantum yield for disappearance of **1**	Quantum yield for the formation of **3a**
None	0.102	0.080
Air	0.072	0.026
1,2-DBE,[b)] 0.19 M	0.121	0.073

a) A 0.01 M solution of 1 in methanol containing 0.1 M HCl was irradiated. b) 1, 2-DBE represents 1,2-dibromoethane.

Absorption Spectra. The absorption spectra of **1** and *N*-methylphthalazinium iodide were studied. The absorption spectra of **1** in MeOH, EtOH, and 2-PrOH were essentially identical. A red shift was observed upon an addition of acid. The spectra of **1** in methanol containing 0.1—1.0 M HCl were very similar in shape to the spectrum of *N*-methylphthalazinium iodide in methanol as shown in Fig. 3.

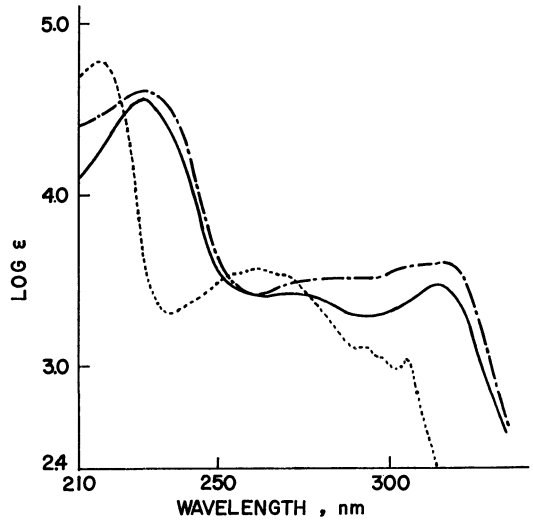

Fig. 3. UV spectra of **1** and *N*-methylphthalazinium iodide: ------, **1** in methanol; ——, **1** in methanol containing 1.0 M HCl; -·-·-, *N*-methylphthalazinium iodide in methanol.

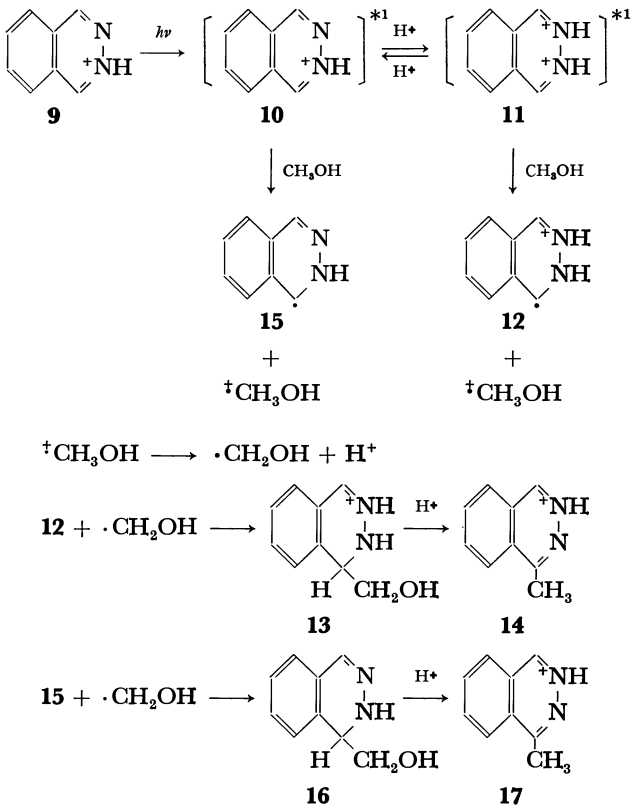
Discussion

A proposed mechanism for the photoalkylation of azaaromatic compounds is illustrated in Scheme 1 taking an example of the photomethylation of **1** in acidified methanol.

Absorption spectra shown in Fig. 3 strongly suggest that **1** exists at its ground state predominantly in the



Scheme 1.

form of monoprotonated phthalazinium cation (**9**) in methanol containing 0.1—1.0 M HCl. However, at the excited state **1** may exist either in the excited monoprotonated form (**10**) or in the excited diprotonated form (**11**) in acidified methanol.[4]

The excited diprotonated species **11** picks up an electron from methanol to form the cation radical **12** and the cation radical of methanol, $^{\ddagger}CH_3OH$, which is converted to hydroxymethyl radical. A coupling of **12** with hydroxymethyl radical produces the intermediate **13**. The reaction of **13** with a proton affords the monoprotonated 1-methylphthalazinium cation (**14**).

The result of Fig. 1 can be explained by assuming that the reactive species is **11**, since the proportion of **11** in the reaction mixture would increase with increase of the acid concentrations.[5]

A striking feature of the proposed mechanism is the electron transfer from alcohols to the excited protonated azines. This mechanism was derived from the following considerations. Firstly, the electron affinity of **11** is supposed to be high enough to take up an electron from alcohols. An increased electron affinity of the dication of diazines has been recognized by Curphey,[6] who observed that *N,N'*-diethylpyradinium difluoroborate is reduced to the corresponding cation radical upon dissolving it in ethanol even in the dark. Secondly, the solvent effects on the photoreaction of **1** are consistent with the electron transfer mechanism. We observed that the quantum yields of the photoalkylations of **1** in acidified alcohols varied with the sort of alcohols used and decreased in the order of methanol>ethanol≫2-propanol (Table 1). Furthermore, the results of Table 1 indicate that the rate of disapperance of **1** decreases also in the above order. If the photoreaction is initiated *via* a hydrogen abstraction from alcohols by **10** or **11**, the reversed solvent effects must be observed. Absorption spectra shown in Fig. 2 suggest that alcohols may be transformed to their oxonium ions in the presence of higher concentrations of HCl (HCl and alcohols themselves have no absorptions at 220—250 nm where the acidified alcohols exhibited strong absorptions). If this is the case, it is reasonable to assume that the formation of oxonium ions in acidified alcohols would become favorable in more basic 2-propanol than in more acidic ethanol or methanol. An electron abstraction from the oxonium ions would be more difficult than from the free alcohols. Thus, it is supposed that the photoreactivity varies in the observed order, if the photoreaction is initiated *via* the electron transfer from acidified alcohols to **11**. Thirdly, an evidence supporting the electron transfer mechansim was provided by the result that the irradiation of a mixture of **1** and **6** in benzene in the presence of acid brought about the oxidation of **6** to **7** without destruction of **1**. This photooxidation can be best explained in terms of the mechanism involving the electron transfer from **6** to **11** to form the phenoxy radical **8**.[7] Finally, further supporting data for the mechanism were found in the literature. 1) Ochiai and co-workers[8] have found that the photomethylation of pyrimidine derivatives in acidified methanol is favored by the electron-withdrawing substituents attached to the pyrimidine ring, and they have also observed the $\cdot CH_2OH$ radical. 2) Castellano and co-workers[9] have recently detected the cation radicals of **2**, pyrazine, and phenazine in the reaction mixtures by ESR spectroscopy upon irradiation of their acidified methanolic solutions. These results are in accordance with the mechanism shown in Scheme 1.

It must be noted here that the photoreactions of azaaromatic compounds in the absence of acids may proceed through a hydrogen abstraction from alcohols by the excited azaaromatics.[3]

1,2-Dibromoethane caused essentially no quenching effect on the quantum yield for the formation of **3a**. This result suggest that the photoreaction of **1** proceeds from a singlet excited state. A decrease in the quantum yield of the photoalkylation of **1** in the presence of air is explainable on the basis of the assumption that oxygen reacts with the intermediate radical species (**12** or hydroxymethyl radical, or both) to quench further reactions. The effect of temperature on the yields of **3a** and **4** in the photolyses of **1** and **2** may be attributed to the acid-catalyzed dehydration reaction of the type **13**→**14** in the dark. However, a more work has to be done before the final conclusion can be reached.

Experimental

Melting points are uncorrected. UV spectra were recorded with a Hitachi EPS-3T recording spectrophotometer. IR spectra were obtained with a Hitachi model 215 infrared spectrophotometer. NMR spectra were obtained with a Hitachi H-60 high resolution NMR spectrometer, using TMS as an internal standard. Microanalyses were performed with a Yanagimoto MT-1 CHN corder. Mass spectra were obtained with a Hitachi RMU-6E mass spectrometer. Vpc analyses were performed with a Hitachi K-23 gas chromatograph, using a column packed with 30% Silicone grease on Celite 545. Unless otherwise noted, irradiations were carried out with a Taika 15 W low-pressure mercury lamp in an immersion-type apparatus.

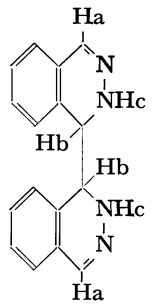
Materials. Phthalazine (**1**) was prepared by the method of Gabriel and Muller[10] and purified by recrystallization from ether, mp 89—91 °C. Quinoxaline (**2**) was prepared by the method of Jones and McLaughlin[11] and purified by distillation, bp 109.5—111 °C/15 mmHg. All other chemicals were of commercial origin and were usually used after purification by distillation or recrystallization.

Preparation of the Authentic Samples. 1-Methylphthalazine (**3**) was prepared by the method of Popp and Wefer;[12] NMR (CCl_4) δ 2.87 (3H, s, $-CH_3$), 7.55—8.00 (4H, m, benzoaromatic H), and 9.12 ppm (1H, s, $-CH{=}N-$); picrate, mp 201—203 °C (lit,[13] mp 205 °C). 2-Methylquinoxaline (**4**) was prepared by the method of Bottcher,[14] bp 121—125 °C/19 mmHg; NMR (CCl_4) δ 2.66 (3H, s, $-CH_3$), 7.25—7.95 (4H, m, benzoaromatic H), and 8.49 ppm (1H, s, $-N{=}CH-$). 3,5,3',5'-Tetra-*t*-butyldiphenoquinone (**7**) was prepared by the method of Cook, English, and Wilson,[7] mp 232—234 °C.

Photoreaction of 1. (A) Irradiation in Acidified Methanol: A solution of 130 mg (1 mmol) of **1** in 100 ml of an anhydrous methanol containing 0.08 M dry HCl or 0.1 M *p*-toluensulfonic acid was placed in a cylindrical quartz vessel and nitrogen was passed into the solution for 20 min. Irradiation was then carried out at room temperature or at refluxing tempera-

ture of the solvent. After irradiation for an appropriate period of time, the irradiated solution was evaporated to dryness under reduced pressure. The residue was neutralized with 10% aqueous Na_2CO_3, and the aqueous mixture was extracted with benzene by means of a liquid extractor. The benzene extract was dried over Na_2SO_4 and then evaporated. The NMR, IR and vpc examinations showed that the residue consisted of a mixture of **1** and **3**. The quantitative analysis of the residue was performed by vpc, employing quinaldine as an internal standard.

(B) Irradiation in Methanol without Added Acid: A solution of 130 mg (1 mmol) of **1** in 100 ml of an anhydrous methanol was irradiated at room temperature as described above. A concentrated HCl (1 ml) was then added to the reaction mixture, and the resulting mixture was refluxed for 1 hr. The mixture was then worked up as described above.



5

(C) Irradiation in 2-Propanol. A solution of 130 mg (1 mmol) of **1** in 100 ml of an anhydrous 2-propanol was irradiated for 3 hr as described above. The solution was concentrated to 5 ml under reduced pressure. The crystals precipitated were collected by filtration and washed with 2-propanol, then with ether. The crystals (10 mg, 8%) were recrystallized from ethanol to give an analytical sample, mp 225—227 °C (decomp.), which was identified as the dimer **5**; NMR (CF_3COOH) δ 5.15 (2H, s, Hb), 7.09—7.21 (2H, broad m, Hc), 7.68—8.08 (8H, m, benzoaromatic H), and 8.6 ppm (2H, s, Ha); MS (50 eV) *m/e* 262 (M^+), 236, 230, 131, and 130. UV (EtOH) λ_{max} 245 (ε 2.56×10^4) and 345 nm (ε 5.63×10^3); IR (KBr) 3300, 3050, 1490 and 1420 cm^{-1}.

Found: C, 73.02; H, 5.59, N, 21.13%. Calcd for $C_{10}H_{14}N_4$: C, 73.26; H, 5.38; N, 21.36%.

The filtrate and washings obtained above were evaporated under reduced pressure and the residue was subjected to vpc analysis. The analysis indicated that the starting material was recovered in an 83% yield.

Photoreaction of **2**. A solution of 130 mg (1 mmol) of **2** in 100 ml of an anhydrous methanol containing 0.08 M dry HCl was irradiated at room temperature or at refluxing temperature of the solvent, in the same manner as previously described for the photolysis of **1**. After irradiation, the irradiated solution was evaporated to dryness under reduced pressure. The residue was neutralized with 10% aqueous Na_2CO_3, and the neutralized solution was extracted with benzene by means of a liquid extractor. The benzene extract was dried over Na_2SO_4 and then evaporated. Examinations of the residue by NMR, IR and vpc revealed that the residue consisted of a mixture of **2** and **4**. The quantitative analysis was performed by vpc with diphenyl ether as an internal standard.

Photoreaction of a Mixture of **1** *and* **6**. A mixture of 65 mg (0.5 mmol) of **1** and 103 mg (0.5 mmol) of **6** in a dry benzene containing 0.1 M trifluoroacetic acid was placed in a cylindrical quartz vessel and degassed by four or five freeze-pump-thaw cycles. Irradiation was then carried out from the outside of the reaction vessel at room temperature for 12 hr. The irradiated solution was extracted with 1 M HCl. The benzene layer was dried over Na_2SO_4 and then evaporated under reduced pressure. The residue was separated by preparative tlc on silica using CCl_4 as an eluent. Extraction of the first spot (R_f 0.3) with $CHCl_3$ and evaporation of the solvent gave 85 mg (83%) of unreacted **6**. Extraction of the second spot (R_f 0.5) with $CHCl_3$ and evaporation of the solvent gave 9 mg (9%) of **7** which melted at 231—233 °C after recrystallization from ethanol and was identical with the authentic sample in every respect. There were other few spots, from which 8 mg of unidentified materials were obtained.

On the other hand, the aqueous acid solution was made to pH 8 with Na_2CO_3 and filtered. The filtrate was extracted with benzene by means of a liquid extractor. The benzene extract was dried over Na_2SO_4 and then evaporated to give 57 mg (88%) of **1**.

Quantum Yield Determinations. A reactant solution (20 ml) in a quartz vessel was irradiated after degassing by four freeze-thaw cycles or under air with a Taika 15 W low-pressure mercury lamp. Although filter was not employed, the spectral examination of the radiation showed that the light source radiated the light with the following wavelength distribution: 74% 2537 Å, 4% 3130 Å, 4% 3660 Å, 4% 4055 Å, and 14% 4358 Å. All studies were made at room temperature. Potassium ferrioxalate actinometer[15] was used for measuring the light intensity. Reproducible output rates of 3.4×10^{18} quanta min^{-1} were recorded. After irradiation for 4 hr, the solution was neutralized with Na_2CO_3 and evaporated to dryness under reduced pressure. The residue was extracted with benzene, and the benzene extract was subjected to vpc analysis.

Substituent Effects in the Benzofuran System. I. Proton and Carbon-13 Chemical Shifts

Tadashi OKUYAMA and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 7, 1973)

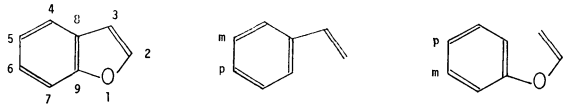
PMR and CMR spectra of benzofuran and its derivatives (2-CH_3, 3-CH_3, 5-CH_3, 6-CH_3, 5-CH_3O, 6-CH_3O, and 5-Cl) have been measured. The chemical shifts of 2-H and 2-C of 5- and 6-substituted derivatives obeyed a modified Hammett equation, $\delta=\rho_1\sigma_1+\rho_2\sigma_2+\delta_0$. Electronic effects were found to be transmitted mainly through the bond 8—3. It was concluded that the ground-state electronic structure is similar to that of styrene rather than phenyl vinyl ether.

A great number of reaction rates and ground-state properties of benzene derivatives have been treated in terms of the Hammett $\rho\sigma$ relationship.[1] Much less is known of its application to fused ring systems which have two transmission paths of substituent effects. Such an application was first undertaken by Jaffé[2a] with the use of a modified Hammett equation.

$$\log (k/k_0) = \rho_1\sigma_1 + \rho_2\sigma_2 \quad (1)$$

The treatment has successfully been applied to the phthalide system.[2a] These treatments on heteroaromatic fused rings have been summarized in a review.[2b] Some examples of the benzofuran system are included but full accounts are not available. Noyce and Nichols[3] have recently treated the solvolysis rates of 2- and 3-benzofuryl derivatives in terms of the σ_{ij} constants with the modified Dewar-Grisdale equation.[4]

Because of our continuing interest in the chemica properties of aromatic olefins as well as enol ethers, we have studied the substituent effects observable in the benzofuran system. Benzofuran (BF) is structurally analogous to both styrene (ST) and phenyl vinyl ether (PVE).



BF ST PVE

Accordingly, its chemical behavior should be dual in its character. First, in the present communication, we will analyze the ground-state electronic structure of BF on the basis of ^1H and ^{13}C NMR observations. In the following two papers, the chemical reactivities will be treated for the bromination[5a] and the cationic polymerization.[5b]

Results

PMR Spectra. The proton magnetic resonance (PMR) spectra of BF and its derivatives have been recorded at a frequency of 100 MHz with a 10% solution in carbon tetrachloride using tetramethylsilane as internal standard. Measurements are accurate within 0.05 Hz. Assignment of signals has been made based on their coupling mode. Spectral feature of unsubstituted phenylene ring is too complicated for simple analysis and was not subjected to further attempts of analysis. Chemical shifts and coupling constants are summarized in Table 1.

CMR Spectra. The ^{13}C NMR spectra of BF derivatives have been obtained usually with a 50% solution in carbon disulfide. The complete proton noise decoupled spectrum of BF gave eight sharp singlets. The signals responsible for quaternary carbon atoms are easily characterized by a partial proton decoupling technique, remaining as singlet. All the signals have been assigned empirically by using the additivity rule.[6] The 6-methoxy derivative, proton spectrum of which is well separated, was subjected to single-frequency decoupling to aid the assignment. The chemical shifts are given in Table 2 as expressed in ppm downfield from TMS. For closely-spaced signals, however, some uncertainties were inevitable and such chemical shifts are presented with parentheses in Table 2.

TABLE 1. THE CHEMICAL SHIFTS AND COUPLING CONSTANTS FOR THE PMR SPECTRA OF SUBSTITUTED BENZOFURANS[a]

Substituent	Chemical shift, ppm						Coupling constant, Hz					
	H-2	H-3	H-4	H-5	H-6	H-7	J_{23}	J_{37}	J_{45}	J_{67}	J_{57}	J_{46}
H	7.507	6.623					2.3	1.0

a) In ppm downfield from TMS. Measured with a 50% solution in CS_2. b) Measured with a neat sample.

Discussion

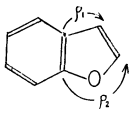
Spectral Characterization. PMR spectra of various methyl-substituted BF's have previously been measured, and the results on the 2- and 3-protons reported.[7] The present results on these derivatives coincide satisfactorily with those reported data.[7] A long-range coupling between the 3- and 7-protons of *ca.* 1 Hz observed here conforms also to the earlier results.[7]

The CMR spectrum of BF has recently been measured.[8] Assignment of signals has been made in analogy to that for indoles.[9] The assignment of C-4, C-5, and C-6 reported contradicts that presented in Table 2. Although the signals responsible for these carbons are very close, a comparison of these signals among various 5- and 6-substituted BF's coupled with the empirical additivity rule[6] permits us to assign them with confidence. Since *ortho*-methyl substitution usually effects a small downfield shift,[6] a signal at 121.6 ppm of BF should be assigned to C-4. It is noticeable by comparing the results on a pair of 5- and 6-substituted derivatives that the chemical shift of C-6 is greater than that of C-5 for both the methyl and methoxy derivatives. Hence, it might be reasonable that the signals at 123.2 and 124.6 ppm should be assigned to C-5 and C-6 of BF, respectively. These assignments are consistent for all the derivatives from the viewpoint of the additivity rule.

Substituent Effects on the Chemical Shifts. A variety of proton and carbon chemical shifts (δ_H and δ_C) of benzene derivatives have been treated in terms of a Hammett-type equation.[1b] They reflect the ground-state electronic structure. The effects of 5- and 6-substituents on δ_H and δ_C at the 2- and 3-positions of BF may be treated in a similar way. Because of two transmitting paths of electronic effects, they should be expressed by an equation similar to Eq. (1):

$$\delta = \rho_1\sigma_1 + \rho_2\sigma_2 + \delta_0 \qquad (2)$$

where ρ_1 and ρ_2 are defined as sensitivity constants through the bonds 8–3 and 9–1–2, respectively.



The constants σ_1 and σ_2 refer correspondingly to the Hammett σ values of substituent relative to carbons 8 and 9, respectively. The value δ_0 is the chemical shift for the parent BF.

Table 3. Sensitivity constants for the effects of 5- and 6-substituents on the proton and carbon chemical shifts of benzofuran

	H-2	H-3	C-2	C-3
ρ_1	0.175	0.017	4.08	0.53
$S_{\rho 1}$	0.041	0.070	0.41	0.33
ρ_2	0.036	0.094	−0.88	−1.04
$S_{\rho 2}$	0.051	0.087	0.51	0.42
δ_0	7.477	6.571	145.43	107.11
$S_{\delta 0}$	0.008	0.014	0.08	0.07
S_δ	0.020	0.035	0.20	0.16

The values ρ_1, ρ_2, and δ_0 were calculated by the least-squares method and are given in Table 3. Noticeable in Table 3 is that both δ_H and δ_C at the 3-position receive virtually no effect or at least no simple electronic effect (with a large standard deviation) by substitution. By contrast, δ_H and δ_C at the 2-position reflect normal electronic effects of ring substituents. Linearities between the calculated values (Eq. (2)) and the observed δ_H and δ_C are illustrated in Figs. 1 and 2. The greater magnitude of ρ_1 as compared with ρ_2 for the 2-position indicates that the electronic effects of substituents are transmitted to C-2 mainly through the bond 8–3, ST-type. A similar tendency was previously observed for the acid dissociation of coumarilic acid.[2b]

As a whole, the electronic structure of the 2–3 double bond of BF system seems to be similar to that of the

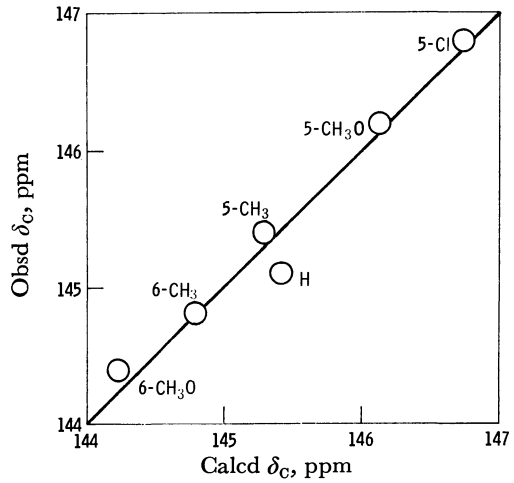

Fig. 2. Plots of the calculated and the observed chemical shifts of C-2 of substituted benzofurans.

extracyclic double bond of ST rather than PVE. However, the ρ_I values are relatively small (markedly for δ_H) as compared with the ρ values for the terminal chemical shifts of styrene, 0.325 (δ_H)[10] and 4.73 (δ_C)[11] ppm/σ. This may probably be due to the substantial difference in the structure; the 2–3 bond is a part of aromatic ring of BF.

Experimental

Materials. Benzofuran (BF) and its 5- and 6-substituted derivatives were prepared from an appropriate salicylaldehyde and diethyl bromomalonate[12] *via* coumarilic acid according to the procedure of Nakazaki.[13] Methyl- and methoxysalicylaldehydes were obtained by the Reimer-Tiemann reaction.[14] 5-Chlorosalicylaldehyde was prepared by the chlorination of salicylaldehyde.[15] Treatments of a salicylaldehyde and bromomalonate by Nakazaki's procedure gave 50—30% of a coumarilic acid which was decarboxylated to give a benzofuran. Bp and elemental analysis data are given in Table 4.

2- and 3-Methylbenzofurans were prepared according to the literature.[16,17] Boiling points and analysis data are included in Table 4.

NMR Measurements. The PMR spectra were obtained on a JNM-4H-100 spectrometer operating at a frequency of 100 MHz at room temperature (*ca.* 22 °C). A 10% solution of a sample in CCl_4 was applied to the measurement and the chemical shifts did not vary within the experimental error of 0.05 Hz by dilution. TMS was used as an internal standard.

The CMR spectra were recorded at *ca.* 24 °C on a JEOL C-60HL spectrometer with a 15.09 MHz RF unit. Samples of neat liquid or 50% solution in CS_2 were used. The signal-to-noise ratio of the spectra was enhanced by the ^{13}C–H noise decoupling. The chemical shift measurements were performed with a nuclear-resonance single-side-band technique, being accurate within 0.2 ppm. CS_2 was used as an external standard. The chemical shifts are given in PPM downfield from TMS by using the chemical shift of CS_2 of 192.8 ppm.

The authors wish to thank Messers. Y. Terawaki and H. Okuda for recording the spectra.

Substituent Effects in the Benzofuran System. II.[1] Electrophilic Bromination

Tadashi OKUYAMA, Kiyomitsu KUNUGIZA, and Takayuki FUENO

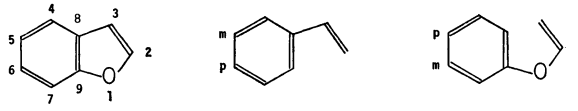
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received August 7, 1973)

Bromination of benzofuran (BF) and its derivatives (5-CH_3, 6-CH_3, 5-CH_3O, and 5-Cl) has been studied kinetically in acetic acid and by product analysis under various conditions. Product analysis revealed that bromine adds to BF in *trans* fashion, electrophilic bromine attacking at the 2-position. Analysis of substituent effects on the rate of bromination showed that the electronic effects are transmitted through both the bond 8—3 and the bonds 9–1–2 by a comparable magnitude. The transition state of the reaction was concluded to closely resemble a cyclic bromonium ion intermediate.

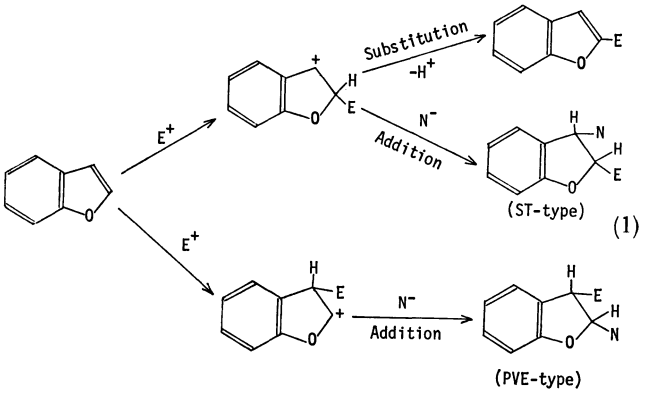
Benzofuran (BF) is a class of heterocyclic compounds which shows a dual character in its reactivity. One type of reactions is the electrophilic substitution as an aromatic compound, resulting in the substitution of the 2-hydrogen. The other is the electrophilic addition to the 2–3 bond as an olefin.[2]

As an olefin, BF can be taken as an analog of either styrene (ST) or phenyl vinyl ether (PVE).



BF ST PVE

BF is often considered as a vinyl ether analog[2] implicitly assuming the 3-attack of an electrophile in addition reaction. However, substitution occurs at the 2-position and, moreover, it was found that the ground-state electronic structure of BF is rather close to ST.[1] Thus, it seems more likely that BF would behave as an ST analog in the addition reaction, an electrophile attacking at the 2-position.

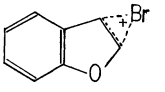


The above confusion arises from the unknown orientation of the addition reaction of BF. The halogenation[3] and the cationic polymerization[4] are the only known electrophilic addition reactions of BF.[2] Product analysis of neither of the two reactions provides any information with regard to the orientation of addition owing to the structural identity of the electrophilic and nucleophilic fragments of the reactions.

The present and the following papers are concerned first with this orientation problem in these reactions. The other purpose of the present investigations is to obtain useful information on the nature of the transition state of the reaction by analyzing the cross-ring transmission of substituent effects.

It is generally accepted that the electrophilic addition of bromine to alkenes proceeds through an intermediate cyclic bromonium ion.[5] However, intermediacy of the cyclic bromonium ion has recently been questioned for some conjugated olefins from the stereochemical studies.[5] Several investigations of the bromination of aryl-substituted olefins have been undertaken, resulting in the above conclusion.[6–9]

The effects of 5- and 6-substituents on the reactivity of BF would be transmitted through both the C–C (8–3) and C–O–C (9–1–2) bonds. This cross-ring transmission of substituent effects can be compared with the effects of *m*- and *p*-substituents of ST and *p*- and *m*-substituents of PVE. Thus, a possible symmetric character of the activated complex like I can be judged by this comparison.

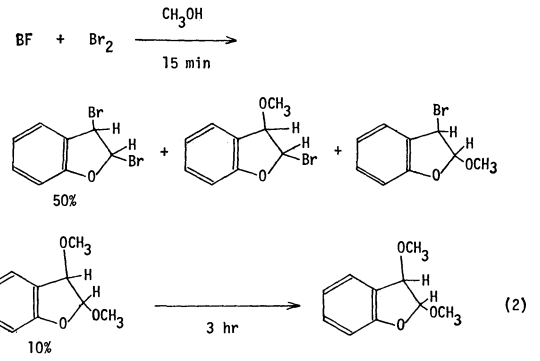


I

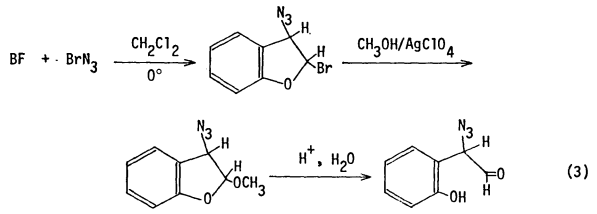
Results and Discussion

Product Analysis. Bromination of BF in carbon disulfide gave quantitatively 2,3-dibromo-2,3-dihydrobenzofuran. In attempts to obtain unsymmetric adducts, the reaction was carried out in nucleophilic solvents. Bromination in acetic acid resulted in essentially the dibromide along with a small amount of acetate. On the other hand, the reaction in methanol initially gave a mixture of several adducts which changed quantitatively into a single product, 2,3-dimethoxy-2,3-dihydrobenzofuran, in 3 hr. The dimethoxide is considered to be a substitution product of the initially formed adducts. The products of the reaction time of 15 min contained about 50% of dibromide, 10% of dimethoxide, and probably two kinds of bromomethoxide by the NMR analysis of the mixture. Thus, it was difficult to know the unambiguous orientation of addition from these products.

Under these circumstances, we have undertaken the addition of an unsymmetric reagent, bromine azide. To the methylene chloride solution of BrN_3 prepared by the method of Hassner *et al.*[9] was added BF. The



3 hr reaction yielded quantitatively 2-Bromo-3-azido-2,3-dihydrobenzofuran. The structure of the bromoazide was determined by the transformation shown in Eq. (3).



This result clearly shows that the electrophilic bromine adds at the 2-position. That is, the orientation is of the ST-type.

The stereochemistry of the products deserves some comment here. Both the adducts, the dibromide and the bromoazide, are isomerically pure by NMR spectrum and the spin-spin coupling between 2-H and 3-H is very small; ~0 and 1.2 Hz, respectively. Brust *et al.*[10] showed that J_{23} is smaller for the *trans* isomer than for the *cis* isomer of 2,3-dimethyl-2,3-dihydrobenzofuran derivatives; $J_{23}(trans)$ ~4 Hz and $J_{23}(cis)$ ~7 Hz. The Karplus equation[11] predicts $J_{23}(trans) = 2.3 \pm 0.7$ Hz and $J_{23}(cis) = 6.7 \pm 0.6$ Hz for the dihedral angles of $120 \pm 5°$ and $25 \pm 5°$, respectively.[10] Thus, the small coupling constants of the adducts strongly suggest their *trans* structure.

In conclusion, the addition of bromine to BF takes place in the *trans* fashion by the orientation of the ST-type.

Kinetic Measurements. Kinetic investigations of BF and its derivatives (5-CH_3, 6-CH_3, 5-CH_3O, and 5-Cl) were carried out spectrophotometrically in acetic acid at 25.0 °C. A simple second-order rate analysis by Eq. (4) did not give satisfactory results.

$$\text{rate} = k_2[\text{BF}][\text{Br}_2] \tag{4}$$

The rate equation for styrene bromination under similar conditions[6] was represented by

$$\text{rate} = k_2[\text{S}][\text{Br}_2] + k_3[\text{S}][\text{Br}_2]^2 \tag{5}$$

where [S] denotes olefin concentration. The rate analysis of the present reaction has been carried out according to Eq. (5) by a least-squares curve fitting by the aid of a computer. As is shown in Fig. 1, the values k_2 and k_3 thus obtained gave an excellent linear correlation of Eq. (6), which is derived by integration of Eq. (5).

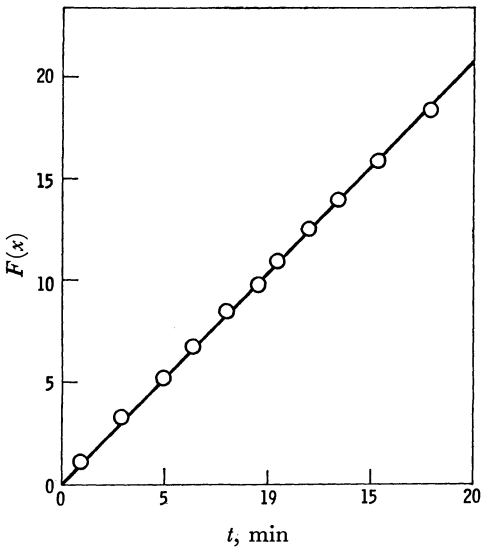


Fig. 1. Typical plots of simultaneous second- and third-order bromination rate according to Eq. (6) (5-methylbenzofuran).

$$t = \frac{\ln[(a-x)/a]}{k_3(a-b)(k_2/k_3+b-a)} + \frac{\ln[(b-x)/b]}{k_2(b-a)} + \frac{\ln[(k_2/k_3+b-x)/(k_2/k_3+b)]}{k_2(a-b-k_2/k_3)} \equiv F(x) \tag{6}$$

where a=initial concentration of BF, b=initial concentration of Br_2, and x=bromine reacted at time t.

Table 1. Rate constants for bromination of substituted benzofurans in acetic acid at 25.0 °C

Substituent	$10^2 k_2$, $M^{-1}s^{-1}$	k_3, $M^{-2}s^{-1}$
H	0.64	3.6
5-CH_3	2.96	35.9
6-CH_3	8.28	616
5-CH_3O	3.48	261
5-Cl	0.053	0.17

The rate constants, k_2 and k_3, for BF and its derivatives are summarized in Table 1. The constants k_2 and k_3 are roughly parallel to each other but analysis of substituent effects will be conducted only on the k_2 values because of lower precision of k_3 determination.

The cross-ring substituent effects can be analyzed by the Jaffé equation.[1,12]

$$\log k = \rho_1\sigma_1 + \rho_2\sigma_2 + \log k_0 \tag{7}$$

where suffixes 1 and 2 correspond to the values concerning the transmitting routes 8-3 (ST-type) and 9-1-2 (PVE-type), respectively. The least-squares treatment of k_2 according to Eq. (7) gave the values with standard deviations: $\rho_1 = -2.21 \pm 0.41$, $\rho_2 = -2.23 \pm 0.53$, and $\log k_0 = -2.01 \pm 0.08$. For the present analysis, the σ^+ values were used for σ_1. Linearity of the calculated and the observed values of $\log k_2$ is illustrated in Fig. 2.

Equality of ρ_1 and ρ_2 ($\rho_2/\rho_1 = 1.01$) is rather un-

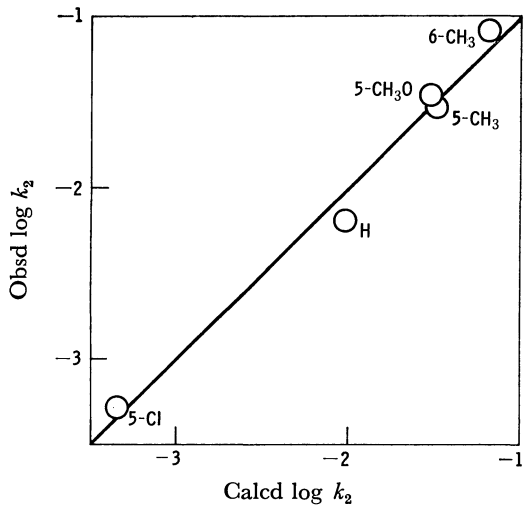

Fig. 2. Linearity of the observed and the calculated log k_2 values (Eq. (7)).

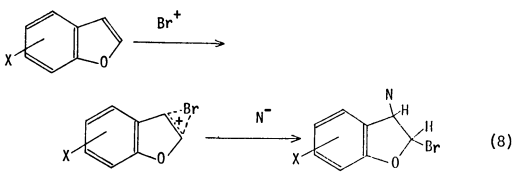
expected because we concluded that both the ground-state electronic structure[1] and the orientation of addition of BF are of the ST-type but not of the PVE-type. The present observation is explainable only by assuming the symmetric transition state closely resembling the intermediate I; the transmission of electronic effects through the route 9–1–2 (PVE-type) cna become effective.



The value of $\rho_2/\rho_1=1.01$ is very close to the relative ρ values of PVE and ST observed for the silver-ion π-complex formation ($\rho_{PVE}/\rho_{ST}=1.03$).[13]

The kinetic observations also show that the electronic effects on the ionic reactivity operate predominantly at the transition state and the ground-state electronic structure seems to have virtually no effect. The ρ_1 value of −2.21 is a reasonable magnitude which is close to the ρ value (−2.24)[6] for the bromination of styrenes bearing an electron-attracting substituent.[15] The latter reaction is assumed to involve a cyclic bromonium ion intermediate.[6]

In conclusion, the assumption of a symmetric cyclic bromonium ion mediating in the bromination of BF is confirmative. The stereochemistry of addition, exclusively *trans*, conforms to this assumption.

Experimental

Materials. The preparation of benzofuran (BF) derivatives was described previously.[1] Acetic acid was refluxed overnight over triacetyl borate and distilled. Bromine and sodium azide were of the best grade commercially available.

Bromination in CS_2. The solutions of BF and Br_2 in CS_2 were prepared separately (*ca.* 1 M) and mixed together at room temperature. Color of Br_2 faded in 1 hr. The reaction mixture was washed with aqueous sodium thiosulfate (0.01 N) and then water. Drying with anhydrous sodium sulfate and evaporation of the solvent left white solid. Recrystallization from petroleum ether gave 2,3-dibromo-2,3-dihydrobenzofuran melting at 86 °C (lit,[16] 86—87 °C). NMR (CCl_4); δ 5.67 (s, 1, 3-H), 6.81 (s, 1, 2-H), and 7—7.5 (m, 4, aromatic H).

Bromination in Acetic Acid. Reaction of equimolar BF and Br_2 (1 M) was carried out in the same way as above. The ethereal extract was dried (Na_2SO_4) and concentrated *in vacuo* leaving an oily product. NMR spectrum of the product was essentially the same as that of the dibromide obtained in CS_2 with indication of the formation of a small amount of acetate (~10%); NMR (CCl_4), δ 2.0 (s, $OCOCH_3$).

Bromination in Methanol. The solutions of 1 M Br_2 in methanol and 1 M BF in methanol were mixed together at room temperature. The color of Br_2 faded essentially in 15 min. The reaction mixture was withdrawn by a syringe at appropriate time intervals, added to 0.01 N sodium thiosulfate, and shaken with ether. The ethereal layer was washed with water, dried over sodium sulfate, and evaporated to dryness leaving an oily product, which was applied to NMR analysis. The final product after 3 hr reaction was 2,3-dimethoxy-2,3-dihydrobenzofuran, which was isolated by distillation in 60% yield, boiling at 130—132 °C (5 mm). NMR (CCl_4); δ 3.31 (s, 3, 3-CH_3O), 3.48 (s, 3, 2-CH_3O), 4.53 (broad s, 1, 3-H), 5.26 (d, J=1.4 Hz, 1, 2-H), and 6.6—7.3 (m, 4, aromatic H).

Reaction with Bromine Azide. A solution of BrN_3 in CH_2Cl_2 was prepared according to the method of Hassner *et al.*[9] To this solution, an equimolar amount of BF was added under stirring at 0 °C and left to stand for 3 hr. The solvent was evaporated under reduced pressure to yield an oil. This crude oil was applied to spectral analyses. NMR spectrum showed that the product is essentially pure bromoazide. NMR (CCl_4); δ 5.03 (broad s, 1, 3-H), 6.03 (d, J=1.2 Hz, 1, 2-H), and 6.9—7.5 (m, 4, aromatic H).

The reaction of the bromoazide with methanol in the presence of $AgClO_4$ gave quantitatively a methoxyazide (an oil), which is a mixture of two isomers (1/2) by NMR spectrum. NMR (CCl_4); δ 3.28 (s, 1, CH_3O), 4.46 (broad s, 0.3, 3-H), 5.66 (d, J=1.2 Hz, 0.3 2-H), 3.47 (s, 2, CH_3O), 4.71 (d, J=5.8 Hz, 0.7) 5.17 (d, J=5.8 Hz, 0.7), and 6.7—7.3 (m, 4, aromatic H). IR (thin film); 2130 cm^{-1} (N_3).

The methoxyazide obtained above (1 g) was hydrolyzed at room temperature in acidic 50% aqueous dioxane (0.2 M HCl). After 5 hr of reaction, the reaction mixture was extracted with ether. The ethereal layer was then shaken with 0.1 M NaOH. The aqueous layer was acidified with 0.1 M HCl and extracted with ether again. The ether extract was washed with water, dried ($MgSO_4$), and evaporated under reduced pressure to leave an oil (0.2 g). IR (thin film); 3300 (broad, OH), 2110 (N_3), and 1675 cm^{-1} (C=O). The product was not pure but further attempts of purification was given up because of its high lability. It is considered from its IR spectrum and acidic character to be mainly *o*-hydroxyphenylazidoacetaldehyde.

Kinetic Measurements. The rate of bromine addition was followed spectrophotometrically at the bromine maximum of 395 nm (ε=200) with use of a Cary Model 15 spectrophotometer. Bromine concentration of a stock solution (10^{-2}—10^{-3} M in acetic acid) was determined by titration with standard thiosulfate. Ten ml of a bromine solution and 10 ml of a benzofuran solution in acetic acid were respectively thermally equilibrated at 25.0 °C, mixed together and placed in a stoppered quartz cuvette inserted in a water-

jacketed cell holder. The decrease of bromine absorption was followed.

Substituent Effects in the Benzofuran System. III.[1] Cationic Polymerization

Tadashi OKUYAMA, Kiyomitsu KUNUGIZA, and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

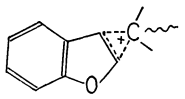
(Received August 7, 1973)

Cationic copolymerizations of various pairs of benzofuran derivatives have been carried out in CH_2Cl_2 using $SnCl_4$–CCl_3CO_2H (2: 1) as catalyst at 0 °C. Effects of 2- and 3-methyl substitutions on the monomer reactivity ratio suggested that the polymeric cation adds at the 2-carbon of benzofuran. Analysis of the effects of 5- and 6-substituents on the reactivity revealed that the transmission efficiency of electronic effects through the two paths, the bonds 8–3 and 9–1–2, is comparable in magnitude. It was concluded that the transition state of the propagation step closely resembles a bridged carbonium ion intermediate.

The bromination of benzofuran (BF) was treated in the preceding paper[1] as a typical example of electrophilic addition reactions. Cationic polymerization includes chain reactions of addition of a polymeric carbonium ion and can be classified as an electrophilic addition reaction.

Cationic polymerizability of BF has long been known since Kraemer and Spilker[2] noted the resinification upon treating BF with sulfuric acid. More recently, BF has attracted the attention of polymer chemists because of its possible formation of optically active polymers.[3] However, the orientation of the reaction is not established, being considered as styrene(ST)-type[4] or vinyl ether(VE)-type.[3b]

On the other hand, we have concluded, by a series of investigations on the structure-reactivity relationship of α,β-unsaturated ethers,[5] that the transition state in the carbonium-ion attack (propagation step) in the cationic polymerization closely resembles a symmetric cyclic carbonium ion like I.



I

This possible symmetric nature of the transition state can be judged by the analysis of the cross-ring transmission of the electronic effects of 5- and 6-substituents on the polymerizability of BF.

Thus, the present investigation concerns with the orientation of polymerization and the substituent effects on the reactivity of BF.

Results

Cationic copolymerizations of various pairs of BF derivatives were carried out in methylene chloride at 0 °C with the use of stannic chloride–trichloroacetic acid (2: 1) as catalyst. The reaction proceeds easily under these conditions; *e.g.*, *ca.* 30% conversion in 1 hr for the 1: 1 pair of BF and the 5-methyl derivative.

The monomer reactivity ratios calculated with the aid of the integral form of the Mayo-Lewis copolymerization equation[6] are given in Table 1. The table includes values of r_1r_2 and $(r_2/r_1)^{1/2}$. The products r_1r_2 provide information about the nature of an attacking polymeric cation and the values $(r_2/r_1)^{1/2}$ are considered to be the best estimation of relative polymerizability of M_2 and M_1.[6,7]

The 6-methoxy and 5-chloro derivatives showed reactivities greatly different from those of other derivatives, and accurate evaluation of the monomer reactivity ratios for the systems involving these derivatives has hardly been achieved. Hence, the reactivities of these derivatives have been estimated by the log-log method, which was conveniently used for the styryl ether system.[7] The relative polymerizability, r, of M_2 and M_1 is expressed as

Table 2. The relative polymerizability, R, of benzofuran derivatives

Substituent	R[a]
H	(1.00)[b]
5-CH_3	4.81 ± 0.70
6-CH_3	6.03 ± 0.21
5-CH_3O	12.9 ± 0.9
6-CH_3O	241 ±24
5-Cl	0.017± 0.002

a) Shown with standard deviation.
b) Reference value.

Table 1. Monomer reactivity ratios[a] for the cationic copolymerization of benzofuran derivatives

Substituent M_1	Substituent M_2	r_1	r_2	r_1r_2	$(r_2/r_1)^{1/2}$
H	2-CH_3	0.25±0.06	0.74±0.01	0.19	1.72±0.24
H	3-CH_3	0.12±0.18	0.50±0.08	0.06	2.04±1.54
H	5-CH_3	0.21±0.06	4.86±0.24	1.02	4.81±0.70
H	5-CH_3O	0.16±0.01	5.83±0.17	0.93	6.03±0.21
5-CH_3O	6-CH_3	0.63±0.05	2.89±0.27	1.82	2.14±0.13
6-CH_3	6-CH_3O				18.7 ±1.3[b]
5-Cl	H				60.5 ±7.3[b]

a) Shown with standard deviation. b) Estimated by the log-log treatment.

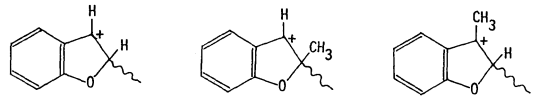
$$r = \frac{\log [M_2]/[M_2]_0}{\log [M_1]/[M_1]_0} \quad (2)$$

The results are included in Table 1.

From $(r_2/r_1)^{1/2}$ and r values given in Table 1, the polymerizabilities, R, relative to the unsubstituted BF were calculated and summarized in Table 2. All the methyl and methoxy derivatives are more reactive than the parent BF. The 6-methoxy substitution greatly enhances the reactivity of BF. The 5-chloro derivative is *ca.* 1/60 as reactive as BF.

Discussion

Effect of the 2- and 3-Methyl Groups. As is seen in Table 1, the product r_1r_2 is much less than unity for the system comprising BF (M_1) and the 2- or 3-methyl derivative (M_2), implying the difference in the nature of attacking cations, M_1^+ and M_2^+. The methyl substitution at either of the 2- and 3-positions enhances the reactivity of BF toward $M_1^+(r_1<1)$, whereas the methyl substitution reduces the reactivity of BF toward $M_2^+(r_2<1)$. The reduction in the reactivity must be attributed to the steric effect of the methyl group close to the reaction center. This steric effect is greater for the 3-methyl than for the 2-methyl group, suggesting the formation of 3-cation. That is, the orientation of the ST-type in polymerization is very probable, in accord with the results of bromination.[1]

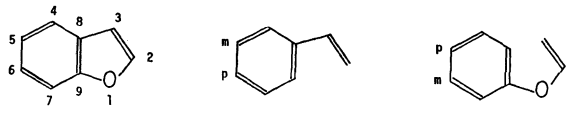


The enhancement in reactivity toward M_1^+ by either 2- or 3-methyl substitution (4 or 8 times) may be reasonably explained by assuming a cyclic onium-type transition state.[8]

Cross-ring Substituent Effects. The effects of 5- and 6-substituents on the polymerizability of BF given in Table 2 can be analyzed by the Jaffé equation;[9]

$$\log R = \rho_1\sigma_1 + \rho_2\sigma_2 \quad (3)$$

where suffixes 1 and 2 refer to the values concerning the transmitting routes 8–3 (ST-type) and 9–1–2 (PVE-type), respectively.



BF ST PVE

The least-squares treatment of R according to Eq. (3) gave $\rho_1=-3.39\pm0.19$ and $\rho_2=-2.79\pm0.34$. Brown-Okamoto's σ^+ values were used for σ_1. Linearity of the calculated and the observed values of $\log R$ is illustrated in Fig. 1.

The contribution of the PVE-type transmission to the observed substituent effects is nearly as great as that of the ST-type in spite of the orientation of addition of the ST-type. This situation is similar to that of bromination.[1] These observations can be considered to be characteristic of symmetric transition state resembling a cyclic onium ion like I and seem to be

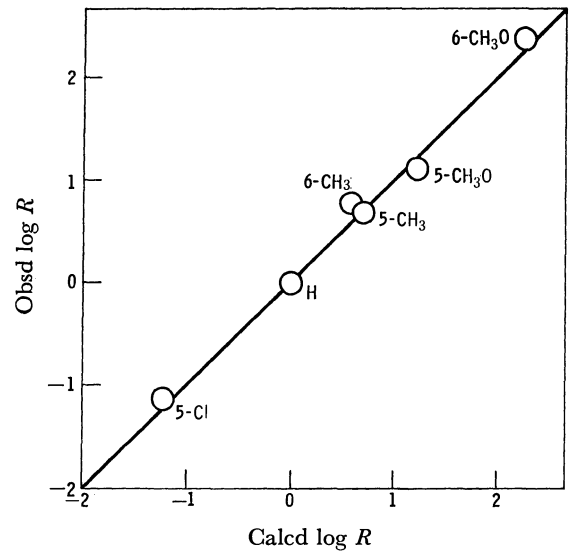


Fig. 1. Linearity of the observed and the calculated log R values (Eq. (3)).

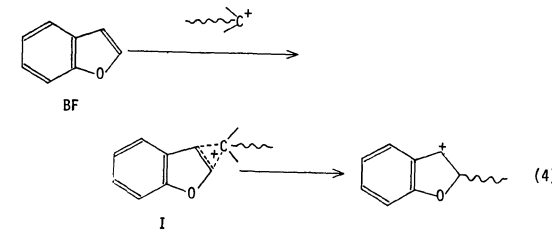
explainable only by this assumption. Thus, the course of polymerization is represented by



BF I (4)

The possibility of symmetric transition state like I has already been suggested by us for the cationic polymerization of vinyl monomers on the basis of various sources of evidence.[5] The present results provide additional confirmative evidence to support our earlier suggestion.[5]

The values ρ_1 and ρ_2 are compared with those for the cationic polymerization of ST and PVE; $\rho_{ST}^+=-2.03$[10] and $\rho_{PVE}=-1.76$.[11] Both ρ_1 and ρ_2 are appreciably greater in magnitude than ρ_{ST} and ρ_{PVE}, respectively. However, relative magnitude, $\rho_2/\rho_1=0.82$, is close to $\rho_{PVE}/\rho_{ST}=0.87$. The transmission efficiency through oxygen atom in cyclic compound, BF, is close to that in acyclic system, PVE.

All the observations in the BF polymerization conforms to the symmetric cyclic transition state which structurally resembles I.

Experimental

Materials. Benzofuran (BF) and its derivatives were obtained as described previously.[12] Methylene chloride was dried and distilled from calcium hydride. Tetralin and stannic chloride were purchased and distilled. Trichloroacetic acid was of the best grade commercially available.

Polymerization. Cationic copolymerization was carried out in methylene chloride under a nitrogen atmosphere at 0 °C by using stannic chloride–trichloroacetic acid (2:1) as catalyst. Monomer and catalyst concentrations were usually

7 vol% and 0.03 M, respectively. The detailed procedure was the same as described before.[6] Monomer reactivity ratios were calculated with the aid of the integral form of the Mayo-Lewis copolymerization equation by the least-squares method based on the VPC analysis as described previously.[6] The relative polymerizability of a great magnitude was estimated by the relative monomer consumption method (the log-log treatment).[7]

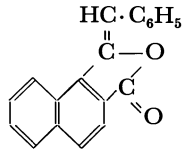
Perkin Synthesis of Bromobenzalphthalides. Their Reactions with Amines and Hydrazine

A. M. Islam, A. M. Khalil, and A. A. El-Maghraby
Department of Chemistry, Al-Mansoura Faculty of Science, Al-Mansoura, A.R.E., Egypt
(Received February 28, 1973)

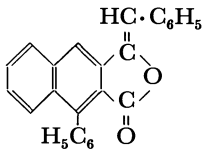
The isomeric 5-bromo- and 6-bromo-3-benzalphthalides were prepared by condensation of 4-bromophthalic anhydride with phenylacetic acids. The reaction of such isomeric bromobenzalphthalides with primary aromatic amines give the corresponding bromobenzalphthalimidines. Bromophthalazinone derivatives were obtained in good yields by the reatcion of bromobenzalphthalides with hydrazine hydrate.

It has been reported[1-4] that symmetric anhydrides react with phenylacetic acids in the presence of sodium or potassium acetate to give the corresponding monobenzal derivatives. The interaction of asymmetric anhydrides with phenylacetic acids in the Perkin reaction should lead to the formation of structural isomers.

The condensation of naphthalene-1,2-dicarboxylic[2] and 1-phenylnaphthalene-2,3-dicarboxylic anhydrides[3-4] with phenylacetic acid was reported to give only one isomer (I and II).

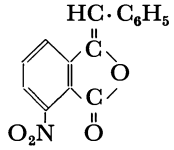


I



II

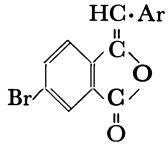
On the other hand, there are a few instances which report the isolation of two structural isomers from a Perkin condensation of phenylacetic acid with 3-nitrophthalic[5] and 4-nitrophthalic anhydrides,[6-7] though Zelmens and Vanages[8] isolated only one isomer (III) in the former case.



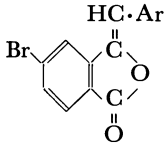
III

Recently, however, Islam[9] found that the condensation of 3-nitrophthalic anhydride with phenylacetic acid gives actually a mixture of the two structural isomers 4-nitro- and 7-nitro-3-benzalphthalides.

In the present investigation, we report that the condensation of 4-bromophthalic anhydride with phenylacetic or *p*-nitrophenylacetic acid gave isomeric bromobenzalphthalides (IVa—b) and (Va—b).



IV

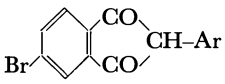


V

a: Ar=C_6H_5; b: Ar=$C_6H_4\cdot NO_2$-*p*

These products (IV—V) showed stretching frequency at 1780 cm^{-1} characteristic for benzalphthalides.[10]

The isomeric nature of these products was proved unequivocally by the fact that both (IVa) and (Va) were readily rearranged under the influence of sodium methoxide, to 5-bromo-2-phenylindan-1,3-dione (VIa). Similarly, both (IVb) and (Vb) were rearranged to 5-bromo-2-(*p*-nitrophenyl)indan-1,3-dione (VIb).



VI

a: Ar=C_6H_5; b: Ar=$C_6H_4\cdot NO_2$-*p*

The compounds (VI) showed stretching frequency at 1690—1655 cm^{-1} characteristic for the 1,3-dione group.[10]

Unequivocal chemical evidence for these structural isomers IVa, IVb, Va, and Vb was achieved by the direct synthesis of particular isomers.

Condensation of 6-bromophthalide with benzaldehyde in the presence of catalytic amounts of piperidine gave a product, mp 139 °C, identical with the product IVa. On this basis, the isomer IVa was identified as 3-benzal-6-bromophthalide, while the second isomer of high melting point 180 °C was tentatively given structure Va as 3-benzal-5-bromophthalide.

Similarly, condensation of 6-bromophthalide with *p*-nitrobenzaldehyde gave a product, mp 160 °C, identical with (IVb). The high melting isomer (mp 220 °C) was tentatively given structure (Vb).

It is worth to note that in this series, the benzalphthalides substituted at position 6 always possess lower melting points than the corresponding 5-substituted analogues.

In agreement with the previous work,[11] reaction of bromobenzalphthalides (IV) and (V) with amines gave the corresponding bromobenzalphthalimidines.

Thus, 3-benzal-6-bromophthalides (IVa—b) reacted readily with primary aromatic amines such as aniline,

Experimental

Analytical data were determined in the microanalytical unit at Cairo University, Infra-red spectra were recorded on SP 1200 a Pye-Unicam Spectrophotometer. Melting points are uncorrected.

Condensation of 4-Bromophthalic Anhydride with Phenylacetic Acid. A mixture of 4-bromophthalic anhydride (22.7 g), phenylacetic acid (13.6 g) and freshly fused sodium acetate (2.0 g) was fused together at 180—200 °C for one hour. The cold reaction mass was washed with dilute sodium carbonate solution (100 ml) to remove unreacted materials. The remaining solid (15 g, 50%) was extracted with boiling ethanol (100 ml), which on crystallization gave 3-benzal-6-bromophthalide (IVa) (9.0 g, 30%) as yellow powder, mp 139—141 °C. Found: C, 60.26; H, 3.38; Br, 27.0%. Calcd for $C_{15}H_9O_2Br$: C, 59.80; H, 3.00; Br, 26.58%.

The alcohol-insoluble residue was recrystallized from acetic acid to give 3-benzal-5-bromophthalide (Va), (4.5 g, 15%) as pale yellow crystals, mp 180—182 °C. Found: C, 59.67; H, 3.22; Br, 26.9%. Calcd for $C_{15}H_9O_2Br$: C, 59.80; H, 3.00; Br, 26.58%.

5-Bromo-2-phenylindan-1,3-dione (VIa). A solution of (IVa) (3 g) in methanol (80 ml) was treated with sodium methoxide solution (100 ml) and the mixture was heated under reflux for 1 hr. The cold mixture was diluted with water and acidified with cold dilute sulphuric acid. Recrystallization of the obtained brown solid from methanol gave (VIa) (1.4 g, 46.4%) as reddish-brown prisms, mp 164—165 °C. Found: C, 60.15; H, 3.44%. Calcd for $C_{15}H_9O_2Br$: C, 59.80; H, 3.00%.

Similarly, (Va) (3 g) gave the same product (VIa) (1.2 g, 40%).

acetic Acid. A mixture of 4-bromophthalic anhydride (22.7 g), *p*-nitrophenylacetic acid (18.1 g) and freshly fused sodium acetate (2 g) was fused together at 220—240 °C for one hour. The cold mass was washed with dilute sodium carbonate solution, boiled with acetic acid, and cooled. The insoluble part was recrystallized from acetic acid to give 5-bromo-3-(*p*-nitrobenzal)-phthalide (Vb) (8.1 g, 23%) as yellow crystals, mp 219—221 °C. Found: C, 51.94; H, 2.19; N, 3.92%. Calcd for $C_{15}H_8NO_4Br$: C, 52.02; H, 2.31; N, 4.04%.

The mother-liquor gave, on concentration and addition of ethanol, a dark yellow solid which was recrystallized from dilute acetic acid to give 3-(*p*-nitrobenzal)-6-bromophthalide (IVb) (2.7 g, 8%) as yellow crystals, mp 159—161 °C. Found: C, 51.87; H, 2.41; N, 4.23%. Calcd for $C_{15}H_8NO_4Br$: C, 52.02; H, 2.31; N, 4.04%.

*5-Bromo-2-(*p*-nitrophenyl)-indan-1,3-dione* (VI*b*). A mixture of (IVb) (3.4 g) and methanol (100 ml) was heated with sodium methoxide solution (100 ml) under reflux for one hour. The cold reaction mixture was diluted with water (100 ml) and acidified with cold dilute sulphuric acid. Recrystallization of the reddish brown solid obtained from acetic acid gave (VIb) (2.1 g, 63%) as reddish brown needles, mp 199—200 °C. Found: C, 51.73; H, 1.98; N, 4.12%. Calcd for $C_{15}H_8NO_4Br$: C, 52.02; H, 2.31; N, 4.04%.

Similarly, (Vb) (3.4 g) gave the same compound (VIb) (1.9 g, 65%), mp 199—200 °C.

3-Benzal-6-bromophthalide (IVa). A mixture of 6-bromo phthalide (2.2 g), benzaldehyde (1 g) and 3 drops of piperidine was fused at 220—240 °C for 3 hr. After being cooled, the obtained solid was recrystallized from ethanol to give (IVa), mp 139—141 °C (1.4 g, 47%) as yellow crystals. The melting point did not depress when mixed with a sample of (IVa) obtained from 4-bromophthalic anhydride.

*3-(*p*-Nitrobenzal)-6-bromophthalide (IVb).* A mixture of 6-bromophthalide (2.2 g), *p*-nitrobenzaldehyde (1.5 g) was treated similarly. The obtained solid was recrystallized from acetic acid to give (IVb) (2.1 g, 61%) as pale yellow crystals, mp 159—161 °C. The melting point did not depress when mixed with a sample of (IVb) obtained from 4-bromophthalic anhydride.

Bromobenzalphthalimidine (VII—VIII). A mixture of the bromobenzalphthalides (0.1 mol) and appropriate amine (0.12 mol) in acetic acid (30 ml) containing freshly fused sodium acetate (0.1 g) was heated under reflux for 36 hr.

Table 2. Reaction of bromobenzalphthalides with hydrazine

Bromobenzal-phthalide	Product	Mp (°C)	Yield (%)	Analysis %: Calcd / Found C	H	N

Vb	Xb	235—236	77	50.00	2.77	11.66
				49.91	2.53	12.01

The reaction mixture was decomposed with dilute hydrochloric acid. Recrystallization of the product gave the corresponding bromobenzalphthalimidines (*cf.* Table 1).

Bromophthalazones (IX—X). A mixture of bromobenzalphthalides (0.1 mol) and hydrazine hydrate (3 ml, excess) in ethanol (30 ml) was heated under reflux for 20 min. The cold solution was diluted with water (70 ml). Recrystallization of the obtained solid from ethanol gave the corresponding bromophthalazones as colourless crystals (*cf.* Table 2).

Bitter Principles of *Isodon umbrosus* HARA. The Structures of Umbrosin A and B

Isao KUBO, Tadao KAMIKAWA, Takahiko ISOBE,* and Takashi KUBOTA**

Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi, Osaka 558

(Received November 15, 1973)

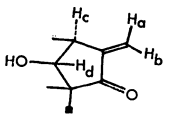
Two new *ent*-kaurene derivatives have been isolated from *Isodon umbrosus* HARA and formulated by spectroscopic and chemical evidence as structures (**1**) and (**2**), respectively. Antimicrobial activity has been tested.

Our continuing investigation of the bitter principles of various *Isodon* species (Labiatae) has led to the isolation of several new diterpenes, which have been assumed to possess enmein or kaurene type skeletons on the basis of spectral and chemical evidence.[1]

We should now like to report the structures of umbrosin A (**1**), $C_{20}H_{30}O_4$, mp 225—228 °C(decomp.), $[\alpha]_D$ −126° (c=1.0, pyridine), and umbrosin B (**2**), $C_{20}H_{28}O_4$, mp 262—265 °C (decomp.), $[\alpha]_D$ −150° (c=1.0, pyridine). Both compounds display a highly specific antibacterial activity against gram positive bacteria.[2]

Results and Discussion

The main bitter principle, umbrosin A (**1**) exhibits a UV absorption at 233 nm (ε 8400), IR bands at 1730 and 1640 cm^{-1}, and NMR signals at 5.25 and 6.13 δ (1H, broad singlets), typical for a five-membered ring ketone conjugated with an exocyclic methylene group, as exemplified by the D-ring of enmein[3] and oridonin.[4] Its environment was confirmed by spin decoupling, thus: the irradiation of the H_c proton at 3.05 δ (1H), collapsed the broad singlets of the H_a and H_b protons to sharp singlets, showing the removal of allylic coupling. The other broad singlet of the H_d proton at 4.90 δ (1H) also collapsed to a sharp singlet. The appearance of a broad singlet for the H_d proton indicates the dihedral angle between the protons H_c and H_d to be roughly 90°.



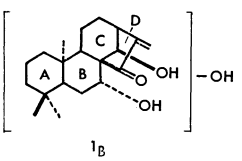
1_A

In addition, the IR spectrum shows the presence of hydroxyl groups at 3300 cm^{-1}, and the NMR spectrum exhibits evidence for three tertiary methyl groups at 0.85, 0.90, and 1.04 δ (3H, singlets), and for two other methine protons on oxygenated carbons at 3.96 and 4.45 δ (discussed later).

Umbrosin A forms a triacetate (**3**), $C_{26}H_{36}O_7$, mp 187—189 °C, of which IR spectrum shows no hydroxyl group, indicating that three oxygen atoms in umbrosin A are unhindered hydroxyl groups. These data and the analogy with congeners isolated from *Isodon* species support a tetracyclic diterpene structure with the *ent*-kaurene type skeleton for umbrosin A, in which the partial structure $\mathbf{1}_A$ would form the D-ring and the hydroxyl group should be situated at C_{14} and α-oriented.

Catalytic hydrogenation of umbrosin A, followed by oxidation with Jones' reagent, gave a diketone (**4**), $C_{20}H_{30}O_4$, of which IR spectrum still shows the presence of hydroxyl groups at 3300 cm^{-1} and a newly produced band due to a six-membered ring ketone at 1710 cm^{-1}. The latter compound yielded a diacetate (**5**), $C_{24}H_{34}O_6$ which exhibits in the NMR spectrum the signals of two acetoxyl groups, indicating that one hydroxyl group was oxidised and the other two were resistant to Jones' oxidative condition. This can be rationalized by assuming an intramolecular hydrogen bond between the two hydroxyl groups, which suggests, in turn, the O—O distance in the –O–H···O–H group is within 3 Å.[5] This assumption is also supported by the formation of an acetonide (**6**), $C_{23}H_{34}O_4$ and a phenylboronate (**7**),[6] $C_{26}H_{33}O_4B$ of umbrosin A, respectively.

In the NMR spectrum of **4**, the signals at 4.34 δ (1H, doublet of doublets, $J_{ax\text{-}ax}$=13 and $J_{ax\text{-}eq}$=5 Hz) and 4.93 δ (1H, broad singlet) were assigned to the protons on carbons bearing hydroxyl group. The appearance of a broad singlet for the latter signal shows that the $C_{14\beta}$ proton still remains in **4** and the coupling constant of the former signal is evidence of the axial nature. An examination of Dreiding model indicates that only when a second hydroxyl group is located at C_7 and β-oriented in the assumed skeleton are the above data explicable. The structure of umbrosin A can therefore be represented by $\mathbf{1}_B$, in which the position and configuration of the third secondary hydroxyl group remain to be settled.



1_B

The mass spectrum of umbrosin A allows the possibility of the existence of the hydroxyl group on the A-ring. Thus, it shows a molecular ion at m/e 334 and intense fragment ions at m/e 316, 301, 298, 283, 194, 176, 140, 122, and 107. The most prominent peaks belong to the fragments formed by cleavage of the B-ring; this can be initiated by α-cleavage of the C_{15} ketonic carbonyl group producing the m/e 194 radical ion **a**. The formation of the ion **a** affords a

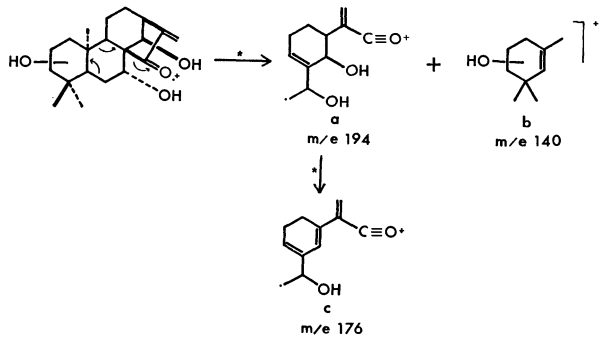
a) Determind in C_5D_5N (**1**, **2** and **4**) or in $CDCl_3$ (**3** and **6**) at 100 MHz. Coupling constants are expressed in Hz. s: singlet, bs: broad singlet, dd: doublet of doublets, tt: triplet of triplets.

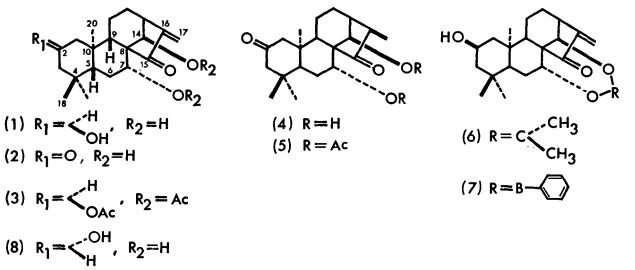
convenient means of locating the remaining hydroxyl group in **1B**.



On the other hand, the NMR spectrum of umbrosin A indicates a signal at 3.97 δ (1H, triplet of triplets, $J_{ax-ax}=12$ and $J_{ax-eq}=4$ Hz) which disappeared on oxidation. The multiplicity and coupling constants of the signal can only arise by interaction of an axial proton with two neibouring axial and two equatorial protons. Hence the third secondary hydroxyl group must be placed at C_2 and α-oriented. The splitting pattern of this proton is quite similar to that of the $C_{2\beta}$ proton of creticoside A isolated from *Pteris cretica* L.[7,8)]

Finally the structure was confirmed by correlation with mebadonin (**8**)[9)] isolated from *Isodon kameba* OKUYAMA, whose structure was determined by X-ray analysis. Catalytic hydrogenation of mebadonin, followed by oxidation with Jones' reagent, gave the same diketone (**4**), and therefore umbrosin A must be represented by **1**, that is *ent*-15-oxokaur-16-ene-2α, 7β,14α-triol. It was also found in *Isodon kameba* OKUYAMA.

A minor bitter principle, umbrosin B (**2**) isolated from a less polar fraction, differs from umbrosin A by having two fewer hydrogens, and shows the presence of a six-membered ring ketone at 1710 cm^{-1} in the IR spectrum. It exhibits the similar NMR to that of umbrosin A, with the exception of lack $C_{2\beta}$ proton at 3.97 δ present in the latter. This suggests that the structure of umbrosin B is *ent*-2,15-dioxokaur-16-ene-7β,14α-diol. Its correlation with umbrosin A was carried out by catalytic hydrogenation of umbrosin B, which yielded **4** in good yield.



Experimental

NMR spectra were determined at 100 MHz using a JEOL PS-100 spectrometer. Mass spectra were measured with a Hitachi RMU-6 spectrometer, high resolution spectra being obtained with a JEOL JMS-D100 instrument. IR spectra were recorded on Nujol mull with a JASCO IRA-1 spectrophotometer. UV data were measured with a Hitachi EPS-2 spectrometer. A Rex Optical Works model NEP-2 was used to measure the optical rotations. Column chromatography was performed on Mallinckrodt silicic acid. Mps were taken in glass capillaries and uncorrected.

Isolation. The dried leaves (1.5 kg) of *Isodon umbrosus* HARA collected near Mt. Amagi (Shizuoka) were extracted with ether (20.5 l). The crude extract was treated with activated charcoal (50 g), concentrated and left to cool overnight. Then a solid (11.4 g) was filtrated off. The filtrate was chromatographed on silicic acid (250 g). Elution with 3% methanol in chloroform gave umbrosin B and A in this order.

Umbrosin A (1). The crude fractions (1.56 g) were recrystallized from ethanol to give pure umbrosin A, as fine needles, mp 225—228° (decomp.), $[\alpha]_D$ −126° ($c=1.0$, pyridine), UV (ethanol) 233 nm (ε 8000), IR (Nujol) 3250, 1730, 1640, 1080 and 1040 cm^{-1}, NMR (see Table 1), Mass *m/e* 334 (M^+), 316 ($M-H_2O$), 298 ($M-2H_2O$), 283 ($M-2H_2O-CH_3$), 194, 176, 149, 122, 107 and 105. (Found: C, 71.34; H, 9.52%. Calcd for $C_{20}H_{30}O_4$: C, 71.82; H, 9.04%),

High resolution mass: 334.2168. $C_{20}H_{30}O_4$ requires: 334.2144.

Umbrosin B (2). The less polar fractions (23 mg) were recrystallized from ethanol to give pure umbrosin B, as needles, mp 262—265° (decomp.), $[\alpha]_D$ −150° (c=1.0, pyridine), UV (ethanol) 232.5 nm (ε 8700), IR (Nujol) 3430, 3200, 1730, 1710, and 1080 cm^{-1}, NMR (see Table 1), Mass m/e 332 (M^+), 314 ($M-H_2O$), 194 and 176. (Found: C, 72.16; H, 8.80%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49%).

Triacetylumbrosin A (3). A solution of umbrosin A (82 mg) in acetic anhydride (1 ml) and pyridine (0.5 ml) was treated as usual manner and recrystallized from acetone–hexane to give the triacetylumbrosin A (**3**), (74 mg), as fine needles, mp 187—189°, IR (Nujol) 1720, 1640 and 1230 cm^{-1}, NMR (see Table 1) also 1.93, 2.00, and 2.05 δ (3H, singlets, $OCOCH_3$), (Found: C, 67.62; H, 8.35%. Calcd for $C_{26}H_{36}O_7$: C, 67.80; H, 7.88%).

Bisdehydrodihydroumbrosin A (4). Umbrosin A (190 mg) in ethanol (10 ml) was hydrogenated over 10% Pd-C (20 mg) for 3 hr. The catalyst was removed by filtration. Then the filtrate was evaporated and crystallized from ethanol to yield the dihydroumbrosin A (185 mg), as rods, mp 239—243 °C (decomp.), IR (Nujol) 3300, 3080, and 1740 cm^{-1}, (Found: C, 71.05; H, 9.43%. Calcd for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59%). To a solution of dihydroumbrosin A (100 mg) in acetone (25 ml) was added Jones' reagent (1 ml) dropwise with stirring and ice cooling. The reaction was complete within 10 min, the mixture was stirred for further 10 min, then worked up by dilution with water (25 ml) and concentrated *in vacuo* to remove acetone. The white precipitate was filtered off and chromatographed on silicic acid (1 g). Elution with chloroform gave the bisdehydrodihydroumbrosin A (83 mg) which was recrystallized from ethanol to give the pure compound, as needles, mp 254—259° (decomp.), $[\alpha]_D$ −126° (c=1.0, pyridine) IR (nujol) 3450, 3200, 1740, and 1710 cm^{-1}, NMR (see Table 1), strongly positive Zimmermann test, (Found: C, 71.95; H, 9.13%. Calcd for $C_{20}H_{30}O_4$: 71.82; H, 9.04%).

Acetylbisdehydrodihydroumbrosin A (5). Bisdehydrodihydroumbrosin A (45 mg) was treated as described above to yield the acetylbisdehydrodihydroumbrosin A (37 mg), as needles, mp 178—179 °C, IR (Nujol) 1740, 1710, and 1260 cm^{-1}, NMR ($CDCl_3$) 1.90 and 2.00 δ (3H, singlets, $OCOCH_3$).

Isopropylideneumbrosin A (6). To a solution of umbrosin A (150 mg) in acetone (25 ml) was added concd sulfuric acid (2 drops). The mixture was left at room temperature for 6 days and then extracted with chloroform (200 ml). The extract was washed with sodium bicarbonate solution and water, dried over magnesium sulfate and evaporated to dryness. The residue was chromatographed on silicic acid, elution with chloroform gave the isopropylideneumbrosin A (51 mg), which was recrystallized from acetone–hexane to yield the pure material, as needles, mp 200—201 °C, IR (Nujol) 3320, 1730, 1645, 1115, and 1030 cm^{-1}, NMR (see Table 1), (Found: C, 73.65; H, 9.35%. Calcd for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64%).

Umbrosin A-phenylboronate (7). Umbrosin A (105 mg) was treated in boiling benzene (25 ml) with phenylboronic acid (55 mg); water was removed with molecular sieves. Removal of the main part of the benzene and addition of ethanol caused the crystallization of the product; almost quantitative yield was obtained. Recrystallization from ethanol gave the umbrosin A phenylboronate (134 mg), as plates, mp 218—219 °C, IR (Nujol) 3550, 1730, 1640, 1600, and 1300 cm^{-1}, Mass m/e 420 (M^+).

Bisdehydrodihydromebadonin (4). Mebadonin (88 mg) was treated as described above to give the bisdehydrodihydromebadonin (**4**) which was identified by mixed mp., IR, and NMR comparison with the bisdehydrodihydroumbrosin A.

Dihydroumbrosin B (4). Umbrosin B (85 mg) was hydrogenated as described above to give the dihydroumbrosin B (**4**), which was identified by mixed mp., IR, and NMR comparison with the bisdehydrodihydroumbrosin A.

We are grateful to Dr. F. McDonald, University of Oklahoma, for recording the mass spectra and Mr. M. Taniguchi, Osaka City University, for carring out the antimicrobial activity tests.

Study in Some Heterochelates. III. Cu(II), Ni(II), Zn(II) or Cd(II)+Histidine or Ethylenediaminetetraacetic Acid+Polyphenols Systems

I. P. MAVANI, C. R. JEJURKAR, and P. K. BHATTACHARYA
Department of Chemistry, M.S. University of Baroda, Baroda-2, India
(Received June 27, 1972)

An extension of Irving-Rossotti technique has been applied to study the formation constant of mixed ligand complexes as follows:

$$[MA] + [L] \rightleftharpoons [MAL]$$

where M=Cu(II), Ni(II), Zn(II), and Cd(II), A=histidine or ethylenediaminetetraacetic acid and LH_2= catechol, pyrogallol or 2,3-dihydroxynaphthalene. The values obtained for the mixed ligand formation constants K_{MAL} are found to be less than the first formation constant K_{ML}, in the binary systems.

The oxidation of mono and diphenols in biological systems by the enzyme phenol oxidases is considered to proceed through the formation of ternary complex.[1] The enzyme is a Cu-protein complex. In the mixed ligand intermediate, copper gets bound with both protein and the substrate phenol. This leads to oxidation of phenol to quinonoid form and Cu(II) gets reduced to Cu(I). This has led us to study the possibility of the formation of similar mixed ligand complexes MAL where M=Cu(II), Ni(II), Zn(II), and Cd(II), A=histidine or ethylenediaminetetraacetic acid, L=catechol, pyrogallol or 2,3-dihydroxynaphthalene. Systems MAL where A=NTA have been reported by us earlier.[2]

Histidine and EDTA are known to form complexes with several metal ions.[3-6] Histidine exhibits bi- or ter-dentate character,[7] coordination taking place from COO^- and from nitrogen of the imidazole or two nitrogens from both imidazole and amino groups. EDTA mostly exhibits quadridentate character,[8] coordination taking place from two nitrogen atoms and two COO^-.

In case of 1:1 histidine or EDTA complexes of metal ions with high coordination numbers, the vacant positions are occupied by water molecules or hydroxyl ions. On addition to this of a bidentate ligand coordinating with metal ion at higher pH, vacant positions around the metal ion are occupied by the secondary ligand, resulting in the formation of the mixed ligand complexes of the type M·histidine·L or M·EDTA·L. The copper complexes retain blue colour and do not indicate reduction to Cu(I). This may be because of the difference between the proteins in the enzymes and the polycarboxylic amino acids used in the present work. The reaction can be represented as follows:

$$[MA] + [L] \rightleftharpoons [MAL]$$

$$K_{MAL} = \frac{[MAL]}{[MA][L]}$$

A=histidine or EDTA.

The charges have been avoided for the sake of generalisation. The formation constants K_{MAL} corresponding to the association of polyhydroxy phenol, with M·Histidine or M·EDTA have been determined by the modified form of Irving-Rossotti technique.[9,10]

Experimental

Disodium salt of EDTA (Riedel-Haens), histidine, polyhydroxy aromatic ligand (A.R. quality), $NaClO_4$ (A.R. Fluka), perchloric acid (Baker analysed), sodium hydroxide (Chamapol, Czechoslovakia) were used. In order to avoid complexing tendency of anion, metal perchlorates were prepared in solution and their metal contents were determined. All solutions were prepared in doubly distilled water.

Metrohm pH meter type E350A (accuracy ±0.05) was employed for all the pH measurements. Titrations were carried out at 30 °C, using a constant temperature bath (±0.1 °C).

The ionic strength of the solution was raised to 0.2 M. Fifty milliliters of each sample wa titrated against 0.2 M NaOH. Nitrogen gas was passed through the solutions to avoid oxidation of the aromatic ligands. The pH titration curves for systems Ni-histidine-catechol and Ni-EDTA-catechol are represented in Figs. 1 and 2. Similar curves are obtained in other systems of Cu^{2+}, Zn^{2+}, and Cd^{2+}.

2: 0.024 M perchloric acid, 0.176 M sodium perchlorate.
3: 0.02 M perchloric acid, 0.002 M EDTA, 0.002 M metal perchlorate, 0.176 M sodium perchlorate.
4: 0.024 M perchloric acid, 0.002 M secondary ligand, 0.174 M sodium perchlorate.
5: 0.02 M perchloric acid, 0.002 M EDTA, 0.002 M metal perchlorate, 0.002 M secondary ligand, 0.174 M sodium perchlorate.

Discussion

It is evident from curves (1) and (3) that 1:1 complex of histidine and EDTA with Cu^{2+}, Ni^{2+}, Zn^{2+}, and Cd^{2+} are formed at lower pH and are stable at higher pH. The separation between two curves starts at low pH and reaches maximum at pH ~5 in histidine and at pH ~4.2 in EDTA. This shows that 1:1 complex formation is complete at lower pH. At higher pH, the curves converge showing absence of hydrolysis or hydroxy complex formation. M+histidine or EDTA+secondary ligand (catechol, pyrogallol, 2,3-dihydroxynaphthalene) curve (5) is not below the M+histidine or EDTA curve (3), in the lower pH range. This is an evidence that in this range where M^{2+} and histidine or EDTA 1:1 complexation takes place, the polyhydroxy phenols do not combine with metal ion. In the polyhydroxy phenols curve (4) one and two equivalents of extra perchloric acid (where primary ligand is histidine or disodium salt of EDTA respectively) have been added to compensate for hydrogen ions liberated by the combination of M^{2+} with histidine or EDTA, in the M+primary ligand+secondary ligand solutions. Below pH 5.5 in histidine and 4.5 in EDTA, the curve (5) is not overlapping curve (4) but it is slightly above it. This is due to the fact that in the lower pH range amino acids take up hydrogen ion

Table 1. Stability constants of mixed ligand chelates (30 °C)

Ligand	$\log K^{Ni\cdot Hist}_{Ni\cdot Hist\cdot L}$	$\log K^{Zn\cdot His}_{Zn\cdot His\cdot L}$	$\log K^{Cd\cdot Hist}_{Cd\cdot Hist\cdot L}$
Catechol	6.82	7.24	5.76
Pyrogallol	5.69	6.84	—
2,3-Dihydroxy-naphthalene	8.53	—	7.74

from the solution and exist as a mixture of species $CH_2NH_3^+\cdot COOH$ and $CH_2NH_3^+\cdot COO^-$. After pH 6 curve (5) goes below the curve (4). This confirms that in this range coordination of secondary ligand with M·histidine or M·EDTA takes place resulting in the liberation of extra hydrogen ions. Reactions can be represented as follows:

$$M^{2+} + \text{Histidine} \rightleftharpoons [M\ Hist]^+ + H^+$$

$$[M\ Hist]^+ + C_6H_4(OH)_2 \rightleftharpoons [M\ Hist(C_6H_4O_2)]^- + 2H^+$$

and in case of EDTA, (disodium salt),

$$M^{2+} + Na_2H_2\ EDTA \rightleftharpoons [MEDTA]^{2-} + 2Na^+ + 2H^+$$

$$[MEDTA]^{2-} + C_6H_4(OH)_2 \rightleftharpoons [MEDTA(C_6H_4O_2)]^{4-} + 2H^+$$

From the horizontal distance between curve (4) and curve (5), $\bar{n}$ values have been calculated. pL has been calculated using known equation.[9] The precise values of mixed complex formation constants have been worked out as done in earlier communication.[10] The values have been reported below:

Table 2. Stabliity constants of mixed ligand chelates (30°C)

Ligand	$\log K^{Cu\cdot EDTA}_{Cu\cdot EDTA\cdot L}$	$\log K^{Zn\cdot EDTA}_{Zn\cdot EDTA\cdot L}$	$\log K^{Ni\cdot EDTA}_{Ni\cdot EDTA\cdot L}$	$\log K^{Cd\cdot EDTA}_{Cd\cdot EDTA\cdot L}$
Catechol	7.01	3.73	4.44	3.53
Pyrogallol	6.13	—	—	—
2,3-Dihydroxy-naphthalene	7.73	5.25	5.38	4.96

In case of Cu·Hist·L system and also Zn·Hist·2,3-dihydroxynaphthalene the method could not be applied because the coordination of secondary ligand starts before the formation of M·histidine 1:1 complex is complete. In the system M·EDTA·pyrogallol, where (M=Zn, Ni, or Cd) calculations could not be possible because the separation between curves (4) and curve (5) is very small. In the system Cd·Hist·Pyrogallol, there is a precipitation after pH 6 onwards and hence calculation was not carried out.

It is observed that in all cases K_{MAL} has lower value than K_{ML}. The value of $K^{M\cdot EDTA}_{M\cdot EDTAL}$ is less than K^{M}_{ML} (where L=polyhydroxy aromatic ligands) by about 3 to 4.5 log unit, and $K^{M\cdot Hist}_{M\cdot HistL}$ is less than K^{M}_{ML} by about 1 to 1.2 log unit. This can be explained to be due to electrostatic repulsion between the incoming charged ligand and already existing charged ion histidine or EDTA. The values of K_{MAL} are higher where A=histidine. This is because histidine has one negative charge and hence exerts lesser repulsion on the incoming ligand than EDTA with four negative charges.

The order of the stability constants of the complexes with different metal ion is as follows:

2,3-dihydroxynaphthalene > catechol > pyrogallol

This is in accordance with their basicities. It is also observed that the difference $K^{Cu\cdot EDTA}_{Cu\cdot EDTA\cdot L} - K^{Cu}_{CuL_1}$ is more than $K^{Ni\cdot EDTA}_{Ni\cdot EDTA\cdot L} - K^{Ni}_{Ni\cdot L_2}$. This can be explained by the

consideration of Jahn-Teller effect in case of copper complexes as done earlier.[11,12]

Thanks are due to Prof. S. M. Sethna, Head, Chemistry Department, M. S. University of Baroda, Baroda-2 for providing necessary laboratory facilities. The authors also thank University Grant Commission, New Delhi for the award of Junior Research Fellowship to I.P.M. and C.R.J.

ESR Spectra of Quadridentate Salicylaldehyde Schiff Base Complexes of Cobalt(II) and Copper(II) in Chloroform and in Dichloromethane

Makoto CHIKIRA, Toshio KAWAKITA, and Taro ISOBE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received December 4, 1973)

Synopsis. ESR parameters for the titled complexes have been obtained from the spectra of "powders of frozen solutions." The spectra of "not crushed frozen solutions" indicated that the axes of g_3 (3.23—3.68) of the cobalt complexes are in the molecular planes.

Chloroform has been frequently used as a solvent for ESR measurements of many metal chelate complexes. However, chloroform does not form good glass at 77 K, and therefore, the typical ESR patterns of frozen solutions cannot be observed for some metal chelate complexes in chloroform. This phenomenon had been explained by Fierz and von Zelewsky for frozen chloroform solutions of bis(1,3-diphenyl-1,3-propanedionato)copper(II) as follows:[1] When the sample tube of the chloroform solution was cooled directly with liquid nitrogen, some metal complexes are aligned in certain orientations in considerably large grains of chloroform crystals. We have observed the same phenomena for salicylaldehyde Schiff base complexes of cobalt(II) and of copper(II) both in chloroform and in dichloromethane. In order to obtain correct ESR parameters of these complexes in these solvents, we measured the ESR spectra of the "powders of the frozen solutions" by the method as explained below.

The dewar and sample tube system is set as shown in Fig. 1. A stream of dry nitrogen is passed through the upper part of the sample tube during the measurement to prevent the condensation of oxygen or moisture into the sample tube. After both the dewar and sample tube were filled with liquid nitrogen, a chloroform solution is added dropwise into the sample tube from the capillary. When the spectra of cobalt(II) complexes were measured, the capillary filled with dry nitrogen or dry argon was used. The solid sample deposited at the bottom of the tube should be further crushed to fine powders by a bamboo rod.

The ESR spectra of *N,N'*-ethylene-bis(5-methoxysalicylideneiminato)copper(II) (Cu(5MeOSalen)) in chloroform measured by the two different methods are shown in Fig. 2, where (a) is measured by simply freezing the solution as usual, while (b) is measured by the above-mentioned method. As figure 2 shows, the spectra obtained by the usual method did not show any structures due to $g_{//}$ and $A_{//}$. These phenomena were also observed for commercially obtained chloroform which contains about 1% ethanol. These spectra clearly indicate that when the chloroform solution is rapidly frozen in the sample tube by liquid nitrogen, the chloroform crystal has a tendency to grow toward a certain direction with respect to the sample tube and to align the coordination plane of the complex perpendicular to the direction of the sample tube. The same phenomena were also observed in the case of the other quadridentate salicylaldehyde Schiff base complexes of copper(II). The ESR spectra of *N,N'*-ethylene-bis(salicylideneiminato)cobalt(II) (Co(Salen)) in chloroform are shown in Fig. 3. In this case, the intensities of the spectra in the field range

between 1600 and 2400 gauss measured by the usual method did not decrease so much as that of the $g_{//}$ component of Cu(5MeOSalen) did, though the patterns of the spectra in this region became very complicated. It is naturally supposed that the orientation of Co(Salen) in rapidly frozen solutions is similar to those of Cu(5MeOSalen) in chloroform crystals. Therefore, if the principal axis of the g tensor corresponding to the progressions between 1600 and 2400 gauss had directed perpendicular to the molecular planes of the cobalt complexes, similar decrease in the intensity of these progressions could have been observed. These experimental results suggest that the peaks observed in this region are not due to the component of the g tensor perpendicular to the molecular plane. The ESR spectrum of Co(Salen) in chloroform indicates that more than 3 kinds of paramagnetic centers exist in the chloroform crystals. The observed ESR parameters were slightly different from those reported by Busset, *et al.* for the ESR spectra measured at 113 K.[2] Though they have reported the time development of the signals, we could not observe such phenomena but always observed the reproducible spectra. Similar phenomena due to the crystallizations of the solvents were observed for the dichloromethane solutions of cobalt(II) complexes. In the case of dichloromethane solutions, the peaks due only to one paramagnetic centers were more intensely observed than those of any other centers, so that various magnetic parameters could be estimated. This is the first report that the high field part of the ESR spectra of the low spin planar salicylaldehyde Schiff base complexes of cobalt(II) in the non-coordinating solvent like dichloromethane could be clearly analysed.

In Table 1, the magnetic parameters of various quadridentate salicylaldehyde Schiff base complexes of cobalt(II) in chloroform and in dichloromethane are shown. It should be noted that the g_2 values obtained in this experiment are considerably smaller than those reported for Co(Salen) in chloroform by Busset, *et al.*[2] All the attempts to correlate these parameters to the possible ground electronic configurations of these complexes by the usual second-order perturbation calculations[2–4] have failed. It seems necessary to calculate the g values by diagonalizing the spin orbit interactions for several possible electronic configurations.

Experimental

The salicylaldehyde Schiff base complexes of cobalt(II) and copper(II) were obtained according to the literature.[5] Chloroform and dichloromethane were purified by the usual methods.[6] Deoxygenated solutions of cobalt(II) complexes were prepared with a vaccum line and transfered into the sample tube in an atmosphere of dry argon. ESR spectra at X-band were measured with a Hitachi 771 spectrometer. The resonance fields were calibrated with that of powders of DPPH.

Solubility Studies of Ion-pairs in Organic Solvents

Takejiro TAKAMATSU

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 26, 1973)

Synopsis. The solubilities of several types of ion-pairs were measured in many organic solvents at 25 °C. A good correlation holds between the logarithmic solubilities and the solubility parameters of solvents over the whole range of polarity.

In the previous paper,[1] the extraction behavior of ion-pairs of the $Ru(phen)_3A_2$ type was studied from the viewpoint of the ionic equilibrium involved in the extraction system. However, no clear discussion was given of the distribution ratio in connection with the physical parameter of the extraction solvent. The distribution ratio is generally determined as the ratio of the solubilities of the solute in the two phases. Therefore, the solubility measurement of the ion-pairs in the organic solvents seems to be useful in order to elucidate the solvent characters, which mainly govern the distribution ratio.

In this paper, the solubilities of several types of ion-pairs, such as $Ru(phen)_3A_2$ and MA will be measured; M refers to the alkali metal ions, and A, to the chloride ion, the perchlorate ion, and the tetraphenylborate ion. The results obtained will be discussed with respect to the two characteristic parameters of solvents, *i.e.*, the solubility parameter and the dielectric constant.

Experimental

Reagents. The organic solvents used here were purified several times by using a 1 m distillation column packed with helical steel wire, as was recommended in the literature.[2] The $Ru(phen)_3A_2$ salts were prepared as follows: 200 mg of $RuCl_3 \cdot H_2O$, 526 mg of *o*-phenanthroline, and 218 mg of hydroxylammonium sulfate were dissolved in 50 ml of an ethanol–water (1: 1) solution and the pH of the solution was adjusted to 6 with a saturated $Ba(OH)_2$ solution. After refluxing for two days at 100 °C, the $BaSO_4$ was filtered out and the excess *o*-phenanthroline was removed by washing the solution several times with chloroform and then with *n*-hexane. After the resulting solution had been dried *in vacuo*, the residue was dissolved with a minimum volume of acetonitrile and any undissolved precipitates present were filtered out. $Ru(phen)_3Cl_2$ could be crystallized by adding chloroform to the filtrate. $Ru(phen)_3(ClO_4)_2$ was obtained by adding a large excess of sodium perchlorate to a slightly acidic solution of $Ru(phen)_3Cl_2$. $Ru(phen)_3(B(C_6H_5)_4)_2$ (abbreviated as $Ru(phen)_3(BPh_4)_2$) was prepared by adding a slight excess of sodium tetraphenylborate to an aqueous solution of $Ru(phen)_3Cl_2$. The addition of sodium tetraphenylborate should be restricted to a minimum; otherwise, contamination with the excessive tetraphenylborate ions takes place. All the precipitates were dried for two days *in vacuo*. (Calcd for $Ru(phen)_3Cl_2$: C: N: Cl, 6.10: 1.19: 1.0; Found: 6.09: 1.17: 1.0, Calcd for $Ru(phen)_3(BPh_4)_2$: H, 5.03; C, 78.81; N, 6.56%; Found: H, 4.81; C, 78.78; N, 6.60%.) The $KBPh_4$ and $CsBPh_4$ were prepared by adding small excesses of KCl and CsCl respectively to an aqueous sodium tetraphenylborate solution. After the precipitates had been washed several times with water, they were dried for two days *in vacuo*. The other reagents were purchased with reagent-grade purities.

Solubility. The solubility measurements were carried out as follows. After the $Ru(phen)_3A_2$ and $MBPh_4$ had been added to approximately 10-ml portions of pure solvents in test tubes equipped with ground stoppers, the equilibration was performed in a thermostat at 25 °C by shaking the solution

for 7—8 days. The absorbance of the equilibrated solution was measured at 448 nm for $Ru(phen)_3A_2$ and at 274 nm for $MBPh_4$, from the molar absorptivities, 18500[1] and 1950 respectively. The solubilities of the other salts were measured gravimetrically.

Results

The observed solubilities of $Ru(phen)_3A_2$ in various solvents are listed in Table 1, together with the characteristic parameters of the solvents. The logarithmic solubilities ($\log S$) are shown as a function of the solubility parameters (δ) of the solvents (Fig. 1) and of the reciprocal of the dielectric constants ($1/\varepsilon$) of the solvents (Fig. 2). In Fig. 3, the solubilities of the other salts are plotted against δ values of the solvents.

As a result, a good correlation can be obtained between $\log S$ and δ in the solvents of the same sort, although the slopes of the plots are different from one sort of solvent to another. No clear relation, however, could be drawn between the dielectric constants and the solubilities in the low-polarity range.

The Application of the Regular Solution Theory to the Ion-pair Systems

Takejiro TAKAMATSU

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 6, 1973)

Synopsis. The solubilities of these ion-pairs, KCl, KBr, and KI, were measured in alcohols. The logarithmic solubilities could be well correlated with the solubility parameters of the solvents.

In the previous paper,[1] the solubilities of such ion-pairs as chloride, perchlorate, and tetraphenylborate salts of alkali metals and Ru(II)(phen)$_3$ could be well correlated to the solubility parameters of solvents.

In this study, the solubilities of the typical ion-pairs, KCl, KBr, and KI, were measured in alcohols. By using the solubility parameters of the ion-pairs (δ_1) calculated from the lattice energies of the ionic crystals, a better application of the regular solution theory to the ion-pair systems will be suggested.

Experimental

All the reagents used here were purchased as reagent-grade pure. The alcohols were purified by distillation as has been described before.[1] The solubility measurements were performed gravimetrically at 25 °C in a fashion similar to that previously described.[1]

Results and Discussion

The solubilities of KCl, KBr, and KI in alcohols are shown in Fig. 1 as a function of the solubility parameters of the solvents (δ_2), which were calculated according to Eq. (1) by using the heat of vaporization

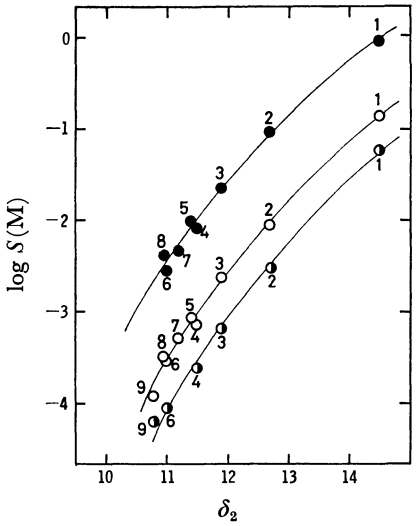

Fig. 1. The relation between log S and δ_2.
In all the figures, (◑): KCl, (○): KBr, (●): KI
(1): methanol, (2): ethanol, (3): 1-propanol, (4): 2-propanol, (5): 1-butanol, (6): 2-butanol, (7): isobutyl acohol, (8): 1-amyl alcohol, (9): isoamyl alcohol

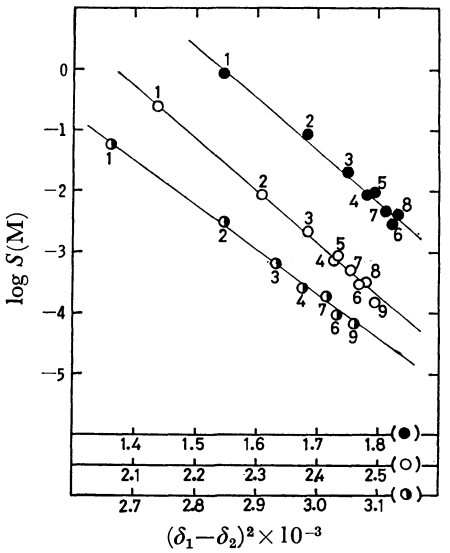

Fig. 2. The relation between log S and $(\delta_1-\delta_2)^2$

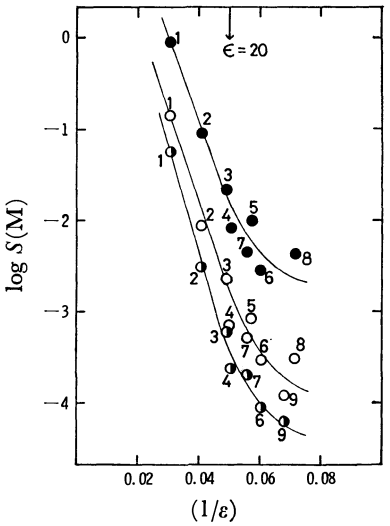

Fig. 3. The relation between log S and $1/\varepsilon$

Table 1. The calculated δ_1 values of ion-pairs

	r_c+r_a (Å)	U (kcal/mol)	V (ml^3)	δ_1
KCl	3.14	162.78	37.29	66.11
KBr	3.28	156.64	42.50	60.75
KI	3.49	148.25	51.20	53.76

at 25 °C (ΔH_{25}) cited from the literature.[2]

$$\delta_2 = \left(\frac{\Delta H_{25}-RT}{V}\right)^{1/2} \quad (1)$$

Although smooth correlations are obtained between the solubilities of the ion-pairs and δ_2, a slight bending is observed for all the systems, as is shown in Fig. 1.

Therefore, the solubility parameters of the ion-pairs (δ_1) were estimated from the square root of the lattice energy density, $(U/V)^{1/2}$, where the lattice energy, U, was approximated from Eq. (2), which was derived by Kapustinskii,[3] and the molar volume, V, from Eq. (3):

$$U = 574.4\left(\frac{z_1 z_2}{r_c + r_a}\right)\left(1 - \frac{0.345}{r_c + r_a}\right) \quad (2)$$

$$V = 2N(r_c + r_a)^3 \quad (3)$$

where r_c and r_a refer to the ionic radii of the cation and the anion respectively at the sixth coordination, and N, the Avogadro's number. In Table 1, the calculated values are shown. The relations between the logarithmic solubilities ($\log S$) and $(\delta_1 - \delta_2)^2$ are demonstrated in Fig. 2. As is shown in Fig. 2, these plots give an excellent straight line.

In Fig. 3, the plots between $\log S$ and the reciprocal of the dielectric constants ($1/\varepsilon$) are shown for comparison. Although a fairly good correlation is observed in the range of high polarity, no relationship holds in the low-polarity range.

In conclusion, the regular solution theory could be applied to the ion-pair systems by estimating the δ_1 values from the lattice energies of the ionic crystal. However, the slopes of the plots could not be discussed here because of the lack of data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(5), 1289—1290 (1974)

The Reaction of α-Ethoxybenzyl *t*-Butyl Peroxide with Grignard Reagents

Masao Ōkubo, Hiroshi Saitō, and Toshiaki Tomiyoshi

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honsho-cho, Saga 840

(Received May 25, 1973)

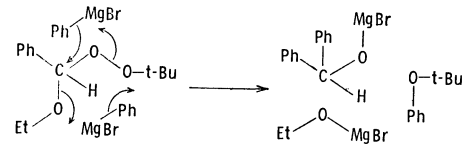
Synopsis. Effect of the ethoxyl group of the peroxide in the title was examined. Reactivities of some peroxides having oxygen- and nitrogen-atom adjacent to O-O linkage against magnesium compounds and alkali iodide were compared, and effect of the coordination of heteroatoms to the cationic species was discussed.

It was previously found that di-*t*-butyl peroxide (I) did not react with phenyl-[1] and methyl-[2]magnesium bromide (PhMgBr and MeMgBr) in tetrahydrofuran (THF) at 60 °C. Peroxide I reacts with Grignard reagents prepared from primary and secondary alkyl halides,[3] but the formation of *t*-butanol and olefins, both of which may be the result of "the reducing action of the β-hydrogen atom" of alkyl groups of reagents,[4] has been reported. These are excluded in this work to avoid complication of the reaction products. On the other hand, benzoyl peroxide (II) and *t*-butyl perbenzoate (III) reacts rapidly with PhMgBr in THF at 0 °C.[1] In these cases, the acceptance of the electron by peroxidic linkage[5] can probably be facilitated by the coordination of the neighboring carbonyl-oxygen to the Mg-atom of PhMgBr. Thus, the authors desired to see the effect of neighboring heteroatoms on the reactivity of peroxides with PhMgBr. α-Ethoxybenzyl *t*-butyl peroxide (IV)[6] was chosen as a model compound with neighboring ethereal oxygen.

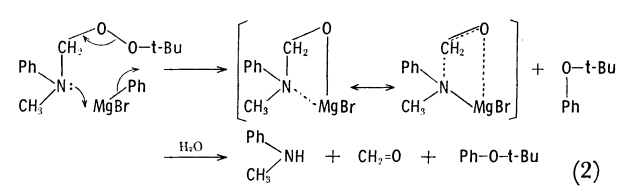
Table 1. Molar ratio and extent of reaction (in THF, at 60 °C, 7 hr, under N_2)

Purity of peroxide (wgt %)	[PhMgBr]/[P.O.]	P.O. reacted (%)	Yield of Ph–O–*t*-Bu (%)
70.7	1.8	38.1	67.1
70.7	3.1	68.9	59.1
70.7	4.5	97.4	69.9
85.6	2.0	65.3	
85.6	3.0	85.2	63—70
85.6	4.8	100	

A 85.6%-pure sample of IV was obtained by the repeated treatments of benzaldehyde diethylacetal with *t*-BuOOH at 80 °C.[6] The main products of the reaction of IV with PhMgBr after hydrolysis were benzhydrol and phenyl *t*-butyl ether. The reaction proceeds moderately at 60 °C in THF under an N_2-atmosphere, but the final extent of the reaction varies with the molar ratio of the reactants, as is shown in Table 1. It may be seen that about 4 mol of PhMgBr are necessary for the complete decomposition of IV. The products and their yields obtained using 4.8 molar PhMgBr will now be given. Benzhydrol was obtained quantitatively based on the reacted peroxide. The yield of phenyl *t*-butyl ether was 63—70%, almost independent of the purity (Table 1). *t*-Butanol was about 25%. Ethanol was found to have a 36—50% yield; however, it must really be much higher, as this product is readily lost in treating the reaction mixture. Small amounts of by-products were triphenylmethane and benzhydryl ethyl ether, both of which came from benzaldehyde diethylacetal, the sole contaminant in the sample of IV.



The mechanism of the reaction can be suggested on the basis of these results (Formula 1). Ethereal oxygen coordinates to the Mg-atom, and the ethoxyl anion is withdrawn from the aldehyde-carbon, thus facilitating the attack of the phenyl anion of the other Grignard molecule to produce benzhydrol. One more phenyl anion attacks the butoxyl-oxygen (*t*-Bu—O(—O–+Ph—)MgBr) to produce phenyl *t*-butyl ether. These are the main reactions. The considerable yield of *t*-butanol suggests the possibility of inverse heterolysis (*t*-Bu—O—)O–+Ph—)MgBr). As 4 mol of Grignard reagent are needed to complete the reaction, PhMgBr in Formula 1 should be written as dimers and thus takes a structural configuration favoring the attack of the cationic Mg-atom on the butoxyl-oxygen. Another mechanism in which Grignard molecule directly attacks the O–O linkage, can be rejected because 35 and 15% of peroxide remained unreacted after heating the reaction mixture for more than 7 hr even with two and three molar PhMgBr respectively. Probably, the dimerization process of PhMgBr($2PhMg\text{-}Br \rightleftharpoons Ph_2Mg \cdot MgBr_2 \rightleftharpoons Ph_2Mg + MgBr_2$) favors the release of the phenyl anion. Though there are some uncertainities, the initial abstraction of the ethoxy group has at least been ascertained.



N-Methyl-*N*-phenylaminomethyl *t*-butyl peroxide (V),[9] which has neighboring nitrogen atom, was also examined. Peroxide V decomposed completely with an equimolar PhMgBr at 60 °C in about 7 hr and formed *N*-methylaniline (73%) and phenyl *t*-butyl ether (81%) (Formula 2). Formaldehyde was detected as 2,4-dinitrophenylhydrazone. α-Cyanodiphenylmethyl *t*-butyl peroxide (VI)[10] was unchanged after having been treated with two molar PhMgBr at 60 °C for 7 hr. Around the O–O linkages peroxide VI structurally resembles triphenylmethyl *t*-butyl peroxide,

which is stable to PhMgBr, but it is uncertain why the nitrile group itself does not react. Although these heteroatom-containing peroxides are not crowded to the same extent sterically around the O–O linkages, the adjacent oxygen and/or nitrogen, which can coordinate to the Mg-atom, seems to play an important part in reactions with PhMgBr.

Table 2. Correlation of reactivity

	Structure of P.O.	Mg-reagents: PhMgBr	Mg-reagents: $MgBr_2$ + ⟨⟩	Iodometry (a)	Iodometry (b)	Iodometry (c)
II	Ph–C(=O)–O–O–C(=O)–Ph	±	+	○	—	—
III	Ph–C(=O)–O–O–C$(CH_3)_3$	±	−	×	○	—
I	$(CH_3)_3$C–O–O–C$(CH_3)_3$	−	−	×	×	○
V	CH_2(Ph)HC_3–N–O–O–C$(CH_3)_3$	+	+	○	−	−
IV	Ph–CH(Et–O)–O–O–C$(CH_3)_3$	+	−	×	○	—
VI	Ph_2–C(N≡C)–O–O–C$(CH_3)_3$	−	−	×	×	○

Concerning the reaction of Grignard reagents with organic peroxides, we found that $MgBr_2$ and II in THF form an orange-colored complex, which acts as a moderate reagent for the bromine-addition to olefins, especially easily to cyclohexene, at room temperature.[11] In this colored complex, the carbonyl-oxygen of II is considered to coordinate to the Mg-atom and to induce a positive charge on the bromine atom. Thus, the combination of $MgBr_2$ and cyclohexene may be regarded as a magnesium reagent, based on the mechanistic resemblance. Peroxide V slowly afforded 1,2-dibromocyclohexane at 60 °C, but the IV and VI peroxides did not react at the same temperature. The reactivities to these two magnesium reagents of some peroxides containing and not containing adjacent heteroatoms are classified in Table 2. The methods of iodometry used are also included in the table. Method a), using a saturated KI solution and acetic acid, is applied to "highly reactive" peroxides, such as II and *t*-BuOOH.[12] Method b) is applied to "moderately reactive" peroxides such as III,[7] which reacts with alkali iodide alone in acetic acid, but so slowly that a catalytic amount of ferric ion is necessary for iodometry. Method c) is used to titrate "stable" peroxides such as I, which can be decomposed only in refluxing acetic acid.[13]

As Table 2 shows, diacyl-type (II) and *N*-containing (V) peroxides, both of which react with two magnesium reagents, are titrated by Method a). Perester-type (III) and *O*-containing (IV) peroxides, both of which react only with PhMgBr, are titrated by Method b). Di-*t*-alkyl-type (I) and *CN*-containing (VI) peroxides cannot react with both of the two magnesium reagents; they are titrated only by Method c). This correlation of reactivities seems reasonable when it is taken into account that Grignard reagents behave as ion-pairs and that alkali iodide is also known to exist as ion-pairs at a high concentration in a low dielectric solvent such as acetic acid.[14] The diminution of the rate of reaction of alkali iodide with acyl peroxides in ethanol by adding water,[15] which is a highly dielectric solvent, may thus be the result of the degree of association of the ion-pairs becoming lower and the participation of the counter cation being retarded. The higher reactivity of V than IV may be at least in part due to the higher coordinating ability of nitrogen. The non-reactivity of I and di-triphenylmethyl peroxide to PhMgBr has been ascribed to steric hindrance,[16] but the absence of adjacent heteroatom is probably another important factor.

Experimental

The purity of the IV peroxide was determined by integrating the NMR spectrum of aldehyde-protons of unreacted acetal (5.5 ppm) and of IV (5.8 ppm). In the iodometry, ferric chloride was used as a catalyst;[7] the amount of it was determined so as to obtain the same value as that found by the NMR method.

To a filtered solution of PhMgBr (prepared from 2.9 g of bromobenzene and excess Mg-turnings in 30 ml of THF), 1.0 g of IV (85.6% pure) in 20 ml of THF was added all at once under an N_2-stream. The reaction flask was transferred into a water bath (60 °C) and stirred gently. After 7 hr, the peroxide-content became nearly zero. The reaction products were analyzed by glc.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(5), 1291—1292 (1974)

The Preparation of 5,8-Quinolinediol and 1,4-Acridinediol Derivatives[1)]

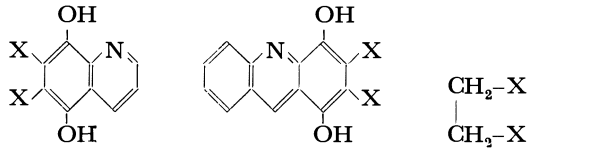
Shōshichi OGUCHI

Department of Chemistry, Faculty of Education, The Tokyo Gakugei University, Koganei, Tokyo 184

(Received September 8, 1973)

Synopsis. Compounds of 6,7-di X substituted 5,8-quinolinediol (X=$COOC_2H_5$; CN; $COCH_3$) have been prepared from diethyl pyridine-2,3-dicarboxylate and the respective active methylene compounds. Similarly, 2,3-di X substituted 1,4-acridinediol (X=$COOC_2H_5$) has been prepared.

In previous papers, it was reported that ethyl pyrazine-2,3-dicarboxylate and quinoxaline-2,3-dicarboxylate condensed with ethyl succinate to form 5,8-dihydroxyquinoxaline[2)] and 1,4-dihydroxyphenazine derivatives respectively. The condensation of pyridine 2,3-dicarboxylate or quinoline 2,3-dicarboxylate with a compound which has two adjacent active methylenes like ethyl succinate would lead to the formation of the analogous rings. Both 5,8-quinolinediol[3)] and 1,4-acridinediol derivatives contain an oxine-type structure and are expected to form a metal chelate.[4)] Quinolino-5,8-quinone and its dioxime are also interesting in their bacteriostatic properties.[5)]



I: X=$COOC_2H_5$ IV: X=$COOC_2H_5$ V: X=$COOC_2H_5$
II: X=CN VI: X=CN
III: X=$COCH_3$ VII: X=$COCH_3$

Thus, 6,7-di X substituted 5,8-quinolinediols (I: X=$COOC_2H_5$, II: X=CN, III: X=$COCH_3$) have been prepared from diethylpyridine 2,3-dicarboxylate and the respective active methylene compounds (V, VI, VII) by procedure analogous to that previously reported.[2)] Similarly, the condensation of diethyl quinoline-2,3-dicarboxylate with ethyl succinate gave diethyl 1,4-dihydroxyacridine-2,3-dicarboxylate (IV: X=$COOC_2H_5$). However, the analogous compounds of IV, X=CN and X=$COCH_3$, were not obtained under similar conditions. The oxidation of I and IV with silver oxide gave the corresponding quinoline 5,8-quinone and acridino-1,4-quinone respectively.

Experimental

Diethyl 5,8-dihydroxyquinoline-6,7-dicarboxylate (I). Procedure A: A mixture of 2.23 g (0.010 mol) of diethyl pyridine-2,3-dicarboxylate, 1.92 g (0.011 mol) of diethyl succinate, and 0.50 g (0.022 mol) of powdered sodium in 6 ml of xylene was heated at 110 °C under stirring and with moisture excluded. If the reaction did not start within ten minutes after stirring, a few drops of ethanol were added; then the reaction definitely began and the solution turned reddish brown and viscous. After an hour the solution was cooled and most of the unreacted sodium was destroyed by the addition of ethanol; then the mixture was acidified with hydrochloric or acetic acid. The mixture was extracted twice with 10 ml portions of xylene, and the solvent was removed by steam distillation. The residue from steam distillation was filtered and washed with water. Yield, 2.2 g (73.7%). Pale yellow needles (from methanol); mp 112.5—113 °C. It forms reddish precipitates in concentrated aqueous sodium hydroxide and turns yellow with concentrated sulfuric acid. Found: C, 58.58; H, 4.95; N, 4.63%. Calcd for $C_{15}H_{15}O_6N$ (I): C, 59.01; H, 4.95; N, 4.59%. IR: (KBr) ~3420 (OH), 1730 (C=O) cm^{-1}.

Diacetate of I: mp 162.5—163 °C. Colorless pillows (from ethanol); Found: N, 3.62%. Calcd for $C_{19}H_{19}O_8N$: N, 3.60% IR: 1775 (OAc), 1725 (C=O) cm^{-1}. *Dibenzoate of I*: mp 183—183.5 °C. Colorless needles (from ethanol); Found: N, 2.73%; Calcd for $C_{29}H_{23}O_8N$: N, 2.78%.

Oxidation of I. I (0.2 g) in benzene was shaken with silver oxide (prepared from 1 g of silver nitrate) for two hours. The precipitate which was subsequently filtered out was extracted with ethyl acetate. The extract from the ethyl acetate was recrystallized from chloroform and petroleum ether. Yield, 0.04 g. Yellowish crystals, mp 176 °C (decomp.). Found: C, 59.22; H, 4.30; N, 4.59%. Calcd for $C_{15}H_{13}O_6N$ (Quinone of I): C, 59.40; H, 4.32; N, 4.62%. IR: (KBr) 1742, 1690 cm^{-1}.

6,7-Dicyanoquinoline-5,8-diol (II). Procedure B: A mixture of 2.23 g of diethyl pyridinedicarboxylate (0.01 mol), 0.80 g of succinonitrile (0.01 mol) and 0.88 g of powdered metal potssium (0.022 mol) in 5 ml of xylene was stirred, with moisture excluded for half an hour at room temperature. By the same treatment of the product as with I, 0.64 g (30%) of pale yellowish crystals (from ethanol) was obtained. mp> 320 °C. Found: C, 62.53; H, 2.50; N, 19.73%: Calcd for $C_{11}H_5O_2N_3$ (II): C, 62.45; H, 2.55; N, 19.87%. IR: (KBr) ~3200 (OH), 2200 cm^{-1} (CN). *Monoacetate*: Colorless plates (from ethanol) mp 232 °C. Found: C, 61.09; H, 2.86; N, 16.48%. Calcd for $C_{13}H_7O_3N_5$ (Monoacetate of II): C, 61.66; H, 2.79; N, 16.60%. IR: (KBr) ~3200 (OH), 2490 (CN), 1788 cm^{-1} (OAc).

6,7-Diacetylquinoline-5,8-diol (III). By Procedure A, III was prepared by the condensation of diethyl 2,3-pyridinedicarboxylate with acetonylacetone. Yield, 36%; mp 243 °C (decomp.). Yellowish crystals (from aqueous ethanol). Found: C, 63.24; H, 4.48; N, 5.71%. Calcd for $C_{13}H_{11}O_4N$ (III): C, 63.67; H, 4.52; N, 5.71%. IR: (KBr) ~3220 (OH), 1682 cm^{-1} (C=O).

Diethyl 1,4-dihydroxyacridine-2,3-dicarboxylate (IV). By Procedure A IV was prepared from diethyl quinoline-2,3-dicarboxylate, ethyl succinate, and sodium metal. Recrystallization from ethanol gave 43% of pale yellowish needles (mp 177 °C). Found: C, 63.91; H, 5.05; N, 4.04%. Calcd for $C_{19}H_{17}O_6N$ (IV): C, 64.22; H, 4.82; N, 3.94%. IR: (KBr) ~3350 (OH), 1690 (C=O), 1660 cm^{-1} (C=O). NMR: (δ in $CDCl_3$) 1.43 (t, 6H, CH_3–), 4.41 (quart, 4H, $-CH_2-$), 7.5—8.4 (m, 5H, aromatic), 9.24 (s, 2H, –OH). *Diacetate*: mp 149—150 °C (from ethanol) Pale yellowish pillows. Found: C, 62.59; H, 5.05; N, 3.30%: Calcd for $C_{23}H_{21}O_8N$:

C 62.86; H 4.82; N, 3.19%. IR: (KBr) ~1780 (OAc) 1730 cm^{-1} (C=O). NMR: (δ in $CDCl_3$) 1.32 (t, 6H, CH_3–), 2.32 (s, 6H, $COCH_3$), 4.30 (quart, 4H, –CH_2–), 7.3—8.3 (m, 5H, aromatic).

Oxidation of IV. By a procedure analogous to that described before, IV (0.1 g) in an ether solution was oxidized to the corresponding quinone (0.07 g) with silver oxide. The quinone was yellowish needles. Mp 184 °C (from ether). Found: C, 64.23; H, 4.20; N, 3.95%. Calcd for $C_{19}H_{15}O_6N$ (quinone of IV) C, 64.58; H, 4.28; N, 3.96%. IR: (KBr) 1762, 1685 cm^{-1}.

Lilac Aldehydes

Seiji WAKAYAMA and Satoshi NAMBA

Chemical Laboratory, Hokkaido University of Education, Sapporo 064

(Received November 8, 1973)

Synopsis. New odorous aldehydes, diastereomers, have been found in lilac flower oil and named lilac aldehydes. The structure was established to be 2-(1'-formyl)ethyl-5-methyl-5-vinyl tetrahydrofuran. Absolute configurations have also been inferred.

Odorous ingredients of lilac flower oil[1] and lilac alcohols,[2] naturally occurring odorous components, were previously reported.

This paper describes the isolation of aldehydic components having an excellent green tone and their identification as diastereomeric 2-(1'-formyl)ethyl-5-vinyltetrahydrofuran (I) by combined gas chromatography-mass spectometry.*

In the gas chromatogram (Fig. 1) three unidentified peaks subsequent to number 13 peak of linalool were the aldehydes having R_t 6.6, 7.3, and 8.5 min.

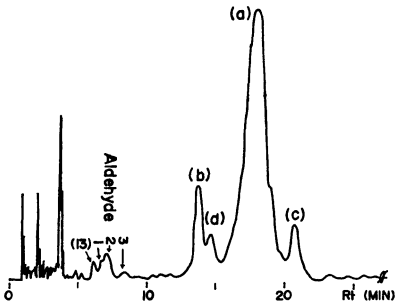

Fig. 1. Gas chromatogram of the lilac flower oil.
Column: 20% DEGS, 3 mm×3 m, Carrier Gas: He 30 ml/min, Oven Temp.: 120 °C, TCD

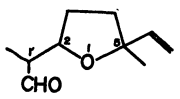
The mass spectra of the aldehydes are shown in Fig. 2; *m/e* 168 M^+, 153 $(M-CH_3)^+$, 141 $[M-(CH=CH_2)]^+$, 111 $[M-(CH\langle^{CH_3}_{CHO})]^+$, 55 $(CH_2=CH-C\equiv O)^+$, 43 $(CH_3-CO)^+$, 29 $(CHO)^+$. These fragments suggest structure (I) for the aldehydes.

In agreement with this formulation, R_t and mass spectra of the aldehydes synthesized from *d*-linalyl acetate were identical with those of natural aldehydes.

The structure of the aldehydes is comfirmed to be (I).

The aldehydes had been synthesized as intermediates for synthesizing lilac alcohols, but occurrence in nature has not yet been recorded. We wish to call them lilac aldehydes.

We intended to comfirm the absolute configurations



(I)

* Hitachi RM 50 GC, Ionization voltage 70 eV.

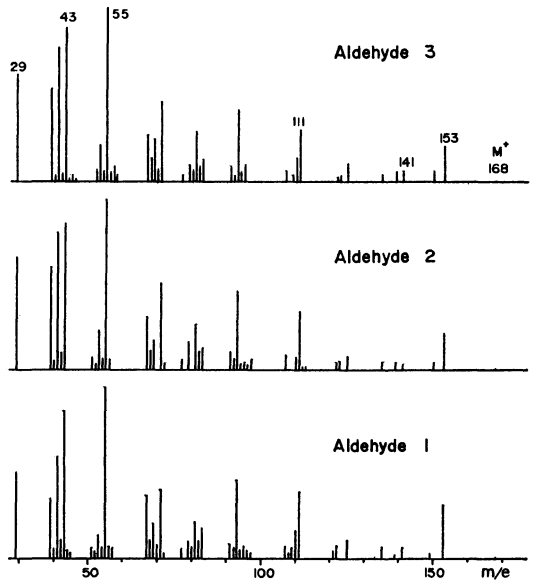


Fig. 2. Mass spectra of the lilac aldehydes.

of lilac aldehydes by converting them by reduction into lilac alcohols whose absolute configurations are comfirmed.** The gas chromatogram of the synthetic lilac aldehydes is shown in Fig. 3. Fractions corresponding to each peak were separated by repeated gas chromatography (PEG 20 M, 6 mm×5 m, 165 °C, He 45 ml/min). 2.4, 7.3, and 9.7 mg of d-2, d-3, and d-4 aldehydes, respectively, were reduced with $LiAlH_4$ to give the alcohols. The gas chromatograms of the alcohols are shown in Fig. 4. Judging from R_t and mass spectra, the alcohols were confirmed to consist of lilac alcohol-a, -b, -c, and -d.

Natural lilac aldehyde fraction exhibiting three peaks in gas chromatogram were reduced in the same manner as in synthetic aldehydes. The derived alcohols were also a mixture of the four diastereomeric lilac alcohols (Fig. 4).

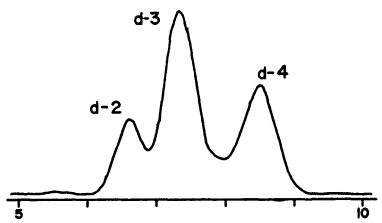

Fig. 3. Gas chromatogram of the synthetic *d*-lilac aldehydes.
Columun: 20% DEGS, 3 mm×3 m, carrier gas: He 30 ml/min, oven temp.: 120 °C, TCD.

** Since *d*-lilac alcohols in lilac flower oil amount to 70 per cent, lilac aldehydes would be *d*-series in view of biogenesis.[2] Due to too small amount of available natural aldehydes, measurements of $[\alpha]_D$ have not been carried out.

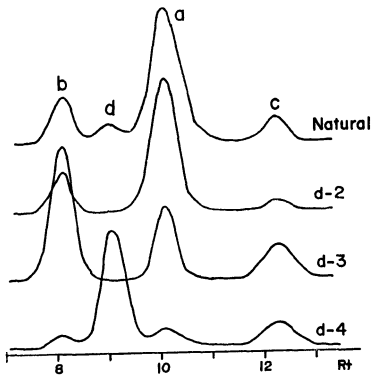

Fig. 4. Gas chromatograms of the reduced alcohols of natural and synthetic aldehydes.
Column: 15% DEGS, 3 mm×2 m, carrier gas: He 30 ml/min, oven temp.: 130 °C, TCD.

Although synthetic as well as natural lilac aldehydes showed only three peaks in gaschromatograms due to too small difference of R_t in two isomers, they were found to be a mixture of four diastereomers just as in lilac alcohols.

In the process of separation by liquid chromatography on alumina, it is interesting that natural lilac aldehydes were eluted in ether fraction, while synthetic lilac aldehydes were eluted in benzene–hexane (1: 1) fraction in the same manner as usual carbonyl compounds. Such an anomaly in natural lilac aldehydes seems to be due to an interaction between lilac aldehydes and abundantly existent lilac alcohols.

The characteristic greenish tone of the lilac flower seems to be duplicated by adding lilac aldehydes to lilac alcohols. This might also be ascribed to the interaction between the alcohols and the aldehydes.

Synthetic Studies of Amino Acids by the Use of Copper(II) Complexes. V.[1] The Preparation of Hydroxy Amino Acids by a Set of Improved Procedures

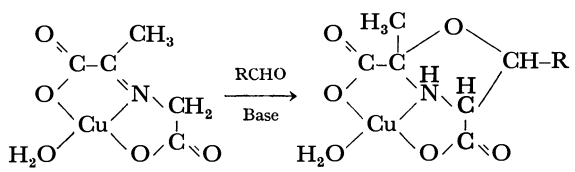
Shohji OHDAN, Tetsuya ICHIKAWA, Younosuke ARAKI, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received December 7, 1973)

Synopsis. A variety of hydroxy amino acids were prepared by a brief treatment of a resulting mixture, which was obtained by a base-catalyzed condensation reaction of *N*-pyruvylideneglycinatoaquocopper(II) with aldehydes, on a column of Amberlite IR-120B (H form) resin.

The base-catalyzed condensation reaction of *N*-pyruvylideneglycinatoaquocopper(II) (**1**) with aldehydes has been shown[2c,d] to be especially useful in the preparation of 2-amino-2-deoxyaldonic acids from aldehydo sugar derivatives, in contrast with the reaction of bisglycinatocopper(II) *etc.* And it has recently been confirmed that glycine can be isolated from some of the corresponding copper(II) complexes in fairly good yields merely by treating the solution of the complexes on a column of Amberlite IR-120B (H form), even in the case of the solution in aqueous DMF.[1] In order to establish a more effective and facile method of preparing hydroxy amino acids, the present authors undertook an investigation of the preparation of hydroxy amino acids by a set of improved procedures—*i.e.*, the base-catalyzed condensation reaction of **1** with aldehydes[2] and the facile isolating procedure of amino acids.[1]



1

R–CH(OH)–CH(NH_2)–COOH

Base-catalyzed condensation reactions of **1** with acetaldehyde (**2**), propionaldehyde (**3**), *n*-butyraldehyde (**4**), benzaldehyde (**5**), 2,4-*O*-ethylidene-*al*-D-erythrose (**6**), and 2,3;4,5-di-*O*-isopropylidene-*al*-D-arabinose (**7**) were carried out. Each resulting reaction mixture was then divided into two aliquots for the subsequent treatment after adjusting the pH to 4.5 with an aqueous acetic acid solution; one was directly adsorbed on a column of IR-120B (H form), followed by elution with an aqueous ammoniacal solution after washing with water (A procedure); while the other was treated on a column of the ion-exchange resin after the removal of the copper(II) ion by treating it with hydrogen sulfide gas, as has been done traditionally (B procedure), for comparison with the A procedure. The reaction conditions and yields of the corresponding hydroxy amino acids obtained by both A and B procedures are summarized in Table 1. It is possible to discuss the comparative merits of the two procedures directly on the basis of these results because their samples came from the same source. The expected superiority of the A procedure to the B procedure is apparently exhibited in the cases of **2**, **3**, and **6**, which were found to give the corresponding hydroxy amino acid copper(II) complexes easily soluble in water; however, the yields of hydroxy amino acids were not so much improved in the cases of **4**, **5**, and **7**, which were found

Table 1. An examination of the comparative merit of A and B procedure[a]

Run	Aldehydes (R–CHO)	R–CHO/**1**	Reaction period (min)	Yields (%) of the corresponding hydroxy amino acids obtained by	
				A procedure[b]	B procedure[c]
1	Me– (**2**)[d]	1.5	120	87.6	71.7
2	Et– (**3**)[e]	3.0	240	90.1	70.0
3	*n*-Pr– (**4**)[e]	3.0	240	60.8	57.7
4	Ph– (**5**)[e]	3.0	540	61.2	65.5

6	(**7**)[d]	1.1	90	40.1[f]	34.0[f]

a) All the reactions were carried out by the use of **1** (5.200 g, 20 mmol) and divided into two aliquots after the treatments as described in d and e. b) The one aliquot was directly adsorbed on a column (3×9 cm) of Amberlite IR-120B (H form), and the column was eluted with 0.5 M aqueous ammoniacal solution (2000 ml) after washing with distilled water (5000 ml). c) The other aliquot was treated with hydrogen sulfide gas, and was successively treated on the column of the ion exchange resin as described in b after the filtration of the resulting copper sufide through the filter-cell. d) The condensation reaction was carried out in an aqueous solution (distilled water: 100 ml) at pH 9.5—9.8 at room temperature, and the resulting mixture was then acidified with 5 M aqueous acetic acid (pH 4.5). The procedure of d and b is termed as A-1 procedure. e) The condensation reaction was carried out in a mixture of methanol (60 ml) and 1 M methanolic sodium methoxide solution (14 ml) at room temperature under nitrogen atmosphere. To the resultant mixture, was added 5 ml of a 5 M aqueous acetic acid solution, and the mixture was diluted with distilled water to a volume of 200 ml. The procedure of e and b is termed as A-2 procedure. f) These products were isolated as the corresponding deblocked derivatives.

to give the corresponding copper(II) complexes less soluble in water. This defficiency in the procedure in the latter cases was, as will be described later, overcome by carrying out treatment with the ion-exchange resin batchwise or by the use of aqueous *N,N*-dimethylformamide as the solvent for the condensation reaction and/or as a dissolution-assisting agent prior to treatment on the column of the resin. Consequently, it can be expected that a variety of hydroxy amino acids can be effectively prepared by this set of improved procedures and that, in addition, the copper(II) ion can be recovered by a subsequent washing of the column with an appropriate eluent.

18	*p*-Cl–Ph–	3.0	A-6	2.0	75.9
19	**6**	1.1	A-1 (pH 9.5)	0.75	79.7[c)] (60[2d)])
20	**6**	1.1	A-7 (pH 9.5)	0.75	77.5[2d)]
21	**7**	1.2	A-1 (pH 9.5)	1.5	63.2[c)] (65[2d)])
22		1.1	A-1 (pH 9.5)	1.5	45.4[c)] (22[2d)])

a) All the reactions were carried out by the use of **1** (2.600 g, 10 mmol). b) The yields shown in parentheses correspond to those obtained by the B procedure. c) These products were isolated as the corresponding deblocked derivatives.

A-3: The resultant mixture treated in such a way as in A procedure was stirred with the amount of the ion-exchange resin corresponding to that of being packed in a column of 3×9 cm in water to adsorb the corresponding product (batchwise operation), after which the resin was transfered into a column and the column was washed and eluted successively in the same way as has been described in A procedures. A-4: The condensation reaction was carried out in aqueous methanol (50 ml+50 ml), and the resultant mixture was treated as has been described in A-3. A-5: Prior to the admixture with aqueous acetic acid in A-2 procedure, the resultant reaction mixture was mixed with 50 ml of *N,N*-dimethylformamide. A-6: In place of methanol in A-2 procedure, aqueous *N,N*-dimethylformamide (50 ml+50 ml) was used as the solvent for the condensation. A-7: The volume of water (5000 ml) for washing in A-1 procedure was reduced to 1000 ml.

In the above connection, an extension of the A procedure was, with some modifications, attempted with respect to a variety of aldehydes; the reaction conditions, the details of the A procedures, and the yields of the hydroxy amino acids are summarized in Table 2. To homogenize the reaction systems, aqueous methanol, methanol, aqueous DMF, and DMF were used as solvents for the condensation reactions besides water. Moreover, a batchwise operation was found to be effective for the cases affording corresponding copper(II) complexes less soluble in water in order to adsorb the corresponding hydroxy amino acids on the ion-exchange resin. Furthermore, the addition of DMF to the resulting mixture prior to its treatment on the column of the resin was found to be more advantageous than the batchwise operation, and the use of DMF as the solvent for the condensation reaction was found to be exceedingly advantageous because of its eminent shortening effect in the reaction period. Thus, the set of improved procedure was confirmed to be sufficiently applicable to the preparation of a variety of hydroxy amino acids.

Experimental

All the hydroxy amino acids obtained herewith were respectively identified with the corresponding authentic specimens.[2c,d)] The preparation of DL-threonine will be described as a representative of the set of improved procedures.

DL-*Threonine.* A mixture of *N*-pyruvylideneglycinatoaquocopper(II) (**1**) (2.600 g, 10 mmol) and acetaldehyde (0.85 ml, 15 mmol) in water (50 ml) was stirred at pH 9.8 at room temperature for 2 hr. After the reaction, the pH of the resultant reaction mixture was adjusted to 4.5 with a 5 M aqueous acetic acid solution.

The resultant solution was then treated by the A-1 procedure and poured onto a column (3×9 cm) of Amberlite IR-120B (H form). The column was washed with distilled water (5000 ml) and successively eluted with a 0.5 M aqueous ammoniacal solution (2000 ml). The effluent was concentrated *in vacuo* almost to dryness, and the residue was treated with ethanol (10 ml) to give white crystals of DL-threonine (1.042 g, 87.6%). Mp 216 °C (dec) [lit,[2c)] 216 °C (dec)].

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(5), 1297—1298 (1974)

Reaction of *N*-Nitroso-1,2,3,4-tetrahydroisoquinolines with Base. A New Method for the Conversion of 1,2,3,4-Tetrahydroisoquinolines into 3,4-Dihydroisoquinolines

Kazuo SAKANE, Ken-ichi TERAYAMA, Eiichi HARUKI, Yoshio OTSUJI, and Eiji IMOTO

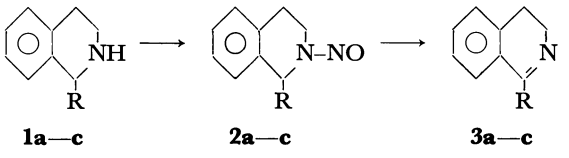
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received December 27, 1973)

Synopsis. Treatment of *N*-nitroso-1,2,3,4-tetrahydroisoquinoline (**2a**) and its 1-methyl derivative (**2b**) with base gave the corresponding 3,4-dihydroisoquinolines (**3a** and **3b**). However, similar treatment of *N*-nitroso-1,2,3,4-tetrahydroisoquinoline-1-acetic acid (**2c**) gave a mixture of **3b** and 1,2,3,4-tetrahydroisoquinoline-1-(α-hydroxyimino)acetic acid (**4**).

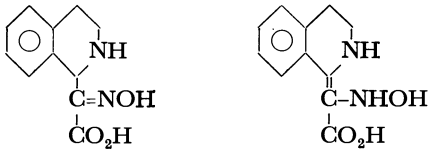
Reaction for the preparation of 3,4-dihydroisoquinolines from 1,2,3,4-tetrahydroisoquinolines can be classified into two types: direct dehydrogenation using oxidizing agents such as Hg(II)-EDTA[1] and potassium ferrate (VI),[2] and the elimination of a substituent attached to *N*-heteroatom and a hydrogen at the 1-position of tetrahydroisoquinolines, such as the base-induced elimination of hydrogen halide from *N*-halogeno-1,2,3,4-tetrahydroisoquinolines,[3,4] and the photochemically induced elimination of *p*-toluenesulfinic acid from *N*-tosyl-1,2,3,4-tetrahydroisoquinolines in the presence of base.[5] . We report here a new method belonging to the latter.

N-Nitroso-1,2,3,4-tetrahydroisoquinolines derived from 1,2,3,4-tetrahydroisoquinolines were converted into 3,4-dihydroisoquinolines with base. The sequence of the reactions employed is outlined in Chart 1. The procedure is simple and the yields are generally good.



1a—c **2a—c** **3a—c**

a, R=H; b, R=CH_3; c, R=CH_2CO_2H.



4a **4b**

Chart 1.

N-Nitroso-1,2,3,4-tetrahydroisoquinolines (**2a—c**) were prepared by the nitrosation of the corresponding 1,2,3,4-tetrahydroisoquinolines (**1a, b**) or the hydrochloride (**1c**) with isoamyl nitrite or sodium nitrite in hydrochloric acid. Treatment of **2a** and **2b** with aqueous sodium hydroxide resulted in the formation of the corresponding 3,4-dihydroisoquinolines in high yields, no other products being detected in the reaction mixture. Total yields of **3a** and **3b** from **1a** and **1b** were 70 and 80%, respectively. It is almost certain that **3a** and **3b** are produced by the base-induced elimination of hydrogen hyponitrite from *N*-nitroso compounds, although the reaction of this type has scarcely been reported. Daeniker[6] noted that *N*-nitroso-*N*-benzylaniline undergoes the elimination of hydrogen hyponitrite on being treated with a base.

However, a similar treatment of **2c** with sodium hydroxide afforded two products, **3b** and 1,2,3,4-tetrahydroisoquinoline-1-(α-hydroxyimino)acetic acid (**4**). The yields of **3b** and **4** from **2c** were 20 and 70%, respectively. Compound **3b** probably arises by the decarboxylation of **3c**, a primary product of the reaction of **2c** with base. On the other hand, the base-induced migration of the nitroso group from nitrogen to the carbon adjacent to the carboxyl group in **2c** accounts for the production of **4**. The migration of nitroso group of this kind, *viz.*, migration of nitroso group from nitrogen to an active methylene, has been observed in the reaction of *N*-nitroso amino acid.[6]

The structure of the compounds were confirmed by means of analytical and spectral data or by comparison with the respective authentic samples. The spectral data suggested that **4** exists in the form of **4a** or **4b**, or in equilibrium between **4a** and **4b**.

Experimental

*3,4-Dihydroisoquinoline (**3a**) from 1,2,3,4-Tetrahydroisoquinoline (**1a**).* A mixture of 1.3 g (0.01 mol) of **1a** and 4.6 g (0.04 mol) of isoamyl nitrite was allowed to stand at room temperature for 1 hr, and the excess isoamyl nitrite was evaporated. The residue dissolved in benzene was passed through a column of alumina using *n*-hexane–benzene mixture as an eluent to give 1.5 g (90%) of *N*-nitroso-1,2,3,4-tetrahydroisoquinoline (**2a**) as yellow solids: IR (KBr) 2920, 1420, 1355, 1330, 1160, 1100, 1040, 920, 805, and 750 cm^{-1}; NMR ($CDCl_3$) δ 2.84 (t, J=6.4 Hz, 2/3H), 2.99 (t, J=5.9 Hz, 4/3H), 3.76 (t, J=6.4 Hz, 2/3H), 4.42 (t, J=5.9 Hz, 4/3H), 4.71 (s, 4/3H), 5.27 (s, 2/3H), and 7.10 ppm (m, 4H). The NMR spectrum exhibited the same pattern as that reported by Chow and Colon[7] for **2a** indicating that **2a** exists in a pair of *syn* and *anti* conformers along the axis of the N–N partial double bond in the ratio 2: 1.

Compound **2a** thus obtained was used without further purification for the preparation of **3a**. A mixture of 1.5 g (0.009 mol) of **2a** in 20 ml of ethanol and 10 ml of 20% aqueous NaOH was refluxed for 10 hr, cooled, diluted with water and then taken up in CH_2Cl_2. The CH_2Cl_2 solution was extracted with 3 M HCl. The aqueous extract was made basic with 10% NaOH and extracted with CH_2Cl_2.

The extract was washed with water and dried over Na_2SO_4. Removal of CH_2Cl_2 left an oil, which was dissolved in benzene and passed through a column of alumina with benzene to give 0.9 g (70%) of **3a**. The IR spectrum (film) showed an absorption at 1630 cm^{-1} (C=N) and was identical with that of the authentic sample prepared by the method of Snyder and Werber.[8] The picrate, mp 172—175 °C, showed no depression in the mixed melting point test with the picrate from the authentic sample of **3a**.

*1-Methyl-3,4-dihydroisoquinoline (**3b**) from 1-Methyl-1,2,3,4-tetrahydroisoquinoline (**1b**).* *N*-Nitroso-1,2,3,4-tetrahydroisoquinoline (**2b**) was prepared from 1.5 g (0.01 mol) of **1b** and 4.6 g (0.04 mol) of isoamyl nitrite by a method similar to that described above. A solution of the crude product in benzene was chromatographed on alumina. Elution with *n*-hexane–benzene gave 1.5 g (85%) of **2b** as a yellow viscous oil: IR (film) 2970, 2930, 2860, 1495, 1430, 1360, 1315, 1295, 1150, 1110, and 760 cm^{-1}; NMR ($CDCl_3$) δ 1.47 (d, J=7.3 Hz, 3/2H), 1.72 (d, J=7.3 Hz, 3/2H), 2.80—3.30 (m, 2H), 3.40—5.10 (m, 2H), 5.91 (q, J=7.3 Hz, 1H), and 7.17—7.50 ppm (m, 4H, aromatic).

The oil **2b** was used without further purification for preparation of **3b**. A 1.5 g (0.0085 mol) sample of **2b** in 20 ml of ethanol was treated with 10 ml of 20% NaOH. Work-up of the reaction mixture yielded an oil, which upon distillation gave 1.1 g (92%) of **3b** as a colorless oil, bp 127—138 °C/20 mmHg: IR (film) 1630 cm^{-1} (C=N). The IR spectrum of this compound was identical with that of the authentic sample prepared by the method of Lora-Tamayo, Madronero, and Munoz.[9] The picrate, mp 187—190 °C, showed no depression in the mixed melting point test with the authentic specimen.

*1,2,3,4-Tetrahydroisoquinoline-1-acetic Acid (**1c**) Hydrochloride.* A mixture of 17 g (0.078 mol) of ethyl 1,2,3,4-tetrahydroisoquinoline-1-acetate[10-12] in 50 ml of 3 M HCl was refluxed for 1 hr. A half of water was removed under atmospheric pressure at 130—140 °C (oil bath temperature) left solids. The solids were extracted with 30 ml of boiling acetone, and the insoluble material (HCl salt of **1c**) was separated by filtration. The filtrate was evaporated to dryness, and the residue (unhydrolyzed ester) was repeatedly hydrolyzed. The solids obtained by hydrolysis were combined and recrystallized from dioxane–methanol to give 17 g (quantitative) of the hydrochloride of **1c** as white crystals; mp 183—184 °C: IR (KBr) 3500—2400 (OH), and 1720 cm^{-1} (C=O). Found: C, 58.44; H, 5.91; N, 6.42%. Calcd for $C_{11}H_{14}NO_2Cl$: C, 58.02; H, 6.15; N, 6.15%.

*N-Nitroso-1,2,3,4-tetrahydroisoquinoline-1-acetic Acid (**2c**).* To a solution of 2.0 g (0.0088 mol) of the hydrochloride of **1c** in 20 ml of 3 M HCl was added 20 ml of 10% sodium nitrite under cooling in an ice–water bath. The mixture was stirred for 1 hr under cooling. The resulting solids were filtered, and recrystallized from aqueous ethanol to give 1.7 g (90%) of **2c** as white needles, mp 167—169 °C: IR (KBr) 3100—2300 (OH) and 1720 cm^{-1}. Found: C, 59.71; H, 5.50; N, 12.48%. Calcd for $C_{11}H_{12}N_2O_3$: C, 59.99; H, 5.49; N, 12.72%.

*Reaction of **2c** with Aqueous Sodium Hydroxide.* A mixture of 3.0 g (0.014 mol) of **2c**, 50 ml of ethanol and 30 ml of 20% NaOH was refluxed for 10 hr. The precipitates were occasionally filtered. Additional precipitates obtained upon cooling the mixture were separated by filtration. The filtrate was extracted with CH_2Cl_2. The extract was washed with water, dried over Na_2SO_4, and then evaporated. The residue was chromatographed on a column of alumina. Elution with CH_2Cl_2 gave 0.4 g (20%) of **3b**. The IR spectrum of this compound was identical with the authentic sample.

The precipitates were combined and dissolved in water. The solution was acidified with concd HCl and allowed to stand for 2 hr. The resulting precipitates were filtered, and recrystallized from aqueous ethanol to give 2.1 g (70%) of 1,2,3,4-tetrahydroisoquinoline-1-(α-hydroxyimino) acetic acid (**4**) as white needles, mp 145—146 °C: IR (KBr) 3520, 3350, 2900—2200, and 1680 cm^{-1} (C=O); UV (EtOH) λ_{max} (log ε) 212 (3.90) and 294 nm (3.87); NMR (CF_3COOH) δ 3.10—3.70 (m, 4H), 4.17—5.10 (m, 2H), 6.15—6.70 (m, 1H), and 7.56 ppm (m, 4H, aromatic). Found: C, 59.90; H, 5.50; N, 12.45%. Calcd for $C_{11}H_{12}N_2O_3$: C, 59.99; H, 5.49; N, 12.72%.

Pyrolysis of Tris(2,3-dibromopropyl) Phosphate and Its Related Compounds

Yoshiki OKAMOTO, Norio KIMURA, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka 565

(Received Junuary 18, 1974)

Synopsis. The main product obtained by the pyrolysis of halogenated alkyl phosphate was found to be alkyl halide. The phosphoryl group was substituted for the halogen atom, olefins being minor products.

In a previous paper, we reported that the products obtained by the pyrolysis of *n*-hexyl phosphates were the mixtures of hexene isomers, the acid having a conspicuous influence on the isomer distribution.[1)]

Tris(2,3-dibromopropyl) phosphate (I) is wellknown as an effective fire retardant for synthetic polymers, but its behavior in pyrolysis has not yet been studied.

We have investigated the pyrolysis of I and its related compounds as regards the behavior of halogen atom.

Tris(2,3-dichloropropyl) phosphate (II)[2)] and trihexyl phosphate (III) were prepared by the reaction of phosphorus oxychloride with 2,3-dichloropropyl alcohol and hexyl alcohol, respectively.

Tris(2-chloroethyl) phosphate (IV),[2)] tris(1-methyl-2-chloroethyl) phosphate (V)[2)] and tris(1-chloromethyl-2-chloroethyl) phosphate (VI)[2)] were prepared by the addition of phosphorus oxychloride to ethylene oxide, propylene oxide and epichlorohydrin, respectively.

I and diethyl 2,3-dibromopropyl phosphate (VII)[2)] were prepared by the addition of bromine to the corresponding allyl phosphates at −15 °C. After they had been treated with a cation exchange resin column chromatography to remove trace of free acid, they were dried *in vacuo*.

In each run of pyrolysis, 0.1 mol of the phosphate was decomposed in a 20 ml-distilling flask heated (250—260 °C) with a metal bath at reduced pressure (3 mmHg).

The decomposition was over in a few minutes. The pyrolysis products were trapped in a tube cooled with liquid nitrogen. They were analyzed with glc on a 3 m×3 mmϕ column, packed with Ucon LB 550X on Chromosorb W (60—80 mesh) at column temperature of 160 °C, using nitrogen gas as the carrier. The glc peaks were identified by comparing their retention times with those of authentic samples, or by analysis of NMR and mass spectra of the fractions obtained by preparative glc.

The results of the pyrolysis of several halogenated alkyl phosphates are given in Table 1.

In the pyrolysis of I, 1,2,3-tribromopropane as the main product, *cis*- and *trans*-1,3-dibromopropene, 2,3-dibromopropene-1 and 3-bromopropene-1 were given as distillable products. No free bromine and a trace amount of hydrogen bromide could be detected. The residue was halogen-containing polymerized alkyl phosphate, the structure of which is still unidentified. II gave a mixture of 1,2,3-trichloropropane as a major product, 2,3-dichloropropene-1, 1,3-dichloropropene and a trace amount of 3-chloropropene-1. IV gave 1,2-dichloroethane as a major product and a small amount of vinyl chloride. In the pyrolysis of VII, 87% ethyl bromide was obtained but only a trace amount of 1,2,3-tribromopropane. In the case of the equimolar mixture of I and III, 50% hexyl bromide was obtained but only a trace amount of 1,2,3-bromopropane. In the case of the equimolar mixture of II and III, 21% hexyl chloride was obtained, which was less than the corresponding hexyl bromide from the mixture of I and III. In the case of the equimolar mixture of I and II, 49% of 1-bromo-2,3-dichloropropane and 35% of 1,2,3-tribromopropane, formed

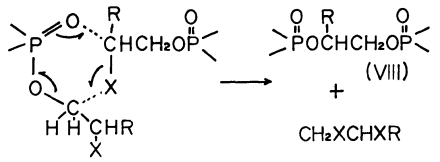
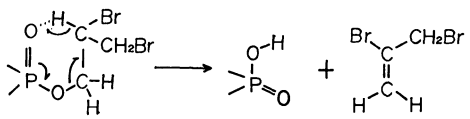
a) 25 wt%

by the transfer of bromine, and 5% of 1,2,3-trichloropropane and 4% of 1,2-dibromo-3-chloropropane, formed by the transfer of chlorine, were obtained.

The main products obtained by the pyrolysis of the halogenated alkyl phosphates were alkyl halides (95—67%), and olefins were minor products, different from the behaviors of unsubstituted alkyl phosphates in the pyrolysis.[1] This suggests that the formation process of alkyl halide involves intermolecular transfer of halogen atom, and the transfer of bromine atom occurred more easily than that of chlorine atom. The halogen substitution occurred more readily at the carbon atom having no halogen atom in the neighboring position. The following mechanism is suggested to account for the behavior.

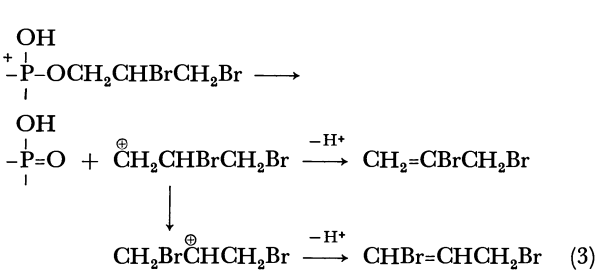


The formation of 2,3-dibromopropene-1 or 2,3-dichloropropene-1 might proceed through a six-membered ring transition intermediate as in the pyrolysis of alkyl carboxylate.[3]



1,3-Dibromopropene or 1,3-dichloropropene might be given through the isomerization of 2,3-dihalopropyl cation which was formed by acid catalyzed pyrolysis, into 1-halomethyl-2-haloethyl cation, followed by the elimination of a proton as follows.

3-Bromopropene-1 can be obtained from further decomposition of VIII.



Secondary alkyl phosphates V and VI gave more olefinic products than the halogen substituted products. This decomposition may proceed preferentially through reaction (2) or (3).

The effects of additives on the pyrolysis of I were studied. The results are given in Table 2.

Addition of sodium phosphates to I induced the substantial change in the yields of 2,3-dibromopropene-1 and *cis*-1,3-dibromopropene, which might be formed *via* reaction (2) or (3), in the same manner as the case of the pyrolysis of III.[1] However, the formation of alcohol could not be observed. Addition of phosphoric acid increased 3-bromopropene-1 and 1,3-dibromopropene, but decreased 1,2,3-tribromopropane. It was observed that by the addition of sodium acetate 2,3-dibromopropane markedly increased, whereas 1,2,3-tribromopropane decreased. Antimonous trioxide is also known to be an effective fire retardant when it is used with halogen-containing material. It was found that its addition caused serious changes of the composition of the products.

Effects of Substituents on pK_a and τ_{OH} Values of Hydroxyaryl-1,3,5-triazines; σ_p^- Values of 1,3,5-Triazinyl Groups.

Yukio OHTO, Yōji HASHIDA, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho, Kiryu, Gunma 376

(Received January 25, 1974)

Synopsis. Regular relations were found between substituents in the *s*-triazine nucleus and pK_a values, τ_{OH} values of *o*- and *p*-hydroxyphenyl-*s*-triazines, and stabilities of chelation of the *o*-isomers. The substituent constants (σ_p^-) for some *s*-triazinyl groups were also found.

No detailed information has been given on the relation between chemical constitutions of 2-(*o*-hydroxyaryl)-nitrogen heteroaromatics and their stability of chelation because of the difficulty of obtaining a series of 2-(*o*-hydroxyaryl)-nitrogen heteroaromatics. However, a number of hydroxyaryl-*s*-triazines are readily available by the photolysis of aryloxy-chloro-*s*-triazines followed by treatment with nucleophiles.[1] These *s*-triazine derivatives can provide an appropriate series of 2-(*o*-hydroxyaryl)-nitrogen heteroaromatic for studying the substituent effects on the strength of chelation. This paper deals with the effects of substituents in the *s*-triazine nucleus on pK_a value and ^{1}H chemical shift of phenolic proton of hydroxyaryl-*s*-triazine giving substituent constants for the *s*-triazine nucleus.

Experimental

The NMR spectra were recorded on a Varian A-60D spectrometer in DMSO-d_6 with tetramethylsilane as an internal standard, and the pK_a values were measured spectrophotometrically in water at 25 °C.

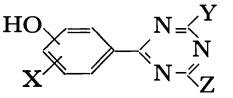
Materials. Hydroxyaryl-*s*-triazines were synthesized by the method described previously.[1]

Results and Discussion

pK_a *Values of Hydroxyaryl-s-triazines.* In the ordinary chelated phenols the stabilities of chelation are regularly correlated with their pK_a values. Thus, the stabilities of chelation of *o*-hydroxyaryl-*s*-triazines were discussed in connection with their pK_a values. The pK_a values of various hydroxyaryl-*s*-triazines are given in Table 1.

We see that the pK_a values of *o*-hydroxyphenyl-*s*-triazines are higher than those of the corresponding *p*-isomers, suggesting that chelate ring formation takes place in each *o*-hydroxyphenyl-*s*-triazine. The pK_a values of *o*- and *p*-hydroxyphenyl-*s*-triazines vary regularly with two substituents in the *s*-triazine nucleus [$pK_a(o) = -0.890\ \Sigma\sigma_m + 11.37$, where $\Sigma\sigma_m$ denotes a summation of σ_m values of two substituents in the *s*-triazine nucleus]. However, the pK_a values of *p*-hydroxyphenyl-*s*-triazines were affected to a lesser extent than the *o*-isomers by the substituents in the *s*-triazine nucleus; the relatively large difference in pK_a value between the *o*-hydroxyaryl-*s*-triazines is considered

TABLE 1. pK_a VALUES AND ^{1}H CHEMICAL SHIFTS OF PHENOLIC PROTONS OF HYDROXYARYL-*s*-TRIAZINES



No.	HO–	X	Y	Z	pK_a	τ_{OH}
1	*o*-OH	H	$-OC_6H_5$	$-OC_6H_5$	10.92	−1.57

18	2-OH	6-H	$-OCH_3$	$-OCH_3$	11.17[a]	−2.52[a]
19	2-OH	6-OCH_3	$-OCH_3$	$-OCH_3$	11.97[a]	−2.10[a]

a) reported in the previous paper.[1]

to be due not only to the difference in the original acidity of *s*-triazinyl-phenol but also to the difference in stability of the chelation. If steric requirements in all the *o*-hydroxyaryl-*s*-triazines are similar in magnitude as might be anticipated in these cases, the relative strength of intramolecular hydrogen bond can be evaluated by means of the difference in pK_a value between *o*- and corresponding *p*-hydroxyaryl-*s*-triazines [$\Delta pK_a = pK_a(o) - pK_a(p)$]. When ΔpK_a values are plotted against the $\sum\sigma_m$ values, a straight line of negative slope ($\Delta pK_a = -0.248 \sum\sigma_m + 2.77$) was obtained, suggesting that the stability of chelation varies with the substituents in the *s*-triazine nucleus, although the substituent effect is small. Similar relations were also observed in the case of 5-methyl-2-hydroxyphenyl-*s*-triazines, showing that the greater the electron-donating tendency of the two substituents in the *s*-triazine nucleus, the higher the pK_a value owing to the formation of stronger chelated ring due to an increase in electron density at the ring nitrogen atom. Thus, among the *o*-hydroxyaryl-*s*-triazines of the same phenol moiety the relative stability of chelation can be represented by the summation of σ_m values of two substituents in the *s*-triazine ring.

Chemical Shifts of Hydroxyl Protons of Hydroxyaryl-s-triazines. Substituent effects on the chemical shifts of hydroxyl protons of hydroxyaryl-*s*-triazines were investigated. Effects of substituents on the NMR signals of phenolic protons have been studied with many substituted phenols;[2] in each case a good correlation holds between the substituents in the *meta* and *para* positions and ^1H chemical shifts of phenolic protons. ^1H Chemical shifts (in τ) of phenolic protons of hydroxyaryl-*s*-triazines are given in Table 1. In this case also the difference in τ_{OH} value between *p*-*s*-triazinylphenols is relatively small [$\tau_{OH}(p) = -0.487 \sum\sigma_m - 0.091$]; the large difference in τ_{OH} value between *o*-isomers [$\tau_{OH}(o) = 2.27 \sum\sigma_m - 2.79$] being ascribed to the difference in the strength of chelation. A linear relation holds between the $\Delta\tau_{OH}$[$\Delta\tau_{OH} = \tau_{OH}(o) - \tau_{OH}(p)$] and $\sum\sigma_m$ values ($\Delta\tau_{OH} = -2.77 \sum\sigma_m + 2.71$). Similar relations are also observed in the case of 5-methyl-2-hydroxyphenyl-*s*-triazines. Thus, among the *o*-hydroxyaryl-*s*-triazines of the same phenol and different *s*-triazine moieties, not only the ΔpK_a and $\Delta\tau_{OH}$ values but also the $\sum\sigma_m$ values of two substituents in the *s*-triazine nucleus can be utilized as a measure for the relative stability of chelation.

Substituent Constants of s-*Triazinyl Groups.* The *s*-triazinyl group is known as an electron-attracting substituent. However, so far there has been no quantitative evaluation for the electron-withdrawing powers of common *s*-triazinyl groups. In the *p*-hydroxyphenyl-*s*-triazines, each pK_a value was smaller than that of phenol, indicating that the *s*-triazinyl group is electron-attracting regardless of two substituents in the *s*-triazine nucleus. However, the pK_a value of this series also varies regularly with the $\sum\sigma_m$ value [$pK_a(p) = -0.635 \sum\sigma_m + 8.60$].

Since a good linear relation holds between the substituent and dissociation constants of phenols ($pK_a = -2.23\sigma + 9.92$),[3] substituent constants for the *s*-triazinyl groups of σ_p^- character can be obtained from the pK_a values of *p*-*s*-triazinylphenols. The results are given in Table 2. When these σ_p^- values are plotted against the $\sum\sigma_m$ values, a straight line with a positive slope of 0.30 is obtained, indicating that the substituents in the *s*-triazine nucleus affect the electron-attracting power of *s*-triazine nucleus only to a minor extent.

In the case of τ_{OH} value, a linear correlation is also observed between the $\sum\sigma_m$ and τ_{OH} values of *p*-hydroxyphenyl-*s*-triazines. Substituent constants attributable to *s*-triazinyl groups were also obtained from τ_{OH} values using an equation obtained by plotting τ_{OH} values of substituted phenols[2] against the substituent constants σ_p^-.

The σ_p^- values of the two series agree fairly well. $\sum\sigma_m$ was found to become zero at $\sigma_p^- = 0.61$, indicating the *s*-triazinyl group itself to be a fairly electron-attracting substituent. The bis(dimethylamino)- and dichloro-*s*-triazinyl groups were found to have the smallest and greatest σ_p^- values of the common *s*-triazinyl groups, being 0.47 and 0.85, respectively. This shows that the electron-attracting powers of the common *s*-triazinyl groups are comparable to those of ordinary acyl and other related groups.

TABLE 2. σ_p^- VALUES OF *s*-TRIAZINYL GROUPS

Y	Z	$\sum\sigma_m$ (σ_mY+σ_mZ)	σ_p^- (a)	(b)	(d)
-Cl	-Cl	0.747	(0.82)[c]	(0.88)[c]	0.85

Photo-induced Condensation Reaction of *p*-Quinones with Aldehydes

Kazuhiro MARUYAMA and Yo MIYAGI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 27, 1973)

Synopsis. The quantum yield of a photo-induced condensation product between a *p*-quinone and an aldehyde was determined, the reaction course being investigated by CIDNP technique.

Quantum Yield of the Reaction. Qualitative inspection on photo-induced reaction of *p*-quinones with aldehydes has been reported by Bruce and Cutts.[1] Their conditions for the reaction were unusual; a quinone dissolved in an aldehyde was subjected to irradiation to yield acylated hydroquinone derivatives. In the present investigation a more dilute mixture of *p*-quinone and aldehyde in a suitable solvent was irradiated by Xenon arc lamp. The quantum yields of major products, 2-acylated hydroquinones, are given in Tables 1—3 for several combinations of *p*-quinones and aldehydes.

Monochromatic light of 445 nm was used in the reaction of *p*-benzoquinone, and that of 425 nm in the reaction of 1,4-naphthoquinone. Each absorption band corresponds to the n→π^* excitation band of the respective carbonyl groups.

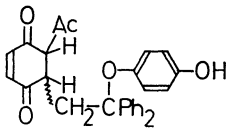
a) Initial concentration of *p*-benzoquinone, $[BQ]_0$, was 0.01 mol/l. b) Mean quantum yield during 90 min reaction. The yields were determined by absorption at 360 nm. c) Mean quantum yield during 95 min reaction.

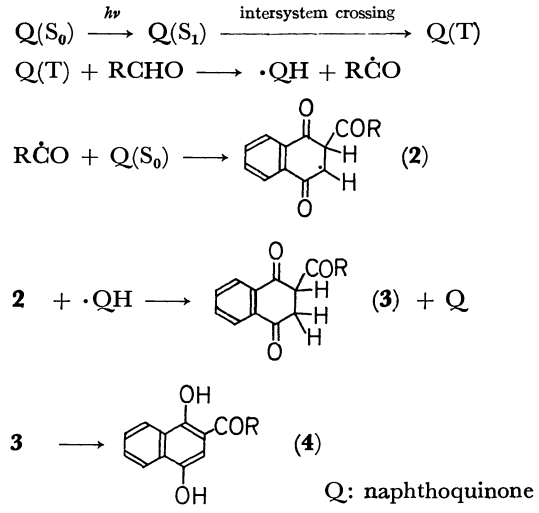
The mean quantum yields estimated in the duration of every 30 min remain constant in the reaction of *p*-benzoquinone with aldehydes, but they change with time in the reaction of 1,4-naphthoquinone with propanal. This can be ascribed to the quenching effect by the major product, 2-acyl-1,4-naphthohydroquinone, accumulated in the reacting solution. The following indirect evidence deduced from the investigation of the reaction by means of CIDNP would support the view. The fresh solution of 1,4-naphthoquinone and an aldehyde dissolved in carbon tetrachloride showed fairly strong polarized PMR signals during the course of irradiation, but the intensity is strongly depressed without exception when the corresponding 2-acyl-1,4-naphthohydroquinones were added to the solutions.

Reaction Mechanism. Thus, 2-acylated hydroquinone was obtained from *p*-quinone and aldehyde in a free form or in the form of quinhydrone addition compound.[2] On the mechanism of these condensation reactions, Bruce and Cutts included the addition of acyl radical to the quinone followed by subsequent enolization of the primary adduct.[1] In the reaction of *p*-benzoquinone with acetaldehyde they obtained the scavenged product (**1**) of the reactive intermediate radical by 1,1-diphenylethylene added in the reaction system.



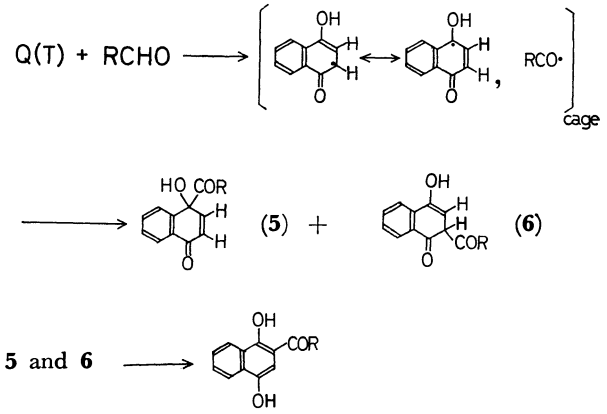
(**1**)

According to this mechanism the reaction should proceed as follows.



Scheme 1.

The reaction could proceed in part through the above reaction scheme, but our investigation by CIDNP technique revealed a modified aspect. The polarized PMR signal (multiplet, emission and absorption) observed in the region δ=3.70—4.30 and the polarized signal (emission) due to 2,3-protons of naphthoquinone can be interpreted by this mechanism. However, both the strongly polarized signals (emission) in the region δ=6.25—6.45 and the strongest polarized alkyl proton signal or signals (absorption) of acyl group suggest the concomitant generation of **5** or **6** through direct recombination of the radical pair in an original solvent cage[3] (Fig. 1), (Scheme 2). The polarized emission signals observed in the region δ=6.25—6.45 can be reasonably interpreted by taking account of the olefinic protons of **5** and **6**. No evolution of carbon monoxide during the course of irradiation supports our scheme.



Scheme 2.

Experimental

Quantum yields were determined by the use of ferrous succinate as an actinometer. Monochromatic light was attained with a Shimadzu RF-501 spectrophotometer. CIDNP examinations were carried out with a JEOL 60 MHz NMR spectrometer (solvent; CCl_4). Details are described elsewhere.[4]

Synthesis of (4-Pyridyl)-1,2-ethanediol

Herbert S. AARON and Jacob I. MILLER

Chemical Research Division, Edgewood Arsenal, Aberdeen Proving Ground, Maryland, 21010 USA

(Received August 13, 1973)

Synopsis. A conflict in the literature regarding the physical properties of 4-(pyridyl)-1,2-ethanediol has been resolved. The melting point and solubility data of this compound are correct as reported in *J. Org. Chem.*, **30**, 1331 (1965).

Furuyama, Mori, and Wakasa[1] recently modified our procedure[2] for the synthesis of (4-pyridyl)-1,2-ethanediol (I) and obtained a liquid product reported to be insoluble in acetone, and which seemed to dissolve only in solvents with a Hildebrand solubility parameter greater than 12.7. Although no analytical data was offered to establish the purity of their product, they suggested that the melting point and solubility we reported for I were in error. However, their claim that Haas *et al.*[3] also indicated a similar doubt with respect to our results is incorrect. Actually, our paper was uncited by Haas *et al.*, and was probably unknown to them, since it appeared only shortly before their own publication. The fact that Haas *et al.* obtained I as a pasty mass that could not be readily purified (by unspecified means) does not disprove our results. Indeed, these workers recrystallized the corresponding 2-pyridylglycol from methylene chloride, which has a solubility parameter of only 9.8.[4]

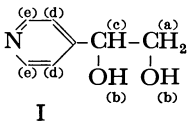
In view of the claim[1] that I was insoluble in acetone, we ran the reaction as described by Furuyama *et al.*, in order to evaluate their product. The solubility discrepancy is apparently resolved from the fact that the crude product thus obtained did give an initial appearance of being insoluble in acetone, but only because it contained about 18% of a mixture of acetone-insoluble magnesium and potassium salts of isonicotinic acid. In our hands, the modified procedure[1] gave a 54% yield of crude I (unrecrystallized), after separation from these salts. By our original procedure, a 35% yield of the purified product had been obtained.[2]

Experimental

(4-Pyridyl)-1,2-ethanediol (I) was obtained as a clear, viscous, yellow oil (22 g); as described.[1] A less-than-theoretical yield was signalled by the strong odor of 4-vinylpyridine on the inorganic filter cake. The crude product appeared, initially, to be insoluble in acetone. However, when a 1.1 g portion was stirred into 6 ml of acetone, it formed an opaque gum, which slowly dissolved, and left an insoluble, tan, solid residue II, 0.15 g, mp 265—320 °C. Combustion, NMR (in D_2O) and atomic absorption analysis (for K and Mg) indicated II was a mixture of inorganic salts of isonicotinic acid, consistent with a composition of four parts $C_5H_4NCOOK \cdot 1/2H_2O$ (IIA) and one part $C_5H_4NCOO(Mg)OH \cdot 1/2H_2O$ (IIB).

Found: C, 42.0; H, 3.0; N, 7.9; O, 25.2; Mg, 2.5; K, 19.3%. Calcd for 4/1 mixture of IIA/IIB: C, 42.4; H, 3.1; N, 8.2; O, 25.3; Mg, 2.8; K, 18.5%.

After II had been filtered off, the acetone solution was allowed to stand overnight, and an additional 0.03 g of solid precipitated. This material shriveled in a capillary tube at about 290 °C, but did not melt, even when heated to 340 °C; it was not further characterized. The acetone solution was then concentrated under reduced pressure to give 0.8 g of I as an oil, which slowly crystallized, when seeded.[2] A larger batch (14.5 g) of the initial liquid product (I), above, was similarly treated (60 ml of acetone, 10 min stirring) to give 2.3 and 0.4 g of insoluble salts, respectively, and 11.8 g (54%) of crude I, as a tacky, orange solid. The NMR spectrum of I, mp 69—71 °C (from CH_2Cl_2), was recorded in deuteroacetone, on a Varian A-60D Spectrometer (60 MHz, internal TMS reference, ambient probe temperature of 33 °C): δ 3.65, $2H_{(a)}$ m; 3.90, $2H_{(b)}$ s; 4.76, $H_{(c)}$ ~t; 7.40, $2H_{(d)}$ ~d; 8.48, $2H_{(e)}$ broad m. In D_2O, unless heated,[1] the $H_{(b)}$ and $H_{(c)}$ signals overlapped at about δ 4.88.



I

We thank Mr. Donald Hench, Mrs. Marjorie Buckles and Mr. John Corliss and staff for the analytical results, and Mrs. Linda Szafraniec for the NMR data.

A Study of Catalysis by Metal Phosphates. II.[1] A Kinetic Study of the Dehydrogenation of 2-Propanol over the Cadmium Phosphate Catalyst and an Investigation of the Acid-base Character of the Catalyst

Fumio Nozaki and Haruo Ohta

Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received April 12, 1973)

The dehydrogenation of 2-propanol over the *ortho* cadmium phosphate catalyst has been investigated by means of a conventional tubular-flow reactor operating at atmospheric pressure. The adequate temperature for the calcination of catalyst was about 400 °C. The reaction-rate data were approximately arranged by Eq. (3), using the Langmuir-type expression described in the text. The catalytic activity for dehydrogenation to acetone was completely poisoned by the addition of a small amount of CCl_3COOH during the course of the reaction, whereas the activity for dehydration to propylene was greatly enhanced. The behavior of $CH_2ClCOOH$ and C_6H_5COOH as poisons was also investigated. C_5H_5N had no effect on the catalytic reaction. It has been concluded that the cadmium phosphate is to be characterized as a basic catalyst.

A preliminary study of various *ortho* metal phosphate catalysts revealed that two phosphates, $Ca_3(PO_4)_2$ and $Cd_3(PO_4)_2$, had a high and selective activity for the dehydrogenation of 2-propanol to acetone; in this they strongly contrasted with the other phosphates which generally catalyzed the dehydration for propylene formation.[2]

Ishiguro and Ohtsuka[3] have already reported that the cadmium phosphate catalyst selectively promotes the dehydrogenation of 2-propanol; however, they have not presented the detailed reaction kinetics or a characterization of the catalyst.

In this paper, we will describe a further study of the cadmium phosphate catalyst.

Experimental

Materials. The cadmium phosphate catalyst was prepared from $Cd(NO_3)_2$ and Na_3PO_4 according to the method of Ishiguro and Ohtsuka.[3] The catalyst was calcined at the prescribed temperatures between 300 and 600 °C for 4 hr in an air stream. In all cases, the catalysts were white in color.

The N_2 and 2-propanol used in the catalytic tests were the highest pure grade of reagent.

Procedures. The apparatus and procedure for the measurements of the catalytic reaction were the same as those described in the previous report.[1] The experimental data of the catalytic reactions were represented by the total conversion of 2-propanol (x) and the selectivity to acetone (S).[4]

In order to reveal the acid-base character of the catalyst during the course of reaction, the effects of pyridine (C_5H_5N), trichloroacetic acid (CCl_3COOH), monochloroacetic acid ($CH_2ClCOOH$), and benzoic acid (C_6H_5COOH) on the catalytic reaction were investigated by means of the following procedure: 2-propanol with the additive of 0.067 mol/l was prepared for the tests. After we have ascertained that the catalytic reaction for 2-propanol without the additive proceeds at a stationary state, we exchange the feed instaneously with 2-propanol containing the additive and then follow the change in the catalytic activity and in the selectivity.

Results and Discussion

Effect of Reaction Conditions on the Catalytic Activity and Selectivity. The changes in the catalytic activity and in the selectivity with the calcination temperature of the catalyst are shown in Fig. 1. The catalytic activity increased with an increase in the calcination temperature, passed through a maximum at about 400 °C, and then almost disappeared above 500 °C. The catalyst, even when it was calcined at the low temperature of 300 °C, exceeds 80% in selectivity for dehydrogenation to acetone. The selectivity to acetone over the catalyst calcined at 400 °C displayed only a slight decrease of up to 5%, depending on the reaction temperature and the time factor (W/F). Thus, the dehydration of 2-propanol to propylene was negligible in amount under appropriate reaction conditions.

Reaction Rates and Rate Equation. The kinetic studies have been made over the catalyst calcined at 400 °C, wherein the selectivity to acetone was excellent and the activity was almost unchanged throughout the time of the reaction.

In the low range of W/F up to 4 g-cat·hr/mol, the observed conversion of 2-propanol was approximately proportional to W/F, without regard to the reaction temperature. Therefore, one may assume the differential

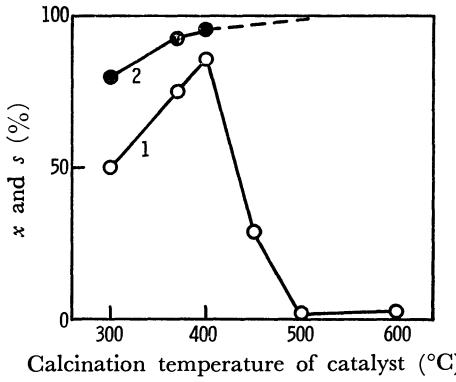

Fig. 1. Effect of the calcination temperature of catalyst on the reaction.

Reaction temperature: 295 °C, Catalyst weight (W): 1.5 g, Feed rate of 2-propanol and N_2 (F): 0.23 mol/hr, Mol-fraction of 2-propanol in feed $\left(y_0 = \frac{IPA}{IPA+N_2}\right)$: 0.26

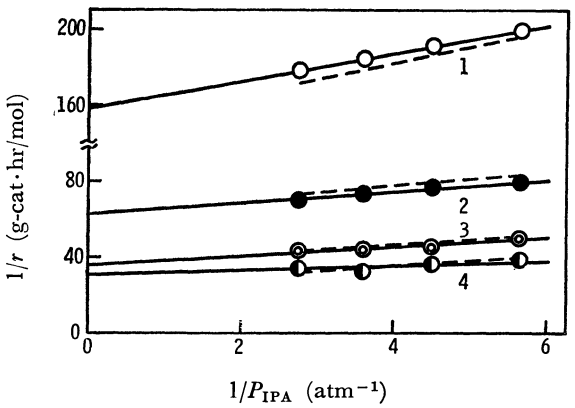

Fig. 2. $1/r$ *vs.* $1/P_{IPA}$ plots.
1: 220 °C, 2: 245 °C, 3: 260 °C, 4: 270 °C
The dotted lines show the correlation between $1/r_{calc}$ and $1/P_{IPA}$, where r_{calc} is the reaction rate computed from Eq. (3).

reactor, in which the reaction rates, $r(=y_0x/(W/F)$ mol/g-cat·hr), can be obtained from the slopes of the linear relationships between y_0x (y_0: mol-fraction of 2-propanol at the inlet of reactor) and W/F.

The observed reaction rates are illustrated in Fig. 2, plotted as reciprocal relations between r and P_{IPA}.

A plot of $1/r$ *vs.* $1/P_{IPA}$ gives a straight line for each of the reaction temperatures. The following equation can be derived and rearranged to the conventional form of the Langmuir-type rate expression:

$$\frac{1}{r} = \frac{1}{k} + \frac{1}{kK}\frac{1}{P_{IPA}} \tag{1}$$

or:

$$r = k\frac{KP_{IPA}}{1+KP_{IPA}} \tag{2}$$

where k is the rate constant (mol/g-cat·hr) and where K is the adsorption equilibrium constant for 2-propanol (atm^{-1}). The intercepts to the ordinate and the slopes of the straight lines give the values of k and K shown in Fig. 3.

Both $\log k$ and $\log K$ are correlated to $1/T$ by straight lines, with slopes of $(-E/R)$ and (Q/R) respectively,

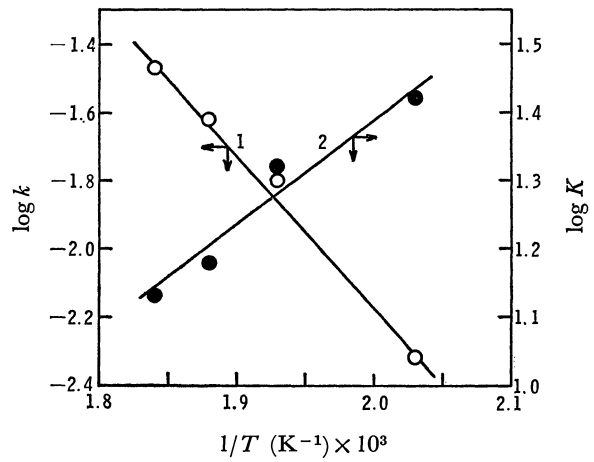

Fig. 3. Arrhenius plots for k and K.
1: $\log k$ *vs.* $1/T$, 2: $\log K$ *vs.* $1/T$

where E is the activation energy for the reaction and where Q is the adsorption heat of 2-propanol. We obtained approximately $E=19$ kcal/mol and $Q=6.7$ kcal/mol. By substituting these values into Eq. (2) and by evaluating the pre-exponential factors of k and K, we obtain:

$$r = 1.84\times10^{-2}\exp\left(\frac{-19000}{RT}\right)\frac{2.3\times10^{-2}P_{IPA}\exp\left(\frac{6700}{RT}\right)}{1+2.3\times10^{-2}P_{IPA}\exp\left(\frac{6700}{RT}\right)} \tag{3}$$

Considering the stoichiometry of the reaction and using Eq. (2) for the rate expression, we obtain Eq. (4) as a conventional integral form for the ideal tubular reactor:[5]

$$W/F = y_0\int_0^x \frac{dx}{r} = \frac{y_0}{k}\left[\frac{1}{K}\left(1+\frac{1}{y_0}\right)\ln\frac{1}{1-x}+x\left(1-\frac{1}{K}\right)\right] \tag{4}$$

At a constant temperature of 260 °C, a series of the conversion data was obtained under conditions in which W/F varied widely from 1.5 to 22.3, and y_0, from 0.183 to 0.383. Fig. 4 shows a plot of W/F *vs.* $y_0[\{(1+1/y_0)/K\}\ln(1/1-x))+x(1-1/K)]$ for $K=13.0$, which is evaluated from Eq. (3) for K at 260 °C. A good linear correlation is shown in Fig. 4. Consequently, it can be concluded that Eq. (3) is satisfactory for the rate equation under all the present experimental conditions.

When comparing 2-propanol which contained much acetone and 2-propanol without acetone for the feed of the reaction, no essential differences in reaction rates could be detected. Thus, the retardation effect of acetone on the reaction rate was found to be negligible.

Acid-base Character of the Catalyst. The coexistence of C_5H_5N in the reactant flow had no effect on the catalytic reaction within the limits of experimental error, whereas CCl_3COOH showed a remarkable influence on the catalyst activity, as is shown in Fig. 5. Dehydrogenation to acetone was retarded rapidly and was poisoned completely after the reaction had been continued for about 30 min by using 2-propanol with 0.067 mol/l CCl_3COOH. In contrast, dehydration to

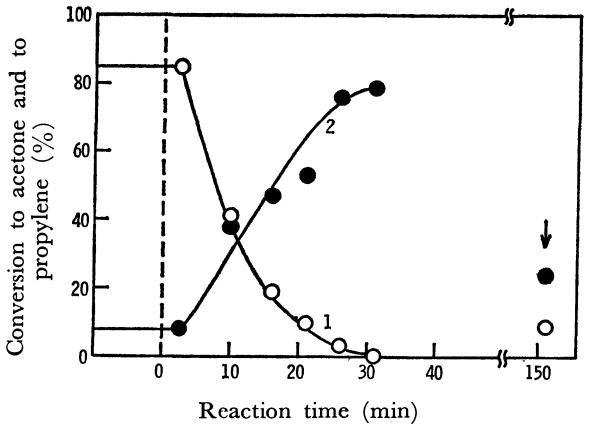

Fig. 5. Influence of CCl_3COOH addition on the catalytic reaction.
1: Conversion to acetone
2: Conversion to propylene
Reaction temperature: 305 °C, Concentration of CCl_3COOH in the feed of 2-propanol: 0.067 mol/l, The other reaction conditions are the same as noted in Fig. 1. The dotted line shows the time when the feed of 2-propanol without the additive was exchanged with 2-propanol containing CCl_3COOH. The data marked by an arrow show the result after the catalyst has been reactivated by passing through N_2 at 350 °C for 2 hours.

propylene increased remarkably, as CCl_3COOH had been accumulated on the catalyst surface. The disappearance of the dehydrogenation activity upon the addition of a small amount of CCl_3COOH to the catalyst indicates that the active sites of the catalyst contributing to the dehydrogenation reaction are basic. The required quantity of CCl_3COOH which completely poisoned the dehydrogenation activity of the catalyst was almost unchanged with the change in the reaction temperature or in the concentration of CCl_3COOH; it was estimated to be about 0.05 mmol/g-cat from the results shown in Fig. 5. However, it was difficult to determine the exact amount of CCl_3COOH for the complete poisoning because of the presence of poison

adsorbed on the sties which are not active for the catalytic reaction.

To make sure that the catalyst can be characterized as basic, the influences of $CH_2ClCOOH$ and C_6H_5COOH on the catalytic reaction were also investigated. As is shown in Figs. 6 and 7, the dehydrogenation to acetone was explicitly poisoned by the addition of the organic acids, although their rates of poisoning the dehydrogenation and also their degree of enhancing the dehydration are somewhat different from that of CCl_3COOH.

None of the catalysts poisoned with CCl_3COOH, $CH_2ClCOOH$, or C_6H_5COOH regained their catalytic activity for dehydrogenation when the catalytic reaction of 2-propanol without the additive was continued at the reaction temperature of 300 °C for two hours, or when it was passed through N_2 at 300 °C for two hours. By passing it through N_2 at such a slightly higher temperature as 350 °C, however, some of the catalytic activity for dehydrogenation was restored, although the degree of the recovery depended primarily on the species of the poisons, as is shown in Figs. 5—7. The enhanced dehydration activity directly attributable to the addition of CCl_3COOH or $CH_2ClCOOH$ readily disappeared when it was passed through N_2; in contrast, the recovery of dehydrogenation activity was rather difficult. The detailed role of CCl_3COOH or $CH_2ClCOOH$ in the appearance of dehydration activity during the poisoning test is not yet clear. However, a feasible and tentative explanation is that Brönsted acid molecules adsorbed on the catalyst surface catalyze the dehydration to propylene. The reason for this is that the decreasing order of dehydration activity of the catalysts poisoned with the organic acids is as follows: $CCl_3COOH > CH_2ClCOOH > C_6H_5COOH$; this order is in accord with expectations based on the acid strength. Since the acid molecules adsorbed on the catalyst surface other than basic sites would be rapidly desorbed, the ready recovery of dehydration activity is understandable, as has been described above.

The effect of H_2O on the catalytic reaction was not observable under the same conditions as those studied for the poisoning of CCl_3COOH, except that the concentration of H_2O varied over a wide range between 0.098 and 0.65 mol/l.

On the basis of the observations presented above, it appears clear that the cadmium phosphate is intrinsically a basic catalyst. However, the catalyst structure which causes this basic character must remain the subject for a future study.

(Received April 23, 1973)

The rotational spectra of ten isotopic species of ethylene oxide, $^{12}C_2H_4{}^{16}O$, $^{12}C^{13}CH_4{}^{16}O$, $^{12}C_2H_4{}^{18}O$, $^{12}C_2H_3D^{16}O$, *cis*- and *trans*-$^{12}C_2H_2D_2{}^{16}O$, $^{12}C^{13}CH_2D_2{}^{16}O$, and $^{12}C_2H_2D_2{}^{18}O$ were observed. A least-squares fit including centrifugal distortion effect to the first order was made to derive the effective values of the A′, B′, C′, τ'_{aaaa}, τ'_{bbbb}, τ'_{cccc}, and τ'_{aabb} parameters and their correlation factors; τ'_{bbcc} and τ'_{aacc} were found to be insignificant. The rotational constants were used to determine the r_0, r_s, and r_m structures. The structural parameters were derived as:

$r_0(CC)=1.470\pm0.003$, $r_s(CC)=1.466\pm0.002$, $r_m(CC)=1.462\pm0.003$,

$r_0(CH)=1.085\pm0.004$, $r_s(CH)=1.085\pm0.001$, $r_m(CH)=1.086\pm0.004$,

$r_0(CO)=1.434\pm0.002$, $r_s(CO)=1.431\pm0.001$, $r_m(CO)=1.428\pm0.002$,

$\angle_0HCH=116.28\pm0.69$, $\angle_sHCH=116.61\pm0.09$, $\angle_mHCH=116.92\pm0.69$,

$\theta_0=22.34\pm0.46$, $\theta_s=21.99\pm0.11$, $\theta_m=21.63\pm0.48$ in units of Å and degrees; θ represents the angle of the H_2C plane to the CC bond. The indicated error limits are 2.5 times the variances.

Ethylene oxide is one of the molecules for which bent bonds can be expected.[1] Cunningham *et al.* first investigated the r_0 structure on the basis of the microwave spectra of several isotopic species and showed both C-C and C-O distances were considerably different from those in aliphatic hydrocarbons and ethers.[2] Turner and Howe carried out a computer calculation of the r_0 structure which uses the rotational constants obtained by Cunningham *et al.* to improve the structural parameters:[3]

The rotational spectra of ethylene oxide in the ground and excited vibrational states were observed in the present study in order to get further information on the molecular structure and the vibrational modes. The present paper will report on the microwave spectra of ten isotopic species in their ground vibrational states. The rotational and centrifugal distortion constants were determined by a least-squares fit. Effective parameters were obtained by assuming some of the centrifugal distortion constants.

The structural parameters, r_0, r_s, and r_m, were derived from the rotational constants by taking into account correlations among the rotational constants.

Experimental

The species studied in the present work are normal ethylene oxide, *cis*- and *trans*-dideutero ethylene oxide, monodeutero ethylene oxide, and the ^{13}C- and ^{18}O-substituted species. Normal ethylene oxide was purchased from the Matheson Co., the *cis*- and *trans*-dideutero species were provided by Mr. Masahiro Kawasaki of the Tokyo Institute of Technology, monodeutero ethylene oxide was present in the dideutero species as an impurity, and the ^{13}C- and ^{18}O-isotopic species were used in their natural abundance.

The microwave spectrum was observed using a conventional Stark modulation spectrometer with a waveguide cell cooled with dry ice. Since the vibrational frequencies are higher than 600 cm^{-1}, the rotational spectra of ^{13}C- and ^{18}O-species were assigned by comparing the change in spectral intensity at room temperature and at the temperature of dry ice. The observed frequencies and their assignments are listed in Table 1.

Analysis of Data

Since the analysis showed effects of centrifugal distortion of as much as 30 MHz for the $J=8$—8 transition of normal ethylene oxide, a least-squares fit including centrifugal distortion to the first order was carried out.

The parameters describing the transition frequencies are expressed as follows:[4]

$$\begin{aligned} A' &= A - \hbar^4(3\tau_{bcbc}-2\tau_{acac}-2\tau_{abab})/4, \\ B' &= B - \hbar^4(3\tau_{acac}-2\tau_{abab}-2\tau_{bcbc})/4, \\ C' &= C - \hbar^4(3\tau_{abab}-2\tau_{bcbc}-2\tau_{acac})/4, \\ \tau'_{aaaa} &= \hbar^4\tau_{aaaa}, \\ \tau'_{aa\beta\beta} &= \hbar^4(\tau_{aa\beta\beta}+2\tau_{aa\beta\beta}), \quad (\alpha\neq\beta) \end{aligned} \tag{1}$$

where α and β stand for a, b, or c. As has been pointed out by Watson,[5] when the centrifugal distortion is treated by the first-order perturbation, at most eight parameters (three effective rotational constants, τ'_{aaaa}, τ'_{bbbb}, τ'_{cccc}, and the two linear combinations of τ'_{aabb}, τ'_{bbcc}, and τ'_{aacc}) can be experimentally determined. A detailed analysis of the correlation among the parameters showed that the observed spectra contained sufficient information to determine only four centrifugal terms with statistical significance. Since τ'_{aacc} and τ'_{bbcc} were estimated to be indistinguishable from zero by preliminary calculations where one of the two parameters was put equal to zero to give the other the stated value, they were both tentatively set equal to zero in the present analysis. The same situations were encountered in all the isotopes. Table 2 lists the converged values of the parameters.*

* The listed values should be understood as effective ones which are enough to account for the frequencies listed in Table 1. Systematic errors can be introduced from the assumption that $\tau'_{aacc}=\tau'_{bbcc}=0$, the shortages in observation of high-J transitions and R-type transitions, and perhaps even from the lack of transitions of the a- or c-type. A preliminary analysis of the millimeter-wave spectrum of normal species indicates that the inclusion of high-J transitions gives τ'_{cccc} a negative value, as is expected from the theory of centrifugal distortion.

Table 1. Observed frequencies and their deviations from calculated frequencies (in MHz)

a) Values marked by * and + agree essentially with previous measurements in Ref. 2 and in R. J. Myers and W. D. Gwinn, cited in NBS Monograph 70 "Microwave Spectral Tables", Vol. IV, p. 197 (1968) issued by U. S. Department of Commerce respectively. One of the latter values for 8_{53}—8_{44} of *cis*-$^{12}C_2H_2D_2{}^{16}O$ seems to be a typographical error. b) Correction due to centrifugal distortion. c) $\Delta=\nu$(obsd)$-\nu$(calcd), where ν(calc)'s are obtained by use of the parameters given in Table 2.

Within the quoted uncertainties, we can assert that the values of A', B', and C' are equal to those of A, B, and C respectively. The B values for the ^{16}O- and ^{18}O-species have appreciable differences both in the normal and the *trans*-dideutero species. Since the oxygen atom is on the b axis, this is due to the effect of zero-point vibration. The correlation matrix for the rotational constants has appreciable off-diagonal elements.** These correlations were taken into account when these rotational constants were used in the calculation of the structural parameters.[6]

Calculation of Structurel Parameters

By the use of the rotational constants of the ten isotopic molecules, it was possible to apply the method of r_s(Costain)[7] and r_m(Watson).[8] Since the rotational constants are indirect observations,[6,9] nondiagonal weight matrices, which took correlations into account, were used in the calculation.

Equation (1) shows that the values of $\tau_{\alpha\beta\alpha\beta}$'s are needed to obtain the rotational constants, whereas only a combination of $\tau_{\alpha\alpha\beta\beta}$ and $\tau_{\alpha\beta\alpha\beta}$ is determined when the centrifugal distortion is treated to the first order. However, as the $\tau_{\alpha\beta\alpha\beta}$'s are expected to be small and as their isotopic differences are even smaller, the effective rotational constants, A', B', and C', were used without corrections for the calculation of the structural parameters.***

Because of the C_{2v} symmetry, there are four independent structural parameters to be determined.

The r_0 Structure. The r_0 structure was derived by a least-squares fitting of all the observed rotational constants. The weight matrix, **W**, was calculated as:

$$\mathbf{W}=\begin{pmatrix}\mathbf{D}_1^{-1} & & & \\ & \mathbf{D}_2^{-1} & & \mathbf{0} \\ & & \ddots & \\ & \mathbf{0} & & \mathbf{D}_{10}^{-1}\end{pmatrix} \quad (2)$$

where the suffixes are for each isotopic species and where

** For example, suppose that 1_{10}—1_{01}, 1_{11}—0_{00}, and 2_{12}—1_{01} transitions are observed with equal accuracy. In the rigid rotor approximation, their frequencies are $A-C$, $A+C$, and $A+3C$ respectively. The correlation factor between A and C is calculated to be −0.5222.

*** The rotational constants corrected for $\tau_{\alpha\beta\alpha\beta}$ and their isotopic differences should be used for the calculation of the r_0 and r_s structures respectively, if we were to be in strict accordance with the original definitions. Thus, the structures derived in the present study contain systematic errors introduced by the neglect of the corrections, but they may be assumed to be within the reliability intervals of the structural parameters.

a) Both τ'_{bbcc} and τ'_{aacc} are assumed to be zero. b) Variance of parameter. 2.5 times v_i indicates a reliability intervals of the corresponding parameter. c) The standard deviation of transition frequencies is represented by σ.

$\mathbf{D}_i^{-1}$ are the 3×3 submatrices corresponding to the rotational constants A, B, and C. The method for estimating this weight matrix has been described in a separate paper.[6]

The bond length, r_0(CH), was assumed to be longer than r_0(CD) by about 0.002 Å.[10] In order to verify this difference, four parameter sets were investigated; besides r(CO) and r(CC) and the angle, θ, between H_2C plane and CC bond, which were taken as variables, the following assumptions were made for r(CD), ∠HCH, and ∠DCH:

Set 1) $r(CH)=r(CD)$, $\angle HCH=\angle DCH$,

Set 2) $r(CH)\neq r(CD)$, $\angle HCH=\angle DCH$,

Set 3) $r(CH)=r(CD)$, $\angle HCH\neq\angle DCH$, and

Set 4) $r(CH)\neq r(CD)$, $\angle HCH\neq\angle DCH$.

The analysis led to the following conclusions: a) The most proper set of parameters in the r_0 structure is set 1, since higher correlations emerge among the parameters in the other sets, and b) the isotope effects on r_0(CH) and ∠HCH cannot be detected. The resulting parameters, summarized in Table 4, agree with those reported in previous papers.[2,3]

The r_s Structure Obtained from Kraitchman's Formula. The structure of ethylene oxide was derived from the conventional Kraitchman method;[11] the coordinates of each atom were first calculated by solving an equation

in a matrix form as:

$$\begin{bmatrix} P_{aa}P_{ab}P_{ac} \\ P_{ba}P_{bb}P_{bc} \\ P_{ca}P_{cb}P_{cc} \end{bmatrix} = \mu \begin{bmatrix} P_{ab}P_{ac} & P_{ac}P_{aa} & P_{aa}P_{ab} \\ P_{bb}P_{dc} & P_{bc}P_{ba} & P_{ca}P_{bb} \\ P_{cb}P_{cc} & P_{cc}P_{ca} & P_{ca}P_{cb} \end{bmatrix} \cdot \begin{bmatrix} a_s^2 \\ b_s^2 \\ c_s^2 \end{bmatrix} \quad (3)$$

where:

$$P_{\alpha\beta} = P_\alpha' - P_\beta, \quad (4)$$

$$P_\alpha = (-I_\alpha + I_\beta + I_\gamma)/2, \quad (5a)$$

$$P_\alpha' = (-I_\alpha' + I_\beta' + I_\gamma')/2, \quad (5b)$$

$(\alpha, \beta, \gamma = \text{a, b, or c})$

and

$$\mu = M\Delta m/(M+\Delta m).$$

The I_a, I_b, I_c quatities are the principal moments of inertia of one of the reference species (normal, *trans*-D_2 and *cis*-D_2- ethylene oxide), and the primed quantities, I_a'"s, are the principal moments of inertia of one of the species in which one of the atoms in the reference molecule is replaced by an isotope. M is the molecular weight of the reference species, Δm is the change in the molecular weight caused by the isotopic substitution, and a_s, b_s, and c_s are the coordinates of the substituted atom referred to the principal axis system of the reference species.

A direct substitution of the observed values into Eq. (3) gave imaginary values to those coordinates which are expected to be equal to or close to zero. Hence, the following conditions were imposed: 1) The values of P_a' for the ^{18}O species of normal, *trans*-D_2-, and *cis*-D_2- ethylene oxides were set equal to P_a. The observed values of $P_a'-P_a$ were taken into account in the error analysis of the results by the use of the law of the propagation of errors.[6] 2) The values of P_c' for the ^{18}O species of the normal and the *trans*-D_2-ethylene oxide were set equal to P_c, with the observed values of $P_c'-P_c$ treated in the same manner as $P_a'-P_a$.

The calculations were carried out for the sets of isotopic species (the normal ^{18}O-, ^{13}C-, and D_1-ethylene oxides), *trans*-D_2-, *trans*-D_2-^{18}O-, *trans*-D_2-^{13}C-, and D_1-ethylene oxides), and (*cis*-D_2-, *cis*-D_2-^{18}O-, *cis*-D_2-^{13}C-, and D_1-ethylene oxides), taking the first species in each set as the reference molecule. The principal axis coordinates of the O, C, and H atoms for the normal *trans*-D_2-, and *cis*-D_2- species thus calculated are shown in Table 3. The coordinates of the H atoms in the deuteroethylene oxides which are not replaced by D could not be determined by the present method; even the use of the first-moment equation provided only the b and c coordinates of the hydrogen atoms in the *cis*-D_2 molecule. The values thus derived are shown in parentheses in Table 3. The remaining coordinates, the a and c coordinates of the *trans*-D_2 and the c coordinates of the *cis*-D_2 species, could not be obtained by the first-moment equation or by setting the cross products of inertia at zero. The structural parameters calculated from the coordinates are also summarized in Table 3, along with their estimated error limits. The r_s(CH) derived for the normal species is longer than that for the dideutero species by about 0.003 Å, but they overlap in their reliability intervals.

∠HCH	116.50(43)	—	—
θ[b]	21.59(28)	—	—
∠OCC	59.21(13)	59.21(13)	59.18(11)

a) Coordinates and bond lengths are in Å and angles are in degreees with reliability intervals indicated in parentheses. b) Rotational constants of the D_1 species species were used to derive the coordinates of the H or D atoms. c) Calculated by the first moment equation. d) Angle of the C-C bond to the H_2C plane.

The value of c_s(C) of the *trans*-D_2 species combined with the r(CC) indicates that the principal axis system of the species is obtained by the rotation of 7.15° around the b-axis, following the displacement of the origin of that of the normal species. For the *cis*-D_2-species, the rotation angle of 4.25° around the a-aixs is derived from the c_s(C), c_s(O), r(CC), and r(CO) values. A μ_s value of 0.14 D can be expected for the latter species if one assumes that the total dipole moment of 1.88 D of the normal species is unchanged and lies along the symmetry axis of the ring.

The r_s Structure Derived by a Least-squares Fit. The r_s parameters were also derived from a least-squares fit of the changes caused by isotope substitutions in the principal moments of inertia. The analysis was based on either a diagonal or a nondiagonal weight matrix.[6] The converged parameters were not significantly different, but the correlation factors obtained for a nondiagonal weight matrix were somewhat smaller. This tendency is contrary to that observed for the r_0 structure. The parameters derived from the non-diagonal weight matrix are shown in Table 4. Strong correlations were observed between r_s(CH) and r_s(CD) and between $\angle_s$HCH and $\angle_s$DCH, but the other parameters were not affected. No significant differences were observed between r_s(CH) and r_s(CD) or between $\angle_s$HCH and $\angle_s$DCH.

The r_m Structure. The r_m structure was derived from an approximate equation: $I_e = 2I_s - I_0$ as proposed by Watson for estimating the equilibrium structure.[8] He pointed out that one of the disadvantages of the r_m structure is that the equation is not sufficiently

Table 4. Structural parameters of ethylene oxide[a,e]

accurate for the hydrogen-deuterium isotope effects.

The calculation of the r_m structure followed the derivation of the r_0 structure, with I_0 replaced by $I_m = 2I_s - I_0$. The weight matrix used in the derivation of the r_0 structure was used. Typical r_m parameters obtained with a nondiagonal weight matrix are listed in Table 4.

Discussion

In calculating the structural parameters, the rotational constants were treated as indirect observations. In other words, the rotational constants were derived by a least-squares fit of directly-observed transition frequencies. The correlations found among the rotational constants were accounted for by the use of nondiagonal weight matrices. The use of a nondiagonal weight matrix for the analysis of mutually-correlated data was first done by Morino *et al.* in their study of gas-phase electron diffraction.[9] As Kirchhoff suggested,[12] similar situations are often encountered in microwave spectroscopy. The present study is an application of this method with a slight modification (see Ref. 6 for details). A comparison of the present results with those derived assuming a mutual independence of rotational constants led to the following conclusions:

a) The parameters converged to slightly different values, although the reliability intervals estimated from a 2.5-fold variance covered the differences.

b) The correlation factors among the parameters were also different.

c) No general statement can be made as to whether a conventional use of a diagonal weight in the calculation gives smaller variances and less correlations than that of a nondiagonal weight.

The r_s structure derived from Kraitchman's method is consistent with that derived statistically within the estimated error limits (Tables 3 and 4). Therefore, the apparent isotopic differences in the parameters obtained by Kraitchman's formula (Table 3) are artifacts, as has been indicated by the present statistical analysis.

A comparison of the structural parameters of three-membered ring compounds is presented in Table 5. The CX bond lengths of these compounds are compared with those of $(CH_3)_2X$ in Table 6. The CC bond length in $(CH_3)_2CH_2$ is reported to be 1.526± 0.002 Å.[13] An inspection of Tables 5 and 6 shows that, in three-membered rings of the $H_2C\text{-}X\text{-}CH_2$ type, the CC length is shortened for X=O, S, NH, PH, and SO, whereas the CX lengths are longer than their typical values by about 0.02 Å. The angles, φ, of the H_2C plane to the line bisecting the CCX plane are significantly different from zero. Since φ is expected to be equal or very close to zero in normal chemical bonds, the departure from zero in the three-membered rings is an indication of strain in the bonding.

The author is grateful to Professor Kunio Kozima for his help and encouragement and to Mr. Masahiro Kawasaki, whose sample of dideuteroethylene oxides were vital in the present study. Grateful acknowledgements also go to Professor Yonezo Morino, Professor Kozo Kuchitsu, Dr. Takeshi Oka, and Dr. Charles D. LeCroix for their helpful comments on the manuscript.

Chemical Behavior of Intermediates Produced in Sulfuric Acid Glass by Gamma Irradiation. II. Yield of Trapped Hydrogen Atoms in the System Containing Metallic Ions

Teikichi SASAKI

Chemistry Division, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken 319-11

(Received May 24, 1973)

The yield of trapped hydrogen atoms, H_t, in gamma-irradiated sulfuric acid glass is remarkably increased by adding a small amount, 10^{-2} M, of metallic ions. The increase is followed with a slow decrease at the higher solute concentrations. The efficiency of the formation depends on the kind of cationic solute. The largest $G(H_t)$ is observed in a system containing Co^{2+} ions; it amounts to 8.7. These findings can be explained by a mechanism in which not only mobile electrons produced by the initial ionic processes, but also excited states of the matrix molecule, contribute to the H_t formation. The excitation energy is transferred from the matrix molecule to the solute, which consequently undergoes ionization; the resulting electron causes the H_t formation. This mechanism seems to be supported by the observation that the yield of H_t increases with a decrease in the charge-transfer energy of the solute in the rigid matrix.

The photochemical production of hydrogen atom in an aqueous acidic solution containing Fe^{2+} ions was first found by Weiss *et al.*[1] Afterwards, it was proposed that its primary process is the formation of an excited state of the Fe^{2+} ion, from which an electron is transferred to the water molecule of the surrounding hydration shell.[2,3] This explanation was also given for the photochemical reaction in other frozen solutions.[3,4]

On the other hand, it has been considered that H_t in the gamma-irradiated acidic frozen solution is produced only through ionic processes. In their spectrophotometric study of irradiated glasses containing transition metals, Brown and Dainton[5] have found that some kinds of solutes are reduced according to:

$$M^{n+} + e_m^- \longrightarrow M^{(n-1)+} \qquad (1)$$

where $M^{n+}=Mn^{2+}$, Ni^{2+} *etc.* Since the mobile electron is considered to be a precursor of H_t in the acidic matrix, a decrease in the H_t yield can be anticipated for these systems containing cationic solutes.

In the present systematic study, however, a remarkable increase in the H_t yield was observed only upon the addition of a small amount of the transition-metal ion to the sulfuric acid glass. The yield curves always have maxima and their trends are analogous to those obtained photochemically by Moorthy and Weiss.[3] The largest G value amounts to 8.7, which is much larger than the value reported for H_t formation through ionic processes in the pure matrix: $G(H_t)\simeq 1.2$.[6] Although the primary processes are somewhat different from those in the photochemical production, excited states of the water molecule seem to play an important role in the formation. In the gamma irradiation, a secondary electron excites the matrix molecule during the slowing-down processes. Then an excitation energy seems to be transferred from the molecule to the solute, which consequently undergoes ionization.

Experimental

Sample Preparation. The water was redistilled. The sulfuric acid and all the chemicals from the Kanto Kagaku Co., Ltd. were of an analytical reagent grade. A small amount of cationic sulfate was added to an aqueous solution of 6 M sulfuric acid, after which the solution was cooled to 77 K.

The samples for ESR measurements were prepared as has previously been described.[7] On the other hand, the samples for gas-chromatographic analysis were degassed and then sealed in Pyrex cells with breakable seals. The sample volume was constantly 10 ml.

Irradiation and Measurement. The gamma irradiations were carried out by means of a 45 kCi ^{60}Co source at the dose rate of 6.4×10^{18} eV g^{-1} hr^{-1}. The dose absorbed was determined by Fricke dosimetry. The sample was usually exposed in the dark at 77 K for one hr.

The ESR spectra were obtained with an X-band Hitachi 771-type spectrometer equipped with 100 kHz modulator and were scanned without power saturation. The absolute H_t yields were determined by comparison with the signal intensity of a calibrated amount of the DPPH radical in a tetrahyrdofuran solution frozen at 77 K. The relative H_t yields were obtained from the signal intensity of the higher field. The SO_4^- yield was relatively determined from the signal height in the central part of the spectrum where its anisotropic singlet appeared. For the measurements of the H_2 yield, the irradiated sample was melted and the H_2 gas was recovered with a Toepler pump. The gas analyses were performed with a Yanagimoto G-8-type gas chromatograph, and the yield was determined absolutely by comparison with a standard volume of pure H_2 gas.

Results

The bright brown color due to the SO_4^- radical was not observed for the irradiated samples containing a large amount of the cationic solute.

The ESR spectrum of the irradiated sulfuric acid glass consisted of a doublet splitting by 510 G and a singlet centered at 3288 G. These have been ascribed to the H_t and SO_4^- radicals respectively.[8] A power saturation of the H_t signal in the samples containing a paramagnetic cation was observed to begin at approximately 3×10^{-2} mW. This observation agrees with the results obtained previously for H_t power saturations in the sulfuric acid glasses.[9] The intensity ratios of the low-field line to the high-field line in the H_t signal were measured for the following systems; 6M sulfuric acid glass and the glasses containing the 0.04 M Co^{2+} ion and the 0.5 M Co^{2+} ion. For all

●: Ni^{2+}, ⊙: Fe^{2+}

the above systems, the ratios were 1.1 ± 0.1 under the microwave power employed.

The addition of the Ni^{2+} ion resulted in an abrupt increase in the H_t yield, as is shown in Fig. 1(b). As the intense H_t signal declines in the presence of a strong electron scavenger, TeO_4^{2-}, as may be seen in Fig. 1(c), it is considered that a mobile electron contributes to a reaction of the H_t formation. On the other hand, the SO_4^- yield decreases upon the addition of the cationic solute. The details for the systems containing Fe^{2+} and Ni^{2+} ions are shown in Fig. 2. For the other systems, it was difficult to obtain analogous scavenger

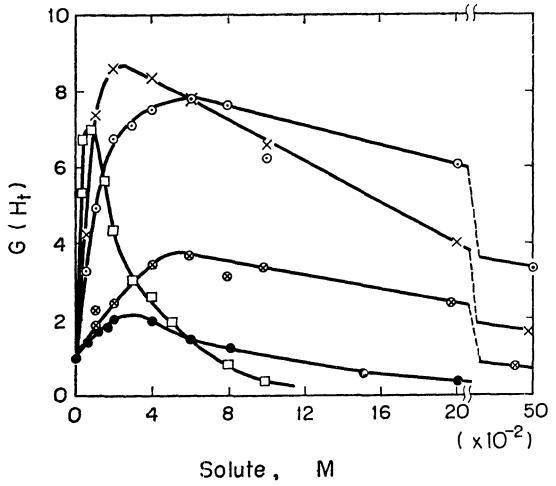

Fig. 3. $G(H_t)$ for the 6 M sulfuric acid glass containing various kinds of cationic solute.

Table 1. Maximum $G(H_t)$ in 6M sulfuric acid glass containing various kinds of cationic solute

Solute	Max. $G(H_t)$	Solute concentration $\times10^{-2}$ M
none	1.0	—
VO^{2+}	2.1	2.5
Ni^{2+}	3.7	5.5
Fe^{2+}	7.8	6.0
Co^{2+}	8.7	2.5
Mn^{2+}	6.5	0.8

curves because of the complexity in the central part of the ESR spectra. The decrease in the SO_4^- yield has been also previously observed for the system containing the Fe^{2+} ion and ascribed to a hole scavenging by the solute.[10] The present monotonous decreases suggest that the G value for initial ionic processes is almost constant, even in the presence of the solutes.

Figure 3 shows the curves of the H_t yield in the systems containing the cationic solute. The curves have two principal characteristics. The first is a remarkable increase in the H_t yields, followed by a slow decrease. Especially in the system containing the Co^{2+} ion, the maximum G value amounts to 8.7, which is much larger than yield of H_t in the pure matrix ($G(H_t)=1.0$). At the higher solute concentration, the $G(H_t)$ becomes less than 1.0 because of Reaction (1). It is noteworthy that these cationic solutes can scavenge mobile electrons as well as positive holes. The second is that the slope of the increasing curve and the maximum H_t concentration depend on a kind of solute. The maximum $G(H_t)$ are summarized in Table 1, together with the solute concentrations. In all the systems, the G value reaches its maximum at the solute concentrations of 0.8×10^{-2}—6×10^{-2} M.

The decreases at the higher solute concentrations suggest that the excited states of the solute also participate in the H_t formation, as has been observed in the photochemical production.[3] To confirm this presumption the second solute effect on the H_t formation

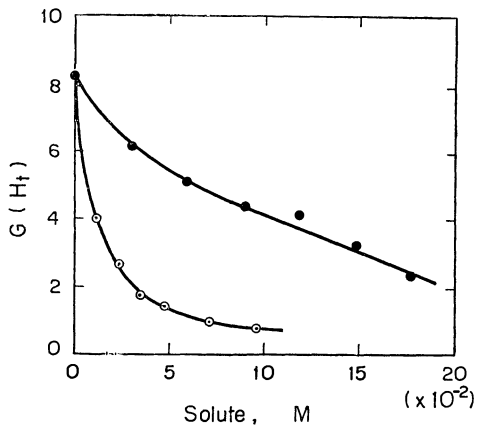

Fig. 4. Second solute effect on the H_t formation in the 6 M sulfuric acid glass containing 4×10^{-2} Co^{2+} ion. ●: Ni^{2+}, ⊙: TeO_4^{2-}

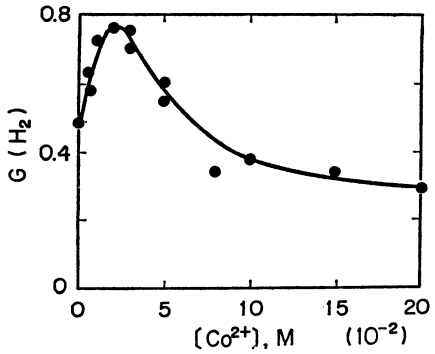

Fig. 5. $G(H_2)$ values determined after melting the irradiated 6 M sulfuric acid glass containing Co^{2+} ion.

was studied. Monotonous decreases in the H_t yield with an increase in the solute concentration were observed; the results are shown in Fig. 4. The depression of the H_t formation seems to be easily attained by the addition of the TeO_4^{2-} ion, which acts not only as an electron scavenger but also probably as a quencher for excited states of the Co^{2+} ion.

The $G(H_2)$ value for the pure matrix was determined to be 0.48 which is almost a half of the H_t yield. The H_2 yield for the system containing the Co^{2+} ion is shown in Fig. 5. Although the yield increases about 1.5 times upon the addition of 2.5×10^{-2} M of the Co^{2+} ion, the absolute value is incompatible with the results of the H_t yield. This discrepancy may arise from the complex reactions during the melting procedures.

Discussion

The primary processes in the radiation effects on matter are ionization and the formation of various excited states of the matrix molecule:

$$S \longrightarrow S^+ + e^- \text{ (or } e_m^-) \quad (2)$$

$$S \longrightarrow S^* \quad (3)$$

According to the following reactions, the mobile electron in the 6 M sulfuric acid glass produces H_t at almost the same rates:[7,11]

$$e_m^- + H^+ \longrightarrow H\ (\rightarrow H_t) \quad (4)$$

$$e_m^- + HSO_4^- \longrightarrow H\ (\rightarrow H_t) + SO_4^{2-} \quad (5)$$

Assuming that H in the acidic glasses is produced only through Reactions (4) and (5), the yield could not exceed $G\simeq4$, which is the ultimate yield of the ionic processes in the aqueous solution at 293 K.[12]

On the other hand, the behavior of the excited states of the water molecule in an aqueous solution is scarcely known, while triplet formation through energy transfer from the excited matrix molecule to the solute have been observed in several organic systems[13] and energy-transfer processes in scintillator systems have been well established.[14] In the liquid water, the probability of energy transfer from the excited states to the solute would be very small, because the excited singlets are quenched in the time of a single vibration, 10^{-13} s, and the excited triplets are unknown.[15] However, in the vapor phase, isotope exchange experiments gave $G\simeq12$ for the total activated water[16] and $G\simeq8$ for the total H-atom formation.[17] Moreover, in the frozen system of an ethylene glycol-water mixture containing a small amount of triptophane, Steen has obtained $G\simeq10$ for the total light emission from its singlet and triplet states.[18] Because the $G(e_t^-)$ has been determined to be approximately 3,[19] the last observation indicates that an excitation energy is efficiently transferred from the excited matrix molecule to the solute. Moorthy *et al.*[3] have elucidated that the excited states of the solute bring about the H_t production by exposing an acidic frozen solution containing the Fe^{2+} ion or the I^- ion to 2537 Å light. In these cases, the H_t yield increases with an increase in the solute concentration and reaches maximum at $[I^-]\simeq0.01$ M for the polycrystalline specimen and at $[Fe^{2+}]\simeq0.2$ M for the glassy specimen. For these observation, a mechanism was proposed that a primary process is a direct excitation of the solute, followed by electron detachment from the excited state, which causes the H_t production by means of Reactions (4) and (5).

As regards the present results, it seems impossible to interpret the large $G(H_t)$ on the basis of the ionic processes alone. Though more direct evidence on the reaction processes is necessary, the following mechanism would, however, account for the yield curves in Fig. 3.

In the present systems, it may be considered that the excitation energy of the matrix molecule is efficiently transferred to the solute, which is consequently excited to its metastable states. The energy of the lowest electronic excited state of the isolated water molecule is *ca.* 7.5 eV, while its ionization energy is 12.6 eV.[20] On the other hand, as regards the solute, *e.g.*, the Fe^{2+} ion, the lowest charge-transfer energy in the rigid matrix is 4.7 eV.[21] These data indicate that the excited states of the water molecule can be converted to those of the Fe^{2+} ion. Hydration ligands surrounding the Fe^{2+} ion and hydrogen bondings probably facilitate energy transfer:

$$S^* + Fe^{2+} \longrightarrow S + Fe^{2+*} \quad (6)$$

Because the energy transferred exceeds its ionization energy, the Fe^{2+*} ion undergoes ionization or, in some cases, is competitively deactivated by light emissions

and radiationless transitions:

$$Fe^{2+*} \longrightarrow Fe^{3+} + e^- \text{ (or } e_m^-) \quad (7)$$

$$Fe^{2+*} \longrightarrow Fe^{2+} \quad (8)$$

The resulting mobile electron is converted to H_t through Reactions (4) and (5). There is no difference in the physicochemical properties of the mobile electrons formed through the two reactions, (2) and (7).

At lower solute concentrations the mechanism described above predicts the promotion of the H_t formation with a decrease in the ionization energy of the solute. As is listed in Table 2, the initial increase in the rate of the H_t formation, *i.e.*, $dG(H_t)/d[S]$ is closely related to the decline in the charge transfer energy, E_{ct}, of the solute. Especially, the excitation energy is most efficiently utilized for the H_t formation in the system containing the Co^{2+} ion, and the maximum $G(H_t)$ amounts to 8.7.

Table 2. Efficiencies of the H_t formation in the sulfuric acid glass containing cationic solute

Solute	$dG(H_t)/d[S]$[a] $\times 10^{-2}\,M^{-1}$	E_{ct}[b] eV	Ref.
VO^{2+}	0.68	5.2	22)
Ni^{2+}	0.85	5.2	23)
Fe^{2+}	3.9	4.7	21)
Co^{2+}	6.5	4.6	24)
Mn^{2+}	17.1	4.5	23)

a) The values were taken from the initial slopes in Fig. 3.
b) E_{ct} denotes an absorption edge of charge transfer band in the optical spectrum and was taken from the UV spectrum in the rigid matrix.

On the other hand, the decrease in the H yield at higher solute concentrations must be due to Reaction (1) and the deactivation of the excited states. The latter process may be caused by a resonance energy transfer between the excited and the ground states of the solute, as is found in the system of the liquid scintillator.[25]

Here, it is worthwhile to interpret on the basis of the present mechanism the results obtained at 77 K by Dainton *et al.*[5] They have observed the hyper-reduced ion in the gamma-irradiated sulfuric acid glasses containing transition-metal ions. The solute concentrations were 0.12 M Mn^{2+} and 0.5 M Ni^{2+} ions where the $G(H_t)$ were less than 1.0, as is seen in Fig. 3. Therefore, the observations may be attributed to a predominant contribution from Reaction (1). On the contrary, they could not observe the reduced form in the system containing the 0.01 M Fe^{2+} ion. This may be due not only to the hole scavenging by the solute, but also to the predominance of Reaction (7) over the competitive reaction (1) at that solute concentration where $G(H_t)$ amounts to 5.0. This presumption is also consistent with their results, which have revealed the absence of the reduced species.

The author is grateful to Dr. Shin-ichi Ohno for his helpful discussions and encouragement. He also wishes to thank Dr. Akihisa Sakumoto for his making available the gas chromatograph.

Vibrational Spectra and Normal Coordinate Analysis of Bis(methylthio)mercury

Noriko IWASAKI, Jo TOMOOKA*, and Koichi TOYODA
Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860

(Received July 23, 1973)

The IR and Raman spectra of bis(methylthio)mercury and methyl(methylthio)mercury were studied. Fundamental vibrations were assigned as follows: frequencies 698, 330, 530 and 174 cm^{-1} to C–S stretching, S–Hg stretching, C–Hg stretching and C–S–Hg bending vibrations, respectively. The fundamental vibrations were confirmed by normal coordinate analysis. The force constants of S–C and S–Hg stretching vibrations were estimated to be 2.16 and 1.5 md/Å, respectively.

Irukayama *et al.*[1] reported on the IR spectra of ethyl(methyl)mercury, bis(ethylmercury)sulfide, and bis(ethylthio)mercury in NaCl region. Since sulfur atoms greatly contribute to formation of complexes between mercury and proteins such as cystine in a living body, it seems important to find also in the biochemical field vibrational bands characteristic of S–Hg and C–Hg linkages. We have carried out spectroscopic studies on a series of alkylmercury compounds containing sulfur.

Assignment of the IR and Raman spectra of bis(methylthio)mercury $(MeS)_2Hg$ and methyl(methylthio)-mercury MeHgSMe was made in order to get information on S–Hg and C–Hg bond vibrations. Molecular structure was discussed. Bradley and Kuncher[2] determined the geometry of $(MeS)_2Hg$ by X-ray diffraction. They concluded that a skeletal S–Hg–S bond was linear in form and methyl groups at both ends were oriented in *trans* around S–Hg–S bond, but the conformations of hydrogens could not be determined. We have confirmed the assignment by normal coordinate analysis.

Experiment

$(MeS)_2Hg$ and MeHgSMe were prepared by the methods of Wertheim[3] and Kondo,[4] respectively. The mp and IR spectra were in good agreement with those given by them.

Instruments used for IR measurements were a JASCO-DS 403G grating infrared spectrophotometer from 4000 to 250 cm^{-1} and a FIS-3 Hitachi far infrared spectrophotometer from 400 to 30 cm^{-1}. IR spectra of $(MeS)_2Hg$ were measured by the KBr disk method in the region 4000—400 cm^{-1} and Nujol method in the far IR region. Raman spectrum was measured in powder state. Measurements of IR and Raman spectra of MeHgSMe were carried out in liquid state(mp 25 °C).

Assignment

Band assignments were made by comparing the spectra of $(MeS)_2Hg$ with those of MeHgSMe and Me_2Hg. It was assumed that the structure of MeHgSMe belongs to the C_s point group. Assignment of Me_2Hg was made in reference to Gutowsky's investigation.[7] The vibrational modes of Me group and the remaining skeleton were discussed. Observed vibrational spectra are shown in Figs. 1—5.

Methyl Group Fundamental Frequencies. Assignment of degenerate and symmetric stretching frequencies of Me group is straightforward. It is well-known that the bands of Me group deformation vibrations occur near 1400, 1300 and 1000 cm^{-1}. It can be predicted that the bands observed for both $(MeS)_2Hg$ and MeHgSMe are due to the Me group attached to sulfur atom (Me–S) and those for both MeHgSMe and Me_2Hg are due to the Me group attached to mercury atom (Me–Hg).

The frequencies of 1422, 1313 and 952 cm^{-1} in $(MeS)_2Hg$ were thus assigned to degenerate deformation, symmetric deformation and rocking vibrations of the former, respectively. The frequencies are in good correspondence with the frequencies 1432, 1307 and 950 cm^{-1} in dimethyldisulfide[5] and 1432, 1322 and 964 cm^{-1} in methylmercaptane.[6] Similarly, IR bands at 1404, 1177 and 768 cm^{-1} in MeHgSMe were assigned to the deformation vibrations of the latter. The splitting was observed at the symmetric deformation band of Me–S in $(MeS)_2Hg$ as in Me_2GeO, the reason not being known.

Skeletal Fundamental Frequencies. The band at 698 cm^{-1} in $(MeS)_2Hg$ and MeHgSMe can be assigned to C–S stretching vibration.

Gutowsky[7] suggested that C–Hg stretching frequency was 550 cm^{-1} in IR and 515 cm^{-1} in Raman spectra of Me_2Hg. Goggin and Woodward[8] also observed C–Hg stretching bands at 538—546 cm^{-1} and Cl–Hg stretching band at 313 cm^{-1} in IR spectra of MeHgX (X=Cl, Br and I). The results indicate that S–Hg stretching bands might appear in the range 500—200 cm^{-1}. Strong bands are observed near 330 cm^{-1} for $(MeS)_2Hg$ and MeHgSMe but not Me_2Hg. $(MeS)_2Hg$ exhibits anti-symmetric(B_u) and symmetric(A_g) stretching vibrations of S–Hg–S bond at 338 cm^{-1} in IR and 295 cm^{-1} in Raman spectra. The weak bands at 336 cm^{-1} in Raman and 302 cm^{-1} in IR seem to be essentially forbidden, since their frequencies are very close to the allowed ones.

Similarly the IR absorption band at 198 cm^{-1} and Raman shift of 175 cm^{-1} in $(MeS)_2Hg$ are assigned to anti-symmetric(B_u) and symmetric(A_g) C–S–Hg bending vibrations, respectively. In the region below 150 cm^{-1}, frequencies 126 and 95 cm^{-1} (Fig. 2) are regarded to be the fundamental bands of S–Hg–S bending vibrations(A_u and B_u), since their combinations are most consistent with the observed values 1077 and 1047 cm^{-1}. It is assumed that the Raman shifts of 65, 38 and 29 cm^{-1} (Fig. 3) are assigned to the torsional vibration of methyl group around S–Hg–S axis or lattice vibrations.

Results and Discussion

Normal coordinate treatment for $(MeS)_2Hg$ was performed using the molecular geometry shown in Fig. 6 (C_{2h}). Normal vibrations of species constitute

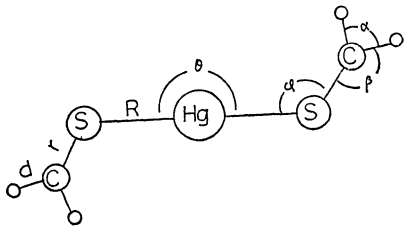

Fig. 6. Molecular geometry of $(CH_3S)_2Hg$ (C_{2h}).

$8A_g+6A_u+4B_g+9B_u$. Molecular parameters of skeleton were taken from results of X-ray diffraction.[2] The methyl group was regarded to be tetrahedral.[10] Thus, bond distances(Å): Hg–S, 2.36; S–C 1.70; C–H 1.09, bond angles(degree): S–Hg–S 180; Hg–S–C 111; S–C–H 109.5; H–C–H 109.5.

The internal rotations of Me groups and the torsional vibrations about S–Hg–S axis were neglected since they possessed frequencies low enough to be separated. A computer program by Shimanouchi[11] and modified for this work was used for carrying out the numerical calculations with the GF matrix method. The potential function employed was based on a modified Urey-Bradley force field. It was necessary to introduce an intramolecular tension term[12] to bring the calculated frequencies close to the observed ones. Repulsive force between non-bonded S and S atoms was ignored.

ϕ) dispersion. I) starting values; II), III) refined for A_g and B_g species; IV), V) refined for A_u and B_u species. * As in column I. ** md·Å.

At first contributions of the force constants concerned with mercury atom to the calculated frequencies were estimated. Final adjustments of all the force constants were accomplished by the Jacobian matrix.[11]

The MUBF constants given in Table 1 fall in a reasonable range, *e.g.*, for alkyl sulfide[13] K(C–S)=1.75, H(HCS)=0.17, K(C–H)=4.250, and H(HCH)=0.37 md/A.

K(Hg–S) in question is evaluated to be 1.5 md/Å. Cooney and Hall[14] measured the Raman spectra of sodium sulfide mercury Na_2HgS_2, in which only a single line was observed at 352 cm^{-1}. The data and the result of X-ray investigation suggest that the ion HgS_2^{2-} is linear in form. For a linear XYX-type molecule, the symmetric stretching frequency is approximately given by

$$\nu = 1303.16[(K+2F)/\mu N]^{1/2}$$

where K and F are stretching and repulsive force constants, respectively. Substituting 352 cm^{-1} into ν, we obtain 2.02 md/Å for the value of $K+2F$, which is slightly greater than 1.5 md/Å in Table 1.

In the Gordy rule,[15] which is simple and applicable to various molecules,

$$K_G = 1.67N(x_A x_B/d^2)^{3/4} + 0.30$$

where N is the bond order, x_A and x_B are the electronegativities of bonded atoms A and B, respectively, d is bond distance at equilibrium and K_G is the stretching force constant. Since potential energy distribution(PED) for Hg-S and S-C stretching coordinates are nearly 100% (Table 2), the evaluation of K_G(Hg–S) and K_G(S–C) was attempted, the results being 1.22 and 3.35 md/Å, respectively, for the values 1.5 and 2.17 md/Å in Table 2.

Table 2. Calculated and observed vibrational frequencies (cm^{-1})

Calcd	Obsd	Assignment
A_g species		
2978	2978	C-H asym str

2978	2978	C-H asym str
1421	1422	S-C str
948	952	Me rock
B_u species		
2977	2978	C-H asym str
2917	2917	C-H sym str
1422	1422	Me deg deform
1311	1310	Me sym deform
954	952	Me rock
698	698	S-C str
338	338	Hg-str
198	198	C-S-Hg bend
88	95	S-Hg-S in-plane bend

The calculated frequencies are in good agreement with those observed within experimental error (Table 2). Repeated calculations showed a reproducible tendency for A_g frequency to be lower than B_u for Hg–S stretching vibrations and A_u frequency higher than B_u for S–Hg–S bending vibrations. The frequency 126 cm^{-1} was thus assigned to A_u rather B_u. Ambiguity in assignment near 100 cm^{-1} region did not affect the resulting values of force constants so much.

Each PED located to one symmetry coordinate is given in Table 2. It is also possible to employ a local symmetry force field instead of MUBFF. Some normal coordinates which mix two kinds of symmetry coordinate indicate total PED exceeding 100%. This is due to negligence of the negative PED contributions or cross terms.

The selection rules indicate that methyl groups at both ends have *trans* conformation with respect to the S–Hg–S bond. Normal coordinate analysis of $(MeS)_2Hg$ was made on the basis of C_{2h} point group. Using MUBFF, K(S–Hg), H(CSHg) and H(SHgS) were evaluated to be 1.5, 0.11 and 0.122 md/Å, respectively. Separation into group vibrations was satisfactory.

This work was partly supported by a grant of the Ministry of Education of Japan. We wish to thank Prof. Tatsuo Mizayawa, Osaka University, for the use of Raman and far IR spectrometers. Thanks are also due to JASCO Co., Ltd. and JEOL Co., Ltd. for the measurement of Raman spectra, and to Mr. Fumitsugu Muraoka for his assistance. Numerical computations were carried out with FACOM 230–60 computer system of Kyushu University.

A Photo-selection Study of the Charge-transfer Phosphorescence

Takako AMANO* and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 18, 1973)

The polarization of the charge-transfer phosphorescence has been studied by the method of photo-selection. It has been measured relative to the electric vector of the excitation light corresponding to the charge-transfer band in wavelength for the complexes of tetracyanobenzene, *o*-, *m*-, and *p*-dicyanobenzenes, tetrachlorophthalic anhydride, and phthalic anhydride as electron acceptors, and methyl-substituted benzenes as electron donors, in organic glass at 77 K. It has been shown that the degree of polarization through excitation into the charge-transfer band is almost constant in the phosphorescence region, while it gradually decreases as the ionization potential of the donor increases for any of the acceptors. These observations can reasonably be interpreted in terms of a model in which the charge-transfer phosphorescence is polarized normal to the molecular plane, irrespective of the complex, and in which the change in the polarization degree of the charge-transfer phosphorescence is responsible for the change in the direction of the transition moment of the charge-transfer absorption band.

Phosphorescences of molecular complexes different from those of the constituent molecules themselves were observed by Iwata *et al.* for the complexes containing tetracyanobenzene (TCNB), phthalic anhydride (PA), tetrachlorophthalic anhydride (TCPA), and pyromellitic dianhydride as electron acceptors and methyl-substituted benzenes as electron donors.[1] These phosphorescences were ascribed to the phosphorescence from the lowest triplet state of the complex with the charge-transfer character. Hayashi *et al.* observed the ESR spectra of the phosphorescent triplet states of the TCNB, *o*-dicyanobenzene(*o*-DCNB), *m*-DCNB, and *p*-DCNB complexes and determined the contribution of the charge-transfer character in the lowest triplet states from an analysis of the observed fine structure constants.[2-4]

It seemed that it would be interesting to clarify the S-T mixing mechanism in the triplet states of these complexes. Kobayashi *et al.* studied energy-transfer processes involving the triplet states of TCNB complexes and estimated the contribution of the phosphorescence state from the phosphorescence radiative rate constant.[5] Tsujino *et al.* confirmed that the TCNB complexes in the phosphorescent state are produced directly from the excited Franck-Condon state.[6] We ourselves tried to apply the photo-selection method to the charge-transfer phosphorescence in order to obtain some information on this problem. In this paper the experimental results of the polarization of the charge-transfer phosphorescence will be presented, and the nature of the charge-transfer triplet state of these complexes and also that of the lowest excited charge-transfer singlet state will be discussed.

Experimental

The phosphorescence spectra and their polarizations were measured by means of an apparatus described previously.[7] The degree of polarization was calculated using this formula:

$$P = \frac{I_{//} - I_{\perp}}{I_{//} + I_{\perp}}$$

in which $I_{//}$ and $I_{\perp}$ refer to the intensities of the emitted light polarized parallel to and perpendicular to the exciting light respectively.

All the measurements were carried out at 77 K in an ether-isopentane(EP) (1 : 1 volume ratio) or an ethanol glass solution, the concentrations of the samples being 10^{-2}—10^{-4} M of the donor and 10^{-3}—10^{-5} M of the acceptor. The sample was transferred into a Pyrex cell, degassed, and sealed off.

The absorption spectra were measured at room temperature by a Shimadzu MPS-50L spectrophotometer.

Benzene, *p*-xylene, and mesitylene were of a reagent grade and were purified further through distillation under reduced pressure. Durene of an u.p. grade supplied by the Tokyo Kasei Co. was used without purification. Hexamethylbenzene(HMB), TCPA, PA, *o*-DCNB, *m*-DCNB, and *p*-DCNB were repeatedly recrystallized from ethanol and sublimed *in vacuo*. TCNB was prepared according to Lawton *et al.*[8] and was purified through recrystallization from ethanol several times. Ether, isopentane, and ethanol were carefully purified by modifications of methods described in a book by Kuwata.[9]

Results

The phosphorescence spectra of the TCNB-HMB complex in ethanol obtained by the excitation of the Hg 405 nm and TCNB obtained by the excitation of the Hg 313 nm line are shown in Fig. 1, together with the absorption spectra of TCNB, HMB, and the TCNB-HMB complex in an ethanol solution. Figure 2 illustrates the degree of polarization, P, of the phosphorescence of the TCNB-HMB complex analyzed at 540 nm plotted as a function of the excitation wavelength. It is shown that the polarization measured in the charge-transfer absorption region is nearly constant within the limits of experimental error. The P values of the phosphorescence excited in the local excitation region are smaller than those excited in the charge-transfer band. Figure 3 shows that the polarization degree measured by the excitations at 436, 365, and 313 nm depends upon the wavelength of the phosphorescence spectrum. It is found that the polarization is roughly constant throughout the region of the phosphorescence spectrum obtained by excitation with the charge-transfer band. It may be concluded from Figs. 2 and 3 that the degree of polarization relative to the charge-transfer band is about 0.4. This value indicates that the transition moment of the phosphorescence is nearly parallel to that of the charge-transfer

band and that the phosphorescence is, therefore, polarized mostly perpendicular to the molecular plane. Being influenced by the uncomplexed TCNB molecules and/or some other impurities, the *P* values gradually decrease in the shorter-wavelength region of the phosphorescence obtained by excitation at 365 and at 313 nm, as is shown in Fig. 3. Similar behavior of the phosphorescence polarization was also observed for all the other complexes upon excitation into the S-S transition region of the constituent molecules.

Figure 4 compares the polarization of the phosphorescences of the TCNB complexes with HMB, durene, mesitylene, *p*-xylene, and benzene in an ethanol solution relative to the excitation of the molecule to the charge-transfer band. The polarizations were found to be nearly constant throughout the phosphorescence region for any of the complexes. Furthermore, it is apparent that the degree of polarization increases as the number of the CH_3-radical of the donor increases from benzene to HMB.

Similar results were also obtained for the *o*-DCNB, *m*-DCNB, *p*-DCNB, TCPA, and PA complexes with methylated benzenes; they are shown in Figs. 5—9

respectively.

Table 1 summarizes and compares the polarization degrees of the charge-transfer phosphorescences of the complexes and the ionization potentials of the corresponding donor molecules.

Discussion

The experimental results described in the previous section are seemingly similar to those of the fluorescence polarization experiment with TCNE complexes with benzene, toluene, *p*-xylene, and *o*-xylene studied by Prochorow *et al.*[10] They interpreted the change in the polarization relative to the charge-transfer band by means of a model of a partially disoriented complex. According to this model, the P values would decrease with a decrease in the stability of a complex (with an increase in the amount of the disoriented forms). It seems inadequate to apply this model to the phosphorescence polarization, however, since the previous experimental and theoretical studies of TCNB-methyl-substituted benzene complexes show that the lowest triplet states differ considerably from each other in electronic structure, while the lowest charge-transfer singlet states of TCNE complexes, rather, resemble each other.[3]

The transition moment between the ground state, $|G\rangle$, and the lowest triplet state, $|T\rangle$, is roughly given by[11]:

$$\mu_{TG} = \frac{\langle T|H_{so}|S_k\rangle}{|E_T - E_{S_k}|}\mu_{S_kG}$$

where $|S_k\rangle$ represents the perturbing singlet state and where E_T and E_{sk} denote the energies of $|T\rangle$ and $|S_k\rangle$ respectively. No *a priori* information about the perturbing singlet state is available. The lowest

triplet state of the TCNB complex is approximately expressed as[3]:

$$|T\rangle = \alpha|^3CT\rangle + \beta|^3DA^*\rangle$$

where $|^3CT\rangle$ and $|^3DA^*\rangle$ represent the lowest charge-transfer triplet configuration and the lowest excited triplet configuration respectively, and where $|\alpha|^2+|\beta|^2=1$. For example, $|\alpha|^2$ equals 0.95 for the TCNB-HMB complex and $|\alpha|^2$ equals 0.07 for the TCNB-benzene complex.[3]

Let us extend this relation to such an extreme case as $|\alpha|^2=0$, so that the phosphorescence of an acceptor itself can be discussed along the same lines as that of its complex compound, since the position of the phosphorescence shifts towards shorter wavelengths as the donor changes from HMB to benzene, and since the phosphorescence spectrum of TCNB itself is located at a little higher energy than that of the TCNB-benzene complex. Therefore, it may be expected that the polarization of the phosphorescence derived from the locally-excited configuration is analogous to that of TCNB itself.

Along these lines, the polarization degree of the shortest wavelength band, presumably including the 0–0 band of the phosphorescence spectrum of TCNB relative to the first and second absorption bands, was measured; negative values were obtained for both bands. This indicates that the phosphorescence of TCNB is predominantly polarized perpendicular to the molecular plane. The transition borrows its intensity from the $(\sigma\pi^*)$ transition, as in the case of aromatic hydrocarbon.[11] It then follows that $|^3DA^*\rangle$ couples with $\pi\sigma^*$ or $\sigma\pi^*$ state of TCNB through spin-orbit interaction and that the transition between $|G\rangle$ and $|^3DA^*\rangle$ is polarized alomst normal to the molecular plane.

It is easily derived, as is illustrated schematically in Fig. 10, that $|^3CT\rangle$ couples with a higher charge-transfer transition from a π donor-orbital to a σ acceptor-orbital in a way similar to that in which $|^3DA^*\rangle$ couples with the $\pi\sigma^*$ transition in the acceptor as far as one-electron spin-orbit Hamiltonian is concerned. Such a higher charge-transfer transition should also be polarized along the direction connecting the donor with the acceptor nearly perpendicular to the molecular plane. If the other terms can be neglected, the polarization of the phosphorescence can be expressed as a linear combination of the polarizations of the locally-excited transition and the charge-transfer transition described above. It may, therefore, be safely concluded that the phosphorescence is polarized nearly perpendicular to the molecular plane, irrespective of the complex. The validity of this conclusion seems to be verified by the fact that the polarization degree of the TCNB-HMB complex, in which the contribution of $|^3CT\rangle$ to $|T\rangle$ is very large, is about 0.4 relative to excitation into the charge-transfer absorption band, which is polarized nearly normal to the molecular plane.

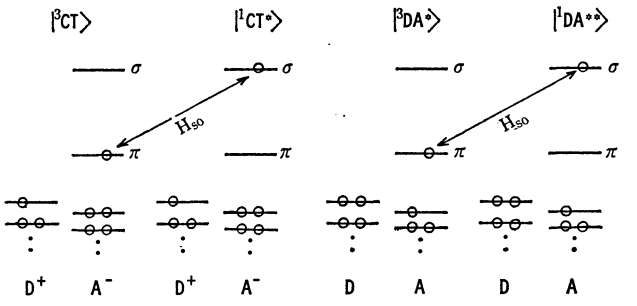

Fig. 10. Schematic diagram of one-electron spin-orbit interaction in donor-acceptor system.

It then follows that the experimental change in the values of the TCNB complexes can be determined not by the change in the phosphorescence polarization, but by the change in the transition moment of the charge-transfer absorption band. The wavefunctions of the TCNB complex in the ground and excited states are generally given by:[13]

$$\Psi_G = a^0\Phi_G + \sum b_i^0\Phi_i(D^+A^-) + \sum c_i^0\Phi_i(DA^*)$$
$$\Psi_E = a\Phi_G + \sum b_i\Phi_i(D^+A^-) + \sum c_i\Phi_i(DA^*)$$

where Ψ_G and Ψ_E represent the ground and excited state wavefunctions respectively. The transition moment is approximately expressed as:

$$\langle\Psi_G|\mu|\Psi_E\rangle \simeq \sum b_i^0 b_i\langle\Phi_i(D^+A^-)|\mu|\Phi_i(D^+A^-)\rangle + \sum (a^0c_i+c_i^0a)\langle\Phi_i(DA^*)|\mu|\Phi(DA)\rangle + \sum (a^0b_i+b_i^0a)\langle\Phi_i(D^+A^-)|\mu|\Phi(DA)\rangle.$$

In the case of TCNB complexes, $|a^0| \gg \sum|b_i^0|$, $\sum|c_i^0|$, and $|a| \ll 1$. For the sake of simplicity, we assume that $a^0=1$, $b_i^0=c_i^0=0$, and $a=0$ and that the lowest charge-transfer state mainly consists of the lowest charge-transfer singlet configuration, $\Phi(D^+A^-)$, and the lowest locally-excited singlet configuration, $\Phi(DA^*)$. The transition moment of the charge-transfer absorption band is approximately given by:

$$\mu_{S_1G} = a\mu_{CT} + b\mu_{DA^*} \quad (1)$$

where:

$$\mu_{CT} \equiv \langle\Phi(D^+A^-)|\mu|\phi(DA)\rangle$$
$$\mu_{DA}{}^* \equiv \langle\Phi(DA^*)|\mu|\Phi(DA\rangle$$
$$a \equiv b_1 \quad \text{and} \quad b \equiv c_1.$$

The polarization of μ_{CT} is nearly normal to the molecular plane, while that of μ_{DA^*} is parallel to it. As the donor changes from benzene to HMB, the charge-transfer singlet configuration increases its contribution and the in-plane character of the direction of the transition moment decreases, but the out-of-plane character increases. The above considerations may similarly be applied to the *o*-DCNB, *m*-DCNB, and *p*-DCNB com-

Table 2. Coefficients and contribution of charge-transfer character in the lowest charge-transfer singlet state of TCNB complexes calculated from degree of polarization.

Donor	*a*	*b*	CT(%)

plexes and may also be applied to the TCPA and PA complexes.

The *a* and *b* coefficients can be estimated from Equation (1) using the *P* values. By the use of the values, $|\mu_{CT}| \approx 0.3$ Å and $|\mu_{DA^*}| \approx 0.3$ Å, obtained from the experimental values of the oscillator strengths, 0.02 and 0.03 respectively, and assuming that the transition moments, μ_{CT} and μ_{TG}, are polarized normal to the molecular plane and that the μ_{DA^*} moment is polarized in the molecular plane, one can make a rough estimation of the *a* and *b* coefficients and the charge-transfer character in the lowest charge-transfer singlet state of the TCNB complexes. Table 2 summarizes the results. It can be said that these results coincide considerably well with those reported by Iwata *et al.*[12] Table 3 shows the contributions of the charge-transfer character in the lowest charge-transfer singlet states of the complexes calculated under an assumption of the same values of the transition moments as those of the TCNB complexes and using the same assumptions described above.

The authors wish to express their deep gratitude to Dr. Yasuhiko Gondo and Dr. Nobuyuki Nishi for their helpful discussions.

A Study of Quenching of Triplets by Ferrocene

Masae KIKUCHI,* Koichi KIKUCHI,** and Hiroshi KOKUBUN**

**The Research Institute for Iron, Steel and other Metals, Tohoku University, Katahira, Sendai 980*

***Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980*

(Received September 11, 1973)

Rate constants for quenching of several triplets by ferrocene have been determined in ethanol. Most triplets have been found to be deactivated by ferrocene, yielding no observable transient absorption. The rate constant increases with increasing triplet energy in the range 8000—17000 cm^{-1}. The quenching mechanism has been discussed, the lowest triplet level of ferrocene being estimated to be 15000±1000 cm^{-1}.

It is well-known that ferrocene is an excellent quencher for many triplets of organic compounds.[1-3] Fry *et al.*[1] investigated the quenching of typical triplets by ferrocene and found that all triplets whose levels are located between 14000 and 23800 cm^{-1} are quenched by ferrocene at about a diffusion-controlled rate. However, they found no evidence for the formation of excited states of ferrocene, and could not account for the quenching mechanism.

Scott and Becker[4] observed an S→T absorption of ferrocene at 18940 cm^{-1} and a long-lived emission interpreted to be phosphorescence in EPA at 77 K, since the location corresponds to the band assigned to S→T absorption. Armstrong *et al.*[5] observed S→T absorption bands of ferrocene at 14000, 16500 and 18500 cm^{-1}, but no emission in EPA at 77 K. Smith and Meyer[6] observed phosphorescence at 20 K which has an emission peak at 21500 cm^{-1} in argon and at 20000 cm^{-1} in methane matrix. Information on the triplet of ferrocene is very conflicting and the lowest triplet level of ferrocene cannot be estimated exactly. However, it seems certain that the triplet level is higher than 14000 cm^{-1}.

All the triplet levels of the compounds studied by Fry *et al.* are higher than 14000 cm^{-1}. Thus a study of quenching by ferrocene for triplets having energy levels lower than 14000 cm^{-1} is expected to clarify, whether it is a triplet energy transfer or not. A triplet with energy level lower than 14000 cm^{-1} can not be quenched if the quenching is due to triplet energy transfer, but can be quenched if it is due to another mechanism. We have determined accurately the rate constants of quenching of several triplets whose levels are located between 8000 and 23800 cm^{-1}.

Experimental

Materials. Ferrocene (G. R. grade, Tokyo Kasei) was purified by recrystallization from benzene, zone refining twice, and sublimation twice. Pentacene and tetracene (G. R. grade, Tokyo Kasei) were used without further purification, but confirmed by measuring absorption and fluorescence spectra. Ethanol (G. R. grade, Wako Junyaku) was used without further purification. All other reagents were purified by standard methods.

Apparatus and Procedure. The flash energy was usually about 130 J, its half duration being about 10 μs. A Hoya-U2 or Toshiba V-051 filter was used for excitation. All measurements were made at room temperature. Ethanol solutions were degassed by repeating bulb to trap distillation in vacuum. Benzene solutions were degassed by freeze-pump-thaw method.

Results and Discussion

The dependence of decay curves of triplets upon the concentration of ferrocene has been studied. The observed first-order rate constants, k_{obs}, of perylene and anthracene are plotted against the ferrocene concentration in Fig. 1 as a typical example. From the plots the quenching rate constant k_q is obtained, since the observed first-order rate constant is given by

$$k_{obs} = k_t + k_q\,[\text{Ferrocene}] \qquad (1)$$

where k_t is the pseudo-first order rate constant of triplet deactivation in the absence of ferrocene.

TABLE 1. RATE CONSTANTS FOR QUENCHING OF TRIPLETS BY FERROCENE AND ΔG-VALUES

Compound	Triplet level (cm^{-1})	Quenching rate constant ($M^{-1}s^{-1}$)	ΔG (kcal/mol)
Triphenylene	23800	$(6.5\pm0.5)\times10^9$	−6.2
Naphthalene	21300	$(7.0\pm1.5)\times10^9$	2.1
β-Acetonaphthone	20700	$(6.0\pm0.5)\times10^9$	
1,2,5,6-Dibenzanthracene	18300	$(5.0\pm1.0)\times10^9$	
Pyrene	16800	$(6.0\pm0.5)\times10^9$	5.5
Phenazine	15250	$(4.6\pm0.5)\times10^9$	
Eosine	14800	$(3.5\pm0.5)\times10^9$	
Anthracene	14700	$(3.5\pm0.5)\times10^9$	8.2
Perylene	12600	$(1.3\pm0.1)\times10^9$	7.1
Tetracene	10250	$(4.6\pm0.5)\times10^7$	10.8
Pentacene[a]	8000	$\ll10^7$	

a) In benzene.

The quenching rate constants in ethanol are summarized in Table 1. It is apparent that triplets having higher energy than 16000 cm^{-1} are quenched by ferrocene at about a diffusion-controlled rate* in accordance with the result of Fry *et al.*, but the quenching rate decreases with lowering triplet level between 8000 and 15000 cm^{-1}, and finally pentacene triplet, 8000 cm^{-1}, is scarcely quenched at all.

It is well-known that the rate of triplet energy transfer becomes slower owing to the reversible energy transfer when triplet levels of donor and acceptor are close to each other.[7-9] Sandros[8] studied the reversible energy transfer between biacetyl and many aromatic hydrocarbons, and found that the rate constant of energy transfer, k, is related to the difference of triplet levels of donor and acceptor, ΔE_T, as follows:

$$k = k_D \cdot \frac{1}{1+\exp(-\Delta E_T/RT)} \qquad (2)$$

where k_D is the diffusion-controlled rate constant, R is the gas constant and $\Delta E_T = E_T(\text{Donor}) - E_T(\text{Acceptor})$. Since $k \simeq k_D$ when $\Delta E_T \gg RT \simeq 200$ cm^{-1}, $k = \frac{1}{2} k_D$ when $\Delta E_T = 0$ cm^{-1}, and $k < k_D/140$ when $\Delta E_T < -1000$ cm^{-1}, the rate constant of the energy transfer decreases about two orders of magnitude as compared with the diffusion-controlled rate constant when the triplet level of acceptor (quencher) is higher than that of donor by 1000 cm^{-1}. Irrespective of the triplet level of ferrocene, it is obvious that the dependence of the quenching rate constant on the triplet level (Table 1) is too small as compared with the case of the energy transfer. Thus the results cannot be explained by energy transfer only.

It has been reported that the triplet level of ferrocene is higher than 14000 cm^{-1}, but it is necessary i) to confirm by kinetic study that triplet of tetracene is quenched not by energy transfer but by another mechanism, and ii) to clarify the reason why no transient absorption of ferrocene can be observed. We carried out the kinetic study of i) by examining the data given in Table 1. Assuming that tetracene triplet is quenched by energy transfer from tetracene triplet to ferrocene, we can calculate the triplet level of ferrocene by Eq. (2). From the values $k_D = 6 \times 10^9$ M^{-1} s^{-1} and $k = 4.6 \times 10^7$ M^{-1} s^{-1}, $\Delta E_T = E_T(\text{tetracene}) - E_T(\text{ferrocene}) = -990$ cm^{-1} was obtained. Thus the triplet level of ferrocene is estimated to be 11240 cm^{-1}. If this is the case, all the triplets having levels higher than about 12000 cm^{-1} should be quenched by ferrocene at the diffusion-controlled rate. However, this is inconsistent with the results (Table 1). Thus we could conclude that the quenching of tetracene triplet is not due to energy transfer, and that the triplet level of ferrocene is higher than 12000 cm^{-1}, which is in line with earlier reports.[4-6] For ii) we carried out an energy transfer experiment for a mixed system of eosin (D), tetracene (A) and ferrocene (F), in which eosin is at first irradiated selectively by a flash, the triplet eosin acting as an energy donor. The reaction scheme is described as follows.

* Most published rate constants for triplet quenching are about 5×10^9 M^{-1} s^{-1}.

$$(0)\quad D \xrightarrow{\phi_{ST} I_{ab}} {}^3D$$
$$(1)\quad {}^3D \longrightarrow D$$
$$(2)\quad {}^3D + F \longrightarrow D + {}^3F$$
$$(3)\quad {}^3D + A \longrightarrow D + {}^3A$$
$$(4)\quad {}^3F + A \longrightarrow F + {}^3A$$
$$(5)\quad {}^3F \longrightarrow F$$
$$(6)\quad {}^3A \longrightarrow A$$
$$(7)\quad {}^3A + F \longrightarrow A + {}^3F$$

If the rate of deactivation of tetracene triplet is negligibly small in comparison with that of other triplets, the concentration of tetracene triplet immediately after flashing is given by

$$[{}^3A]_0 = \frac{1}{k_1 + k_2[F] + k_3[A]} \cdot \left(k_3[A] + \frac{k_4[A]}{k_4[A] + k_5} \cdot k_2[F] \right) \cdot \phi_{ST} I_{ab} . \qquad (3)$$

When $[F] = 0$, we have

$$[{}^3A]_0^0 = \frac{k_3[A]}{k_1 + k_3[A]} \cdot \phi_{ST} I_{ab} . \qquad (4)$$

From Eqs. (3) and (4) we get

$$\frac{[{}^3A]_0^0}{[{}^3A]_0} = 1 + \frac{k_2[F]}{k_1 + k_3[A]} - \frac{[{}^3A]_0^0}{[{}^3A]_0} \cdot \frac{k_4[A]}{k_4[A] + k_5} \cdot \frac{k_2[F]}{k_3[A]} \qquad (5)$$

Figure 2 shows the plot of $[{}^3A]_0^0/[{}^3A]_0$ *vs.* [F] for $[D] = 6.3 \times 10^{-6}$ M and $[A] = 5.0 \times 10^{-5}$ M. A straight line was obtained. This implies that the third term of the right-hand side of Eq. (5) is negligibly small as compared with the first and the second terms. Thus, $k_5 \gg k_4$ [A] or $k_4 \approx 0$. But it is obvious that $k_5 \gg k_4[A]$, because $k_4 \approx 0$ is very unlikely. Eq. (5) can thus be written as

$$\frac{[{}^3A]_0^0}{[{}^3A]_0} = 1 + \frac{k_2[F]}{k_1 + k_3[A]}, \qquad (6)$$

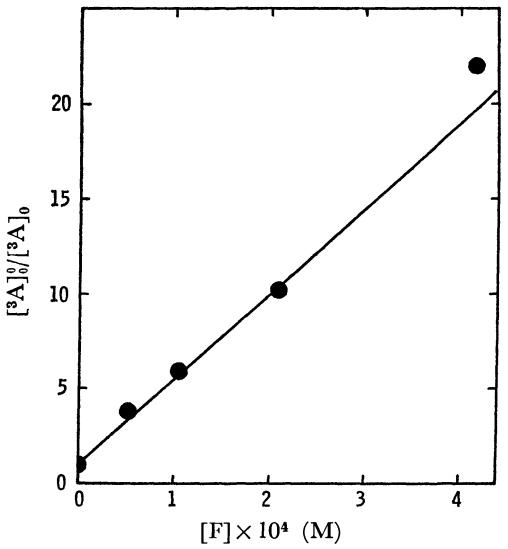

Fig. 2. The plot of $[{}^3A]_0^0/[{}^3A]_0$ *vs.* [F].
Straight line was calculated according to Eq. (6) by using independent data.

where $[A]=5.0\times10^{-5}$ M**. The slope, $k_2/(k_1+k_3[A])$, agrees with the calculated value using $k_1=1.0\times10^3$ s^{-1}, $k_2=3.5\times10^9$ M^{-1} s^{-1}, and $k_3=1.5\times10^9$ M^{-1} s^{-1}, which have been obtained by other independent flash experiments. $k_5\gg k_4[A]$ implies that the energy transfer from ferrocene triplet to tetracene is inefficient. This is attributable to the fast deactivation of ferrocene triplet, because $k_5\gg10^5$ s^{-1} if k_4 is of the order of the diffusion-controlled rate constant. This is consistent with the fact that no transient absorption owing to ferrocene has been observed by the conventional flash technique.

The triplet level of ferrocene can be estimated as 15000 ± 1000 cm^{-1} by the following considerations; 1) it has been reported that the triplet level of ferrocene is higher than 14000 cm^{-1}, 2) all triplets having a level higher than 16000 cm^{-1} are quenched with the diffusion-controlled rate, 3) the quenching rates of anthracene and eosin triplet are nearly one-half of the diffusion-controlled rate, 4) the quenching of tetracene triplet by energy transfer to ferrocene is highly improbable, 5) the rate constant of energy transfer decreases by about two orders of magnitude as compared with the diffusion-controlled rate constant when the triplet level of acceptor is higher than that of donor by 1000 cm^{-1}, and is practically the diffusion-controlled rate constant when the triplet level of donor is higher than that of acceptor by 500 cm^{-1}, 6) the reversible energy transfer is very inefficient because the lifetime of ferrocene triplet may be very short,7) as the rate of energy transfer depends on ΔE_T predominantly and other factors, it would be suitable to estimate the error as ±1000 cm^{-1}.

Rosenblum *et al.*[10] have reported that ferrocene forms a charge transfer complex with tetracyanoethylene owing to low ionization potential of ferrocene. The quenching of fluorescence due to charge transfer interaction between fluorescer and quencher is widely known.[11] Thus it is necessary to examine the possibility of triplet quenching by charge-transfer interaction, although quenching of triplet by charge transfer interaction has scarcely been reported at all. The changes of free enthalpy (ΔG) involved in the electron transfer reactions[11] are calculated approximately and listed in Table 1. It seems that a qualitative correlation between the rate constant and ΔG is satisfactory. This strongly suggests that charge transfer interaction is involved in the quenching.

If the triplet quenching by ferrocene is exclusively attributed to the electron transfer reaction, detection of anion originating in the triplet might be expected. However, no additional transient absorption was observed by the addition of ferrocene. Triphenylene which is most expected to produce anion was also examined in acetonitorile, but no additional transient absorption was observed. If the quenching is due to the charge transfer interaction, it seems most likely that the lifetime of charge transfer complex is extremely short.

Porter and Wright[12] studied the quenching action of various metal ions to naphthalene triplet in water and in ethylene glycol, and found that paramagnetic metal ions of first transition series deactivate the triplet at the rate constant, $k_q\approx5\times10^7$ M^{-1} s^{-1}. As the rate constant of quenching for tetracene triplet is 4.6×10^7 M^{-1} s^{-1}, the quenching ability of ferrocene for tetracene triplet is similar to that of Fe^{2+} and Fe^{3+}. However, pentacene triplet has not been quenched by ferrocene in benzene, and paramagnetic quenching cannot be considered, since ferrocene is diamagnetic. It thus seems that the iron atom in ferrocene does not contribute directly to the quenching.

If several compounds with triplet levels between 8000 and 15000 cm^{-1} are contained simultaneously in ferrocene as impurities, the results might be interpreted as those given in Table 1. But quenching by such impurities is improbable since no emissoin due to impurities has been observed in concentrated solution of ferrocene. The result in Fig. 2 denies the existence of such impurities.

Consequently, it seems that the quenching of triplet by ferrocene might occur according to the following mechanisms. As the triplet level of ferrocene has been estimated as 15000 ± 1000 cm^{-1}, a triplet with a level higher than 15000 cm^{-1} would be quenched mainly by the energy transfer, but a triplet with a level lower than 13000 cm^{-1} would be quenched by another mechanism. The most probable mechanism would be the instantaneous formation of charge transfer complex with an extremely short lifetime.

The authors wish to express their thanks to Professor Masao Honma for his kind guidance and encouragement in the course of the work. H. K. and K. K. wish to thank the Mitsubishi Foundation for financial support.

** Eq. (6) is also satisfied when $k_4[A]+k_5\ll k_6+k_7[F]$, where $[A]=5\times10^{-5}$ M, $k_6=1.2\times10^3$ s^{-1} and $k_7=4.6\times10^7$ M^{-1} s^{-1}. However, this assumption is improbable, since the triplet level of ferrocene is higher than that of tetracene.

Medium Effects for Single Ions in Dimethyl Sulfoxide, *N,N'*-Dimethylformamide, and Propylene Carbonate

Niro MATSUURA and Kisaburo UMEMOTO

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received September 27, 1973)

The solubility products of thallium halides were measured in dimethyl sulfoxide, *N,N'*-Dimethylformamide, and propylene carbonate for the purpose of obtaining the values of the medium effect for these electrolytes on transfer from water to these solvents. The medium effects for cations were estimated from the standard potentials of metal/ion couples obtained by the method of the corrected rubidium scale. The medium effects for halide ions were calculated from the medium effects for thallium halides and the thallium ion. A comparison of extrathermodynamic assumptions was made for the values of the medium effect for the silver ion as estimated by various methods; the method of the corrected rubidium scale was found to give a reasonable result.

The significance of the medium effect in non-aqueous solution chemistry and the current status of the extrathermodynamic assumptions needed to estimate the medium effect for single ion have been reviewed in several recent, stimulating works.[1-8]

The medium effect, $\log {}_m\gamma$, is defined as a measure of the difference between the free energy of a solute, i, in its aqueous (${}_wG_i^\circ$) and non-aqueous (${}_sG_i^\circ$) standard states:

$$ {}_sG_i^\circ - {}_wG_i^\circ = RT \ln {}_m\gamma_i \quad (1) $$

For the 1 : 1 electrolyte:

$$ \ln {}_m\gamma_i = \ln {}_m\gamma_\pm{}^2 = \ln {}_m\gamma_+ + \ln {}_m\gamma_- \quad (2) $$

where ${}_m\gamma_+$, ${}_m\gamma_-$, and ${}_m\gamma_i$ are the medium effects for the cation, the ainon, and the electrolyte respectively. Therefore, the solubility products of the AB salt in the solvent, S, K_s^s, are related to the solubility product in water, K_s^w, through:

$$ K_s^w = K_s^s({}_m\gamma_+)({}_m\gamma_-) \quad (3) $$

Expressions like Eq. (3) relate the constants for a variety of equilibria in a solvent, S, to the equilibrium constants in water. A knowledge of the medium effect for any one ion would render accessible such knowledge for all other ions in the same solvent on the basis of the thermodynamic data for the complete electrolytes. The knowledge of the medium effects for single ions enables us to express any ionic activity and electromotive force series on a single scale, referred to the aqueous standard state.

The medium effects for single ions can not be determined exactly by rigorous thermodynamic methods. In spite of the limitations imposed by extract thermodynamics, though, many investigators have estimated at least approximate values for the medium effect for single ions with the aid of extrathermodynamic assumptions. One of the methods used is based on the "normalized potential scale" method originated by Pleskov.[9] In this method, the standard potential of the rubidium electrode is assumed to be a solvent-independent reference point for a universal series of standard electrode potentials(Rubidium Scale). Pleskov's method of the rubidium scale has been proved by estimating the change in the solvation energy of the rubidium ion with the solvent by the application of a modified Born equation(Corrected Rubidium Scale).[6,10,11] Other than the rubidium-rubidium ion, ferrocene-ferricinium[12] and iron(II-III) complexes of *o*-phenanthlorine[13] have been proposed as reference redox couples. Another way of estimating the medium effect is the "reference electrolyte" method.[1-5] This method is based on the assumption that the medium effect for an ideal reference electrolyte—composed of very large symmetrical ions as similar in size and structure as possible—can be divided equally between the anion and the cation. The number of proposed extrathermodynamic solutions has multiplied, and some discrepancies have been observed among the results obtained by various methods.

The objective of the present paper is, first, to estimate the medium effects for alkali metal, thallium, silver, halide, and perchlorate ions in dimethyl sulfoxide (DMSO), *N,N'*-Dimethylformamide(DMF), and propylene carbonate(PC) on the basis of the normalized potential scale which was previously determined on the assumption of the corrected rubidium scale method.[11] Then, the medium effects for the silver ion obtained in this work were compared with those estimated by other various extrathermodynamic methods in order to verify the applicability of the method of the corrected rubidium scale.

Experimental

Solvents and Electrolytes. The purification of solvents, the preparation and purification of tetraethylammonium iodide(TEAI) and thallium perchlorate, and the preparation of the thallium amalgam electrode have been described elsewhere.[11,14] The tetraethylammonium chloride(TEACl) and tetraethylammonium bromide(TEABr) were obtained commercially and were purified by recrystallization from an ethyl alcohol-ethyl acetate mixture. The electrolytes were dried in a vacuum oven for several tens of hours at 60—70 °C.

Procedure. The solubilities of thallium halides in DMF and PC were determined by potentiometric titration. A 0.002 M solution of thallium perchlorate was titrated with a 0.01 M solution of tetraethylammonium halide(TEAX). The indicator electrode was the thallium amalgam electrode, and the reference electrode was an aqueous saturated calomel electrode(SCE) equipped with a non-aqueous salt bridge.[11] Nitrogen gas was bubbled through the solution before and during the run of the titration. The potential of the cell was measured by means of Yokogawa Hewlett-Paccard Model 2727 potentiometer. The temperature was kept at 25±0.05 °C.

Table 1. Solubility products K_s ($mol^2 l^{-2}$) of thallium halides at 25 °C[a)]

	DMSO			DMF			PC		
	solubility $\times 10^3$	$f_\pm$	$K_s \times 10^6$	solubility $\times 10^5$	$f_\pm$	$K_s \times 10^9$	solubility $\times 10^6$	$f_\pm$	$K_s \times 10^{12}$
TlCl	1.99	0.89	3.16	5.25	0.97	2.62	2.24	1.00	5.01
TlBr	2.74	0.88	5.78	8.91	0.97	7.37	3.31	1.00	11.0
TlI	5.32	0.84	19.8	31.6	0.93	87.1	12.0	1.00	144.0

a) Solubilities are in mol l^{-1}. $f_\pm$ is salt activity coefficient. The values of solubility in DMF and PC were determined by potentiometric titration and those values in DMSO by polarographic amperometry.

The solubility of thallium halides in DMSO were rather high, and they could not be determined accurately by potentiometric titration. They were, however, determined by polarographic amperometry. The thallium halides were shaken with DMSO for twenty hours at 30 °C and then for ten hours at 25 °C. Pure DMSO and 0.1 M of tetraethylammonium perchlorate were added to the DMSO solution saturated with thallium halide, and then the polarogram was recorded. The concentration of thallium halide was determined from the magnitude of the diffusion current by using a predetermined calibration curve. The solubilities of thallium halides in DMF were also determined by polarographic amperometry in order to obtain auxiliary data.

Results and Discussion

The Determination of the Solubility Products of Thallium Halides. The potentiometric measurements for thallium salt were made with the following cell:

$$\text{aqueous SCE} \left| \begin{matrix}\text{salt}\\ \text{bridge}\end{matrix} \right| \text{TlClO}_4 \quad 0.002\,\text{M} \left| \text{Tl(Hg)} \right. \quad \text{(A)}$$

For the thallium amalgam electrode, it was found that the Nernst equation was nearly obeyed in all the solvents containing thallium perchlorate in the concentration range from 1×10^{-4} to 2×10^{-3} M as is shown in Fig. 1.

The titrations of thallium perchlorate with tetraethylammonium halides were carried out in the right-hand-half cell of Cell A. The titration curve shown in Fig. 2 is typical of the curves when 0.002 M $TlClO_4$ was titrated with 0.01 M TEAX in PC and DMF at 25 °C. In all the titration curves, we found one well-defined end point of titration corresponding to this rection:

$$Tl^+ + X^- = TlX\downarrow \qquad (4)$$

The precipitation of TlX appeared soon after the titration started. The solubilities of TlX were calculated from the titration curves by using the Nernst equation; the results are given in Table 1. No further complex formation of the thallium ion with the halide ion was observed in these solvents, even in the presence of an excess concentration of the halide ion. In the presence of an excess concentration of the halide ion, the potential of the thallium amalgam electrode was found to be very stable. This electrode would be useful as a reference electrode of the second kind for electromotive force measurements in these solvents.

For the calculation of the solubility products of thallium halides, the complete dissociation of the salts was assumed, since the association between the perchlorate anion and metal ions has been found to be negligibly small in these solvents at the concentrations below 10^{-2} M.[15] The salt activity coefficient, f, was calculated by means of the Debye-Hückel equation:

$$\log f_\pm = -\frac{A\sqrt{\mu}}{1+Ba\sqrt{\mu}} \qquad (5)$$

where A and B are constants and were calculated to

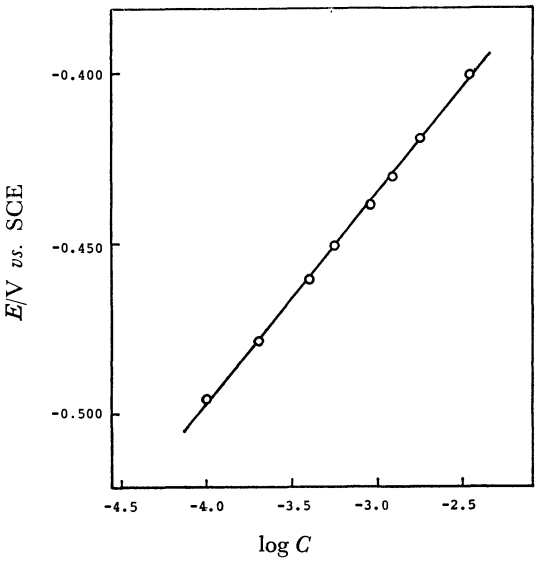

Fig. 1. Relation between the potential of the thallium amalgam electrode and the concentration of thallium perchlorate in PC at 25 °C.

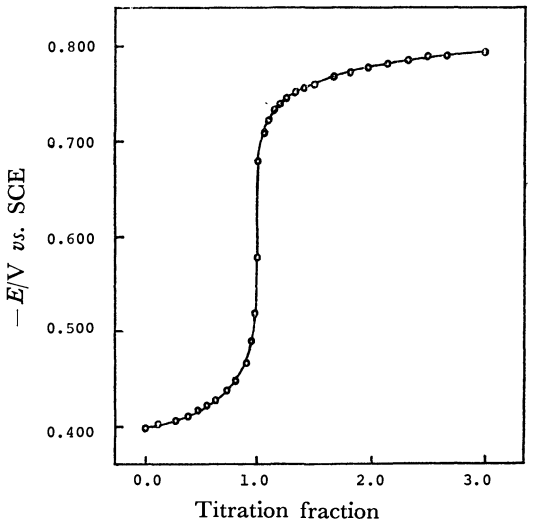

Fig. 2. The titration curve of 0.002 M $TlClO_4$ with 0.01 M TEACl in PC at 25 °C.

Table 2. Solubility products pK_s (molality) and medium effects for electrolytes

	DMSO		DMF		PC		Water
	pK_s	ΔpK_s[a]	pK_s	ΔpK_s[a]	pK_s	ΔpK_s[a]	pK_s

a) $\Delta pK_s = pK_s^s - pK_s^w$. b) Ref. 6. c) R. Alexander, E. C. F. Ko, Y. C. Mac, and A. J. Parker, *J. Amer. Chem. Soc.*, **89**, 3703 (1967). Correction for solvent molality was made. d) Ref. 4. Correction for solvent molality was made. e) not determined.

be respectively, 1.18 and 0.435 for DMSO, 1.73 and 0.493 for DMF, and 0.717 and 0.368 for PC by using the dielectric constants of these solvents. The ion-size parameter, *a*, has been determined to be 3.6 for DMSO, 5.0 for DMF, and 0.0 for PC.[14] The activity coefficients and solubility products of thallium halides are given in Table 1.

The solubility products of TlX in DMF as determined by polarographic amperometry were different by 10 per cent from the solubility products as determined by potentiometric titration. Accordingly, the values given in Table 1 must involve an uncertainty of this order.

In Table 2, the solubility products of thallium halides, pK_s, are listed in the molality scale, along with those of potassium perchlorate available in the literature. To convert from molar to molal pK_s, the solvent density of these solvents was used.

The medium effects for thallium halides, $\log {}_m\gamma_{TlX}$ were calculated by means of the following equation:

$$\log {}_m\gamma_{TlX} = \Delta pK_s = pK_s^s - pK_s^w \quad (6)$$

The results are listed in Table 2. Equation (6) is strictly valid only when no crystal solvates are formed. We assumed an absence of solvates in all these solvent-solute combinations.

Estimation of the Medium Effects for Single Ions. The medium effects for alkali metal, thallium, and silver ions were calculated from the difference between the standard potentials of the metal electrode in an aqueous solution, $E_w°$, and in a non-aqueous solution, $E_s°$, estimated on the basis of the corrected rubidium scale:[14]

$$\log {}_m\gamma_{M^+} = (E_s° - E_w°)/0.05916 \quad (7)$$

The medium effects for halide ions were calculated from:

$$\log {}_m\gamma_{X^-} = \log {}_m\gamma_{TlX} - \log {}_m\gamma_{Tl^+} \quad (8)$$

where, X=Cl, Br, I. The medium effect for perchlorate was calculated from $\log {}_m\gamma_{KClO_4}$ and $\log {}_m\gamma_{K^+}$ in the same manner. The medium effects for individual ions thus estimated are summarized in Table 3. A positive value of a medium effect means a lower solvation energy (tighter solvation) in water than in other solvents. This is the case for most small anions. The solvation of halide ions depends on strong hydrogen bonding, which is available in water but not in DMSO, DMF, and PC. The tighter solvation of cations in DMSO and DMF is characterized by the solvent structure, especially by the strong Lewis basicity of these solvents. PC is a weaker Lewis base; accordingly, the cationic solvation of PC is weaker than that of water.

Table 3. Medium effects for single ions (Molality scale). Reference solvent is water

a) not determined.

A Comparison of Extrathermodynamic Assumptions. It will now be interesting to compare the values of the medium effect for the single ions estimated in this work with those values estimated on the basis of other extrathermodynamic assumptions. For this purpose, the medium effect for the silver ion was examined, since, among the ions studied in this work, the silver ion has been studied most extensively by various methods.

In Fig. 3 we have plotted the medium effects for the silver ion in DMSO, DMF, PC, and acetonitrile (ACN). The classification of Assumptions 1–5 and the values of the medium effect estimated by these assumptions were taken from Ref. 3. The values from the rubidium scale method are denoted by R, and those from the corrected rubidium scale method, by B.

Each individual assumption has its own inherent limitations.[1] Assumption 1, which equates the medium effect for the tetraphenylarsonium cation with that for the tetraphenylboride anion, $\log {}_m\gamma_{Ph_4As^+} = \log {}_m\gamma_{Ph_4B^-}$, involves difficulty in dividing the medium effect for the reference electrolyte equally among the component cation and anion; moreover, the accuracy of the determined solubility products of the reference electrolyte is not sufficient. In Assumptions 2 and 3, the electrostatic interaction of solvent with very large anions, which were formed in the transition states for the S_N2 or S_NAr reaction, is assumed to be unchanged, $\log {}_m\gamma_{ArF} = \log {}_m\gamma_{ArN_3F^-}$ or $\log {}_m\gamma_{CH_3I} = \log$

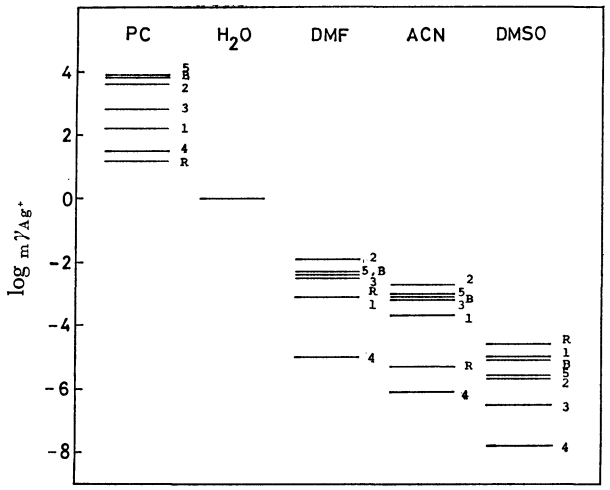

Fig. 3. A comparison of extrathermodynamic assumptions, leading to the medium effect for silver ion for transfer from water to other solvents at 25 °C. The assumptions are (1) $\log {}_m\gamma_{Ph_4As^+} = \log {}_m\gamma_{Ph_4B^-}$; (2) $\log {}_m\gamma_{ArF} = \log {}_m\gamma_{ArN_3F^-*}$; (3) $\log {}_m\gamma_{CH_3I} = \log {}_m\gamma_{NCSCH_3I^-*}$; (4) $\log {}_m\gamma_{Fe(C_5H_5)_2} = \log {}_m\gamma_{Fe(C_5H_5)_2^+}$; (5) Negligible liquid junction potential; (B) Corrected rubidium scale; (R) Rubidium scale.

${}_m\gamma_{NCSCH_3I^-*}$, but the large anions have a large polarizability and the electrostatic interaction of these anions with solvents must be affected by the solvent polarity. Assumption 4 equates the medium effect for ferrocene with that for the ferricinium cation, $\log {}_m\gamma_{Fe(C_5H_5)_2} = \log {}_m\gamma_{Fe(C_5H_5)_2^+}$. This assumption must be criticized in view of the large increase in the solubility of ferrocene on transfer from water to organic solvents, which would result in a serious change in the medium effect for ferrocene. Moreover, the electrostatic interaction of the ferricinium ion with solvent must be affected by the solvent polarity. Assumption 5 neglects the liquid junction potential in a cell composed of silver wire in a silver perchlorate solution connected by a proper non-aqueous salt bridge of tetraethylammonium picrate: the liquid junction potential of the aqueous and non-aqueous interface would not be completely eliminated. Assumption R neglects the change in the electrostatic interaction of the rubidium ion with solvents of different dielectric properties. Assumption B simplifies too much the change in the solvation energy of the rubidium ion with solvents mainly electrostatic in nature.

At this time we have no reason to defend any one assumption with confidence. However, it seems reasonable to support assumptions which give focusing values for the medium effect.

As is shown in Fig. 3, the internal coherency of the values of the medium effect as estimated by individual assumptions for different solvents is excellent except for the method of the rubidium scale; the magnitudes of the medium effect for the silver ion estimated by individual assumptions lie in this order; PC>H_2O>DMF>ACN>DMSO; only the values of the medium effect estimated by the method of the rubidium scale for DMSO and ACN are in an inverse order. Accordingly, the method of the rubidium scale is considered to be unfavourable as a universally-applicable method for these solvents. In this connection, the limitation of the assumption of rubidium scale must be overcome by the method of the corrected rubidium scale. Most values of the medium effect for the silver ion lie in ranges between 3 and 4 in PC, −2 and −3 in DMF, −3 and −4 in ACN, −5 and −6 in DMSO. The values of the medium effect for the silver ion, as estimated by the method of the corrected rubidium scale, lie in these ranges for all the solvents. Accordingly, it would be reasonable to say that the method of the corrected rubidium scale is one of the most reliable methods of estimating the medium effect for single ions.

It is quite interesting that the assumption of the negligible liquid junction potential seems reasonable, since the values of the medium effect estimated by this assumption lie in the focusing ranges. The method of the negligible liquid junction potential determines directly, unlike the other extrathermodynamic assumptions, the medium effect for the ion from the electrode potential measured against a silver-silver perchlorate electrode in the reference solvent. The practical procedure is very easy to comprehend.[3] Therefore, this method would throw light on the urgent problem in the non-aqueous electrochemistry of normalizing the potential of a given redox system directly to the water scale by measuring the cell potential.

The authors wish to express their thanks to Mr. Zen'ichi Takeuchi for his cooperation in the experimental work.

Solvent Effects on the Formation of Aromatic Hydrocarbon Ions and Mo^{5+} on the Surface of Al_2O_3–MoO_3

Hisashi UEDA

National Chemical Laboratory for Industry, 2-19-19 Mita, Meguro-ku, Tokyo 153

(Received October 3, 1973)

The formation of two aromatic hydrocarbon ions on the surface of Al_2O_3–MoO_3 has already been postulated. The concentrations of these paramagnetic species were measured for various solvents by using DPPH single crystals as the reference standard. The formation of two different aromatic ions on the surface of Al_2O_3–MoO_3 could also be confirmed by the solvent dependence. The intensity of microwave magnetic field H_1 and the modulation width were considered in this measurement. Without solvent molecules such as benzene on the oxide surface, an ESR signal without cation hyperfine structure was almost exclusively observed. The intensities and intensity ratio between the two components of the ESR absorption at $g=2.00$, with and without hyperfine structure, change with solvent. The results indicated that solvent molecules, when adsorbed on the oxide surface, form a surface structure or a surface system which makes the charge transfer from the oxide surface to the solute hydrocarbon easier.

The electron spin resonance (ESR) method is used in studies of catalysis for various purposes, being (1) to know the orbital function of the unpaired electron spin or the crystal field in the bulk or on the surface of solid catalysts,[1] and (2) to detect the reaction intermediates (molecular or atomic) in a stable or in a semi-stable state.[2] As another application, the interaction among the system components can also be analysed if the mixture (catalyst, reaction-substrate, reaction-intermediates, reaction products, and reaction-byproducts) is considered as a reaction system consisting of these system components.[3] If such a system is treated as a reaction system, some additive added to the system, or the solvent used to dissolve the substrate should also be treated as a system component. For this reason, a study of solvent effects on the formation of the paramagnetic species is expected to clarify some facts important for the study of catalysis. In order to see some of the dynamic aspects of the system, quantitative measurements and processings of the concentrations of the system components are necessary. As intermediates paramagnetic species were chosen and quantitative ESR method was used to find the solvent effects on the perylene– (or anthracene)–Al_2O_3–MoO_3 system.

Experimental

Quantitative ESR Measurement. Quantitative ESR measurements normally employ several reference standards with which comparisons are made between these references and the samples to be measured.[4] If DPPH is used as a reference, it is diluted in the form of a solution or a solid mixture to obtain the unpaired electron concentration almost equal to that of the sample.[5] However, decomposition of DPPH during the course of dilution or storage is inevitable and an accurate and consistent measurement is not easy. Thus a single crystal of DPPH has been used as a reference. The maximum measurable number of unpaired electron spins obtained with the ESR instrument used, a JES-3BX, under the usual adjustment conditions of detector and amplifier, changes with input microwave power and modulation width. At 10 μW and 2.0 G modulation width at 100 kHz, 2×10^{19} unpaired electron spin gives a final first derivative output voltage of 10 mV on the recording device. A 10 mg single crystal contains 1.5216×10^{19} molecules and if weighed by a microbalance, 10.00 mg is obtained as effective figures. The number of unpaired electron spins contained in a (10.00 ± 0.005) mg crystal is $(1.5216\pm0.0008)\times10^{19}$ or 1.521×10^{19}.

The dependence of the ESR signal on the input microwave power should also be considered.[6] The magnitude of the microwave magnetic field H_1 is determined by the incident power to the resonant cavity, P, and the "Q" of the cavity. Therefore, the Q value for each sample should be known to estimate the relative H_1 value. The ESR absorption energy is proportional to H_1.[2,7] If we denote the Q value of an empty resonant cavity by Q_0, and the H_1 value by H_{10}, we have $H_{10}^2=k\cdot P\cdot Q_0$ where k is a constant. If a sample is placed in the cavity, we have $H_1^2=k\cdot P\cdot Q$. From these two relations we get $H_1^2=H_{10}^2\cdot Q/Q_0$. Q/Q_0 is estimated by the intensity of an Mn^{2+} line from the $MnSO_3$/MgO sample fixed in the cavity. The microwave circuit is so adjusted as to give the strongest signal amplitude.

Modulation width should be taken into consideration in order to analyze an ESR spectrum having two spectral components.[8] If one of the components has a hyperfine structure (hfs), the modulation width should be small enough to observe the hfs. Since the first derivative absorption function is obtained experimentally as a function of the magnetic field H, $f(H)=f_1(H)+f_2(H)$, the integral absorption function $F(H)=F_1(H)+F_2(H)$ must be derived from $f(H)$. If the amplitude of $f(H)$, A_1, is plotted against the modulation width, h, it is proportional to h until h reaches h_{max}, after which A_1 shows a decreasing tendency. A_1 is directly proportional to $F_1(H_c, h_{max})$, which is the height of $F_1(H)$ observed by h_{max} modulation width, where H_c is the value of the magnetic field for the peak point of the absorption curve. The height of $F_2(H)$ is $F_2(H_c, h'_{max})$, where h'_{max} differs from h_{max}. If the relation between the amplitude of $f_1(H)$ (or $f_2(H)$) observed with a modulation width h and $F_1(H_c, h_{max})$ (or $F_2(H_c, h'_{max})$) is known, the latter value can be estimated from A_1 or (A_2). From these quantities the spin concentration, y, was calculated as $y=N_2/M$, where M is the weight of the sample placed in the 45 mm × 5.0 mm ϕ cylindrical section the sample tube where microwave magnetic field is the strongest, and N_2 is the total number of the paramagnetic species contained in the same space. N_2 is determined by the relation

$$N_2=\frac{N_1}{I_1}\times\frac{S(\text{sample})}{S(\text{DPPH})}\times\frac{I(P')}{J(P')},$$

where N_1 is the number of molecules in the DPPH single crystal, $I(P')$ is the intensity of $F_1(H)$ or $F_2(H)$ at P' (dimension, mV G), I_1 is that for the DPPH single crystal at 1 μW,

and $J(P')$ is equal to $I(P')/I(1\ \mu W)$ determined by the power dependence curves. S(sample) or S(DPPH) is equal to

$$\int_{H=0}^{H=+\infty} h(H-H_0)\mathrm{d}H/h(0)$$

where $h(H-H_0)$ is the spectrum function written in H(dimension, mV) and the integral value is obtained by a double integration of the first derivative absorption curve. The values of S observed for DPPH (single crystal sealed in a vacuum), perylene cation, R^+O^{*2-}, and Mo^{5+} are 2.8488, 6.61, 13.75, and 108.18 G, respectively.

Preparation of Sample. If the amount of MoO_3 supported on Al_2O_3 is small, (1—3%), the amount of cation formation after contact with a hydrocarbon solution is also small.[9] A fairly large number of cations are formed when the wt% of MoO_3 is above 5%. For this reason, 8.5% of MoO_3 was supported on γ-alumina. The method of preparation is the same as that given in a previous paper.[10] The solvent well shaken with concentrated sulfuric acid, distilled twice, and then distilled into the vessel in which perylene crystals had been placed. After dissolving perylene this solution was mixed with the Al_2O_3–MoO_3 which had been evacuated to 10^{-4} mmHg in a vacuum line. Immediately after contact of the perylene solution a certain amount of perylene cation was formed, gradually increasing as shown in Fig. 2. The first spectrum was recorded at 10—12.5 min after contact of the solution and the subsequent measurements were made at 1, 2, 3, and 6 hr, 1, 2, 3 day, and so on.

It seems that the solvent molecules are working as something more than a simple dispersing medium of perylene molecules.[11] The following experiment was made to see the solvent effect. An aromatic compound was adsorbed on the surface of Al_2O_3–MoO_3, to which the solvent vapor was introduced. For this purpose, anthracene, whose vapor pressure is higher than that of perylene, is more suitable. 0.5 g of Al_2O_3–MoO_3 and 50 mg of anthracene was mixed well and placed in a sample tube, which was placed in the microwave resonant cavity and connected to the vacuum line. During evacuation, the anthracene vapor was adsorbed by the oxide and ESR absorption without hyperfine structure was gradually built up. The notation R^+O^{*2-} was used for this species.[12] Here R denotes anthracene, O^{*2-} the oxygen anion located at some particular points on the oxide surface at which the p-orbitals of an O^{2-} ion might be expected to overlap with the π-orbitals of the aromatic compound adsorbed more easily than at other positions. Various solvent vapors were introduced into the sample and the ESR spectrum after vapor introduction was recorded.

Results

The ESR spectrum obtained by perylene–Al_2O_3–MoO_3–solvent system is shown as "total" in Fig. 1. The total spectrum can be analyzed to consist of Component-1 and Component-2. The amplitude of the strongest hyperfine line A (or the central line) was read from the total spectrum. Using ΔH_{msl} of each hyperfine component line, amplitude A, and combination coefficients ${}_8C_r/70$, the first derivative hyperfine spectrum which represents a pure perylene cation on a solid surface was drawn (Component-2, Fig. 1). The difference between total and Component-2 is Component-1. Component-2 is due to perylene cation, R^+, and Component-1 to R^+O^{*2-}.[10,11,12] The absorption intensity of ESR spectrum (Fig. 1) changes with time after the formation of the paramagnetic species as

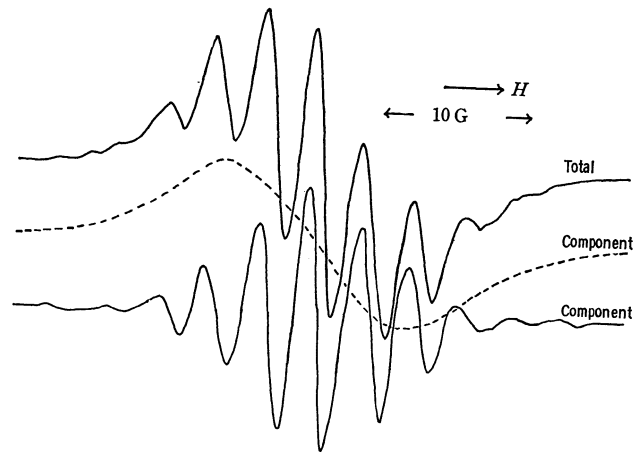

Fig. 1. The two component spectra, Component-1 and Component-2, contained in the observed spectrum, total.

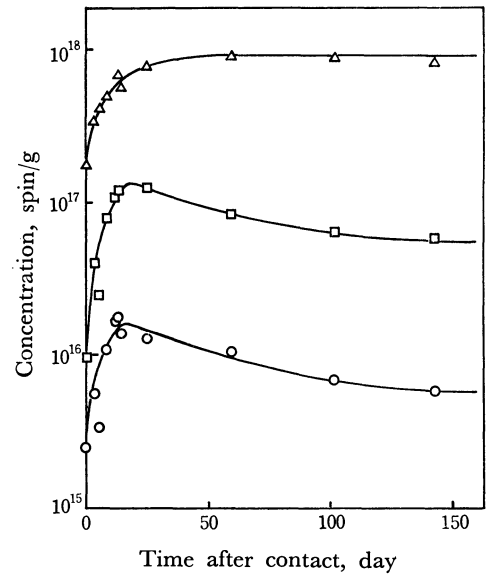

Fig. 2. The time dependence of the concentrations of the paramagnetic species observed.
△: Mo^{5+}, □: R^+O^{*2-}, ○: R^+

shown in Fig. 2. The temperature of storage and that of the measurements was 20 °C. The results in Table 1 were calculated so as to give the values which would be obtained under the conditions, $Q=Q_0$ and input power of 1 μW, or obtained with H_{10} for 1 μW. All the data were calculated as if they were obtained with the same H_1 value and without any power saturation. The change in the ESR spectra of anthracene–Al_2O_3–MoO_3 system when a solvent vapor was introduced is shown in Fig. 3. The temperature of measurement was 20 °C. The modulation width, microwave imput power and signal amplification factors were 20 mG, 1.0 mW, 5×10^2; 32 mG, 1.0 mW, 1×10^3; 50 mG, 0.1 mW, 2×10^3; 50 mG, 0.1 mW, 2×10^3; 25 mG, 1.0 mW, 1×10^3; 10 mG, 0.1 mW, 1×10^3. Solvents used have different structures. However, they were added into the sample tube in vapor phase in small amounts making the difference in Q which was slightly affected by different solvent vapor negligibly.

TABLE 1. SOLVENT EFFECT ON THE FORMATION OF R^+, R^+O^{*2-}, AND Mo^{5+} a)

Discussion

Formation of Two Paramagnetic Species. Evidence to show the formation of two paramagnetic species, R^+ and R^+O^{*2-}, has been given in a few cases. The reactivity of R^+ with H_2O is higher than that of R^+O^{*2-} and with use of this R^+O^{*2-} was separated from R^+.[11] The ESR microwave saturation factor of R^+ is larger than that of R^+O^{*2-} which makes the shape of the ESR spectrum of the mixture of these two paramagnetic species strongly power dependent.[13] The experimental results were analysed assuming the presence of two paramagnetic hydrocarbon species. The following assumption was found to be correct: if Component-1 is a spurious signal formed by a broadening of Component-2, the ratio between Component-1 and Compontne-2 should be the same for all the solvents used provided that the measurements are made under the same conditions, *i. e.*, the same H_1 value, and the same modulation width. However, the results (Table 1) show that the ratio greatly depends on the solvent, *viz.* 15 for *n*-hexane, 70 for *t*-butyl benzene, and 46 for 1,3,5-trimethyl benzene. Thus, the solvent effects give evidence to conclude that Component-1 and Component-2 are due to chemically different paramagnetic species.

Necessity of a Solvent in a Cation Formation. The effect of introduced benzene vapor on the ESR of Al_2O_3-MoO_3-anthracene system indicates that solvent molecules are necessary for observing an ESR spectrum having hfs of the anthracene cation. However, a perylene cation might give an ESR spectrum without a hyperfine structure if trapped on a solid surface. The hyperfine structure in the ESR of a hydrocarbon cation is given by two spin Hamiltonian terms, anisotropic which depends on the direction of the external magnetic field, and isotropic which does not. In solution the anisotropic term cannot be observed since it is averaged out by the tumbling motion of the molecule.[14] On a solid catalyst surface the hfs can only be partly observed because of the restricted motions.[15] However, if the sample is cooled to liquid nitrogen temperature, the hfs almost vanishes.[15] Thus, the appearance of a hfs in the ESR upon introduction of a solvent can be due to either (A) formation of the cation by the action of the solvent vapor, or (B) change of the cation, which existed but whose ESR spectrum did not show a hfs, to one which shows a hfs in the spectrum. If (B) is the case it would only be explained as motions of the cation on the surface of the oxide, which have been frozen, resume their activities because the solvent molecules defreeze them. Such defreezing should be due to a partial dissolution of the cation by the solvent molecules on the oxide surface. However, such a partial dissolution will disappear if the solvent is removed from the sample. The hfs in the ESR spectrum once formed does not change when the sample is evacuated subsequently.[11] Thus, case (B) is ruled out. It is concluded that the solvent molecule is necessary for the formation of an aromatic cation on the oxide surface.

Role of the Solvent Molecule in the Cation Formation. If solvent molecules are indispensable to the formation of a hydrocarbon cation, the question arises as to how a "solvent" molecule differs from a "solute" molecule. The solvent dealt with is a substance which is liquid at room temperature and can dissolve aromatic hydrocarbons. This indicates that the solvent molecule can move freely and occupy the oxide surface continuously, cover the narrower places like small pores, and move from one place to another on the surface. The following three roles are possible for solvents. (A) The solvent dissolves the solute and

carries it to the micropores where the parent cation (or the positive electric charge source) lies. (B) The solvent molecule accepts a positive charge from the parent cation and delivers it to the solute molecule by thermal molecular motions. (C) The oxide surface combined with a certain arrangement of the adsorbed solvent molecules, as a whole, promotes the charge transfer process. In this case the aromatic cation formation occurs if an aromatic compound and a positive charge exist on both ends of this surface and solvent arrangement. The possibility for (A) will be excluded because a small amount of solvent (contact pressure <10 mmHg) can cause the formation of anthracene cation. It is hard to distinguish (B) from (C). An experiment carried out with mixed solvents of benzene and cyclohexane (Table 1) seems to exclude (B). If (B) holds, the total formation of the solute cation will be the sum of its formations due to benzene and cyclohexane. If (C) is correct, a small number of cyclohexane present in the surface arrangement of benzene molecules would weaken the function of this surface–benzene system and a linear relation between the composition of the mixed solvent and the cation formation could not be expected. If the solvent or the third component is a liquid at 20 °C, (B) should be more probable. However, when naphthalene which is solid at 20 °C was added as a third component, 10 mg of naphthalene to 30 mg of anthracene, a strong ESR signal of anthracene cation was observed.[16] Thus (C) is more probable.

The results obtained by alkylated benzenes are shown in Table 1. The results shown for toluene to cumene are similar. In the case of dimethylbenzenes, the formation of the paramagnetic species decreases in the order *p*-, *o*-, and *m*-. In the case of trimethyl derivatives, the formation of the paramagnetic species decreases in the order 1,2,3-trimethyl benzene (TMB), 1,2,4-TMB, and 1,3,5-TMB. It is desirable to analyze the results and know what physical factors of the solvent molecules are responsible for the difference. The results from trimethyl benzenes (Table 1) indicate that the molecule with a lower molecular symmetry produces more cation, indicating that a higher dielectric constant favors cation formation. The effect of ionization potential may be studied by computing the energy eigen-values of the molecular orbitals in the methyl substituted benzene cation molecules. The steric effects may also be seen in the series of toluene, ethyl benzene, propyl benzene, and butyl benzene, the formation of perylene cation decreasing in this order.

Paramagnetic Species other than R^+, R^+O^{*2-}, and Mo^{5+}. ESR absorption which is not due to any of these three species is always found in the spectra obtained by Al_2O_3–MoO_3 and has not been interpreted.[3,10] The observed concentration of Mo^{5+} is far greater than the sum of R^+ and R^+O^{*2-}. If benzene is used as a solvent, $(Mo^{5+})=8.5\times10^{17}$ spin/g, while the sum $((R^+)+(R^+O^{*2-}))=2.86\times10^{16}$ spin/g, and is 8.2×10^{17} spin/g less than the former. This indicates that at least this amount of static electricity is compensated by some positively charged species, T^+. Though R^+ and R^+O^{*2-}, both having net positive electric charge, decrease with time, the concentration of Mo^{5+}, having a net negative charge, increases with time. This seems to indicate that the neutralization of R^+ and R^+O^{*2-} takes place not by Mo^{5+} but by some other negatively charged species, T^-. Thus, if the Al_2O_3–MoO_3–hydrocarbon catalytic reaction system is analyzed, T^+ and T^- should be included in the system components.

The Diffusion of Gases at High Pressures. V. The Diffusion of CTH_3 in the CO_2–Ar System

Shinji TAKAHASHI

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received October 5, 1973)

The diffusion coefficients of radioactive methane (CTH_3) in argon and in mixtures of carbon dioxide with argon(0.719, 0.497, and 0.245 mol fractions of argon) were measured at the temperatures of 25, 50, and 75 °C in the 15~250 atm pressure range. The measurements were made through a plug of porous bronze in the diffusion cell by using the radioactive tracer technique. The diffusion coefficient-density products, $D\rho$, for the CTH_3-argon system increased slightly with the density in the region below 5 mol/l, and decreased slightly in the region above 5 mol/l. The $D\rho$ for the CTH_3-mixture systems decreased slightly with the density over the whole range studied here. The density dependence of $D\rho$-values at high densities could not be predicted by Enskog-Thorne's theory.

This investigation is a part of a continuing research project into the diffusion coefficients of gases at high pressures. The previous investigations were made for the diffusion coefficients of $^{14}CO_2$ in the CO_2–Ar[1,2] and CO_2–CH_4 system[3] and for those of CTH_3 in the CH_4–CO_2 system.[4] This paper will present the diffusion coefficients of CTH_3 in the CO_2–Ar system. Measurements were made at the temperatures of 25, 50, and 75 °C in the 15~250 atm pressure range. The mole fractions of argon in the mixtures were 0.719, 0.497, and 0.245.

Experimental

The apparatus and the experimental procedure were the same as those described previously.[1] The diffusion path in the cell was porous bronze plug with pores of about 10 μ. Radioactive methane (CTH_3), obtained from the New England Nuclear Corp., was diluted with non-radioactive methane to a specific activity of about 450 μCi/mmol. The purities of the carbon dioxide and argon used in this investigation were 99.9%. Mixtures of carbon dioxide with argon were prepared in the cylinders. The exact compositions were determined by absorbing carbon dioxide from samples into a potassium hydroxide solution. Under the conditions studied, the mixtures were not in a liquid state.[5]

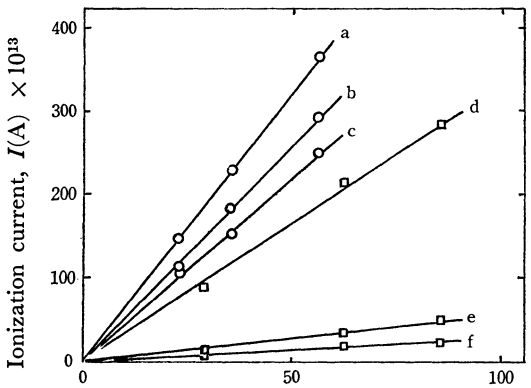

Fig. 1. Relations between the amounts of radioactive methane and the ionization currents at 50 °C.
○: for pure argon, □: for the mixture of 0.497 mol fraction of argon. Pressure(atm) — a, d: 14.55; b, e: 97.8; c: 243.0; f: 194.6

The proportionality between the concentration of radioactive methane and the ionization current, essential for a quantitative treatment of the diffusion data, was confirmed experimentally for pure argon and for mixtures. As examples, the results for pure argon and for the mixture of the 0.497 mol fraction of argon at 50 °C are shown in Fig. 1.

Results and Discussion

In Table 1, showing the experimental results, D is the diffusion coefficients of radioactive methane (CTH_3) in argon and in mixtures. The densities of argon were calculated from the compressibility factors obtained by Michels *et al.*[6] The densities of carbon dioxide–argon mixtures were calculated by using the compressibility chart described in a previous paper.[2] In Fig. 2 the diffusion coefficient-density products, $D\rho$, are plotted against the densities. Curves a, b, c, and d are drawn through the experimental points for the systems where the mole fractions of argon, x_3, are 1.000, 0.719, 0.497, and 0.245. Curve e has been obtained in a previous investigation[4] for the diffusion of CTH_3 with carbon dioxide; it is shown for the sake of comparison. The D at $x_3=1.000$ is the diffusion coefficient of radioactive methane with argon, D_{13}, where the subscripts 1 and 3 denote radioactive methane and argon respectively. The values of $D_{13}\rho$ increase slightly with the density in the region below 5 mol/l, and decrease slightly in the region above 5 mol/l.

The extrapolation of $D\rho$ *vs.* ρ curves to 1 atm provides a basis for comparison with published low-pressure experimental results and with theoretical values. Applying the mass correction[7] to the binary diffusion coefficient of normal methane with argon, D_{43}, which was measured by Carswell[8] at only 25 °C, the binary diffusion coefficient of radioactive methane with argon, D_{13}, was obtained. On the other hand, theoretical values of D_{13} at 1 atm were obtained by applying the mass correction to the binary diffusion coefficients of normal methane with argon, D_{43}, given by:[9]

$$(D_{43})^\circ = 0.002628\frac{\sqrt{T^3(M_4+M_3)/2M_4M_3}}{p\sigma_{43}^2\Omega_{43}^{(1,1)*}}$$

Here, $(D_{43})^\circ$ is the first approximation to diffusion coefficient of normal methane with argon (cm^2/s); T, the temperature (K); M, the molecular weight;

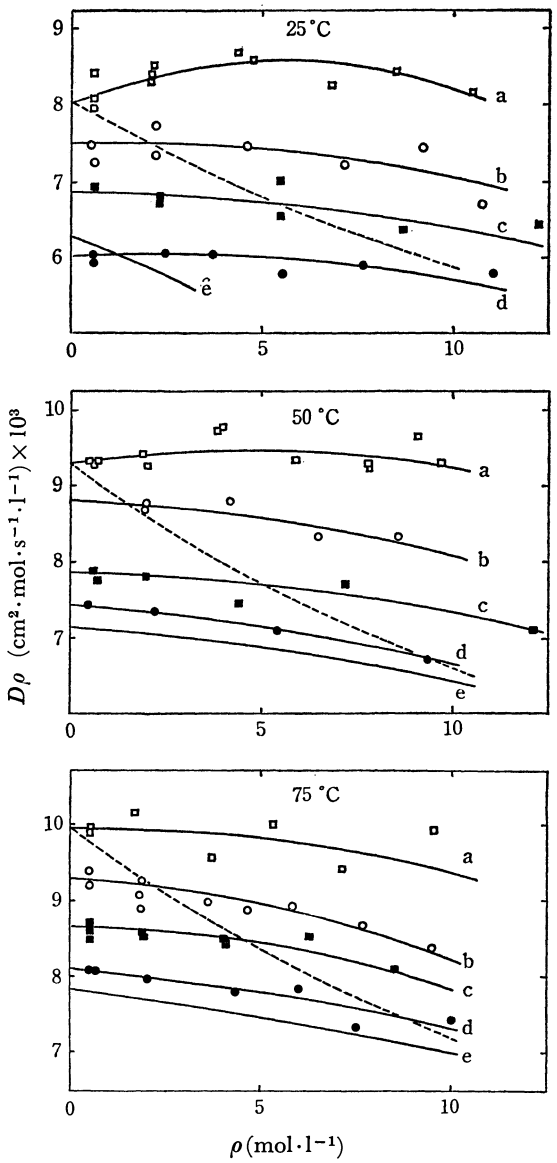

Fig. 2. Variation of $D\rho$ with density.
□, ○, ■, and ● are the experimental points obtained in the present investigation and the mole fraction of argon (x_3) are as follows; □: 1.000, ○: 0.719, ■: 0.497, ●: 0.245. Solid lines (a~d) are the smoothed curves for the experimental points; a: $x_3=1.000$, b: $x_3=0.719$, c: $x_3=0.497$, d: $x_3=0.245$. Solid lines(e) are the smoothed curves obtained in the previous investigation for $x_3=0.000$. Dashed lines are the theoretical curves for $D_{13}\rho$.

p, the pressure (atm); σ_{43}, the potential parameter (A); $\Omega_{43}^{(1,1)*}$, the reduced collision integral. The subscripts 3 and 4 denote argon and normal methane respectively. The values obtained by Carswell and the theoretical values are compared with those extrapolated in this investigation in Table 2. The deviation of the value obtained by Carswell from that extrapolated is not small, but the deviation of the theoretical values are −5~−10%, consistent with those of the values observed for other systems.[10]

According to Enskog-Thorne's theory,[11] which is the only theoretical treatment offering any practical application, the binary diffusion coefficient at high pressures is given by:

$$D_{13}\rho = (D_{13})^{\circ}\rho/\chi_{13} \quad (2)$$

Here, $(D_{13})^{\circ}$ is the binary diffusion coefficient calculated on the basis of the low-density kinetic theory; it is obtained by applying the mass correction to the values given, for example, by Eq. (1). χ_{13} is a correction factor depending on the density of gas; it is given by:

$$\chi_{13} = 1 + 0.2618 n_1 \sigma_1^3 (8 - 3\sigma_1/\sigma_{13}) + 0.2618 n_3 \sigma_3^3 (8 - 3\sigma_3/\sigma_{13}) + \cdots\cdots \quad (3)$$

where n_1 and n_3 are the numbers of molecules per unit volume (cm^{-3}) and where σ_1 and σ_3 are the collision diameters (cm). σ_{13} is $(\sigma_1+\sigma_3)/2$ according to an empirical combining rule. Since radioactive methane is present as only a trace in this investigation, the second term on the right-hand side of Eq. (3) may be neglected. In the calculation of $D_{13}\rho$ at high pressures by means of Eqs. (2) and (3), the extrapolated values of $D_{13}\rho$ at 1 atm were used in place of $(D_{13})^{\circ}\rho$; σ_1 and σ_3 are approximated by the parameters for the Lennard-Jones (12-6) model—3.882 Å for normal methane and 3.418 Å for argon.[12] As is shown in Fig. 2, the theoretical values of $D_{13}\rho$ decrease with the density; they are about 26% lower than those obtained in the present experiment at $\rho=5$ mol/l. Such discrepancies, which have been found for many systems,[13] seem to result from the fact that, in the derivation of Eq. (3), the rigid-sphere model was assumed and the properties of real gases were not taken into consideration. Therefore, it may be expected that the agreement between the theory and the experiment will be better if χ_{13} is evaluated from the P-V-T relations of real gases according to Enskog's suggestion. The results obtained by applying his suggestion will be reported later.

The diffusion coefficients of radioactive methane in mixtures, D_{1m}, at 1 atm may be calculated by using Wilke's equation:[14]

$$1/D_{1m} = x_2/D_{12} + x_3/D_{13} \quad (4)$$

Here, x_2 and x_3 are the mole fractions of carbon dioxide and argon, D_{12} and D_{13} are the binary diffusion coefficients of radioactive methane with carbon dioxide and with argon, and $x_2+x_3\fallingdotseq 1$. In Table 3 the values of D_{1m} at 1 atm given by Eq. (4) are compared with

Table 2. Comparison of the extrapolated values (D_{extra}) of the binary diffusion coefficients at 1 atm with the theoretical values (D_{theor}) and with that reported by Carswell (D_{obs})

those extrapolated. In the calculation of D_{1m} at 1 atm by using Eq. (4), the values extrapolated in this investigation were used for D_{12} and those extrapolated in the previous paper[4] were used for D_{13}. As is shown in Table 3, the deviation is 2.8% on the average; therefore, Eq. (4) seems to be approximately valid.

As Enskog-Thorne's theory has not yet been extended to ternary systems, the prediction of $D_{1m}\rho$ at high pressures was made by using Eq. (5), derived from Eq. (4):

$$1/D_{1m}\rho = x_2/D_{12}\rho + x_3/D_{13}\rho \quad (5)$$

where D_{1m}, D_{12}, and D_{13} are the values at the same density, ρ(mol/l), and where $x_2+x_3 \fallingdotseq 1$. According to Eq. (5) $D_{1m}=D_{12}$ at $x_3=0$, $D_{1m}=D_{13}$ at $x_3=1$, and $1/D_{1m}\rho$ should vary linearly with x_3. By using the values of $D_{1m}\rho$ read from the smoothed curves in Fig. 2, the values of $1/D_{1m}\rho$ were plotted against the mole fractions of argon, x_3, at ρ=2, 4, 6, 8, and 10 mol/l in Fig. 3. Although the plots do not give very good straight lines, the deviation of the values given by Eq. (5) from the smoothed values obtained in Fig. 2 is 2.1% on the average; therefore, Eq. (5) seems to be approximately valid also at high pressures in the present system.

The author wishes to express his deep gratitude to Professor Hiroji Iwasaki for his kind direction and encouragement throughout this work.
