CT absorption band. Each photoconduction spectrum is normalized to the light intensity at 360 nm. The resistivity in the dark, and the maximum wavelengths of the photoconduction and the absorption are summarized in Table 2. A large photoconduction peak was observed in all CT salts in the long wavelength side of the CT absorption band (Fig. 4 and Table 2). In TPP-TCP (Fig. 4a) and TPT-TCP (Fig. 4c), another smaller photoconduction peak was observed at the absorption edge of the LE band of the cation. However, it was not seen clearly in TPP-TCM (Fig. 4b) and TPT-TCM (Fig. 4d), perhaps because it was hidden by the large peak. In TPP-ClO_4 and TPT-ClO_4, in which CT interaction is absent between the cation and the anion, only the small peak was found. This indicates that the large photoconduction peak is due to the excitation at the CT band, and the small one to the local excitation of the cation. A relatively small photocurrent was observed when a CT salt was illuminated with a light in the near IR region (800—1100 nm). This may be due to the presence of the deep traps of charge carriers. The spectral dependence curve was reproducible in repeated measurements, and did not depend on the sample of single crystals. The effect of air on the photoconduction spectra was very small.

A typical time response curve of the photocurrent is given in Fig. 5 for TPT-TCP salt. Upon excitation in the CT band (650 nm), the photocurrent increased immediately and rapidly reached a steady state value. When the excitation was removed, the photocurrent decayed rapidly with a considerably long tail, approaching the initial value of the dark current. This suggests that the photoconduction by CT excitation is not strongly limited by charge carrier traps, although shallow traps are present in the crystal. The excita-

			1.2	0.9	1000

a) wavelength of illuminating light.

tion at 450 nm caused a slightly slower response of the photocurrent.

The temperature dependence of the dark conduction and photoconduction was investigated between 273—323 K. Both for dark- and photocurrents, $i = i_0\exp(-E_a/kT)$ holds. A typical result is given in Fig. 6 for TPT-TCP salt both in vacuum and in air. The activation energy E_a of the photocurrent, 0.45 eV in vacuum and 0.4 eV in air, is approximately the same as that of the dark current, 0.4 eV both in vacuum and in air. The photocurrent at 1000 nm had also essentially the same activation energy 0.5 eV as the photocurrent at 650 nm. The other salts gave essentially the same results (Table 3).

ESR Absorption. A weak ESR signal observed initially in perchlorate salts of TPP and TPT cations disappeared by recrystallization of the salts. Therefore, all CT salts were prepared carefully from the corresponding perchlorate salt which gave no ESR signal. Even when prepared in this way, CT salts showed a single broad ESR absorption band which showed no marked change by further recrystallizations. This indicates that the absorption is not due to impurities. As an illustration, the ESR signal of TPT-TCP salt is given in Fig. 7. The *g*-values and the total spin concentrations of the CT salts are listed in Table 4. As the value of spin concentration changed to some extent with the crystal, average values are listed. The total spin concentrations 10^{15}—10^{16} spins/gram are much smaller than those observed in many strong molecular CT complexes,[9,10] and almost the same as those measured in weak molecular complexes.[11] These ESR signals seem to arise from the defects in the crystal. Upon illumination with a visible light, intensity of an ESR signal increased slightly but the *g*-value showed no shift (Fig. 7). The ratio of the ESR intensity on excitation with a white light to that in the dark is listed in Table 4. No ESR absorption was observed when the perchlorate salts of the cation and

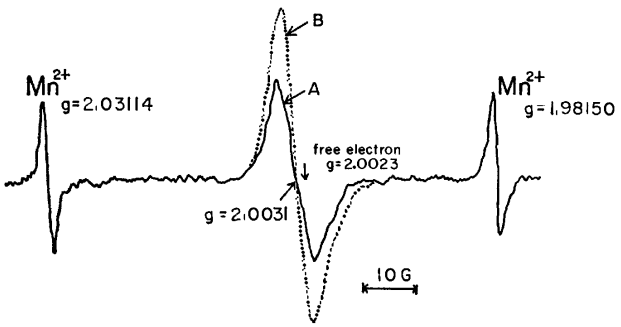

Fig. 7. ESR absorption spectra of TPT-TCP salt in vacuum at room temperature.
—— in the dark, ---- on illumination with a white light.

Table 4. *g*-Values, total spin concentration ([S]) and the ratio (R) of ESR intensity on illumination with a white light to that in the dark of organic CT salts

Salts	*g*-Value	[S] (spins/gram)	R
TPP-TCP	2.00270	1×10^{15}	1.3
TPT-TCP	2.00310	2×10^{15}	1.8
TPP-TCM	2.00295	1×10^{16}	1.3
TPT-TCM	2.00380	5×10^{15}	1.4
ADPT-TCP	2.00530	2×10^{15}	1.5
ADPP-TCM	2.00480	1×10^{15}	1.35

alkali metal salts of the anion were irradiated. The lights in the CT band region and in the near IR region (500—1200 nm) were effective on increasing the ESR signal, while those of shorter than 450 nm were ineffective.

The photoresponse curve of an ESR signal of TPT–TCP salt is given as an example, in Fig. 8. The curve at room temperature showed a fairly rapid rise and decay, and was similar to that of the photocurrent shown in Fig. 5. No significant difference in ESR absorption was found between that in vacuum and in air. The spectral response, time response and the effect of air of the photo-ESR absorption suggest a close relationship between the photo-induced paramagnetism and the photoconduction of the CT salts.

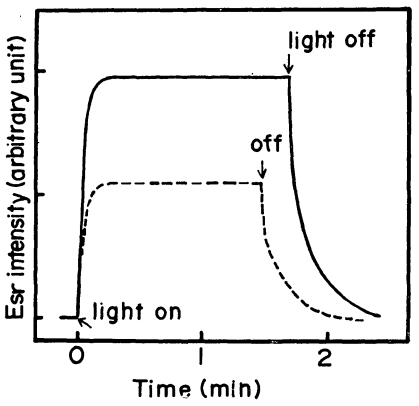

Fig. 8. Time response curves of photo-ESR absorption of TPT-TCP salt in vacuum at room temperature. —— on illumination at 500—1200 nm, ---- on illumination at 500—700 nm.

The temperature dependence of an ESR absorption in the dark and on irradiation was investigated in the range 213—323 K. The total spin concentration and the *g*-value of an ESR signal in the dark showed no significant change when temperature was lowered, indicating that the amount and nature of the paramagnetic species which existed originally in the material are independent of the temperature. The photo-ESR absorption showed a gradual decrease in its spin concentration with the decrease of temperature, activation energy being slightly negative (<0.2 eV). Thus, both the paramagnetic species induced by light and those originally present in the crystal in the dark are not produced by the thermal activation process.

Discussion

General Feature of the Electrical Conduction. *(i) All CT salts show a larger photoconduction peak at the long wavelength side of the interionic CT absorption band, and the photoconduction is almost unaffected by the presence of air*: This photoconduction is much larger than that observed in the perchlorate salt of the corresponding cation. A good reproducibility of the photoconduction was observed during the course of repeated measurements. Even when measured on different single crystals, the behavior of the photoconduction remained almost unchanged. This suggests that the observed conduction in this region is intrinsic and the photoexcitation of the interionic CT band contributes to the photoconduction.

Charge carriers seem to be generated in the bulk rather than on the surface of a crystal. Carrier generation in the bulk can account for the CT absorption peak not coinciding with the photocurrent peak; the number of photons reaching the bulk of a crystal are larger at the edge of the absorption band than at the absorption peak. The photocurrent, which is insensitive to the presence of air, also supports bulk carrier generation.

(ii) All CT salts show a smaller photoconduction in the near IR region of 800—1100 nm, which is also insensitive to the presence of air: This suggests the presence of deep traps at 1.0—1.4 eV below the conduction level. As the value is considerably larger than the observed activation energy, the dark current cannot be caused by the thermally activated carrier generation from these deep traps.

(iii) When excited in a LE band of the cation, the photoconduction does not appear significantly: This may be due to the fact that the photon is absorbed mostly on the surface of a crystal. However, the photon in the absorption edge of the LE band can reach the bulk of a crystal, and produce the photocarrier as in the case of CT band excitation as follows,

$$(D^{-}A^{+}) \xrightarrow{h\nu} (D^{-}A^{+*}) \longrightarrow (D\cdot A\cdot)^{*} \longrightarrow (D\cdot + A\cdot)$$

ground state — locally excited state — excited CT state — photocarriers

(iv) The photocurrent in the CT absorption region is proportional to about the 0.5 power of the incident light intensity: As the photocunduction in this region seems to be intrinsic, one photon absorption produces two charge carriers. However, if the carriers disappear with recombination between electrons and holes during migration, the concentration of the carrier would be proportional to the 0.5 power of the light intensity. Thus the photoconduction in our system may be recombination limited.

(v) Both dark conductivity and photoconductivity in the CT absorption and near IR regions have the same activation energy: As can be seen in Table 3, the most striking results obtained for the electrical properties of organic CT salts is that the values of activation energy for dark conduction and photoconduction are the same without any exception with respect to the six CT salts investigated. The property seems to be general with this kind of organic salts, and is basically important for framing up the conduction mechanism in the salts as in the following.

Mechanism of the Electrical Conduction in Organic CT Salts. The property mentioned above reminds us that a "trapping conduction mechanism" is the simplest model for explaining the agreement of the values of the activation energy of dark conduction and photoconduction. The trapping conduction model is shown schematically with TPT–TCP salt in Fig. 9 as an example. The TPT–TCP crystal has trapped carriers 0.4 eV below the conduction level which are thermally

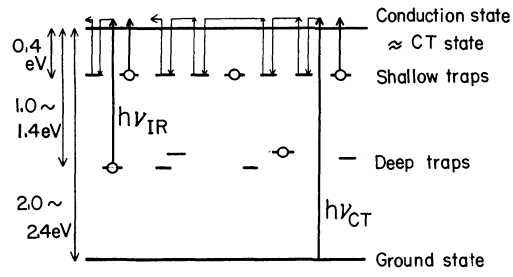

Fig. 9. Trapping conduction model with TPT-TCP salt.

excited up to conduction level in the dark, and the carriers generated in this way migrate through the crystal repeating the trapping and detrapping processes. Thus, the activation energy in dark conduction should be 0.4 eV, the depth of the trap levels below the conduction level, being the energy required for the trapping conduction.

In the case of photoconduction, the photocarriers are spontaneously generated in the conduction level by the absorption of light in the CT band, since the energy level of the conduction state is approximately equal to that of the excited CT state. The photocarriers thus generated migrate by the trapping conduction mechanism. In this mechanism, no activation energy is required for the carrier generation, and the activation energy of 0.4 eV as observed should be consumed in the carrier migration process. Thus, both for dark conduction and photoconduction the same amount, 0.4 eV, of activation energy is required. Photocarriers generated from the deep trap levels by near IR illumination also require the same activation energy 0.4 eV for their migration.

In our present model, only electron carriers are considered. As the molecular size of the acceptor cation is considerably larger than that of the donor anion, the acceptor radical A·, *i.e.*, electron, might contribute predominantly to the photocurrent. Molecular arrangement in the crystal supports this view.[12]

Photoconduction and Paramagnetic Species. An investigation of the ESR of the salts revealed that (a) CT salts showed a temperature independent ESR absorption even in the dark, (b) the perchlorate salts in which CT ineraction is absent gave no ESR signal, (c) the total spin concentration was of the order 10^{15}—10^{16} spins/gram, the amount changing considerably measured on different samples, (d) photo-illumination increased the ESR signal, the photo-ESR absorption showing a similar time response and spectral response with photocurrent, and (e) the temperature dependence of the photo-ESR absorption showed a slightly negative activation energy, the signal increasing with the lowering of temperature, and the time response curve of the phot-ESR absorption showed considerably longer rise and decay at lower temperatures.

The temperature independent ESR signal in the dark may be due to the charge carriers trapped in shallow traps (Fig. 9). These trapped carriers may be generated from crystal defects by CT interaction, because of (b) and (c). Photocarriers and the paramagnetic species of the photo-ESR may be the same (d), as can be seen in Fig. 9. The slightly negative activation energy of the photo-ESR (e) may be understood by the decrease of the recombination of the paramagnetic species with the lowering of temperature. Actually, the time response curve of the photo-ESR absorption shows considerably longer rise and decay at lower temperatures. Since paramagnetic species and the charge carriers are the same, the behavior of the photo-ESR signal is in line with the recombination limited photoconductivity, a photocurrent being proportional to the 0.5 power of the light intensity.

In the case of strong molecular CT complexes, such as perylene-iodine complex, a good coincidence between the values of the activation energy of dark current and of unpaired spin concentration was observed. This was used for proof that the paramagnetic species observed in the ESR spectroscopy were identical with the carriers.[9] This kind of coincidence is not necessary in our system, since the thermal activation process in the dark conduction is the carrier migration process. If the carrier concentration in the dark is equal to the spin concentration, about 10^{15} electrons/gram, the mobility of the carrier is estimated to be 10^{-5}—10^{-6} cm^2/volt·sec from the relation $i=Ne\mu$, where N is carrier concentration, e electric charge and μ mobility. The value seems to be very small as compared with the observed mobilities of organic compounds.[13] However, taking account of the fact that a fairly large energy is required for the carrier migration, and that the photoconduction is recombination limited, this small value of mobility is conceivable.

Another Mechanism of the Electrical Conduction. Although the above mechanism can account for the results of the electrical and magnetic properties of the organic CT salts, it should be noted that other mechanisms are possible for both carrier generation and migration. At first, charge carriers can be generated by the interaction between crystal imperfections and CT excitons migrating in a crystal. In this case, the carrier generation is extrinsic. This mechanism is the same as that suggested by Akamatu and Kuroda for the photoconduction of pyrene complexes.[3] Both mechanisms can explain the spectral, temperature and light intensity dependences of the photocurrent, but from the fact that the behavior of the photoconduction shows a good reproducibility when measured on several samples of single crystals, we consider the former mechanism, that is, the intrinsic carrier generation, to be plausible.

With weak molecular CT complexes, Akamatu and Kuroda suggested that the energy equivalent to the difference of the energy between the conduction level and the CT exciton level is required for the separation of a D^+A^- ion-radical pair. In this case, CT excitons cannot be separated spontaneously into charge carriers. However, in interionic CT salts, the interaction between two neutral radical species, D·A·, in the excited CT state may be small and consequently an energy required for the charge separation is smaller than that in the case of molecular CT complexes, and the photocarriers can be generated from the excited CT state with a very small thermal energy compared with the activation energy for the migration. Thus, the energy level of the conduction state can be approximately

equal to that of the excited CT state, and the intrinsic charge carrier generation seems to be possible in organic CT salts.

A hopping mechanism may be possible for the carrier migration process, instead of the trapping conduction. In this case, the charge carrier migrates from an ion to another with an activation energy 0.4—0.8 eV. This value seems to be fairly large for the activation energy for hopping conduction. However, these two mechanisms, *i.e.*, trapping conduction and hopping conduction, can explain the experimental results, and the latter possibility cannot be excluded.

Heterocyclic Azomethine Compounds and Their Reduction Products as Analytical Reagents. II. The Reaction of 1-Picolylideneamino-2-naphthol with Zinc(II)

Makoto OTOMO, Kiyoshi FUKUI, and Kazunobu KODAMA

Department of Synthetic Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received May 15, 1973)

The acid dissociation constants of 1-picolylideneamino-2-naphthol in aqueous dioxane media of various concentrations and the stability constant of the zinc(II) chelate in a 50 v/v% aqueous dioxane medium were determined potentiometrically at 25 °C and $\mu=0.1$. The acid dissociation constants, pK_{a_1}, pK_{a_2}, and pK_{a_3}, at the zero dioxane mole fraction, evaluated by means of a least-squares treatment of the experimental data, are 3.1_6, 4.3_1, and 10.3_1 respectively. The overall stability constant of the zinc chelate was calculated be to $\log\beta_2=12.7_9$. 1-Picolylideneamino-2-naphthol can be used as a sensitive reagent for the extractive spectrophotometric determination of zinc. The zinc chelate extracted into chloroform has an absorption maximum at 520 nm. The bathochromic shift is as large as 120 nm. The color system obeys Beer's law over a concentration range up to 2×10^{-5} M. The molar absorptivity is 4.5×10^4 l/mol·cm at 520 nm.

In a preceding paper,[1] the acid dissociation constants of picolinaldehyde 2-hydroxyanil and some of its derivatives and their reactions with metal ions have been reported. The applicability of these compounds as sensitive reagents for the extractive spectrophotometric determinations of certain divalent-metal ions has also been pointed out. There has, however, been no reported characterization of metal complexes derived from the Schiff bases of 1-amino-2-naphthol or any of its ring-substitution products. In the present work, the chelate formation between 1-picolylideneamino-2-naphthol, a new heterocyclic azomethine compound, and zinc(II) and its application to the extractive spectrophotometric determination of traces of zinc are investigated. Of the divalent-metal chelates with this reagent which can be extracted into chloroform, the zinc chelate has the largest molar absorptivity.

Experimental

Materials and Apparatus. 1-Picolylideneamino-2-naphthol is synthesized as follows. A suspension of 1-amino-2-naphthol (0.05 mol)(purified by Kurzer's method[2]) in benzene(300 ml) is refluxed with freshly-distilled picolinaldehyde (0.055 mol) for a period of 15 min. The resulting crude product is recrystallized from a mixture of methanol and benzene (1 : 1) to obtain yellow fine crystals (4 g, 33%); mp 186—187 °C (with decomposition); IR (KBr): 1627 cm^{-1} (-CH=N-). Found: C, 77.49; H, 4.64; N, 11.26%. Calcd for $C_{16}H_{12}ON_2$: C, 77.40; H, 4.87; N, 11.28%.

A 1×10^{-4} M solution of the reagent in chloroform and a 1×10^{-2} M stock solution of zinc perchlorate are used for the spectrophotometric study. An Iwaki model KM mechanical shaker is used for the shaking.

All the other reagents and apparatus used have been reported previously.[1]

Potentiometric Titrations. As the reagent and the zinc chelate are insoluble in water, the titration is carried out in an aqueous dioxane medium. The experimental conditions and the method for the determination of the acid dissociation constants have been described previously.[1] For the determination of the stability constant, a 50 v/v% dioxane solution containing the ligand (2.5×10^{-3} M), sodium perchlorate (0.1 M), and zinc perchlorate (1.25×10^{-3} M) is titrated with a 0.1850 M sodium hydroxide solution at 25± 0.1 °C.

Standard Procedure for the Zinc Determination. An aliquot of a zinc solution is transferred into a 50-ml separatory funnel along with a 5 ml of a 1 M sodium perchlorate solution and 2 ml of a 1 M tris(hydroxymethyl)aminomethane-hydrochloric acid buffer solution (pH 8.5). The solution is diluted to 10 ml with water and then shaken for 1 min with 10 ml of the reagent solution. The absorbance of the chloroform extract is then measured at 520 nm against the reagent blank.

Results and Discussion

Acid Dissociation Constants. The potentiometric titration curves of the monosodium salt of 1-picolylideneamino-2-naphthol with perchloric acid show that this reagent behaves as a tribasic acid, the equations used to calculate the acid dissociation constants being:

$$\frac{(1-R)[H^+]}{R-2} = \frac{R[H^+]}{R-2}\cdot\frac{1}{K_{a1}} + K_{a2} \quad (1)$$

$$\frac{2-R}{R[H^+]^2} = \frac{R-1}{R[H^+]}\cdot\frac{1}{K_{a2}} + \frac{1}{K_{a1}K_{a2}} \quad (2)$$

and:

$$K_{a3} = \frac{(R-2)[H^+]}{3-R} \quad (3)$$

where $R=\{(3-a)C_A+[H^+]-[OH^-]\}/C_A$, and where C_A is the total concentration of the ligand, and a, the degree of neutralization. The pK_a values of the ligand acid in aqueous dioxane media of various concentrations are given in Table 1. The values of pK_{a1} and pK_{a2} are attributed to the removal of protons from the azomethine and the pyridine nitrogens respectively, whilst that of pK_{a3} is attributed to the dissociation of the naphtholic proton. The values of pK_{a1} and pK_{a2} decrease, and that of pK_{a3} increases, with an

TABLE 1. ACID DISSOCIATION CONSTANTS OF 1-PICOLYLIDENEAMINO-2-NAPHTHOL IN AQUEOUS DIOXANE MEDIA
$\mu=0.1$, 25°C

Mole fraction of dioxane	pK_{a1}	pK_{a2}	pK_{a3}
0	3.1_6	4.3_1	10.3_1
0.1122(37.5 v/v%)	3.0_5	4.2_4	10.7_5
0.1739(50 v/v%)	2.9_5	4.1_7	11.4_0
0.2598(62.5 v/v%)	2.8_6	4.0_9	11.5_3
0.3872(75 v/v%)	2.7_4	4.0_3	12.2_8

increase in the mole fraction of dioxane. On plotting each pK_a value against the mole fraction of dioxane, an approximately linear relationship is obtained in every case. The value of pK_a's at the zero dioxane mole fraction, evaluated by a least-squares treatment of the experimental data, are also included in Table 1.

The pK_{a3} value for 1-picolylideneamino-2-naphthol in the 50 v/v% dioxane medium is lower by 0.9 log unit than the pK_{OH} value for PAN[3] under the same conditions. Contrary to this observation, it has been found that the pK_{a3} values for picolinaldehyde 2-hydroxyanil and its methyl and chloro derivatives are somewhat higher than those for the corresponding azo dyes.[1,4] These results may be explained according to Hadzi's observation[5] that *o*-hydroxyazonaphthols exist as azo-hydrazo tautomers, whereas *o*-hydroxyazophenols are true azo compounds.

Stability Constant of the Zinc Chelate. The results of the continuous variation method show that zinc reacts with the reagent in a neutral to a slightly basic medium to form a 1 : 2 metal-to-ligand chelate easily extractable into chloroform. Therefore, the potentiometric titration is carried out in the molar ratio of 1 : 2.

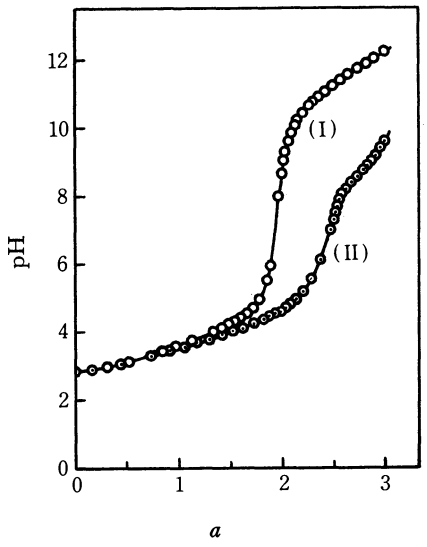

Fig. 1. Potentiometric titration curves of 1-picolylideneamino-2-naphthol and its zinc chelate in 50 v/v% aqueous dioxane, $\mu=0.1$, 25 °C; abscissa a represents moles of alkali added per mole of ligand (tribasic acid).
(I): Ligand, 2.50×10^{-3} M.
(II): Ligand, 2.50×10^{-3} M; Zn, 1.25×10^{-3} M

The titration curves of the reagent in a 50 v/v% dioxane medium in both the presence and absence of zinc are shown in Fig. 1. The pH inflection at $a=2.5$ in the former case suggests that the formation reactions of the 1 : 1 chelate, ZnL^+, and the 1 : 2 chelate, ZnL_2, proceed predominantly below and above $a=2.5$ respectively. The successive stability constants can be obtained from the following relationships[6]:

$$L=\frac{K_{a2}K_{a3}(3C_A+[OH^-]-[Na^+]-[H^+])}{2[H^+]^2+[H^+]K_{a2}} \quad (4)$$

$$\bar{n}=\frac{C_A-(K_{a2}K_{a3}+[H^+]K_{a2}+[H^+]^2)L/K_{a2}K_{a3}}{C_M} \quad (5)$$

where C_A and C_M are the total concentrations of the ligand and of zinc respectively. The values of $\bar{n}$ and L at each point of the titration curve are calculated from Eqs. (4) and (5). From these data, the formation curve is then plotted, a symmetrical pattern being followed. The successive stability constants are estimated from the values of pL at $\bar{n}=0.5$ and $\bar{n}=1.5$ to be 7.6_0 for $\log K_1$ and 5.1_9 for $\log K_2$, by means of the equations given by Schrøder.[7] These values are considerably lower than those for the zinc-PAN chelate ($\log K_1=11.2$, $\log K_2=10.52$[3]) and the zinc-picolinaldehyde 2-hydroxyanil chelate ($\log K_1=10.8$, $\log K_2=8.0$[4]), but higher than those for the zinc chelates of salicylidene-2-aminopyridine ($\log K_1=5.8$, $\log K_2=4.3$[4]) and *o*-aminophenol ($\log K_1=5.99$, $\log K_2=4.96$[8]). 1-Picolylideneamino-2-naphthol, therefore, acts as a terdentate ligand toward zinc to form two five-membered chelate rings. This consideration is supported by the spectral properties of the other divalent-metal chelates with the reagent in chloroform, as will be shown below.

Extractive Spectrophotometric Determination of Zinc. As has already been shown above, the 1 : 2 zinc-1-picolylideneamino-2-naphthol chelate is readily extracted into organic solvents, such as chloroform, 1,2-dichloroethane, *o*-dichlorobenzene, and nitrobenzene, to give a reddish-violet color. Chloroform is chosen because the largest absorbance is obtained in it. The color system obeys Beer's law. It is, therefore, tested for the extractive spectrophotometric determination of traces of zinc. However it is not possible to obtain the distribution coefficients of the reagent and the zinc chelate because of their low stability.

Absorption Spectra: The absorption spectra of the reagent and its zinc chelate in chloroform are shown in Fig. 2, the absorption maximum of the zinc chelate against the reagent blank being found at 520 nm. It may be noted that the bathochromic shift observed on chelation with the reagent is about 120 nm, much larger than that observed with PAN, *i.e.*, 80 nm. This is an advantage in the spectrophotometric determination of metals.

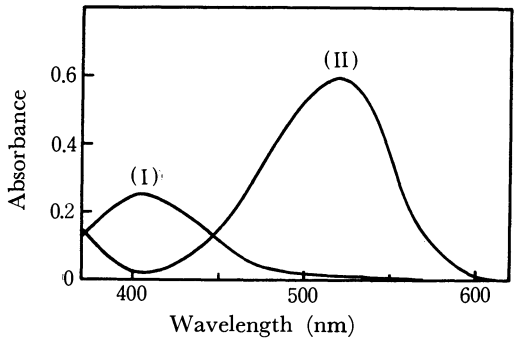

Fig. 2. Visible absorption spectra of 1-picolylideneamino 2-naphthol and its zinc chelate in chloroform.
(I): Reagent, 5.0×10^{-5} M; reference, $CHCl_3$.
(II): Zn, 1.30×10^{-5} M (8.5 μg); reagent, 2.0×10^{-4} M; pH, 8.5; reference, reagent blank.

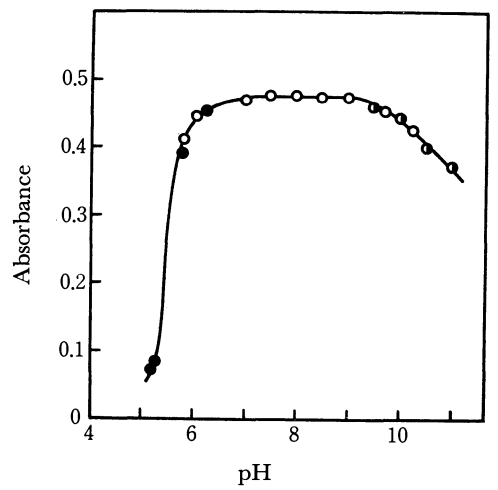

Fig. 3. Effect of pH.
Zn, 1.07×10^{-5} M (7.0 μg); reagent, 2.0×10^{-4} M; reference, reagent blank; ●, hexamethylenetetramine-HCl buffer; ○, tris(hydroxymethyl)aminomethane-HCl buffer; ◑, ammonia-ammonium chloride buffer.

Effect of pH: The absorbance of the organic phase is measured as a function of the pH of the aqueous phase, the results being shown in Fig. 3. At any pH examined, the absorption maximum of the chloroform extract is found at 520 nm, indicating that only one species is extracted. The zinc chelate is extracted above pH 5. The absorbance of the extract is at its maximum at pH 7.5—9.0

Color Stability and Effect of the Shaking Time: The zinc chelate is not very stable in either the aqueous or the organic phase. The absorbance of the chloroform extract decreases by 4.0% per 30 min for 7.3 μg of zinc. The absorbance is thus measured within 5 min after extraction. The maximum absorbance is obtained when a zinc solution is shaken with a chloroform solution of the reagent for 45 s to 2 min at pH 8.5.

Effect of the Reagent Concentration: About a 10-fold excess of the reagent is enough to obtain a constant absorbance.

Beer's Law and Sensitivity: Beer's law is obeyed over the concentration range up to 2×10^{-5} M (13 μg of zinc in 10 ml). At 520 nm, the molar absorptivity is 4.5×10^{4}. The spectrophotometric sensitivity is estimated to be 1.5×10^{-3} μg of zinc per cm^2, corresponding to log $I_0/I=0.001$. The sensitivity of the present method is much higher than that of the methods using zincon (molar absorptivity, $\varepsilon=1.9\times10^{4}$ at 610 nm[9]) or xylenol orange ($\varepsilon=2.74\times10^{4}$ at 550 nm[10]); however, it is lower than those with PAN ($\varepsilon=5.6\times10^{4}$ at 550 nm[11]), 5-chloro-PAN ($\varepsilon=8.4\times10^{4}$ at 564 nm[12]), or dithizone ($\varepsilon=9.6\times10^{4}$ at 532 nm[13]).

Reactions with Other Divalent-metal Ions. 1-Picolylideneamino-2-naphthol reacts with many divalent-metal ions in a neutral or slightly basic medium to form extractable colored chelates. The cobalt(II) chelate, however, changes in color from reddish-violet to brown during the course of extraction with chloroform at pH 8.5, giving a precipitate on the interface. This is probably due to the oxidation of the cobalt(II) chelate to the cobalt(III). In addition, magnesium(II) gives an orange red color to the organic phase during the course of extraction at pH 11, but the color fades away in a moment.

Table 2. Spectral properties of the metal chelates extracted into chloroform

Metal	Absorption maximum (nm)	Molar absorptivity $\times10^{-4}$ (l/mol·cm)	pH
Cd(II)	524	3.6	9.8[b]
Co(II)	523	partly precipitated	8.5
Cu(II)	540	1.5	7.4[b]
Fe(II)[a]	520	0.7	8.5[b]
Hg(II)	530	3.5	6.3[b]
Mn(II)[a]	523	3.7	9.8[b]
Ni(II)	537	3.5	8.5[b]
Pb(II)	520	1.5	9.8[b]
UO_2(II)	510	0.4	6.0
Zn(II)	520	4.5	8.5

a) in the presence of NH_2OH. b) pH value at which the maximum absorbance is obtained.

Table 2 summarizes the spectral properties of several divalent-metal chelates with this reagent extracted into chloroform. The spectrum of each chelate shows a broad, intense band well separated from that of the reagent, the shift being larger than 100 nm. The results tabulated in Table 2 imply that 1-picolylideneamino-2-naphthol can also be used as a sensitive reagent for the extractive spectrophotometric determination of cadmium(II) and manganese(II).

The disadvanatge of the present reagent is that its solution and chelates are not very stable. As it is much more sensitive for cadmium(II), manganese (II), and zinc(II) than copper(II), though, a further search for more stable analogs is in progress.

We are grateful to The Asahi Glass Foundation for Contribution to Industrial Technology for its financial support.

Transition-metal Complexes of Pyrrole Pigments. IX.[1,2] Divalent and Trivalent Iron Chelates of Dipyrromethenes

Yukito MURAKAMI, Yoshihisa MATSUDA, Kazunori SAKATA, and Kenji HARADA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received August 10, 1973)

The iron chelates of polymethyl-substituted dipyrromethenes were prepared. The ferrous ion was found to form complexes having a ligand to metal ratio of 2 : 1 with 5,5′-substituted dipyrromethenes, 3,3′,5,5′-tetramethyl- and 3,3′,4,4′,5,5′-hexamethyl-dipyrromethene. On the other hand, the ferric ion gave a complex having a 3 : 1 molar ratio of ligand to metal with a 5,5′-unsubstituted ligand, 3,3′,4-trimethyldipyrromethene. The complexes were studied by means of visible and IR spectroscopy as well as by magnetic susceptibility measurements. The iron(II) chelates were confirmed to be of high spin type with distorted tetrahedral structure (D_2), while the iron(III) chelate demonstrated a low spin character with hexacoordination. The strong ligand-field bands of the latter complex was ascribed to the trigonally distorted octahedral coordination (D_3) along with a high covalent nature of metal-ligand bonds.

In connection with metal complexes of macrocyclic pyrrole pigments which occur naturally and play an eminent role in biochemical catalysis, we have investigated metal complexes of synthetic pyrrole pigments of open chain structure from the viewpoint of coordination stereochemistry.[2-9] These pyrrole derivatives include dipyrromethenes and biladienes with various substituents. We clarified that substituent groups placed at the 5 and 5′ positions of dipyrromethenes in the divalent transition-metal complexes yielded a significant steric hindrance among the substituents in the same complex, so that no planar complexes were obtained even with copper(II) and nickel(II) having a good tendency of planar coordination.

For a transition metal in a highly stabilized trivalent state, however, a hexacoordinated bisdipyrromethene complex with an additional anionic ligand can be obtained. This was exemplified by the characterization of acetatobis(3,3′,5,5′-tetramethyldipyrromethenato)chromium(III).[2] The chromium complex undergoes a significant distortion along the C_2-axis due to the steric effect of the 5,5′-substituents. In contrast to the chromium system, the valency state of iron is more susceptible to the ligand-field effect as judged from its oxidation-reduction potential. In the present work, we have undertaken to elucidate the correlation between the valency state of iron in a complex and the nature of the 5,5′-substituents placed in the ligands with the use of 3,3′,4-trimethyl- (**1**), 3,3′,5,5′-tetramethyl- (**2**), and 3,3′,4,4′,5,5′-hexamethyl-dipyrromethene (**3**) as bidentate ligands.

Experimental

Ligands. *3,3′,4-Trimethyldipyrromethene hydrochloride*: A mixture of 3-methyl-2-formylpyrrole[10] (0.41 g), 3,4-dimethylpyrrole[10] (0.36 g), and dry ethyl ether (60 ml) was added dropwise to 40 ml of dry ethyl ether placed in a reaction flask under nitrogen atmosphere. The hydrogen chloride gas diluted with dry nitrogen was bubbled through the reaction mixture while the addition was continued for 20 min at an ice-sodium chloride temperature. Dry HCl gas was continuously introduced into the mixture until precipitation of the orange solid no longer took place. The precipitates were recovered by filtration and washed with 50 ml of dry ether. Recrystallization from acetone-chloroform gave reddish orange crystals; yield 0.70 g (82%). UV($CHCl_3$): 280 sh (ε 1150), 286 (ε 1180), 306 (ε 884), 378 (ε 6680), 460 sh (ε 63100), and 468 nm (ε 72200). IR(KBr disk): 1621 cm^{-1}(pyrrole skeletal). NMR(CF_3CO_2H, TMS): δ 2.19 (3H, s, 4-C$\underline{H}_3$), 2.44, 2.53 (6H, each s, 3-C$\underline{H}_3$ and 3′-C$\underline{H}_3$), 6.61 (1H, br.s, 4′-$\underline{H}$), 7.77 (2H, s, 5-$\underline{H}$ and 5′-$\underline{H}$), and 7.84 (1H, s, -C$\underline{H}$=).

Found: C, 64.74; H, 6.88; N, 12.32%. Calcd for $C_{12}H_{15}N_2Cl$: C, 64.71; H, 6.79; N, 12.58%.

The synthesis of 3,3′,5,5′-tetramethyl- and 3,3′,4,4′,5,5′-hexamethyl-dipyrromethene has been described.[3]

Tris(3,3′,4-trimethyldipyrromethenato)iron(III). An aqueous solution (3 ml) containing ferric chloride hexahydrate (0.36 g) was added to a mixture of 3,3′,4-trimethyldipyrromethene hydrochloride (0.60 g) and methanol (180 ml). Crystalline precipitates of dark green luster were obtained from the dark reddish reaction mixture upon dropwise addition of aqueous ammonia (28%, 10 ml) with stirring. After being allowed to stand for 1 hr in a freezer, the crystalline solid was recovered and recrystallized from acetone as dark green crystals; yield 0.43 g (77%).

Found: C, 70.34; H, 6.54; N, 14.13%. Calcd for $C_{36}H_{39}N_6Fe$: C, 70.69; H, 6.44; N, 13.74%.

Bis(3,3′,5,5′-tetramethyldipyrromethenato)iron(II). Aqueous ammonia (28%, 10 ml) was added dropwise into a mixture of the hydrated ferrous chloride (1.2 g) dissolved in 30 ml of water and 3,3′,5,5′-tetramethyldipyrromethene (free base, 1.0 g) in 130 ml of ethanol. A crystalline solid of green luster was recovered after the reaction mixture had been allowed to stand for sometime in a freezer. Recrystallization from *n*-hexane gave green crystals; yield 0.58 g (51%).

Found: C, 68.79; H, 6.65; N, 12.24%. Calcd for $C_{26}H_{30}N_4Fe$: C, 68.72; H, 6.66; N, 12.33%.

Bis(3,3′,4,4′,5,5′-hexamethyldipyrromethenato)iron(II) A crystalline solid was obtained from 3,3′,4,4′,5,5′-hexamethyldipyrromethene (free base, 0.50 g) and the hydrated ferrous chloride (0.50 g) in a manner similar to the above iron(II) complex. Recrystallization from *n*-hexane–benzene gave green crystals; yield 0.45 g (82%).

Found: C, 70.33; H, 7.39; N, 10.92%. Calcd for $C_{30}H_{38}N_4Fe$: C, 70.58; H, 7.50; N, 10.98%.

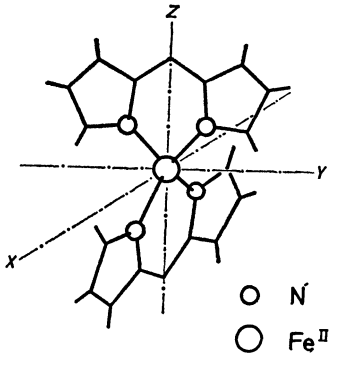
Physical Measurements. Electronic spectra covering the 250—2000 nm region were recorded on a Hitachi EPS-2 spectrophotometer for chloroform solutions at room temperature. Infrared spectra were measured with a JASCO DS-403G spectrophotometer by a Nujol mull technique. Magnetic susceptibility measurements of solid powdered samples were carried out with Gouy balance. Calibrations were made with use of fresh distilled water and cupric sulfate pentahydrate, while diamagnetic corrections were performed by using Pascal's constants.

Results and Discussion

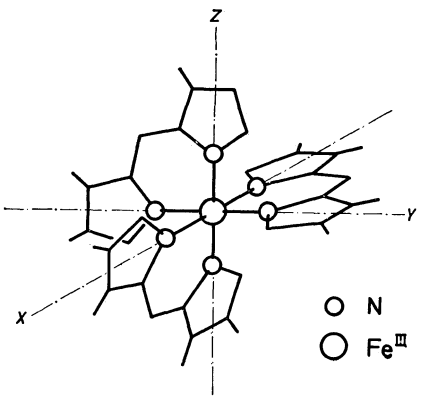
The reactions of ferrous chloride with dipyrromethene ligands **2** and **3** resulted in the formation of the corresponding iron(II) complexes having a 2 : 1 ligand to metal ratio (bis-complex), while a ferric salt reacted with ligand **1** to give the 3 : 1 dipyrromethene-iron(III) complex (tris-complex). In the latter reaction, ferrous chloride was also utilized in place of the ferric salt to afford the same complex. On the other hand, the reactions of ferric chloride with ligands **2** and **3** failed to give any characteristic metal complex. For the dipyrromethene-iron chelate system, the trivalent iron state appears to be electronically more stable than the divalent state due to the chelate effect, unless other factors such as steric effect come into play. The absence of bulky substituent groups at the 5,5'-positions in one dipyrromethene ligand resulted in the formation of a tris-complex. When methyl groups are substituted at these positions, a significant steric interaction was generated among these substituents of different ligand molecules in the same complex to such an extent that the formation of a tris-complex is completely inhibited. This effect favors the formation of a neutral divalent iron complex, bis-complex.

A hexacoordinated chromium(III) complex was obtained with ligand **2** accompanied with acetate group as an additional anionic ligand.[2] Judging from the standard reduction potentials −0.41 and 0.77 V for chromium(III) and iron(III), respectively,[11] the trivalent state of chromium in a complex is intrinsically more stable than that of iron. The sterically crowded structure of hexacoordinated chromium(III) complex was relaxed by adopting the acetate ion as the third ligand.

The plausible structures for bis- and tri-complexes



4



5

are illustrated schematically by **4** and **5**, respectively. A discussion will be made on the basis of these structures.

Electronic Spectra. The electronic absorption spectra for the three iron complexes are shown in Fig. 1, covering the 250—2000 nm region. The absorption bands lying above 20000 cm^{-1} are attributed to charge transfer transitions from metal to ligand and $\pi \rightarrow \pi^*$ transitions within a ligand molecule. The ligand-field bands are observed in a region lying below 18000 cm^{-1} (Figs. 2 and 3) for tris(3,3',4-trimethyldipyrromethenato)iron(III) and bis(3,3',4,4',5,5'-hexamethyldipyrromethenato)iron(II), respectively.

The coordination site symmetry for the tris-complex can be O_h with some minor trigonal distortion, if any. It is rather difficult to presume the spin state of iron(III) on the basis of spectral behavior alone. This is due to the fact that the ligand-field energy for the high spin state is frequently comparable to

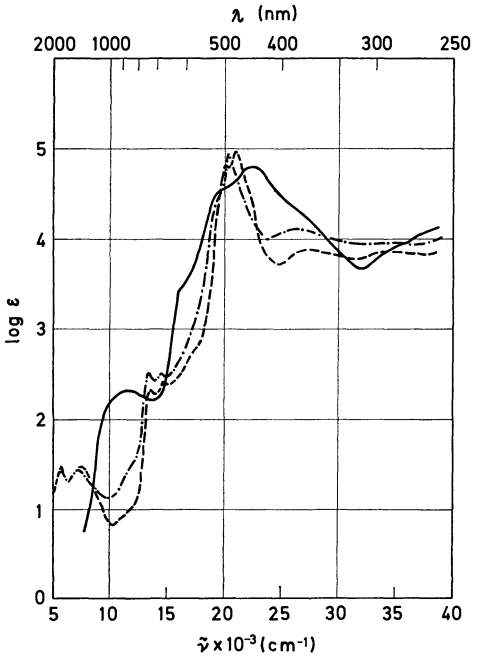


Fig. 1. Electronic absorption spectra of iron chelates in chloroform at room temperature: ——, tris-complex I; ----, bis-complex II; .—.—, bis-complex III. Refer to the footnote of Table 1 for abbreviations.

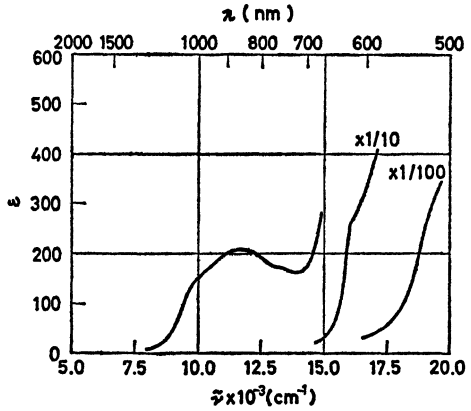

Fig. 2. Ligand-field spectrum for tris(3,3′,4-trimethyldipyrromethenato)iron(III) in chloroform at room temperature. Numbers in this figure (1/10 and 1/100) refer to the reduction factor of the absorption intensity.

that for the low spin, and thermal equilibrium between these two states can be expected consequently. On the basis of the below-mentioned magnetic data, the energy level scheme for low spin state[12-14] (Fig. 4) is adopted here for the elucidation of the spectrum.[15] The ground state is $^2T_{2g}(t_{2g}^5, {}^2I)$ and can be split into $^2A_1$ and ^2E states under D_3 coordination symmetry. The spin-allowed excited levels with $t_{2g}^4e_g$ configuration are classified into three groups on the basis of the magnitude of energy separation: $^2A_{2g}$, $^2T_{1g}$, $^2T_{2g}(^2I)$; $^2E_g(^2I)$; and higher excited levels. The assignments of ligand-field bands with self-consistency are listed in Table 1. In spite of the satisfactory assignments of these bands, their absorption intensity is apparently too strong for the ordinary O_h coordination symmetry. The causes for this might be given as follows: a) distortion from O_h to D_3 to release the steric strain generated within a complex molecule; and b) d-p orbital mixing through strong covalent interaction between ligand and metal. Both *Dq* and *B* values were evaluated as shown in Table 1. The Racah parameter (*B*) for the complex is much smaller than the free ion value (~1300 cm^{-1}), indicating a strong

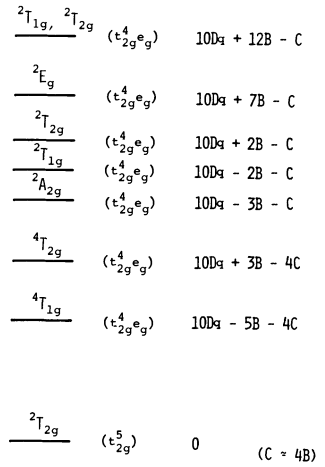

Fig. 4. The energy level scheme with configuration interaction for a low spin d^5 ion under O_h coordination symmetry.

TABLE 1. LIGAND-FIELD BANDS FOR DIPYRROMETHENE-IRON CHELATES AND THEIR ASSIGNMENTS[a]

	14500 (314)		

a) Measured in chloroform at room temperature. b) I, tris(3,3′,4-trimethyldipyrromethenato)iron(III); II, bis(3,3′,5,5′-tetramethyldipyrromethenato)iron(II); III, bis(3,3′,4,4′,5,5′-hexamethyldipyrromethenato)iron(II). c) Evaluated *Dq* and *B* values under O_h are 1440 and 600 cm^{-1}, respectively.

nephelauxetic effect.

Cobalt(II) complexes with substituted dipyrromethenes exhibit distortion from regular tetrahedral coordination toward planar to an extent that the 5,5′-substituents do not generate any detectable steric effect within a complex molecule.[6] The covalent nature of the coordinate bond may cause a tendency for a tetracoordinated complex to distort toward planar geometry. A similar state of affairs can be expected in the present case, and the bis-complex may assume tetrahedral coordination along with some minor distortion toward planar geometry. Thus, the D_2 local symmetry around iron(II) is tentatively assigned to these complexes. The distortion may arise partly from the skeletal structure of ligand molecule. As has been found for bisdipyrromethenato-copper(II) and -nickel(II) by X-ray diffraction measurements,[16,17] the N-

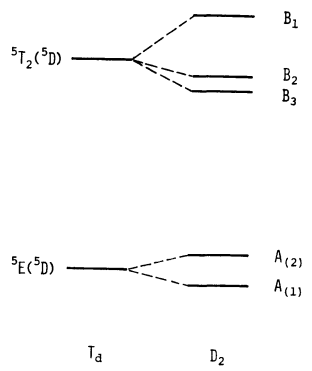

Fig. 5. The energy level schemes of direct concern for a high spin d^6 ion under T_d and D_2 symmetries.

M–N angle within a chelate ring is slightly smaller than the tetrahedral angle. This gives rise to the distortion toward two-fold axial symmetry. The energy level schemes for $T_d(^5D)$ and $D_2(^5D)$ are illustrated in Fig. 5. The possibility of being in the low spin state was excluded on the basis of the fact that the ligand field generated by the present ligands is not strong enough to make spin-pairing for d^6 ion under tetrahedral symmetry as in the case for the corresponding cobalt(II) complexes.[6] This was approved by the magnetic susceptibility measurements described in the following.

If the magnitude of energy separation between $A_{(1)}$ and $A_{(2)}$ levels does not differ widely from that of the thermal energy at the temperature of measurement, a thermal pumping effect which provides some population in $A_{(2)}$ level can be expected. This effect may give two groups of ligand-field bands, each consisting of two absorption peaks with a smaller separation; $B_1 \leftarrow A_{(1)}$, $A_{(2)}$ and B_2, $B_3 \leftarrow A_{(1)}$, $A_{(2)}$. These assignments for the present bis-complexes are summarized in Table 1. A higher energy band in each group, attributable to the transition from $A_{(1)}$ level, shows a greater broadness relative to the lower one (Fig. 3). This is most likely due to vibronic coupling with the vibrational levels of larger energy separation for $A_{(1)}$ level, providing wider phonon wings.

Vibrational Spectra. The IR absorption spectra for the iron chelates, covering the 1500—1700 cm^{-1} region, are shown in Fig. 6. A strong band appearing in the 1600 cm^{-1} range is assigned to the skeletal stretching mode of the pyrrole rings.[3,6,8,9] A slight shift of this band to lower energy is observed for each ligand upon metal-coordination.

In the far-infrared region 700—200 cm^{-1}, the bis-complexes showed absorption peaks of medium intensity in the 400—350 cm^{-1} range in a manner similar to those observed for the cobalt(II), nickel(II), and copper(II) chelates of some dipyrromethenes.[3] This band can be associated with the metal-ligand (M–N) stretching mode since the corresponding band for each free ligand is absent: 388 cm^{-1} for bis(3,3′,5,5′-tetramethyldipyrromethenato)iron(II) and 368 cm^{-1} for bis(3,3′,4,4′,5,5′-hexamethyldipyrromethenato)iron-(II). On the other hand, we failed to assign such a vibrational mode to the tris-complex.

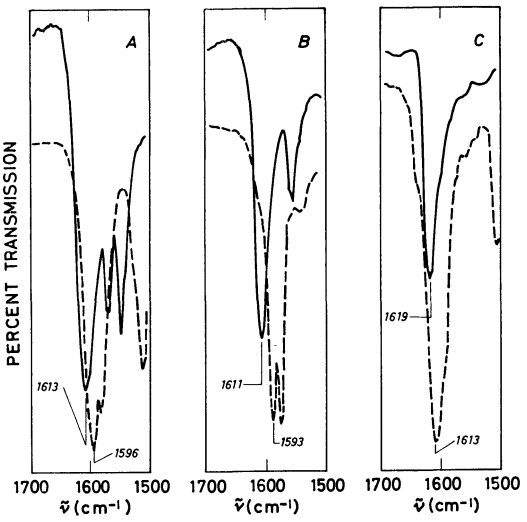

Fig. 6. Infrared spectra of iron chelates (----) and dipyrromethene free base (——) by a Nujol mull technique: A, 3,3′,5,5′-tetramethyldipyrromethene and its iron(II) chelate; B, 3,3′,4,4′,5,5′-hexamethyldipyrromethene and its iron(II) chelate; C, 3,3′,4-trimethyldipyrromethene and its iron(III) chelate. Number refers to the skeletal vibrational mode of the pyrrole rings.

Magnetic Susceptibilities. The results of magnetic susceptibility measurements are listed in Table 2. It became obvious that the tris-complex holds a spin-paired d^5 system, even though μ_{eff} value is no doubt larger than the spin-only value. The effective magnetic moments for some low-spin iron(III) complexes formed with cyano, ethylenediamine,[13] tertiary arsine,[14] and substituted xanthates[18] were found to lie in a 2.2—2.5 range at ordinary temperature. However, there remains some ambiguity as to whether thermal population on the high spin state is still allowed. Further study on the behavior of magnetic susceptibility with variation of temperature is required for clarification of this state of affairs. The bis-complexes apparently

a) See Table 1, footnote b) for abbreviations.

hold a high spin state. The effective magnetic moments are slightly larger than the spin-only value. This difference may arise from the incomplete quenching of orbital angular momentum.

Asymmetric Reactions. IX. On the Catalytic Hydrogenation of Olefinic Compounds with Bis(dimethylglyoximato)cobalt(II)-base Complex[1]

Seiji TAKEUCHI, Yoshiaki OHGO, and Juji YOSHIMURA

Laboratory of Chemistry of Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 28, 1973)

Examination of the catalytic hydrogenation of twenty-one olefinic compounds with bis(dimethylglyoximato)-cobalt(II)-pyridine complex indicates that all $H_2C{=}C\langle^{Y}_{Y}$ type olefinic compounds having an electron-withdrawing and a weakly electron-donating substituent are reducible. Isolation and further hydrogenation of the alkyl complexes in the case of $H_2C{=}C\langle^{Y}_{Y}$ type olefinic compounds, and deuterogenation of α-phenylacrylophenone support the view that α-alkyl complexes are the intermediates in hydrogenation. It is concluded that the electron-withdrawing effect accelerates both the first (alkyl complex formation) and the second (reductive-cleavage of alkyl moiety) steps, while steric compression prevents the first step and accelerates the second step. The reaction mechanism is discussed.

Schrauzer and Windgassen reported that bis(dimethylglyoximato)cobalt(II)-base, $Co^{II}(DMG)_2B$, catalyzes the reductive methylation of amines and thiols with formaldehyde under hydrogen atmosphere,[2] and that the formation of substituted alkyl and alkenylcobaloximes from $Co^{II}(DMG)_2B$ and alkenes or alkines is sometimes followed by reductive cleavage of the alkyl moieties as a side reaction.[3] We have extended the hydrogenation to the homogeneous catalytic hydrogenation of reactive olefinic compounds, α-diketones, α-ketocarboxylic acid esters and unsaturated compounds carrying N=N or N=O double bond[4] and also to their asymmetric hydrogenation with the use of Co^{II}-$(DMG)_2$-quinine complex.[5] We have examined the electronic and steric effects of the substituents of olefinic compounds on their hydrogenation and on the nature of intermediate alkyl complexes, since they are important for making clear the mechanism of the asymmetric hydrogenation.

Results and Discussion

The reaction of the reduced cobaloximes with olefinic compounds having an electron-withdrawing substituent gives α-alkyl complexes (α-ACs) in nearly neutral medium and β-one in alkaline solution, the actually reacting species being considered to be the hydridocobaloxime; $HCo(DMG)_2B$, and cobaloxime(I); $[Co^{I}(DMG)_2B]^-$, respectively.[3] In order to clarify the limitation of the catalytic hydrogenation of olefinic compounds with $Co^{II}(DMG)_2$-pyridine, various substrates were hydrogenated in a slightly alkaline methanol or ethanol under the atmospheric pressure of hydrogen at room temperature. The results are summarized in Table 1, together with the previous ones.[4]

It is apparent that; 1) monosubstituted ethylene compounds (**1**—**3**) are scarcely hydrogenated; 2) α,α-disubstituted compounds (**5**—**11**) ($H_2C{=}C\langle^{Y}_{Y}$), having an electron-withdrawing group (X: $COOCH_3$, COPh, CN) and a weakly electron-donating group (Y: CH_3, Phenyl, NHCOR, CH_2COOCH_3), are commonly hydrogenated very smoothly, but not α,β-disubstituted compounds (**12**—**14**) except for **15** in which both the substitutents are electron-withdrawing; 3) only trisubstituted ethylene compounds having two electron-withdrawing groups (**20**—**21**) are slowly hydrogenated.

The results indicate that the reactivity of olefinic compounds is controlled by electronic and steric effects of substituents. However, the interrelation between these effects and the reactivity is still ambiguous. The slow but successful hydrogenation of **15**, **20**, and **21** may be attributed to the electron deficiency of the ethylenic bond due to the substituents, but the large difference between compounds **5**—**11** and **12**—**14** seems to depend only on the position of both electron-withdrawing and donating substituents. For more detailed discussion, it is necessary to isolate alkyl complexes, and examine their reducibility. Acrylonitrile (**1**), methyl acrylate (**2**) and styrene (**3**) gave the same results as those by Schrauzer and Windgassen[3] (Table 2). They stated that no product was obtained in the reaction of methacrylonitrile (**5**) with reduced cobaloxime under alkaline conditions.[3] We have isolated the corresponding α-AC both under neutral and alkaline conditions.

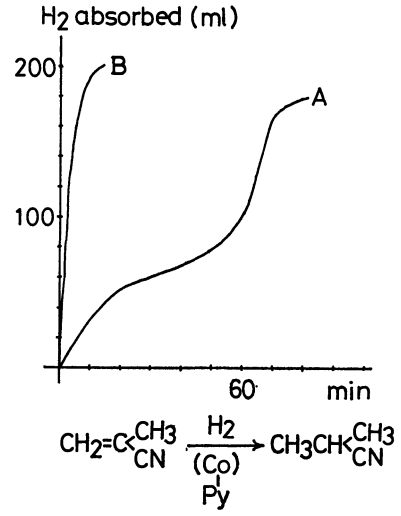

Fig. 1. Hydrogen absorption in the hydrogenation of methacrylonitrile under weakly (A) and strongly (B) alkaline conditions.
Conditions: substrate 7.5 mmol, S/Co=1.9; NaOH/Co=2.8 (A), 3.7 (B).

Table 1. Catalytic hydrogenation of various olefinic compounds with $Co^{II}(DMG)_2$-pyridine

No.	Substrates	S/Co[a]	Reaction[b] time	Products (yield)
1	$CH_2=CHCN$	1	—	—[c]
2	$CH_2=CHCO_2CH_3$	1	—	—[c]

a) S/Co; molar ratio of substrate (S) to catalyst (Co). b) Time required for the absorption of theoretical amount of hydrogen. c) Molecular hydrogen was consumed only for formation of the alkyl complex. d) As the hydrogenated material was soluble in water, the yield was lowered.

Table 2. Isolation of alkyl complexes and hydrogenation of α-alkyl complexes

No.	Substrate	Alkyl complex (AC)[a]		Hydrogenation	Alkyl group in α-AC	Autocatalyzed[c] Hydrogenation	Catalytic Hydrogenation[d]
		Neutral	Alkaline				
1	$CH_2=CHCN$	α-AC	β-AC	None	$-CH(CN)CH_3$	None	Fast
2	$CH_2=CHCO_2CH_3$	α-AC	β-AC	None	$-CH(CH_3)CO_2CH_3$	Slow	Fast
3	$CH_2=CHPh$	α-AC	α-AC	None	$-CH(Ph)CH_3$	None	None
5	$CH_2=C(CH_3)CN$	α-AC	α-AC	Relatively slow	$-C(CH_3)(CN)CH_3$	Fast	Very fast
11	$CH_2=C(Ph)COPh$	—	(α-AC)[b]	Very fast	$-C(Ph)(COPh)CH_3$	—	—

a) For example, α- and β-AC of acrylonitrile imply $CH_3(CN)CHCo(DMG)_2$-pyridine and $CNCH_2CH_2Co(DMG)_2$-pyridine, respectively. b) The structure was deduced from the result of deuterogenation. c) Hydrogenation only with molecular hydrogen. d) Hydrogenation with $Co^{II}(DMG)_2$-pyridine and molecular hydrogen in slightly alkaline methanol solution.

Hydrogenation of **5** under weakly alkaline conditions proceeds stepwise, while under strongly alkaline conditions very smoothly (Fig. 1). The presence of α-AC was easily proved by the NMR spectrum, and the α-AC was isolated by concentrating the reaction mixture after the reaction had been interrupted at the first stage when a half-equimolar amount of hydrogen was absorbed. In the case of dimethyl itaconate (**8**) under alkaline conditions, a small amount of β-AC was obtained, and the yield was increased to 30% under strongly alkaline conditions by use of a large excess of imidazole as the axial base.

All β-AC described above could not be hydrogenated even in the presence of excess $Co^{II}(DMG)_2B$ or palladium-charcoal. Both the results with β-AC and **5** strongly indicate that the α-AC is the actual intermediate in the hydrogenation. Since AC could not be detected in all other cases in which the hydrogenation proceeded very fast, deuterogenation of α-phenylacrylphenone (**11**) under deuterium atmosphere in slightly alkaline methanol-d_1 was examined. The ratio of deuterium on β-carbon to that on α-carbon of the corresponding saturated product was determined by NMR spectrum to be about 2.3. This also indicates that the deuterogenation of **11** proceeds *via* α-AC, as in a similar reaction with pentacyanocobaltate.[6] Thus, it is con-

cluded that α-ACs are formed in both neutral and alkaline solution in the cases of $H_2C{=}C\langle^{Y}_{Y}$ type olefinic compounds.

Autocatalytic and catalytic hydrogenation of thus isolated α-ACs was examined (Table 2). Hydrogenation in the absence of catalyst (autocatalytic hydrogenation) of α-AC from **5** proceeded relatively fast, while that of α-AC from **2** slowly. α-ACs from **5**, **1**, and **2** were hydrogenated much faster in the presence of Co^{II}-$(DMG)_2B$ than in the absence of the catalyst. The results show that their reactivity is in the order **5**>**2**>**1**>**3**, indicating that the bulkiness (steric compression including DMG ring) of substituents causes the sequence of the former three. The remarkable stability of α-AC from **3**, inspite of the greater bulkiness of phenyl group than that of methoxycarbonyl group or cyano group, suggests that the electron-withdrawing effect of substituents plays a more decisive role than the steric one. Thus, it can be concluded that both the electron-withdrawing effect and steric compression of substituents accelerate the second step (reductive cleavage) of the hydrogenation, the former playing a more important role.

On the other hand, compounds **4**, **12**—**14**, and **16**—**18** gave neither the saturated product nor the corresponding α-AC. If we compare these compounds with **1**—**3**, **5**—**11**, **20**—**21**, respectively, in structure, we realize the higher electron density of the former. **20** and **21** were hydrogenated more slowly than **5**—**11**, though they have two electron-withdrawing substituents. If they undergo hydrogenation via α-ACs, the α-ACs from **20** and **21** would be more unstable than those of **5**—**11**. Thus, the slow rate may be attributed to the steric hindrance in the formation of α-ACs. It can be considered that the electron-withdrawing effect of substituents accelerates the formation of alkyl complex, and the steric compression of substituents prevents it and the electron-withdrawing effect should overcome the steric hindrance to give α-AC.

It is thus concluded that the electron-withdrawing effect accelerates both the first (alkyl complex formation) and the second (reductive cleavage of the alkyl moiety) steps, while steric compression prevents the first step and accelerates the second step as shown schematically in Fig. 2.

In the first stage, electronic effect (E) and steric effect (S) make $\Delta G_1^{\neq}$ smaller by lowering the free energy of transition state and greater by elevating it, respectively. In the second stage, though it is not evident how E and S affect the transition state, both E and S make $\Delta G_2^{\neq}$ lower by elevating the potential energy of alkyl complex.

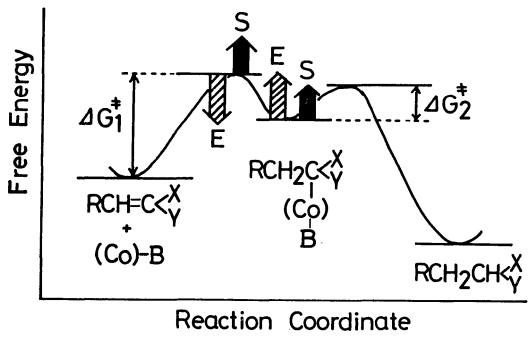

Fig. 2. Schematic presentation of electronic (E) and steric (S) effects of substituents on the hydrogenation.

Nonreactivity of **1**—**2** and **3** would be explained by the absence of steric and electronic acceleration in the second step, respectively, while that of **4** or **12**—**14** by the insufficient electronic acceleration, in the first step. In the hydrogenation of $H_2C{=}C\langle^{X}_{Y}$ type olefinic compounds both electron-withdrawing and steric compression effects of the substituents tend to lower the activation energy of both the two steps, leading to smooth hydrogenation.

On the mechanism of the hydrogenation, Schrauzer and Windgassen stated that the reductive cleavage is apparently catalyzed by cobaloxime(I), which exists in equilibrium with hydridocobaloxime.[3] It is thus understandable that the rate of hydrogenation of olefinic compounds is faster in alkaline solution than in neutral solution as in the case of **5**.

When **5** reacts predominantly with the hydridocobaloxime to form relatively stable α-AC[7] the equilibrium may shift to the hydridocobaloxime, and the concentration of cobaloxime(I), which acts as a reductant of the α-AC, becomes smaller. However, when the alkalinity of the solution becomes higher, the equilibrium shifts to cobaloxime(I) and the rate of of the formation of α-AC decrease, and consequently, the reductive cleavage of the α-AC by cobaloxime(I) will become effective. The mechanism of the hydrogenation is shown in Fig. 3.

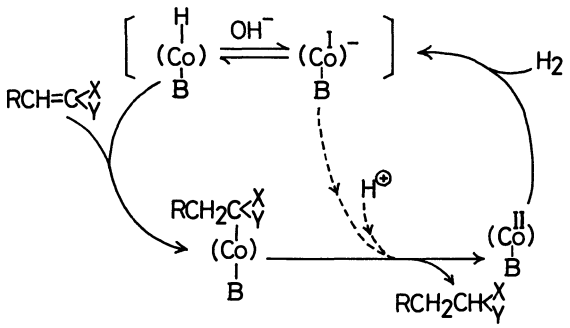

Fig. 3.

Experimental

Catalytic Hydrogenation of Various Olefinic Compounds in the Presence of Pyridino Bis(dimethylglyoximato)cobalt(II). Dimethylglyoxime (0.48 g, 4 mmol) was added to a solution of $CoCl_2 \cdot 6H_2O$ (0.5 g, 2 mmol) in methanol or ethanol, and the mixture was stirred under nitrogen atmosphere for a few min. Aqueous sodium hydroxide (1 ml of 4.87 M, 4.9 mmol), pyridine (0.16 g, 2 mmol) and a substrate (1-10 equivalent to cobalt) were successively added. The flask was purged with hydrogen gas and the solution was then stirred under the atmospheric pressure of hydrogen at room temperature. After absorption of the theoretical amount of hydrogen, the reaction mixture was diluted with water and extracted with ether or methylene chloride. The organic layer was washed with water, dried over anhydrous sodium

sulfate, and concentrated to give the corresponding product which was purified and confirmed by IR and NMR spectra.

Hydrogenation in neutral solution was carried out in a similar way, except for the use of cobaltous acetate in place of cobaltous chloride and sodium hydroxide.

Isolation of α-Cyanoisopropylcobaloxime. Methacrylonitrile (0.25 g, 3.7 mmol) was added to a solution of $CoCl_2 \cdot 6H_2O$ (0.5 g, 2 mmol), dimethylglyoxime (0.48 g, 4 mmol) in aqueous sodium hydroxide (1 ml of 4.87 M solution) and pyridine (0.16 g, 2 mmol). The resulted solution was shaken under hydrogen atmosphere until *ca.* 19 ml (0.9 mmol) of hydrogen was absorbed (6 min). The solvent was then removed *in vacuo* to give crude α-cyanoisopropylcobaloxime (0.9 g). The crude complex showed a sharp absorption of cyano-group at 2200 cm^{-1} in IR spectrum, and characteristic methyl-proton signals (isopropyl; δ 0.7, singlet, 6H; DMG; δ 2.0, singlet, 12H) in NMR spectrum. The complex could not be recrystallized, because it decomposed in ether or chloroform to give black complex whose IR spectrum showed no absorption of CN and alkyl groups. The complex was obtained even when 1.2 ml of aqueous sodium hydroxide (4.87 M solution) was used. Smooth hydrogenation occurred when 1.5 ml of aqueous sodium hydroxide (4.87 M solution) was used.

Deuterogenation of α-Phenylacrylophenone. A solution of anhydrous cobaltous chloride (0.27 g, 2 mmol), dimethylglyoxime (0.48 g, 4 mmol), and α-phenylacrylophenone (2.8 g, 13.5 mmol) in 3.82 M sodium deuteroxide in dideuterium oxide (1.38 ml, 4.7 mmol of NaOD), pyridine (0.16 g, 2 mmol), and methanol-d_1 (30 ml) was shaken under deuterium atmosphere until 289 ml (13 mmol) of D_2 was absorbed 58 min). The reaction mixture was concentrated *in vacuo*, and the residue was extracted with ether. The ether extract was washed with water, dried over anhydrous magnesium sulfate, and evaporated to give an oily product (2.4 g). The crude product was purified by vacuum distillation (124—126 °C/1 mmHg), and the main fraction (1.9 g) crystallized (mp 38.5—41 °C) on standing. NMR spectra of the crude and purified products showed relatively broad signals of α- and β-protons at δ 4.66 and δ 1.50, respectively. The ratio of integration of the signals of phenyl proton, α- and β-proton was 10 : 0.14 : 1.12 in the crude product and 10 : 0.15 : 1.07 in the purified product. The ratio of deuterium distribution in β-carbon to α-carbon was estimated to be 2.5 (crude) and 2.3 (purified), respectively.

Reductive Cleavage of Various Alkyl Complexes. a) Catalytic Cleavage. Catalytic cleavage was carried out in a similar manner to that for hydrogenation of olefinic compounds, except for the use of alkyl complexes instead of olefinic compounds as substrate. α-Phenylethylcobaloxime was recovered quantitatively after reaction for 4 days. α-Cyanoethylcobaloxime and α-methoxycarbonylethylcobaloxime underwent reductive cleavage within 1 hr to give propionitrile and methylpropionate, respectively. *b) Autocatalytic Cleavage.* α-Methoxycarbonylethylcobaloxime underwent reductive cleavage even in the absence of the catalyst when it was dissolved in methanol and stirred under hydrogen atmosphere at room temperature for 1 day. β-Alkyl complexes underwent no reductive cleavage.

β-Alkyl Complex from Dimethyl Itaconate. Dimethyl Itaconate (2.5 g, 1.6 mmol) was added to a catalyst solution (in MeOH) prepared from $CoCl_2 \cdot 6H_2O$ (2.5 g, 10 mmol), dimethylglyoxime (2.45 g, 20 mmol), aqueous sodium hydroxide (10 ml of 4.67 M solution, 47 mmol) and imidazole (4.22 g, 62 mmol), and the resulting solution was shaken under hydrogen atmosphere. After absorption of *ca.* 274 ml (12 mmol) of hydrogen within 26 min, the reaction mixture was poured into water and extracted with methylene chloride. The extract was washed with water, dried over calcium chloride, and concentrated to give an oily product which crystallized by scratching. The crude alkyl complex (1.7 g, 34%) was purified by recrystallization from methanol. Yellow crystals, mp 166 °C (167—168 °C dec.). Spectral data showed typical absorptions for β-alkyl complex; *i. e.*, characteristic absorption of ester (1720—1730 cm^{-1}) in IR and broad doublet signal at δ 2.45 (Co–CH_2; 2H) and broad multiplet (–CH–) and doublet (–CH_2CO–) at δ 2.3—1.9 (3H) in NMR spectrum.

Found: C, 42.29; H, 5.97; N, 16.49%. Calcd for $C_{18}H_{29}N_6O_8Co$: C, 41.87; H, 5.62; N, 16.28%.

When the amount of aqueous hydroxide and imidazole was decreased to about half (5 ml, 24 mmol) and one fourth (0.7 g, 10 mmol), respectively, the formation of alkyl complex was negligible.

The authors are indebted to Mr. H. Matsumoto for the NMR measurements, and members of the Laboratory of Organic Analysis for the microanalyses.

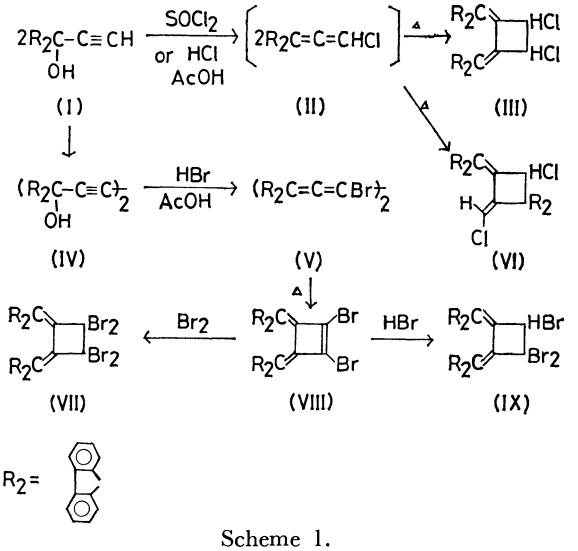
The Thermal [2+2] Cycloaddition of 1-Halo-2-(9-fluorenylidene)ethylene to Afford Fluorene-9-spiro-1′-[2′-halo-3′-(9-fluorenylidene)-4′-halomethylene]cyclobutane

Fumio Toda, Hiroharu Motomura, and (in part) Hirofumi Oshima
Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790
(Received July 21, 1973)

The thermal [2+2]cycloaddition products of 1-chloro-(II) and 1-bromo-2-(9-fluorenylidene)ethylene (X) were found to be two head-to-tail dimers, fluorene-9-spiro-1′-[2′-chloro-3′-(9-fluorenylidene)-4′-chloromethylene]-cyclobutane (VI) and its bromo-analog (XI) respectively.

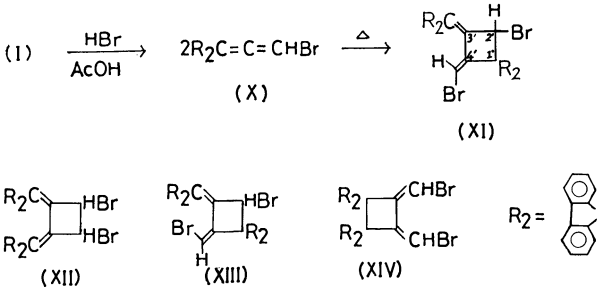
It has previously been reported[1] that the previously-assigned structure[2] 1-chloro-2-(9-fluorenylidene)ethylene (II) for the compound which was produced by the reaction of 9-ethynyl-9-hydroxyfluorene (I) with $SOCl_2$, is erroneous; rather, it is the head-to-head [2+2] cycloaddition dimer of II, 3,4-dichloro-1,2-bis(9-fluorenylidene)cyclobutane (III) (Scheme 1). We have now studied on the structures of the dimers of II and its Br-analog (X), and found that these dimers are two head-to-tail cycloaddition products, fluorene-9-spiro-1′-[2′-chloro-3′-(9-fluorenylidene)-4′-chloromethylene]cyclobutane (VI) and its Br-analog (XI) respectively.



Scheme 1.

On the reaction of I with concd HCl in AcOH at 0 °C, II could not be isolated, but its head-to-tail cycloaddition dimer (VI) was obtained. The UV spectral data of VI were identical with those recorded for the dimer of II.[1] The heating of the Br-analog of II (X), which could be isolated by the reaction of I with concd HBr in AcOH, afforded the head-to-tail cycloaddition dimer (XI). The spectral data of XI were comparable to those of VI.

It is clear that the dimers of II and X were not the heat-to-head dimers, III and XII respectively, because the UV spectra of VI (276 (ε, 54000) and 375 nm (30000)) and XI (274 (ε, 51400) and 380 nm (32800)) differ widely from those of 3,3,4,4-tetrabromo- (VII) (278 (ε, 38600), 338 (9000) and 502 nm (23900)) and 3,3,4-tribromo-1,2-bis(9-fluorenylidene)cyclobutane (IX) (270 (ε, 30500), 328 (12700) and 472 nm (21400)), which were prepared by the addition of Br_2 and HBr

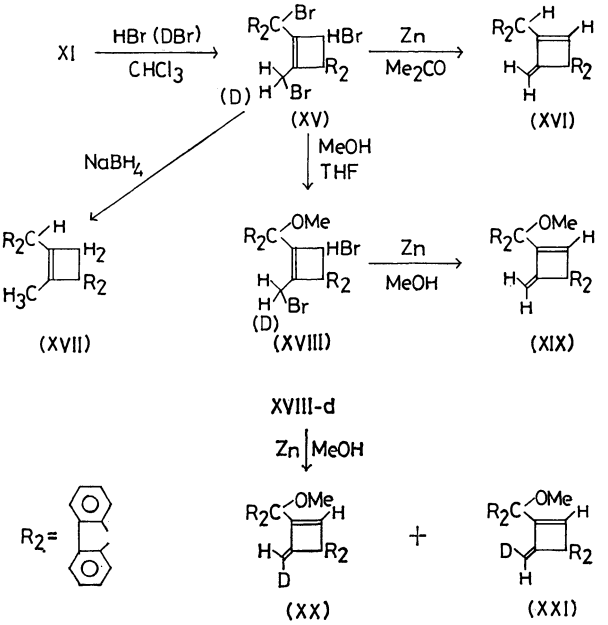


Scheme 2.

respectively to 1,2-dibromo-3,4-bis(9-fluorenylidene)-cyclobut-1-ene (VIII). The cyclobutene (VIII) was prepared by the intramolecular cycloaddition of 2,3-dibromo-1,4-bis(9-fluorenylidene)buta-1,3-diene (V), which had itself been obtained by the reaction of the diacetylenediol (IV) with concd HBr in AcOH.

Any possibility that the dimer of II and X are the tail-to-tail cyclodimerization products (for example, XIV for the dimer of X) can be rejected, because the absorption bands of the dimers of II and X in the visible region are not assignable to the tail-to-tail dimers containing only a buta-1,3-diene chromophore. In order to clarify the structures of VI and XI, some addition and elimination reactions were investigated on XI.

The reaction of XI with HBr afforded the 1,4-



Scheme 3.

addition product (XV). The heating of XV in MeOH-THF afforded the methanolysis product (XVIII). On the NMR spectra, the CH_2 of both XV and XVIII appeared as two AB-type doublets, centered at 6.20 and 6.45 and at 5.88 and 6.11 τ respectively. Because these signals were little affected by raising temperature to 150 °C, the magnetic nonequivalence of the two hydrogens of CH_2 is probably due to an assymmetry effect. The CHD proton signals of XV-*d* and XVIII-*d* appeared as two singlets at 6.22 and 6.43 and at 5.92 and 6.13 τ respectively. This splitting of the CHD proton singal is also due to an assymmetry effect. These data support the structure of XI.

The reduction of XV with $NaBH_4$ afforded XVII, which showed CH, CH_2, and CH_3 signals at 4.95 (s), 7.54 (q), and 8.53 τ (t) respectively. This formation of the CH_3 group supports the presence of the *exo*-methylene moiety in XI. The multiplicity of the latter two signals suggests the presence of a long-range coupling between them.

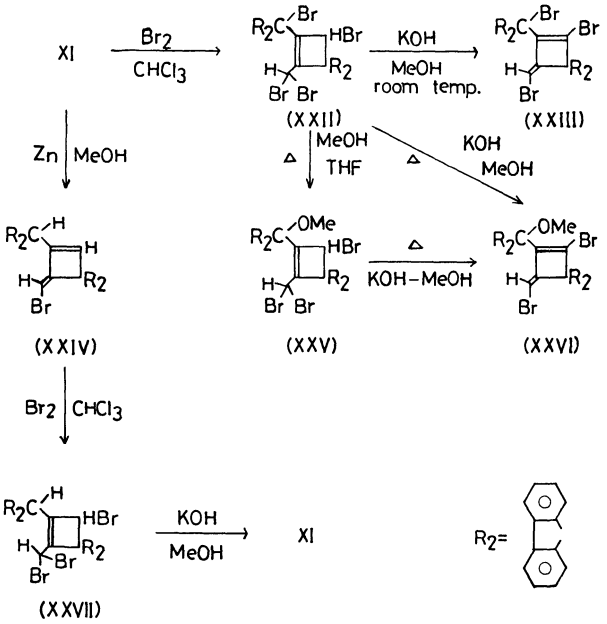
The reaction of XV and XVIII with Zn afforded XVI and XIX respectively. The NMR signals of the $=CH_2$ protons of XVI and XIX appeared at 5.83 and 5.98 and at 5.93 and 6.06 τ respectively. The absence of spin-spin coupling between the two geminal protons of $=CH_2$ is likely, because it has been established that such a coupling of the *exo*-methylene bonded to cyclobutene ring is not detectable.[3] Of the two $=CH_2$ proton signals of XVI and XIX, that at higher magnetic field can be assigned to the hydrogen directed toward the spiro-fluorene ring, therefore it is shielded by this ring.

XVIII-*d*, which was derived from XV-*d*, was allowed to react with Zn to afford a 1 : 1 mixture of XX and XXI. In the NMR spectrum of this mixture, the intensities of the signals at both 5.96 and 6.09 τ were about one half of those of the corresponding signals of XIX. These results also support the structure of XI.

The addition of Br_2 to XI afforded the 1,4-addition product (XXII). The treatment of XXII with KOH–MeOH at room temperature and at an elevated temperature under reflux afforded XXIII and XXVI respectively. The latter may be formed by the 1,4-elimination of HBr, accompanied by the methanolysis of Br on the fluorene ring, because the heating with KOH–MeOH of XXV, which had been prepared by the methanolysis of XXII, afforded XXVI (Scheme 4).

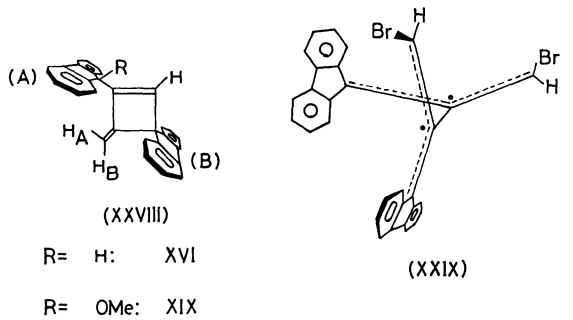
The heating of XI with Zn in MeOH afforded XXIV, which showed three proton signals at 3.28 (=CH), 5.08 (=CH), and 5.15 τ (CH), in an equal integral ratio. The addition of Br_2 to XXIV afforded XXVII in a 60% yield. The dehydrobromination of XXVII with KOH–MeOH afforded the original dimer (XI). All these reactions again support the structure of XI (Scheme 4).

The geometry around the bromomethylene moiety of XI was determined on the basis of the following data. The signal of the olefinic proton of XI appeared at such a lower field that it overlapped the signals of aromatic protons (1.90—2.86 τ), probably because of a deshielding effect by the biphenylene moiety bonded to *exo*-methylene carbon. For by the same reason, the olefinic proton of VI appeared at 2.85 τ. If the reverse geometry of XI (XIII) is correct, this olefinic proton must be shielded by the spiro-fluorene ring and resonate at a much higher magnetic field. Studies of a molecular model also suggest that the geometry of XIII is unfavorable, because of a serious steric repulsion between the 9-fluorenylidene group and the Br of the bromomethylene moiety.



Scheme 4.

However, there is still a question why the difference between the chemical shifts of the two methylene protons of XVI or XIX is so small-less than 0.15 ppm. A plausible answer to the question is that the H_A of XVI or XIX is shielded by the fluorene-ring (A) which is arranged almost perpendicular to the four-membered ring and then faces H_A, and that the shielding is comparable to that of H_B by the fluorene-ring (B) (see the XXVIII shown in Scheme 5).



Scheme 5.

It has been reported[4,5] that the thermal [2+2] cycloaddition of allene often proceeds *via* the biallyl biradical intermediate, and that the most easily formed conformation for the biradical was that in which the two flat allylic ends were orthogonal and in which the larger one of the substituents on each terminal carbon was inward; ring closure was assumed to be faster than the rotation of the parts of the allylic system to form other conformers. However, some instances which do not follow this tendency because of steric bulkiness have also been reported.[6,7]

The dimerization of X can be formulated by assuming XXIX as an intermediate (Scheme 5). So as to avoid the steric interaction between the fluorene ring and Br, the cyclization of XXIX must proceed *via* its favorable conformation, in which Br is outward, thus finally affording the dimer of the most favorable geometry around the *exo*-methylene moiety (XI).

The contrast between the unusual[8,9] head-to-tail dimerization of X to afford XI and the head-to-head dimerization of 3-chloro-1,1-diphenylpropa-1,2-diene (II) to afford 3,4-dichloro-1,2-bis(diphenylmethylene)-cyclobutane (III)[1] is probably due to a much bigger steric interaction between non-flexible fluorene rings than that between flexible diphenylmethyl groups. It has been reported that the four phenyl rings of III are arranged as a propeller, and that they are free from steric interactions among them.[4]

Experimental

All the melting points are uncorrected. The IR, UV, and NMR spectra were measured in Nujol mull, $CHCl_3$, and $CDCl_3$ respectively. The mass spectra were measured with an ionization energy of 75 eV.

Reaction of II with HCl. To an ice-cooled solution of II (6.2 g) in AcOH (60 ml), we added concd HCl (10 ml) under stirring over a period of 30 min. The stirring was continued for 1.5 hr under cooling with an ice-bath. The solid thus precipitated was filtered and washed with water and then with MeOH. The recrystallization of the dried solid from AcOEt afforded VI as orange prisms; 5.5 g (80%); mp 225 °C (lit,[1] mp 223—224 °C). NMR: 1.9—2.8 (m, Ph, 16H), 2.85 (s, =CH, 1H), and 4.24 τ (s, CH, 1H).

Isolation of X. Into an ice-cooled solution of II (4.73 g) in AcOH (60 ml), concd HBr (10 ml) was stirred over a of 30 min; the stirring was then continued for 1.5 hr under cooling with an ice-bath. The solid thus precipitated was filtered and washed repeatedly with water and then with MeOH. The solid was dissolved in ice-cooled acetone. Water was added to this solution, after which the solution was allowed to remain in a refrigerator to afford X as yellow needles; 5.15 g (86%). During the measurement of the melting point, X dimerized to XI and melted at 207.5—208.5 °C. IR: 1940 cm^{-1} (C=C=C).

Found: C, 67.15; H, 3.35%. Calcd for $C_{15}H_9Br$: C, 66.94; H, 3.37%.

Thermal Dimerization of X. A solution of X (3.8 g) in benzene (50 ml) was heated under reflux for 30 min. The crude crystals which remained after the evaporation of the solvent were recrystallized from AcOEt to afford XI as orange prisms; 3.0 g (80%); mp 207.5—208.5 °C. IR: 1150 cm^{-1}; λ_{max}: 266 (ε, 46800), 274 (51400), and 380 nm (32800); NMR: 1.9—2.8 (m, Ph and =CH, 17H) and 4.15 τ (s, CH, 1H).

Found: C, 67.25; H, 3.34%. Calcd for $C_{30}H_{18}Br_2$: C, 66.94; H, 3.37%.

Synthesis of VIII. Into an ice-cooled solution of IV (0.6 g) in AcOH (30 ml), we added concd HBr (5 ml) over a period of 30 min. The stirring was continued for 1.5 hr. The reddish-purple crystals thus formed were filtered and washed repeatedly with water and then with MeOH to afford V; 0.46 g (54%); IR: 1945 cm^{-1} (C=C=C). A solution of V (0.4 g) in benzene (10 ml) was heated under reflux for 30 min. The recrystallization from AcOEt of the crude product obtained by the evaporation of benzene afforded VIII as orange yellow needles; 0.28 g (70%); mp 221.5—222 °C. λ_{max}: 226 (ε, 53700), 275 (54900), 343 (32300), and 375 nm (31600).

Found: C, 67.46; H, 2.90%. Calcd for $C_{30}H_{16}Br_2$: C, 67.19; H, 3.01%.

Addition of Br_2 to VIII. Into a solution of VIII (0.2 g) in $CHCl_3$ (50 ml), a solution of Br_2 (0.15 g) in $CHCl_3$ (5 ml) was stirred over a period of 20 min. After the stirring had continued for 30 min, the solvent was evaporated to leave crude crystals. The recrystallization of the crystals from AcOEt afforded VII as reddish-purple prisms; 0.22 g (80%); mp 235—237 °C. λ_{max}: 278 (ε, 38600), 338 (8950), and 502 nm (23900); NMR: 1.35—3.36 τ (m, Ph).

Found: C, 51.53; H, 2.40%. Calcd for $C_{30}H_{16}Br_4$: C, 51.77; H, 2.32%.

Addition of HBr to VIII. Through a solution of VIII (0.2 g) in $CHCl_3$ (50 ml), HBr was bubbled for 10 min. The subsequent evaporation of the solvent left crude crystals. Recrystallization from AcOEt afforded IX as reddish-purple needles; 0.22 g (85%); mp 219—221 °C. λ_{max}: 270 (ε, 30500), 328 (12700), and 472 nm (21400); NMR: 1.55—3.25 (m, Ph, 16H) and 3.90 τ (s, CH, 1H).

Found: C, 58.54; H, 2.82%. Calcd for $C_{30}H_{17}Br_3$: C, 58.38; H, 2.78%.

Addition of HBr to XI. Through a solution of XI (0.93 g) in $CHCl_3$ (20 ml), HBr was bubbled for 5 min. The subsequent evaporation of the solvent left crude crystals. Recrystallization from AcOEt afforded XV as pale yellow plates; 1.0 g (94%) mp 165—167 °C. λ_{max}: 253 (ε, 90000), 280 sh (53600), 295 sh (34500), and 306 sh nm (19200); NMR: 1.9—2.9 (m, Ph, 16H), 4.79 (s, CH, 1H), 6.20 (d, J=10 Hz, CH, 1H), and 6.45 τ (d, J=10 Hz, CH, 1H).

Found: C, 57.92; H, 2.94%. Calcd for $C_{30}H_{19}Br_3$: C, 58.19; H, 3.09%.

The addition of DBr to XI by means of the same procedure as that of HBr addition afforded XV-*d* in a 90% yield. NMR: 1.9—2.9 (m, Ph, 16H), 4.79 (s, CH, 1H), 6.22 (s, CHD, 1/2H), and 6.43 τ (s, CHD, 1/2H).

Methanolysis of XV. A solution of XV (0.46 g) in MeOH–THF (1 : 1) (30 ml) was heated under reflux for 1 hr. The recrystallization from AcOEt of the crude crystals obtained by the evaporation of the solvent afforded XVIII as pale yellow plates; 0.39 g (93%); mp 173—175 °C. IR: 1085 cm^{-1} (OMe); λ_{max}: 274 (ε, 64300), 285 sh (5000), and 305 sh nm (1100); NMR: 2.0—2.8 (m, Ph, 16H), 5.13 (s, CH, 1H), 5.88(d, J=10 Hz, 1H), 6.11 (d, J=10 Hz, 1H), and 7.06 τ (s, OCH_3, 3H).

Found: C, 65.48; H, 3.73%. Calcd for $C_{31}H_{22}OBr_2$: C, 65.28; H, 3.88%.

The methanolysis of XV-*d* by means of the same procedure as was used for XV afforded XVIII-*d* in a 90% yield. NMR: 2.1—2.8 (m, Ph, 16H), 5.13 (s, CH, 1H), 5.91 (s, CHD, 1/4H), 6.12 (s, CHD, 3/4H), and 7.07 τ (s, OCH_3, 3H).

Debromination of XVIII. A mixture of XVIII (0.2 g), Zn-powder (0.7 g), and MeOH (70 ml) was heated under reflux for 1 hr. The Zn-powder was then filtered off, after which the filtrate was evaporated to dryness to leave crude crystals. Recrystallization from AcOEt then afforded XIX as pale yellow prisms; 0.99 g (68%); mp 175.5—177 °C. IR: 1665 (C=C) and 1110 and 1080 cm^{-1} (OMe); λ_{max}: 249 (ε, 27400), 268 (25600), 273 sh (24700), 297 sh (10000), and 310 nm (9300); NMR: 2.2—2.8 (m, Ph, 16H), 3.28 (s, =CH, 1H), 5.93 (s, =CH, 1H), and 6.06 τ (s, =CH, 1H); *m/e* (relative intensity): 410 (M^+, 10), 379 (M^+–OMe, 10), 215 (M^+–(9-methoxyfluorenyl), 24), 195 (9-methoxyfluorenyl, 100), and 180 (fluorenone, 22).

Found: C, 90.59; H, 5.22%. Calcd for $C_{31}H_{22}O$: C, 90.69; H, 5.40%.

The debromination of XVIII-*d* with Zn by means of the same procedure as was used for XVIII afforded a 1 : 1 mixture of XX and XXI. NMR: 2.2—2.8 (m, Ph, 16H), 3.29 (s, =CH, 1H), 5.96 (s, =CHD, 1/2H), 6.09 (s, =CHD, 1/2H), and 7.01 τ (s, OCH_3, 3H).

Debromination of XV. A mixture of XV (0.7 g), Zn-powder (2 g), and acetone (50 ml) was heated under reflux for 1.5 hr. The Zn-powder was then filtered off, after which the filtrate was evaporated to dryness to leave crude crystals. Recrystallization from AcOEt afforded XVI pale yellow prisms; 0.38 g (90%); mp 177—179 °C. IR: 1660 (C=C) and 880 cm^{-1} (=CH); λ_{max}: 252 (ε, 87700), 264 (79500), 290 (32700), 303 (29200), and 309 nm (23400); NMR: 2.1—2.9 (m, Ph, 16H), 3.41 (s, =CH, 1H), 4.99 (s, CH, 1H), 5.83 (s, $=CH_2$, 1H), and 5.98 (s, $-CH_2$, 1H); *m/e* (relative intensity): 380 (M^+, 11), 215 (M^+-fluorenyl, 100), and 165 (fluorenyl, 30).

Found: C, 94.77; H, 5.06%. Calcd for $C_{30}H_{20}O$: C, 94.70; H, 5.30%.

Reduction of XV with $NaBH_4$. A solution of XV (0.68 g) and $NaBH_4$ (0.4 g) in MeOH-THF (1 : 1) (80 ml) was allowed to remain at room temperature for 1 hr. The subsequent evaporation of the solvent left crude crystals, which were then washed with water and dried. Recrystallization from MeOH-AcOEt afforded XVII as pale yellow needles; 0.4 g (90%); mp 162—163 °C. λ_{max}: 266 sh (ε, 25900), 269 (26200), 274 sh (22700), 280 sh (19400), 296 (10000), and 304 nm (10800); NMR; 2.1—2.9 (m, Ph, 16H), 4.95 (s, CH, 1H), 7.54 (q, J=2.5 Hz, CH_2, 2H), and 8.53 τ (t, J=2.5 Hz, CH_3, 3H).

Found: C, 94.05; H, 5.50%. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%.

Addition of Br_2 to XI. To a solution of XI (0.5 g) in $CHCl_3$ (20 ml), we added a solution of Br_2 (0.5 g) in $CHCl_3$ (5 ml) over a period of 30 min. The crude crystals which remained after the evaporation of the solvent were recrystallized from acetone to afford XXII as pale yellow prisms; 0.48 g (83%); mp 161—162 °C. λ_{max}: 253 (ε, 90000), 280 sh (53600) 295 sh (34500), and 306 sh nm (19200); NMR: 1.95—2.85 (m, Ph, 16H), 3.34 (s, $CHBr_2$, 1H), and 4.89 τ (s, CHBr, 1H).

Found: C, 51.55; H, 2.74%. Calcd for $C_{30}H_{18}Br_4$: C, 51.62; H, 2.60%.

Methanolysis of XXII. A solution of XXII (1.08 g) in MeOH-THF (1 : 1) (60 ml) was heated under reflux for 2 hr. The subsequent evaporation of the solvent left crude crystals. Recrystallization from acetone afforded XXV as pale yellow prisms; 0.84 g (90%); mp 170.5—171.5 °C. IR: 1645 (C=C) and 1100 and 1090 cm^{-1} (OMe); λ_{max}: 244 (ε, 26000), 275 (24300), and 285 nm (19900); NMR: 2.1—2.7 (m, Ph, 16H), 2.80 (s, $CHBr_2$, 1H), 5.28 (s, CHBr, 1H), and 7.07 τ (s, OCH_3, 3H).

Found: C, 57.10; H, 2.95%. Calcd for $C_{31}H_{21}OBr_3$: C, 57.35; H, 3.25%.

Dehydrobromination of XXII. A mixture of finely-powdered XXII (0.53 g), KOH (1 g), and MeOH (20 ml) was stirred at room temperature for 1 hr. The crude crystals thus formed were filtered and washed with water and MeOH. Recrystallization from AcOEt afforded XXIII as pale yellow prisms; 0.41 g (86%); mp 166.5—168 °C. λ_{max}: 253 (ε, 50300), 297 sh (13300), and 308 sh (7200); NMR: 2.15—2.85 τ (m, Ph and =CH).

Found: C, 58.50; H, 2.76%. Calcd for $C_{30}H_{17}Br_3$: C, 58.38; H, 2.78%.

Reaction of XXII with KOH-MeOH. A mixture of finely-powdered XXII (0.53 g), KOH (1.5 g) and MeOH (60 ml) was heated under reflux for 2 hr. The crude porduct formed by the addition of water to the reaction mixture was filtered, washed with water, and dried. Recrystallization from AcOEt afforded XXVI as pale yellow prisms; 0.37 g (63%); mp 179.5—181.5 °C. IR: 1070 cm^{-1} (OMe); λ_{max}: 243 (ε, 33600), 257 (33200), 271 (35800), and 309 nm (5900); NMR: 2.15—2.80 (m, Ph, 16H), 3.10 (s, =CH, 1H), and 7.15 τ (s, OCH_3, 3H).

Found: C, 65.55; H, 3.23%. Calcd for $C_{31}H_{20}OBr$: C, 65.52; H, 3.55%.

Dehydrobromination of XXV. A mixture of XXV (0.15 g), KOH (0.5 g), and MeOH (20 ml) was heated under reflux for 1 hr. The crude product formed by the addition of water to the reaction mixture was filtered, washed with water, and dried. Recrystallization from AcOEt afforded XXVI: 0.14 g (71%).

Reduction of XI with Zn. A mixture of XI (1 g), Zn-powder (2.5 g), and MeOH (100 ml), was heated under reflux for 2 hr. The Zn-powder was then filtered off, after which the evaporation of the solvent left crude crystals. Recrystallization from AcOEt afforded XXIV as colorless plates; 0.6 g (70%); mp 161—163 °C. IR: 1650 cm^{-1} (C=C); λ_{max}: 258 (ε, 75000) and 303 nm (28000); NMR: 2.2—2.9 (m, Ph, 16H), 3.28 (s, =CH, 1H), 5.08 (s, CHBr, 1H), and 5.15 τ (s, CH, 1H).

Found: C, 78.17; H, 3.91%. Calcd for $C_{30}H_{19}Br$: C, 78.44; H, 4.17%.

Addition of Br_2 to XXIV. A solution of XXIV (0.32 g) and Br_2(0.2 g) in $CHCl_3$ (10 ml) was allowed to remain at room temperature for 2 hr. The subsequent evaporation of the solvent left an oil, which was crystallized by the addition of a small amount of MeOH. Recrystallization from AcOEt afforded XXVII as colorless plates; 0.26 g (60%); mp 178—179 °C. λ_{max}: 270 (ε, 27800) and 304 nm (4600); NMR: 1.8—2.9 (m, Ph, 16H), 3.64 (s, $CHBr_2$, 1H), 4.93 (s, CHBr, 1H), and 5.23 τ (s, CH, 1H).

Found: C, 57.88; H, 2.98%. Calcd for $C_{30}H_{19}Br_3$: C, 58.16; H, 3.07%.

Dehydrobromination of XXVII. A mixture of XXVII (0.15 g), KOH (0.5 g), and MeOH (20 ml) was heated under reflux for 2 hr. The crude crystals obtained by the addition of water to the reaction mixture were recrystallized from AcOEt to afford XI; 0.12 g (92%).

Peptides. V. Some Carbonates of Ethyl 2-Hydroximino-2-cyanoacetate and Related Compounds as Esterification Reagents for Peptide Synthesis

Masumi ITOH

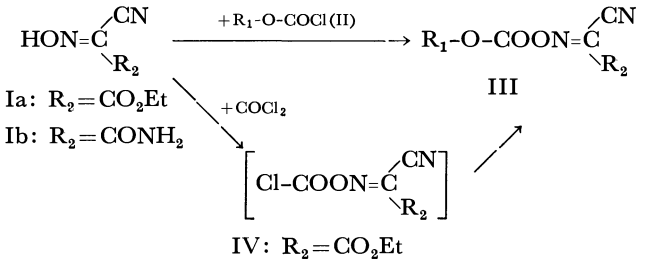
Research Laboratories, Fujisawa Pharmaceutical Co., Ltd. Kashima-cho, Higashiyodogawa-ku, Osaka 532

(Received August 22, 1973)

Some carbonates (III) of ethyl 2-hydroximino-2-cyanoacetate (Ia) and 2-hydroximino-2-cyanoacetamide (Ib) were prepared and utilized as simple esterification reagents for acylamino acids.

The applications of some carbonates in the preparation of acylamino acid esters[1,2] have been reported, but the reactivity of these carbonates is rather low and these applications have been limited to the preparation of aryl esters. The present author wishes to report a generally-applicable esterification of acylamino acids by the use of carbonates (III) of strongly acidic oximes such as ethyl 2-hydroximino-2-cyanoacetate (Ia),[3] which has previously been proposed as an additive for racemization suppression.[4]

The oxime carbonates were prepared, as is shown in Scheme 1, by the reaction of oximes with alkyl or aryl chloroformates under the conditions of a Schotten-Baumann reaction (method A), or through a labile chloroformate, ethyl 2-chloroformyloximino-2-cyanoacetate (IV), prepared from Ia with phosgene in an anhydrous organic solvent (method B). The carbonates thus prepared are listed in Table 1. These carbonates are generally stable enough and remain unchanged over one year in closed bottles, but some of them are extremely unstable and are difficult to prepare. Ethyl 2-*t*-amyloxycarbonyloximino-2-cyanoacetate (IIIm; R_1=*t*-amyl), for example, was prepared by Method B, but it decomposed instantly after characterization by taking its infrared (IR) spectrum.



Scheme 1.

Preliminary experiments on the reaction of oxime carbonates with *N*-benzyloxycarbonylglycine in an attempt to prepare the corresponding esters were done in the presence of a tertiary base at room temperature; by the help of thin layer chromatography (tlc) on silica gel G, it was noticed that the reaction does not take place in the absence of base or in the presence of water. The reactivity of carbonates (III) is parallel to the acidity of the parent oximes, and the carbonates of 2-hydroximinopropane,[5] 1-hydroximinoethane,[6] 1-hydroximino-2-propanone[7] (pK_a 8.4), and diethyl 2-hydroximinomalonate[8] (pK_a 7.1) were less reactive. Thus, Ia (pK_a 4.6) and 2-hydroximino-2-cyanoacetamide[9] (Ib, pK_a 5.2) were selected as suitable parent oximes from among them. The rate of esterification depends largely on the basicity of the tertiary amines

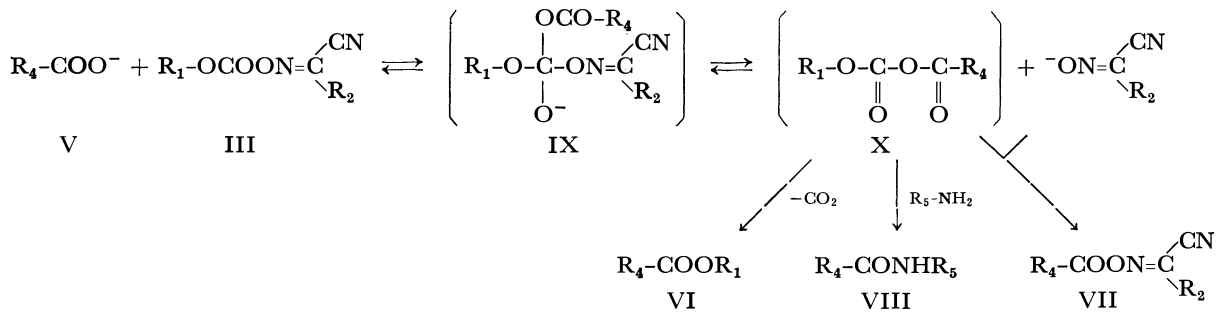
a) Two equivalents of reagents were used. TEA = triethylamine, DMA = *N*,*N*-dimethylaniline, NEM = *N*-ethylmorpholine. Abbreviations used throughout this work are those recommended by IUPAC-IUB commission on biochemical nomenclature (*J. Biol. Chem.*, **247**, 977 (1972)).



Scheme 2.

used and on the polarity of the solvents used. The reaction was completed fast by the use of a stronger base in a polar solvent.

When benzoic acid was used as a model, reverse esters, ethyl 2-benzoyloximino-2-cyanoacetate (VIIa) or 2-benzoyloximino-2-cyanoacetamide (VIIb), were obtained as by-products, accompanied by ordinary esters. The yield of the reverse esters varied depending upon the substituents of the carbonates, bases, and solvents used. The yield of VIIa increased up to 56.8% when the reaction of benzoic acid with ethyl 2-methyloxycarbonyloximino-2-cyanoacetate (IIId) was carried out using *N*,*N*-dimethylaniline in dichloromethane, while it was suppressed completely by the use of triethylamine in methanol.

In the case of *N*-benzyloxycarbonylglycine, on the contrary, the yields of such reverse esters are negligible. The esters prepared are summarized in Table 2. IIId and ethyl 2-ethyloxycarbonyloximino-2-cyanoacetate (IIIe) were also allowed to react with L-phenylalanine and hydroxyacetic acid to afford fully-protected acids, methyl *N*-methyloxycarbonyl-L-phenylalaninate and ethyl ethyloxycarbonyloxyacetate respectively. Some of the esters prepared were subjected to gas chromatography (Examples 6 and 7 in Table 2) and to mass spectrometry (Examples 8, 12, and 15 in Table 2) in order to characterize them. This procedure might be suitable for obtaining a simple characterization of multifunctional acids.

This esterification may proceed through a mixed anhydride-type intermediate (X), as is shown in Scheme 2. When the intermediate, X, is stable enough and when its decarboxylation is rather slow, it may react with the oxime anion to afford the reverse ester, VII. This mechanism is supported by the peptide formation from *N*-benzyloxycarbonylamino acids with amino acid esters, using ethyl 2-isobutyloxycarbonyloximino-2-cyanoacetate (IIIf) as a coupling reagent, at −15 °C. However, its use does not show remarkable advantages over the usual mixed anhydride method, because it requires conditions similar to the usual ones and it will act as an esterification reagent

Table 3. Some active esters of acylamino acids

$$R_4\text{-COOH} + R_1\text{-O-COON=C}\begin{matrix}\text{CN}\\ R_2\end{matrix} \longrightarrow R_4\text{-COOR}_1 + \text{HON=C}\begin{matrix}\text{CN}\\ R_2\end{matrix}$$

R_1	R_2	R_4	Base/Solvent	Yield (%)	Ref.
$-C_6H_4$-NO_2 (*p*)	$CONH_2$	Z-Phe	TEA/THF	60.0	10a

$-C_6Cl_5$	COOEt	Z-Glu	TEA/DMF	62.5	13

for acylamino acid unless the reaction is performed at low temperature.

The aryl esters of *N*-benzyloxycarbonylamino acids were prepared by the use of ethyl 2-(*p*-nitrophenyl)-oxycarbonyloximino-2-cyanoacetate (IIIi), ethyl 2-(2,4,5-trichlorophenyl)-oxycarbonyloximino-2-cyanoacetate (IIIj) and ethyl 2-(pentachlorophenyl-)oxycarbonyloximino-2-cyanoacetate (IIIk), in moderate yields, as is shown in Table 3.

Experimental

The capillary melting points were observed on a Hoover "Uni-Melt" apparatus and are uncorrected. The optical rotations were determined with a JASCO optical rotatory dispersion recorder, Model ORD/UV-5. The gas-liquid chromatographic work was done with a Varian Aerograph, Model A-700, using a column (3/8 in×10 ft) packed with SF-96 on Neopak (60/80), and on a Shimadzu gas chromatograph, GC-2C, using a column (3 mm×1.5 m) packed with 5% SE-30 on Shimailte W (60/80). The spectrometers used throughout this work were as follows: IR spectra: Hitachi Model EPI-S2; nuclear magnetic resonance spectra: Varian A-60, and mass spectra: JEOLCO Model JMS 01 SG.

Materials. Commercially-available methyl, ethyl, isobutyl, trichloroethyl, and benzyl chloroformates were purchased and used for the preparation of the carbonates. The allyl chloroformate was prepared according to the literature.[15]

The Preparation of Oxime Carbonates (III). A-i) In an Aqueous Solution: Chloroformate (II, 0.1 mol) was added dropwise to a suspension of ethyl 2-hydroximino-2-cyanoacetate sodium salt[3] (16.4 g, 0.1 mol) or 2-hydroximino-2-cyanoacetamide sodium salt[3] (13.5 g, 0.1 mol) in a mixture of acetone (15 ml) and water (100 ml) at 0—+5 °C. The mixture was then stirred for 3 hr while the pH of the solution was maintained at 7—8. The product was then extracted from the solution by ether (IIId,e,n,o,p, and q) or ethyl acetate (EtOAc) (IIIf,g and h). The extract was washed with water and dried over magnesium sulfate. After evaporation, the residue was distilled or recrystallized from a suitable solvent, as will be shown below. In some cases (IIIb,c and g), a crude product was obtained by the filtration of the reaction mixture. The compounds (III, R_1-O-COON=CR_2R_3) prepared in this manner are as follows: (R_1, R_2, R_3, mp °C or bp °C/mmHg, recrystallization solvent, elemental analysis (calcd) shown) IIIb: Et, $CONH_2$, CN, 194—196, EtOAc, C, 39.12; H, 3.69; N, 22.78% (C, 38.92; H, 3.81; N, 22.70%); IIIc: *iso*-Bu, $CONH_2$, CN, 156—158, EtOAc, C, 44.86; H, 5.27; N, 19.57% (C, 45.07; H, 5.20; N, 19.71%); IIId: Me, COOEt, CN, 69—71, C_6H_6-hexane, C, 41.99; H, 3.90; N, 14.10% (C, 42.00; H, 4.03; N, 14.00%); IIIe: Et, COOEt, CN, 127.5/0.8, ···, C, 45.08; H, 4.63; N, 13.17% (C, 44.86; H, 4.71; N, 13.08%); IIIf: *iso*-Bu, COOEt, CN, 60—62, EtOAc-petroleum ether, C, 56.98; H, 4.30; N, 10.25% (C, 56.52; H, 4.38; N, 10.14%); IIIh: allyl, COOEt, CN, 122—124/0.9, --, C, 47.56; H, 4.40% (C, 47.79; H, 4.46%); IIIn: Et, Me, Me, 66—66.5/5, --, C, 49.81; H, 7.68% (C, 49.65; H, 7.64%); IIIo: Et, H, Me, 67—70/6, --, C, 46.38; H, 7.01; N, 10.49% (C, 45.80; H, 6.92; N, 10.68%); IIIp: Et, H, COMe, 81—85/8.5, --, C, 44.96; H, 5.62; N, 8.45% (C, 45.28; H, 5.70; N, 8.80%); IIIq: Et, COOEt, COOEt, 120/0.1, C, 46.27; H, 5.69; N, 5.53% (C, 45.98; H, 5.78; N, 5.36%).

A-ii) In Organic Solvents; A typical example is as follows. A solution of *β,β,β*-trichloroethyl chloroformate (10.5 g, 0.05 mol) in benzene (C_6H_6) (35 ml) was added dropwise to a solution of ethyl 2-hydroximino-2-cyanoacetate (Ia, 7.2 g, 0.05 mol) and triethylamine (TEA) (7.0 ml, 0.05 mol) in C_6H_6 (50 ml) under ice-cooling. The mixture was then stirred for 1 hr below 10 °C and allowed to stand overnight at room temperature. The solution was washed with water and dried over magnesium sulfate. After evaporation, the residue was triturated with petroleum ether and filtered to give IIIl; 12.3 g, mp 50—52 °C. A part of the sample was recrystallized from EtOAc-petroleum ether; mp 51—53 °C.

Found: C, 30.59; H, 2.14; N, 9.29; Cl, 32.70%, Calcd for $C_8H_7O_5N_2Cl_2$: C, 30.26; H, 2.22; N, 8.82; Cl, 33.50%.

For the preparation of IIIa, chloroform was used as the solvent. For IIIm, a solution of Ia and TEA in C_6H_6 was added to a solution of *t*-amyl chloroformate in an ether-toluene mixture.[16] The carbonates prepared in this manner are as follows: (R_1, R_2, R_3, mp °C, recrystallization solvent, elemental analysis (calcd) shown) IIIa: Me, $CONH_2$, CN, 174—175 (decomp), EtOAc, C, 35.33; H, 2.99; N, 24.31% (C, 35.09; H, 2.95; N, 24.56%); IIIm: *t*-Amyl, COOEt, CN, oil, ···, ···. This decomposed spontaneously after IR measurement.

B-i) Preparation of Ethyl 2-Chlorocarbonyloximino-2-cyanoacetate (IV): A solution of Ia (7.2 g) and TEA (7.0 ml) in dry C_6H_6 (50 ml) was added dropwise to a solution of phosgene in C_6H_6 (52.5 ml, 0.05 mol) at 5 °C. The mixture was stirred for 2 hr, allowed to stand overnight, and used for the next step without further treatment. In another run, the

reaction mixture was filtered and evaporated to dryness under reduced pressure. The pale yellow oil (8.6 g) thus obtained showed IR absorptions at 1870 and 1740 cm^{-1} and was very unstable toward moisture.

B-*ii) Preparation of Oxime Carbonates (III)*: A typical example is as follows. A solution of pentachlorophenol (13.3 g, 0.05 mol) and *N,N*-dimethylaniline (6.0 g, 0.05 mol) in CH_2Cl_2 (50 ml) and C_6H_6 (50 ml) was added dropwise into the stirred solution of IV described in B-i) at 5—10 °C. The mixture was then stirred for 2 hr and allowed to stand overnight. The mixture was subsequently washed with water, dried over magnesium sulfate, and evaporated to dryness under reduced pressure. The residue was filtered with a small amount of ether to give a crude powder; 5.5 g. Recrystallization from EtOAc-petroleum ether gave needles (IIIk); mp 122—124 °C.

Found: C, 33.02; H, 1.09; N, 6.25; Cl, 40.70%. Calcd for $C_{12}H_5O_5N_2Cl_5$: C, 33.17; H, 1.16; N, 6.45; Cl, 40.80%.

IIId, IIIi and IIIj were prepared by a similar procedure except for the following modifications: C_6H_6 (40 ml) for IIId, CH_2Cl_2 (50 ml) for IIIi and pyridine in C_6H_6 (50 ml) for IIIj. The following are the R_1, R_2, R_3, mp °C, recrystallization solvent, elemental analysis (calcd) shown; IIId: Me, COOEt, CN, 68—70, C_6H_6-hexane, ···; IIIi; C_6H_4-$NO_2(p)$, COOEt, CN, 90—93, C_6H_6-petroleum ether, C, 47.41; H, 2.90; N, 13.77% (C, 46.91; H, 2.95; N, 13.68%); IIIj: $C_6H_2Cl_3(2,4,5)$, COOEt, CN, 101—103, C_6H_6-petroleum ether, C, 39.29; H, 1.88; N, 6.95; Cl, 29.18% (C, 39.42; H, 1.93; N, 7.66; Cl, 29.10%.)

Preliminary Reactions of N-*Benzyloxycarbonylglycine with Some Oxime Carbonates. A) A Comparison of The Reactivity of Carbonates by The Help of Tlc*: The stoichiometric amount of oxime carbonate (2 mmol) cited below was added to a solution of *N*-benzyloxycarbonylglycine (0.42 g, 2 mmol) and TEA (0.28 ml, 2 mmol) in dioxane (5.0 ml) at room temperature. The reaction mixture was checked by tlc on silica gel G (solvent: $CHCl_3$–MeOH (9 : 1)). With 2-ethyloxycarbonyloximinopropane (IIIn), ethyloxycarbonyloximinoethane (IIIo), 1-ethyloxycarbonyloximinopropan-2-one (IIIp) and diethyl 2-ethoxycarbonyloximinomalonate (IIIq), the reaction did not take place at all. When dimethylformamide was used as the solvent, the reaction proceeded slightly with only IIIq. The reaction was completed with ethyl 2-ethoxycarbonyloximino-2-cyanoacetate (IIIe) and 2-ethoxycarbonyloximino-2-cyanoacetamide (IIIb) within 20 min and 2 hr respectively.

B) Comparison of The Solvent Effects: 2-Isobutyloxycarnyloximino-2-cyanoacetamide (IIIc, 0.43 g, 2 mmol) was allowed to react with *N*-benzyloxycarbonylglycine (0.42 g, 2 mmol) and TEA (0.28 ml, 2 mmol) in the following solvent (5.0 ml) for 3 hr at room temperature. The rate of ester formation was compared by tlc as has been described in A). The rate increased in the following order: THF≒dioxane<MeCN<dimethylformamide.

General Procedure for The Preparation of Esters. Oxime carbonate (III, 0.01 or 0.02 mol, according to the number of functional groups) was added portionwise to a solution of carboxylic acid (0.01 mol) and tertiary amine (0.01 or 0.02 mol) in a suitable solvent (20 ml), as is shown in Table 2, at room temperature. The mixture was then stirred for a further 2 hr and extracted with EtOAc, $CHCl_3$ (ex. 6) or ether (ex. 7). The organic layer was washed with water, 1M $NaHCO_3$ solution, water, 1M HCl and water successively, and dried over magnesium sulfate. The subsequent evaporation of the solvent gave a product, which was purified or analyzed by the method cited below for each section. Reverse esters (VII) were less soluble than normal esters (VI) and were easily separated by treatment with EtOAc containing petroleum ether. Remarks on each experiment shown in Table 2 follows: ex. 2) ethyl 2-benzoyloximino-2-cyanoacetate (VII), mp 99—101 °C (from EtOAc-petroleum ether), C, 58.60; H, 3.93; N, 11.60% (calcd for $C_{12}H_{10}O_4N_2$: C, 58.53; H, 4.09; N, 11.38%), IR (Nujol, cm^{-1}) 1770, 1745; ex. 3) 2-benzoyloximino-2-cyanoacetamide (VII), mp 223—226 °C (from THF), C, 55.69; H, 3.05; N, 19.30% (calcd for $C_{10}H_7O_3N_3$: C, 55.30; H, 3.25; N, (19.35%), IR (Nujol, cm^{-1}) 1770, 1695; ex. 6) diethyl adipate (VI) was checked by gas-liquid chromatography (glc) and identified with an authentic sample; 1,4-bis(α-cyano-α-carbamoylmethyleniminoxycarbonyl)butane (VII), mp 200—202 °C (from THF), C, 42.63; H, 3.54; N, 24.67% (calcd for $C_{12}H_{12}O_6N_6$: C, 42.86; H, 3.60; N, 24.99%), IR (Nujol, cm^{-1}) 3450, 3200, 1795, 1705; ex. 7) ethyl 2-ethoxycarbonyloxyacetate (VI), fractionated by preparative glc, IR (neat, cm^{-1}) 1745, nuclear magnetic resonance (in $CDCl_3$, ppm) 1.29 (methyl, 3H, triplet, J=7.5 Hz), 1.31 (methyl, 3H, triplet, J=7.5 Hz), 4.25 (two methylene, 4H, quartet, J=7.5 Hz), 4.61 (methylene, 2H, singlet); ex. 8) mass spectrometry *m/e* 223 (M^+), IR (neat, cm^{-1}) 3350, 1740, 1700; ex. 11) IR (neat, cm^{-1}) 3350, 1730, 1700; ex. 12) mass spectrometry *m/e* 299 (M^+); ex. 13) ethyl *N*-benzyloxycarbonyl-L-tryptophanate, mp 80—83 °C (from EtOAc-petroleum ether), C, 68.56; H, 6.05; N, 7.64% (calcd for $C_{21}H_{22}O_4N_2$: C, 68.83; H, 6.05; N, 7.65%), IR (Nujol, cm^{-1}) 3350, 1730, 1700; ex. 14) ethyl *N*-benzyloxycarbonyl-L-phenylalaninate, checked by tlc and identified with an authentic sample, IR (neat, cm^{-1}) 3350, 1730, 1700; ex. 15) methyl *N*-methoxycarbonyl-L-phenylalaninate, mass spectrometry *m/e* 237 (M^+), IR (neat, cm^{-1}) 3350, 1730, 1700.

Peptide Formation by the Use of Ethyl 2-isobutyloxycarbonyloximino-2-cyanoacetate (IIIf). A) Ethyl N-*Benzyloxycarbonylglycyl-*L-*leucinate*: To a solution of *N*-benzyloxycarbonylglycine (1.05 g, 5 mmol) and TEA (0.70 ml, 5 mmol) in EtOAC (15 ml), a solution of IIIf (1.21 g, 5 mmol) in EtOAc (10 ml) was added dropwise at —15 °C. The mixture was then stirred for 30 min at the same temperature. A solution of ethyl L-leucinate hydrochloride (1.0 g) and TEA (0.70 ml) in CH_2Cl_2 (15 ml) was subsequently added dropwise to the solution described above, and the mixture was stirred for 1 hr. The product was taken up into EtOAc. The extract was washed with water, 1M $NaHCO_3$ solution, water, 1M HCl, and water again, and dried over magnesium sulfate. Evaporation gave an oily product; 1.4 g (80%). To confirm the structure, the product was saponified to give *N*-benzyloxycarbonylglycyl-L-leucine; mp 100—102 °C (lit,[18] 101—102 °C). The sample was identified with an authentic specimen by means of its IR spectra.

B) Methyl N-*Benzyloxycarbonylglycyl-*L-*phenylalaninate*: This compound was prepared in a similar manner in an 86% yield. A part of the product was saponified to give *N*-benzyloxycarbonylglycyl-L-phenylalanine; mp 124—126 °C (lit,[19] mp 125—126 °C). An admixture of the sample and an authentic specimen melted at 124—126 °C.

The author wishes to express his thanks to Mr. Daizo Morino and Mr. Yoshiaki Yasuda for their skillful technical assistance.

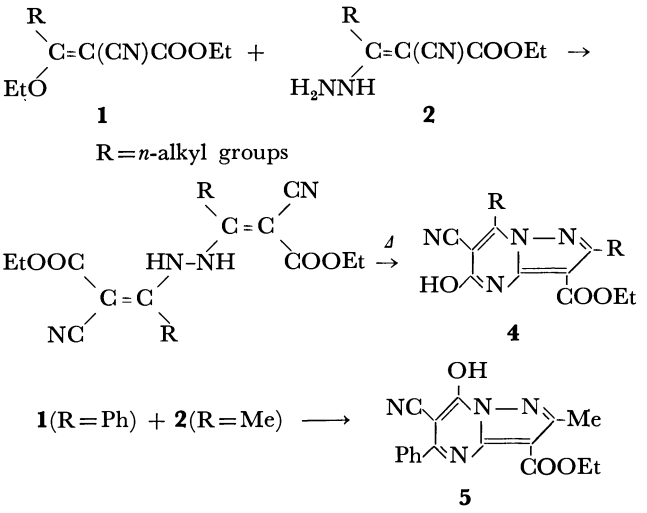
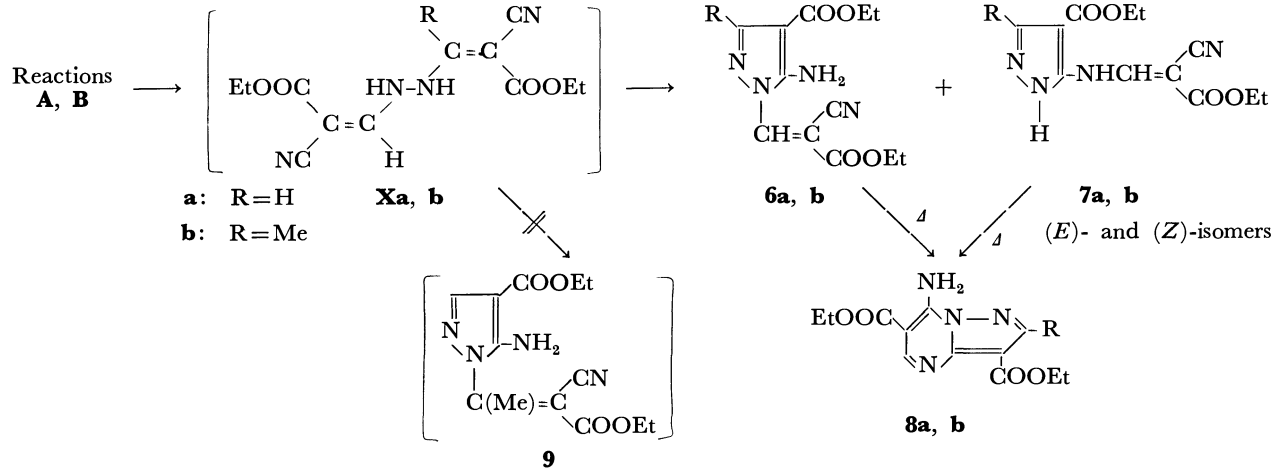
(Received October 5, 1973)

The reaction of ethyl ethoxymethylenecyanoacetate with its hydrazino derivative in the presence of pyridine in ethanol at room temperature gave ethyl (4-ethoxycarbonyl-5-aminopyrazol-1-yl)methylenecyanoacetate(**6**) and two geometric isomers of ethyl (4-ethoxycarbonylpyrazol-5-ylamino)methylenecyanoacetate(**7**). Compound **6** itself, under the same conditions, rearranged to compound **7**. Both compounds, **6** and **7**, upon heating cyclized exclusively to the same product, diethyl 7-aminopyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylate(**8**). From the results of other combination reactions on methylenecyanoacetic ester homologs, a plausible reaction mechanism involving a rearrangement is discussed.

A previous work[3] has been shown that the reaction of (1-alkoxyalkylidene)cyanoacetic esters (**1**: R=*n*-alkyl groups) with their hydrazino derivatives (**2**) in the presence of pyridine in ethanol at room temperature gave bis(substituted vinyl)hydrazines, whose cyclization led to the formation of only 5-hydroxypyrazolo[1,5-*a*]pyrimidines(**4**), while methyl (α-methoxybenzylidene)-cyanoacetate(**1**: R=Ph) or (1-ethoxyethylidene)malononitrile reacted with the hydrazino reactant(**2**: R=Me) to afford 7-hydroxy(or amino)pyrazolopyrimidine (**5**) as a major product directly, along with the 5-hydroxy (or amino) one. It has also been found that similar condensations on methylenecyanoacetic ester homologs(**1** and/or **2** being R=H) all lead to the 7-amino product as the only final product. The formation of the 7-amino (or hydroxy) product in these reactions suggests that a certain rearrangement must occur if **2** itself does not initially cyclize to 5-aminopyrazole(**3**) during the reaction.



The reaction of ethyl ethoxymethylenecyanoacetate (**1**: R=H) with its hydrazino derivative (**2**: R=H)[4,5] under the same conditions as have been described in the earlier paper, Reaction **A**, afforded at first ethyl (4-ethoxycarbonyl-5-aminopyrazol-1-yl)methylenecyanoacetate(**6a**) instead of the expected intermediate(**Xa**), followed by two geometric isomers of ethyl (4-ethoxycarbonylpyrazol-5-ylamino)methylenecyanoacetate, (*E*)- and (*Z*)-**7a**. The elemental analyses of all these compounds indicated that they all had the same composition ($C_{12}H_{14}O_4N_4$). Their structures were chiefly verified by the following spectral studies. As can be seen from Table 1, the NMR spectrum of **6a** shows two sharp singlet signals(both 1H), corresponding to the vinyl proton and C–H proton on the pyrazole ring, and a broad singlet signal(2H) of the NH_2 protons. The IR spectrum of **6a** shows the pre-



Scheme 1.

Table 1. Characteristic NMR and IR data of compounds **6** and **7**

Compd	Solv.	NMR (δ-Values from TMS)			NH (Ring)	IR (cm^{-1}, Nujol)		
		R (Ring)	=CH	NH (Exo)		ν NH_2		ν NH
6a	$CDCl_3$	8.29(H)	8.19	5.23(NH_2)		2478	3372	
	CD_3SOCD_3	8.57(H)	8.69	6.35(NH_2)				
6b	$CDCl_3$	2.64(Me)	8.16	5.31(NH_2)		3475	3350	
	CD_3SOCD_3	2.65(Me)	8.18	6.26(NH_2)				
(*E*)-**7a**	CD_3SOCD_3	8.27(H)	8.48 d (J=15 Hz)	9.40 d	13.39		3310(sh)	3250
(*Z*)-**7a**	CD_3SOCD_3	8.26(H)	8.28 d (J=14 Hz)	11.42 d	13.39		3312(sh)	3250
(*E*)-**7b**	$CDCl_3$	2.53(Me)	8.83 d (J=14 Hz)	9.30 d	10.80 br		3309(sh)	3251
	CD_3SOCD_3	2.37(Me)	8.48 d (J=14 Hz)	9.25 d	13.10			
(*Z*)-**7b**	$CDCl_3$	2.53(Me)	8.30 d (J=13 Hz)	11.58 d	10.60 br		3310(sh)	3252
	CD_3SOCD_3	2.38(Me)	8.28 d (J=13 Hz)	11.38 d	13.15			

sence of a typical primary amino group. On the other hand, the NMR spectra of the two isomers of **7a** show the doublet signal due to the vinyl proton coupled with the adjacent NH proton. The downfield NH signal attributed to an intramolecular hydrogen-bonding between the amino and the ester groups was assigned to that of the (*Z*)-form.[5]

Also, a similar reaction of the ethoxy reactant(**1**: R=H) with ethyl (1-hydrazinoethylidene)cyanoacetate(**2**: R=Me), Reaction **B**, gave the corresponding compounds, ethyl (3-methyl-4-ethoxycarbonyl-5-aminopyrazol-1-yl)methylenecyanoacetate (**6b**)[6] and two isomers of ethyl (3-methyl-4-ethoxycarbonylpyrazol-5-ylamino)methylenecyanoacetate, (*E*)- and (*Z*)-**7b**.

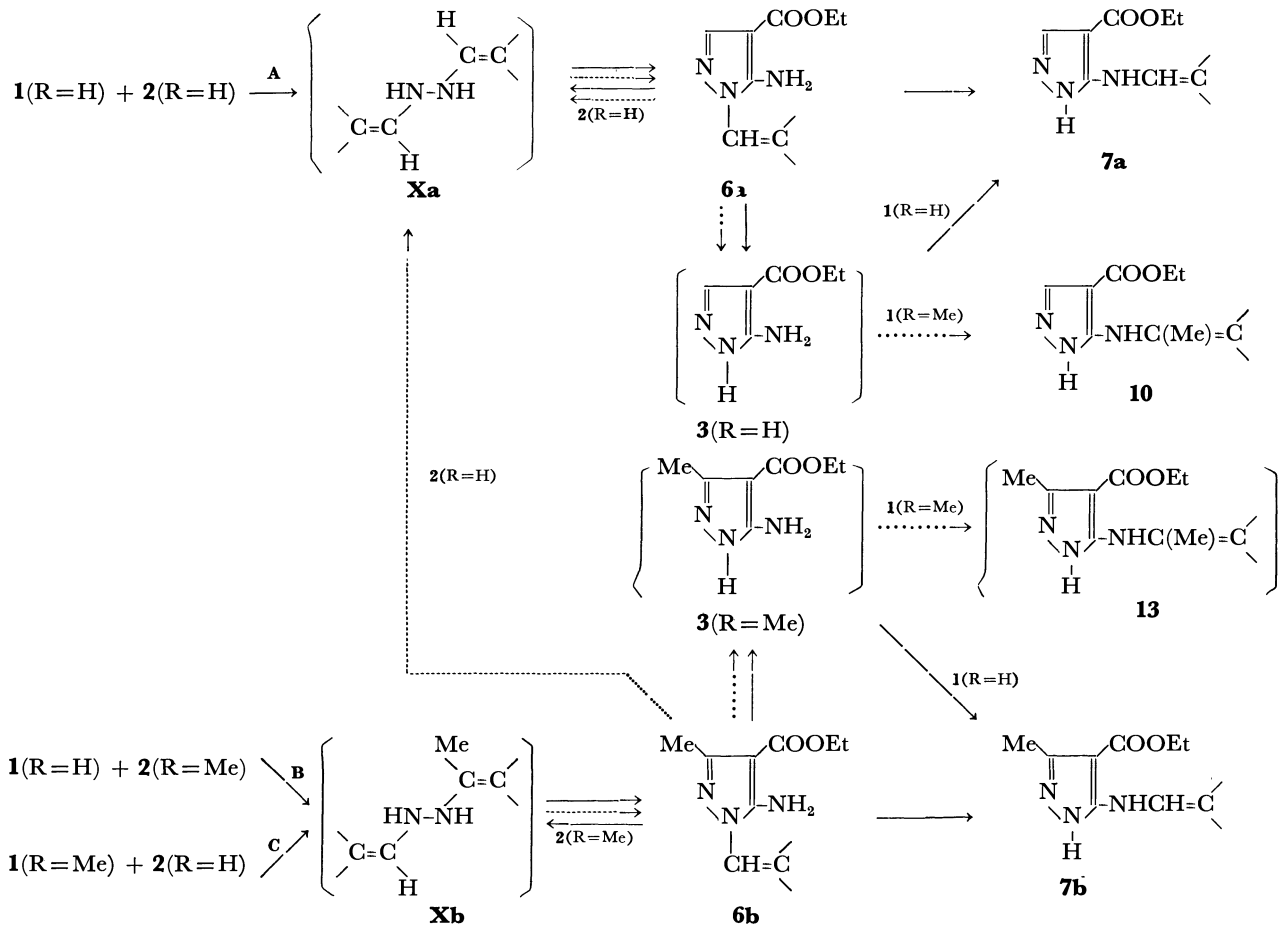
The two isomers of **7** were also prepared by the condensation of the ethoxy reactant(**1**: R=H) with ethyl 5-aminopyrazole-4-carboxylates(**3**), derived from the hydrazino reactants(**2**: R=H and Me), under the same conditions, and upon heating above 210 °C or by refluxing in acetic acid or in ethanolic hydrochloric acid they were cyclized to form the corresponding diethyl 7-aminopyrazolopyrimidine-3,6-dicarboxylates(**8**) exclusively.[7] Also, a similar treatment of **6** resultsed in the same product(**8**) instead of the 5-amino one. This fact implies that **6** must rearrange to **7** prior to its cyclization. In fact, when only **6** was placed under the same conditions as in the original reaction, a rearrangement occurred and a mixture of the geometric isomers of **7** resulted.

In view of the above facts, it seems reasonable to assume that both reactions, **A** and **B**, proceed through an initial intermediate(**X**) which cyclizes partially to **6** without the occurrence of an initial cyclization of the reactant(**2**) to **3**. In Reaction **B** the absence of ethyl [1-(4-ethoxycarbonyl-5-aminopyrazol-1-yl)ethylidene]cyanoacetate(**9**) suggests that the partial cyclization of an initial intermediate(**Xb**) takes place preferentially at the side of the methylvinyl group to give **6b**.

On the other hand, when ethyl (1-ethoxyethylidene)-cyanoacetate(**1**: R=Me) reacts with the hydrazino reactant(**2**: R=H), Reaction **C**, the same result as in Reaction **B** should be obtained because the same initial intermediate(**Xb**) is involved. In practice, however, this reaction afforded, besides **7b**, two unexpected compounds, **6a** and **7a**, which were identical with those obtained previously from Reaction **A**, and a minor compound, ethyl [1-(4-ethoxycarbonylpyrazol-5-ylamino)ethylidene]cyanoacetate(**10**). Compound **10** was also obtained by the condensation of **1**(R=Me) and **3**(R=H) under similar conditions, and when refluxed in ethanolic hydrochloric acid it cyclized to the 7-hydroxy and 7-aminopyrazolopyrimidines(**11** and **12**). These results may be elucidated by the following assumptions.

In connection with the present work, it was found that some 1-acyl-5-aminopyrazoles, on fusing or upon refluxing in acetic acid, rearrange to the corresponding 5-acylaminopyrazoles.[8] Considering that the acyl group of 1-acylpyrazoles is labile and is readily transacylated by aminolysis with strong amines,[9] the rearrangement of 1-(substituted vinyl)-5-aminopyrazoles(**6**) as well as 1-acyl-5-aminopyrazoles, would seem to be based on an intermolecular aminolysis rather than a Dimroth-type intramolecular rearrangement mechanism. In the reaction system, the aminolysis of **6** may occur not only with another molecule of the same type, but also with the hydrazino reactant molecule (**2**). The fact that the isolated **6a** and **6b**, when treated with aniline under the same conditions as in the original reaction, both underwent aminolysis to give the same product, ethyl anilinomethylenecyanoacetate,[5] lends some support to the above speculation.

The present competitive reactions are shown in Scheme 2 below. In Reactions **A** and **B**, the aminolysis of **6** with the hydrazino reactant(**2**) reproduces itself *via* the intermediate (**X**) and simultaneously gives 5-aminopyrazoles(**3**), which then condense with the ethoxy reactant(**1**) to form the same compound (**7**) as that obtained by the aminolysis of **6** with another molecule of the same type. On the other hand, Reaction **C** is complicated by the presence of the different hydrazino reactants(**2**) from Reaction **B**. Thus, **6b** undergoes aminolysis with **2**(R=H) to give **6a** *via*



Scheme 2.

Xa with 5-aminopyrazole(**3**: R=Me), and the additional aminolysis of **6a** with **2**(R=H) leads to **3** (R=H), with the reproduction of **6a**. The condensation of the two resulting 5-aminopyrazoles(**3**: R=H and Me) with the ethoxy reactant(**1**: R=Me) ought to yield compounds **10** and **13** respectively, but an attempt to isolate **13** was unsuccessful. It can, therefore, be presumed that the formation of both **7a** and **7b** in Reaction **C** is based on the intermolecular aminolysis.

Experimental

All the melting points are uncorrected. The melting points of compounds **6** and **7** were determined with rapid heating because they varied with slow heating due to the ease of isomerization or cyclization. The NMR spectra were taken on a Varian HA-100 spectrometer, using TMS as the internal reference. The chemical shifts are expressed in terms of δ values(s: singlet, d: doublet, t: triplet, q: quartet). The IR spectra were recorded on a Hitachi 215 grating spectrophotometer.

*Reaction of Ethyl Ethoxymethylenecyanoacetate(**1**: R=H) with Its Hydrazino Derivative(**2**: R=H); Reaction **A**.* To a solution of 1.69 g (0.01 mol) of **1**(R=H) and 1.55 g(0.01 mol) of **2**(R=H) dissolved in ethanol at room temperature, a few drops of pyridine were added, and then the mixture was allowed to stand overnight at the same temperature. The crystals thus formed were collected and washed with ethanol to give 0.93 g(33.4%) of light yellow needles of ethyl (4-ethoxycarbonyl-5-aminopyrazol-1-yl)methylenecyanoacetate(**6a**), which were later recrystallized from acetone; mp 173—176 °C.

Found: C, 51.98; H, 5.10; N, 20.46%. Calcd for $C_{12}H_{14}O_4N_4$: C, 51.80; H, 5.04; N, 20.14%.

The mother liquor was allowed to stand until the following day at room temperature. The usual work-up of the resulting precipitate, followed by recrystallization from ethanol afforded 1.35 g(47.5%) of colorless needles of ethyl (*E*)-(4-ethoxycarbonylpyrazol-5-ylamino)methylenecyanoacetate (**7a**); mp 181.5—183 °C.

Found: C, 52.10; H, 4.98; N, 21.02%. Calcd: the same value as **6a** above.

Further, after the above filtrate had been allowed to stand for 3 days, the deposit was separated and washed with ethanol. The recrystallization of this from ethanol gave 0.24 g (8.6%) of colorless needles of ethyl (*Z*)-(4-ethoxycarbonylpyrazol-5-ylamino)methylenecyanoacetate(**7a**); mp 178—182 °C.

Found: C, 51.92; H, 4.85; N, 20.06%. Calcd: the same value as **6a** above.

The same esters, (*E*)- and (*Z*)-**7a**, were also prepared *via* a reaction between equimolecular amounts of **1**(R=H) and ethyl 5-aminopyrazole-4-carboxylate(**3**: R=Me) under the conditions described above; yields, 47.0 and 6.1% respectively.

*Reaction of the Ethoxy Reactant(**1**: R=H) with Ethyl (1-Hydrazinoethylidene)cyanoacetate(**2**: R=Me); Reaction **B**.* This reaction was carried out in the same manner as with Reaction **A**. Thus, from 1.69 g(0.01 mol) of **1**(R=H) and 1.69 g(0.01 mol) of **2**(R=Me), there was obtained the following three compounds.

Ethyl (3-methyl-4-ethoxycarbonyl-5-aminopyrazol-1-yl)-

methylenecyanoacetate(**6b**): light yellow needles; mp 184—185.5 °C from ethanol; yield, 0.35 g(12.0%).

Found: C, 53.50; H, 5.44; N, 18.92%. Calcd for $C_{13}H_{16}O_4N_4$: C, 53.40; H, 5.48; N, 19.17%.

When the reaction was conducted at a lower temperature (at about 5 °C), this ester(**6b**) was obtained as a mixture containing mostly another geometric isomer which melted at 164—165 °C. The characteristic NMR data of the other isomer are shown below; NMR($CDCl_3$): 2.41(s, Me-ring), 8.18(s, =CH), 6.05 (s, NH_2); (CD_3SOCD_3): 2.27(s, Me), 8.66(s, =CH), 7.68 (s, NH_2).

Ethyl (*E*)-(3-methyl-4-ethoxycarbonylpyrazol-5-ylamino)-methylenecyanoacetate(**7b**): colorless needles; mp 150—152 °C from ethanol; yield, 1.64 g(55.7%).

Found: C, 53.49; H, 5.37; N, 18.96%. Calcd: the same value as **6b** above.

Ethyl (*Z*)-(3-methyl-4-ethoxycarbonylpyrazol-5-ylamino)-methylenecyanoacetate(**7b**): colorless needles; mp 152—188.5 °C from ethanol; yield, 0.90 g (30.8%).

Found: C, 53.60; H, 5.48; N, 19.08%. Calcd: the same value as **6b** above.

The same esters, (*E*)- and (*Z*)-**7b**, were also obtained by the reaction of an equimolecular mixture of **1**(R=H) and ethyl 3-methyl-5-aminopyrazole-4-carboxylate(**3**: R=Me) under the conditions described above; yield, 24.0 and 31.0% respectively.

Cyclization of **6** *and* **7**. Each compound was treated under the following conditions to yield the corresponding cyclization products(**8**).

i) After the heating of each compound above 210 °C for 2 hr, the reaction mass was recrystallized from ethanol. The yields of **8** were over 80%.

ii) Each compound was refluxed in acetic acid for 3—5 hr, and then the reaction mixture was concentrated to an appropriate volume by means of a rotary evaporator. The resulting crystals were collected and washed with water. The recrystallization of the crystals from ethanol gave **8** in yields of 62—84%.

iii) A mixture of each compound(2 mmol) in ethanol (50 ml) containing a few drops of concentrated hydrochloric acid was refluxed for 4 hr. After the reaction mixture had been evaporated to dryness by means of a flash evaporator, the residue was diluted with water, and then the solution was made alkaline with sodium carbonate. The precipitate thus formed was purified by recrystallization from ethanol. The yields of **8** were 69—93%.

Diethyl 7-aminopyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylate (**8a**): colorless plates; mp 243—244 °C; IR(Nujol, cm^{-1}): 3344, 3236, 3125, 1727, 1692; NMR($CDCl_3$): 8.48(s, C_2–H), 8.99(s, C_5–H), 1.42(t), 4.43(q) and 4.44(q) (2COOEt).

Found: C, 51.66; H, 5.05; N, 20.02%. Calcd for $C_{12}H_{14}O_4N_4$: C, 51.80; H, 5.04; N, 20.14%.

Diethyl 2-methyl-7-aminopyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylate(**8b**): colorless needles; mp 192—194 °C; IR (Nujol, cm^{-1}): 3344, 3247, 3215, 1730, 1698; NMR($CDCl_3$): 2.64(s, C_2–H), 8.90(s, C_5–H), 1.40(t), 4.39(q) and 4.42(q) (2COOEt).

Found: C, 53.36; H, 5.47; N, 19.10%. Calcd for $C_{13}H_{16}O_4N_4$: C, 53.40; H, 5.48; N, 19.17%.

Rearrangement of **6** *to* **7**. To a solution of **6a**(1 mmol) dissolved in ethanol containing acetone at room temperature, a few drops of pyridine were added, and then the mixture was allowed to stand at the same temperature for 5 days. After the mixture had then been evaporated to dryness at 40 °C by means of a rotary evaporator, the recrystallization of the residue from ethanol gave **7a** as a mixture of the geometric isomers in a yield of 80.5%; it was identified by comparison with samples prepared as has been described in Reaction **A**.

When **6b** was treated in the same manner, (Z)-**7b**, identical with the sample described in Reaction **B**, was obtained in a yield of 67.2%.

*Reaction of Ethyl (1-Ethoxyethylidene)cyanoacetate(***1***: R=Me) with the Hydrazino Reactant(***2***: R=H); Reaction* **C**. A mixture of 1.83 g(0.01 mol) of **1**(R=Me) and 1.55 g(0.01 mol) of **2**(R=H) was dissolved in ethanol(70 ml) at room temperature, and to this a few drops of pyridine were added. After it had then been allowed to stand at room temperature for 2 days, the reaction mixture was concentrated to one-half of its volume at 40 °C by means of a rotary evaporator. The resulting precipitate was recrystallized from ethanol to give 0.32 g (11.5%) of colorless needles; mp 172—174 °C; the results of the elemental analysis and the IR spectrum of the product were identical with those of **6a**.

The mother liquor was further concentrated and allowed to stand overnight in a refrigerator. The recrystallization of the precipitate formed from ethanol gave colorless needles of 0.42 g(14.4%); mp 178—180 °C; the results of the elemental analysis and the IR spectrum of the product were identical with those of (*Z*)-**7a**.

Furthermore, the above filtrate was evaporated almost to dryness, and then allowed to stand until the following day. There was thus obtained 0.47 g (16.1%) of colorless needles which, on recrystallization from ethanol, melted at 169—180 °C and were identical with (*Z*)-**7b** previously prepared.

Finally, after it had stood in a refrigerator, the resulting viscous filtrate gave 0.05 g(1.6%) of colorless needles of ethyl [1-(4-ethoxycarbonylpyrazol-5-ylamino)ethylidene]cyanoacetate(**10**); mp 201—203 °C from ethanol; IR(Nujol, cm^{-1}): 3300(sh), 3216, 2117, 1672, 1595; NMR(CD_3SOCD_3): 2.68(s, Me), 8.41(s, H-ring), 12.40(s, NH-*exo*), 13.55(s, NH-ring), 1.27(t), 1.30(t), 4.25(q) and 4.31(q) (2COOEt).

Found: C, 53.60; H, 5.42; N, 19.01%. Calcd for $C_{13}H_{16}O_4N_4$: C, 53.40; H, 5.48; N, 19.17%.

Compound **10** was also prepared by the reaction of equimolecular amounts of **1**(R=Me) and the aminopyrazole(**3**: R=H) under the conditions described above; yield, 14.0%. Upon admixture with a sample obtained as has been described above, the melting point was not depressed.

Cyclization of **10**. A solution of **10**(3 mmol) in ethanol containing a few drops of concentrated hydrochloric acid was refluxed for 7 hr, and then the reaction mixture was concentrated to a small volume by means of a rotary evaporator. The precipitate thus formed was collected and recrystallized from ethanol to give 0.4 g(55.2%) of colorless needles of ethyl 5-methyl-6-cyano-7-hydroxypyrazolo[1,5-*a*]pyrimidine-3-carboxylate(**11**); mp 244—246 °C; IR(Nujol, cm^{-1}): 3190, 3078, 2233, 1705, 1700, 1675, 1625; NMR(CD_3SOCD_3): 2.63(s, C_5–Me), 8.21(s, C_2–H), 1.32(t) and 4.28(q)(COOEt).

Found: C, 53.82; H, 4.21; N, 22.74%. Calcd for $C_{11}H_{10}O_3N_4$: C, 53.66; H, 4.07; N, 22.76%.

The mother liquor was further allowed to stand overnight in a regrigerator, and the precipitate thus formed was restallized from ethanol to yield 0.05 g(5.7%) of colorless needles of diethyl 5-methyl-7-aminopyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylate(**12**); mp 134—136 °C; IR(Nujol, cm^{-1}): 3350, 3245, 1693, 1663, 1620, 1597; NMR(CD_3SOCD_3): 2.67(s, C_5–Me), 8.52(s, C_2–H), 8.64(s, NH), 1.31(t), 1.35(t), 4.28(q) and 4.30(q)(2COOEt).

Found: C, 53.42; H, 5.40; N, 19.12%. Calcd for $C_{13}H_{16}O_4N_4$: C, 53.40; H, 5.48; N, 19.17%.

Aminolysis of **6** *with Aniline*. A mixture of **6a**(1 mmol)

and aniline(1 mmol) was dissolved in ethanol (15 ml) containing one drop of pyridine at room temperature, and then the mixture was allowed to stand overnight at the same temperature. After the solution had been concentrated to a small volume by means of a flash evaporator and cooled in a refrigerator for 2 hr, the collection of the resulting crystals, followed by the recrystallization from ethanol, afforded 0.15 g(69.5%) of long colorless needles of ethyl anilinomethylenecyanoacetate consisting of a mixture of the geometric isomers; mp 108—113 °C.

Found: C, 66.99; H, 5.62; N, 13.08%. Calcd for $C_{12}H_{12}O_2N_2$: C, 66.65; H, 5.59; N, 12.96%.

Also, a similar treatment of **6b** with aniline gave the same product as that prepared above in a yield of 73.0%. This compound was identical with the product prepared from the ethoxy reactant (**1**: R=H) and aniline.[5]

The authors are indebted to Dr. Kiyoko Yamamoto for her fruitful discussions and to Mr. Shigenobu Murakami and Miss Keiko Tanaka for their helpful technical assistance. Thanks are also due to Dr. Haruo Homma and his staff for their elemental analyses and to Mr. Jun Uzawa for his help in taking the NMR spectra.

Autoxidation of Aromatic Hydrocarbons Catalyzed with Cobaltic Acetate in Acetic Acid Solution. III. Oxidation of *p*-Toluic Acid[1]

Mikito KASHIMA and Yoshio KAMIYA[2]

Polymer Research Laboratory, Ube Ind. Ltd., 8-2, *Goi, Ichihara-city, Chiba*, 290

(Received March 20, 1973)

The oxidation of *p*-toluic acid catalyzed with cobaltic acetate was studied kinetically in acetic acid. The maximum absorption rate of oxygen was obtained in the initial stage of reaction, being represented by the same equation as in the case of toluene, ethylbenzene and cumene. That is, the kinetic equation is of first order with respect to the initial concentration of *p*-toluic acid, of second order with respect to the initial concentration of Co(III), and of inverse first order with respect to the initial concentration of Co(II). The relative reactivity of *p*-toluic acid per active hydrogen was lower than that of toluene, but higher than that of ethylbenzene and cumene. The apparent chain-length in the oxidation of *p*-toluic acid was much shorter than that of *p*-xylene oxidation.

Many procedures have been developed for obtaining terephthalic acid by the autoxidation of *p*-xylene under applied oxygen pressure with cobaltous salts of aliphatic acids as catalyst, together with various promoters such as aldehydes[3,4] and ketones.[5,6] The roles of transition metal ion used as the catalyst are not yet fully clarified since the main purpose of these methods was to increase the yield of terephthalic acid.

Recently, aromatic oxidation catalyzed with cobaltic acetate has received considerable attention.[7-9] The reactions were mainly studied under nitrogen atmosphere for academic purposes, but they should be carried out under oxygen atmosphere for practical purposes. Thus we have reported the reaction mechanism and the role of catalyst in the liquid-phase oxidation of aromatic hydrocarbons catalyzed with cobaltic acetate under oxygen atmosphere.

It has been clarified that *p*-toluic acid was easily oxidized to terephthalic acid with cobaltic acetate under oxygen pressure in acetic acid. The oxidation of *p*-toluic acid to terephthalic acid was apparently initiated by the electron transfer equilibrium between *p*-toluic acid and cobaltic acetate. The oxidation proceeds with a short chain-length comparable to the one obtained in the oxidation of toluene catalyzed with Co(III).

Experimental

Materials. Glacial acetic acid of reagent grade was used. *p*-Toluic acid was vigorously stirred in boiling water and filtered after cooling. The procedure was repeated until no chloride ion was detected. It was then recrystallized from methanol-water solution. Cobaltous acetate was of special grade. The preparation and titration of cobaltic acetate, and the determination of water content in the solution were carried out by the same method as reported in part I.[10]

Procedure. The reaction mixture was charged into a 300 ml. stainless-steel autoclave, and temperature was increased gradually under applied oxygen pressure. The amount of absorbed oxygen was calculated on the basis of pressure drop. To keep oxygen pressure as constant as possible, fresh oxygen was charged into the autoclave as fresh oxygen was charged into the autoclave as soon as a pressure drop of 1 kg/cm^2 had been observed.

Analysis. The solid materials formed by the addition of 150 ml. of water into the reaction mixture were filtered from the aqueous solution, and washed twice with 50 ml of methanol. The crude terephthalic acid was dried at 100 °C.

The filtrate and methanol washings were mixed and concentrated to a syrup containing catalyst, *p*-toluic acid and other substances. It was dissolved in 10% sodium carbonate aqueous solution. The resulting solution was filtered and then acidified with hydrochloric acid. The resulting precipitate was filtered, washed twice with water, and dried at 60 °C to give unreacted *p*-toluic acid and terephthalaldehydic acid. A known weight of this precipitate was dissolved in a portion of M/10 sodium hydroxide. Hydrochloric acid of M/10 was added to this alkaline solution until pH of solution decreased to 3.8. An ethanol solution of hydroxylamine hydrochloride was then added to the solution and pH was again adjusted to 3.8 by adding M/10 sodium hydroxide. The amount of terephthalaldehydic acid contained in the precipitate was calculated by the following equation.

Yield of terephthalaldehydic acid (%)

$$= 1.50(x-y)/w$$

where x and y are the values of volume (ml) of NaOH and HCl aqueous solution, respectively, and w is weight (g) of precipitate.

Results and Discussion

Rate Law. When *p*-toluic acid (TA) was oxidized with cobaltic acetate under applied oxygen pressure in acetic acid at 80 °C, the reaction proceeded without an induction period. The maximum rate of oxygen absorption (v_m) was obtained in the initial stage of reaction.

The effect of oxygen partial pressure on v_m was studied in the case of the constant concentration of TA (0.333 M) and cobaltic acetate (0.084 M) in acetic acid at 100 °C with an agitation velocity of 1000 rpm. The maximum rate of oxygen absorption was independent of oxygen pressure above 4 kg/cm^2. All experiments were therefore carried out under oxygen pressure of 5 kg/cm^2 unless otherwise stated.

The relation between TA concentration and the maximum rate of oxygen absorption is shown in Fig. 1. The rate of oxidation is proportional to TA concentration below about 2 in the molar ratio of TA to cobaltic acetate, and is inversely proportional to that above the molar ratio 2. Two factors might be considered for explaining the above result: (a) acetate anions on cobaltic ion are replaced by *p*-toluate anions to form a less active cobaltic ion,[11] and (b) the solubility tof TA in acetic acid may be constant from the fac

that the yield of terephthalic acid and the amount of oxygen absorbed are constant even when the ratio of TA to cobaltic acetate exceeds 2 (see Fig. 2). The cohesion of undissolved TA may cause a decrease in the apparent concentration of cobaltic acetate.

The effect of the initial concentration of cobaltous acetate on the maximum rate of oxygen absorption and the induction period are shown in Fig. 3. It is clear that cobaltous ion inhibits oxidation remarkably and the induction period increases with the concerntration of Co(II). The reaction proceeds very slowly when the ratio Co(III)/Co(II) is nearly equal to 1. Figure 4 shows a plot of v_m against the square of the initial concentration of cobaltic ion when the concentrations of *p*-toluic acid and cobaltous ion are maintained constant. It is evident that the reaction is of second order with respect to the concentration of Co(III).

Thus v_m obtained in oxidizing TA with cobaltic acetate under oxygen pressure can evidently be represented by the equation

$$v_m = k[TA][Co(III)]^2[Co(II)]^{-1} \quad (I)$$

which is similar to the equation obtained in the oxidation of toluene,[10] ethylbenzene and cumene.[1]

Thus the oxidation of TA catalyzed with cobaltic acetate is also initiated by the electron transfer equilibrium between TA and cobaltic acetate.

Effect of Temperature. The rate of oxygen absorption becomes maximum at 100 °C. Both the yield of terephthalic acid (TPA) and the amount of absorbed oxygen showed a similar change in the temperature range 60—120 °C, giving maximum value at 100 °C (see Fig. 5). However, the molar ratio of TPA formed to cobaltic ion consumed decreased gradually with temperature rise. The tendency was most remarkable above 100 °C. This indicates that the self-decomposition of cobaltic acetate occurs considerably above 100 °C as follows:

$$Co(OAc)_3 \rightarrow \cdot CH_3 + Co(OAc)_2 + CO_2$$
$$Co(OAc)_3 \rightarrow \cdot CH_2COOH + Co(OAc)_2$$

In view of the fact the yield of TPA shows only a slow decrease above 100 °C, methyl and carboxymethyl radicals do not seem to contribute to the formation of TPA. The apparent activation energy was cal-

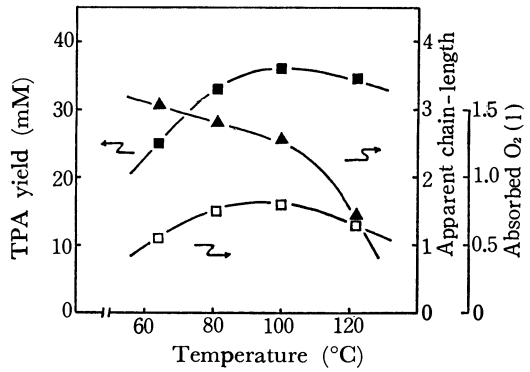

Fig. 5. The effect of temperature on TPA yield, the amount of absorbed O_2, and the apparent chain-length in the oxidation of TA (50 mM).
■ TPA yield, □ absorbed O_2,
▲ apparent chain-length

culated to be 10 kcal/mol, comparable to the one obtained by Kamiya *et al.*[12]

We have reported that the decreasing order of relative reactivities toward cobaltic acetate was as follows; primary>secondary>tertiary hydrogen, which was entirely inverse to the order for free radicals. The reactivity of TA per active hydrogen toward Co(III) was slightly smaller than that found in the oxidation of toluene with Co(III), but larger than that obtained for ethylbenzene and cumene (see Table 1). This result is not explicable in terms of the C–H bond rupture process, but supports the view that the electron transfer process is rate-determining step.

Table 1. Relative reactivities per active hydrogen of aromatic compounds toward Co(III) at 60 °C

Hydrocarbon	$k\times10^5$, ($M^{-1}s.^{-1}$)	Ratio
Toluene	3.08	1
p-Toluic acid	2.29	0.74
Ethylbenzene	1.67	0.54
Cumene	1.57	0.51

Reaction Products. Terephthalic acid was mainly obtained by the oxidation of TA with cobaltic acetate in acetic acid. A small amount of terephthalaldehydic acid (TAA) was also obtained as a by-product. The yield of TPA increased gradually with time, taking the constant value of 42% after 90 min, while the yield of TAA reached the steady value of 2% soon after the reaction started (see Fig. 6). It is thus apparent that the reaction proceeds successively TA→TAA→TPA, and that the oxidation of TAA is very fast.

The conversion of Co(III) and the ratio of Co(III)/(total Co) were found to take the constant value, 55% and 0.35, respectively after 90 min. Accordingly, the molar ratio of the yield of TPA to the consumed Co(III) was calculated to be 3.1 after 90 min, indicating that the apparent chain-length is much shorter than that obtained in the autoxidation of *p*-xylene. This suggests that the reaction is continued not by the abstraction of hydrogen from TA with peroxy radical, but by the regeneration of Co(III) from the oxidation of Co(II) with peracid or peroxy radical.

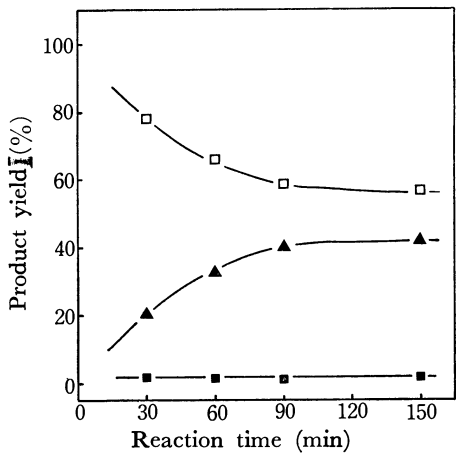

Fig. 6. Product yield and TA conversion in the oxidation of TA at 100 °C under 10 kg/cm².
TA, 0.333 M; Co(III), 0.081 M; Co(II), 0.02 M.
□ TA conversion, ▲ TPA, ■ TAA

Reaction Mechanism. It is clear that the oxidation of TA catalyzed with cobaltic acetate also proceeds through the electron transfer equilibrium as in the case of toluene, ethylbenzene and cumene, since the rate of oxygen absorption can be represented by the same equation independent of substrates, the apparent activation energies are almost equal to each other, and the relative reactivity of TA toward Co(III) is only a little smaller than that of toluene.

For the kinetics of second-order dependence on Co(III) and inverse first-order dependence on Co(II) of v_m, the following elementary reactions might play an important role in the early stage of reaction assuming that the active species of catalyst is the dimer of cobaltic acetate.

$$2\mathrm{Co(III)} \overset{K_1}{\rightleftarrows} \mathrm{Co(III)_2} \quad (1)$$

$$\mathrm{R\text{-}CH_3} + \mathrm{Co(III)_2} \overset{K_2}{\rightleftarrows} [\mathrm{R\text{-}CH_3{}^+AcO^-Co(III)}] + \mathrm{Co(II)} \quad (2)$$

$$[\mathrm{R\text{-}CH_3{}^+AcO^-Co(III)}] \overset{k_3}{\longrightarrow} \mathrm{R\text{-}CH_2\cdot} + \mathrm{Co(III)} + \mathrm{AcOH} \quad (3)$$

$$\mathrm{R\text{-}CH_2\cdot} + \mathrm{O_2} \overset{k_4}{\longrightarrow} \mathrm{R\text{-}CH_2OO\cdot} \quad (4)$$

$$\mathrm{R\text{-}CH_2OO\cdot} + \mathrm{Co(III)} \overset{k_5}{\longrightarrow} \mathrm{R\text{-}CHO} + \mathrm{Co(II)} + (1/2)\mathrm{O_2} + \mathrm{AcOH} \quad (5)$$

When the concentration of *p*-tolyl and *p*-tolylperoxy radicals reaches a stationary concentration in the early stage of reaction, the following equation can be introduced.

$$[\mathrm{R\text{-}CH_2\cdot}] = k_3[\mathrm{X}],\ [\mathrm{R\text{-}CH_2OO\cdot}] = k_3k_5^{-1}[\mathrm{X}][\mathrm{Co(III)}]^{-1}$$

where (X) is $K_1K_2k_3[\mathrm{R\text{-}CH_3}][\mathrm{Co(III)}][\mathrm{Co(II)}]^{-1}$ and R is C_6H_4COOH. The absorption rate of oxygen can then be represented by $(-dO_2/dt)=(1/2)k_3[\mathrm{X}]$. Then, v_m is abbreviated as

$$v_m = (1/2)K_1K_2k_3[\mathrm{R\text{-}CH_3}][\mathrm{Co(III)}]^2[\mathrm{Co(II)}]^{-1} \quad (\mathrm{II})$$

This equation is qualitatively in agreement with the experimental results. However, it will become more complicated or changed as the oxidation proceeds,

since the oxidation of aldehyde plays an important part.

We postulated that the active species of catalyst was the dimer of cobaltic acetate since no spectroscopic evidence could be found for the formation of Co(IV). However, it is possible that the active species of catalyst is Co(IV) produced by the disproportionation,

$$2\text{Co(III)} \overset{K_1'}{\rightleftarrows} \text{Co(IV)} + \text{Co(II)}$$

We can thus consider the following elementary reactions in the early stage of reaction.

$$\text{R-CH}_3 + \text{Co(IV)} \xrightarrow{k_2'} \text{R-CH}_2\cdot + \text{Co(III)} + \text{AcOH}$$

$$\text{R-CH}_2\cdot + \text{O}_2 \xrightarrow{k_3'} \text{R-CH}_2\text{OO}\cdot$$

$$\text{R-CH}_2\text{OO}\cdot + \text{Co(III)} \xrightarrow{k_4'} \text{R-CHO} + \text{Co(II)} + (1/2)\text{O}_2 + \text{AcOH}$$

Resolving these elementary reactions by the same method as mentioned above, we obtain

$$v_m = K_1'k_2'[\text{R-CH}_3][\text{Co(III)}]^2[\text{Co(II)}]^{-1}$$

This equation is also in agreement with Eqs. (1) and (II).

Phenanthro[4,5-*bcd*]furan Derivatives. II. A Synthesis of 3-Hydroxyphenanthro[4,5-*bcd*]furan (Morphenol)

Takaaki HORAGUCHI and Takahachi SHIMIZU

Department of Chemistry, Faculty of Science, Niigata University, Igarashi, Niigata 950-21

(Received September 28, 1973)

3-Hydroxyphenanthro[4,5-*bcd*]furan (I) was synthesized by the dehydrogenation, with 20% palladium on charcoal, of 3-oxo-1,2,3,8,9,9a-hexahydronaphtho[4,5-*bcd*]furan (XII), which had itself been prepared *via* a naphtho[1,8-*bc*]furan derivative (IX) starting from 8-hydroxy-1-tetralone (IV).

3-Hydroxyphenanthro[4,5-*bcd*]furan (I), which is a degradation product of morphine, had not been synthesized in spite of many attempts. These failures have been attributed to the presence of a ring strain[1] in the phenanthro[4,5-*bcd*]furan derivative which is the fundamental ring skeleton of morphenol. Recently, though, 5-hydroxy-1-methoxyphenanthro[4,5-*bcd*]furan (II) was synthesized,[2] as the first synthetic phenanthro[4,5-*bcd*]furan derivative, starting from methyl 3-(8-hydroxy-5-methoxy-1-oxo-1,2,3,4-tetrahydro-2-naphthyl)propionate (III), however, the product (II), unlike morphenol, has a methoxyl group at the 1-position. This paper will show that this synthetic course is applicable also to morphenol (I) and, therefore, would be useful for the preparation of general phenanthro[4,5-*bcd*]furan derivatives.

Results and Discussion

8-Hydroxy-1-tetralone (IV) was condensed[3] with ethyl formate in the presence of sodium methylate to give 8-hydroxy-2-hydroxymethylidene-1-tetralone (V). When a mixture of V and methyl acrylate was heated under reflux in aqueous methanol containing triethylamine, methyl 3-(8-hydroxy-1-oxo-1,2,3,4-tetrahydro-2-naphthyl)propionate (VI) was obtained along with IV; the ester (VI) gave an absorption corresponding to the phenolic hydroxyl group at τ −2.04 in the nuclear magnetic resonance spectrum and a conjugated-carbonyl band at 1634 cm^{-1} in the infrared spectrum. The ester was saponified to the corresponding carboxylic acid (VII) for practical separation from IV.

When VII was treated with ethyl bromoacetate at 170 °C, followed by hydrolysis, the expected di- and monocarboxylic acids, 3-(2-carboxy-4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-3-yl)propionic acid (VIII) and 3-(4,5-dihydro-3*H*-naphtho[1,8-*bc*]furan-3-yl)propionic acid (IX), were obtained in yields of 34 and 2% respectively; on the other hand, the use of VI in place of VII gave slightly increased yields (42% and 6%), which were comparable to those of the corresponding carboxylic acid (X and XI) in the synthesis of II (43% and 8%).[2] The monocarboxylic acid (IX), which was also obtained from the dicarboxylic acid by decarboxylation (59%), was subjected to polyphosphoric acid-catalyzed intramolecular cyclization to give 3-oxo-1,2,3,8,9,9a-hexahydrophenanthro[4,5-*bcd* furan (XII) in a 45% yield.

Finally, the aromatization[3,4] of XII with 20% palladium on charcoal afforded two phenolic compounds with different melting points, 142.5—143 °C and 175—179 °C (dec.), in 16 and 10% yields respectively. The lower-melting product was identified as 3-hydroxyphenanthro[4,5-*bcd*]furan (I) from its physical and spectral properties. It showed a purple fluorescence in a potassium hydroxide solution and a green fluorescence in concentrated sulfuric acid. The infrared spectrum gave absorptions at 3220 (OH) and at 814 and 822 cm^{-1} (2H), the ultraviolet spectrum was almost concordant with that of methyl morphenol,[5] and the nuclear magnetic resonance spectrum corresponded to the structure of I.

The other phenolic product, although it has not been subjected to elemental analysis, is perhaps 3,5-dihydroxyphenanthrene (XIV) in view of the following facts: (i) the nuclear magnetic resonance spectrum exhibited absorptions corresponding to two phenolic hydroxyl groups at τ 0.58 and 1.23, (ii) an isomeric 3,4-dihydroxyphenanthrene has been known to have a melting point of 143 °C,[6] (iii) the infrared spectrum is similar to that of morphenol in the 700—900 cm^{-1} region, showing the existence of two and three neighboring hydrogen atoms on the aromatic ring system.

Our synthetic course leading to 5-hydroxy-1-methoxyphenanthro[4,5-*bcd*]furan (II) is applicable also to morphenol. This suggests that the synthetic course would be generally useful for phenanthro[4,5-*bcd*]furan derivatives. It seemed that almost no effects of a methoxyl group appeared except in the intramolecular cyclization reaction (IX→XII). The yield (45%) of XII from IX was considerably lower than that (67%) of XIII. The cause of the difference in yields might be due to the steric effect of a methoxyl group; however, it is not yet clear. The effect of a methoxyl group will be further investigated by preparing 3-hydroxy-5-methoxyphenanthro[4,5-*bcd*]furan (XV).

Experimental

All the melting points are uncorrected. The column chromatography was performed over silica gel (WAKOGEL C-200, Wako Pure Chemical Industries, Ltd.). The polyphosphoric acid was prepared from 85% phosphoric acid (100 ml) and phosphorus pentoxide (123 g) by heating it at 160—165 °C for 5 hr. Unless otherwise stated, sodium sulfate was employed as the drying agent. The infrared spectra were determined with a JASCO Model DS 402G infrared spectrophotometer. The ultraviolet spectra were determined with a Shimadzu Model UV-200 spectrophotometer. The nuclear magnetic resonance spectra were determined at 100 MHz with a JEOL Model 4H-100 NMR spectrometer, using tetramethylsilane as the internal standard. Their chemical shifts are presented in terms of the τ value.

8-Hydroxy-2-hydroxymethylidene-1-tetralone (V). Ethyl formate (14.5 ml) was added to a mixture of sodium methylate (8.0 g) and benzene (50 ml) over a 5-min period, with stirring and cooling at 0 °C in nitrogen atmosphere; the stirring was then continued for one more hr. To the solution, IV (10 g) in benzene (50 ml) was added over a 30-min period at 0 °C, after which the mixture was stirred for an additional 4.5 hr at room temperature. The viscous mixture was then decomposed with 80 ml of 1 M sulfuric acid and extracted with benzene. The benzene layer was extracted with seven 55-ml portions of aqueous 1 M potassium carbonate. The alkaline solution thus obtained was acidified with 6 M hydrochloric acid, and the resulting precipitates were collected by filtration and recrystallized from *n*-hexane to give 5.35 g (76%) of V as yellow needles; mp 63—64 °C. IR(KBr): 1622 cm^{-1} (C=O). NMR($CDCl_3$): τ −3.45, −3.32 (d, C=CHOH), −1.90 (ϕ-OH).

Found: C, 69.65; H, 5.34%. Calcd for $C_{11}H_{10}O_3$: C, 69.83; H, 5.33%.

3-(8-Hydroxy-1-oxo-1,2,3,4-tetrahydro-2-naphthyl)propionic Acid (VII). A mixture of V (4.0 g), methyl acrylate (20.0 g), triethylamine (1.8 g), and 80% methanol (50 ml) was heated under reflux at 112 °C for 8 hr. The solution was then extracted with ether, and the ether layer was washed with four 30 ml-positions of aqueous 1 M potassium carbonate and with water, and dried. The ether was then evaporated, and the residue was hydrolyzed with a 3 M potassium hydroxide solution. The alkaline solution was acidified with 6 M hydrochloric acid, and the resulting precipitates were collected by filtration. They were then recrystallized from aqueous ethanol to give 3.7 g (75%) of VII as colorless needles; mp 164—165 °C. IR(KBr): 1717 (COOH), 1630 cm^{-1}(C=O).

Found: C, 66.78; H, 6.02%. Calcd for $C_{13}H_{14}O_4$: C, 66.68; H, 6.03%.

3-(2-Carboxy-4,5-dihydro-3H-naphtho[1,8-bc]furan-3-yl)propionic Acid (VIII) and 3-(4,5-Dihydro-3H-naphtho[1,8-bc]furan-3-yl)propionic Acid (VIII) and 3-(4,5-Dihydro-3H-naphtho[1,8-bc]furan-3-yl)propionic Acid (IX). A mixture of VII (2.0 g), ethyl bromoacetate (18.6 g) and potassium carbonate (12.8 g) was heated slowly up to 170 °C and then refluxed for 7 more hr at this temperature. The dark brown mixture was extracted with acetone, and then the acetone was evaporated. The residue was then separated after saponification with a 3 M potassium hydroxide solution into two moieties, one of which is insoluble in benzene. The benzene-insoluble moiety was recrystallized from tetrahydrofuran-benzene to give 0.8 g (34%) of VIII as colorless needles; mp 219—220 °C. IR (KBr): 1700 cm^{-1} (COOH).

Found: C, 68.37; H, 5.49%. Calcd for $C_{15}H_{14}O_5 \cdot 0.43\ C_6H_6$: C, 68.37; H, 5.40%.

The other moiety, in benzene, was chromatographed over silica gel and eluted with benzene-ether (97 : 3). A yellow fraction was collected, and the solvent was evaporated. The residue was crystallized from benzene-*n*-hxeane to give 40 mg (2%) of IX as colorless plates; mp 98—99 °C. IR(KBr): 1705 cm^{-1} (COOH). NMR ($CDCl_3$): τ −1.13 (COOH), 2.55 (H on the furan ring). UV: λ_{max}^{EtOH} 250 nm (ε 9500).

Found: C, 73.16; H, 6.10%. Calcd for $C_{14}H_{14}O_3$: C, 73.03; H, 6.13%.

When 1.3 g of the ester (VI) was used in place of the acid (VII), 0.6 g (41%) of VIII and 80 mg (6%) of IX were obtained.

Decarboxylation of VIII. A mixture of 10.0 g of quinoline, 1.0 g of VIII, and 1.0 g of copper powder was heated at 155 °C for 1.5 hr and then at 160 °C for 10 more min. The mixture was acidified with 1 M hydrochloric acid and extracted with ether. The ether extract was washed with four 30-ml portions of 2 M hydrochloric acid and with water, and dried, and then the ether was evaporated. The residue was crystallized from benzene-*n*-hexane to give 0.5 g (59%) of IX as colorless plates; mp 98—99 °C.

3-Oxo-1,2,3,8,9,9a-hexahydrophenanthro[4,5-bcd]furan (XII). A mixture of 0.5 g of IX and 69 g of polyphosphoric acid was stirred at 75 °C for 4 hr. The reaction mixture was poured onto ice and extracted with ether. The ether was washed with water, with four 45-ml portions of 1M aqueous potassium carbonate, and with water, and then dried. The ether was evaporated to give crystals. Recrystallization from ethanol–*n*-hexane gave 0.21 g (45%) of XII as colorless needles; mp 109—110 °C. IR(KBr): 1670 cm^{-1} (C=O). NMR($CDCl_3$): τ 2.45—2.90 (multiplet, ϕ-H), 6.57—7.03 (m, $-CH_2-$, -CH-), 7.40—7.72 (m, $-CH_2-$), 7.95—8.73 (m, $-CH_2-$).

Found: C, 79.13; H, 5.67%. Calcd for $C_{12}H_{12}O_2$: C, 79.23; H, 5.70%.

3-Hydroxyphenanthro[4,5-bcd]furan (I). A mixture of XII (0.2 g), 20% palladium on charcoal (0.4 g), and α-methylnaphthalene (3.5 g) was heated at 230 °C for 30 hr under nitrogen atmosphere. The reaction mixture was filtered, and the filtrate was extracted with ether. The ether layer was extracted with five 45 ml-portions of a 1 M potassium hydroxide solution, and the alkaline solution thus obtained was washed with three 30 ml-portions of carbon tetrachloride and then made acidic with 6 M hydrochloric acid. The resulting precipitates were extracted with ether, and the ether extract was washed with water, dried, and then concentrated. The residue was chromatogtaphed over silica gel and eluted with benzene-ether (9 : 1) to give colorless crystals from the first fraction. Recrystallization from benzene gave 32 mg (16%) of I as colorless needles; mp 142.5—143 °C. IR(KBr): 3220 (OH), 822, 813 (2H), 760 cm^{-1} (3H). NMR($CDCl_3$): τ 0.49(OH), 2.0—2.56 (ϕ-H). UV: λ_{max}^{EtOH} 234 (ε 47500), 240 (ε 49300), 257 (ε 23900), 269 (ε

17500), 317 (ε 13400), 335 (ε 4300), 353 nm (ε 6100).

Found: C, 80.75; H, 3.96%. Calcd for $C_{14}H_8O_2$: C, 80.76; H, 3.87%.

The latter fraction was also collected to give a phenolic compound. Recrystallization from benzene gave 20 mg (10 %) of colorless needles, which may be 3,5-dihydroxyphenanthrene (XIV) judging from the following spectral properties. IR(KBr): 3240 (OH), 840, 814 (2H), 762 cm^{-1} (3H). NMR(CD_3COCD_3): τ 0.58, 0.78 (d, ϕ-H), 1.23 (OH), 2.24—2.96 (m, ϕ-7H). UV: λ_{max}^{EtOH} 235 (ε 38700), 252 (ε 61400), 285 (ε 9800), 310 (ε 10900), 328 (ε 2600), 345 (ε 6000), 365 nm (ε 8300).

The authors wish to thank Mr. Y. Takahashi for the elemental analyses, Mr. H. Saisu for the infrared analyses, and Mr. T. Ono for the nuclear magnetic resonance analyses.

Charge Transfer Complexes and Self-association of Flavin Adenine Dinucleotide

Fujio TAKAHASHI and Hirotoshi MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 20, 1973)

Synopsis. Spectrophotometric studies on the formation of FAD-L-tryptophane and FAD-D-tryptophane complexes, and the optical rotatory and polarographic studies of FAD have been carried out. The steric influence of ribosyl and ribityl groups on FAD for the complex formation is discussed. The dimerization of FAD in solution is suggested.

Many papers have appeared on the charge transfer complexes of flavins with tryptophane.[1] Flavin adenine dinucleotide (FAD) is known to form the charge transfer complex as an electron acceptor with caffeine,[2] while the intramolecular interaction between the flavin and adenine moieties in FAD has been established.[3] The ribosyl and ribityl groups in FAD are so bulky that they may sterically influence the complex formation with an electron donor. It was expected that FAD complex formation with L-tryptophane and D-tryptophane causes a difference in equilibrium constants and the thermodynamic parameters. If we suppose that ribosyl and ribityl groups interact with a side chain of indole, the molecular rotations of FAD-tryptophane complexes might differ from the sum of the individual molecular rotations of pure samples of FAD and tryptophanes. For optical rotatory dispersion studies, the molecular of FAD has been measured at very low concentration (10^{-4} mol/l) in the region of shorter wavelength than 450 nm.[4] In our studies, it was necessary to make the concentrations of FAD and tryptophanes higher (10^{-3}~10^{-2} mol/l) for the facilitation of complex formation. For comparison the molecular rotation of FAD was determined at the same concentration. It was found that the molecular rotation of FAD at 590 nm changes with concentration. This paper presents spectrophotometric studies on the formation of FAD-L-tryptophane and FAD-D-tryptophane complexes, and the optical rotatory and the polarographic studies of FAD.

TABLE 1. ANALYTICAL DATA OF FAD AND TRYPTOPHANES

b) *n*-BuOH : AcOH : H_2O = 4 : 1 : 1.

Experimental

The analytical data of FAD and tryptophane are given in Table 1. Requisite amounts of FAD and/or tryptophane were dissolved in 0.1 mol/l of phosphate buffer (pH 7.0) for the measurements. The adsorption spectra and the optical activities were determined with a Shimadzu spectrophotometer SV50AS and a JASCO automatic spectropolarimeter Model J-5, respectively. The polarograms were determined with a dropping mercury electrode.

Results and Discussion

From the differential absorption spectrum, the absorption maximum was found to appear at 505 nm and the absorbance of FAD-trypotphane systems was thus determined at 505 nm. The results are plotted according to Benesi-Hildebrand's equation[5] in Fig. 1. The equilibrium constant K for each temperature T was obtained from the values of slopes and intercepts. From the plots of log K vs. $1/T$, the enthalpy changes and entropy changes were calculated. The results are summarized in Table 2. It can be expected that FAD, in which flavin and adenine groups form an intramolecular complex, can form a complex weaker than flavin mononucleotide (FMN). Thus it is reasonable that the ΔH for FAD-tryptophane complexes is smaller than that for FMN-tryptophane complex (−7.4 kcal/mol).[1] The values of ΔH and ΔS for FAD-L-tryptophane and FAD-D-tryptophane systems,

System	K (l/mol) 25 °C	35 °C	45 °C	ΔH (kcal/mol)	ΔS (eu)
FAD-L-Tryptophane	$22._3$	$18._3$	$16._2$	−3.0	−3.9
FAD-D-Tryptophane	$20._5$	$17._6$	$15._2$	−2.8	−3.5

respectively, actually show no difference. It seems that ribosyl and ribityl groups can not sterically influence the complex formation. The side chain of indole might be located on the site opposite the ribosyl and ribityl groups in the FAD-tryptophane complex. Equimolar concentrations of FAD and tryptophane solutions were mixed for the determination of the molecular rotation of the complex. In the solution of 0.015 mol/l FAD and 0.015 mol/l L-tyrptophane or D-tryptophane, 20.3% or 19.2% FAD forms the complex at 28 °C as calculated from the values in Table 2. The molecular rotation of the mixture of FAD and tryptophane was compared with the sum of the individual molecular rotations of pure samples at 28 °C, and found to be almost the same. We see that the ribosyl and ribityl groups might not influence the molecular rotation for complex formation.

The plots of the molecular rotation *vs.* the concentration of FAD are given in Fig. 2. The molecular rotation of FAD was estimated to be $[M]^{28}_{590}$ -3.5×10^2 by the extrapolation to the zero concentration of FAD. In contrast to the extrapolation to higher concentration, the molecular rotation was found to be in the direction of positive value. Wave heights of polarograms are plotted against the concentration of FAD (Fig. 2). It seems that the reduction velocity of FAD decreases in higher concentration. The half-wave potential of FAD was found to be −0.55 V *vs.* SCE. The wave height is proportional to concentration in the region $10^{-3}\sim10^{-2}$ mol/l. Dimerization of FAD was suggested as a result of the nuclear magnetic resonance study.[6] The concentration dependence of the molecular rotation might confirm the dimerization of FAD. The dimer of FAD might hardly be reduced at the electrode, if the two flavin moieties associate with each other back to back and are enclosed by the two adenine moieties in FAD. If this is the case, the dimer can not form FAD-tryptophane complex. This can be justified because the plots in Fig. 1 fall on a line according to Benesi-Hildebrand's equation, which is derived by assuming the formation of 1 : 1 complex.

Dimerization constant K_2 could be calculated if we assume the observed molecular rotation R of FAD to be the weight average of monomer R_1 and dimer R_2:

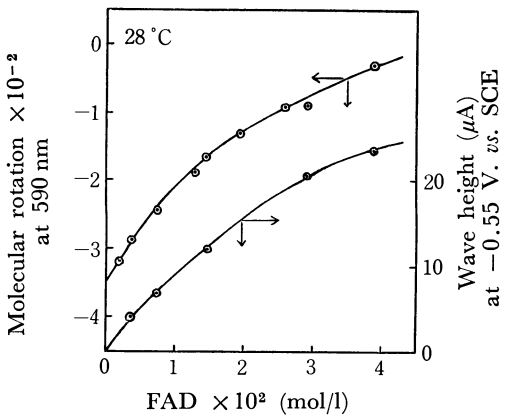

Fig. 2. The optical activities and the polarographic data of FAD 0.1 mol/l phosphate buffer (pH 7.0)

$$R = (M/C)R_1 + (2D/C)R_2, \quad C = M + 2D \tag{1}$$

where C, M, and D are FAD concentrations of total, monomer and dimer, respectively.

$$K_2 = D/M^2 \tag{2}$$

From Eqs. (1) and (2), we obtain,

$$R = -\left\{(R_2-R_1)2K_2\right\}^{1/2}\left\{(R-R_1)/C\right\}^{1/2} + R_2. \tag{3}$$

Plots of R *vs.* $\{(R-R_1)/C\}^{1/2}$ by means of this equation with data in Fig. 2 gives a straight line, from which the values of K_2 and R_2 are determined to be 22±5 l/mol and $+6.5\times10^2$ (28 °C), respectively. In the systems in Fig. 1, less than 3.3% FAD dimerizes and more than 17% FAD forms the charge transfer complex with tryptophane, which are calculated from the values of K_2 and the data in Table 2. The dimer concentration is not very high in the systems. The values of data in Table 2 might be reliable within 5% error.

The authors express their sincere thanks to Professor Shuichi Suzuki of Tokyo Institute of Technology for his encouragement.

Carbonylation of Phenylacetylene by Rhodium Carbonyl Chloride

Jitsuo KIJI, Susumu YOSHIKAWA, and Junji FURUKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

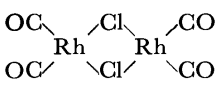
(Received July 16, 1973)

Synopsis. The reaction of phenylacetylene with carbon monoxide catalyzed by rhodium carbonyl chloride ($Rh_2(CO)_4Cl_2$) gives 3,6-diphenyl-1-oxa-[3,3,0]bicycloocta-3,6-diene-2,4-dione.

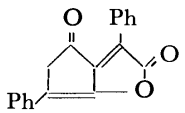
Although acetylenic compounds are known to react with carbon monoxide under the influence of transition-metal catalysts,[1] there have been few studies of the carbonylation of acetylene with rhodium carbonyl chloride ($Rh_2(CO)_4Cl_2$, I); the carbonylation of diphenylacetylene giving a cyclopentadienone and a quinone is catalyzed by I in benzene.[2] This paper will deal with a novel carbonylation of phenylacetylene with I.

Results and Discussion

The reaction was carried out in a benzene solution under the pressure of carbon monoxide. After the reaction, no phenylacetylene was recovered and deep-red needles were separated from the reaction mixture. The elemental analysis and the mass spectrum indicated that the product (II) is composed of two molecules of phenylacetylene and three molecules of carbon monoxide. The infrared spectrum taken with a KBr disk has three carbonyl bands, at 1788 (sh), 1753 and 1740 cm^{-1}, which can be assigned to an unsaturated γ-lactone and a five-membered cyclic ketone. The NMR spectrum in hexa-deuteriodimethyl sulfoxide at 90 °C shows a sharp singlet at 6.2 τ due to methylene protons and complicated peaks at 1.7—2.6 τ due to phenyl protons. The hydrogenation of II over platinum on carbon absorbed two moles of hydrogen to form a saturated compound, $C_{19}H_{16}O_3$ (by mass spectrometry). The reaction of II with 2,4-dinitrophenylhydrazine gave the corresponding hydrazone, in which the γ-lactone ring remained unchanged. From these observations, the product was proved to be 3,6-diphenyl-1-oxa-[3,3,0]bicycloocta-3,6-diene-2,4-dione (II).



I



II

This reaction is characteristic of terminal acetylenes. The formation of II can be explained by the following mechanism; phenylacetylene adds oxidatively to rhodium to form a rhodium hydride,[3] and this is followed by the insertion of phenylacetylene and carbon monoxide. These processes involve two internal cyclizations, which give five-membered cycles. Many examples of a similar internal cyclization to form a lactone have been reported by Chiusoli and Cassar.[4]

The products other than II were oily polymeric materials containing a γ-lactone moiety, but their structure could not be determined. The formation of this polymeric product can presumably be explained on the assumptions that the mode of the insertion of phenylacetylene was not uniform and that the resulting intermediates were not suitable for the cyclization giving II, but gave a linear structure containing the γ-lactone group.

Similarly, from the reaction of *t*-butylacetylene a colorless carbonylated product was obtained.[5] Methylacetylene gave a 1,4-quinone derivative. In this carbonylation of α-acetylene, the substituent on the acetylenic carbon has a great influence on the course of the reaction.

Experimental

Carbonylation. A benzene solution containing 400 mg of $Rh_2Cl_2(CO)_4$ and an excess of phenylacetylene (8 g) was allowed to react with carbon monoxide under a pressure of 50 kg/cm^2 at 120 °C. After 12 hr, II was separated from the reaction mixture, gathered, and washed with benzene to give deep-red needles (yield, 1.07 g); mp 234—235 °C. Found: C, 79.08; H, 4.46; O, 16.42%. Calcd for $C_{19}H_{12}O_3$: C, 79.01; H, 4.19; O, 16.63%.

Hydrogenation of II. Compound II (370 mg) was hydrogenated in ethyl acetate (150 ml) at room temperature under an atmospheric pressure, using Pt on carbon (5%, 500 mg) as the catalyst. Subsequent chromatography on silica gel with ethyl acetate gave 146 mg of colorless product (III); mp 140—141.5 °C. IR (KBr): 1770, 1750 cm^{-1} (ν_{CO}). Found: C, 78.16; H, 5.70; O, 16.27. Calcd for $C_{19}H_{16}O_3$: C, 78.10; H, 5.48; O, 16.42.

The Relation between the Electronic Spectra and the Oxidation and Reduction Potentials of Benzenoid Hydrocarbons

Tanekazu KUBOTA, Hiroshi MIYAZAKI, Kiyoshi EZUMI, and Masumi YAMAKAWA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received April 5, 1973)

Synopsis. It was shown that the ^1L_a band of benzenoid hydrocarbons is in a linear relation to $(E_{1/2}^{red}-E_{1/2}^{oxd})$ value led from the half-wave reduction and oxidation potentials. The theoretical background and the binding conditions of the application of this relation were clearly given.

In an earlier paper[1] we have theoretically shown the linear relation of the electronic spectra to the non-aqueous oxidation and reduction potentials of organic substances. That is, we wrote:[1]

$$E_{1/2}^{red} - E_{1/2}^{oxd} = k_1 \cdot {}^1E_{HO\to LV}^{UV} + k_2 \quad (1)$$

where $E_{1/2}^{red}$ and $E_{1/2}^{oxd}$ are the half-wave potentials (in volts) of the non-aqueous reduction and oxidation respectively. The ${}^1E_{HO\to LV}^{UV}$ is the singlet electronic transition energy, in which the contribution from the highest occupied molecular orbital (HOMO) to the lowest vacant MO (LVMO) is predominant. The absolute value of the k_1 constant equal 1 theoretically under suitable conditions[1] when an electron volt is taken as the energy unit for ${}^1E_{HO\to LV}^{UV}$. It should be noticed that Eq. (1) is an extension of Eq. (2) (given below), which also satisfies the experimental results quite well.[1] Here, ε_{LV} and ε_{HO} are the energy at the LVMO and the HOMO respectively:

$$E_{1/2}^{red} - E_{1/2}^{oxd} = k_1(\varepsilon_{LV}-\varepsilon_{HO}) + k_3 \quad (2)$$

In order to derive Eq. (1) from Eq. (2), however, there are necessary some binding conditions regarding the treatment of electronic transitions from the viewpoint of the electronic structures of molecules;[1] these conditions limit the applicability of Eq. (1) to the ${}^1E_{HO\to LV}^{UV}$ transition. Previously Pysh and Yang,[2] and Peover[3] reported the linear relation of the p-band of benzenoid alternant hydrocarbons (AH) to the value of $E_{1/2}^{red}-E_{1/2}^{oxd}$. However, there have been no detailed discussions of this physical meaning from the standpoint of electronic structures, *i.e.*, the nature of applied electronic transitions and the value of k_1 in Eq. (1) and (2). Note particularly that the k_2 value in Eq. (1) should depend not only on solvation energy of the cation or anion radical,[3] generated by electrolysis, but also on the electronic-state terms.[1]

Although Eqs. (1) and (2) can well explain the ^1L_a band of the electronic spectra of heterocyclic amine *N*-oxide,[1] it seems to be theoretically important to check whether or not these equations can be applied to other systems, especially to AH substances. This is because the AH's are the fundamental substances for testing theoretical treatments concerning molecular physics. The ^1L_a band (*p*-band)[4] reported in the literature is adopted as the value of ${}^1E_{HO\to LV}^{UV}$. Actually, the energies at the ^1L_a and ^1L_b (α-band) bands are cited from Clar's book,[5] in which the main vibrational peaks at the ^1L_a and ^1L_b bands are given. Either the vibrational peak appearing on the longest-wavelength side or that showing the strongest intensity was selected. However, the derived conclusion has the same, regardless of the choice. In addition, Peover *et al.*[6] reported the value of $E_{1/2}^{red}$ and $E_{1/2}^{oxd}$ of AH's measured in acetonitrile. As the molecular orbital energies we have used those calculated by Koutecký,[7] adopting the variable β method within the PPP π electron technique, since his purpose was to interpret the polarographic reduction and oxidation potentials. All the experimental and theoretical data mentioned above are collected in Table 1.

Figure 1 gives the linear relation of the $(E_{1/2}^{red}-E_{1/2}^{oxd})$ values against the ^1L_a band energies, the relation of Eq. (1) being well satisfied. The slope of $|k_1|=0.941$ is quite reasonable from the theoretical point of view.[1] Also, note that the good linear relation of Eq. (2), $(E_{1/2}^{red}-E_{1/2}^{oxd}=-0.815\ (\varepsilon_{LV}-\varepsilon_{HO})+1.701)$, also holds with the standard deviation of $\sigma=\pm0.071$ volt. We have also checked the constancy of the electron repulsion and CI terms,[1] given by $(J_{ho\cdot lv}-2K_{ho\cdot lv}-{}^1E_{CI})$, for the ^1L_a band of the compounds listed in Table 1. Our results[8] calculated using the PPP approximation with a constant β value (−2.37 eV) indicate that $(J_{ho\cdot lv}-2K_{ho\cdot lv})$ and $(J_{ho\cdot lv}-2K_{ho\cdot lv}-{}^1E_{CI})$ are within the maximum variations of 2.25±0.30 and 2.35±0.35 ev respectively in all the compounds except for benzene,[4] for which they are 2.92 and 3.33 eV respectively. It is possible to put these values as a constant, this condition being required for deriving Eq. (1).[1] In the case of ^1L_b band, however, each point is considerably scattered from the relation of Eq (1). Since the effect of the configuration interaction on the ^1L_b band seems to be much larger than that on the ^1L_a band,[9] the above result is reasonably expected. It is now clear, from the facts thus far presented, that Eqs. (1) and (2) can be safely applied also to the benzenoid AH's, and that, conversely speaking, the treatment of Eqs. (1) and (2) is reasonable.

Next, let us consider some other points. For the AH's this equation: I_p (ionization potential)$+E_A$ (electron affinity)=constant is well known.[4b] In other words, when Koopmans' theorem[4b,10] is applied, the ε_{HO} (or ε_{LV}) can be expressed in terms of the ε_{LV} (or ε_{HO}) on the basis of the above relation. Therefore, using Eq. (2), $(E_{1/2}^{red}-E_{1/2}^{oxd})$ can be linearly expressed by either the ε_{LV} or the ε_{HO}. Since $(E_{1/2}^{red}-E_{1/2}^{oxd})$ is proportional to ${}^1E_{HO\to LV}^{UV}$ (Eq. (1)),[1] we can conclude that the ε_{LV} or ε_{HO}, thus, $E_{1/2}^{red}$ or $E_{1/2}^{oxd}$, is also in a linear relation only to the ^1L_a band for the AH substances.[11] That is, this relation is easily given by this equation: $E_{1/2}^{red}$ (or $-E_{1/2}^{oxd}$)$=(k_1/2){}^1E_{ho\to lv}^{UV}+k_4$ (new constant). This kind of plot employing the data given in Table 1

Table 1. Various benzenoid hydrocarbons, with their half-wave oxidation and reduction potentials (V *vs.* SCE), SCF-MO energies at LVMO and HOMO, and observed positions (eV) at ^1L_a (p) and ^1L_b (α) bands

Compound	Oxidation and reduction potentials[a]		SCFMO energies[b]		Observed band positions[c]	
	$E_{1/2}^{oxd}$	$E_{1/2}^{red}$	ε_{HO}	ε_{LV}	^1L_a-band (p)	^1L_b-band (α)
Benzene	2.38[6)d)]	(−3.53)[e)]	−10.661	−1.339	6.205[f)]	4.761[f)]
Naphthalene	1.65	−2.63	−9.700	−2.300	4.350[f)]	4.174[f)]
Anthracene	1.19	−2.07	−9.086	−2.914	3.310[f)]	—

Perylene	1.04	−1.73	−8.808	−3.192	2.857[f)]	3.674[f)]

a) Taken from the Ref. 6 unless otherwise noted. These values were measured *vs.* SCE in CH_3CN containing 0.1 N. Et_4NClO_4. Generally speaking $E_{1/2}^{red}$ values correspond to those of a good reversible one-electron reduction wave at a dropping mercury electrode.[6)] The values of $E_{1/2}^{oxd}$ are also for the reversible one-electron oxidation at a rotating platinum electrode,[6)] except for anthracene, 1,2-benzanthracene, and 1,2-benzpyrene where the reversibility is not so good as an overall electrode reaction.[6)] In turn the reversibility on the $E_{1/2}^{oxd}$ values of benzene, naphthalene, and perylene is not clearly given in the cited literature.[6)] b) See Ref. 7. The relation of I_p+E_A = constant is well known for AH's[4b,c)] (see text). ε_{LV} was obtained from ε_{HO} by adopting the 12.0 eV for the constant.[7)] c) Taken from the Ref. 5 (see text). d) This is the value[6)] corrected *vs.* SCE on the data reported by H. Lund, *Acta Chem. Scand.*, **11**, 1323 (1957), where the potential was measured in CH_3CN *vs.* Ag electrode. e) This value was estimated from the extrapolation of the linear relation between $E_{1/2}^{red}$ and ε_{LV} in a series of benzenoid AH's.[6,7)] f) Obtained in CH_3OH-C_2H_5OH mixture. g) Obtained in benzene. For comparative purpose the 300 cm^{-1} was added to the value of the recorded ^1L_a band alone for correcting to that in ethanol. See E. Clar, *Spectrochim. Acta*, **4**, 116 (1950). h) Obtained in dioxane. i) Obtained in ethanol.

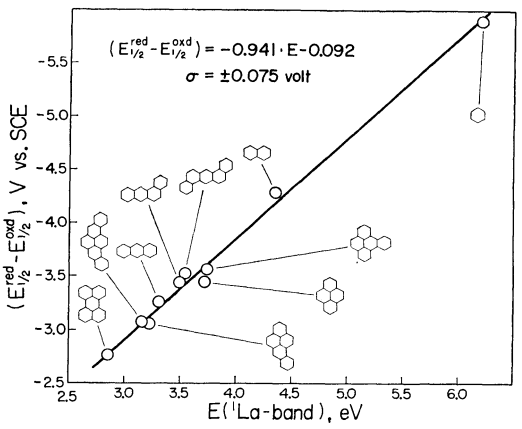

Fig. 1. The relationship between the observed values of ^1L_a band and $(E_{1/2}^{red}-E_{1/2}^{oxd})$ for benzenoid hydrocarbons.

also leads to a good linear relation with the slopes of −0.536 and −0.405 for the $E_{1/2}^{red}$ and $E_{1/2}^{oxd}$ plottings respectively. These absolute values of the slope are near the theoretical one, 0.5.

The Decomposition of Organic Substances by Laser Heating

Pil Hyon KIM,* Susumu NAMBA,* and Ko TAKI**

*The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

**Faculty of Industrial Hygiene, Kitasato University, Sagamihara-shi, Kanagawa 228

(Received July 26, 1973)

Synopsis. Gaseous organic substances were decomposed by the laser heating of various solid targets (boiling points are different) which were placed in them. This method gives the products which have never been obtained by means of the conventional heat decomposition.

The laser irradiation of a solid target causes the vaporization of the target material. Laser irradiations of graphite carbon and copper cyanide have been reported previously by the present authors.[1-3] In these cases, the vaporized or fragmented species produced by the laser irradiation (carbon atoms or CN radicals) have reacted with gaseous substances to give various products containing the target material.

In the reaction of carbon vapor with hydrocarbons, an isotopic experiment[4] using carbon-14 labeled ethane as the substrate or carbon-14 enriched graphite as the target showed that the carbon vapor not only reacts with the substrate, but also decomposes the substrate by means of the collision. This decomposition may be considered to be heat decomposition.

The pulse-laser irradiation of the target produces a vapor of the target material, the temperature of which is about the boiling point of the target. It is expected that the collision of this vapor with a gaseous substance or the heated target surface induces the heat decomposition of the substance. In this case, it is considered that the decomposition temperatures of the substances have distributed from the boiling point of the target material to the lower temperature.

In pulse-laser irradiation, the vapor is produced so quickly (less than 10^{-3} s), and the temperature of vapor or the heated target surface decreases so rapidly, that decomposition at the boiling point of the target is possible. In the conventional heating method, however, the heating rate is not so fast as the pulse-laser heating, so the heat decomposition at a temperature above the decomposition temperature of the organic compound is not exactly possible because the organic compound is decomposed during the heating process before reaching the desired temperature.

In laser heating, as, in view of the above considerations, the decomposition temperature of the substance may be decided by the boiling point of the target material, the gaseous substances can be decomposed at various temperatures by using various targets. For instance, in case of the nickel target the maximum decomposition temperature is about 2850 °C (the boiling point of nickel).

In this investigation, the decomposition of gaseous organic substances has been studied by means of the pulse-laser irradiation of various targets of nickel, zinc and red phosphorus.

TABLE 1. RELATIVE PRODUCT YIELD IN THE DECOMPOSITION OF METHANE, ETHANE, TOLUENE AND ETHANOL FOR 7 PULSE LASER IRRADIATIONS ON NICKEL, ZINC OR PHOSPHORUS TARGET

Substance	Product	Relative yield		
		Ni target	Zn target	P target
Methane	C_2H_6	0.26	1.3	($\sim10^{-7}$ mol)
	C_2H_4	0.03	0.12	
	C_2H_2	1.00 ($\sim10^{-6}$ mol)	1.00 ($\sim10^{-7}$ mol)	(0)
Ethane	CH_4	0.86	0.57	2.2
	C_2H_4	2.08	2.4	42.4
	C_2H_2	1.00	1.00	1.00
	C_4H_{10}	0.23	0.58	10.4
Toluene	CH_4	0.40	0.12	
	C_2H_6	0.13	0.16	
	C_2H_4	0.04	0.07	
	C_2H_2	1.00	1.00	
Ethanol	CH_4	4.13		
	C_2H_6	0.23		
	C_2H_4	4.7		
	C_2H_2	1.00		

Experimental

The decomposition techniques were almost the same as those reported previously.[1-4] Nickel (bp 2850 °C) and zinc (bp 908 °C) plates, and a red phosphorus (bp 280 °C) tablet were used as the targets. Each target, placed in a 7-cm^3 cell filled with the substance gas, was irradiated by means of a focused laser beam. The laser used was a normal ruby laser, the output energy and pulse duration of which were 3J and 0.5 ms respectively. The gas pressure of the gaseous substance was 600—700 Torr, while that of the liquid substance was the saturated vapor pressure at 60—70 °C.

The volatile products were collected and analyzed by gas chromatography using silica gel and squalane columns. The most reliable value of the detection was about 10^{-8} mol.

Results and Discussion

The relative product yields in the decomposition of methane, ethane, toluene, and ethanol are shown in Table 1.

In methane decomposition, the acetylene yield goes down with the decrease in the boiling point of the target material; finally, at the decomposition temperature under the phosphorus boiling point no acetylene is obtained at all but the ethane yield increases. It is roughly estimated that the high-temperature decomposition gives C, CH, and CH_2, mainly resulting in acetylene, while low-temperature decomposition gives

CH_3 mainly resulting in ethane. The main processes of the decomposition may be estimated to be as follows:

(1) $CH_4 \xrightarrow{\text{Ni target}}$ fragmented C, CH and CH_2 $\longrightarrow C_2H_2$

(2) $CH_4 \xrightarrow{\text{Zn target}}$ fragmented C, CH, CH_2 and CH_3 $\longrightarrow C_2H_2$ and C_2H_6

(3) $CH_4 \xrightarrow{\text{P target}}$ fragmented $CH_3 \longrightarrow C_2H_6$

The fact that the acetylene yield is decreased by lowering the decomposition temperature was also observed by the following experiment. When the power density of the irradiated laser beam was decreased to about 1/10 by the use of a filter, no vapor was produced from the nickel target and the substance was decomposed at the heated target surface whose temperature was below the boiling point of nickel. In this case, the acetylene yield decreased to 1/40, but the ethylene yield was not so affected.

The conventional heat decomposition[5] of methane at 800—1120 °C gives two elements (C and H). The main reaction process is the elimination of hydrogen from methane. On the other hand, the arc discharge gives traces of acetylene and ethane. The products are the same as those in the case of laser heating.

In ethane decomposition, acetylene was produced mainly at high temperatures and butane was produced mainly at low temperatures, as is shown in Table 1. The shock-wave heating of ethane[6] at 1250—1660 K gives methane, ethylene, and acetylene as in laser heating. The acetylene yield increases with the temperature, as in laser heating. However, no butane is detected. This is probably because the butane produced is broken down rapidly by staying at the high temperature. The proposed mechanism may be similar to that in laser heating, but the butane produced in laser heating may be not broken down by the rapid quenching.

In toluene decomposition, the gaseous hydrocarbons were obtained as is shown in Table 1; traces of bibenzyl and biphenyl were also detected. In this case, the substituted methyl group may be cleaved easily, and these fragments undergo further product formation. However, the decomposition at the phosphorus boiling point did not give acetylene or other gaseous hydrocarbons.

The decomposition of methanol gave hydrogen, carbon monoxide, and a small amount of hydrocarbon, but no acetylene was obtained at various temperatures. Methyl iodide and dimethylamine gave acetylene, but methylamine did not give acetylene. In the conventional decomposition of methanol[5] above 500 °C, the processes are considered to be the elimination of hydrogen, giving formaldehyde, and the subsequent decomposition to carbon monoxide and hydrogen. In methanol and methylamine, it may be difficult to form the carbon species which are the precursors of acetylene because carbon monoxide and the CN radical are easily produced; consequently, acetylene is not obtained.

In the decomposition of ethanol, methane, acetylene, and, ethylene were obtained as is shown in Table 1. In the conventional heating,[5] the main products are ethylene and methane, but acetylene is not obtained. In arc discharge,[5] however, the acetylene yield is comparable with that of ethylene.

It may be noted that the laser heating induces the decomposition of organic substances at high temperatures and gives products which are not obtained in the conventional heating, such as acetylene in methane decomposition and butane in ethane decomposition. These results may be caused by the rapid heating and rapid quenching which are the characteristics of the pulse-laser heating.

The Pyrolysis of Hexyl Phosphates and Their Salts

Yoshiki OKAMOTO, Norio KIMURA, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi Osaka 565

(Received September 5, 1973)

Synopsis. The isomer distribution of hexene from the tri-*n*-hexyl phosphate changes gradually as the decomposition proceeded. However the formation of the isomers other than 1-hexene was appreciably depressed by the addition of anhydrous disodium hydrogen phosphate.

There have been several reports on the thermal decomposition of alkyl phosphates,[1] alkyl phosphorochloridates,[2] and alkyl phosphites.[3] The olefins obtained by these procedures were mixtures of the isomers. The isomer distributions of the olefin and the mechanism of the formation of the isomer on the thermal decomposition of phosphate had not yet been studied.

In the present paper, the isomer distributions of the *n*-hexene obtained from the pyrolysis of *n*-hexyl phosphates under several different conditions were determined, and the pyrolysis method of obtaining 1-hexene as the sole product has been investigated.

Mono-(I), di-(II), and tri-*n*-hexyl phosphate (III) were prepared in the usual way.[4]

The sodium dihexyl phosphate and the disodium hexyl phosphate were prepared by the addition of an equivalent of alcoholic sodium hydroxide to II and to I respectively; after the solvent had then been distilled off, the residues were dried *in vacuo*. The lithium salts were prepared in the same manner. The magnesium or calcium hexyl phosphate was prepared by the double decomposition in the aqueous solution of sodium hexyl phosphate and the corresponding metal halide respectively. The precipitate was filtered and, after several washing with water, dried *in vacuo*.

In every run of pyrolysis, 0.1 mol of the phosphate was decomposed in a 10-ml distilling flask heated by means of a metal bath at reduced pressure (30 mmHg). The decomposition of phosphate began in the range from 280° to 310 °C, and was over in a few minutes. The pyrolysis products were trapped in a tube cooled with liquid nitrogen in 90—95% yields. They were analyzed with glc on two columns: a 3 m×3 mmϕ column (A), packed with PEG 1000 (10%) on Chromosorb W (60—80 mesh), at the column-temperature of 110 °C, and a 15 m×3 mmϕ column (B), packed with ODPN (40%) on C-22 fire brick (60—80 mesh), at the column-temperature of 25 °C, using nitrogen gas as the carrier. The glc peaks were identified by comparing their retention times with those of authentic samples. The A column was used for the determination of the yields of *n*-hexene and *n*-hexanol. The B column was used for the determination of the relative ratio of the *n*-hexene isomers.

The isomer distribution of hexene from the pyrolysis of III changed gradually as the decomposition proceeded. (Fig. 1) At the beginning of the decomposition, only 1-hexene was produced, but the ratio of 1-hexene to the other isomers gradually decreased with the progress of the decomposition; finally it approached the ratio which was attained by refluxing 1-hexene with phosphoric acid for 24 hr. When a small amount of

phosphoric acid was added to III, from the beginning of the decomposition the hexene isomers were produced.

The isomer distributions of the hexene obtained by the overall pyrolysis of III and the metal *n*-hexyl phosphates are shown in Table 1.

Although III gave a mixture of all the hexene isomers, disodium or dilithium hexyl phosphate gave 1-hexene and *n*-hexanol. The temperatures of the beginning of the decomposition of alkali metal hexyl phosphates were higher (300 °C) than that of III (280 °C), but that of calcium or magnesium hexyl phosphate was the same as that of III, according to the results of TGA analysis. Calcium or magnesium hexyl phosphate also gave a mixture of all the hexene isomers.

When a few tablets of sodium hydroxide were added to III, the formation of any isomer other than 1-hexene was inhibited, but a considerable amount of *n*-hexanol was produced (74%).

The formation of the isomers of hexene other than 1-hexene by means of the pyrolysis of III was appreciably depressed (at least the formation of *n*-hexanol was) by the addition of a large excess of anhydrous disodium phosphate or tetrasodium pyrophosphate. (Table 2)

The formation of the isomer of hexene by means of the pyrolysis of III may be autocatalyzed with the phosphoric acid resulting from its decomposition. The effect of the addition of sodium hydroxide or the salt may be explained on the basis of the neutralization of the acid. The differences in the behavior of the decompositions of sodium, lithium, calcium, and magnesium hexyl phosphates may be due to the differences in the valences and electronegativities of the metals.[5,6]

The hexanol may be produced by means of the hydrolysis of the hexyl phosphate by the alkali metal hydroxide resulting from the hydrolysis of the alkali metal hexyl phosphate.

The ESR Spectra of Bis(*t*-butyl and ethyl acetoacetato)copper(II) Complexes in Various Hydrocarbon Solvents

Hiroshi YOKOI

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received September 10, 1973)

Synopsis. The X-band ESR spectra of bis(*t*-butyl acetoacetato)copper(II) and bis(ethyl acetoacetato)copper-(II) in several non-coordinating solvents of hydrocarbon were measured at 77 K. Remarkable solvent effects on dimer formation were revealed for the complexes.

Recently, it has been revealed through ESR investigations that various copper(II) chelates of β-diketones, N-alkylsalicylaldimines, and related compounds are dimerized into triplet-state dimers to varying extents in toluene and chloroform.[1-5] However, there are many points to be clarified as to the factors on which the dimer formation depends. It is the purpose of this paper to investigate the solvent effects on such dimer formation using various hydrocarbon liquids as non-coordinating solvents.

Experimental

The copper(II) chelates employed here are bis(*t*-butyl acetoacetato)copper(II) and bis(ethyl acetoacetato)copper(II) (hereinafter abbreviated as Cu(*t*-Buoac)$_2$ and Cu(Etoac)$_2$ respectively). They were prepared and purified according to the usual method.[6] The chelate reagents were commercially available. The solvents used were ethylbenzene, toluene, methylcyclohexane, and 2-methylpentane, all of which were purchased as G. R. grade reagents. The first three solvents were further purified by succesive shaking with sulfuric acid and sodium hydroxide, followed by drying over sodium and, finally, fractional distillation. The methylcyclohexane was also passed through a column packed with silica gel. The ESR spectra were recorded at the temperature of liquid nitrogen over the field range of 0 to 6000 G by means of a Hitachi 771 X-band ESR spectrometer. All the sample solutions used for the ESR measurements were in the concentration of 1.0×10^{-2} M. The approximate solubilities of the Cu(*t*-Buoac)$_2$ in the solvents were determined at room temperature by the usual spectrophotometric method.

Results and Discussion

The ESR spectra of Cu(*t*-Buoac)$_2$ in the three solvents, toluene, methylcyclohexane, and 2-methylpentane, are shown in Fig. 1. The spectrum in ethylbenzene was analogous in line shape to that in toluene. The (A) spectrum in Fig. 1 is a typical one for mononuclear copper(II) complexes in a magnetically-diluted polycrystalline state.[7] On the other hand, it is clear that both the (B) and (C) spectra in the figure are made up of the superposition of a monomer spectrum quite similar to the (A) spectrum and a triplet-state spectrum resulting from dimers: this is quite analogous to the situation previously reported for Cu(Etoac)$_2$ in toluene.[1] Accordingly, it may be concluded that Cu(*t*-Buoac)$_2$ also is dissolved in methylcyclohexane and 2-methylpentane in the form of the monomeric and dimeric species which are at equilibrium ($2M \rightleftharpoons M_2$). Moreover, both of the triplet-state ESR spectra observed for Cu(*t*-Buoac)$_2$ in this work and for Cu(Etoac)$_2$ in toluene are quite similar in line shape.

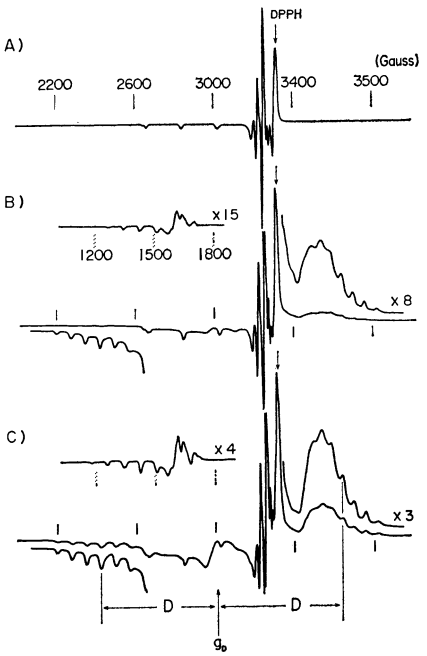

Fig. 1. The X-band ESR spectra of bis(*t*-butyl acetoacetato)copper(II) at 77 K in the following solvent at a concentration of 1.0×10^{-2} M.
(A): toluene, (B): methylcyclohexane, (C): 2-methylpentane.

The large absorption line observed at the highest field in Fig. 1 (A) is due to the extra-hyperfine structure of $M_I=3/2$.[8] As this figure shows, accordingly, this complex in toluene has nearly tetragonal g and A tensors. The magnetic parameters for the monomers of (A) in Fig. 1 were as follows; $g_{//}=2.270$, $g_{\perp}=2.052$, $|A_{//}|=192\times10^{-4}$ cm^{-1}, and $|A_{\perp}|=25\times10^{-4}$ cm^{-1}. On the other hand, the parameters for the triplet-state dimers of (B) and (C) in Fig. 1, g_D and D, which are defined in Fig. 1 (C), were as follows; $g_D=2.185$ and $D=623\times10^{-4}$ cm^{-1}. The copper-copper distance in the dimers, R, could then be estimated to be 3.65 Å from the equation of $R=(0.650\,g_D/D)^{1/3}$, using the above-determined g_D and D values.[1-3] These g_D, D, and R values are also close to those for the dimers of Cu(Etoac)$_2$ in toluene.[1] Therefore, the two dimeric structures seem to be almost the same; in these dimers, monomeric halves are situated with parallel planes, and the directly-coordinating oxygen atoms of adjacent molecules occupy the apical positions of the copper atom.[1]

Figure 1 indicates that there are remarkable solvent effects on the dimer formation for these kinds of copper(II) complexes; that is, the equilibrium constant, K, of $2M \rightleftharpoons M_2$ is largely dependent upon the property of the solvents. The K value for Cu(*t*-Buoac)$_2$ in toluene is close to zero, as has been described above. On the other hand, the K value for the complex in methylcyclohexane is quite small compared with that in 2-methylpentane, since it is clear that the ratio of the intensity of triplet-state ESR signals to that of doublet-state ones in (B) is smaller than that in (C).[1] Thus, the K values increase remarkably in this order: toluene<methylcyclohexane<2-methylpentane. On the other hand, the dielectric constants decrease in the same order: toluene(2.38)>methylcyclohexane(2.02)>2-methylpentane (1.88).[9] Moreover, it was found that the solubilities of the complex also decrease in the same order: toluene (1.30 M)>methylcyclohexane (0.37 M)>2-methylpentane (0.26 M), where the concentrations written in parentheses express the approximate concentrations of saturated solutions at room temperature. These facts suggest that the solubility of a complex in a solvent becomes smaller as the dielectric constant of the solvent decreases and, furthermore, that the complex tends to be dissolved in a solvent with a low dielectric constant in the form of dimers rather than in the form of monomers.

There seems to be no significant difference in property between toluene and ethylbenzene.[9] The ESR spectra of Cu(Etoac)$_2$ in both of the solvents are shown in Fig. 2. These two spectra are different in line shape, especially over the field range of 3100 to 3400 G. However, since their half-field ESR spectra for $\Delta M=2$ transitions are almost the same, there is no doubt that the same triplet-state dimers are formed in both solutions. Accordingly, it can be expected from the line shape of (B) that, in this solution, there exists another species, which may possibly be a polymer, besides the dimer and monomer species. In any event, it is obvious from Figs. 1 and 2 that the dimer formation for these kinds of copper(II) complexes is susceptible to a slight difference in the properties of the solvents.

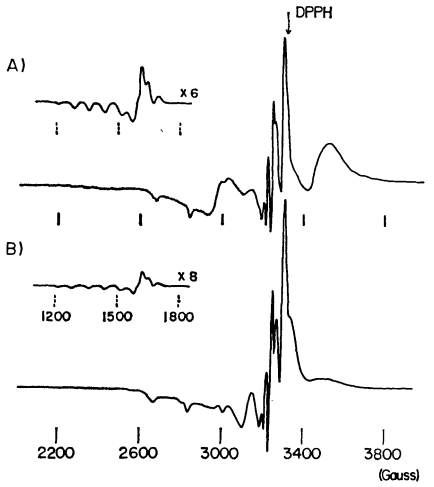

Fig. 2. The X-band ESR spectra of bis(ethyl acetoacetato)copper(II) at 77 K in the following solvents at a concentration of 1.0×10^{-2} M.
(A): toluene, (B): ethylbenzene.

Computer-assisted In-phase AC Polarography: Determination of Cadmium(II) Ions

Shizuo FUJIWARA, Michio HIROTA, Katsuhiko SAWATARI,
Hiroyuki KOJIMA, and Yoshio UMEZAWA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received August 17, 1973)

Synopsis. An on-line polarograph is used to detect the in-phase component of the ac response. The applied ac voltage and resulting current are sampled simultaneously and multiplied and then integrated. The detection limit of Cd(II)(0.1 M KCl) is 1.85×10^{-7} M by accumulation.

In ac polarography, two kinds of electrolytic currents flow at the mercury solution interface: one is the faradaic current which has in-phase and out-of phase components with applied alternating voltage, and the other is the charging current, which is an out-of-phase component. Both phase components provide meaningful information about the electrode kinetics. In quantitative analysis, the in-phase component of the ac electrolytic current must be selectively detected without the superposition of any out-of-phase charging current, because the elimination of the charging current plays the most decisive role in enhancing the signal-to-noise (S/N) ratio. In view of the above concideration, analog-type phase-sensitive ac polarography has successfully been used in trace analysis.[1-8]

In the present study, a computer-assisted on-line polarograph was used to perform phase-sensitive(in-phase) ac polarography. In recent years, many instruments have been interfaced for purposes of sampling, handling, and data collecting and processing. With the availability of such systems, the purchase of various pieces of hardware is sometimes no longer necessary; *i.e.*, a digital computer sometimes performs functions numerically similar to those of hardware.[9]

Method

Figure 1 shows the principle of the present method. By means of two channels of an analog to digital(A/D) converter, the polarographic current $I(t_i)$ and the applied alternating voltage $\Delta E(t_i)$ are sampled at the same time. The product of $I(t_i)$ and $\Delta E(t_i)$ is then integrated over the period of each cycle of the alternating voltage. The summed-up products give the in-phase (sine) component of the fundamental current.[1,3] It is a great convenience that the method does not require any troublesome adjustment of the timing circuit which triggers the start of sampling at the time when the applied alternating voltage is zero.[10] Furthermore, the limitation of the detection may be improved by the aid of the accumulation(ensemble average).

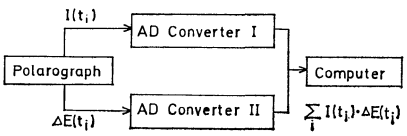

Fig. 1. The principle of the in-phase ac polarography.

Experimental

Apparatus. The block diagram of the present system is shown in Fig. 2. The polarograph used in the present work was built in our laboratory. The alternating voltage is applied by means of a Yokogawa Hewlett-Packard(YHP) function generator Model 3310B. Trigger pulses from a YHP frequency counter Model 5326B are fed into the computer to initiate the sampling.

Computer. Model JRA-5 of JEOLCO is used. The memory capacity of this computer is 4096 words, and the basic cycle time is 20 μs. The output voltage of the puncher-driving circuit is used to control the drop synchronizer. The waiting time before sampling can be set beforehand. The reference voltage signal and the current signal are input to a two-channel A/D converter, converted into 8-bit digital data, and stored in the memory. These two channels of the A/D converter are conveniently used in the present ex-

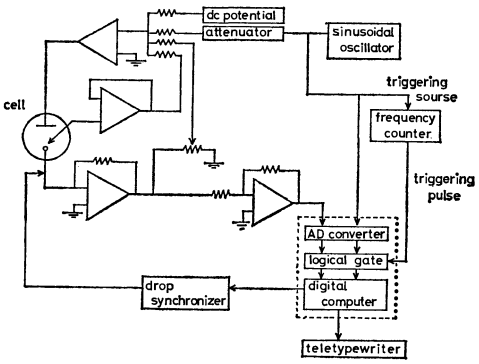

Fig. 2. The block diagram of the apparatus.

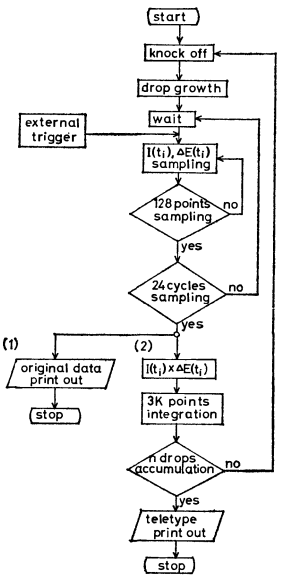

Fig. 3. The flow chart of the program.

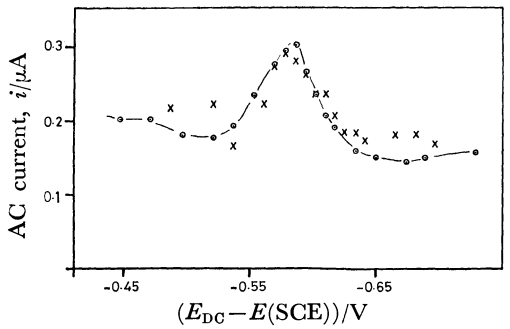

Fig. 4. In-phase ac polarogram of cadmium(II); the effect of accumulation.
$[Cd^{2+}]=7.5\times10^{-6}$ M, [KCl]=0.1 M,
frequency=27.9 Hz, peak-to-peak voltage=30 mV,
○: ensemble average for 4 drops.
×: 1 drop.

periment to perform a simultaneous sampling of both the polarographic current $I(t_i)$ and the applied alternating voltage $\Delta E(t_i)$. These two digitalized signals($I(t_i)$ and $\Delta E(t_i)$) are multiplied, and the product is integrated over n cycles, where $n=24$. The output of the computer is usually typed on a teletypewriter or is converted into analog voltages and written on the chart paper of a recorder. In addition, the experimental data can be perforated on paper tapes in the digital form of 6 holes if necessary.

Program. A machine language is used for programing in which the number of instructions are 17, including the orders for A/D and D/A conversions. The flow chart of the present experiment is shown in Fig. 3.

Conditions. An alternating voltage of 27.9 Hz and 30 mV (peak-to-peak) was superposed on the direct voltage. The mercury reservoir height was 35.0 cm. The measurements were done at (25.0±0.5)°C.

Procedure

(1) Fix the electrode potential at an appropriate value.
(2) Knock off a mercury drop with a pulse from the computer.
(3) Wait $200n$ μs and then begin to sample the analog data of both the polarographic current and applied voltage simultaneously every $(180+20m)$ μs, where $n=2^{14}$ and $m=5$. Thus, 3072 words of the data storage capacity of the computer are occupied.
(4) Calculate Eq. (1) by means of the computer:

$$X=\sum_i I(t_i)\cdot\Delta E(t_i) \qquad (1)$$

(5) In order to calculate the average of many drops, repeat the above procedures(2—4) and add the results.
(6) Write the results using a teletypewriter.

The above procedure is repeated above 20 times by changing the applied dc potential every 10 mV around the peak potential.

Results

The working curve of the present method was obtained by taking the Cd^{2+} ion in a 0.1 M KCl solution as an example. The peak current in this case is linearly proportional to the concentration of the Cd^{2+} ion in the range from 10^{-6} M to 5×10^{-4} M. As has been mentioned, in the present method, the calculation of the ensemble average of the output data for many drops easily be performed by means of the computer. A typical example showing the effect of ensemble average for 4 drops is demonstrated in Figure 4, where as appreciable enhancement of S/N ratio can be observed. The detection limit of this system was found to be 1.85×10^{-7} M for an accumulation of 8 drops, which is almost equivalent to that of conventional analog-type phase-sensitive ac polarography. For obtaining a larger S/N ratio, an accumulation of many more mercury drops would be necessary. Even with the advantages presented above, it should be mentioned that new developments which would avoid some time-consuming processes in the experiment are strongly desired: i) If much larger bit numbers of an A/D converter were available, the data for many mercury drops could be directly accumulated as they are, resulting in a decrease in the total experimental time. ii) A decrease in the cycle time of the computer would effectively reduce the time needed for the experiment.

Catalytic Activities of Salicylaldehyde Derivatives. IV. A Synthesis of 2-Formyl-3-hydroxyphenyltrimethylammonium Chloride

Makoto Ando and Sakae Emoto
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 2, 1973)

Synopsis. 4-Ethoxy-1,3-benzodioxan-5-yltrimethylammonium salt, prepared from 4-ethoxy-5-nitro-1,3-benzodioxane *via* 5-dimethylamino-4-ethoxy-1,3-benzodioxane, was hydrolyzed to obtain 2-formyl-3-hydroxyphenyltrimethylammonium chloride in a good yield.

In a previous paper,[1] among the salicylaldehyde derivatives tested 4-formyl-3-hydroxyphenyltrimethylammonium bromide was found to be the most powerful catalyst in the racemization of L-glutamic acid in the presence of cupric ions at pH 10 and at 80 °C. Yoshikawa *et al.*[2] pointed out that the catalytic effects of nitrosalicylaldehydes on the racemization under the conditions described above were decreased in the order of 4-, 6-, 5-, and 3-nitrosalicylaldehydes at an early stage of the reaction. Accordingly, it was expected that 2-formyl-3-hydroxyphenyltrimethylammonium chloride (**1**) might also be an effective catalyst in the racemization.

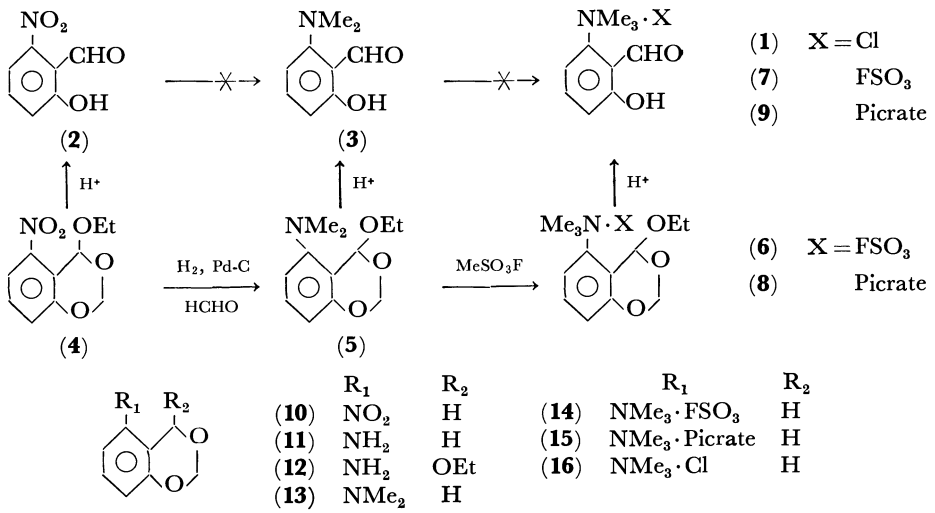
The reductive methylation of 6-nitrosalicylaldehyde (**2**)[3] over palladium on carbon (Pd-C) in the presence of formaldehyde did not give 6-dimethylaminosalicylaldehyde (**3**), although a similar treatment of *m*-nitrobenzaldehyde afforded *m*-dimethylaminobenzaldehyde.[4] On the other hand, 4-ethoxy-5-nitro-1,3-benzodioxane (**4**)[3] gave 5-dimethylamino-4-ethoxy-1,3-benzodioxane (**5**), which was then hydrolyzed to **3** with acid. With the usual methylating reagents, the *N*-methylation of **3** and **5** was unsuccessful. However, when methyl fluorosulfate (MFS)[5] was used, the *N*-methylation of **5** took place easily to give syrupy 4-ethoxy-1,3-benzodioxan-5-yltrimethylammonium fluorosulfate, (**6**), together with crystalline 2-formyl-3-hydroxyphenyltrimethylammonium fluorosulfate (**7**), a hydrolysis product of **6**. On the other hand, no separable product was obtained from **3**. Both fluorosulfates, **6** and **7**, were converted, separately or not separately, into **1** via the corresponding picrates, (**8**) and (**9**), the former being then easily hydrolyzed to **1**.

Some other methods of preparing **1** from 5-amino-1,3-benzodioxane derivatives were also attempted. The catalytic reduction of 5-nitro-1,3-benzodioxane (**10**)[3] and **4** over Pd-C gave the corresponding 5-amino derivatives, (**11**) and (**12**). 5-Dimethylamino-1,3-benzodioxane (**13**) was prepared from **10** by reductive methylation. The *N*-methylation of **13** with MFS gave 1,3-benzodioxan-5-yltrimethylammonium fluorosulfate (**14**) alone. The corresponding picrate (**15**) and then chloride (**16**) were obtained in the usual way. The attempted bromination of benzodioxane rings of **11**, **13**, and **16** to **1** proceeded with unsatisfactory results. The catalytic activity of **1** will be discussed together with that of other salicyalaldehydes in the near future.

Experimental

All the mps and bps are uncorrected. The hydrogenation was carried out at room temperature under atmospheric pressure with 10% Pd-C.

*5-Dimethylamino-4-ethoxy-1,3-benzodioxane (**5**).* A solution of 4-ethoxy-5-nitro-1,3-benzodioxane (**4**) (15 g) and aqueous 37% formaldehyde (40 ml) in ethanol (300 ml) was hydrogenated with Pd-C (6 g). After 5 mol of hydrogen had been absorbed, the filtrate from the catalyst was concentrated under reduced pressure to a syrup, which was then extracted with ether. The extracts, washed with a dil sodium hydroxide solution and then with water, were fractionally distilled in a vacuum to afford 12.3 g (83%) of **5**; bp 123—124 °C/4 mmHg.



Scheme.

Found: C, 64.66; H, 7.69; N, 6.15%. Calcd for $C_{12}H_{17}O_3N$: C, 64.55; H, 7.68; N, 6.27%.

*6-Dimethylaminosalicylaldehyde (**3**).* A mixture of **5** (13.6 g), sulfuric acid (55 ml), ethanol(150 ml), and water (150 ml) was refluxed for 1 hr while being stirred. To the cold mixture, 4 M sodium hydroxide aqueous solution (550 ml) was added, and it was all shaken with ether. The aqueous solution, treated with charcoal, was neutralized with dil hydrochloric acid. Benzene extracts of an oily product were concentrated under diminished pressure; the residue was passed through a silica gel column (250 g). At first **3** was eluted with benzene; fractional distillation then gave 4.8 g (48%) of **3**; bp 114—117 °C/2 mmHg.

Found: C, 65.35; H, 6.78; N, 8.28%. Calcd for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.48%.

Hydrochloride: Mp>280 °C.

Found: C, 53.61; H, 6.01; N, 7.02; Cl, 17.78%. Calcd for $C_9H_{12}O_2NCl$: C, 53.60; H, 6.00; N, 6.95; Cl, 17.58%.

*2-Formyl-3-hydroxyphenyltrimethylammonium Fluorosulfate (**7**) and 4-Ethoxy-1,3-benzodioxan-5-yltrimethylammonium Picrate (**8**).* Into ice-cooled MFS (5 g), ice-cooled **5** (10 g) was stirred all at once. Within 30 min it became viscous and difficult to stir. After 2 hrs' stirring, the reaction mixture was allowed to stand overnight at room temperature. The resultant glassy mixture was dissolved in a mixture of water and ethyl acetate. The aqueous layer, treated with charcoal, was concentrated under diminished pressure to a syrup, which was then treated with acetone to precipitate 2.2 g (17%) of **7**; mp 192—193 °C (decomp). The filtrate, concentrated to a syrup, was treated with picric acid (5 g) in methanol. Recrystallization from methanol gave 8.3 g (40%) of **8**; mp 163—164 °C. Although the total yield of **7** and **8** was nearly constant, each yield was considerably variable.

Compound **7**: Found: C, 42.90; H, 5.24; N, 4.90; S, 11.38%. Calcd for $C_{10}H_{14}O_5NFS$: C, 43.01; H, 5.05; N, 5.02; S, 11.48%.

Compound **8**: Found: C, 49.00; H, 4.73; N, 12.20%. Calcd for $C_{19}H_{22}O_{10}N$: C, 48.93; H, 4.75; N, 12.01%.

*2-Formyl-3-hydroxyphenyltrimethylammonium Picrate (**9**).* By the usual treatment, **7** was converted into **9**, which was then recrystallized from methanol; mp 209—210 °C; yield 94%.

Found: C, 46.94; H, 3.95; N, 13.83%. Calcd for $C_{16}H_{16}O_9N_4$: C, 47.06; H, 3.95; H, 13.72%.

*2-Formyl-3-hydroxyphenyltrimethylammonium Chloride (**1**).*

a) From 9: By the usual process, **1** was obtained; it was then recrystallized from methanol; mp 217 °C (decomp); yield 92%.

Found: C, 55.88; H, 6.51; N, 6.50; Cl, 16.41%. Calcd for $C_{10}H_{14}O_2NCl$: C, 55.69; H, 6.54; N, 6.49; Cl, 16.44%.

b) From 8: In the usual way, upon treatment with dil hydrochloric acid, hydrolysis occurred to give **1** in a 58% yield.

c) From 5: MFS (5 g) and **5** (10 g) were treated as has been described in the preparation of **7** and **8**. A resultant syrupy mixture of **6** and **7** was treated with picric acid (10 g) in methanol. Diluting the solution with water gave, upon the removal of a clear supernatant, a non-crystalline residue, which was then treated with nitrobenzene and dil hydrochloric acid. The aqueous layer, washed with ether, was concentrated to give **1**. Recrystallization from methanol afforded 4.2 g (43%) of **1**.

*5-Amino-1,3-benzodioxane (**11**).* A solution of 5-nitro-1,3-benzodioxane (**10**) (10 g) in ethanol (250 ml) was hydrogenated with Pd-C (2.5 g). After 3 mol of hydrogen had been absorbed, the treatment of the reaction mixture as has been described in the preparation of **5** gave 7.8 g (94%) of **11**; mp 71—72 °C.

Found: C, 63.41; H, 5.96; N, 9.21%. Calcd for $C_8H_9O_2N$: C, 63.56; H, 6.00; N, 9.27%.

Hydrochloride: Mp>280 °C.

Found: C, 51.35; H, 5.36; N, 7.42; Cl, 18.76%. Calcd for $C_8H_{10}O_2NCl$: C, 51.21; H, 5.37; N, 7.47; Cl, 18.90%.

N-*Acetyl Derivative*: Mp 154—155 °C.

Found: C, 62.28; H, 5.75; N, 7.15%. Calcd for $C_{10}H_{11}O_3N$: C, 62.16; H, 5.74; N, 7.25%.

*5-Amino-4-ethoxy-1,3-benzodioxane (**12**).* A solution of **4** (5 g) in ethanol (150 ml) was hydrogenated with Pd-C (1 g) to give 3.7 g (85%) of **12**; bp 120—123 °C/3 mmHg.

Found: C, 61.61; H, 6.50; N, 7.17%. Calcd for $C_{10}H_{13}O_3N$: C, 61.52; H, 6.71; N, 7.18%.

N-*Acetyl Derivative*: Mp 146 °C.

Found: C, 60.66; H, 6.37; N, 5.78%. Calcd for $D_{12}H_{15}O_4N$: C, 60.75; H, 6.37; N, 5.90%.

*5-Dimethylamino-1,3-benzodioxane (**13**).* In a way similar to that used in the synthesis of **5**, **13** was given from **10** in a 77% yield; bp 104—105 °C/4 mmHg.

Found: C, 67.12; H, 7.05; N, 7.86%. Calcd for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.82%.

Hydrochloride: Mp 182 °C (decomp).

Found: C, 55.88; H, 6.49; N, 6.51; Cl, 16.48%. Calcd for $C_{10}H_{14}O_2NCl$: C, 55.69; H, 6.54; N, 6.49; Cl, 16.44%.

*1,3-Benzodioxan-5-yltrimethylammonium Fluorosulfate (**14**).* MFS (3.3 g) and **13** (5 g) were treated as has been described for the *N*-methylation of **5**. The addition of ethyl acetate to the final residue precipitated 6.5 g (84%) of **14**; mp 142 °C. It was soluble in acetone.

Found: C, 45.12; H, 5.45; N, 4.84; S, 10.97%. Calcd for $C_{11}H_{16}O_5NFS$: C, 45.03; H, 5.50; N, 4.78; S, 10.93%.

*1,3-Benzodioxan-5-yltrimethylammonium Picrate (**15**).* In the usual way, **15** was obtained from **14** in a 98% yield; mp 162 °C.

Found: C, 48.32; H, 4.21; N, 13.27%. Calcd for $C_{17}H_{18}O_9N_4$: C, 48.34; H, 4.30; N, 13.27%.

*1,3-Benzodioxan-5-yltrimethylammonium Chloride (**16**).* In the usual way, **16** was obtained from **15** in a 73% yield; mp 202—203 °C (decomp).

Found: C, 57.48; H, 6.97; N, 6.29; Cl, 15.51%. Calcd for $C_{11}H_{16}O_2NCl$: C, 57.52; H, 7.02; N, 6.10; Cl, 15.43%.

The authors wish to thank Dr. Haruo Homma and his co-workers of this Institute for their elemental analyses. This work was partially supported by a Research Grant of Life Sciences given by this Institute.

The Reaction of Styryl Sulfoxides or Sulfones with Boranes[1)]

Norioki MIYAMOTO, Daisuke FUKUOKA, Kiitiro UTIMOTO, and Hitosi NOZAKI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

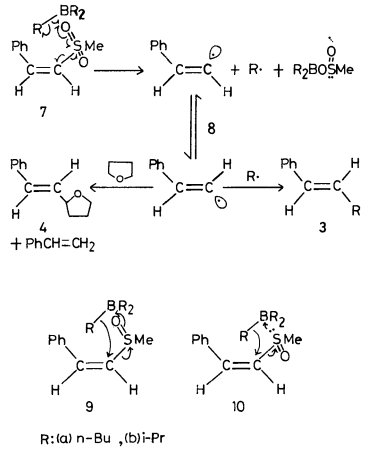
(Received July 24, 1973)

Synopsis. The title reaction produces β-alkylated styrene **3** in preparative yields. The formation of *trans* **3** from the *cis* sulfoxide **2** or the sulfone **7** is explained by considering the vinylic radical **8** as the intermediate.

Studies of the reaction of the trialkylboranes with the α,β-unsaturated carbonyl compounds[2)] have opened a valuable route to the β-alkylated ketones. We now wish to describe the reaction of the boranes with the styryl sulfoxides or sulfones,[3)] which are formally the S-analogs of the α,β-enones.

The reaction of methyl styryl sulfoxide (**2**) with a trialkylborane (**1**) in THF was performed under reflux in a nitrogen atmosphere; it gave mainly the β-alkylated styrene (**3**),[4)] along with *trans*-β-(2-tetrahydrofuryl)styrene (**4**), styrene itself, methyl styryl sulfide (**5**),[5-7)] and methyl 2-tetrahydrofuryl sulfide (**6**).[8)] Practically the same results were obtained in toluene, except for the formation of *trans*-1,3-diphenylpropene[9)] instead of **4**. Each product was characterized by glc analyses prior to the oxidative work-up of the reaction mixture to decompose the remaining **1**. The results are summarized in Table 1.

Whereas no trace of *cis* **3**[4)] was produced from the *trans* sulfoxide **2**,[5)] a similar reaction of the *cis* isomer of **2** with **1** gave rise to a mixture of *trans* and *cis* **3**.[4)] In sharp contrast to the vinylic sulfoxides, both of the corresponding *trans*[5)] and *cis*[6)] sulfones (**7**) afforded the *trans* **3** exclusively; the *cis* isomer of **3** was not observed in the reaction mixture.[11)] The vinylic sulfoxides and sulfones were found to be stable in the absence of **1**.[12)] Apparently, the formation of styrene and the solvent-incorporation product (**4** or *trans*-1,3-diphenylpropene) should be ascribed to the formation of the vinylic radical (**8**)[13)] resulting from the homolytic cleavage of the C–S bond induced by the attack of **1**. The exclusive formation[14)] of the *trans* isomers of **3** and **4** from the *cis* sulfones (**7**)[6)] may be ascribed to the rapid equilibration[13)] between the sterically-hindered *cis* form and the more reactive *trans* form of the vinylic radical (**8**). Similarly, the formation of the *trans* isomers of **3** and **4** from the *cis* sulfoxide (**2**) can be explained by assuming the vinylic radical (**8**)[13)] as the intermediate. Meanwhile, the preferential formation of the *cis* **3** from the *cis* sulfoxide (**2**) is presumably due to the ionic pathway (**9** or **10**), which is reminiscent of the S_N1 mechanism. Thus, the two competing routes would account for the formation of the mixture of *trans* and *cis* **3** from the *cis* sulfoxide (**2**) (Scheme 1).



Scheme 1

The substitution reaction has been successfully extended to the methyl phenethynyl sulfone.[15)] The products isolated were found to be the 1-phenylalkyne-1 (*a*,[16)] 70%; *b*,[17)] 73%),[10)] phenyl(2-tetrahydrofuryl)-acetylene (8.4% and 10% respectively),[10)] and phenylacetylene (6.3% and 3.2% respectively).[10)] The corresponding sulfoxides[15)] gave practically the same results, though the reaction proceeded rather sluggishly.

TABLE 1. REACTION OF STYRYL SULFOXIDES OR SULFONES WITH BORANES

Experimental

The IR spectra were obtained on a Shimadzu IR-27-G spectrometer in neat liquid films unless otherwise stated. The NMR spectra were obtained on a JEOL-60-H spectrometer in $CDCl_3$. The chemical shifts are given in ppm from the TMS internal standard; the abbreviations of s, d, t, q, and m are used with their common meanings.

Preparation of cis *Methyl Styryl Sulfoxide (2).* The oxidation was carried out according to the method of Russell and Ochrymowycz.[13] An aqueous solution (50 ml) of $NaIO_4$ (4.5 g, 21 mmol) was added to an acetonitrile (50 ml) solution containing *cis* methyl styryl sulfide[6] (**5**, 3.0 g, 20 mmol) at −10 °C. The mixture was stirred at room temperature for 12 hr, filtered to remove $NaIO_3$, and extracted with chloroform. The removal of the solvent *in vacuo* and subsequent column chromatography afforded the *cis* sulfoxide (**2**) (3.1 g, 93%[10]) as a viscous oil; bp 130—134 °C/0.3 mmHg IR 1030 cm^{-1}, NMR δ 2.56 (s, 3H, Me), 6.50 (d, 1H, vinylic), and 7.00 ppm (d, 1H, vinylic). Found: C, 65.1; H, 6.1%. Calcd for $C_9H_{10}OS$: C, 65.4; H, 6.2%.

Reaction of Methyl Styryl Sulfoxide (2), the Corresponding Sulfone (7), or Methyl Phenethynyl Sulfone with the Boranes (1). The borane (**1**, 3.1 mmol) was added to a THF (20 ml) solution of the sulfoxide or the sulfone (3.0 mmol) under nitrogen. The mixture was stirred under reflux. The progress of the reaction was followed by the tlc analyses of the aliquots. After 48 hr, the reaction mixture was oxidized with alkaline H_2O_2 and extracted twice with ether. The extracts were dried (Na_2SO_4), and concentrated *in vacuo*, and the residue was distilled (or alternatively chromatographed on silica gel). The products were purified by means of preparative glc (HVSG 20%, 2 m, 200°). *trans-β-*(2-Tetrahydrofuryl)styrene (**4**): bp 120—123 °C/4 mmHg, IR 1050 and 963 cm^{-1}; NMR δ 4.33 (m, 1H, methine) and 6.11—6.62 ppm (m, 2H, vinylic). Found: C, 83.1; H, 8.0%. Calcd for $C_{12}H_{14}O$: C, 82.7; H, 8.1%. Phenyl(2-tetrahydrofuryl)acetylene: bp 118—120 °C/5 mmHg. IR 1050 cm^{-1}, NMR δ 4.92 ppm (m, 1H, methine). Found: C, 83.4; H, 6.9%. Calcd for $C_{12}H_{12}O$: C, 83.7; H, 7.0%.

The Reactions of 2-Hydroxystilbenes with Lead Tetraacetate and Manganic Acetate

Keifumi NOGAMI and Kazu KUROSAWA

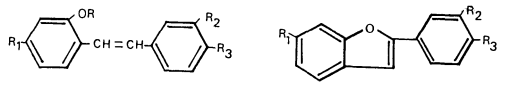
Department of Chemistry, Faculty of Sceince, Kumamoto University, Kurokami-2-39-1, Kumamoto 860

(Received August 23, 1973)

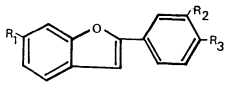
Synopsis. Four 2-hydroxystilbenes (Ia~Id) were oxidized with lead tetraacetate to give corresponding 3-arylbenzofurans (IIa~IId) in moderate yields. IId and IIe were also obtained by the reactions of Id and Ie respectively with manganic acetate in poor yields.

In the reactions of lead tetraacetate and manganic acetate with phenolic compounds, an oxidative cyclization has been observed when a compound possesses a hydroxy group and an aromatic or a vinylic hydrogen which are located in spatially suitable positions.[1-4] It is now demonstrated that 2-hydroxystilbenes gave 2-arylbenzofurans with lead tetraacetate in moderate yields.

When 4'-methoxy-2-hydroxystilbene(Ib), prepared from salicylaldehyde and 4-methoxybenzyl-triphenylphosphonium chloride by the Wittig reaction, was treated with lead tetraacetate, a compound (IIb) was isolated. This compound (IIb)(mp 146 °C), $C_{15}H_{12}O_2$, showed no absorption in the hydroxyl region (3500 cm^{-1}) in its IR spectrum. The NMR spectrum of this compound did indicate, however, the presence of a *p*-substituted phenyl group[δ 6.87 (d, 2H) and δ 7.73)(d, 2H)(AA'XX'-system)], a methoxy group [δ 3.80 (s, 3H)], four aromatic protons [δ 7.0—7.6 (m, 4H)], and a singlet [δ 6.80 (1H)]. These spectroscopic properties indicated that the structure of this compound is 2-(4'-methoxyphenyl)-benzofuran.



Ia–e (R=H)
IIIa–d (R=OAc)



IIa–e

a $R_1=R_2=R_3=H$
b $R_1=R_2=H$, $R_3=OCH_3$
c $R_1=OCH_3$, $R_2=R_3=H$
d $R_1=R_3=OCH_3$, $R_2=H$
e $R_1=H$, $R_2=R_3=OCH_3$

Three other 2-hydroxystilbenes (Ia, Ic and Id) were prepared, their reactions with lead tetraacetate gave 2-arylbenzofurans (IIa, IIc and IId). The results are shown in Table 1. It seems that the reaction of 2-hydroxystilbenes with lead tetraacetate can be used as a convenient one-step synthesis of 2-arylbenzofurans, although the yields are not very good and depend on the reaction temperature and solvent used.

The reaction of 2-hydroxystilbenes with manganic acetate also yielded 2-arylbenzofurans (IId and IIe) in poor yields.

Experimental

The NMR spectra were recorded in a deuteriochloroform solution by means of a Hitachi R-24 NMR spectrometer, with tetramethylsilane as the internal reference; The IR spectra were recorded in a chloroform solution by means of a JASCO IRA-1 grating spectrometer; The UV spectra were measured for a methanol solution by means of a Hitachi EPS-3T spectrophotometer. The melting points were determined by means of a Yanagimoto hot-stage apparatus and are uncorrected.

Preparation of 2-Hydroxystilbenes. The general procedure for the preparation of 2-hydroxystilbene was as follows. Benzyl-triphenylphosphonium chloride[5] (22 mmol) was treated with sodium ethoxide, prepared from metallic sodium (20 mmol) and ethanol (50 ml). To this solution we then added 2-hydroxybenzaldehyde (15 mmol), and the solution was heated at 90 °C with stirring until all the aldehyde had disappeared. After the removal of the ethanol *in vacuo*, the residue was triturated with water and extracted with benzene. The benzene layer was washed with aqueous sodium bisulfite, and the benzene was removed *in vacuo*. The product was then purified through a silica column [a mixture of Wakogel C 100 (180 g) and B 10 (20 g)], eluted with benzene, and recrystallized from benzene; it could thus be characterized as an acetate. Thus, 2-hydroxystilbene (Ia) (mp 137—138 °C(lit,[6] mp 147 °C)) was obtained in a in 66% yield. ν_{max}: 3580 and 3300 cm^{-1} (OH); $\lambda_{max}(\varepsilon)$: 304 (35000) and 316 nm (25300). 2-Acetoxystilbene (IIIa) (mp 54 °C(lit.[7] mp 54 °C)). ν_{max}: 1760 cm^{-1}. 2-Hydroxy-4'-methoxystilbene (Ib); mp 145—146 °C; 23% yield. ν_{max}: 3580 and 3300 cm^{-1} (OH); $\lambda_{max}(\varepsilon)$: 310 (36,100) and 324 nm(23,600). Found: C, 79.61; H, 6.41%. Calcd for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%. 2-Acetoxy-4'-methoxy-

Oxidation of 2-Hydroxystilbene with Lead Tetraacetate. The general procedure for the oxidation of 2-hydroxystilbenes was as follows. 2-Hydroxystilbene (4.4 mmol) was heated with lead tetraacetate (6.6 mmol) in a solvent (70 ml) with stirring for a period of time as is shown in the table. After the removal of the solvent *in vacuo*, the residue was triturated with water and extracted with chloroform. The crude products were purified either on silica plates or through a silica column, with chloroform as the eluting solvent, and then recrystallized from ethanol. Ia gave 2-phenylbenzofuran (IIa) (mp 118 °C(lit,[8] mp 120 °C)) in a 21% yield. ν_{max}: 1560, 920 and 880 cm^{-1}; $\lambda_{max}(\varepsilon)$: 290 (19,000), 300 (16,800) and 327 nm(18,800); δ: 6.92(s, -CH) and 7.0—8.0(m, 9H). Ib gave 2-(4′-methoxyphenyl)benzofuran (IIb) (mp 146 °C) in a 25% yield. ν_{max}: 1570, 920 and 880 cm^{-1}; $\lambda_{max}(\varepsilon)$: 294 (21,400), 303 (20,000) and 331 nm(24,400). Found: C, 80.19; H, 5.57%. Calcd for $C_{15}H_{12}O_2$: C, 80.33; H, 5.29%. Ic gave 6-methoxy-2-phenylbenzofuran (IIc) (mp 81 °C) in a 24% yield. ν_{max}: 1560, 960 and 920 cm^{-1}; $\lambda_{max}(\varepsilon)$: 293 (18,200), 300 (17,600) and 331 nm(23,100); δ: 3.79 (s, OCH_3), 6.85(s, -CH) and 6.8—7.8 (m, 8H, aromatic). Found: C, 80.04; H, 5.45%. Calcd for $C_{15}H_{12}O_2$: C, 80.33; H, 5.29%. Id gave 6-methoxy-2-(4′-methoxyphenyl)benzofuran (IId) (mp 159 °C (lit,[9] mp 159 °C)) in a 4% yield. ν_{max}: 1560, 960 and 920 cm^{-1}; $\lambda_{max}(\varepsilon)$: 295 (22,500) and 334 nm(26,000); δ: 6.89(d, 2H) and 7.67 (d, 2H)(*p*-substituted phenyl), 3.79(s, OCH_3), 3.80(s, OCH_3), 7.33(d, 1H) and 6.8—7.0 (m, 2H)(aromatic), and 6.73(s, 1H, vinylic).

The oxidation of 2-hydroxystilbenes with manganic acetate was also carried out in a similar manner. Id gave IId (3%) and IIId (13%). Ie yielded 2-(3′,4′-dimethoxyphenyl)-benzofuran (IIe) (5%); mp 112—114 °C. ν_{max}: 1570, 920 and 880 cm^{-1}; $\lambda_{max}(\varepsilon)$: 294 (14500) and 333 nm(20800); δ: 3.89(s, OCH_3), 3.94(s, OCH_3), 6.89(s, -CH) and 6.8—7.7 (m, 7H, aromatic). Found: C, 75.28; H, 5.35%. Calcd for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55%.

(Received August 27, 1973)

Synopsis. The rates of the reactions of various aromatic amines with diazotized sulfanilic acid have been studied. It was found that, among the *N,N*-disubstituted anilines, the activating effect of amino groups is roughly proportional to their pK_a values.

The kinetics of diazo-coupling reactions have been studied extensively in order to elucidate the reaction mechanism and the structural effects of the reactions on the reactivity.[1] As to the structural effect of the azo components on the reactivity, studies of phenols[2-4] and active methylene compounds[5] have been reported. However, much less work has been done on the reactions of aromatic amines; quantitative studies of the effects of amino groups in the electrophilic aromatic substitution have not been extensively undertaken, probably because of their basic properties and powerful substituent effects.[6]

This paper will report the quantitative results of the reactions of various aromatic amines with diazotized sulfanilic acid.

Experimental

Materials. *N,N*-Di-*iso*-propylaniline and *N*-ethyl-*N*-methylaniline were prepared by alkylating aniline and *N*-methylaniline with the corresponding alkyl iodides.[7] 9-Aminoanthracene was synthesized by the method of Kaufler.[8] The other aromatic amines were of commercal origin and were purified by distillation under reduced pressure. Their purities were confirmed by means of their physical constants and by vaporphase chromatography.

Kinetic Measurements. The diazo-coupling reaction of aromatic amines is known to be expressed by Eq. (1):[1]

$$\text{Rate} = k_2(\text{Ar-}\overset{+}{\text{N}}_2)(\text{Ar}'\text{-NH}_2) \quad (1)$$

In our experiment, the rate measurements were carried out spectrophotometrically in the presence of a large excess of amine in an aqueous buffer solution at a constant ionic strength of 0.04 at 20 °C. Then, the apparent rate constant (k') was calculated from Eq. (2):

$$k't = \ln\frac{E_\infty}{E_\infty - E_t} \quad (2)$$

where E_t and E_∞ represent the concentrations of the dyestuff formed at time t, and at an infinite time, respectively. The second-order rate constant (k_2) was obtained by dividing the k' value by the concentration of free amine, which can be calculated from the pK_a value, the concentration of amine, and the pH value of the medium. The buffering agents were of conventional CH_3COONa–CH_3COOH or CH_3COONa–HCl systems.

pK_a *Measurements.* The pK_a values of amines were determined spectrophotometrically under conditions identical with those of the kinetic experiments (20 °C, μ: 0.04, Table 1). As can be seen from Table 1, excepting the results for *N,N*-di-*n*-propylaniline, there is no serious disagreement between the present results and the published values; the slight disagreement may be ascribed to the differences in temperature and ionic strength.

Results and Discussion

The kinetic results are summarized in Table 1. As is shown in Table 1, the structural change of amine does not affect the reaction rate to any marked degree.

From the results (No. 1—3), it can be seen that the reactivity increases in the order of; primary<secondary <tertiary amine. This reactivity order is essentially the same as that obtained for alkylation;[9] it may be explained by an increased resonance donation of the lone pair of electrons of the amino nitrogen atom due to the alkyl group in the amino substituent.[6]

TABLE 1. RATE CONSTANTS OF THE REACTION OF DIAZOTIZED SULFANILIC ACID WITH AROMATIC AMINES AT 20 °C

No.	Amine	pK_a	k_2 (l/mol·min)

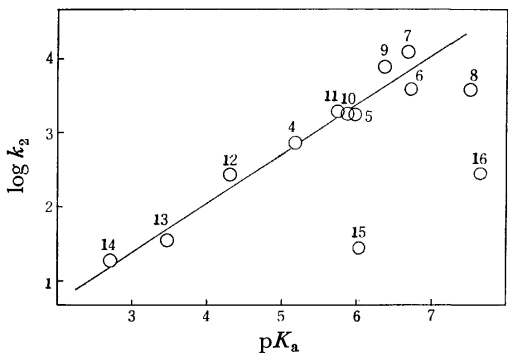

Fig. 1. Relationship between pK_a-value and rate constant. Figures refer to compounds in Table 1.

From the results of *N,N*-disubstitued anilines (No. 4—14), it was found that, among the di-*n*-alkyl-substituted amines (No. 4—7, 9), the activating effect of the amino group increases in the following order: NMe_2< $NMe(Et)\approx NEt_2$<N-*n*-$Pr_2\approx$N-*n*-Bu_2. This order is in accord with that of the inductive effect of the alkyl group, which may be explained on the basis of the effect of the alkyl group on the electron density at the amino nitrogen atom. On the other hand, the replacement of the hydrogen atom in the amino alkyl group by such an electron-attracting group as a hydroxy or cyano group (NO. 12—14) lowered the reactivity of dialkylaniline considerably.

Thus, it may be expected that a parallel correlation holds between the basicities of amines and the activating effects of their amino groups, since the electron-donating abilities of amino groups are considered generally proportional to their electron densities at the amino nitrogen atom. The relation between the basicity and the activating effect of a series of *N,N*-disubstituted anilines (No. 4—14) is shown in Fig. 1. From Fig. 1, it can be seen that a linear correlation holds between the basicities and the activating effects; an increase in the pK_a value by three units results in an increase in the reactivity by a factor of about 100.

The results (No. 15, 16) in Table 1 show that the introduction of methyl group into the ortho position leads to an increase in the basicity, but decreases the rate constant of *N,N*-dialkylaniline by a factor of about ten. The increase in the basicity may be ascribed mainly to the steric inhibition of the resonance; a departure from the coplanarity of the dialkylamino group with an aromatic ring as a result of the presence of an ortho methyl group should result a decrease in the electron donating ability of the amino group and is, therefore, base-strengthening. Consequently, although the methyl group s electrondonating, a methyl group in the ortho position of dialkylaniline lowers the reactivity of amine; thus, the plots of *o*-methyl-dialkylamines deviated markedly from the pK_a—log k line, as is shown in Fig. 1. In this sense, a linear relation between the basicities and the reactivities of the amines is considered to hold when the coplanarities of the amines are not hindered.

In the cases of 1-naphthylamine (No. 17) and 9-aminoanthracene (No. 20), the hydrogen atom at the peri position in the former, and the two hydrogen atoms the 1,8-positions in the latter, are considered to inhibit the interaction between the amino group and the aromatic ring to some extent. This inhibition is expected to become significant in the cases of secondary and tertiary amines. This estimation can easily be seen in the case of *N,N*-dimethyl-1-naphthylamine (No. 18), in which the reactivity is lower than that of 1-naphthylamine (No. 17), unlike the cases of the aniline series. Generally, it is well known that, in the electrophilic aromatic substitution, the reactivities of fused aromatic ring systems are much higher than those of monocyclic aromatic systems; there is a tendency for the reactivity to increase with an increase in the number of the condensed ring.[10] However, it can be seen from a comparison of the results of (No. 17′) and (No. 20) that the reactivities of 1-naphthylamine and 9-aminoanthracene are of the same order, suggesting that the steric inhibition by the hydrogen atom is larger in the latter than in the former.

(Received September 3, 1973)

Synopsis. Conformations of ten epimeric alcohols have been examined by the measurements of the OH stretching absorptions. The preference of the OH quasi-axial conformations was shown.

Iwamura and Hanaya[1] measured the O–H stretching absorption bands of epimeric 1-tetralols and 4-chromanols in carbon tetrachloride and pointed out that the epimer with the quasi-axial OH group shows a singlet absorption band and that with the quasi-equatorial OH group a doublet band. The doublet OH absorption of tetralol (**1**) was ascribed to the coexistence of the isomers with the quasi-axial and quasi-equational OH groups with the ratio 1 : 0.54.[2] The apparent conformational energy ($-\Delta G_{25°C}$) of the benzylic OH group was estimated to be 0.37 kcal/mol.

This paper reports on the measurements of the OH stretching absorptions and an estimation of the conformational energies for 4-chromanol (**2**), 4-thiochromanol (**3**), 4-thiochromanol 1,1-dioxide (**4**), and their derivatives which are considered to have a configuration similar to that of 1-tetralol. The OH absorption bands are analyzed in a similar way to that used for 1-tetralol.[1] The NMR spectra of these compounds were also examined to confirm the conformations.

Results and Discussion

The OH stretching absorption maxima of 4-chromanol (**2**), 4-thiochromanol (**3**), 4-thiochromanol 1,1-dioxide (**5**), and their derivatives (**5a**～**7b**) including 5,8-dimethyl-4-chromanol (**8**) are given in Table 1. The NMR measurements are summarized in Table 2 for the signals assigned to the protons at 4-positions of these compounds. Bolger and co-workers[3] have determined the conformations of **5a** and **5b** by NMR study. The NMR spectra of **6a**, **6b**, **7a**, and **7b** are interpreted in a similar manner to those of **5a** and **5b**. A double doublet signal due to the proton at 4-position of **6a** indicates that the hydroxyl group of this compound has quasi-equatorial conformation as regards the heterocyclic ring. The same situation is also suggested for the conformation of **7a**. The triplet signals observed for the protons at the 4-positions of **6a** and **7b** indicate quasi-axial conformations.

Epimers with a quasi-axial OH group each show a single absorption maximum, while those with the quasi-equatorial OH group have a doublet absorption band (Table 1). From the fact that the infrared spectra of these epimers are similar to those of 1-tetralols, it is assumed that these compounds have a similar conformation to that of 1-tetralol, in which the heterocyclic ring prefers a half-chair conformation.

The conformational free energies ($-\Delta G$) of the benzylic OH group for compounds **2**, **3**, and **4** were calculated by means of the graphical devision of the infrared OH absorptions in a similar manner to that for 1-tetralol[1] (Table 3). These values lead to the conclusion that the quasi-axial OH conformation is predominant in compounds **2**, **3**, and **4** and component of the epimer with this conformation increases in the order **1**<**4**≈**3**<**2**. This is consistent with the results by Katekar and Moritz,[4] who showed the preference of the quasi-axial OH conformation in **2** and **3** by examination of their infrared and NMR spectra.

From the half-chair conformations of the heterocyclic rings in **2**, **3**, and **4**, preference of the quasi-axial OH conformation should be attributed to the large steric repulsion between the equatorially oriented OH group and the aromatic hydrogen atom disposed parallel to the OH group, over the one 1,3-diaxial H···OH interaction in the heterocyclic ring.[5] The assumption is consistent with the result for 5,8-dimethyl-4-thiochro-

manol (**8**). The infrared spectrum of **8** shows a singlet OH absorption maximum at 3616 cm^{-1} which can be assigned to the quasi-axial OH group. In this case, the steric repulsion between the equatorially oriented OH group and the bulky methyl group at 8-position would be more serious than that between the OH group and the hydrogen atom at 8-position, leading to an overwhelming selection of the quasi-axial conformation in **8**.

Experimental

Materials. *cis*-(**5a**) and *trans*-4-Flavanol (**5b**),[6] 4-chromanol (**2**),[7] 4-thiochromanol (**3**),[8] and 4-thiochromanol 1,1-dioxide (**4**)[9] were prepared by standard procedures. *cis*-(**6a**) and *trans*-2-Methyl-4-thiochromanol (**6b**), *cis*-(**7a**) and *trans*-2-m thyl-4-thiochromanol 1,1-dioxide (**7b**) were prepared by the sodium borohydride reduction or the Merewein-Ponndorf reduction of 2-methyl-4-thiochromanone 1,1-dioxide, respectively. *cis*-2-Methyl-4-thiochromanol (**6a**): mp 74—75 °C (lit, 74—75.5 °C).[10] *trans*-2-Methyl-4-thiochromanol (**6b**): bp 116—118 °C/1 mmHg; the *p*-nitrobenzoate crystallized from ethyl acetate, mp 156—157 °C. Found: C, 61.75; H, 4.69; N, 4.25%. Calcd for $C_{17}H_{15}O_4NS$: C, 62.00; H, 4.25%. *cis*-2-Methyl-4-thiochromanol 1,1-dioxide (**7a**): mp 130—131.5 °C. Found: C, 56.70; H, 5.95%. Calcd for $C_{10}H_{12}O_3S$: C, 56.60; H, 5.70%. *trans*-2-Methyl-4-thiochromanol 1,1-dioxide (**7b**): mp 105—106 °C. Found: C, 56.82; H, 5.74%. Calcd for $C_{10}H_{12}O_3S$: C, 56.60; H, 5.70%. 5,8-Dimethyl-4-chromanol (**8**): Reduction of 5,8-Dimethyl-4-chromanone with sodium borohydride yielded 5,8-dimethyl-4-chromanol (**8**) as colorless needles from ligroin, mp 108—110 °C. Found: C, 73.75; H, 7.80 %. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

Measurements. The NMR spectra were measured in $CDCl_3$ using a Hitachi H-60 spectrometer with TMS as an internal standard. The infrared spectra were recorded with a Perkin-Elmer 125 or a JASCO DS-403G double beam grating spectrophotometer. A KCl cell of 30 mm in optical length was used. The concentration of the solution was *ca.* 0.005 mol/l in carbon tetrachloride purified by distillation over phosphorus pentoxide. The band due to intermolecular hydrogen bonding was not observed at this concentration.

The authors wish to express their gratitude to Associate Professor Hiizu Iwamura, the University of Tokyo, for his helpful discussions and suggestions during this work.

**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606*

(Recieved September 20, 1973)

Synopsis. By means of MO calculation, cobalt(III) and copper(II) were considered to decompose primary and secondary hydroperoxides through the oxidative fission of their O–H bond. However, in basic solvents such as pyridine, copper(II) was found to promote the fission of their C–H bond of the α-position by the complex formation with them.

By the use of the extended Hückel and the simple Hückel MO method, Yonezawa *et al.* discussed the catalytic decomposition of *t*-butyl hydroperoxide (*t*-butyl HPO) by transition metals.[1] The interaction of methyl HPO with lower-valent transition metals was also studied by MO calculation.[2] However, no calculation has been carried out for the Cu(II)-HPO system, in which Cu(II) shows interesting catalytic activities.[3]

Previously, we have ourselves studied the catalytic action of copper(II) chloride in the decomposition of primary and secondary HPOs (—1,2,3,4-tetrahydro-1-naphthyl, benzyl and cyclohexenyl HPOs—) in pyridine and suggested that the reaction proceeds through an ionic dehydration by the pyridine-Cu(II) system.[4] The carbon-hydrogen bond of the α-position is considered to be weakened by the coordination of the HPOs to Cu(II) through the O lone-pair electron.

The present study has been undertaken in an attempt to obtain support for the mechanism of the ionic dehydration and also to elucidate the catalytic action of Cu(II) in the radical decomposition of HPO by the comparison with that of Co(III).

Method of Calculation

The semi-empirical SCF-MO method with the CNDO-type approximation was used. The reasonance integral, H_{rs}, was calculated by means of Wolfsberg-Helmholz approximation:[6] $H_{rs}=-kS_{rs}(I_r+I_s)$ where k was taken as 0.5 for the atomic orbital (AO) pair including the d-orbital and as 0.4 for the AO pair including only s- and p-AOs. For an atom pair which do not form a bond, H_{rs} is taken as zero. Slater-type AOs were used for the s- and p-AOs, and the double-ζ type orbital was used for the d-orbital.[7] The two-atomic part of the total energy, E_{AB}, proposed by Pople *et al.*,[8] was used as a measure of the strength of the bond between A and B, atoms.[5] The MO calculations were carried out for a closed-shell system, followed by the correction for an unpaired electron, because Cu(II)-HPO systems have odd numbers of electrons.

As model compounds for primary and secondary HPOs, methyl HPO (MHPO) and 1-methylallyl HPO(MAHPO) were employed. Square planar Cu(II)$(NH_3)Cl_2$ was used as a model catalyst in pyridine, and Co(III)$(OH)_5$ was employed as a cobalt catalyst in the non-basic solvent. The bond lenghts and bond angles of these compounds were estimated from the values in the literature;[9] the distance between Cu(II) or Co(III) and the oxygen atom of HPO was taken as 1.95 or 2.22 Å respectively.

Results and Discussion

Cu(II) Catalyst. Cu(II) is considered to form a complex with HPOs, as is shown in Fig. 1. Calculations were carried out for both the O_1- and O_2-coordinations; the results are given in Tables 1 and 2.

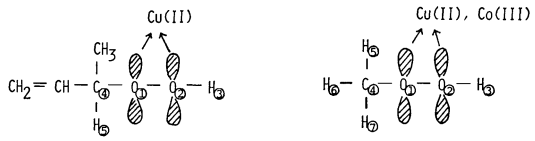

Fig. 1. Coordination position of MHPO and MAHPO.

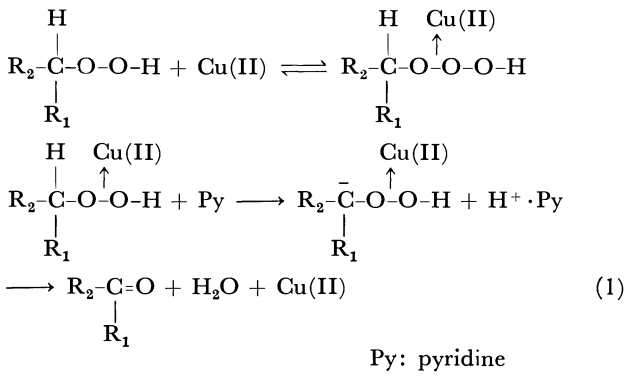
The values of E_{total} and E_{Cu-O} show that, in both MHPO and MAHPO complexes, O_1 coordination is preferable to O_2 one. These results disagree with those of the previous study[1] in which it was proposed, from the consideration of the orbital electron density of free HPO, that the metal ion forms a complex with HPO through the O_2 lone pair. However, it is more probable that the O_1 complex is a major species in the reaction, because the Cu(II)-HPO complex seems more suitable than free HPO for the discussion of the coordination position. As can be seen from the tables, the C–H bonds of the α-position are weakened by the coordination of the HPOs to Cu(II), since the absolute value of E_{C-H} is decreased by 0.09—0.16 eV. Therefore, these results support the reaction mechanism for the ionic dehydration of primary and secondary HPOs by the Cu(II)-pyridine system previously proposed:



Co(III) Catalyst. Higher-valent transition metals are known to decompose HPO by the one-electron oxidation of a peroxidic bond to produce the peroxy radical and proton:

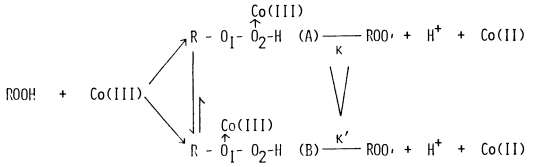
$$ROOH + M^{+(n+1)} \longrightarrow ROO\cdot + H^+ + M^{n+} \quad (2)$$

When MHPO coordinates to Co(III) through the O_1 or O_2 lone-pair, it may be seen from Table 3 that the absolute value of $E_{O_1-O_2}$ is increased, but that of $E_{O_2-H_3}$ is decreased: this is in good agreement with the experimental result (Eq. (2)). The decrease in the absolute value of $E_{O_2-H_3}$ is larger in the O_2 coordination (about 1.1 eV) than that in the O_1 coordination (about 0.16 eV), suggesting that Reaction (2) proceeds more easily from the O_2 coordination than from the O_1 coordination. On the other hand, the O_1 coordination seems more favorable than O_2 coordination from the consideration of E_{total} and E_{Co-O}. Therefore, it is plausible that Co(III) forms two complexes with HPO in equilibrium with one another (see A and B below) and that the B complex, in high concentration, cannot contribute to Reaction (2) so much as the A complex. That is, the rate of the decomposition of the B complex in a higher concentration is small compared with that of the A complex in a low concentration. In this way, the decomposition of HPO seems to be catalyzed by Co(III).



Cu(II), though effective in the decomposition of HPO, is considered not to promote the fission of the O_2–H_3 bond of HPO (Eq. (2)).[3] However, it can be seen from Tables 1 and 2 that the absolute value of $E_{O_2-H_3}$ is decreased by 0.7 eV (O_1 coordination)—1.1 eV (O_2 coordination), which suggests that Cu(II) can promote Reaction (2) as well as Co(III). Therefore, it can be expected that, in a non-basic solvent, Cu(II) promotes the direct decomposition of HPO (Eq. (2)) at the initial stage of the reaction (induction period), where the transformation of Cu(II) to Cu(I) occurs, and that, at the later stages of the reaction, the rapid oxidation of the alkyl radical by Cu(II) (Eq. 3) would predominate over Reaction (2):[3,10]

$$R\cdot + Cu(II) \longrightarrow R^+ + Cu(I) \quad (3)$$

The authors are very much indebeted to Professor Hiroshi Kato for his helpful advice and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(2), 513—514 (1974)

Preferential Precipitation of Δ-$[Co(en)_3]_2(d\text{-}C_4H_4O_6)_3$ by Alcohol Addition to the $[Co(en)_3]^{3+}$–$d\text{-}C_4H_4O_6^{2-}$ Aqueous Systems

Hayami YONEDA, Gen TAKEMOTO, and Ushio SAKAGUCHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-Sendamachi, Hiroshima 730

(Received December 18, 1973)

Synopsis. Alcohol addition to the aqueous $[Co(en)_3]^{3+}$—*d*-tart systems causes the preferential precipitation of Δ-$[Co(en)_3]_2(d\text{-tart})_3$. The yield lies in between 54—55% under experimental conditions employed.

Tris(ethylenediamine)cobalt(III) ($[Co(en)_3]^{3+}$) ion is the prototype of many tris-chelated cobalt complexes. The optical activity and the interaction with $d\text{-}C_4H_4O_6^{2-}$ (*d*-tart) ions of $[Co(en)_3]^{3+}$ have attracted much interest of many workers.[1-6] The fact that the Λ-form of $[Co(en)_3]^{3+}$ can easily be precipitated by *d*-tart ions while the Δ-form can not has long been used as the method of resolution[7] of $[Co(en)_3]^{3+}$ by way of Λ-$[Co(en)_3]X\cdot(d\text{-tart})$ (X=Cl$^-$, Br$^-$). Thus, the specific interaction, as found[8,9] for the system Λ-$[Co(en)_3]^{3+}$—PO_4^{3-}, between Λ-$[Co(en)_3]^{3+}$ and *d*-tart ions may be supposed operative in such resolution processes.

It is reported here that the alcohol addition to the aqueous $[Co(en)_3]^{3+}$—*d*-tart systems causes the precipitation of $[Co(en)_3]_2$ $(d\text{-tart})_3$ and that the dominant diastereoisomer is Δ-$[Co(en)_3]_2(d\text{-tart})_3$. This result is somewhat contrary to the expectation from the above-mentioned method of resolution.

Experimental

Complexes used in this work are prepared after the literature methods.[10,11] Sixty-eight grams of $[Co(en)_3]Cl_3.3H_2O$ and 172 g of $KNa(d\text{-}C_4H_4O_6)$ are dissolved in water to a volume of 1500 ml. To every 100 ml of the solution is added the varying amount of alcohol. The identity of the precipitated complex has been confirmed by chemical analysis. Found: C, 25.69; H, 6.91; N, 15.01%. Calcd for $[Co(C_2H_8N_2)_3]_2(d\text{-}C_4H_4O_6)_3\cdot 11(12)H_2O$: C, 25.72(25.31) H, 7.37(7.43); N, 15.00(14.76)%. The precipitate redissolved in water is passed through an anion exchanger (Dowex-1 X8) to convert the tartrate to the chloride. The optical rotation has been measured on a Yanaco OR-50D automatic digital polarimeter and the concentration of the complex is determined spectrophotometrically. The CD spectra are recorded on a JASCO Model ORD/UV-5 spectrometer with a CD attachment. Similar procedure has been applied to tris(ethylenediamine)cobalt(III) bromide and acetate.

Results

The results are summarized in Fig. 1, which shows the variation of the amount of Δ-$(-)_{589}$-$[Co(en)_3]_2$ $(d\text{-tart})_3$ precipitated against the volume of added alcohol. It is clear that more precipitation of Δ-diastereoisomer than the Λ-isomer is induced by the alcohol addition to the aqueous $[Co(en)_3]^{3+}$—*d*-tart systems(see, Fig. 2). Tris(ethylenediamine)cobalt(III) acetate behaves in a similar manner to the corresponding chloride and bromide and the result for the acetate has been deleted. The best attainable yield of the Δ-form is low and lies in between 54—55%. The above results contrast, in two points, well with the case of the usual method for resolution of $[Co(en)_3]^{3+}$;[7] first, $[Co(en)_3]_2(d\text{-tart})_3$ is precipitated while in the latter case $[Co(en)_3]X\cdot d\text{-tart}$ precipitates; second, Δ-$[Co(en)_3]_2(d\text{-tart})_3$ predominates, though slightly, while in the latter Λ-$[Co(en_3]X\cdot d\text{-tart}$ is dominant.

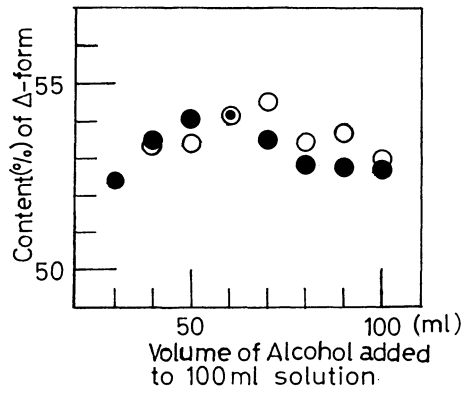

Fig. 1. The variation of the fraction of Δ-$(-)_{589}$-$[Co(en)_3]_2(d\text{-tart})_3$ precipitated against the volume of added alcohol. Open and closed circles refer to chloride and bromide starting materials, respectively.

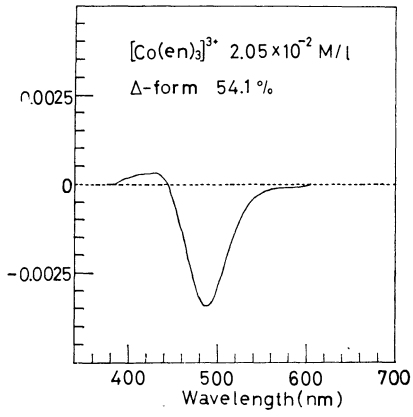

Fig. 2. The CD spectrum obtained when 60 ml alcohol is added to the 100 ml chloride solution.

Concentration by evaporation of the solution containing $[Co(en)_3]X_3$(X=Cl$^-$, Br$^-$) and *d*-tart ions yields Λ-$(+)_{589}$-$[Co(en)_3]X\cdot d\text{-tart}$, which is consistent with the conventional procedure for resolution. Of the two diastereoisomers Δ-$(-)_{589}$-$[Co(en)_3]_2(d\text{-tart})_3$ was observed to be the first to precipitate also in aqueous solution, because the reaction of $[Co(en)_3]X_3$(X=Cl$^-$, Br$^-$) with $Ag_2(d\text{-tart})$ precipitates first the Δ-diastereoisomer when evaporated. Alcohol is responsible, there-

fore, for the formation of $[Co(en)_3]_2(d\text{-tart})_3$ and the preferential precipitation of the Δ-diastereoisomer occurs both in pure and alcoholic water.

The problem remains to be settled why alcohol addition causes the precipitation of the form $[Co(en)_3]_2(d\text{-tart})_3$ rather than $[Co(en)_3]X\cdot d\text{-tart}$. More interesting is why *d*-tart ions prefer Δ-$[Co(en)_3]^{3+}$ in the case of $[Co(en)_3]_2(d\text{-tart})_3$ while Λ-$[Co(en)_3]^{3+}$ in $[Co(en)_3]X\cdot d\text{-tart}$. The association constant between Δ- and Λ-$[Co(en)_3]^{3+}$ and *d*-tart ions may shed some light on these problems. The work along this direction is in progress.

Magnetic Susceptibilities of Octacoordinated Uranium (IV) Complexes

Tetsuhiko YOSHIMURA,* Chie MIYAKE, and Shosuke IMOTO

Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 564

(Received March 6, 1973)

Magnetic susceptibility measurements were carried out on octacoordinated uranium(IV) complexes, such as tetrakis(acetylacetonato)uranium(IV), tetrakis(trifluoroacetylacetonato)uranium(IV), tetrakis(benzoylacetonato)-uranium(IV), tetrakis(dibenzoylmethanato)uranium(IV), tetrakis(thenoyltrifluoroacetonato)uranium(IV), tetrakis(cupferronato)uranium(IV), and uranium(IV)tetrachloride, in the temperature range from room temperature to the temperature of liquid nitrogen or liquid helium. The Curie-Weiss law holds above the temperature of liquid nitrogen, with a magnetic moment of 3.5—2.92 BM. For the latter two complexes, a temperature-independent paramagnetism was observed in the low temperature range; the other complexes also seemed to show the same trend. We tried to interpret the magnetic behavior on the basis of the crystal-field model of the square antiprism structure or the dodecahedron structure of the complexes.

The measurement of the magnetic behavior is one of the most useful and effective methods for the study of the electronic state of a complex. Particularly, the temperature-independent paramagnetism (TIP) at low temperatures often gives decisive information on the ground state of the central metal ion being studied. The configuration of the valence electrons of the uranium ion was early considered to be $(6d)^2$, because uranium dioxide magnetically diluted with thorium dioxide had a magnetic moment nearly equal to the spin-only value. Indeed, the quenching of the orbital angular momentum leading to the contribution only of the spin angular momentum to the observed magnetic momentum is, in many cases, characteristic of the d-electron, while in lanthanoid ions, which have unfilled 4f shell, the Russell-Saunders coupling has been found to be more feasible. Hutchison and Candela have, however, shown that the configuration $(5f)^2$ of the uranium ion (IV) with the $^3H_4$ term as the ground state is also capable of giving a magnetic moment near the spin-only value if the ion is influenced by the crystal field with cubic symmetry.[1] The TIP of the octahedral Cs_2UCl_6 at low temperatures could be reasonably explained by this scheme, taking into consideration the high-frequency interaction between the ground singlet state $^1\Gamma$ of the $^3H_4$ term and the lowest excited state (about 1 kcm^{-1} above the former). If the configuration be assumed to be $(6d)^2$, the ground state resulting from the splitting of $^3F_2$ in the octahedral crystal field would be the triplet $^3\Gamma_4$, which does not show the TIP at low temperatures. Recently, Mulak and Czopnik measured the magnetic susceptibility of $U(SO_4)_2 \cdot 4H_2O$ and $U(CH_3COCHCOCH_3)_4$ and explained the observed TIP on the basis of the splitting behavior of the $^3H_4$ term in a crystal field of a slightly distorted archimedian antiprism symmetry.[2] In the present study, the magnetic susceptibility of octacoordinated uranium (IV) complexes with the structure of dodecahedron as well as that of square antiprism is measured in the range from room temperature to the temperature of liquid nitrogen or liquid helium, and the results are interpreted on the basis of the crystal field theory.

* Present address: The Environmental Science Institute of Hyogo Prefecture, Hyogo-ku, Kobe.

Experimental

Magnetic susceptibility measurements in the range from room temperature to the temperature of liquid nitrogen were carried out with a torsion magnetometer of the Faraday type in the magnetic field of 5.0 kOe, and the measurements from the temperature of liquid nitrogen to that of liquid helium, with the Torsion Magnetic balance MB2 of the Shimadzu Seisakusho Ltd. in 10.66 and 8.685 kOe. The temperature was measured using an Au-Co/Cu thermocouple or a carbon-resistance thermometer. The value of the magnetic susceptibility was calibrated by using $NiCl_2$ powder as the standard. The measurements were made for seven complexes: tetrakis(acetylacetonato)uranium(IV) ($U(acac)_4$), tetrakis(trifluoroacetylacetonato)uranium(IV) ($U(tfac)_4$), tetrakis(benzoylacetonato)uranium(IV) ($U(bac)_4$), tetrakis-(dibenzoylmethanato)uranium(IV) ($U(dbm)_4$), tetrakis-(thenoyltrifluoroacetonato)uranium(IV) ($U(TTA)_4$), tetrakis (cupferronato) uranium(IV) ($U(cupf)_4$), and uranium(IV) tetrachloride (UCl_4); the methods of preparation have been described elsewhere.[3] UCl_4 is so deliquescent that it was sealed into a glass tube in a vacuum; the correction for the glass tube was made by measuring the magnetic susceptibility of the empty glass tube under the same conditions as were used for the specimen. Correction for diamagnetism was made for the U(IV) ion and the chloride ion by using the value reported by Dawson;[4] for H_2O and the acetylacetonato ion, by using the value reported by Earnshaw,[5] for benzoylacetone, by using the value reported by the Handbook,[6] and for all others, by using the value of Pascal's constant. The values of the diamagnetic increment used for the correction were as follows: $U(acac)_4$, -240; $U(tfac)_4$, -280; $U(bac)_4$, -404; $U(dbm)_4$, -592; $U(TTA)_4$, -368; $U(cupf)_4$, -315; UCl_4, -123 ($\times 10^{-6}$ cgs emu).

Results

Figure 1 shows the relationships between the reciprocal molar magnetic susceptibility and the temperature for $U(acac)_4$, $U(tfac)_4$, $U(bac)_4$, $U(dbm)_4$, $U(TTA)_4$, and $U(cupf)_4$. These complexes are found to follow the Curie-Weiss law over the temperature range measured except for the lowest part, where a slight positive deviation from the straight line is observed. The magnetic moment and the Weiss constant calculated from the straight line are shown in Table 1. Figure 2 represents the temperature dependence of the magnetic susceptibility for $U(cupf)_4$ and UCl_4 in the

temperature range from the temperature of liquid nitrogen to the temperature of liquid helium.[7] TIP is suggested for both complexes from the curved χ^{-1} *vs.* T relationships at low temperatures. The magnetic moment and the Weiss constant of $U(cupf)_4$ and UCl_4, as estimated from the linear part of the curve in the higher temperature range, are also given in Table 1.

Discussion

Among the octacoordinated uranium(IV) complexes studied in the present experiment, only $U(acac)_4$, $U(dbm)_4$, and UCl_4 have been elucidated as to the structure around the central uranium ion. In Table 1 we have summarized the structures and the magnetic moments of the octacoordinated uranium(IV) compounds already determined, together with those obtained in the present study. From the table, it seems that the complexes with the square antiprism structure show relatively lower magnetic moments than do those with dodecahedron structure.

Dodecahedron. In UCl_4 and $U(dbm)_4$ the nearest surrounding anions around the central U(IV) ion are known to form a dodecahedron and to produce a tetragonal crystal field with D_{2d} symmetry. The ground state of the uranium ion with the ground term of $^3H_4$ in the configuration $(5f)^2$ is then split into five singlets and two doublets under the influence of the electric field. From his study of the visible absorption spectra of UCl_4 at the temperature of liquid helium, McLaughlin inferred that the ground state is the singlet, $^1\Gamma_{t4}$, with the lowest excited state of $^1\Gamma_{t1}$, spaced 551 cm^{-1} above.[11] However, the TIP observed in the present experiment does not agree with this scheme, because such a large splitting as 551 cm^{-1} would give rise to TIP in the temperature range below about 500 K.

Another example of the analysis of the absorption spectra for the complex of dodecahedron coordination has been given in the case of $ZrSiO_4$ doped with the U(IV) ion, where the ground state was also assigned to be $^1\Gamma_{t4}$, but where the lowest excited state was estimated to be the doublet, $^2\Gamma_{t5}$ 155 cm^{-1}, above the singlet.[12] Recently Troc *et al.* carried out a detailed analysis of the magnetic susceptibility measured for uranium compounds with a Th_3P_4-type structure, in which each cation is surrounded by eight nearest anions, thus forming an octaverticon with the point symmetry D_{2d}.[13] According to these results, the ground

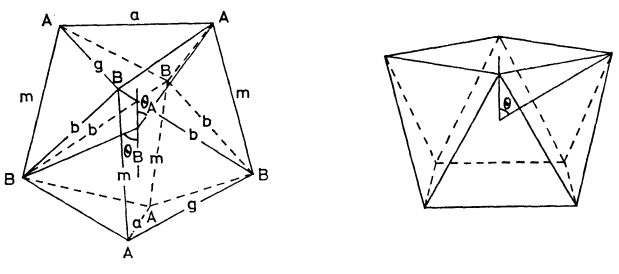

Fig. 3.

state for U_3P_4 was found to be composed of two close-spaced singlets, $^1\Gamma_{t3}$ and $^1\Gamma_{t2}$, with a separation of 8.9 cm^{-1}.

Here we shall apply the crystal field theory straightforwardly to the octacoordinated U(IV) complexes with a dodecahedron environment. The dodecahedron is characterized by two angles, θ_A and θ_B, as is shown in Fig. 3. As the values of θ_A and θ_B for several known complexes all fall into a relatively narrow range, that is, $\theta_A=34$—$37°$ and $\theta_B=72$—$74°$, it will be assumed in the following calculation that $\theta_A=35°$ and $\theta_B=73°$. The potential function of the crystal field is given by:

$$V = B_2^0O_2^0 + B_4^0O_4^0 + B_4^4O_4^4 + B_6^0O_6^0 + B_6^4O_6^4,$$

where O_2^0, O_4^0, O_4^4, O_6^0, and O_6^4 are equivalent operators, and where

$$B_2^0 = e^2Z(3\cos^2\theta_A+3\cos^2\theta_B-2)\alpha\langle r^2\rangle/a^3$$

$$B_4^0 = e^2Z(35\cos^4\theta_A+35\cos^4\theta_B-30\cos^2\theta_A - 30\cos^2\theta_B+6)\beta\langle r^4\rangle/16a^5$$

$$B_4^4 = -35e^2Z(\sin^4\theta_A+\sin^4\theta_B)\beta\langle r^4\rangle/16a^5$$

$$B_6^0 = e^2Z(231\cos^6\theta_A+231\cos^6\theta_B-315\cos^4\theta_A - 315\cos^4\theta_B+105\cos^2\theta_A+105\cos^2\theta_B-10)\cdot \gamma\langle r^6\rangle/64a^7$$

$$B_4^6 = -63e^2Z[(11\cos^2\theta_A-1)\sin^4\theta_A+(11\cos^2\theta_B-1)\cdot \sin^4\theta_B]\gamma\langle r^6\rangle/64a^7.$$

The α, β, and γ are the multiplying factors and are given for the $^3H_4$ term as $\alpha=-2.10\times10^{-2}$, $\beta=-7.346\times10^{-3}$, and $\gamma=6.099\times10^{-5}$. The U–O distance, a, was taken as 2.32 A, the value determined for tetrakis(acetylacetonato)uranium(IV), and the mean values of the n-th power of the radial distance of the 5f electron, $\langle r^2\rangle$, $\langle r^4\rangle$, and $\langle r^6\rangle$, were taken from the literature; $\langle r^2\rangle=1.68$, $\langle r^4\rangle=5.00$ and $\langle r^6\rangle=24.4$ a.u.[14] Z is the charge of the anion ligated to the central metal ion. The values of the coefficients, B_n^m, assuming that $Z=2$, are then given in cm^{-1} as follows: $B_6^0=-49.53$, $B_4^0=2.54$, $B_4^4=123.37$, $B_6^0=-1.97$, and $B_6^4=-16.67$. The splitting scheme of the $^3H_4$ term calculated on the basis of this potential function is shown in Fig. 4. This scheme shows that the ground state is the singlet, $^1\Gamma_{t3}$, with the lowest excited state, $^1\Gamma_{t2}$, located 23 cm^{-1} (33 K) above. A similar calculation showed the splitting to be 45 cm^{-1} if the two characteristic angles were taken to be $\theta_A=37°$ and $\theta_B=74°$.

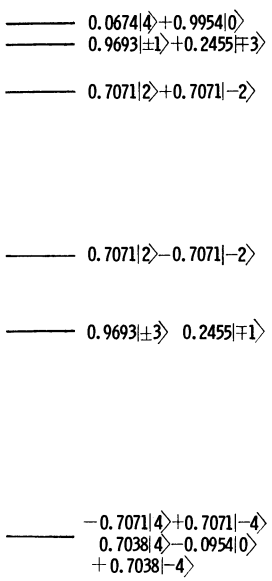

Fig. 4.

The magnetic susceptibility is written in the form:

$$\bar{\chi} = N\mu^2\mu_B^2/3kT(1-\exp(-\delta/kT))/(1+\exp(-\delta/kT))2kT/\delta \quad (1)$$

where δ is the splitting between $^1\Gamma_{t2}$ and $^1\Gamma_{t3}$ and where μ_B is the Bohr magneton. The magnetic moment is given by $\mu=\sqrt{32}\,pg$, where g is the spectroscopic splitting factor and where p is the coefficient of $|1\pm4\rangle$ in the eigenvector of the $^1\Gamma_{t3}$ state. The value of p is $1/\sqrt{2}$ for $\delta=0$; it is slightly decreased with an increase in δ, but it hardly reaches 0.69 in the present model. The spectroscopic splitting factor is 0.8 for the pure $^3H_4$ term, but is calculated to be 0.83 in the intermediate coupling scheme; this gives $\mu=3.27$—3.32 within the range of $p=0.696$—0.707. The temperature dependence of Eq. (1) with $\mu=3.30$ is presented in

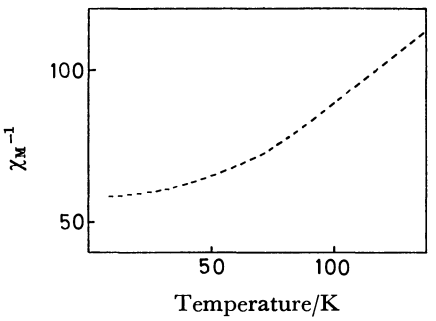

Fig. 5. Reciprocal susceptibility theoretically obtained as a function of temperature.
μ: 3.3, δ: 108 cm^{-1}, δ/k: 160

Fig. 5, where it may be seen that the reciprocal susceptibility shows a marked deviation from the straight line below about $T=\delta/2k$, suggesting the TIP at lower temperatures. The apparent magnetic moment gained from this figure is $\mu=3.43$, which is about 5% larger than that obtained in the higher temperature range, $\delta \ll kT$. Thus, the magnetic behavior of octacoordinated U(IV) complexes which would show TIP at low temperatures (below about 100 K (70 cm^{-1})) and which have the apparent magnetic moment of $\mu=3.4$—3.5 seems likely to be explained by the present scheme. From the values in Table 1, $U(cupf)_4$ is also considered to belong to this group along with $U(dbm)_4$ and UCl_4; it seems very possible that dodecahedron is the coordination polyhedron of $U(cupf)_4$.

Square Antiprism. For the complexes having the coordination polyhedron of archimedian antiprism with the octahedral symmetry of D_{4d}, the energy level scheme was calculated by Mulak and Czopnik using the c/a ratio as a parameter, and it was shown that either the singlet state, $|0\rangle$, or the doublet states, $|\pm4\rangle$ and $|\pm3\rangle$, can be the ground state, according to the value of c/a.[2] They assumed that the ground

state was $|\pm 3>$, which would be split into two closely-spaced singlets under the distortion of the rhombic or lower symmetry. However, the value of c/a determined by X-ray analysis for $Zr(acac)_4$, which is isomorphous with $U(acac)_4$, is 0.908; this value leads to the ground state being $|0>$, with the lowest excited level being $|\pm 1>$. According to Lippard and Russ, the polyhedron of $Zr(acac)_4$ is a distorted square antiprism; it is approximately formed by twisting the perfect square antiprism around the 8 axis by 10—20 degrees.[15] This twisting gives rise to the splitting of the $|\pm 2>$ state and markedly lowers the $1/\sqrt{2}$ $(|2>-|-2>)$ state. The calculation carried out along the lines of the analysis by Mulak and Czopnik, with the value of $c/a=0.908$, showed that the splitting between $|0>$ and $|\pm 1>$ is about 30 cm^{-1} and that the $1/\sqrt{2}$ $(|2>-|-2>)$ state is located near the $|\pm 1>$ doublet if the twisting angle is 10—15 degrees, as is shown in Fig. 3. We shall show that this energy level scheme can also be used in explaining the magnetic behavior of octacoordinated U(IV) complexes with a distorted square antiprism structure.

As the magnetic susceptibility is anisotropic in the tetragonal crystal field, components both parallel to and perpendicular to the symmetry axis should be considered. The parallel component of the magnetic susceptibility is given as follows;

$$\chi_{//} = Ng^2\mu_B^2/kT \cdot 2\exp(-\delta/kT)/(1+2\exp(-\delta/kT)) \quad (2)$$

where δ is the splitting between $|0>$ and $|\pm 1>$. The $\chi_\perp$ component is given by;

$$\chi_\perp = 2Ng^2\mu_B^2[10(1-\exp(-\delta/kT))/\delta + 4.5(1-\exp(-\delta/kT))\exp(-\Delta/kT)/\Delta]/ (1+2\exp(-\delta/kT)+\exp(-(\delta+\Delta)/kT)) \quad (3)$$

taking into account the high-frequency interaction between $|0>$ and $|\pm 1>$ and that between $|\pm 1>$ and $1/\sqrt{2}(|2>-|-2>)$, where Δ is the splitting between $|\pm 1>$ and $1/>\sqrt{2}(|2>-|-2>)$. When $\Delta \ll kT$,

$$\chi_\perp = 2Ng^2\mu_B^2[10(1-\exp(-\delta/kT))/\delta + 4.5\exp(-\delta/kT)/kT]/(1+3\exp(-\delta/kT)) \quad (4)$$

The average magnetic susceptibility, χ, is represented by Eq. (5); at lower temperatures ($Tk \ll \delta$) it becomes $40Ng^2\mu_B^2/3\delta$.

$$\bar{\chi} = 1/3\chi_{//} + 2/3\chi_\perp \quad (5)$$

Under these conditions, the only contribution to the paramagnetic susceptibility is the temperature-independent paramagnetism due to the high-frequency interaction between the excited levels, $|\pm 1>$, and the ground state of $|0>$. In Fig. 6 are plotted the average magnetic susceptibilities of Eq. (5), with the values of g and Δ/δ being assumed to be 0.827 and 0.1 respectively. TIP is seen at the lower temperatures, and the apparent magnetic moment of 3.24 is obtained from the straight part of the curve. This value is somewhat larger than the values experimentally obtained for $U(acac)_4$, $U(bac)_4$, $U(tfac)_4$, and $U(TTA)_4$, as in the case of the complexes with a dodecahedron structure. Thus, the behavior of magnetic susceptibility observed seems likely to be explained by the crystal field model with D_{2d} or D_{4d} symmetry, corresponding to dodecahedron or square antiprism respectively.

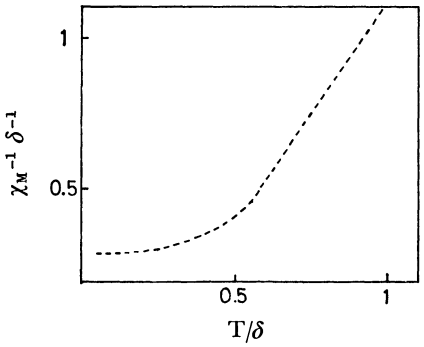

Fig. 6. Reciprocal susceptibility theoretically obtained as a function of temperature measured by energy difference between ground state and first excited state. $g=0.827$, Δ/δ: 0.1.

Theory of Ion Cyclotron Resonance Power Absorption for Nonreactive and Reactive Ions

Katsuyuki AOYAGI[1)]

Faculty of Engineering, Hokkaido University, Sapporo 060

(Received March 22, 1973)

An exact solution of the equation of motion and exact expressions of the ion current in ion cyclotron resonance power absorption were obtained. Instantaneous and total power absorptions together with power absorption line shapes were derived. Ion current expressions were also derived for both nonreactive and reactive ions over the whole range of pressure. The results agreed with those obtained previously for high and low pressures with appropriate approximation. The rate constants for the disappearance of primary ions and for the formation of nonreactive secondary ions were obtained from the ion cyclotron resonance experiments. The results showed good agreement with those obtained by other methods.

A charged particle moving in a strong uniform magnetic field describes a helical orbit which is a combination of a translation along a field line and a circular motion in a plane perpendicular to the direction of the magnetic field. The motion along the magnetic field is independent of the strength of the magnetic field. The circular motion in the plane is independent of the translational motion along the field lines. The angular frequency or cyclotron frequency ω of the circular motion is independent of the velocity of the ion and is given by

$$\omega = \frac{e\mathbf{H}}{mc}, \tag{1}$$

where e is the charge of the particle, $\mathbf{H}$ the magnetic field strength, m the particle mass, and c the velocity of light.[2)]

If a sinusoidal time-varying electric field $\mathbf{E}(t)$ with the frequency ω_1 is applied perpendicular to a static magnetic field $\mathbf{H}$, and the magnetic field is swept, the ion resonates at $\omega=\omega_1$ and absorbs energy from the sinusoidal time-varying electric field. The ion is accelerated and the radius of its orbit increases with time. An absorption of energy by the ions can be readily observed by a marginal oscillator detector[3,4)] or a bridge detector.[5,6)] With a fixed observing frequency, a spectrum obtained by sweeping the magnetic field is linear in the mass.

In the average chemically nonreactive ion undergoing ion cyclotron resonance, the phenomenological equation of motion for an ion is given by[5,9)]

$$\frac{d\mathbf{v}}{dt} = \frac{e}{m}\mathbf{E}(t) + \frac{e}{mc}\mathbf{v}\times\mathbf{H} - \xi\mathbf{v}, \tag{2}$$

where $\mathbf{v}$ is the nonrandom part of the average ion velocity, and ξ the reduced collision frequency that specifies the rate of momentum relaxation of the ion. If the ion undergoes only elastic collisions with the neutral species, the reduced collision frequency is given by[10)]

$$\xi = \frac{nm}{m+M}\langle v\sigma_d(v)\rangle, \tag{3}$$

where n and M are the number density and mass of the neutral species, respectively, and $\sigma_d(v)$ and v are the diffusion cross section and relative velocity of the ion to the neutral pair, respectively. The angle bracket indicates an average over the distribution of relative velocities.

Wobschall *et al.*[5)] and Beauchamp[9)] obtained a steady-state solution of Eq. (2) which leads to the Lorentzian line-shape expression for power absorption. The steady-state power absorption of an ion results in the broadening of ion cyclotron resonance (ICR) line shapes in the high-pressure limit where many collision occur during the ion transit time. The steady-state theory assumes equilibrium between power absorption and collision dissipation, ignoring the transient effect. However, it has been successfully applied to the determination of the collision frequency or the nonreactive cross section of ions from the line-shapes.[5,9)] Beauchamp[5)] and Buttrill[11)] obtained an approximated solution of Eq. (2) for the case $\xi=0$, which leads to an expression for low-pressure power absorption. Line-shapes calculated from the low-pressure theory show good agreement with experimental results at low pressure.[11)] In the presence of ion-molecule reactions, the theory has been extended successfully for determining of ion-molecule reaction rates using ICR signal intensity. The calculated rates show a substantial agreement with those measured by other techniques.[12)]

Recently, a more general solution for the phenomenological equation of motion of an ion in the ICR cell has been given by Comisarow[10)] and Dunbar[13)] which bridges the gap between the low- and high-pressure theories. This "total-pressure theory" has clarified the power absorption expressions for the chemically reactive ions.[10)] The theory has also been used for obtaining the collision relaxation rate and substantial probability for charge transfer by transient ICR experiment.[13)] However, in this theory, the ion current expression is not treated in detail.

In this paper, we propose exact expressions of ion current in the ICR cell, and an exact solution of the phenomenological equation of motion for the velocity of an ion used for deriving the power absorption of an ion and the ion kinetics. The ion-molecule reaction rate constants for the disappearance of primary ions and for the formation of nonreactive secondary ions are determined from ion cyclotron single resonance (ICSR) spectra. Rate constants are compared with values obtained by other methods. Close agreement between the present and previous values was obtained.

Theory

Ion Motion in the ICR Cell. The Cartesian coordinate system is chosen so that the static magnetic field is parallel to the z axis, the electrostatic drift field and the rf electric field are parallel to the x axis, and the ions drift to the y axis. Then ion motion in the x-y plane is independent of motion in the z direction.

The electrostatic trapping field is parallel to the z axis, as usually employed in the ICR cell.[3] The trapping field should not affect the power absorption of an ion.[3] The trapping voltage, however, shifts the ion cyclotron resonance frequency.[14,16] In the ICR cell, the electrostatic drift field only determines the residence time of the center of guide of the circular motion for an ion in the absence of collision.[3]

The actual motion of the ion in the analyzer region of the ICR cell consists of different types motion. A circular motion due to the Lorentz force in the x-y plane with increasing orbit radius with time, in which the ion absorbs energy from the applied rf electric field, and a motion of drift at constant velocity along the $-y$ axis lead to a trochoidal motion of increasing radius in the x-y plane. Furthermore, the ion describes an executed harmonic motion in a parabolic potential field in the x-z plane between the trapping electrodes. The exact solution of Eq. (2) leads to the above complicated motion of the ion in the analyzer region of the ICR cell.

Solution of Equation of Motion. In the absence of reactive collisions, the motion of an ion in the ICR cell can be described by Eq. (2). In the ICR cell, homogeneous electric and magnetic field distributions are assumed, the following electric and magnetic field configurations also being assumed:

$$\mathbf{H} = H_0\boldsymbol{k}, \tag{4}$$

$$\mathbf{E} = E_d\boldsymbol{i} + E_1 \sin(\omega_1 t + \phi_1)\boldsymbol{i} + E_t\boldsymbol{k}, \tag{5}$$

where H_0 is the static magnetic field strength, $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$ unit vectors of the coordinate system, E_d is the electrostatic drift field strength, E_t a function of z giving the electrostatic trapping field strength, and E_1 the observed rf electric field strength from the marginal oscillator or the oscillator for the bridge with frequency ω_1. The phase factor of ϕ_1 has been introduced because the rf phase at $t=0$ is not fixed.

Equation (2) is now separated into an equation of v_z only and two coupled equations of v_x and v_y. The relevant equations of motion are then;

$$\frac{dv_x}{dt} = \frac{e}{m}[E_d + E_1 \sin(\omega_1 t + \phi_1)] + \omega v_y - \xi v_x, \tag{6a}$$

$$\frac{dv_y}{dt} = -\omega v_x - \xi v_y. \tag{6b}$$

In the present investigation, the motion in the z direction does not affect the power absorption and will not be considered further.

An ion whose initial velosity v_0 is due to the thermal velocity leads to a circular motion with phase angle ϕ_0, $v_x(0) = -v_0\cos\phi_0$ and $v_y(0) = v_0\sin\phi_0$ at $t=0$. The exact solution of Eq. (6) is given by[7]

$$\begin{aligned} v_x = {} & v_0 \sin(\omega t - \phi_0) \exp(-\xi t) \\ & + \frac{eE_d}{m}\left[\frac{\xi - (\xi\cos\omega t - \omega\sin\omega t)\exp(-\xi t)}{\omega^2 + \xi^2}\right] \\ & + \frac{eE_1}{m}\{A\sin(\omega_1 t + \phi_1) - B\cos(\omega_1 t + \phi_1) \\ & - [(C\cos\phi_1 + D\sin\phi_1)\sin\omega t \\ & - (B\cos\phi_1 - A\sin\phi_1)\cos\omega t]\exp(-\xi t)\}, \end{aligned} \tag{7a}$$

$$\begin{aligned} v_y = {} & v_0 \cos(\omega t - \phi_0) \exp(-\xi t) \\ & + \frac{eE_d}{m}\left[\frac{\omega - (\xi\sin\omega t + \omega\cos\omega t)\exp(-\xi t)}{\omega^2 + \xi^2}\right] \\ & + \frac{eE_1}{m}\{D\sin(\omega_1 t + \phi_1) + C\cos(\omega_1 t + \phi_1) \\ & - [(B\cos\phi_1 - A\sin\phi_1)\sin\omega t \\ & + (C\cos\phi_1 + D\sin\phi_1)\cos\omega t]\exp(-\xi t)\}, \end{aligned} \tag{7b}$$

where

$$\begin{aligned} A &= [\xi(\xi^2 + \omega_1^2 - \omega^2) + 2\xi\omega^2]/F, \\ B &= \omega_1(\xi^2 + \omega_1^2 - \omega^2)/F, \\ C &= 2\xi\omega\omega_1/F, \\ D &= [\omega(\xi^2 + \omega_1^2 - \omega^2) - 2\xi^2\omega]/F, \\ F &= [(\omega_1 - \omega)^2 + \xi^2][(\omega_1 + \omega)^2 + \xi^2]. \end{aligned}$$

Line Shape Expression for Nonreactive Ion. a) Power Absorption of an Average Nonreactive Ion: Power absorption A of an ion from the rf electric field is given by

$$A = \langle e\mathbf{E}(t)\cdot\mathbf{v}(t)\rangle = eE_1 v_x \sin(\omega_1 t + \phi_1), \tag{8}$$

where v_x represents only the third term of Eq. (7a), because there is no observed effect of either the drift field or the initial velocity of an ion on the power absorption. The third term of Eq. (7b) has an effect on the power dispersion for an ion. The initial velocity of an ion with phase angle ϕ_0 will not contribute to the actual power absorption. Since an ensemble of ions enters the analyzer region in the ICR cell at time dt, the phase angles are expected to be distributed randomly so that the average over a period is 0.

Substituting the third term of Eq. (7a) into Eq. (8), the power absorption can be obtained by averaging over the phase angle ϕ_1 since all values of ϕ_1 are equally probable. With the approximation that

$$\omega_1 + \omega \approx 2\omega, \tag{9}$$

$$\xi \ll \omega_1, \tag{10}$$

the instantaneous power absorption by an ion is found to be

$$\begin{aligned} A(\omega_1 = \omega) = {} & \frac{e^2 E_1^2}{4m[(\omega_1 - \omega)^2 + \xi^2]}\{\xi + [(\omega_1 - \omega)\sin(\omega_1 - \omega)t \\ & - \xi\cos(\omega_1 - \omega)t]\exp(-\xi t)\}, \end{aligned} \tag{11}$$

which is a function of t, ω, ω_1, and ξ. The first term is a steady-state power absorption observed under slow passage conditions. The second term is a transient term of a damped oscillation with frequency $|\omega_1 - \omega|$, giving the ICR heterodyne spectrum.[13] The absorption giving by Eq. (11) agrees with that of Comisarow[10] and that of Dunber[13] who used slightly different methods.

At resonance $\omega_1 = \omega$, the instantaneous power absorption is shown to be

$$A(\omega_1=\omega) = \frac{e^2{E_1}^2}{4m\xi}[1-\exp(-\xi t)]. \quad (12)$$

If the pressure is sufficiently high for each ion to suffer many nonreactive collisions, Eq. (11) is reduced to

$$A(\xi t \gg 1) = \frac{e^2{E_1}^2}{4m}\frac{\xi}{(\omega_1-\omega)^2+\xi^2} \quad (13)$$

by application of the approximation

$$\xi t \gg 1. \quad (14)$$

This high-pressure power absorption represents the Lorentzian line shape and agrees with the results of Beauchamp[9] and Comisarow.[10] In the collisionless limit $\xi \to 0$, Eq. (11) is reduced to

$$A(\xi \to 0) = \frac{e^2{E_1}^2}{4m(\omega_1-\omega)}\sin(\omega_1-\omega)t. \quad (15)$$

This low-pressure power absorption agrees with that of Beauchamp,[9] of Buttrill[11] and also of Comisarow.[10]

b) Total Power Absorption for Nonreactive Ion: Under idealized experimental ICR conditions, the homogeneous electric and magnetic field distributions are assumed in the ICR cell. Ions are produced in a source region with electron impact at a rate n_0 ions per second, and then drift through an anlyzer region at constant drift velocity. It has been assumed that the distribution of ions is uniform inside the ICR cell. There is a constant number $n_0\tau$ of ions in time τ for an ion drift through the analyzer, each absorbing energy at the rate given in Eq. (11). Thus the total power absorption $A(T)$ is obtained by averaging the integration from 0 to τ, the time required for the ions to absorb energy from the applied rf electric field. The averaged total power absorption is given by

$$A(T) = \frac{1}{\tau}\int_0^\tau n_0\tau A(\omega_1=\omega)\mathrm{d}t$$

$$= \frac{n_0e^2{E_1}^2}{4m[(\omega_1-\omega)^2+\xi^2]}\left\{\xi\tau+\frac{(\omega_1-\omega)^2-\xi^2}{(\omega_1-\omega)^2+\xi^2}\right.$$

$$+\left[\frac{\{\xi^2-(\omega_1-\omega)^2\}\cos(\omega_1-\omega)\tau-2\xi(\omega_1-\omega)\sin(\omega_1-\omega)\tau}{(\omega_1-\omega)^2+\xi^2}\right]$$

$$\left.\times\exp(-\xi\tau)\right\}, \quad \text{for } \omega_1=\omega, \quad (16a)$$

and

$$A(T) = \frac{n_0e^2{E_1}^2}{4m\xi}\left\{1-\frac{1}{\xi\tau}[1-\exp(-\xi\tau)]\right\} \quad \text{for } \omega=\omega_1. \quad (16b)$$

Application of (14) in Eq. (16a) gives

$$A(T, \text{High-pressure}) = \frac{n_0e^2{E_1}^2\tau}{4m}\frac{\xi}{(\omega_1-\omega)^2+\xi^2}. \quad (17)$$

This represents the average total high-pressure power absorption expression.

In the collisionless limit $\xi \to 0$, Eq. (16a) is reduced to

$$A(T, \xi \to 0) = \frac{n_0e^2{E_1}^2}{4m(\omega_1-\omega)^2}[1-\cos(\omega_1-\omega)]. \quad (18)$$

The line shapes of ICR total power absorption for an ensemble of ions are represented by Eqs. (16)—(18). The results agree with those of Comisarow.[10]

Line Shape Expression for Reactive Ion. a) Ion Current in the Analyzer Region: When the pressure in the ICR cell is so high that the reactive collision cannot be ignored, ion-molecule reactions occur. In special cases where all ion-molecule collisions are reactive, the calculation of power absorption is particularly simple, since the reactive collision removes the ion as a power-absorption entity. Here, only one species of neutral reactant molecule is present assuming that no two ions formed in different steps have the same mass.

The cross section of ion-molecule reaction is the function of ion velocity. The thermal reaction cross section σ_θ can be estimated from the corresponding rate constant, and is given by[17]

$$\sigma_\theta = \frac{k}{v_\theta}, \quad (19)$$

where v_θ is the average thermal velocity of the reactant ion. The reaction cross section of ion-molecule reaction is also given by[18]

$$\sigma = \frac{S}{P_0Ml}, \quad (20)$$

where P_0 is the rate of primary ion formation in the electron beam, S the total secondary ion current after the primary ion has traveled a distance l from the origin (the electron beam), and M the neutral reactant molecule. In the source region, the angular velocity of the ion is almost equal to its thermal velocity, but is not the same at resonance in the analyzer region. Similarly, the path lengths of the ions in the source and analyzer regions are not the same. Thus, the cross sections of ion-molecule reaction in the source and in the anlyzer regions are not the same, the rate constants in the source and anlyzer regions also being different.

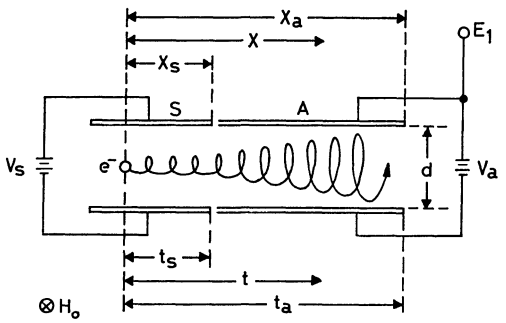

Fig. 1. Side view of the ICR cell showing parameters for kinetic analysis. e^- indicates the location of electron beam which forms the primary ions. The distances x_s, x and x_a are defined by the figure. t_s and t_a are the drift times through the source S and analyzer A regions, respectively.

Figure 1 shows a side cross-sectional view of the ICR cell required for kinetic analysis. Ions are produced in the source region by electron impact which are then made to drift through the analyzer region by the effect of the electrostatic drift field. Drift voltages are applied to the source and analyzer regions of the ICR cell separately. The time at each point x in the analyzer region, which is associated with the drift time t from the electron beam, is given by

$$t = \frac{x_s}{v_s} + \frac{x-x_s}{v_a}, \quad (21a)$$

where x_s and x are the distances indicated in Fig. 1, and v_s and v_a the drift velocities in the source and analyzer regions, respectively. The source exit time t_s and the analyzer exit time t_a for an ion are respectively given by

$$t_s = \frac{v_s}{v_{ds}} = \frac{x_s Hd}{cV_s} \tag{21b}$$

and

$$t_a = t_s + \frac{x_a - x_s}{v_{da}} = t_s + \frac{(x_a - x_s)Hd}{cV_a}, \tag{21c}$$

where V_s and V_a are the source drift and analyzer drift voltages, respectively. x_s, x_a, and d are the parameters defined in Fig. 1.

The equations for the change of ion current with time in the analyzer region are derived for the following primary, secondary, and tertiary chemical systems:[19,20]

Primary ion,

$$M + e^- \longrightarrow P^+, \tag{22}$$

Source-Formed Nonreactive Secondary (*SFNS*) ion,

$$P^+ + M \xrightarrow{k_{ps}} S_n^+ + N, \tag{23a}$$

Analyzer-Formed Nonreactive Secondary (*AFNS*) ion,

$$P^+ + M \xrightarrow{k_{pa}} S_n^+ + N, \tag{23b}$$

Source-Formed Reactive Secondary (*SFRS*) ion,

$$P^+ + M \xrightarrow{k_{ps},\, k_{ss}} S^+ + N, \tag{24a}$$

Analyzer-Formed Reactive Secondary (*AFRS*) ion,

$$P^+ + M \xrightarrow{k_{pa},\, k_{sa}} S^+ + N, \tag{24b}$$

Source-Formed Nonreactive Tertiary (*SFNT*) ion,

$$S^+ + M \xrightarrow{k_{ss}} T_n^+ + N, \tag{25a}$$

Analyzer-Formed Nonreactive Tertiary (*AFNT*) ion,

$$S^+ + M \xrightarrow{k_{sa}} T_n^+ + N. \tag{25b}$$

These obey the following equations in the analyzer region:

$$\frac{dP(t)_a}{d(t-t_{ps})} = -nk_{pa}P(t)_a, \tag{26}$$

$$\frac{dS(t)_{na}}{d(t-t_{ns})} = nk_{pa}P(t)_a, \tag{27}$$

$$\frac{dS(t)_a}{d(t-t_{ss})} = nk_{pa}P(t)_a - nk_{sa}S(t)_a, \tag{28}$$

$$\frac{dT(t)_a}{d(t-t_{ts})} = nk_{ss}S(t)_a. \tag{29}$$

The solutions are found to be

$$P(t)_a = P_0 \exp(-nk_{ps}t_{ps}) \exp[-nk_{pa}(t-t_{ps})], \tag{30}$$

$$S(SFNS, t)_a = P_0\{1-\exp(-nk_{ps}t_{ns}) \times \exp[-nk_{pa}(t-t_{ns})]\}, \tag{31a}$$

$$S(AFNS, t)_a = P_0\{1-\exp[-nk_{pa}(t-t_{ns})]\} \times \exp(-nk_{ps}t_{ns}), \tag{31b}$$

$$S(SFRS, t)_a = P_0\{(\alpha_s+\beta_s)\exp[-nk_{sa}(t-t_{ss})] - \alpha_s \exp[-nk_{pa}(t-t_{ss})]\}, \tag{32a}$$

$$S(AFRS, t)_a = P_0\alpha_s\{\exp[-nk_{sa}(t-t_{ss})] - \exp[-nk_{pa}(t-t_{ss})]\}, \tag{32b}$$

$$T(SFNT, t)_a = P_0\{1-(\alpha_t+\beta_t)\exp[-nk_{sa}(t-t_{ts})] + \gamma_t \exp[-nk_{pa}(t-t_{ts})]\}, \tag{33a}$$

$$T(AFNT, t)_a = P_0\{\alpha_t+\beta_t+\gamma_t-(\alpha_t+\beta_t) \times \exp[-nk_{sa}(t-t_{ts})] + \gamma_t \exp[-nk_{pa}(t-t_{ts})]\}, \tag{33b}$$

where

$$\alpha_s = \frac{k_{pa}}{k_{pa}-k_{sa}} \exp(-nk_{ps}t_{ss}),$$

$$\beta_s = \frac{k_{ps}}{k_{ps}-k_{ss}}[\exp(-nk_{ss}t_{ss}) - \exp(-nk_{ps}t_{ss})],$$

$$\alpha_t = \frac{k_{pa}}{k_{pa}-k_{sa}} \exp(-nk_{ps}t_{ts}),$$

$$\beta_t = \frac{k_{ps}}{k_{ps}-k_{ss}}[\exp(-nk_{ss}t_{ts}) - \exp(-nk_{ps}t_{ts})],$$

$$\gamma_t = \frac{k_{sa}}{k_{pa}-k_{sa}} \exp(-nk_{ps}t_{ts}).$$

Here P_0 is the rate of primary ion formation in ions per second at the electron beam in the source region, n the number density of neutral reactant molecule, k_{ps} and k_{pa} are the ion-molecule reaction rates for the primary ion and k_{ss} and k_{sa} those for the secondary ion in the source and analyzer regions, respectively, and t_{ps}, t_{ns}, t_{ss}, and t_{ts} the source exit times of primary, nonreactive-secondary, reactive-secondary, and nonreactive-tertiary ions, respectively.

In the limits $k_{sa}\to 0$ and $k_{ss}\to 0$, Eq. (32a) is reduced to Eq. (31a). In the limit $k_{sa}\to 0$, Eq. (32b) is reduced to Eq. (31b).

Equations (30) and (31a) can be now rewritten in the following forms:

$$P(t)_{a1} = P_0 \exp[-nk_{pa}(t-t_{ps})] \quad \text{for } k_{pa} \gg k_{ps} \sim 0, \tag{34a}$$

$$P(t)_{a2} = \text{Eq. (30)} \quad \text{for } k_{pa} \neq k_{ps}, \tag{34b}$$

$$P(t)_{a3} = P_0 \exp(-nk_{pa}t_{ps}) \exp[-nk_{pa}(t-t_{ps})] \quad \text{for } k_{pa} \approx k_{ps}, \tag{34c}$$

$$S(SFNS, t)_{a1} = P_0 - P_0 \exp[-nk_{pa}(t-t_{ns})] \quad \text{for } k_{pa} \gg k_{ps} \sim 0, \tag{35a}$$

$$S(SFNS, t)_{a2} = \text{Eq. (31a)} \quad \text{for } k_{pa} \neq k_{ps}, \tag{35b}$$

$$S(SFNS, t)_{a3} = P_0 - P_0 \exp(-nk_{pa}t_{ns}) \times \exp[-nk_{pa}(t-t_{ns})] \quad \text{for } k_{pa} \approx k_{ps}. \tag{35c}$$

Eqs. (34a) and (35a), corresponding to the primary and nonreactive-secondary ion current expressions, have been reported in a slightly different form.[11,17]

b) Total Power Absorption for Primary Ions: Equation (11) can be rewritten in terms of t', the time an ion commences to absorb the power, and t'', the time an ion ceases to absorb the power in the analyzer region, as follows:

$$A(t''-t') = \frac{e^2E_1^2}{4m[(\omega_1-\omega)^2+\xi^2]} \times\{\xi + [(\omega_1-\omega)\sin(\omega_1-\omega)(t''-t') - \xi\cos(\omega_1-\omega)(t''-t')]\exp[-\xi(t''-t')]\}. \tag{36}$$

In the time $t-t_{ps}$ required for a primary ion to drift into the analyzer region, there are $P(t)_a\cdot(t-t_{ps})$ number of ions, each of which absorbs the energy at the rate given by Eq. (36). The total power absorption $A(T,P)$ is thus obtained by averaging the integration from t_{ps} to t_{pa}. The average total power absorption is given by

$$A(T,P)=\frac{1}{(t-t_{ps})}\int_{t_{ps}}^{t_{pa}}P(t)_a\cdot(t-t_{ps})\cdot A(t''-t')dt$$
$$=\frac{P_0e^2E_1^2\exp(-nk_{ps}t_{ps})}{4m_p[(\omega_1-\omega)^2+\xi_p^2]}F(p), \tag{37}$$

where

$$F(p)=\xi_pK_{1p}+K_{2p}-K_{3p}[K_{4p}\cos(\omega_1-\omega)(t_{pa}-t_{ps})$$
$$+K_{5p}\sin(\omega_1-\omega)(t_{pa}-t_{ps})],$$

m_p is the mass of the primary ion, t_{ps} and t_{pa} are the source exit and analyzer exit times, respectively, for the primary ion. $K_{1p}\sim K_{5p}$ are given in Appendix II. Equation (37) is the line shape expression of the total power absorption for the primary ions.

c) Total Power Absorption for Nonreactive Secondary Ions: In time $t-t_{ns}$ required for a nonreactive and stable secondary ion to drift into the analyzer region, there are $S(t)_{na}\cdot(t-t_{ns})$ number of ions, each of which absorbs energy at the rate given by Eq. (36). Thus the total power absorption $A(T,SFNS)$ due to source-formed nonreactive and stable secondary ions is given by averaging the integration from t_{ns} to t_{na}:

$$A(T,SFNS)=\frac{1}{(t-t_{ns})}\int_{t_{ns}}^{t_{na}}S(SFNS,t)_a\cdot(t-t_{ns})\cdot A(t''-t')dt$$
$$=\frac{P_0e^2E_1^2}{4m_n[(\omega_1-\omega)^2+\xi_n^2]}$$
$$\times\{f(NS)-F(NS)\exp(-nk_{ps}t_{ns})\}, \tag{38}$$

where

$$f(NS)=\xi_n(t_{na}-t_{ns})+N_{1n}$$
$$-N_{2n}[N_{3n}\cos(\omega_1-\omega)(t_{na}-t_{ns})$$
$$+N_{4n}\sin(\omega_1-\omega)(t_{na}-t_{ns})],$$
$$F(NS)=\xi_nK_{1n}+K_{2n}-K_{3n}[K_{4n}\cos(\omega_1-\omega)(t_{na}-t_{ns})$$
$$+K_{5n}\sin(\omega_1-\omega)(t_{na}-t_{ns})],$$

m_n is the mass of the nonreactive and stable secondary ion, t_{ns} and t_{na} are the source exit and analyzer exit times for the nonreactive and stable secondary ion, respectively. $N_{1n}\sim N_{4n}$ and $K_{1n}\sim K_{5n}$ are given in Appendix II.

Similarly, the total power absorption $A(T,AFNS)$ due to analyzer-formed nonreactive and stable secondary ions is given by averaging the integration from t_{ns} to t_{na}:

$$A(T,AFNS)=\frac{1}{(t-t_{ns})}\int_{t_{ns}}^{t_{na}}S(AFNS,t)_a\cdot(t-t_{ns})\cdot A(t''-t')dt$$
$$=\frac{P_0e^2E_1^2\exp(-nk_{ps}t_{ns})}{4m_n[(\omega_1-\omega)^2+\xi^2]}[f(NS)-F(NS)]. \tag{39}$$

Equations (38) and (39) are the line shape expressions of total power absorption for the source-formed and analyzer-formed nonreactive and stable secondary ions, respectively. The total power absorption due to nonreactive and stable secondary ions is given by the sum of Eqs. (38) and (39):

$$A(T,S_n)=A(T,SFNS)+A(T,AFNS)$$

d) Total Power Absorption for Reactive Secondary Ions: In time $t-t_{ns}$ required for a reactive secondary ion to drift into the analyzer region, there are $S(t)_a\cdot(t-t_{ns})$ number of ions, each of which absorbs energy at the rate given by Eq. (36). Thus the total power absorption $A(T,SFRS)$ due to source-formed reactive secondary ions is given by averaging the integration from t_{ss} to t_{sa}:

$$A(T,SFRS)=\frac{1}{(t-t_{ss})}\int_{t_{ss}}^{t_{sa}}S(SFRS,t)_a\cdot(t-t_{ss})\cdot A(t''-t')dt$$
$$=\frac{P_0e^2E_1^2}{4m_s[(\omega_1-\omega)^2+\xi_s^2]}[(\alpha_s+\beta_s)R(s)-\gamma_sF(s)], \tag{40}$$

where

$$R(s)=\xi_sR_{1s}+R_{2s}-R_{3s}[R_{4s}\cos(\omega_1-\omega)(t_{sa}-t_{ss})$$
$$+R_{5s}\sin(\omega_1-\omega)(t_{sa}-t_{ss})],$$
$$F(s)=\xi_sK_{1s}+K_{2s}-K_{3s}[K_{4s}\cos(\omega_1-\omega)(t_{sa}-t_{ss})$$
$$+K_{5s}\sin(\omega_1-\omega)(t_{sa}-t_{ss})],$$

m_s is the mass of the reactive secondary ion, t_{ss} and t_{sa} are the source exit and analyzer exit times of the reactive secondary ion, respectively. $R_{1s}\sim R_{5s}$ and $K_{1s}\sim K_{5s}$ are given in Appendix II.

Similarly, the total power absorption $A(T,AFRS)$ due to analyzer-formed reactive secondary ions is given by averaging the integration from t_{ss} to t_{sa}:

$$A(T,AFRS)=\frac{1}{(t-t_{ss})}\int_{t_{ss}}^{t_{sa}}S(AFRS,t)_a\cdot(t-t_{ss})\cdot A(t''-t')dt$$
$$=\frac{P_0e^2E_1^2\alpha_s}{4m_s[(\omega_1-\omega)^2+\xi_s^2]}[R(s)-F(s)]. \tag{41}$$

Equation (40) and (41) are the line shape expressions of total power absorption for the source-formed and analyzer-formed reactive secondary ions, respectively. The total power absorption due to reactive secondary ions is given by the sum of Eqs. (40) and (41):

$$A(T,S)=A(T,SFNS)+A(T,AFRS).$$

In the limits $k_{sa}\to0$ and $k_{ss}\to0$, Eq. (40) is reduced to Eq. (38). In the limit $k_{sa}\to0$, Eq. (41) is reduced to Eq. (39).

e) Total Power Absorption for Nonreactive Tertiary Ions: In time $t-t_{ts}$ required for a nonreactive and stable tertiary ion to drift into the analyzer region, there are $T(t)_a\cdot(t-t_{ts})$ number of ions, each of which absorbs energy at the rate given by Eq. (36). Thus the total power absorption $A(T,SFNT)$ due to source-formed nonreactive and stable tertiary ions is obtained by averaging the integration from t_{ts} to t_{ta}:

$$A(T,SFNT)=\frac{1}{(t-t_{ts})}\int_{t_{ts}}^{t_{ta}}T(SFNT,t)_a\cdot(t-t_{ts})\cdot A(t''-t')dt$$
$$=\frac{P_0e^2E_1^2}{4m_t[(\omega_1-\omega)^2+\xi_t^2]}$$
$$\times\{f(T)-(\alpha_t+\beta_t)R(T)+\gamma_tF(T)\}, \tag{42}$$

where

$$f(T)=\xi_t(t_{ta}-t_{ts})+N_{1t}-N_{2t}[N_{3t}\cos(\omega_1-\omega)(t_{ta}-t_{ts})$$
$$+N_{4t}\sin(\omega_1-\omega)(t_{ta}-t_{ts})],$$

$$R(T) = \xi_t R_{1t} + R_{2t} - R_{3t}[R_{4t}\cos(\omega_1-\omega)(t_{ta}-t_{ts}) + R_{5t}\sin(\omega_1-\omega)(t_{ta}-t_{ts})],$$
$$F(T) = \xi_t K_{1t} + K_{2t} - K_{3t}[K_{4t}\cos(\omega_1-\omega)(t_{ta}-t_{ts}) + K_{5t}\sin(\omega_1-\omega)(t_{ta}-t_{ts})],$$

m_t is the mass of the nonreactive and stable tertiary ion, t_{ts} and t_{ta} are the source exit and analyzer exit times of the nonreactive and stable tertiary ion, respectively. $N_{1t}\sim N_{4t}$, $R_{1t}\sim R_{5t}$, and $K_{1t}\sim K_{5t}$ are given in Appendix II.

Similarly, the total power absorption $A(T,AFNT)$ due to analyzer-formed nonreactive and stable tertiary ions is given by averaging the integration from t_{ts} to t_{ta}:

$$A(T,AFNT) = \frac{1}{(t-t_{ts})}\int_{t_{ts}}^{t_{ta}} T(AFNT,t)_a\cdot(t-t_{ts})\cdot A(t''-t')dt$$
$$= \frac{P_0e^2E_1^2}{4m_t[(\omega_1-\omega)^2+\xi_t^2]}\{(\alpha_t+\beta_t+\gamma_t)f(T) - (\alpha_t+\beta_t)R(T)+\gamma_t F(T)\}. \quad (43)$$

Equations (42) and (43) are the line shape expressions of total power absorption for the source-formed and analyzer-formed nonreactive and stable tertiary ions, respectively. The total power absorption due to nonreactive and stable tertiary ions is given by the sum of Eqs. (42) and (43):

$$A(T,T) = A(T,SFNT) + A(T,AFNT).$$

Intensity Formula at Resonance. *a) Primary Ion*: In general, a full line shape expression is not required for the experimental determination of rate constant. The formula required for the ICSR signal intensity for an ion-molecule reaction described by Eqs. (22)—(25), is given as follows:

Applying the limit $\omega_1\to\omega$ to Eq. (37), we obtain the following intensity equation for primary ions;

$$I(P) = \frac{P_0e^2E_1^2\exp(-nk_{ps}t_{ps})}{4m_p\xi_p}\left\{\frac{1-\exp[-nk_{pa}(t_{pa}-t_{ps})]}{nk_{pa}} - \frac{1-\exp[-(nk_{pa}+\xi_p)(t_{pa}-t_{ps})]}{nk_{pa}+\xi_p}\right\}. \quad (44)$$

Under the approximation $k_{pa}\approx k_{ps}$, the first term of Eq. (44) corresponds to the intensity equation with the primary ion.[19] The second term points out the disadvantage of the old treatment, since k_{pa} should not be equal to k_{ps}. Under the collisionless limit $\xi\to 0$ and approximation $k_{pa}\approx k_{ps}$, Eq. (44) agrees with the intensity equation.[11] It is worthwhile noting that in our case the term of collision frequency ξ_p does not appear in the third order expansion of Eq. (44), and that no effect of collision frequency on signal intensity is considered.

b) Nonreactive Secondary Ion: The limit $\omega_1\to\omega$ in Eqs. (38) and (39) gives the following intensity equations for source-formed and analyzer-formed nonreactive and stable secondary ions, respectively;

$$I(SFNS) = \frac{P_0e^2E_1^2}{4m_n\xi_n}\Big\langle(t_{na}-t_{ns}) - \frac{1-\exp[-\xi_n(t_{na}-t_{ns})]}{\xi_n} - \left\{\frac{1-\exp[-nk_{pa}(t_{na}-t_{ns})]}{nk_{pa}} - \frac{1-\exp[-(nk_{pa}+\xi_n)(t_{na}-t_{ns})]}{nk_{pa}+\xi_n}\right\} \times\exp(-nk_{ps}t_{ns})\Big\rangle, \quad (45)$$

and

$$I(AFNS) = \frac{P_0e^2E_1^2\exp(-nk_{ps}t_{ns})}{4m_n\xi_n}\left\{(t_{na}-t_{ns}) - \frac{1-\exp[-\xi_n(t_{na}-t_{ns})]}{\xi_n} - \frac{1-\exp[-nk_{pa}(t_{na}-t_{ns})]}{nk_{pa}} + \frac{1-\exp[-(nk_{pa}+\xi_n)(t_{na}-t_{ns})]}{nk_{pa}+\xi_n}\right\}. \quad (46)$$

In the collisionless limit $\xi\to 0$, we can obtain the intensity equations of collisionless limiting case for source-formed and analyzer-formed nonreactive secondary ions. Under the approximation $k_{pa}\approx k_{ps}$, the intensity equation for source-formed nonreactive ion of collisionless limiting case corresponds to the secondary ion intensity expression.[11] The limit $k_{ps}\to 0$, applied to Eq. (46) and collisionless limiting case of Eq. (46), gives Eq. (45) and the collisionless limiting case of Eq. (45), respectively.

c) Reactive Secondary Ion: The intensity equations for the source-formed and analyzer-formed reactive secondary ions were similarly calculated:

$$I(SFRS) = \frac{P_0e^2E_1^2}{4m_s\xi_s}\Big\langle\frac{(\alpha_s+\beta_s)\{1-\exp[-nk_{sa}(t_{sa}-t_{ss})]\}}{nk_{sa}} - \frac{\alpha_s\{1-\exp[-nk_{pa}(t_{sa}-t_{ss})]\}}{nk_{pa}} - \frac{(\alpha_s+\beta_s)\{1-\exp[-(nk_{sa}+\xi_s)(t_{sa}-t_{ss})]\}}{nk_{sa}+\xi_s} - \frac{\alpha_s\{1-\exp[-(nk_{pa}+\xi_s)(t_{sa}-t_{ss})]\}}{nk_{pa}+\xi_s}\Big\rangle, \quad (47)$$

and

$$I(AFRS) = \frac{P_0e^2E_1^2\alpha_s}{4m_s\xi_s}\left\{\frac{1-\exp[-nk_{sa}(t_{sa}-t_{ss})]}{nk_{sa}} - \frac{1-\exp[-(nk_{sa}+\xi_s)(t_{sa}-t_{ss})]}{nk_{sa}+\xi_s} - \frac{1-\exp[-nk_{pa}(t_{sa}-t_{ss})]}{nk_{pa}} + \frac{1-\exp[-(nk_{pa}+\xi_s)(t_{sa}-t_{ss})]}{nk_{pa}+\xi_s}\right\}. \quad (48)$$

In the expansion of Eqs. (47) and (48) with respect to ξ, we obtain intensity equations of collisionless limiting case for the source-formed and analyzer-formed reactive secondary ions, respectively.

d) Nonreactive Tertiary Ion: By a similar calculation the following intensity equations for source-formed and analyzer-formed nonreactive and stable tertiary ions are obtained.

$$I(SFNT) = \frac{P_0e^2E_1^2}{4m_t\xi_t}\Big\langle(t_{ta}-t_{ts}) - \frac{1-\exp[-\xi_t(t_{ta}-t_{ts})]}{\xi_t} - \frac{(\alpha_t+\beta_t)}{nk_{sa}}\{1-\exp[-nk_{sa}(t_{ta}-t_{ts})]\} + \frac{\gamma_t}{nk_{pa}}\{1-\exp[-nk_{pa}(t_{ta}-t_{ts})]\} + \frac{(\alpha_t+\beta_t)}{nk_{sa}+\xi_t}\{1-\exp[-(nk_{sa}+\xi_t)(t_{ta}-t_{ts})]\} - \frac{\gamma_t}{nk_{pa}+\xi_t}\{1-\exp[-(nk_{pa}+\xi_t)(t_{ta}+t_{ts})]\}\Big\rangle, \quad (49)$$

and

$$I(AFNT) = \frac{P_0e^2E_1^2}{4m_i\xi_t}\Big\langle(\alpha_t+\beta_t+\gamma_t)\Big\{(t_{ta}-t_{ts}) - \frac{1-\exp[-\xi_t(t_{ta}-t_{ts})]}{\xi_t}\Big\} - \frac{(\alpha_t-\beta_t)}{nk_{sa}}\{1-\exp[-nk_{sa}(t_{ta}-t_{ts})]\} + \frac{\gamma_t}{nk_{pa}}\{1-\exp[-nk_{pa}(t_{ta}-t_{ts})]\} + \frac{(\alpha_t+\beta_t)}{nk_{sa}+\xi_t}\{1-\exp[-(nk_{sa}+\xi_t)(t_{ta}-t_{ts})]\} - \frac{\gamma_t}{nk_{pa}+\xi_t}\{1-\exp[-(nk_{pa}+\xi_t)(t_{ta}-t_{ts})]\}\Big\rangle. \quad (50)$$

In the collisionless limit $\xi\to 0$ of Eqs. (49) and (50) which are expanded to third order with respect to ξ, we obtain the intensity equations of collisionless limiting case for the source-formed and analyzer-formed nonreactive tertiary ions.

Calculation of Rate Constant for the Disappearance of Primary Ions. In ion-molecule reactions, the power absorption due to the primary ion is decreased by the reactive collisions with neutral reactant molecules. The ion-molecule collision rate or reaction rate constant for disappearance of the primary ion can be obtained from Eq. (44). However, there is no effect of collision frequency on ICSR signal intensity. Thus, the collisionless limit $\xi\to 0$ is a fairly good approximation except at the high pressure where the collision broadening occurs.

Equation (44) can be now expanded to give

$$I(P_1, \xi\to 0) = \frac{P_0e^2E_1^2(t_{pa}-t_{ps})^2}{8m_p^2}[1-nk_{pa}(t_{pa}-t_{ps})] \quad \text{for } k_{pa}\gg k_{ps}\sim 0, \quad (51a)$$

$$I(P_2, \xi\to 0) = \frac{P_0e^2E_1^2}{8m_p^2}(t_{pa}-t_{ps})\Big\{(t_{pa}-t_{ps}) - \frac{n}{k_{pa}}[k_{pa}t_p-(k_{pa}-k_{ps})t_{ps}]^2\Big\} \quad \text{for } k_{pa}\neq k_{ps}, \quad (51b)$$

$$I(P_3, \xi\to 0) = \frac{P_0e^2E_1^2}{8m_p^2}(t_{pa}-t_{ps})[(t_{pa}-t_{ps})-nk_{pa}t_{pa}^2] \quad \text{for } k_{pa}\approx k_{ps}. \quad (51c)$$

Solving Eqs. (51a), (51b), and (51c) for k_{pa}, we have

$$k_{pa} = \frac{1}{n(t_{pa}-t_{ps})}\left[1-\frac{I(P_1, \xi\to 0)}{\alpha}\right] \quad \text{for } k_{pa}\gg k_{ps}\sim 0, \quad (52a)$$

$$k_{pa} = \frac{1}{n(t_{pa}-t_{ps})}\left[1-2nk_{ps}t_{ps}-\frac{I(P_2, \xi\to 0)}{\alpha}\right] \quad \text{for } k_{pa}\neq k_{ps}, \quad (52b)$$

and

$$k_{pa} = \frac{(t_{pa}-t_{ps})}{nt_{pa}^2}\left[1-\frac{I(P_3, \xi\to 0)}{\alpha}\right] \quad \text{for } k_{pa}\approx k_{ps}, \quad (52c)$$

where k_{pa} is the collision rate or the rate constant for the disappearance of the primary ions, and

$$\alpha = \frac{P_0e^2E_1^2}{8m_p^2}(t_{pa}-t_{ps})^2.$$

Calculation of Rate Constant for the Formation of Nonreactive Secondary Ions. Single-resonance spectra are usually obtained at constant rf frequency ω_1 by sweeping the magnetic field. The magnetic field at which an ion is in resonance is proportional to m/e as indicated by Eq. (1).

The source exit and analyzer exit times for the primary ion are given by Eqs. (21b) and (21c), respectively. The values of t_{ps} and t_{pa} are related by

$$t_{ns} = (m_n/m_p)t_{ps}, \quad (53a)$$

$$t_{ss} = (m_s/m_p)t_{ps}, \quad (53b)$$

$$t_{ts} = (m_t/m_p)t_{ps}, \quad (53c)$$

$$t_{na} = (m_n/m_p)t_{pa}, \quad (54a)$$

$$t_{sa} = (m_s/m_p)t_{pa}, \quad (54b)$$

and

$$t_{ta} = (m_t/m_p)t_{pa}. \quad (54c)$$

If $nk_it_j<1$, $(i, j=ps, pa, ns, na)$, then the exponentials in the collisionless limit of Eq. (44) can be expanded to the third order. Using Eqs. (53a) and (54a), they can be solved for k_{pa} giving the approximations:

$$k_{pa} = \frac{m_p^2I(NS, \xi\to 0)\cdot(t_{pa}-t_{ps})}{n[m_n^2I(P, \xi\to 0)\cdot\alpha_k+m_p^2I(NS, \xi\to 0)\cdot\beta_k]} \quad \text{for } k_{ps}\neq k_{pa}, \quad (55a)$$

$$k_{pa} = \frac{m_p^2I(NS, \xi\to 0)}{n[2m_n^2I(P, \xi\to 0)+m_p^2I(NS, \xi\to 0)](t_{pa}-t_{ps})} \quad \text{for } k_{pa}\gg k_{ps}\sim 0, \quad (55b)$$

and

$$k_{pa} = \frac{m_p^2I(NS, \xi\to 0)\cdot(t_{pa}-t_{ps})}{n\{m_n^2I(P, \xi\to 0)[2t_{pa}^2-(t_{pa}-t_{ps})t_{ps}]+m_p^2I(NS, \xi\to 0)t_{pa}^2\}} \quad \text{for } k_{pa}\approx k_{ps}, \quad (55c)$$

where

$$\alpha_k = 2(t_{pa}-t_{ps})^2+\frac{3k_{ps}}{k_{pa}}(t_{pa}-t_{ps})t_{ps}+\frac{2k_{ps}^2}{k_{pa}^2}t_{ps}^2$$

and

$$\beta_k = (t_{pa}-t_{ps})^2+\frac{2k_{ps}}{k_{pa}}(t_{pa}-t_{ps})t_{ps}+\frac{2k_{ps}^2}{k_{pa}^2}t_{ps}^2.$$

Under high pressure, if $nk_it_j<1$, $(i,j=pa, ps, na, ns)$, then exponentials in Eqs. (44), (45), and (46) can be expanded to fourth order. Using Eqs. (53a) and (54a), they can be solved for k_{pa} giving the approximations:

$$k_{pa} = \frac{m_p^2I(NS)[3-3nk_{ps}t_{ps}-\xi_p(t_{pa}-t_{ps})]-3m_n^2I(P)nk_{ps}t_{ps}}{2n[2m_n^2I(P)+m_p^2I(NS)](t_{pa}-t_{ps})} \quad \text{for } k_{ps}\neq k_{pa}, \quad (56a)$$

$$k_{pa} = \frac{m_p^2I(NS)[3-\xi_p(t_{pa}-t_{ps})]}{2n[2m_n^2I(P)+m_p^2I(NS)](t_{pa}-t_{ps})} \quad \text{for } k_{pa}\gg k_{ps}\sim 0, \quad (56b)$$

and

$$k_{pa} = \frac{m_p^2I(NS)[3-\xi_p(t_{pa}-t_{ps})]}{n[m_n^2I(P)\cdot(4t_{pa}-t_{ps})+m_p^2I(NS)\cdot(2t_{pa}+t_{ps})]} \quad \text{for } k_{ps}\approx k_{pa}. \quad (56c)$$

Equations (55a)—(56c) were derived on the assumption that a secondary ion does not suffer any reactive collisions in the resonance region of the ICR cell. If

a large fraction of secondary ions react with neutrals in the analyzer region, Eqs. (55a)—(56c) could not be applied. In this case, the rate constant for the formation of reactive secondary ion can be derived from Eqs. (44), (47), and (48).

Results and Discussion

Single- and Double-resonance Spectra. The ion-molecule reactions of acetonitrile have been studied by high-pressure mass spectrometry[21] and ICR spectroscopy.[22] Twenty-three ion-molecule reactions have been observed in acetonitrile by ICDR technique,[22] and the rate constants for the disappearance of ion-molecule reactions in acetonitrile has been measured with a time-of-flight mass spectrometer.[21]

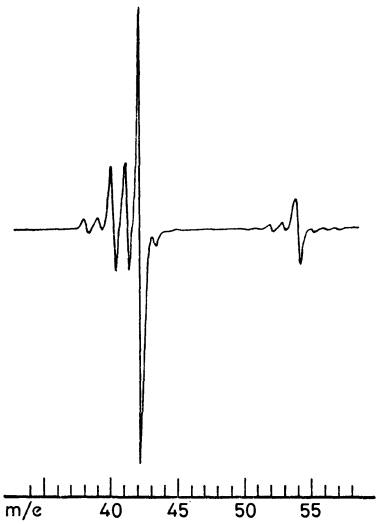

Fig. 2. Single-resonance spectrum of acetonitrile at 60 eV electron energy and 1.1×10^{-5} Torr.

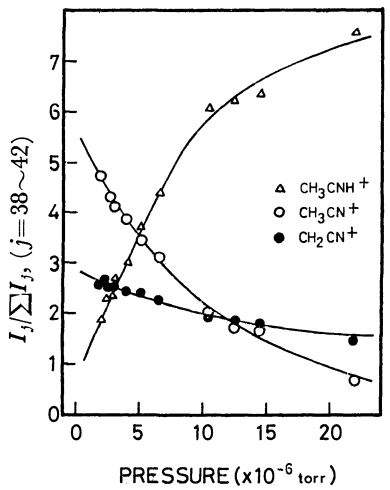

Fig. 3. Variation of single-resonance intensities of the various observed with pressure, at 60 eV electron energy.

However, the rate constant for the disappearance has not been reported by ICR spectroscopy. Equation (52) is applied to determine the rate constant for the disappearace of ions in acetonitrile.

Figure 2 shows a single-resonance spectrum of acetonitrile obtained at 1.1×10^{-5} Torr and electron energy of 60 eV. The spectrum is essentially the same as that reported.[22] The variations of single-resonance intensities with pressure are given in Fig. 3. The primary ion CH_2CN^+ and CH_3CN^+ decrease with increasing pressure. The secondary product CH_3CNH^+ increases with increasing pressure. The weak signal of $CHCN^+$ reaches a maximum, at around 6×10^{-6} Torr, and then decreases with increasing pressure. At a high electron energy, the sequence of reactions becomes complicated, probably because of possible generation of several reactant ions. By ICDR technique, however, one can readily identify the processes that produce each product ion. The ion-molecule reactions, identified by ICDR technique, are listed in Table 1. The results of ICDR experiments are in good agreement with those reported.[22]

Table 1. Ion-molecule reaction in acetonitrile

R1.	$C_2H_2^+$	+ CH_3CN	⟶	CH_3CNH^+	+ C_2H
R2.	HCN^+	+ CH_3CN	⟶	CH_3CNH^+	+ CN
R3.	H_2CN^+	+ CH_3CN	⟶	CH_3CNH^+	+ HCN
R4.	N_2H^+	+ CH_3CN	⟶	CH_3CNH^+	+ N_2
R5.	CH_2CN^+	+ CH_3CN	⟶	CH_3CNH^+	+ CHCN
R6.	CH_3CN^+	+ CH_3CN	⟶	CH_3CNH^+	+ CH_2CN
R7.	CH_2CN^+	+ CH_3CN	⟶	$C_3H_4CN^+$	+ HCN

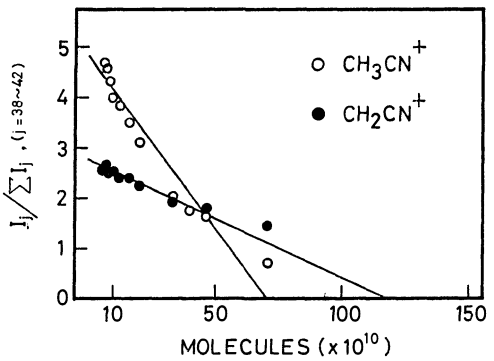

Fig. 4. $I_j/\sum I_j$, (j=38—42), *vs.* number density of neutral reactant molecules for the reaction disappearing CH_3CN^+ with CH_3CN and for the reaction disappearing CH_2CN^+ with CH_3CN.

Determination of Rate Constant for the Disappearance of Primary Ion. From Eqs. (52a, b, c), it is evident that a plot of I *versus* n should give a straight line passing through a point (0, n) with a slope proportional to $1/k_{pa}$. The factor α is generally very small, and has been omitted in plotting Fig. 4. On the assumption that $k_{ps}\ll k_{pa}$, k_{ps} has been ignored in the calculation. Therefore, when $I=0$, Eq. (52a) is reduced to

$$k_{pa}(t_{pa}-t_{ps}) = 1/n,$$

where the source exit time t_{ps} and the analyzer exit time t_{pa} are given by Eqs. (21b) and (21c), respectively. The behavior of single-resonance signal intensities of primary ions CH_2CN^+ and CH_3CN^+ are interpreted by means of Eq. (52a).

The values of $k_{pa}(\mathrm{R5})=1.34\times10^{-9}$ and $k_{pa}(\mathrm{R6})=1.99\times10^{-9}$ cc mol^{-1} s^{-1} for the reactions (R5) and

(R6) obtained from Fig. 4 are in excellent agreement with previous values of $k(\mathrm{R5})=1.78\times10^{-9}$ and $k(\mathrm{R6})=2.01\times10^{-9}$ ml mol^{-1} s^{-1} determined by the conventional technique.[21]

Determination of Rate Constant for the Formation of Nonreactive Secondary Ion. In ion-molecule reactions of acetonitrile, CH_3CNH^+ is not essentially a nonreactive secondary ion. But tertiary ions formed from CH_3CNH^+ are so few that CH_3CNH^+ can be considered to be the nonreactive secondary ion.

In the limits $\xi\to0$ and $k_{ps}\to0$, it is evident that a plot of n *versus* $m_p^2I(NS,\ \xi\to0)/[2m_n^2I(P,\ \xi\to0)+m_p^2I(NS,\ \xi\to0)](t_{pa}-t_{ps})$ of Eq. (55) should give a straight line with a slope proportional to k_{pa} as shown in Fig. 5. The analysis supports the above results for reactions (R5) and (R6).

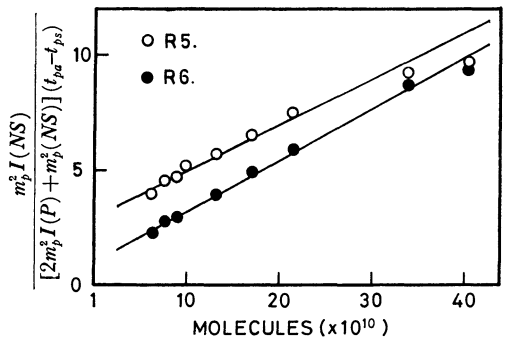

Fig. 5. $m^2{}_pI(NS)/[2m^2{}_nI(P)+m^2{}_pI(NS)](t_{pa}-t_{ps})$ *vs.* number density of neutral reactant molecules for the reaction of R(5) and for the reaction of R(6) listed in Table 1, respectively.

The values $k_{pa}(\mathrm{R5})=2.1\times10^{-9}$ and $k_{pa}(\mathrm{R6})=2.3\times10^{-9}$ cc mol^{-1} s^{-1} for reactions (R5) and (R6) are in very good agreement with previous results. Gupta *et al.*[23] reported $k(\mathrm{R6})=2.15\times10^{-9}$ cc mol^{-1} s^{-1} at 3.7 eV exit ion energy. Martin and Melton[24] reported $k(\mathrm{R6})=3.5\times10^{-9}$ cc mol^{-1} s^{-1} determined by conventional techniques. However, no value of $k(\mathrm{R5})$ has been reported.

Experimental

The ICR spectra recorded with a JEOL JIC-3B spectrometer have been described in detail.[15] The ICR cell was of a three-section square type similar to the conventional one,[3] the grid electrode being added to improve the distribution of the electric field. Ions were produced in the source region by the electron impact and then forced to drift into the analyzer region where they were observed by a Twin-T bridge detector.[6] Single-resonance spectra were obtained in the field modulation mode, and double-resonance experiments were performed in the pulsed modulation mode.[8]

The experimental conditions were as follows: Energy of ionizing electrons=60 eV, source and analyzer drift field strengths=0.2 V/cm, trapping voltage=0.26 V, the observed rf electric field strength and frequency=0.02 V/cm and 100 kHz. Acetonitrile of reagent grade (Wako Pure Chem. Ind., Ltd.) was purified by trap-to-trap distillation before use. The sample was degassed under vacuum utilizing freeze-pump-thaw cycles.

The author would like to thank Professor Koichiro Hayashi for his encouragement, and Professor Junkichi Sohma for advice and discussions. The author is also indebted to Dr. Tetsuo Maruyama of JEOL (U.S.A.), INC. for his support, helpful suggestions and encouragement. The support of JEOL Co., Ltd. is gratefully acknowledged.

Appendix

I) Ion Kinetic Energy in the Absence of Collisions. Kinetic energy of an ion is also derived from Eq. (7) as follows.

$$W(\omega_1=\omega)=\frac{mv_0^2}{2}+\frac{v_0eE_1}{2}\left[t\cos(\phi_0+\phi_1)-\frac{1}{\omega}\sin\omega t\cos(\omega t-\phi_0+\phi_1)\right]+\frac{e^2E_1^2}{8m}\left[t^2+\frac{\sin^2\omega t}{\omega^2}-\frac{2t\sin\omega t\cos(\omega t+2\phi_1)}{\omega}\right]$$

for $\omega_1=\omega$.

If $\phi_0=0$ and $\phi_1=0$, the equation from which the oscillating terms are ignored agrees with that reported previously.[11]

II) List of Notations Used in the Text.

$K_{1p}=\{1-\exp[-nk_{pa}(t_{pa}-t_{ps})]\}/nk_{pa}$,
$K_{2p}=[(\omega_1-\omega)^2-\xi_p(nk_{pa}-\xi_p)]/[(nk_{pa}+\xi_p)^2+(\omega_1+\omega)^2]$,
$K_{3p}=\exp[-(nk_{pa}+\xi_p)(t_{pa}-t_{ps})]/[(nk_{pa}+\xi_p)^2+(\omega_1-\omega)^2]$,
$K_{4p}=(\omega_1-\omega)^2-\xi_p(nk_{pa}+\xi_p)$,
$K_{5p}=(\omega_1-\omega)(nk_{pa}+2\xi_p)$,
$N_{1n}=[(\omega_1-\omega)^2-\xi_n^2]/[(\omega_1-\omega)^2+\xi_n^2]$,
$N_{2n}=\exp[-\xi_n(t_{na}-t_{ns})]/[(\omega_1-\omega)^2+\xi_n^2]$,
$N_{3n}=(\omega_1-\omega)^2-\xi_n^2$,
$N_{4n}=2\xi_n(\omega_1-\omega)$,
$K_{1n}=\{1-\exp[-nk_{pa}(t_{na}-t_{ns})]\}/nk_{pa}$,
$K_{2n}=[(\omega_1-\omega)^2-\xi_n(nk_{pa}-\xi_n)]/[(nk_{pa}+\xi_n)^2+(\omega_1-\omega)^2]$,
$K_{3n}=\exp[-(nk_{pa}+\xi_n)(t_{na}-t_{ns})]/[(nk_{pa}+\xi_n]^2+(\omega_1-\omega)^2]$,
$K_{4n}=(\omega_1-\omega)^2-\xi_n(nk_{pa}+\xi_n)$,
$K_{5n}=(\omega_1-\omega)(nk_{pa}+2\xi_n)$,
$R_{1s}=\{1-\exp[-nk_{sa}(t_{sa}-t_{ss})]\}/nk_{sa}$,
$R_{2s}=[(\omega_1-\omega)^2-\xi_s(nk_{sa}+\xi_s)]/[(nk_{sa}+\xi_s)^2+(\omega_1-\omega)^2]$,
$R_{3s}=\exp[-(nk_{sa}+\xi_s)(t_{sa}-t_{ss})]/[(nk_{sa}+\xi_s)^2+(\omega_1-\omega)^2]$,
$R_{4s}=(\omega_1-\omega)^2-\xi_s(nk_{sa}+\xi_s)$,
$R_{5s}=(\omega_1-\omega)(nk_{sa}+2\xi_s)$,
$K_{1s}=\{1-\exp[-nk_{pa}(t_{sa}-t_{ss})]\}/nk_{pa}$,
$K_{2s}=[(\omega_1-\omega)^2-\xi_s(nk_{pa}+\xi_s)]/[(nk_{pa}+\xi_s)^2+(\omega_1-\omega)^2]$,
$K_{3s}=\exp[-(nk_{pa}+\xi_s)(t_{sa}-t_{ss})]/[(nk_{pa}+\xi_s)^2+(\omega_1-\omega)^2]$,
$K_{4s}=(\omega_1-\omega)^2-\xi_s(nk_{pa}+\xi_s)$,
$K_{5s}=(\omega_1-\omega)(nk_{pa}+2\xi_s)$,
$N_{1t}=[(\omega_1-\omega)^2-\xi_t^2]/[(\omega_1-\omega)^2+\xi_t^2]$,
$N_{2t}=\exp[-\xi_t(t_{ta}-t_{ts})]/[(\omega_1-\omega)^2+\xi_t^2]$,
$N_{3t}=(\omega_1-\omega)^2-\xi_t^2$,
$N_{4t}=2\xi_t(\omega_1-\omega)$,
$R_{1t}=\{1-\exp[-nk_{sa}(t_{ta}-t_{ts})]\}/nk_{sa}$,
$R_{2t}=[(\omega_1-\omega)^2-\xi_t(nk_{sa}+\xi_t)]/[(nk_{sa}+\xi_t)^2+(\omega_1-\omega)^2]$,

$$R_{3t} = \exp[-(nk_{sa}+\xi_t)(t_{ta}-t_{ts})]/[(nk_{sa}+\xi_t)^2+(\omega_1-\omega)^2],$$
$$R_{4t} = (\omega_1-\omega)^2 - \xi_t(nk_{sa}+\xi_t),$$
$$R_{5t} = (\omega_1-\omega)(nk_{sa}+2\xi_t),$$
$$K_{1t} = \{1-\exp[-nk_{pa}(t_{ta}-t_{ts})]\}/nk_{pa},$$
$$K_{2t} = [(\omega_1-\omega)^2-\xi_t(nk_{pa}+\xi_t)]/[(nk_{pa}+\xi_t)^2+(\omega_1-\omega)^2],$$
$$K_{3t} = \exp[-(nk_{pa}+\xi_t)(t_{ta}-t_{ts})]/[(nk_{pa}+\xi_t)^2+(\omega_1-\omega)^2],$$
$$K_{4t} = (\omega_1-\omega)^2 - \xi_t(nk_{pa}+\xi_t),$$
$$K_{5t} = (\omega_1-\omega)(nk_{pa}+2\xi_t).$$

Chemical Behavior of Intermediates Produced in Sulfuric Acid Glass by Gamma Irradiation. I. Reactivities of Mobile Electrons with Inorganic Ions

Teikichi SASAKI

Chemistry Division, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11

(Received March 31, 1973)

The yield of the trapped hydrogen atom, H_t, produced in the 6 M sulfuric acid matrix at 77 K was decreased by the presence of an electron scavenger. Based on the competition reaction kinetics, the reactivities of mobile electrons, e_m^-, with metallic and oxygen-containing ions were determined from the decrease in the H_t yield. It was found that e_m^- is scavenged most efficiently with the TeO_4^{2-} ion. The relative reaction rates of e_m^- with oxyanions were generally larger than those of the corresponding e_{aq}^- reactions. On the other hand, a good accordance in the reaction rates for both forms of electrons was observed in the cases of the reactions with metallic ions. An interpretation was given to the discrepancy in the observed reaction rates that e_m^- in the epithermal energy region goes over the Coulomb barrier, which is too high for e_{aq}^- to pass through, and thus reacts more efficiently with anionic species than does e_{aq}^-. Some unstable intermediates produced at 77 K polymerized with the solute during the thermal annealing. The ESR and optical spectra of the polymerized cadmium and molybdenum are shown, together with those of the primarily-produced species.

It is well recognized that e_m^- in an acidic matrix is converted into H_t:[1]

$$e_m^- + P \longrightarrow H_t \quad (1)$$

where P is a reaction partner of e_m^-, such as an H^+ or HSO_4^- ion. The addition of an electron scavenger, S, depresses the H_t formation:

$$e_m^- + S \longrightarrow S^- \quad (2)$$

From competition reaction kinetics applied to the e_m^- concentration, the following equation is obtained:[2]

$$G_0(H_t)/G(H_t) = 1 + k_s[S]/k_p[P] \quad (3)$$

where $G_0(H_t)$ and $G(H_t)$ are the G values of H_t in the absence and in the presence of the electron scavenger, and where k_s and k_p are the rate constants for the reaction of e_m^- with S and P respectively.

Kevan[2] has reported on the reactivities of e_m^- in the acidic matrix and concluded that the relative rates, except that of the reaction of e_m^- with the H^+ ion, were approximately proportional to those of e_{aq}^- at room temperature. However, similar studies using the other matrices[3,4] showed some deviations from the results which would be expected from the corresponding e_{aq}^- reactions. The disagreement might arise from a difference in the experimental method; Kevan employed acidic matrices with a low H_t yield ($G(H_t)=0.14$—0.27),[5] while the latter authors directly measured the disappearance of trapped electrons, e_t^-, in the matrices of high e_t^- yields ($G(e_t^-)=2.8$).[4]

Recently, Steen and Kongshaug[6] found, by employing an ethylene glycol-water matrix, that the relative scavenging efficiency of such anionic solutes as NO_3^- and $ClCH_2COO^-$ ions diminished with a decrease in the energy of the electron, *i.e.*, in the order of the dry electron, e^-, e_m^-, and the stabilized electron, e_s^-, produced in an ethylene glycol-water matrix at 77 K. We ourselves have also reported[4] that the relative rates of the e_m^- reactions in the same matrix are not always in accordance with those of the e_{aq}^- reactions, and that larger relative e_m^- rates were obtained, especially in the reaction with polynegative complex ions.

For the e_m^- reactions in sulfuric acid glass, Brown and Dainton[7] have studied the reactivities with Ag^+, Cd^{2+}, and In^{3+} ions by means of spectrophotometry. However, no correlation with the reactivity has been derived from their data.

The H_t yield in the frozen solution of 6M sulfuric acid is comparatively large ($G(H_t)=1.3$ at 77 K[8]) and the matrix becomes homogeneously glassy upon rapid freezing, which is convenient for the estimation of the reactivity of e_m^- from the decrease in the H_t yield. In the present paper, the relative rates of the e_m^- reactions in the acidic matrix were determined for 18 inorganic ions. Though it is qualitative, a distinct difference in the reactivity was observed between the e_m^- and e_{aq}^- reactions. This discrepancy seems to arise from an essential difference in the average kinetic energy possessed by the two entities at the time of the scavenging reaction rather than from the difference in the matrix or phase employed.

Experimental

Materials. The water was redistilled, and the ethylene glycol was fractionally distilled. As matrices, a 67 vol % ethylene glycol-water solution was used in the case of the e_m^- reaction with the H^+ ion, while in the other cases 6M sulfuric acid was employed.

Sulfates or alkali metal salts were generally used for the reactivity determinations of e_m^-. In the case of the reaction with the Ag^+ ion, silver nitrate was used as a solute. Since the NO_3^- ion itself is a strong e_m^- scavenger, the reaction rate was estimated from the summation of the efficiencies for Ag^+ and NO_3^- ions. All of the chemicals tabulated in Tables 1 and 2 were of an analytical reagent grade and were used without further purification.

Irradiation and Measurement. The samples which were made into a glassy state without any degassing treatment were exposed to gamma rays from a ^{60}Co source for 2 hr at 77 K. The dose rate was 4×10^{18} eV g^{-1} hr^{-1}. The ESR measurements were performed at 77 K in the absence of power saturation, and the optical measurements were carried out as has previously been described.[4] The H_t yield was determined from the ESR signal intensity in the higher magnetic field, while the estimation of the e_t^- yield was based

on the method which will be described in the following section.

The thermal treatments above 77 K were done by using a variable-temperature accessory. The sample vessel was composed of double tubes of Pyrex glass which were covered with adiabatic material. An inner tube, 20 cm long and 1.5 cm in *i.d.*, was covered with paraffin wax, and a heating coil was wound on the outside of the wall. This tube was then inserted into a larger Pyrex tube covered with asbestos. The vessel was dipped in liquid N_2. The temperature of the sample was measured with a platinum resistance thermometer and held within ± 1 °C with a Chino E501 temperature controller.

Results and Discussion

Electron-scavenging Efficiency of Sulfuric Acid. The total scavenging efficiency of sulfuric acid for e_m^- was estimated from the decrease in the e_t^- concentration. On exposure to gamma rays, the ethylene glycol-water glass acidified with sulfuric acid develops a deep blue color which arise from the e_t^-. The color completely disappears above the acidic concentration of *ca.* 0.5 M or upon photobleaching with a light of wavelengths $\lambda \geq 390$ nm. The SO_4^- radical, which is

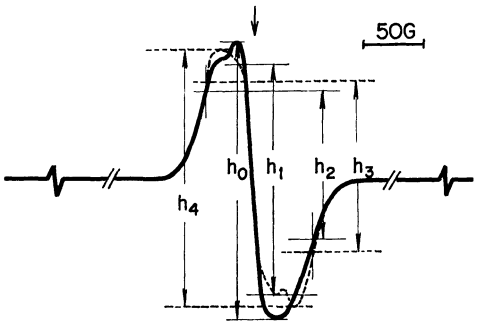

Fig. 1. ESR spectra of gamma-irradiated 67 vol % ethylene glycol-water glass containing 5×10^{-2}M sulfuric acid.
——— before photobleaching
---------- after bleaching by light of tungusten lamp

characterized by its bright yellow color, is not observed in the region of sulfuric-acid concentrations employed.

The ESR spectra (the 1st differential) of the gamma-irradiated sample are shown in Fig. 1. The shapes are essentially the same as those reported previously.[4)] After photobleaching, the central singlet which mainly arises from e_t^- disappears and the triplet which is probably due to the ethylene glycol radical increases, as may be seen in Fig. 1. The H_t yield is dependent upon neither the photobleaching procedure nor the concentration of sulfuric acid.

The absolute e_t^- concentration is proportional to the difference in the intensity of the integrated ESR spectra at the e_t^- position before and after photobleaching. In the preliminary examinations, however, the following simple method was confirmed to give a reliable estimate of the relative e_t^- concentration. By photobleaching, the singlet spectrum of e_t^- is probably converted to the triplet spectrum of the ethylene glycol radical.[9)] Consequently, the contribution of the triplet at the e_t^- position increases by h_1h_3/h_2, where h_1 is the signal intensity of the triplet at the e_t^- position and where h_2 and h_3 are the intensities of the triplet before and after photobleaching respectively. Therefore, the relative e_t^- concentration, $C(e_t^-)$, is approximately given as follows:

$$C(e_t^-) \simeq (h_0 - h_1h_3/h_2)/h_4 \quad (4)$$

where h_0 is the signal intensity at the e_t^- position before photobleaching. A normalization factor, h_4, is the total intensity of the ethylene glycol radical, regardless of the concentration of sulfuric acid employed. These notations are also presented in Fig. 1.

Based on the competition reaction kinetics described previously,[4)] the value of $[C_0(e_t^-)/C(e_t^-) - 1]$, where $C_0(e_t^-)$ is the relative e_t^- concentration in the absence of sulfuric acid, is plotted against the acidic concentration in Fig. 2. The total scavenging efficiency of 8.0 M^{-1} obtained for sulfuric acid is 0.21 of that for the NO_3^- ion in the same matrix. The chemical species which can scavenge e_m^- in the sulfuric acid matrix are H^+ and HSO_4^- ions.[1,10)] Because the reaction rate of e_m^- with the H^+ ion was given as 0.12 $k(e_m^- + NO_3^-)$ in the experiment using chloric acid,[3)] the rate with the HSO_4^- ion is estimated as follows:

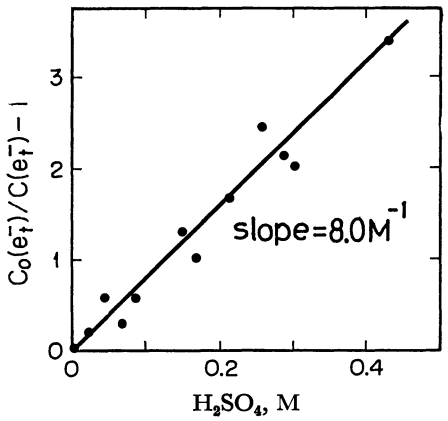

Fig. 2. Relationship between $[C_0(e_t^-)/C(e_t^-)-1]$ and sulfuric acid concentration.

$$k(e_m^- + HSO_4^-) = k(\text{total}) - k(e_m^- + H^+)$$
$$= (0.21/a - 0.12) \times k(e_m^- + NO_3^-) \quad (5)$$

where a is an activity coefficient of the HSO_4^- ion in the medium. Assuming that the coefficient is the same as that in the 0.1 M solution at 0 °C, *i.e.*, 0.34, the reaction rate of e_m^- with the HSO_4^- ion is found to be equal to 0.50 $k(e_m^- + NO_3^-)$.

Electron-scavenging Efficiencies of Inorganic Ions. The ESR spectra of the gamma-irradiated samples which contained the Cd^{2+} ion are displayed in Fig. 3. The spectrum of the 6 M sulfuric acid glass is also shown for purposes of comparison. The doublet pattern of H_t is diminished efficiently by the presence of the Cd^{2+} ion. Because the reduction of the Cd^{2+} ion with e_{eq}^- is very fast ($k < 5.2 \times 10^{10}$ M^{-1} s^{-1}),[11] whereas that of the Cd^{2+} ion with the hydrogen atom is negligibly slow at room temperature ($k = 10^5$ M^{-1} s^{-1}),[12] the above observation implies that the reaction partner of the Cd^{2+} ion is not the hydrogen atom, but e_m^-. This finding allows us to estimate the reactivity of e_m^- from the decrease in the H_t yield.

Frohlinde *et al.* have reported that the H_t in the 6 M sulfuric acid glass is subject to thermal decay, even at 77 K.[14] This was confirmed in the present study; the rate was increased by the addition of the electron scavenger. The fraction decaying in the first

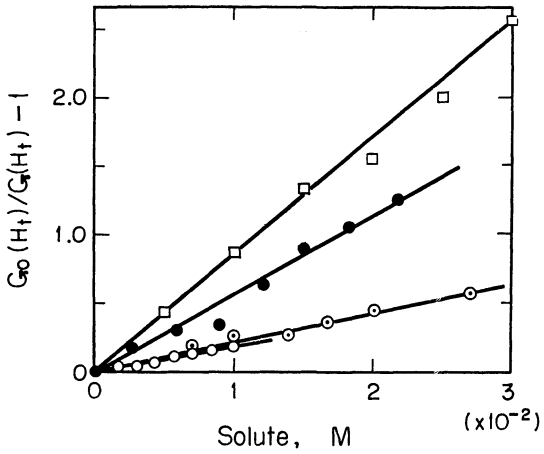

Fig. 4. Relationships between $[G_0(H_t)/G(H_t)-1]$ and solute concentration.
○: Cd^{2+}, ●: Fe^{3+}, ⊙: MoO_4^{2-}, □: TeO_4^{2-}.

2 hr amounted to 18% for the pure matrix and 27% for the matrix containing 5×10^{-2} M Cu^{2+} ions respectively. Therefore, the precise H_t yields were obtained by correcting the thermal decay at 77 K.

Based on Eq. (3), the relative rates of the e_m^- reaction can be determined from the slope of the straight line obtained by plotting $[G_0(H_t)/G(H_t)-1]$ against $[S]$. Some of the plottings are shown in Fig. 4. The relative reaction rates are summarized in Tables 1 and 2. The corresponding data known about the reactivities of e_{aq}^- in neutral solution are also presented. All the values normalized to unity for the reaction of $(e_m^- + Cd^{2+})$ or $(e_{aq}^- + Cd^{2+})$. As may be seen in the tables, the most effective e_m^- scavengers are the Fe^{2+} ion in the cationic solutes and the TeO_4^{2-} ion in the anionic solutes.

In the reaction of the Cr^{3+} ion with e_m^-, the relative rate is less than that which would be expected from the corresponding e_{aq}^- reaction, while in the case of the Ag^+ ion the reactivity amounts to 2.2 times the expected value. At present, it is impossible to give a reasonable interpretation of this irregularity. In the cases of the other metallic ions, the relative rates of the e_m^- reaction are roughly proportional to those of the e_{aq}^- reaction. These results are consistent with the previous observations for e_m^- in the ethylene glycol-water matrix.[4] On the other hand, in the cases of the oxyanions listed in Table 2 the reactivities of e_m^- seem to be independent of those of e_{aq}^-, and they are mostly larger than those of the e_{aq}^- reaction. This discrepancy seems to be closely related to the difference in the kinetic energy at the time of the scavenging reaction. The maximum concentration of e_t^- in alkaline glass has been determined to be 5.4×10^{17} g^{-1}, *viz.*, 2.4×10^{-2} M.[15] Assuming a homogeneous spatial distribution, the e_t^-'s are estimated to be 41 Å distant from each other. Furthermore, the e_t^- yield is reduced to 50% by the addition of 2.5×10^{-2} M acrylamide, an effective electron scavenger.[16] After all, the e_m^- in the acidic glass is also expected to travel a distance of over 20.5 Å before it is captured by the solute. Therefore, the electron in the system containing a

sufficient amount of the scavenger may encounter the solute a few times during the slowing-down processes. It is probable that the e_m^- in the epithermal energy region goes over the Coulomb barrier, which is too high for e_{aq}^- to pass through, and thus reacts more efficiently with the anionic species. In other words, the present results suggest that the electron can be scavenged even in the somewhat higher-energy region before slowing down to the thermal energy. This postulation is supported by the results of a previous experiment,[4] where the relative rates of the e_m^- reaction with polynegative cyano and oxalato complex ions are also larger than those which would be expected from the e_{aq}^- reaction.

(a) 3×10^{-2}M TeO_4^{2-}. The sample has been annealed at 152 K.
(b) 4×10^{-2}M MoO_4^{2-}. The sample has been annealed at 154 K.

Spectra of the Reaction Products. Several fine spectra of the reaction intermediates could be obtained by thermal annealing at *ca.* 150 K, where the SO_4^- radical completely disappears. A difference spectrum (Figs. 3(b)—(a)) and a spectrum after thermal annealing for the samples containing the Cd^{2+} ion, both of which have axially symmetric *g*-factors, are shown in Fig. 5. The spectrum in Fig. 5(a) has a line shape attributable to the Cd^{1+} ion primarily formed.[17,18] The most intense signal in Fig. 5(b), which is complicated by the superposition of the Cd^{1+} ion, is assigned to a diatomic cation, *i.e.*, the Cd_2^{3+} ion found previously at 233 K.[18] These observations indicate that even in the solid phase, the migration of the Cd^{1+} ion takes precedence over the electron transfer from the Cd^{1+} ion to the SO_4^- radical.

Figure 6(a) shows the irradiated specimen containing the TeO_4^{2-} ion. The tellurium of the 5-valency state has an unpaired electron in its 4d shell, and it is expected to give rise to an intense singlet with a weak doublet due to ^{125}Te (6.99%, $I=1/2$). Therefore, the spectral pattern in Fig. 6(a) may be attributed to Te(V), *i.e.*, the TeO_4^{3-} ion. However, this assignment remains somewhat tentative, because no information is known about the spectral characteristics of the Te(V) species.

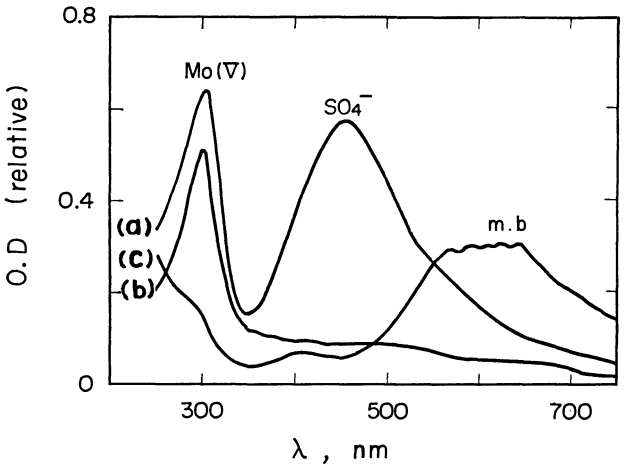

Fig. 7. Optical spectra of gamma-irradiated 6 M sulfuric acid glasses containing 4×10^{-2}M MoO_4^{2-}.
(a) after irradiated at 77 K
(b) after thermal annealing at 154 K
(c) after thermal annealing at 250 K

After the thermal annealing at 154 K, the irradiated glass containing the MoO_4^{2-} ion remained bright yellow, but it turned dark blue above *ca.* 190 K. The optical absorption spectra are displayed in Fig. 7. The spectrum of the blue species is assigned to molybedenum blue,[19] which is a nonstoichiometric polymolybdate composed of the Mo(V) and the Mo(VI) oxides.[20] The ESR pattern of the bright yellow species is shown in Fig. 6(b). There are two magnetic isotopes of molybdenum in natural abundance, ^{95}Mo (15.7%, $I=5/2$) and ^{97}Mo (9.45%, $I=5/2$). The molybdenum of the 5-valency state has unpaired electron in the 4d shell. Hence, we may assign the sixtet splitting to

the hyperfine coupling of ^{95}Mo and ^{97}Mo, which is overlapped with a stronger central singlet due to the nonmagnetic molybednum nuclei.

From these observations it may be concluded that the Mo(V) species primarily produced polymerize with some MoO_4^{2-} ions during the thermal annealing as in the case of the Cd^{1+} ion. By performing thermal-annealing experiments on the frozen specimen, much information would be obtained on the inorganic polymerized species, which are hard to be detected at room temperature.

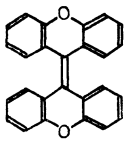
The Dianion of 9,9′-Bixanthenylidene and Its Reaction with Oxygen. A Contribution to Photochromism

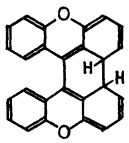
Mikio HOSHINO, Masao MATSUI, and Masashi IMAMURA
The Institute of Physical and Chemical Research, Wako, Saitama 351
(Received April 16, 1973)

The anion produced by the reduction of 9,9′-bixanthenylidene with sodium or potassium metal was identified with the dianion by pulse radiolysis. It appears that the dianion is twisted around the central ethylenic bond. The dianion reacts with oxygen at 100 K to produce a colored form, the spectrum of which is in accord with that of the transient species observed in the flash photolysis of 9,9′-bixanthenylidene. The colored form is expected to be produced *via* a twisted 9,9′-bixanthenylidene, because the oxygen is considered to remove electrons from the twisted dianion. This twisted intermediate may also participate in the photochromic or thermochromic reaction in which the same-colored form is produced.

9,9′-Bixanthenylidene is known to be one of the thermochromic ethylenes, and the structure of the colored form has been assumed to be a dihydro-form of a species, A, which is obtained as the stable photoproduct.[1,2]



Species A



Dihydro- form of A

The same color is observed on UV irradiation at low temperatures, and it fades reversibly in the dark in a few minutes.[3] The above structure of the colored form was assumed by analogy from the facts that *cis*-stilbene, which has the same ethylenic bond, shows photochromism in a deaerated solution and, that its colored form is considered to be the dihydro-form of phenanthrene.[4,5]

A similar dihydro-form has been assumed for the colored form of thermochromic 10,10′-bianthrone. It has been found that, in the presence of oxygen, helianthrone and *meso*-naphthobianthrone are produced; the dihydro-forms of these stable photoproducts are produced in the absence of oxygen.[6–8]

It seems, therefore, that in many cases the colored form of the thermochromic ethylenes is a dihydro-form of the stable photoproducts.

In 1959, Woodward and Wasserman[9] showed that the reaction of the anion of 10,10′-bianthrone with methanol gave rise to the formation of the colored form. We ourselves have found that the colored form of 9,9′-bixanthenylidene is produced by the reaction of its anion with oxygen at low temperatures. The mechanism of this reaction has now been studied by using flash photolysis and pulse radiolysis with the aim of elucidating the mechanism of the photochromic reactions.

Experimental

9,9′-Bixanthenylidene was prepared by the reduction of xanthone with zinc powder and acetic acid in the presence of hydrochloric acid. The purification was done by recrystallization from a methanolic solution. The tetrahydrofuran (THF) and 2-methyltetrahydrofuran (MTHF) were stored on the metallic alloy of potassium and sodium *in vacuo*. The benzene and ethanol were extra-pure reagents from Wako Pure Chemical Industries.

The details of the flash photolysis apparatus have been described previously.[10] The photolysis flash consisted of two xenon lamps, 80 J in power and 50 μs in duration.

The pulse radiolysis was carried out by using 2.7 MeV pulsed electrons, 0.5 or 1.0 μs in duration, generated from a Van de Graaff accelerator; the details have been described elsewhere.[11]

The absorption spectra of stable products were recorded on a Cary 14 R spectrophotometer.

Results and Discussion

Flash Photolysis. Figure 1 shows the transient absorption spectrum observed immediately after the flash photolysis of 9,9′-bixanthenylidene in a deaerated benzene solution. The spectrum had an absorption peak at 620 nm and decayed with a first-order rate constant of $1.8\times10^4\ s^{-1}$ at room temperature. In an aerated solution, the same spectrum was observed; the amount of intermediate species produced (at 620 nm) per flash and the decay rate were identical with those in a deaerated solution within the limits of experimental errors. These results indicate that the transient species may be produced *via* the excited singlet state.

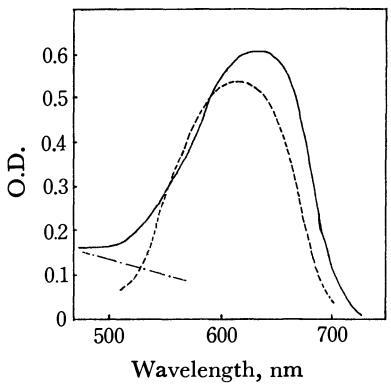


Fig. 1. Absorption spectra of the colored substance.
------: The transient species formed upon flash photolysis in benzene at room temperature;
——: The colored substance produced by the reaction of the dianion of 9,9′-bixanthenylidene with oxygen at low temperature (100 K) in MTHF.

On the other hand, Hirshberg and Fischer[3] found that the colored form is produced on the UV irradiation of 9,9′-bixanthenylidene at low temperatures. The spectrum is in accord with the transient spectrum obtained by the present flash photolysis. They also studied the dependence of the decay rate of the colored form on the temperature, and evaluated the kinetic parameters of a "critical increment" [12] and a frequency factor over the temperature range from −150 to −170 °C. Using these parameters, one can estimate the rate constant of the decay at room temperature to be $2.5 \times 10^4\ s^{-1}$; this value is in agreement with that obtained for the transient species by the flash photolysis.

From these results, it may be concluded that the transient absorption in the flash photolysis is due to the colored form of 9,9′-bixanthenylidene produced by UV irradiation at low temperatures.

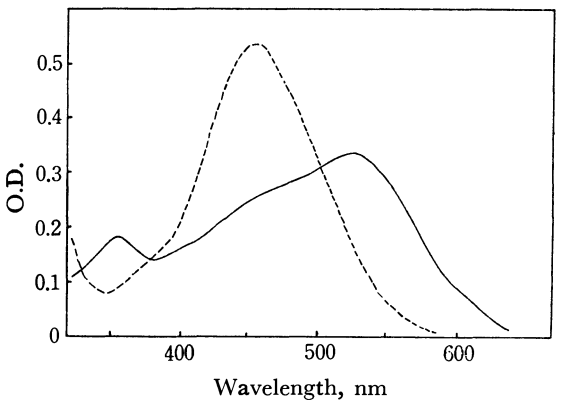

Fig. 2. Absorption spectra of the dianion of 9,9′-bixanthenylidene (——) and potassium xanthenylide (------) in MTHF at room temperature.

Reaction of Dianion with Oxygen. When 9,9′-bixanthenylidene was reduced in a MTHF solution by metallic sodium or potassium, the solution turned reddish-brown and had an absorption peak at 520 nm, as is shown in Fig. 2. The colored species may be regarded as a monoanion or a dianion because the color of the solution fades rapidly upon the introduction of air. It was identified with the dianion by pulse radiolysis, as will be described in the next section.

The solution turned brilliant blue and had an absorption peak at 630 nm when the dianion was in contact with the air at a low temperature (100 K). The resulting spectrum is similar to that of the transient species produced by the flash photolysis, as is shown in Fig. 1, indicating that the two species are identical.

The colored form was stable so long as the solution was kept at 77 K, but it disappeared rapidly with an increase in the temperature. This suggests that the viscosity of the solution plays an important role in the reversion reaction (colored→colorless).

Hirshberg and Fischer[3] found that photochromism occurs above −120 °C in the mixed glassy media of methanol and ethanol. They also mentioned that the phenomenon takes place only in a fluid solution.

Pulse Radiolysis of 9,9′-Bixanthenylidene. Figure 3 shows the transient spectrum of the monoanion of

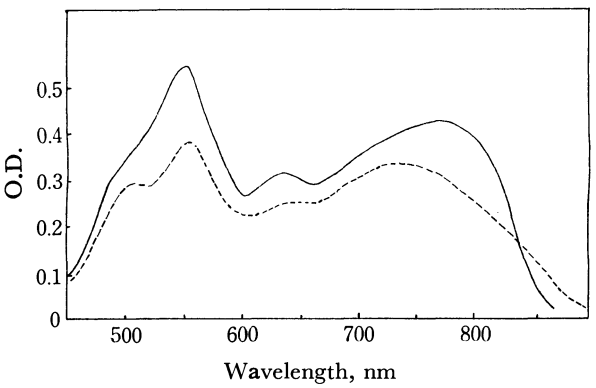

Fig. 3. Absorption spectra of the monoanion of 9,9′-bixanthenylidene.
——: Produced by γ-ray irradiation at 77 K;
------: Produced by pulse radiolysis at room temperature.

9,9′-bixanthenylidene produced by pulsed electron irradiation in a MTHF solution at room temperature. The ion is produced according to:

$$\text{MTHF} \rightsquigarrow e^- + \text{MTHF}^+$$

$$e^- + \text{M} \longrightarrow \text{M}^- \quad (\text{M: solute}).$$

A similar spectrum of the monoanion was observed by the steady Co^{60}-γ rays irradiation of 9,9′-bixanthenylidene in MTHF at 77 K.

In view of the difference between the spectrum of this monoanion and that of the ion produced by the reduction of 9,9′-bixanthenylidene with alkali metals, the latter one may possibly be regarded as being due to the dianion.

It is also noted that the monoanion does not appear to change in structure in going from 77 K to room temperature, because the electronic spectra are similar at both temperatures.

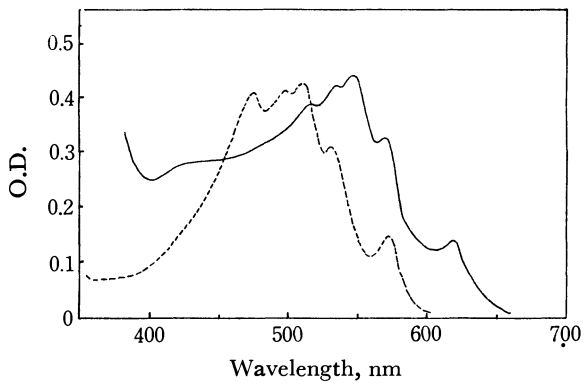

Fig. 4. Absorption spectra of the dianion of 9,9′-bixanthenylidene (——) and potassium xanthenylide (------) at 77 K in MTHF.

Structure of the Dianion. In Fig. 4, the absorption spectrum of the dianion is compared with that of potassium xanthenylide, both of which were obtained in MTHF solutions at 77 K.

If the dianion is assumed to be twisted around the ethylenic bond, the spectrum is expected to be similar to that of the xanthenyl carbanion. Although the

absorption band of the dianion is located in a longer wavelength region compared with that of the carbanion, the same vibrational progression is found in both spectra. It is, therefore, reasonable to assume that the dianion has a twisted structure at 77 K. The slight shift of the absorption band of the dianion to longer wavelengths may be interpreted in terms of the bathochromic effect due to the substituted xanthenyl moiety.

The structure of the stilbene dianion was discussed by Garst *et al.*,[13] who proposed a geometry in which the two benzylidene moieties are rotated around the central ethylenic bond to an angle of 90°. Suzuki *et al.*[14] studied the twisted forms of the dianion of stilbene derivatives and interpreted the absorption spectra on the basis of the MO calculation.

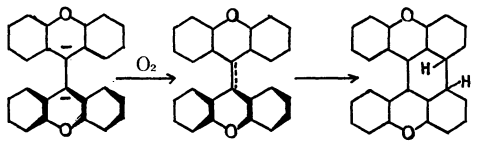
The dianion with a central ethylenic bond is likely to be twisted around the bond.

Intermediate as a Precursor of the Colored Form. The reaction of oxygen with anions of aromatic molecules is considered to give rise to the formation of the original molecules:

$$M^- \text{ (or } M^{2-}) + O_2 \longrightarrow M \text{ (M: aromatic molecule)}$$

where oxygen is assumed to act simply as an electron acceptor.

In the case of the 9,9′-bixanthenylidene dianion, the reaction with oxygen at low temperatures has been shown to produce a colored compound, not original 9,9′-bixanthenylidene. This result may be explained by assuming that the elimination of two electrons from the twisted dianion gives rise to the formation of a metastable intermediate which is also twisted and which immediately forms the colored compound:



(Twisted intermediate)

In view of the fact that the same colored substance is formed in either the photochromic or thermochromic reaction, this intermediate is formed in both cases, although it could not be detected by the flash photolysis.

We wish to thank Miss. Yuriko Moribe for her assistance with the flash photolysis study, and Dr. Tadamasa Shida and Dr. Shigeyoshi Arai for thier enlightening discussions.

The Crystal Structure of *dl*-1,1,4a*α*-Trimethyl-2*α*-hydroxy-8*β*-methoxy-1,2,3,4,4a,5,6,7,8,9-decahydrophenanthrene

Akio FURUSAKI, Nobuyuki HAMANAKA, and Takeshi MATSUMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received April 24, 1973)

The crystal structure of the title compound has been determined from three-dimensional data collected on an automatic, four-circle diffractometer. The racemic crystals are triclinic, with two molecules in a unit cell of these dimensions; $a=10.502$, $b=11.706$, $c=7.488$ Å, $\alpha=71°33'$, $\beta=91°46'$, and $\gamma=116°22'$. The space group is $P\bar{1}$. The structure was solved by the symbolic addition method and was then refined by the block-diagonal-matrix least-squares method, with isotropic temperature factors for the hydrogen atoms and with anisotropic ones for the others. The final R value was 6.7%. The length of the C–C single bond opposite to the double bond in the cyclohexene ring is only 1.34 ± 0.01 Å. This apparent remarkable shortening can be well explained on the assumption that the two atoms concerned vibrate vigorously with parallel and antiparallel harmonic components perpendicular to the plane of the ring. It is shown that, if the root-mean-square amplitudes of the former components are taken to be equal to that of the thermal vibration of the carbon atom adjacent to one of the two atoms, the above C–C distance, corrected for these antiparallel motions, becomes quite reasonable: 1.60 Å.

It has recently been reported that the Birch reduction of 1,1,4a*α*-trimethyl-2*α*-hydroxy-8-methoxy-1,2,3,4,4a,9-hexahydrophenanthrene, I, produced an unexpected product, II.[1] The X-ray study of the *p*-bromobenzoate of II has revealed that the C ring of cyclohexene-type shows an unusual thermal behavior in the crystalline state.[2] In order to obtain more accurate information about the behavior of the C ring, an X-ray crystallographic analysis of II itself has now been carried out.

II

Experimental

Colorless, single crystals of II (racemate), $C_{18}H_{28}O_2$ (mp 162—164 °C), were obtained from a chloroform solution. A crystal with dimensions of about $0.2\times0.3\times0.4$ mm was used for the X-ray measurement. The crystal data are summarized in Table 1. The cell dimensions were measured by using a single-crystal diffractometer with Cu$K\alpha$ radiation ($\lambda=1.54178$ Å). The space group was assumed to be $P\bar{1}$ at the beginning of the study; this choice was later confirmed by a successful refinement. The intensity data were collected on an automatic, four-circle diffractometer at this University, using Cu$K\alpha$ radiation monochromatized with a LiF crystal. The intensity measurement was made by using an ω-2θ continuous scan at a rate of about 0.5°(ω)/min; the background was measured for 30—60 s at each end of the scan range. The intensities thus obtained were corrected for the Lorentz and polarization factors, but not for either the absorption or the extinction effect. In all, out of the structure factors of reflections with 2θ values up to 140°, 2276 above $3\,\sigma(F)$ were selected for the structural study.

Table 1. The crystal data

Crystal system Space group	Triclinic $P\bar{1}$
a	10.502 ± 0.002 Å
b	11.706 ± 0.003
c	7.488 ± 0.002
α	$71°33'\pm2'$
β	$91°46'\pm3'$
γ	$116°22'\pm2'$
Z	2
D_x	1.183 g/cm^3

Structure Determination

The structure was solved by the direct method on the basis of 511 $|E|$ values above 1.30.[3] The origin was specified by assigning positive signs to three linearly-independent reflections, as is shown in Table 2. At the early stage of the structure determination, the symbolic addition procedure was carried out by the use of three symbols, A, B, and C. However, this procedure turned out to be unsuccessful, for no E-maps calculated from the eight possible combinations of the numerical values of the symbols afforded an acceptable structure. This difficulty was overcome by adding a fourth symbol, D. The correct combination of the values of the symbols, $A=B=C=\pi$ and $D=0$, was chosen by the method that had been used in the structure determination of the acetolysis product of II.[4] An E-map calculated with 461 phases clearly revealed the positions of all twenty non-hydrogen atoms. The structure thus obtained was refined at first by the block-diagonal-matrix least-squares method with isotropic temperature factors. After it had been ascertained that there was no other remarkable peak in a Fourier diagram, the structure was further refined by the

Table 2. The starting set

h	k	l	$\|E\|$	φ
2	7	3	4.73	0

least-squares method, anisotropic thermal motions being assumed for all the non-hydrogen atoms. In this way, the discrepancy factor, R, was reduced to 11.9%. Out of the twenty-eight hydrogen atoms in the molecule, twenty-six were located in a difference Fourier map. The least-squares refinement was further repeated including these hydrogen atoms. In this refinement, the following weighting scheme was used:

$$W = 1/\{\sigma(F_o)^2 \exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$ and $Y=\sin\theta/\lambda$.[4] The intensity data were grouped with constant intervals along two coordinates, $|F_o|$ and $\sin\theta/\lambda$. The coefficients, A, B, C, D, and E, were determined by the least-squares fit so as to give as equal values of $\langle W|\Delta F|^2\rangle$ for all the groups as possible. The final R value was 6.7%. The atomic parameters thus obtained are listed in Table 3.

The calculations for the present study were performed on a FACOM 230-60 computer at the Computer Center of Hokkaido University, using our own programs. The atomic scattering factors were taken from International Tables for X-ray Crystallography (1962), Vol. III. The tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan (Document No. 7408).

Results and Discussion

The molecular framework of II and the torsion angles for the tricyclic system are given in Figs. 1 and 2 respectively. The molecular conformation of II is found to resemble closely that of its *p*-bromobenzoate derivative, hereafter called III;[2] the A and B rings take a distorted chair- and a somewhat flattened boat-form respectively, while the C ring has a considerably flattened half-chair conformation, with the methoxyl group oriented axially. A closer examination of the torsion angles shows that the conformational differences between the corresponding A, B, and C rings of II and III become greater in that order. This seems strange at first sight, since II differs from III simply in having a free hydroxyl group instead of a *p*-bromobenzoyloxy group in the A ring. However, this might be explained in terms of the theory that the unstable and flexible conformation of the C ring is more or less influenced by the hydrogen-bond formation of the methoxyl oxygen atom, with the hydroxyl group in another molecule.

The bond lengths and angles calculated with the final coordinates are listed in Tables 4 and 5 respectively. In the present molecule also, the C(12)–C(13) distance is found to be unusually shorter than the normal C–C single bond length. A detailed account of this remarkable shortening will be given later. The intramolecular hydrogen-hydrogen distances less than 2.40 Å are listed in Table 6.

The conformation of the A ring in II is closely parallel to that in III; for example, the greatest of the differences between the corresponding torsion angles is only 2.6°, and the average torsion angles for the two

rings are also in good agreement with each other. The distribution of the valence angles in the A ring is similar to those in III and in the acetolysis product of II, hereafter called IV;[4] *i.e.*, the valence angles at the C(1) and C(3) atoms are significantly greater than the normal tetrahedral angle. This may be due to the existence of the exocyclic double bond, C(5)=C(6). The conformations of the three methyl groups attached to the A ring are shown in Fig. 3. The deviations of the two axial methyl groups, $C(16)H_3$ and $C(17)H_3$, from the staggered conformation, 10° and 7°, are both slightly smaller than the corresponding values for III. On the other hand, the conformation of the equatorial methyl group, $C(15)H_3$, deviates by about 6° from the staggered arrangement; this value is about 3° larger than that for III. These small variances of the rotation angles found in II and III probably result from the delicate difference in the conformations of the tricyclic systems. The hydroxyl group, O(1)H, is equatorially bonded to the A ring. The azimuthal angle of the O(1)–H(O) and C(3)–H(3) bonds around the C(3)–O(1) bond is about 33°. This approach to the eclipsed arrangement may be attributable to the formation of the O(1)–H(O)···O(2′) hydrogen bond. In fact, the O(1)–H(O)–O(2′) angle is about 180°.

Table 7. The deviations (Å) of the atoms from the least-squares plane

C(8)	0.019	C(12)[a]	0.105
C(9)	0.029	C(13)[a]	−0.246
C(10)	−0.053	C(14)	−0.052

a) These atoms were omitted from the calculation of the least-squares plane.

With respect to the plane which bisects the C(5)–C(10)–C(9) or C(6)–C(7)–C(8) angle, the conformation of the B ring in II is less symmetrical than that in IV. Although one of the two ethylenic parts, >C(5)=C(6)<, holds a good planarity, the other, >C(8)=C(9)<, deviates to some extent from a planar configuration. The deviations of the atoms from the least-squares plane through the C(7), C(8), C(9), C(10), C(11), and C(14) atoms are given in Table 7. The angle between this plane and the least-squares plane through the C(4), C(5), C(6), C(7), and C(10) atoms is about 11.8°; this is about 3.3° and 8.2° smaller than the corresponding angles for III and IV respectively.

As will be seen in Fig. 1, the C ring in II is unusually flattened, although it keeps approximately the C_2 symmetry characteristic of the half-chair conformation. The C(12) and C(13) atoms are, respectively, only about 0.14 and 0.18 Å displaced above and below the mean plane through the other four atoms in the ring; the sum of these deviations, 0.32 Å, is remarkably smaller than that in IV, 0.73 Å, and that in cyclohexene, 0.7346 Å.[5] It is of great interest to examine why the C ring in II is forced to take such an unusually-flattened conformation. The closest approach of the methylene groups, $C(1)H_2$ and $C(11)H_2$, is found between the two equatorial hydrogen atoms, H(1–2) and H(11–2), their distance being about 2.10 Å; this is only slightly greater than the distance between the overcrowded hydrogen atoms in phenanthrene, 2.04 Å.[6] Since the less the equatorial nature of the H(11–2) atom is, the more distant the H(1–2) and H(11–2) atoms become, it is clear that the flattened conformation of the C ring prevents the two hydrogen atoms from approaching each other at an extremely small distance. The unusual conformation of the C ring is, therefore, perhaps caused mainly by the strong steric repulsion between the H(1–2) and H(11–2) atoms. On the other hand, an X-ray study of IV has revealed that the C ring in IV takes the normal half-chair form in which the axial positions in II become equatorial and *vice versa*.[4] This is probably because the equatorial hydrogen atoms, H(1–2) and H(11–1), maintain a distance of about 2.23 Å without any large deformation of the C ring. If this is the reason, then the question arises of why the C ring in II does not take the same conformation as that in IV. The most conceivable reason is that the allylic axial methoxyl group might have the effect of stabilizing the cyclohexene system, probably by allowing the transfer of some π-electrons on the C(8)=C(9) double bond into the overlapping antibonding orbital of the C(14)–O(2) bond.[7] The stabilization due to the delocalization of π-electrons would overcome the energy loss resulting from the great deformation of the C ring.

The length of the C(12)–C(13) bond is found to be about 1.343 Å; this is almost equal to the value for III, 1.340 Å. However, both the results of elemental analysis and the NMR spectrum clearly show that the C(12)–C(13) bond should be a single one.[1] This conflict may be resolved by taking account of the unusual thermal vibrations of the C(12) and C(13) atoms. The thermal ellipsoids of atoms in the C ring are shown in Fig. 4, while the root-mean-square deviations and direction cosines in the principal axes of the ellipsoids are given in Table 8. It is found that all

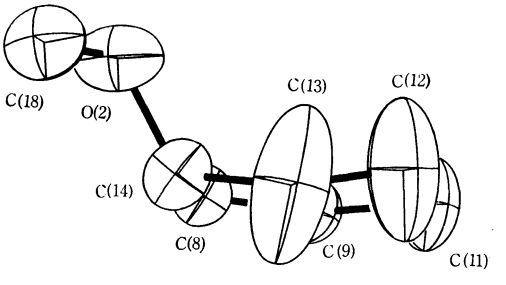

Fig. 4. The thermal behavior of the C ring. The thermal ellipsoids are scaled to enclose 50% probability.

Table 8. The root-mean-square deviations and direction cosines in the principal axes of the thermal ellipsoids

$B_i=8\pi^2u_i^2$ where u_i is the root-mean-square deviation corresponding to the ith axis of the ellipsoid. C_{ia}, C_{ib}, and C_{ic} are the direction cosines of the i axis with respect to the orthogonal coordinate axes by **b** $\times$ **c***, **b**, and **c***.

the six atoms in the C ring vibrate most vigorously in a direction almost perpendicular to the mean plane of the ring. Above all, the anisotropy of the thermal motions of the C(12) and C(13) atoms is very conspicuous; their greatest root-mean-square deviations are about 0.52 and 0.59 Å respectively. In a previous paper,[2] we pointed out that, even though the C(12)–C(13) bond distance is corrected for these large thermal motions, the correction is very small so long as the riding motion is assumed, but that if a highly-correlated antiparallel motion is assumed for the two atoms, the corrected distance becomes too large (1.73 Å). This suggests that the thermal motions of the C(12) and C(13) atoms may contain both parallel and antiparallel components.

Let us consider a one-dimensional harmonic oscillator which moves along the x axis, with the point 0′ as the equilibrium position. If the 0′ point further vibrates harmonically round the origin of the coordinates, 0, much more slowly than the oscillator moves round the 0′ point, then the probability of finding simultaneously the 0′ point between X and $X+dX$ and the oscillator between x and $x+dx$, $P(x, X)dxdX$, may be represented approximately by the following equation:

$$P(x,X)dxdX \propto \exp\left\{-\frac{X^2}{2\bar{u}_1^2}\right\}\times\exp\left\{-\frac{(x-X)^2}{2\bar{u}_2^2}\right\}dxdX$$

$$=\exp\left\{-\frac{1}{2}\left(\frac{1}{\bar{u}_1^2}+\frac{1}{\bar{u}_2^2}\right)\left(X-\frac{x}{1+\bar{u}_2^2/\bar{u}_1^2}\right)^2\right\}$$

$$\times\exp\left\{-\frac{x^2}{2(\bar{u}_1^2+\bar{u}_2^2)}\right\}dxdX,$$

where $\bar{u}_1$ and $\bar{u}_2$ are, respectively, the root-mean-square amplitude of the 0′ point and that of the oscillator with respect to the vibrating point, 0′. Accordingly, the probability of finding the oscillator between x and $x+dx$, $P(x)dx$, is given by the equation:

$$P(x)dx=\int_{-\infty}^{\infty}P(x,X)dxdX\propto\exp\left\{-\frac{x^2}{2(\bar{u}_1^2+\bar{u}_2^2)}\right\}dx$$

$$=\exp\left\{-\frac{x^2}{2\bar{u}^2}\right\}dx.$$

The apparent mean-square amplitude of the oscillator, $\bar{u}^2$, is thus given by the sum of $\bar{u}_1^2$ and $\bar{u}_2^2$. The thermal motions of the C(12) and C(13) atoms in the direction perpendicular to the mean plane of the C ring might be approximated by such a special harmonic oscillator model. In this case, the oscillation of the 0′ point corresponds to the parallel vibrational components of the two atoms arising from the thermal motion of the whole molecule as a rigid body, while the harmonic motion of the oscillator with respect to the 0′ point corresponds to the antiparallel components resulting from the internal vibration of the C ring. Since the thermal vibration of the C(11) atom does not seem to be very closely related to the antiparallel motions of the C(12) and C(13) atoms, it would be reasonable to use its greatest root-mean-square deviation as the approximate $\bar{u}_1$ value of the two atoms. From this value of $\bar{u}_1$, 0.34 Å, and the observed values of $\bar{u}$ for the C(12) and C(13) atoms, 0.52 and 0.59 Å, we obtain $\bar{u}_2$=0.39 and 0.48 Å for these two atoms respectively. In case of the antiparallel motions, the mean-square distance, $\bar{r}^2$, is given by the equation: $\bar{r}^2=s^2+\bar{r}_0^2$, where s is the sum of the $\bar{u}_2$ values of the two atoms and where r_0 is the observed distance between their equilibrium positions. Since both the effect on the $\bar{r}^2$ of the parallel motions of the C(12) and C(13) atoms and that of their thermal vibrations in the directions parallel with the mean plane of the C ring seem to be very small, it is expected that the C(12)–C(13) distance can be corrected to a considerable extent by using this equation. In fact, the value thus obtained, 1.60 Å, is much closer to the standard C–C distance, 1.54 Å, than the uncorrected value, 1.34 Å. That the correction is too great is probably in part due to the underestimation of the $\bar{u}_1$ value used in the calculation, and in part to the presence of the anharmonic components in the thermal motions of the C(12) and C(13) atoms.

The complicated thermal motions found in II are probably caused by the highly-strained conformation of the C ring. Compared with the ordinary half-chair form, such an unusually-flattened conformation is considerably unstable. This would bring about the vigorous, antiparallel vibrations of the C(12) and C(13) atoms. That, in the cyclohexene ring, the bond corresponding to the C(12)–C(13) is too short has previously

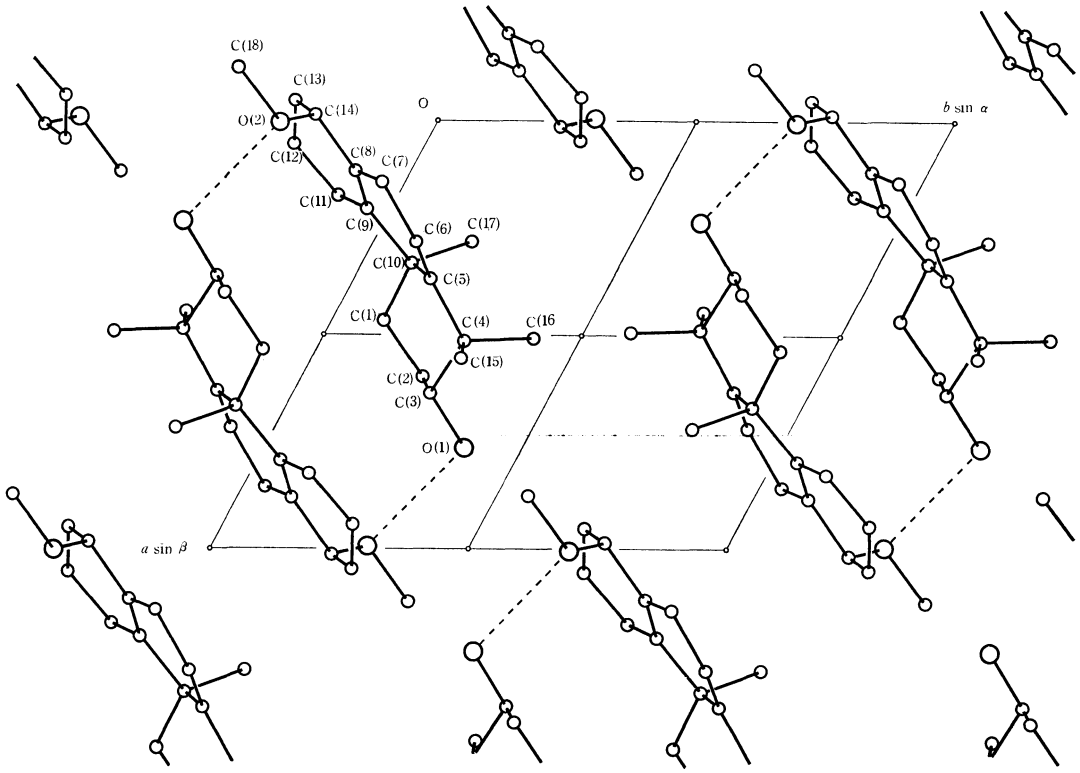

Fig. 5. The molecular arrangement viewed along the c axis.

been noticed in canthaxanthin[8] and in the *trans* isomer of β-ionylidenecrotonic acid.[9] In the former case, the shortening was interpreted as being due to the existence of two separate ring conformations in one single crystal, while, in the latter case, it was not clear whether the shortening was attributable to the conformational disorder or to the large asymmetric vibrations of the ring. When the C ring in II flips from one normal half-chair form to the other, the O(2) atom is shifted by about 0.7 Å. This shows that, if the present crystal had a disordered structure with respect to the two possible half-chair conformations of the C ring, it would contain two kinds of O(2)···O(1′) hydrogen bonding; for the normal half-chair form (A-form) where the O(2) atom is axial, the O(2)···O(1′) distance is estimated to be about 2.7 Å, while, for the other (B-form) where the O(2) atom is equatorial, it is about 3.2 Å.* In the case of such a disordered structure, the number of molecules with the A-form would be considerably larger in the crystal of II than in the crystal of III; in other words, the apparent conformation of the C ring in II would be much closer to the A-form than that in III, because, although the O(2) atom does not take part in the hydrogen-bond formation in the latter crystal, it can form a stable hydrogen bond in the former crystal if the C ring takes the A-form. However, in fact, almost the same conformations are observed for II and III. Accordingly, in the present case, it seems more reasonable to consider the remarkable shortening of the C(12)–C(13) bond as due to the special thermal vibrations of the C(12) and C(13) atoms rather than to the conformational disorder.

As has already been mentioned, out of the twenty-eight hydrogen atoms in a molecule, two were not located in the difference Fourier map. These two are the same axial hydrogen atoms at the C(12) and C(13) atoms that could not be found in the crystal structure of III. The fact that the axial hydrogen atoms are difficult to locate is obviously related to the complicated thermal vibrations of the C(12) and C(13) atoms.

The O(2)–C(18) bond makes an azimuthal angle of about 41° with the C(14)–H(14) bond and one of about 78.8° with the C(13)–C(14) bond around the C(14)–O(2) bond.

The molecular arrangement viewed along the c axis

C(2)···C(18)	3.726(3)	O(2)···C(3)	3.525(4)
		C(3)···C(8)	3.865(4)

I: $x/a, y/b, z/c$ (given in Table 3). II: $x/a, y/b, 1+z/c$. III: $x/a, y/b, -1+z/c$. IV: $1+x/a, 1+y/b, z/c$. V: $-1+x/a, -1+y/b, z/c$. VI: $1+x/a, 1+y/b, -1+z/c$. VII: $-1+x/a, -1+y/b, 1+z/c$. VIII: $-x/a, -y/b, 1-z/c$. IX: $1-x/a, -y/b, 1-z/c$.

* In this estimation, it was assumed that the C(13) atom deviates by 0.367 Å from the plane of the C(8)=C(9) double bond, and that the bond distances and angles for the C(8) and C(14) atoms are equal to those in Tables 4 and 5.

is shown in Fig. 5, while the short intermolecular distances are listed in Table 9. The molecules make a hydrogen bond, O(1)–H···O(2′), with each other at a distance of about 2.80 Å to form a dimer around a center of symmetry. The hydrogen-bonded dimers thus formed are further held together mainly by the ordinary van der Waals interactions.

The Crystal and Molecular Structure of *meso*-(2*S*, 4*s*, 6*R*)-2,4,6-Heptanetriol

Shunsuke KURIBAYASHI

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda 563

(Received June 20, 1973)

The crystal structure of *meso*-(2*S*,4*s*,6*R*)-2,4,6-heptanetriol has been determined by means of X-ray methods. The crystal belongs to monoclinic system (space group Ic), with four molecules in a unit cell with dimensions of a=8.133, b=9.374, c=11.248 Å, and β=93.24°. The structure was solved by three-dimensional Patterson and trial-and-error methods. The final R factor was 0.076. The molecule has the GTTḠ conformation, and all of the OH groups are linked together by intermolecular hydrogen bonds.

The crystal and molecular structures of stereoregular vinyl polymers are of great interest. The structure of stereoregular polyvinyl alcohol has been proposed on the basis of the IR and NMR spectra and X-ray diffractions.[1-9] The configurations and conformations of 2,4,6-heptanetriol as a model compound have been studied by NMR and IR spectroscopy.[10-14] The present paper will report on the crystal and molecular structure of *meso*-(2*S*,4*s*,6*R*)-heptanetriol as a model compound of isotactic polyvinyl alcohol.

Experimental

The sample was prepared by the method reported by Fujii.[15] This compound was a highly viscous liquid, but it crystallized gradually upon standing in cold storage overnight. The specimens suitable for X-ray analysis were crystallized from a dioxane solution. They were colorless and needle-like elongated along the c axes or of a lozenge shape. Since the sample was very hygroscopic, it was enclosed in a glass capillary during exposure to X-rays.

The dimensions of the unit cell were determined by using a Syntex, on-line-controlled, four-circle diffractometer.

The density of the crystal, measured by the flotation method, was about 1.15 g cm^{-3}; this is in good agreement with the calculated value.

The probable space group is Ic or I2/c; the former was chosen, as the molecule can be placed neither on the center of symmetry nor on the two-fold axis. The crystallographic data are listed in Table 1.

Table 1. Crystallographic data

Space group Ic	

Multiple-film equi-inclination Weissenberg methods were applied to the layer lines from 0 to 8 and from 0 to 6 about the c and a axes respectively, using Ni filtered Cu$K\alpha$ radiation. The diffracted intensities were estimated visually by comparison with the standard scale. A total of 874 non-zero independent reflections were observed by these procedures. The corrections for Lorentz polarization and the spot-shape factors were made in the usual way, but no correction was made for absorption or extinction.

Structure Determination

From the three-dimensional Patterson function, it was deduced that the molecular axis made an angle of about 55° with the c axis and that the zigzag plane was nearly perpendicular to the b axis. From the consideration of the interatomic distances and internal rotation angles about the C–C–C–C–C bonds, it was deduced that five molecular models having different sequences of T, G, and/or Ḡ must be taken into account; they were (i) TTTT, (ii) GTTT, (iii) GTTḠ, (iv) TTGT, and (v) GTGT. We rotated each molecular model at an interval of 6° in Eulerian angles, fixing the middle carbon atom at x=0, and z=0, so that the lower-order calculated structure factors, $|F(h0l)|$'s, agreed relatively well with the observed $|F(h0l)|$'s. As a good agreement was obtained for the third model, we terminated these procedures without examining TTGT or GTGT.

The y parameters for all the atoms were introduced on the assumption that the y coordinate of the molecule is very close to 0, as the 020 is much stronger than the other $0k0$ reflections. With these parameters, the block-diagonal least-squares methods with isotropic temperature factors were applied on the TOSBAC 3400-41 using a program, HBLS IV, written by T. Ashida. After ten cycles of iterations, the discrepancy factor, R, for all the observed reflections decreased to 0.14. Further refinements were carried out with anisotropic temperature factors. After six cycles of iterations, the R factor decreased to 0.098. All of the hydrogen atoms were found in the difference Fourier map calculated at this stage, but their coordinates were thought not to be reliable. All of thier positions except for those bonded to oxygen were, therefore, determined assuming C–H bond lengths of 1.09 Å and bond angles of 109.5°. Fixing the calculated coordinates of the hydrogen atoms, six cycles of least-squares refinements were carried out. The R reduced to 0.076. The function to be minimized was $\sum w\Delta^2$, where:

$$w = (20.0/|F_0|) \quad \text{for } |F_0| > 20.0$$
$$w = 1 \quad \text{for } 20.0 \geq |F_0| \geq 5.0, \text{ and}$$
$$w = 0.3 \quad \text{for } |F_0| < 5.0$$

The final atomic coordinates and temperature factors, with their standard deviations, are listed in Tables 2 and 3. A list of observed and calculated

O (3)	95(4)	110(4)	108(4)	−18(3)	−56(3)	23(3)

structure factors is given in Table 4.*

Results and Discussion

The crystal structure projected along the b and c axes are shown in Figs. 1 and 2 respectively. The molecular structure is schematically shown in Fig. 3. As may clearly be seen from this figure, the molecule has a GTTḠ conformation, all of the hydroxyl groups are linked together by intermolecular hydrogen bonds, and their mean distances is 2.71 Å. The shortest van der Waals contact is 3.86 Å for C···C and 3.47 Å for C···O. The torsional angles about the C–C bonds are listed in Table 5. The best plane, composed of C(2) C(3), C(4), C(5), C(6), O(1), and O(3), is expressed by the equation:

$$-0.2495x + 0.9529y + 01856z + 0.1630 = 0$$

where x, y, and z are in Å units with respect to the crystallographic axes. The deviations from this plane are listed in Table 6.

The C–C and C–O bond lengths and the C–C–C

TABLE 5. TORSIONAL ANGLES

	Torsional angles (°)
C(1)-C(2)-C(3)-C(4)	55.2
C(2)-C(3)-C(4)-C(5)	178.5
C(3)-C(4)-C(5)-C(6)	175.9
C(4)-C(5)-C(6)-C(7)	−70.3
O(1)-C(2)-C(3)-C(4)	177.5
O(3)-C(6)-C(5)-C(4)	171.6

* Table 4 has been deposited with the Chemical Society of Japan (Document No. 7403)

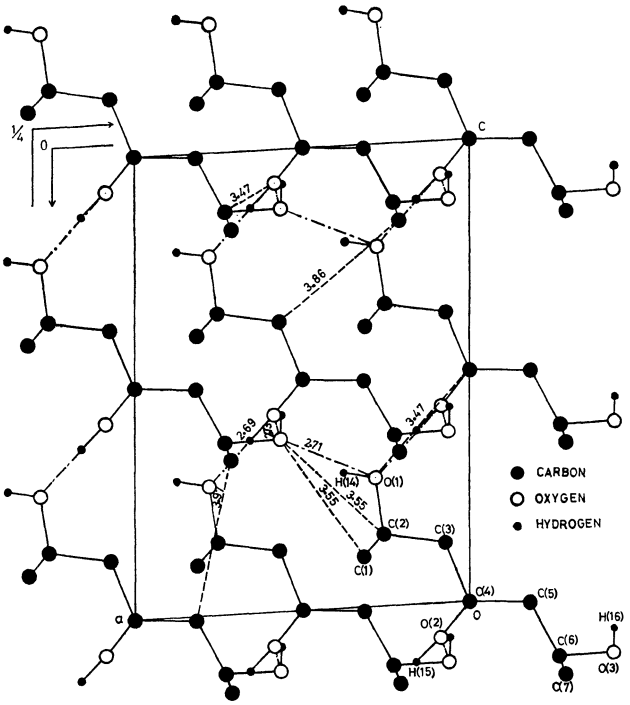

Fig. 1. The crystal structure viewed along the b axis. Only the hydrogen atoms attached to oxygen are indicated. The van der Waals distances shorter than 4.0 Å for C-----C and 3.6 Å for C-----O are shown by broken lines. The hydrogen bonds are also shown by chain lines.

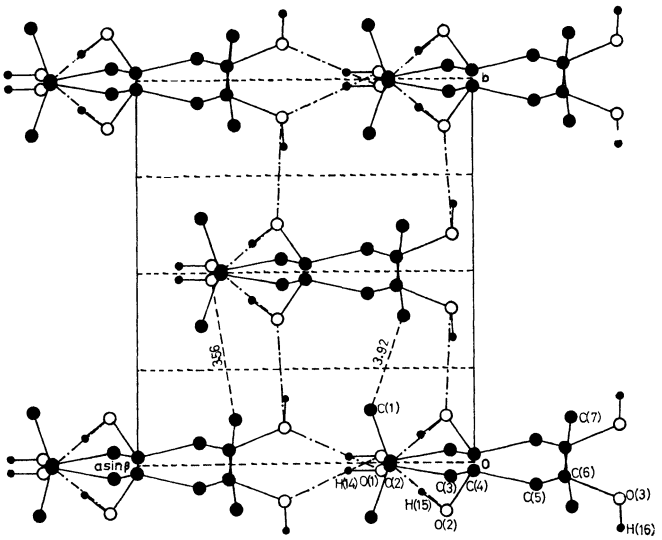

Fig. 2. The crystal structure viewed along the c axis. The hydrogen bonds are shown by chain lines.

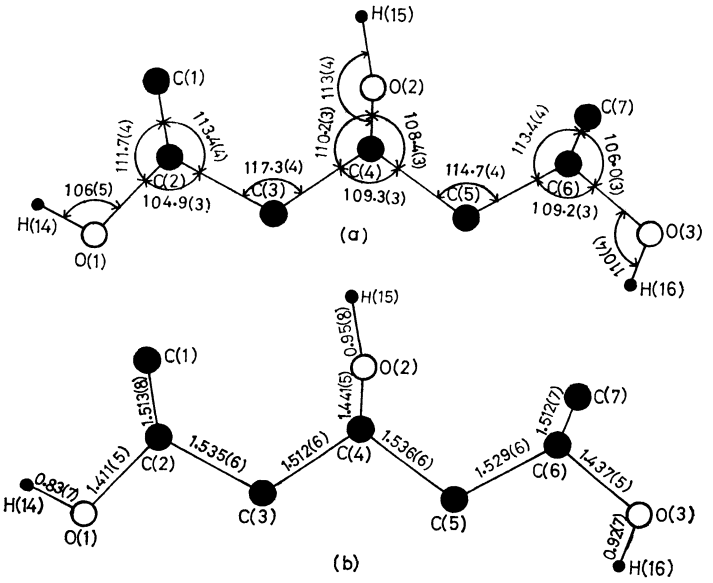

Fig. 3. Bond angles (degree) (a) and lengths (Å) (b).
Hydrogen atoms attached to carbon are omitted.

Table 6. Deviation of each atom from the best plane

Atom	Deviation (Å)
C(2)	−0.063
C(3)	0.007
C(4)	−0.024
C(5)	0.018
C(6)	0.090
O(1)	0.042
O(3)	−0.071

and C–C–O bond angles agree well with those observed in ordinary aliphatic compounds, except for C(2)–C(3)–C(4), which is remarkably large.

It is thought to be unwize to discuss these results in comparison with those obtained by NMR or IR spectroscopy in solution,[10–14] as the solvents and thermal effects may affect the conformations and hydrogen bondings of the molecule. The structure of isotactic polyvinyl alcohol has a TTT sequence, and all of the hydroxyl groups are linked together by intermolecular hydrogen bonds,[1–3] which is quite different from the present trimer structure. There might be some metastable states or polymorphism. We expect to elucidate these points by future studies.

The author is indebted to Mr. Takahiko Kawaguchi of Ritsumeikan University for his assistance in experiments and helpful discussions. The author also wishes to express his thanks to Dr. Tamaichi Ashida and Dr. Toshio Sakurai for providing him computing facilities.

The Thermal Decomposition of Formaldehyde in the Presence of Nitric Oxide

Kohji TADASA,* Naomi IMAI, and Tetsuo INABA

Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Sakai, Osaka 591

(Received June 21, 1973)

The pyrolysis of formaldehyde was investigated in the presence of nitric oxide at 500 °C. The kinetics of the reaction suggests that the pyrolysis proceeds by means of a mechanism which is initiated by this reaction:

$$NO + CH_2O \longrightarrow HNO + CHO$$

and which involves this reaction:

$$HNO + HNO \longrightarrow N_2 + 2OH$$

as one of the chain-carrying steps.

Nitric oxide has generally been used as an inhibitor in the free-radical reactions in the gaseous phase. This compound, however, has been found to have an accelerative effect on the free-radical reaction in addition to an inhibitive one. Thus, the mechanisms of reactions containing nitric oxide are so complex that the reaction schemes proposed by various workers do not necessarily coincide with each other.

Both effects of nitric oxide are typically exhibited in the pyrolysis of dimethyl ether;[1-3] that is, the pyrolysis is suppressed almost completely by the addition of a small amount of nitric oxide, and, after maximal inhibition, it is linearly accelerated by an increased amount of nitric oxide. Thus, the inhibitive and accelerative parts in the kinetics are very clearly separated in the case of dimethyl ether, suggesting that this compound is suitable for a study of the effects of nitric oxide.

It is known that the free-radical decomposition of dimethyl ether follows this stoichiometric relation:

$$CH_3OCH_3 \longrightarrow CH_4 + CH_2O$$

and that the formaldehyde thus formed decomposes easily by a chain reaction following this stoichiometric relation:

$$CH_2O \longrightarrow CO + H_2.$$

In the presence of nitric oxide, however, the amount of hydrogen in the product of dimethyl-ether pyrolysis is very small compared with that of carbon monoxide, in contrast to the case of the absence of nitric oxide, suggesting that the reaction mechanism is complex, though the kinetics is very simple.

This work was attempted in order to investigate the effect of nitric oxide on the thermal decomposition of formaldehyde; we expected to obtain valuable information about its effect on that of dimethyl ether.

Experimental

Materials. The formaldehyde was prepared by the distillation of paraformaldehyde at about 120 °C, condensing the methanol and water involved by means of at −78 °C. The nitric oxide was obtained from the Takachiho Kagaku Co. Ltd. in a research-grade purity of 99.6%. It was subjected to several trap-to-trap distillations.

Apparatus. The reaction was studied in a conventional static system, and was carried out in a cylindrical Pyrex glass vessel of 210 cm^3 placed in an electric furnace, which was itself wrapped in asbestos and placed inside a cylindrical aluminium collar (20 cm in length, 9 cm in diameter, and with walls 1.6 cm thick) to hold the temperature constant.

Procedure. Required quantities of formaldehyde and nitric oxide were introduced into the vessel, which had until then been kept at the experimental temperature. In order to avoid the decomposition of the formaldehyde alone, the two substances were introduced in the order of (i) nitric oxide and (ii) formaldehyde. The products of decomposition were analyzed quantitatively by means of a gas chromatograph.

Analysis. After the pyrolysis, using a Toepler gauge, the unreacted reactants and products were passed through a trap at −78 °C, where a part of the unreacted formaldehyde and the high-boiling-point products, methanol and water, were condensed. The uncondensable fraction at −78 °C was passed through a trap at −196 °C, where the remaining parts of the unreacted formaldehyde, the unreacted nitric oxide, the carbon dioxide, and the nitrous oxide were condensed, while the uncondensable fraction at −196 °C was collected and measured by means of the Toepler gauge. That fraction was composed of carbon monoxide, hydrogen, and nitrogen. The quantity of each fraction of the products was measured by means of a gas chromatograph. Carbon monoxide, hydrogen, and nitrogen were analysed on a 2 m Molecular Sieve 5A column at room temperature, the carbon dioxide and nitrous oxide, on a 4 m Porapak Q column at room temperature, and the methanol, on a 2 m PEG-400 column at 80 °C. No quantitative analysis of formaldehyde was carried out; some of it polymerized on a glass tube of the collecting system, so accurate measurement was very difficult. Identification was achieved by using IR, a mass spectrometer, NMR measurements, and an elemental analyzer as well as a gas chromatograph.

Results

The yields of carbon monoxide, hydrogen, methanol, nitrogen, nitrous oxide, and carbon dioxide were measured at various times during the uninhibited and inhibited pyrolyses of formaldehyde. Some results are shown in Fig. 1. The figure shows that the amount of each product increases linearly with the time after 5 min even though the rate is higher at the beginning of the reaction. In this work the initial rate of the formation of each product was determined from the

* Present address: Department of Agricultural Chemistry, College of Agriculture, Shinshu University, Ina, Nagano 396

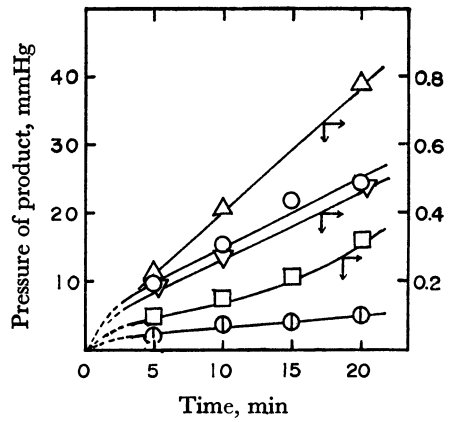

Fig. 1. Yields of products in the pyrolysis of 100 mmHg formaldehyde for 50 mmHg nitric oxide at 500°C.
○: CO, ⊕: N_2, □: N_2O, △: H_2, ▽: CO_2

slope of the line in the yield-time curve, except for the true initial part of the curve.

A series of runs was carried out at 500 °C using a fixed pressure of formaldehyde (100 mmHg) and various pressures of nitric oxide between 10 and 100 mmHg. The results for each product are shown in Figs. 2 and 3. The amount of water, which was measured by means of a gas chromatograph, is not very accurate. The rate of carbon monoxide formation follows a typical inhibition curve. It has a lower limit and then tends to increase with the nitric oxide pressure.

The formation of hydrogen is also inhibited, but after maximal inhibition the rate of its formation is very low compared with that of carbon monoxide, just as in the case of dimethyl ether. The rate of nitrogen formation increases linearly with the pressure of nitric oxide. This means that nitrogen formation is dependent on the first-order kinetics of nitric oxide.

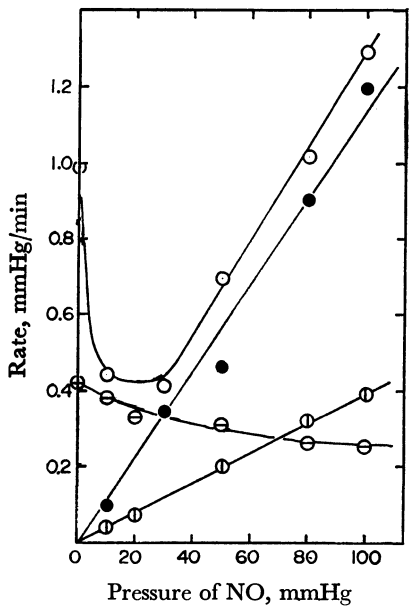

Fig. 2. The rates of product formation as a function of nitric oxide pressure in the pyrolysis of 100 mmHg formaldehyde at 500°C.
○: CO, ●: H_2O, ⊕: N_2, ⊖: CH_3OH.

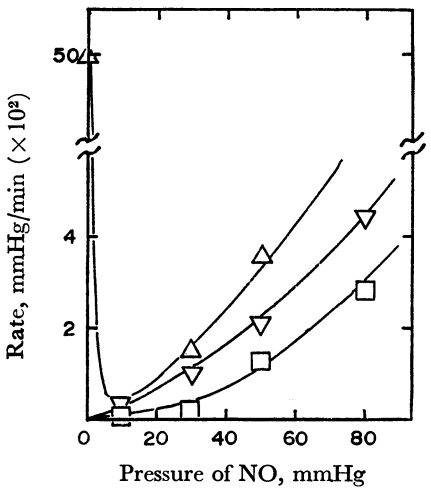

Fig. 3. The rates of product formation as a function of nitric oxide pressure in the pyrolysis of 100 mmHg formaldehyde at 500 °C.
△: H_2, ▽: CO_2, □: N_2O.

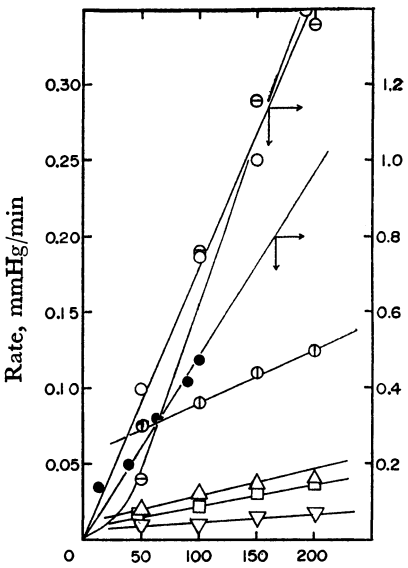

Fig. 4. The rates of product formation as a function of formaldehyde pressure in the pyrolysis of 50 mmHg nitric oxide at 500 °C.
○: CO, ●: H_2O, ⊕: N_2, ⊖: CH_3OH, △: H_2, ▽: N_2O, □: CO_2

The rates of both carbon dioxide and nitrous oxide formation also increase with the nitric oxide pressure, but their dependencies on nitric oxide are not clear because of a poor reproducibility.

Figure 4 shows the change in the rates of product formation at 500 °C using a fixed pressure of nitric oxide (50 mmHg) and various pressures of formaldehyde between 20 and 200 mmHg. These results show that each rate of product formation depends linearly on the formaldehyde pressure between 50 and 200 mmHg. However, the amount of water is not so accurate as in the case of Fig. 2.

Discussion

It has been well known that formaldehyde decomposes thermally *via* the reaction resulting from these two simulatneous stoichiometric equations:

$$2CH_2O \longrightarrow CO + CH_3OH \quad (I)$$

$$CH_2O \longrightarrow CO + H_2 \quad (II)$$

The former is a surface reaction,[4] while the latter is the following free-radical chain reaction.[5,6]

$$2CH_2O \longrightarrow CHO + H + CH_2O \quad (1)$$

$$CHO \longrightarrow CO + H \quad (2)$$

$$H + CH_2O \longrightarrow H_2 + CHO \quad (3)$$

$$CHO + CHO \longrightarrow CO + CH_2O \quad (4)$$

Methanol formation decreases slightly upon the addition of nitric oxide; therefore, Reaction (I) may be affected to only a small extent by the addition of nitric oxide. (A slight reduction of the rate of methanol formation by the addition of nitric oxide presumes a mild inactivation of the surface of a reaction cell by nitric oxide.)

On the contrary, the rate of carbon monoxide formation decreases greatly upon the addition of a small amount of nitric oxide; after the rate reaches its minimum, it increases linearly with the amount of nitric oxide added. The minimum rate of carbon monoxide formation, furthermore approximately equals that of methanol, indicating that the free-radical decomposition (II) is inhibited almost completely and that the increased rate after the minimum value is the result of free-radical decomposition accelerated by the addition of nitric oxide. In this paper, hereafter, the effect of nitric oxide on the free-radical decomposition will be described (mainly the accelerated part). The quantity of carbon monoxide produced by the free-radical process may be regarded as the difference between the total amount of carbon monoxide and that of methanol.

In the free-radical chain decomposition of formaldehyde alone (II), equal amounts of carbon monoxide and hydrogen are formed. On the other hand, in the presence of nitric oxide, as is shown in Figs. 2—4, very little hydrogen is produced after maximal inhibition; water, nitrogen, nitrous oxide, *etc.* are formed instead. A very rough ratio of the main products is:

$$CO:H_2O:N_2 = 1:1:1/2$$

The rates of their formation are first-order both for formaldehyde and nitric oxide after maximal inhibition.

The addition of nitric oxide to the pyrolysis should cause inhibition by means of the scavenging reaction of the hydrogen atom (3i) and, at the same time, acceleration by means of the inhibition reaction (1i):

$$H + NO \rightleftharpoons HNO \quad (3i)\ (-3i)$$

$$NO + CH_2O \longrightarrow HNO + CHO \quad (1i)$$

The formyl radicals formed by (1i) follow produce a hydrogen atom by means of Reaction (2). The very little formation of hydrogen in the inhibited decomposition shows that hydrogen atoms do not abstract the hydrogen atom as in (3); consequently, the chain decomposition of the formaldehyde propagated by (2) and (3) does not occur. Almost all of the H atom should undergo scavenging (3i), and the nitroxyl thus formed should react further. This reaction of nitroxyl should yield a nearly stoichiometric amount of water, since two atoms of hydrogen are formed for one molecule of carbon monoxide and nearly equal amounts of water and carbon monoxide are produced.

Nitroxyl is known to react as:[7]

$$HNO + HNO \longrightarrow N_2O + H_2O \quad (5)$$

The very low yield of nitrous oxide, however, indicates that (5) is not the main reaction for nitroxyl under the present conditions. Two reactions have been proposed between nitroxyl and nitric oxide:

$$HNO + 2NO \longrightarrow N_2 + H + NO_3 \quad (6)^{7}$$

$$HNO + 2NO \longrightarrow HNO_3 + N_2 \quad (7)^{8}$$

Since neither reaction yields water, neither is the main nitroxyl reaction. As another nitrogen formation step, Reaction (8) has been proposed:[9]

$$N_2O + H \longrightarrow N_2 + HO \quad (8)$$

This reaction, combined with Reaction (5) as a nitrous oxide source, should yield nitrogen with a half amount of water. If nitrogen is produced mainly by Reaction (8), however, the nitrogen yield-time curve should have a sigmoidal form and the rate of nitrous oxide formation should fall off. As shown in Fig. 1, this is not the case, indicating that Reaction (8) does not play an important role. (Reaction (8) is known to have a comparatively high activation energy *ca.* 11 kcal/mol.[10])

In the present work, an alternative reaction of nitroxyl (9) is proposed:

$$HNO + HNO \longrightarrow N_2 + 2OH \quad (9)*$$

As far as the energetics of this reaction are concerned, this is likely to occur: ΔH=3.6 kcal/mol.** The OH radical may produce water *via* Reactions (10)[11] and (11):

$$HO + HNO \longrightarrow H_2O + NO \quad (10)$$

$$HO + CH_2O \longrightarrow H_2O + CHO \quad (11)$$

If most of the hydroxyl radicals react as in Reaction (11), formaldehyde decomposes by means of a chain mechanism propagated by Reactions (3i), (9), (11), and (2). In the chain decomposition, the terminating step should be (5), (7), or (10), since nitroxyl radicals are the most abundant radicals. If formaldehyde does not decompose by means of a chain reaction, nitroxyl radicals are formed by Reactions (1i), (2), and (3), and the radical-consuming step should be Reactions (5), (7), or (10). Table 1 lists the simplified reaction mechanisms using the reactions described above and the rate equations derived from them. In this table, a sufficient long chain is assumed for the chain reactions.

Only Cases (i) and (vi) in the table are consistent

* This may proceed in a manner such as;

Reaction scheme	(1i) (2) (3i) (9) (11) (5)	(1i) (2) (3i) (9) (11) (7)	(1i) (2) (3i) (9) (11) (10)
rate equation	$R_{CO}=R_{H_2O}=(2k_{1i}k_9/k_5)$-$[CH_2O][NO]$ $R_{N_2}=(1/2)R_{H_2O}$ $R_{N_2O}=k_{1i}[CH_2O][NO]$	$R_{CO}=R_{H_2O}$ $=(2k_{1i}k_9/k_7^2)[CH_2O]^2$	$R_{CO}=R_{H_2O}=(k_{1i}k_9k_5^2/$ $2k_{10}^2)^{1/3}[CH_2O]^{4/3}[NO]^{2/3}$ $R_{N_2}=(1/2)R_{H_2O}$ $R_{N_2O}=(k_5/2k_9)R_{H_2O}$
case	(i)	(ii)	(iii)

Non chain reaction

	Radical consuming step		
	(5)	(7)	(10)
Reaction scheme	(1i) (2) (3i) (5)	(1i) (2) (3i) (7)	(1i) (2) (3i) (9) (10)
rate equation	$R_{H_2O}=R_{N_2O}$	$R_{H_2O}=0$	$R_{CO}=R_{H_2O}=k_{1i}$- $[CH_2O][NO]$ $R_{N_2}=(1/2)R_{H_2O}$ $R_{N_2O}=(k_5/2k_9)R_{H_2O}$
case	(iv)	(v)	(vi)

a) sufficient long chain is assumed

with the experimental results (excepting the molecular reaction); that is, both stoichiometric relation:

$$CH_2O + NO \longrightarrow CO + H_2O + (1/2)N_2$$

and the rate equation:

$$R_{CO} = k[CH_2O][NO]$$

hold approximately. We suggest that Reaction (11) progresses fast enough at the present temperature; hence, Case (i) is prefarable to (vi). As there is only a little change in the reaction order in the case of (iii), Reaction (10), besides (5), may be adopted as the termination step.

Nitrous oxide, since its formation is dependent on more than the first-order kinetics of nitric oxide, may be formed by (12) besides (5), which, as described in (i), leads to a linear relation to nitric oxide upon the nitrousoxide formation:

$$HNO + NO \longrightarrow N_2O + OH \qquad (12)$$

Thus we obtain: $R_{N_2O(12)}=k_{12}[HNO][NO]=(k_{12}k_{11}^{1/2}/k_5^{1/2})[CH_2O]^{1/2}[NO]^{3/2}$. The occurrence of this reaction (12) has little effect on the values of R_{H_2O} and R_{N_2}.

It has been established that nitric oxide is disproportionated by the chain reaction propagated by (3i) and (6) in the presence of the H atom at low temperatures. (This reaction, however, does not affect the rate of CH_2O decomposition reaction.) Judging from the results, the N_2 formation by (6) is negligible in comparison with that by (9):

$$R_{N_2(6)} = k_6[HNO][NO]^2 = (k_6k_{11}^{1/2}/k_5^{1/2})[CH_2O]^{1/2}[NO]^{5/2}$$

Even if, instead of (2), Reaction (13) occurs, it may produce no variation in the kinetics:

$$CHO + NO \longrightarrow CO + HNO \qquad (13)$$

Several workers have proposed different reaction schemes for the accelerating effect of nitric oxide on the gas-phase decomposition of simple organic compounds. Laidler *et al.* studied the pyrolysis of various organic compounds and proposed a chain mechanism.[12)] Applying their scheme to formaldehyde pyrolysis, the chain is initiated by (1i) and propagated by (2) and (3); consequently, hydrogen should be produced in the same amount of carbon monoxide.

Sabo *et al.* studied the pyrolysis of nitric oxide and acetaldehyde or higher aldehydes and proposed a different chain mechanism, where the propagating steps are:[13)]

$$R + NO \rightleftarrows RNO$$
$$RNO + RNO \longrightarrow RCO + RH + NO$$
$$RCO \longrightarrow R + CO$$

Applying this scheme, formaldehyde should yield equal amounts of CO and RH, that is H_2. Clearly, neither of these two schemes can be accepted for formaldehyde pyrolysis because of the low yield of hydrogen.

Pratt's scheme,[14)] which involves the isomerization of a nitroso compound to an oxime, also can not be applied to our system, because the nitroso compound in this system is nitroxyl.

The Thermal Behavior of Silanol Groups of Silica Gel as Studied by Infrared Spectroscopy. I*

Seiichi KONDO,*1 Masa-aki MUROYA,*2 and Kenzo FUJII*1

*1*Osaka University of Education, Tennoji, Osaka 543*

*2*Osaka Electrocommunication University, Neyagawa, Osaka 572*

(Received July 4, 1973)

The thermal behavior of the silanol of silica gel has been studied by quantitative infrared spectroscopy. Transparent and glass-like plates of silica gel of high purity, after they had been heat-treated at various temperatures below 680 °C, were used for the measurement of OH stretching vibrations ranging from 3100 to 3800 cm^{-1}. These absorption bands were analysed into the several component bands by the simulation method using a Dupont Co. Curve Resolver. The intensity of these bands in area were proportional to the OH concentrations as measured by the thermal method. Each component band disappeared at a temperature which was roughly equal to that obtained from the dielectric and conductivity measurements. From these results, assignment was attempted on the basis of these bands.

The nature of the silanol group of high-specific-surface-area silicas, such as silica gel, aerosil, and porous glass, has been studied in many laboratories in relation to its electric, thermodynamic, optical, and many other physical properties.[1,2] Among them, infrared spectroscopy has been proved to be one of the most useful tools for the investigation of the bond nature of the surfaces of these substances. In the case of aerosil, the broad absorption band of the silanol group has been extensively studied, and a few absorption bands have been reported to exist in this broad band. However, the analysis of these bands is not clear enough except for those very near to 3750 cm^{-1}. Also, few infrared absorption experiments have been carried out on silica gel because of the difficulty of preparing a specimen suitable for the infrared measurement. The purpose of this paper is to try to make a quantitative analysis of the absorption band of silica gel and to study some properties of the resolved component bands.

Experimental

Materials. Ethyl orthosilicate was hydrolyzed to silica sol in the presence of hydrochloric acid at about 70 °C and gelled on a plastic plate such as Teflon. The hydrogel thus formed was dried in air at room temperature. A thin glass-like plate, about 0.15 mm thick and 1 cm^2 wide, was obtained; the infrared transmittance of this sample at 4000 cm^{-1} was about 80%. The specific-surface-area, as determined by the BET N_2 method, and the weight loss of this sample when heat-treated at various temperatures are shown in Fig. 1. The pore volume was 0.33 cc/g. No alkali and alkali earth impurities were detected with the flame spectroscopic analysis within limits of experimental error of about ±1 ppm in the case of the sodium ion in silica gel.

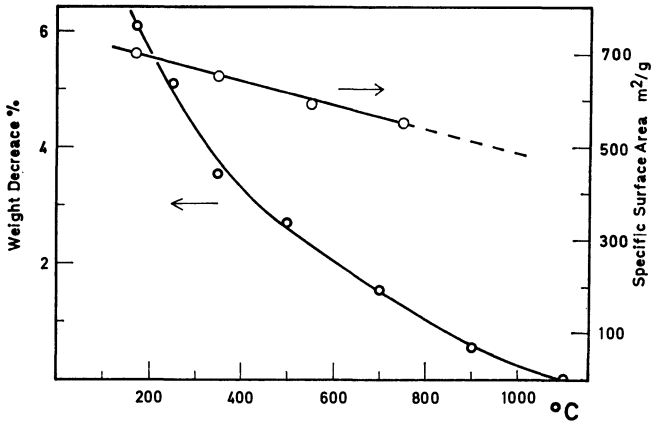

Fig. 1. The effect of heat-treatment on the weight decrease and the specific-surface-area of silica gel

Infrared Spectroscopy. The spectrophotometers used in this work were Japan Spectroscopy Co. types IRA-2 and 402G, and Hitachi Works Co. type IR 225. The absorp-

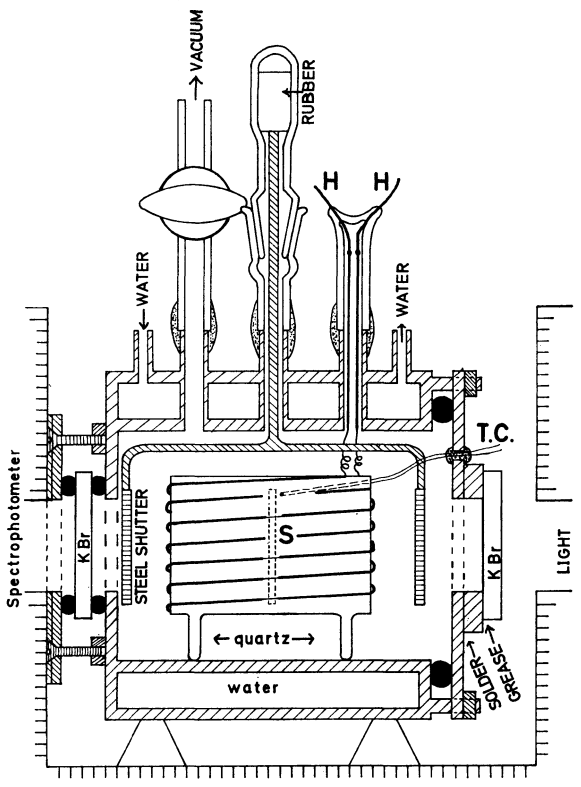

Fig. 2. High temperature vacuum cell for the infrared spectroscopy. The shaded, blank, black, and dotted areas show brass, glass, O ring and "Torr Seal" adhesive respectively unless otherwise specified.

* presented at the 23th (1969) and 27th (1973) annual meetings of the chemical Society of Japan and the 23th (1970) Colloid and Surface Chem. Symposium.

tion cell used in this experiment is shown in Fig. 2. The specimen was kept fixed in a furnace capable of heating the sample up to about 680 °C under a vacuum of 1×10^{-3} Torr. The absorption band was taken at room temperature *in vacuo*. No contamination of silica gel by the oil used in producing the vacuum was seen as far as the infrared spectra were concerned. The absorption intensity was estimated with the accuracy of about ±4% by measuring the area of the absorption curve within the range of the transmittance from about 80 to 20%; in this range the transmittance is practically linear to the extinction coefficient.

The absorption bands thus obtained were resolved into their component bands with Lorentz, Gauss, and mixed types by means of a Dupont Co. Curve Resolver, type 310. It was fairly easy to find the most reasonable combination of component bands with this simulation method. More details of the infrared measurement will be shown elsewhere.[3] The experimental error of the temperature measurement of the specimen was about ±4%.

Results and Discussion

As is well known, the broad absorption band between 3800 and 3000 cm^{-1}, as is shown in Fig. 3(a), can be assigned generally to the OH bond of silanol groups and adsorbed water of silica gel at 70 °C. Upon repeated heavy water adsorption, this band shifts quickly and uniformly to the OD stretching region, keeping its original OH band shape quite well. By elevating the heat-treatment temperature, this broad band at 70 °C becomes narrower—for example, at 180 and 360 °C, as is shown in Figs. 3(b) and (c) respectively; at 680 °C in Fig. 3(d) the band shape is sharp as a result of the condensation and dehydration reaction of silanol. Heating was done sufficiently long to attain the equilibrium condition (constant absorption intensity), as is shown in the upper part of Fig. 5.

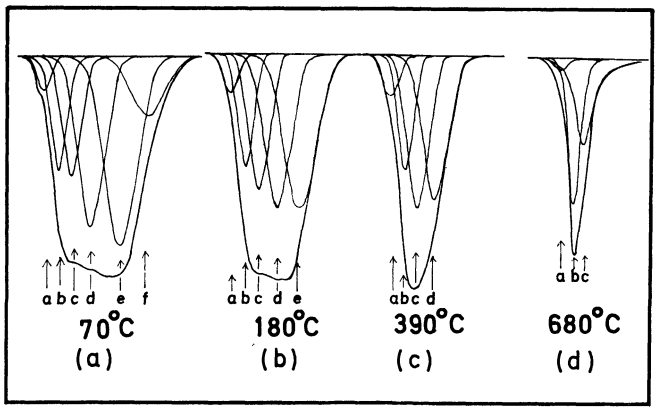

Fig. 3. OH stretching absorption bands and their component bands of silanol in various heat-treatment temperatures. *a*, *b*, *c*, *d*, *e*, and *f* show the maximum wave numbers of the component bands at 3870, 3750, 3630, 3470, 3260, and 3030 cm^{-1}, respctively.

In Fig. 4 a good linear relationship can be seen between the intensity of these bands, being equal to the area of the absorption curve and the hydroxyl concentration of the sample at the corresponding temperature; this relationship can be obtained from Fig. 1

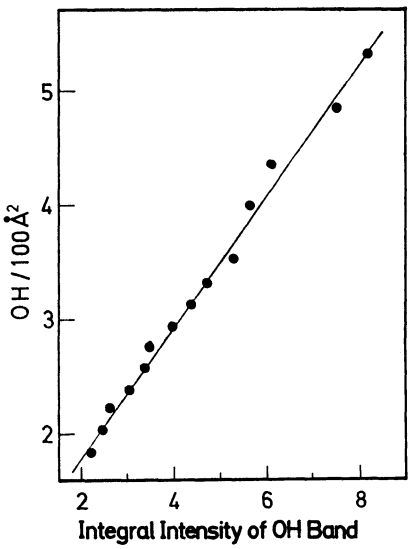

Fig. 4. The relation of the integral intensity of OH band in arbitrary scale to the concentration of silanol per 100 Å².

by dividing the weight decrease by the specific-surface-area. Therefore, the concentration of the silanol under given conditions can be estimated by using this curve derived from the infrared spectra.

The shape of the band at 680 °C is not symmetrical; it can be satisfactorily simulated as the sum of the three component bands at 3870, 3750, and 3630 cm^{-1} ± 10 cm^{-1}, as is shown in Fig. 3(d). The 3750 and 3630 cm^{-1} bands agree with the literature,[1,2] while the 3870 cm^{-1} band seems to be newly found in silica gel in this work. The shapes of the 3750 and 3630 cm^{-1} bands were nearly Lorentzian, while that of the 3870 cm^{-1} band was almost Gaussian in type. The broader

◒: 3870 cm^{-1}.

bands at lower temperatures could easily be analyzed to their component bands in a similar manner; in order they were shown from the higher to the lower temperatures, in Figs. 3(c), (b), and (a). At 70 °C, the broad band was found to consist of six component bands, with their maxima at 3870, 3750, 3630, 3470, 3260, and 3030 $cm^{-1} \pm 10$ cm^{-1}. The existence of the 3470, 3260, and 3030 cm^{-1} bands seems to have been made clear in this work. The concentration of silanol corresponding to each of these component bands can be obtained from the total concentration of silanol at a given temperature multiplied by the fraction of the area of each of these component bands in relation to the total area of the absorption band at this temperature. The results are plotted in Fig. 5. In this figure, the OH concentration of each component band decreases successively by elevating the heat-treatment temperature. The 3030 cm^{-1} band disappears at about 150 °C and can be assigned to adsorbed water, since this temperature agrees well with the temperature of the desorption of adsorbed water obtained from our TGA, dielectric, and conductivity measurements.[4-6] The intensity of the 3260 cm^{-1} band began to decrease at about 150 °C, the temperature of disappearance of the 3030 cm^{-1} band. The same is true for the 3470 cm^{-1} band as may be seen in this figure. These two bands disappear at about 330° and 580 °C respectively. These bands can be assigned to the hydrogen-bonded silanols with various bond energies. During the decrease in these bands, the maximum wave numbers of these bands shift slightly to higher wave numbers, as is shown in Fig. 6. This blue shift may be interpreted in the following two ways: 1) it may be the result of the weakening of the hydrogen-bond interaction of the neighboring atoms following the dehydration reaction; 2) more likely, each component band may be composed of a few secondary components and the dehydration reaction may proceed from the lower-wave-number part of these secondary components.

Since the decrease in the intensity of one band and the increase in that of the other type does not seem to have occurred simultaneously in Fig. 6, the possibility of such a generation of one type of silanol as

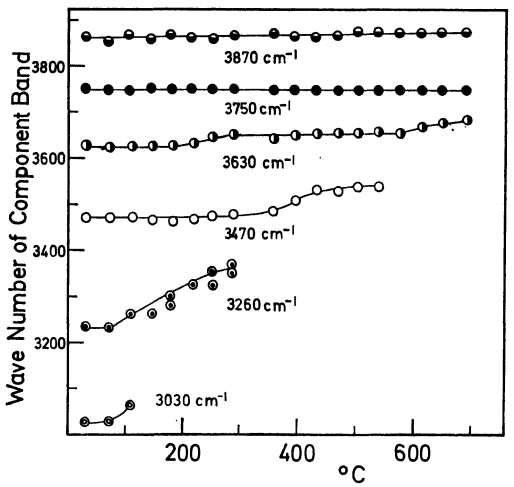

Fig. 6. The shift of the component bands by the elevation of the heat-treatment temperature.

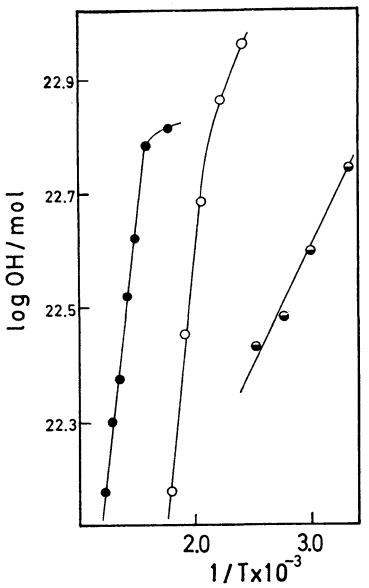

Fig. 7. The logarithm of the silanol concentration of component bands as a function of the reciprocal temperature of heat-treatment.
◒: 3030 cm^{-1}, ○: 3260 cm^{-1}, ●: 3470 cm^{-1}

Table 1.

OH band in cm^{-1} ± 10 cm^{-1}	Temperature of dissociation in °C $\pm$ 4%	ΔH kcal/mol ± 0.2 kcal/mol	O-H···O Distances in Å	Assignment
3030	150	1.9	—	Adsorbed water
3260	330	8.9	2.7	H-bond OH
3470	580	8.1	2.8	H-bond OH
3630	—	—	3.0	? H-bond OH
3750	—	—	—	Free OH
3870	—	—	—	?

a result of the condensation of another type or types of silanols is very small.

The OH equilibrium concentrations of 3030, 3260, 3470, and 3630 cm^{-1} bands are proportional to the reciprocal temperatures in the temperature range of dehydration reaction, as may be seen in Fig. 7. From these relations, we can obtain the enthalpy values, ΔH, of the dehydration reaction of these silanols, as is shown in Table 1. These values are very small compared with that of the usual chemical reaction. Table 1 also shows the O—H···O bond distances estimated from the relation between the absorption frequencies and the O—H···O distances of various compounds,[7] and their possible assignments.

The intensities of the 3630, 3750, and 3870 cm^{-1} bands did not change in the temperature range measured in this study. The 3750 cm^{-1} band, which is assigned to the free silanol, can also be found in other types of silica. However, this band of silica gel overlapped with the 3870 and 3630 cm^{-1} bands pretty heavily even at 680 °C, in contrast with that of aerosil, which can be clearly seen without overlapping at 700 °C.[1] Therefore, it was not possible to resolve

the 3750 cm^{-1} band into its components as in the case of aerosil.[8,9] The OH band at about 3630 cm^{-1} was also found in aerosil.[10-12] However, there are some differences in the deuterium exchange behavior and, hence, in the interpretations between these two materials.

Partially-occupied d-Orbitals Participating in the Activation of Molecular Oxygen

Katsutoshi OHKUBO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received July 4, 1973)

UV spectroscopic and semiempirical SCFMO investigations have been performed on the partially-occupied (formally unoccupied) *d*-orbitals participating in the activation of the ground state, $^3\Sigma_g^-O_2$, with special attention being given to the catalytic activities of onium compounds. The order of the red shifts of the $(p_z)^2 \rightarrow (p_z)(d)$ transition of the onium compounds in an oxygen atmosphere is in satisfactory accordance with those of the magnitude, of the partial occupancy of the *d*-orbitals and of the catalytic activities of the onium compounds in hydrocarbon oxidations. The d_{xz} (or d_{yz}) and $d_{x^2-y^2}$ orbitals are most favorably disposed for the interactions between the Group VI and V onium compounds and the $(1\pi_g)_x$-orbital of the $^3\Sigma_g^-O_2$ respectively. The partial occupation of the formally unoccupied *d*-orbitals results from the *d*-π delocalization between the onium central atom and the neighboring atoms of substituents and the counter-anion.

The liquid-phase oxidation of hydrocarbons such as cumene, tetraline, xylenes, *etc.*, with onium compounds proceeds without any appreciable incubation period and accumulates only hydroperoxide as an oxidation product, at least for 1 hr after the start of reaction under the usual conditions.[1] Among onium compounds involving C, N, O, P, S, As, Se, and Te as their central atoms, the third-row onium (phosphonium and sulfonium) ones have been proved to be the most effective catalysts.[2,3] The distinguished activity of phosphonium compounds as well as of sulfonium compounds may be ascribed to their catalytic activation of the ground state, $^3\Sigma_g^-O_2$, during the initial stage of the reaction:[4,5]

$$\text{onium cat.} + O_2 \underset{2.898\times10^9\sqrt{Te}\,e^{-21370/RT}}{\overset{9.389\times10^9\sqrt{Te}\,e^{-19930/RT}}{\rightleftharpoons}} \text{onium cat.}^{\delta+}\cdots O_2^{\delta-}$$

$$\text{onium cat.}^{\delta+}\cdots O_2^{\delta-} + RH \xrightarrow[\text{(rate determining)}]{1.447\times10^{10}\sqrt{Te}\,e^{-22460/RT}} R\cdot + HO_2\cdot + \text{onium cat.}$$

$$R\cdot + O_2 \xrightarrow{8.538\times10^9\sqrt{Te}\,e^{-6280/RT}} RO_2\cdot$$

$$RO_2\cdot + RH \xrightarrow{1.592\times10^{10}\sqrt{Te}\,e^{-19300/RT}} ROOH + R\cdot$$

$$RO_2\cdot + RO_2\cdot \xrightarrow{1.582\times10^{10}\sqrt{Te}\,e^{-10745/RT}} \text{inactive product}$$

$$\text{onium cat.} \xrightarrow{2.243\times10^{10}\sqrt{Te}\,e^{-18104/RT}} \text{inactive form}$$

where the rate constants ($M^{-1}\,s^{-1}$ or s^{-1} unit) are those in the case of cumene oxidation catalyzed by triphenylsulfonium chloride.

With respect to the catalytic activation of the $^3\Sigma_g^-O_2$, other types of catalysts, such as copper phthalocyanine,[6,7] Cu-pc, and hemoglobin,[8-12] Globin-Fe, participate in the activation of the $^3\Sigma_g^-O_2$:

$$\text{Cu-pc} + O_2 \longrightarrow \text{Cu-pc}^{\delta+}\cdots O_2^{\delta-}$$

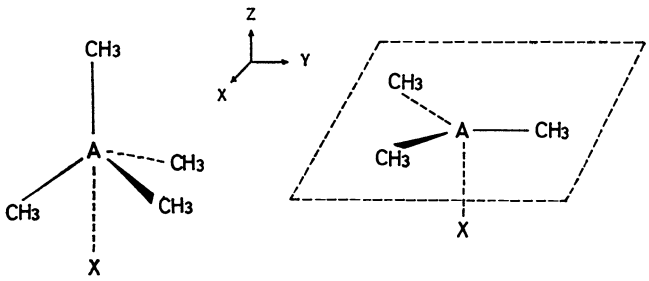
$$\text{Globin-Fe} + O_2 \rightleftharpoons \text{Globin-Fe}^+\cdots O_2^-$$

No successful SCFMO calculation has hitherto been reported on the reaction systems mentioned above,[13] perhaps because there is difficulty in the accurate assessment of the relative locations of the states of O^+, O, and O^- on the energy scale and in the divergency of the SCF calculations.

The goal of the present study is to elucidate the role of partially-occupied (formally unoccupied) *d*-orbitals of onium compounds in the catalytic activation of the ground state, $^3\Sigma_g^-O_2$, on the basis of UV spectroscopic measurements[14] and semi-empirical SCFMO calculations.[15]

Method of Calculation

The following three systems were investigated in this work: (a) trimethylsulfonium compounds, $(CH_3)_3SX$ (X=Cl, Br, I, BF_4, and ClO_4), (b) tetramethylphosphonium compounds, $(CH_3)_4PX$ (X=Cl, Br, I, BF_4, and ClO_4), and (c) trimethyl-selenonium and telluronium chlorides, $(CH_3)_3SeCl$ and $(CH_3)_3TeCl$. The method of calculation is a semiempirical SCFMO, similar to the one described by Yonezawa *et al.*,[15] using the parametrization given in Ref. 16. The geometries used for calculations are illustrated in Fig. 1.



A=P C-P=1.87 Å C-H=1.10 Å CAX=CAC=109°28′
A=S, Se, or Te C-S=1.82 Å: C-Se=1.95 Å; C-Te=2.09 Å C-H=1.10 Å CAC=120°; CAX=90°

Results and Discussion

UV Spectroscopic Phenomena. Let us first discuss the UV spectroscopic phenomena concerned with the interaction between onium compounds and the $^3\Sigma_g^-O_2$. Figure 2 presents the UV absorption spectra of $(C_6H_5)_4PCl$, $(C_6H_5)_3SCl$, $(C_6H_5)_3SeCl$, and $(C_6H_5)_3TeCl$ in absolute ethyl alcohol at 25±1 °C in a nitrogen or oxygen atmosphere; the absorption curves of the said compounds indicate strong and reproducible peak, with absorption maxima, $\lambda_{max}(\log\varepsilon)$, of 204 (4.81)

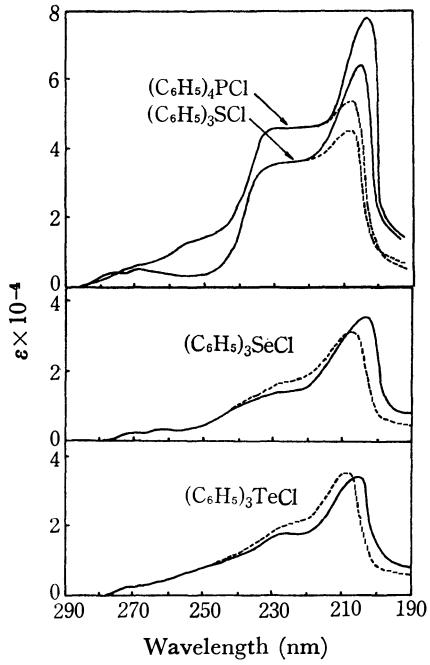

Fig. 2. UV absorption spectra of onium chlorides in C_2H_5OH at 25+1 °C. (Solid and dotted curves indicate the spectra in N_2 and O_2 atmospheres respectively.)

204 (4.88), 204 (4.56), and 205 nm (4.54) respectively in a N_2 atmosphere. These absorption peaks can be assigned to the electron excitation from the *p*-orbitals of the onium central atom to its *d*-orbitals, especially that from the p_z-orbital to the d_{z^2}-one, in view of the singlet excitation energies as evaluated by the SCFMO calculations. (Those for phosphonium chloride are shown in Fig. 3, while those for the others have already been discussed in Ref. 14.)

In an oxygen atmosphere, the above-mentioned peaks

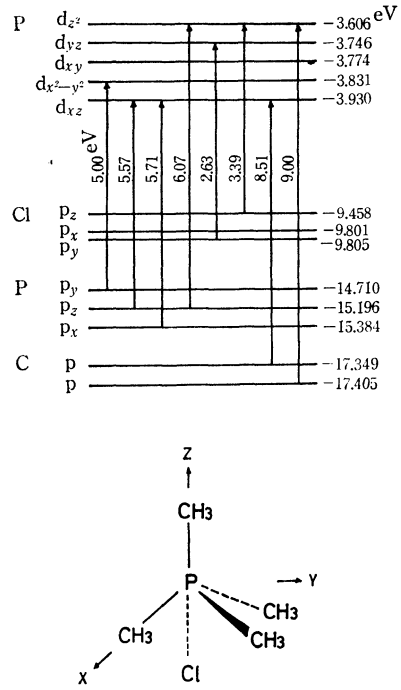

Fig. 3. Calculated excitation energies of $(CH_3)_4PCl$.

are shifted to longer wavelength regions ($\lambda_{max}(\log \varepsilon)$= 208 (4.65), 209 (4.73), 207.5 (4.50), and 208 nm (4.55) respectively). This is a result of the lowering of the low-lying, partially-occupied *d*-orbitals of the onium central atom, which results from the electron migration from the *d*-orbitals to the $1\pi_g$-orbitals of molecular oxygen through the plausible *dp*-σ type orbital overlappings to be shown later in this paper. That is, the more the electron densities of the *d*-orbitals decrease, the more their MO energy levels become lowered.

Interaction between the Partially-occupied d-Orbitals of Onium Compounds and the $1\pi_g$*-Orbitals of the* $^3\Sigma_g^- O_2$. Let us interpret briefly the molecular structures of onium compounds before discussing their interaction with the $^3\Sigma_g^- O_2$ in hydrocarbon oxidation. The energetically-stable phosphonium halides involve tetrahedral T_d onium cations, while the other oniums possess planar C_{3v} cations; the bond distance between the onium central atom and the counteranion has been proved to be a purely ionic one, particularly in polar solvents.[17] With regard to the structures of onium tetrafluoroborates and perchlorates (BF_4 and ClO_4), the planar C_{4v} counter-anions (B–F=1.40 Å; Cl–O=1.50 Å; ∠FBF=∠OClO=90°) have been, shown to give energetically-stable species.[18]

We should now consider the interaction between the partially-occupied *d*-orbitals and the $1\pi_g$-orbitals of the $^3\Sigma_g^- O_2$. In the Group VI onium (sulfonium, selenonium, and telluronium) compounds, a *dp*-σ type overlap between the d_{xy} (or d_{yz}) and the $(1\pi_g)_z$ is most predominant,[19] while in phosphonium compounds a *dp*-σ type orbital overlapping between the $d_{x^2-y^2}$ and the $1\pi_g$ is most probable, as is indicated in Fig. 4. It may be deduced, therefore, that the magnitude of the electron density on the *d*-orbitals (*viz.*, d_{xz} or d_{xy} and/or $d_{x^2-y^2}$) most favorably disposed for the interaction with the $1\pi_g$-orbitals of the $^3\Sigma_g^- O_2$ can be taken as a measure of the activation of the molecular oxygen.

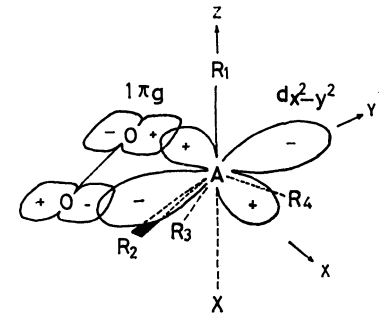

Fig. 4. Orbital overlap between phosphorus d-orbitals and $1\pi_g$-orbitals of O_2.

Correlation between the Partial Occupancy of the d-Orbitals and the Amount of the Red Shift. In this section, the discussion will be focused on the correlation between the electron densities of the *d*-orbitals of onium compounds and the amount of the red shift, $\Delta\lambda$, observed by the UV spectroscopic measurements. From earlier discussions, it is believed that the more the electron density of the *d*-orbitals of the onium central atom

increases, the larger becomes the red shift of $\Delta\lambda$(eV), because the electron is expected to transfer from the onium compound to the $^3\Sigma_g^-$ O_2. Moreover, a parallelism may be expected between the $\Delta\lambda$ values and the catalytic activities of onium compounds, as defined by the maximum rate of oxygen absorption, R_{max}, in M/s units, during the initial stage of hydrocarbon (10 ml) oxidation with the onium compound (3.0 mM) at 85 °C. As can be seen from Table 1, the order of the electron densities of the d_{xz} (or d_{xy}) and/or $d_{x^2-y^2}$ orbitals accords with that of the $\Delta\lambda$ values and also with that of the R_{max} values.

Table 1. Correlation of electron density of partially-occupied *d*-orbitals, amount of red shift, $\Delta\lambda$, and maximum oxidation rate, R_{max}

Onium compound	Electron density			$\Delta\lambda$ (eV)	$R_{max}\times10^4$ (Ms^{-1})	
	d_{xz}	d_{yz}	$d_{x^2-y^2}$		tetralin	cumene
$(CH_3)_4PCl$	0.216	0.191	0.189	0.12	7.44	
$(CH_3)_3SCl$	0.249		0.264	0.14	11.20	1.12
$(CH_3)_3SeCl$	01.05		0.162	0.104		1.04
$(CH^3)^3TeCl$	0.073		0.153	0.09		0.45
None					0.062	0.17

The correlation mentioned above is also realized in a series of sulfonium compounds, as is indicated in Table 2. Table 3 shows that the electron densities of the phosphorus $d_{x^2-y^2}$ orbital correlate well with the R_{max} values obtained from the tetralin oxidation under the conditions listes previously. The results shown in Tables 1, 2, and 3 are in harmony with the idea that the partially-occupied *d*-orbitals participate directly in the catalytic activation of the $^3\Sigma_g^-$ O_2. However, the *d*-orbital energy and the diffuseness of the *d*-orbital expansion should also be taken into consideration in discussing the interaction between the *d*-orbitals and O_2. In this respect, the relatively low activities of the fourth- or fifth-row onium compounds, such as selenonium and telluronium halides, may be ascribed to the diffuse 4*d* or 5*d* orbitals,[16,20] which may be unable to interact strongly with the $1\pi_g$-orbital of O_2.

Table 2. Correlation of electron density of sulfur *d*-orbitals, amount of red shift, $\Delta\lambda$, and maximum oxidation rate, R_{amx}

Sulfonium compound	Electron density $d_{xz}=d_{yz}$	$\Delta\lambda$(eV)	$R_{amx}\times10^4$ (Ms^{-1}) tetralin
$(CH_3)_3SCl$	0.249	0.14	11.20
$(CH_3)_3SBr$	0.230	0.10	10.88
$(CH_3)_3SI$	0.212	0.05	3.80
$(CH_3)_3SBF_4$	0.171	0.03	0.56
$(CH_3)_3SClO_4$	0.148	0.02	0.30

Here, it is necessary to discuss the chemical nature of the activated molecular oxygen. In an interacting system between the partially-occupied *d*-orbitals and the $1\pi_g$-orbitals, electron migrations from the former to the latter and from the $1\pi_u$-orbitals of the $^3\Sigma_g^-$ O_2

Table 3. Correlation between electron density of phosphorus *d*-orbitals and maximum oxidation rate, R_{amx}

Phosphonium compound	Electron density					$R_{max}\times10^4$ (Ms^{-1})
	d_{xy}	d_{yz}	d_{xy}	$d_{x^2-y^2}$	d_{z^2}	tetralin
$(CH_3)_4PCl$	0.216	0.191	0.180	0.189	0.450	7.44
$(CH_3)_4PBr$	0.216	0.194	0.179	0.185	0.342	7.00
$(CH_3)_4PI$	0.209	0.183	0.179	0.183	0.333	3.72
$(CH_3)_4PBF_4$	0.193	0.200	0.184	0.185	0.239	0.45
$(CH_3)_4PClO_4$	0.191	0.166	0.184	0.182	0.218	0.12

to the former may be expected. Such electron migrations increase the O–O bond distance of the oxygen molecule by means of the electron repulsion, and an odd-electron may be localized on each oxygen atom, thus increasing the radical nature of O_2. In this situation, the half-occupied, doubly-degenerate $1\pi_g$-orbitals come to be free from the degenerate state: for instance, a long-range interaction between $(CH_3)_3SCl$ and O_2 (S-Center of the O–O=3.0 Å) brings about the separation of the MO-energies of the $1\pi_g$-orbitals in an energy scale over 0.01 eV.[21] It may be worthy of emphasis here that the order of the catalytic activities: sulfonium≳phosphonium>selenonium>telluronium, is almost contrary to the lowering order of the energy levels of the d_{xz} (or d_{xy}) or the $d_{x^2-y^2}$: −4.8 eV for $(CH_3)_3TeCl$>−4.69 eV for $(CH_3)_3SeCl$>−4.38 eV for $(CH_3)_3SCl$>−3.83 eV for $(CH_3)_4PCl$. This may imply that the *d*-orbitals follow the initial charge to a higher π_g orbital (−0.15 eV[22,23]) rather than the $1\pi_g$ orbital (−12.075 eV) of the $^3\Sigma_g^-$ O_2.

Partial Occupation of the Formally Unoccupied d-Orbitals. Finally, mention should be made of the partial occupation of the formally unoccupied *d*-orbitals of onium compounds. The neighboring atoms of substituents and counter-anion participate directly in the partial occupation of the *d*-orbitals by the aid of the *d*-π (mainly, *dp*-π) delocalization between the central atom of the onium compound and the neighboring atoms. Table 4 shows the circumstances mentioned above in the case of phosphonium chloride; the *dd*-π delocalization between the phosphorus and the counter chlorine *d*-orbitals should also be taken into consideration.

Table 4. Partial occupation of phosphorus *d*-orbitals of $(CH_4)_4PCl$

Species	Basis set		Atom population		Electron density	
	P	Cl	P	Cl	$d_{x^2-y^2}$	d_{z^2}
$(CH_3)P_4^+$	*s,p*		5.089			
$(CH_3)_4P^+$	*s,p,d*		5.430		0.1706	0.1716
$(CH_3)_4PCl$	*s,p*	*s,p*	5.061	7.982		
$(CH_3)_4PCl$	*s,p,d*	*s,p*	5.629	7.538	0.1889	0.1803
$(CH_3)_4PCl$	*s,p,d*	*s,p,d*	5.647	7.520	0.1895	0.1805

Therefore, the more electron-releasing groups of substituents or counteranions are attached to the central atoms, the higher becomes the catalytic activity of the onium compounds. This is in harmony with the experimental phenomena observed in the liquid-

phase oxidation of hydrocarbons with various onium compounds.[2,3]

The Magnetic Properties of Manganese(II) Phthalocyanine. II

Hirokazu MIYOSHI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received July 11, 1973)

The magnetic susceptibilities of manganese(II) phthalocyanine (PcMn) have been measured in the paramagnetic region between 13.8 and 280 K. The deviation from the Curie-Weiss law was found at a moderately high temperature (about 70 K), and the Weiss constant was obtained as 23 K. Comparing the ratio of T_c to θ (0.37) with that of the 2- or 3-dimensional lattice, the data were analysed on the basis of the ferro-magnetic linear-chain model. The magnitude of the intra-chain interaction (J) was deduced as $5.64k$ by comparison with Fisher's classical form of the theory of the ferromagnetic Heisenberg chain. We have also measured the magnetic susceptibilities of cobalt(II) phthalocyanine (PcCo) and of copper(II) phthalocyanine (PcCu), which are isomorphous with manganese(II) phthalocyanine, from 1.8 to 77 K. In PcCo, a broad maximum has been observed, and the data were analysed in terms of the theory of the antiferromagnetic Ising-chain model. On the other hand, PcCu obeyed the Curie law down to 1.8 K. A qualitative explanation of the exchange interactions in PcMn, PcCo, and PcCu was presented on the basis of their electronic states.

Most of the transition-metal phthalocyanines are known to be paramagnetic.[1] So far as the present author knows, most reports of their magnetic properties have been concentrated upon the investigation of their electronic structures within one molecule, though there have been a few of the intermolecular exchange interaction. However, the magnetic interaction revealed by the measurements of the magnetic susceptibility in the low-temperature region is of some interest, since the crystal is composed of discrete molecules at the van der Waals' radii; thus, the magnetic interaction is primarily intermolecular in origin.

Our earlier report[2] has shown that a ferromagnetic transition occurs in manganese(II) phthalocyanine $C_{32}H_{16}N_8Mn$ (hereafter simply denoted as PcMn) at $T_c=8.6$ K. However, no detailed measurements or discussion of the exchange interaction have been made.

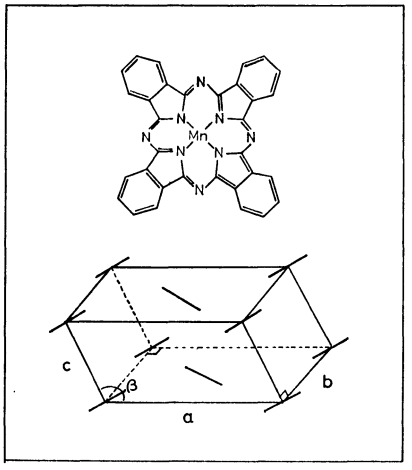

Fig. 1. Molecular and schematic crystal structures of PcMn. The molecular plane is approximately normal to the ab-plane.

To study the magnetic exchange interaction in the phthalocyanines, the magnetic susceptibilities of PcMn, PcCo, and PcCu were measured. They have been shown to be isomorphous with PcNi, whose structure is known[3] (see Table 1). The molecule is almost perfectly square-planar. The base-centered arrangement of two molecules per unit cell is shown in Fig. 1. The planar molecules are stacked along the short b axis at intervals of 4.7 Å, and the molecular planes are inclined to the ac plane at an angle of about 45°. The vertical distance between the nearest neighbors is 3.4 Å; this seems to be the minimum intermolecular separation when only van der Waals' forces are operative. As was pointed out by Mitra *et al.*,[4] this distance may provide a possible pathway for the magnetic exchange interaction. Therefore, the phthalocyanine may form magnetic linear chains along the b axis.

PcMn gives a large positive deviation from the Curie-Weiss law, and PcCo shows a broad maximum. These results are analysed in terms of the theory of linear-chain models. On the other hand, PcCu obeys the Curie law and may not form a magnetic linear chain. These results are also discussed on the basis of their electronic states.

Experimental

PcMn, PcCo and PcCu were prepared by the methods of Linstead *et al.*[5] and of McQueen *et al.*[6] The products were washed with benzene, ethanol, and acetone, and then sublimed at around 500 °C in an atmosphere of pure nitrogen. The single crystal grown by sublimation was in the shape of an elongated flat plate. The results of the elemental analysis of the carbon, hydrogen, and nitrogen of each sample corresponded closely to the calculated values. PcMn: Found: C, 67.70; H, 2.94; N, 19.67%, (Calcd: C, 67.73; H, 2.84; N, 19.75%), PcCo: Found: C, 67.86; H, 2.74; N, 19.57%, (Calcd: C, 67.76; H, 2.82; N, 19.61%), PcCu: Found: C, 66.87; H, 2.57; N, 19.42%, (Calcd: C, 66.72; H, 2.80; N, 19.45%).

All the measurements were carried out in the polycrystalline state. The static (dc) susceptibility measurements

were done by means of a magnetic torsion balance described elsewhere[7] on the samples of 50—150 mg in a field of 10.2 kG. The measurements on PcMn were performed between 1.8 K and 280 K in the temperature region attainable by pumping out the liquid helium and liquid nitrogen. The measurements on PcCo and PcCu were carried out between 1.8 K and 77 K. The temperatures of the samples were measured with a carbon resistor and AuCo-Cu thermocouple calibrated by measuring not only the known magnetic susceptibility of Mn-Tutton salt, but also the vapor pressures of liquid helium, liquid hydrogen, and liquid nitrogen. The ac-susceptibility measurements of PcMn were done by means of a Hartshorn bridge zero-field method (90 Hz) between 13.8 K and 20.2 K by pumping out the liquid hydrogen. The temperature was determined from the susceptibility of the standard sample, $Cr(NH_3)_6Cl_3$,[8] and from the vapor pressures of liquid hydrogen. With this method, the initial susceptibility in the limit of zero field is fairly well approximated because the amplitude of the measuring field may be kept very small.

A diamagnetic correction of -290×10^{-6} emu/mol was used to correct the susceptibility data, following the recent results on diamagnetic PcNi reported by Mitra *et al.*[9]

Results and Discussion

a) PcMn. The dc susceptibility in 10.2 kG appears to deviate from the Curie-Weiss law below 70 K, as is shown in Fig. 2. Below 7 K, it reaches a constant maximum value dependent on the magnetic field strength, as has already been reported.[2] To study the magnetic behavior in the low-temperature region, it is more advantageous to plot $(\chi_m T)^{-1}$ against T^{-1}, which enlarges the deviation from the Curie-Weiss law.[10] The data are plotted as $1/\chi_m T$ to $1/T$ in Fig. 3. The molecular-field result (the Curie-Weiss law) appears as a straight line; $1/\chi_m T=1/C-\theta/CT$. The deviation from the molecular-field result is very large. The Curie constant, C, and the Weiss constant, θ, are estimated as 2.13 and 23 K respectively in the high-temperature region. The susceptibility seems to

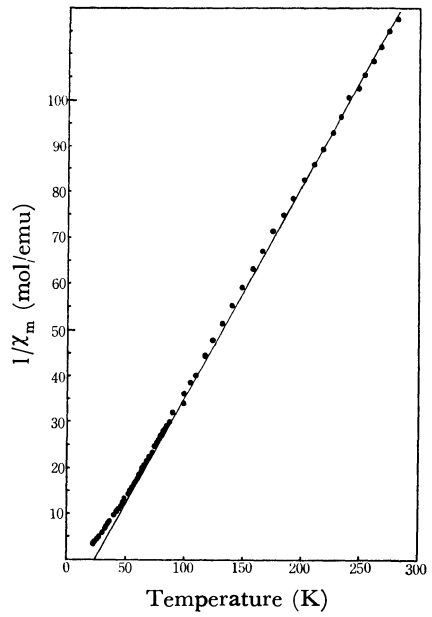

Fig. 2. Reciprocal susceptibilities of PcMn as a function of temperature (H= 10.2 kG).

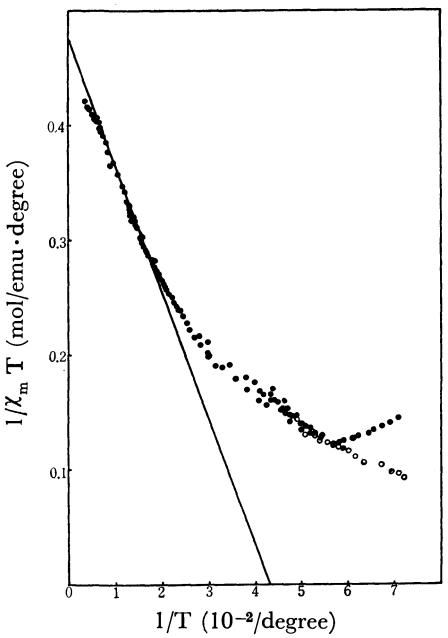

Fig. 3. Reciprocal susceptibilities ($1/\chi_m T$) of PcMn as a function of $1/T$. (●: H=10.2 kG, ○: $H\approx0$ G.)

become dependent on the field at $1/T$=0.057, (T= 17 K). The results of ac-susceptibility measurements have been included in Fig. 3; they coincide with those measured in 10.2 kG above 17 K. This field dependence of the susceptibility is consistent with the results of the magnetization measurements[2] at 4.2, 11.1, and 20.2 K.

It has been reported[1,4] that the ground electronic state of PcMn is a quartet (S=3/2). However, the ground state is not completely understood for the reason that no single crystal ESR data have been reported, though ESR measurements have been made of the powder sample (g=2.0).[11] Because of the lack of detailed information about the magnetic anisotropy, the exchange interaction in PcMn is assumed to be isotropic.

Now, let us compare the ratio of T_c to the θ of PcMn with that of the 2- or 3-dimensional lattice. On the Curie points of Heisenberg model magnetics, many theoretical studies have been made all along the line. Rushbrooke and Wood[12] have obtained an approximate formula for the Curie temperatures of 3-dimensional lattices for $S>1/2$; $T_c=(5/96)(z-1)[11S(S+1)-1](J/k)$, where z is the coordination number of the lattice. Moreover, Stanley and Kaplan[13] have

Table 2. The values of T_c/θ and kT_c/J[12-14] (Heisenberg model of S=3/2)

Lattice	Dimension	z[a]	T_c/θ	kT_c/J
Simple cubic	3	6	0.68	10.48
b. c. c.	3	8	0.73	14.67
f. c. c.	3	4	0.77	6.28
triangle	2	6	0.43	6.5
quadratic	2	4	0.39	3.9
PcMn	—	2	0.37	1.53

a) the coordination number.

given the transition temperature in 2-dimensional lattices for $S>1/2$ as follows; $T_c=(1/5)(z-1)[2S(S+1)-1](J/k)$. The Weiss constant, θ, has also been obtained by the molecular-field model; $\theta=(2/3)zS(S+1)(J/k)$. Using these formulas, the (T_c/θ) ratio can be calculated theoretically in individual lattice. The results are tabulated for $S=3/2$ in Table 2. The experimentally-obtained ratio of PcMn is 0.37, much smaller than that of the 2- or 3-dimensional lattice. This suggests that the dominant exchange interactions in PcMn may form a magnetic linear-chain system.

In the second place, taking into account the crystal structure, PcMn is treated approximately as a ferromagnetic-chain system and the results are compared with the definite theory. At first sight, it seems plausible to apply Fisher's classical Heisenberg result.[15] Fisher replaced the quantum mechanical spin operators with classical vectors. The resulting Hamiltonian for a chain of $N+1$ may be written in a magnetic field. H, as;

$$\mathcal{H} = -2JS(S+1)\sum_{i=1}^{N} \boldsymbol{s}_i \boldsymbol{s}_{i-1} - g\mu_B[S(S+1)]^{1/2}\sum_{i=0}^{N} \boldsymbol{H}\cdot\boldsymbol{s}_i, \quad (1)$$

where the unit vector, $\boldsymbol{s}_i$, is associated with the ith spin, whose magnetic moment is $g\mu_B[S(S+1)]^{1/2}$. Fisher's expression for the magnetic susceptibility of the chain then becomes;[16]

$$\chi_m = Ng^2S(S+1)\mu_B^2/3kT\cdot(1+u)/(1-u), \quad (2)$$

where $u=\coth[2JS(S+1)/kT]-kT/2JS(S+1)$. If the interaction is ferromagnetic ($J>0$), χ_m diverges as $T\to 0$. We may conveniently rewrite the above formula;

$$C/X_mT = (1-u)/(1+u). \quad (3)$$

Using $S=3/2$ and the obtained C value of 2.13, Eq. (3) is fitted to the data in the high-temperature range by adjusting J. The best fit is obtained with $J=5.64k$. The resulting curve of C/χ_mT *versus* J/kT is shown together with the data in Fig. 4. Although the theory

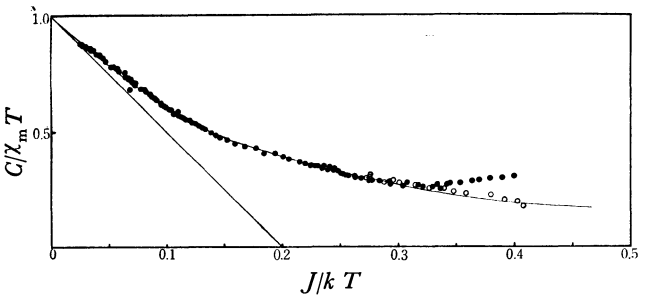

Fig. 4. Reciprocal susceptibilities (C/χ_mT) of PcMn *versus* J/kT (dimensionless units). (●: $H=10.2$ kG, ○: $H\approx 0$ G) C; 2.13, $J/k=5.64$.

is restricted within the classical limits and the real system of PcMn may be more complex, the data agree rather well with Fisher's theory over quite a wide temperature region. Using the value of $J=5.64k$, it is found that kT_c/J is 1.53 (8.6/5.64), smaller than the value of the theory of the 2- or 3-dimensional lattice (see Table 2).

Thus, the preceding discussion confirms the 1-dimensionality of the dominant exchange interactions in PcMn. It is well known theoretically[13,17] that isolated

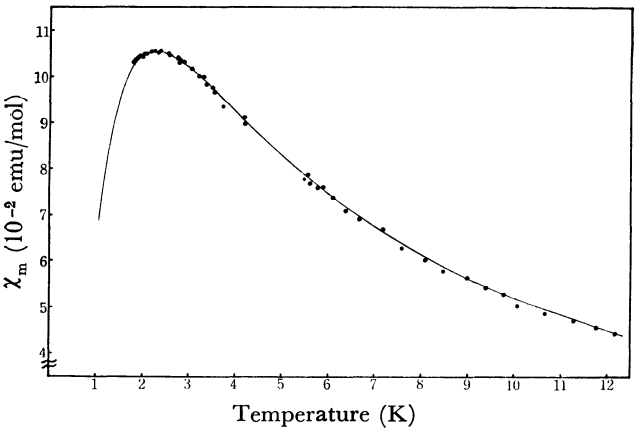

Fig. 5. Molar susceptibilities of PcCo as a function of temperature. The solid line; the parallel susceptibilities of the 1-dimensional Ising theory ($J/k=2.3$, $g=2.66$).

magnetic chains do not give rise to a magnetic transition, and that there occurs a magnetic transition in the presence of a small interaction between chains. Therefore, the magnetic transition in PcMn presumably results from an interchain interaction much smaller than the intrachain interaction.

b) PcCo. The magnetic susceptibilities of PcCo are shown in Fig. 5. The results obey the Curie-Weiss law above 5 K. One feature of the results is the presence of antiferromagnetic interaction among molecules, suggested by the negative Weiss constant, $\theta(-3$ K). Another feature is the existence of a broad maximum at 2.3 K ($\chi_{max}=10.55\times10^{-2}$ emu). Such a maximum can be expected for an antiferromagnetic linear-chain system. Of course, the broad susceptibility maxima could occur also in systems of isolated clusters or 2-dimensional sheets of spins. The structural consideration of phthalocyanines presented earlier does, however, favor the linear-chain model rather than any other one.

The electronic structure of PcCo has been studied by means of ESR measurements.[18] The experimental results confirm that PcCo exists as a doublet ($S=1/2$) and has anisotropic g values. The experimentally-obtained g-value (2.66), determined from the slope of $1/\chi_m-T$ plots, is consistent with the reported data ($g_{//}=1.89$, $g_\perp=2.94$).

Let us analyse the results using the theory of the 1-dimensional antiferromagnetic Ising model, because of the anisotropy shown in g values. The exchange interaction is represented as $-2JS_{iz}S_{jz}$. The expression for the magnetic susceptibility of the Ising chain thus becomes;[19]

$$\left.\begin{aligned}\chi_{//} &= (Ng^2\mu_B^2/4kT)\exp(J/kT)\\ \chi_\perp &= (Ng^2\mu_B^2/4|J|)[\tanh(|J|/2kT)\\ &\quad +(|J|/2kT)\,\mathrm{sech}^2(|J|/2kT)]\\ \chi_p &= (\chi_{//}/3)+(2\chi_\perp/3),\end{aligned}\right\} \quad (4)$$

where $\chi_{//}$, $\chi_\perp$, and χ_p indicate the parallel, perpendicular, and powder susceptibilities respectively. χ_p is the spatial average of $\chi_{//}$ and $\chi_\perp$. χ_p has a broad maximum (χ_{max}) at $kT_{max}/|J|\simeq 0.47$. By comparing

the experimental and theoretical values of the temperature (T_{max}) which corresponds to the broad maximum (χ_{max}), the exchange interaction is estimated to be $J/k=-4.89$. However, using this value, the calculated maximum susceptibility (11.91×10^{-2} emu) does not agree with the experimental one (10.55×10^{-2} emu); this discrepancy is beyond the limits of experimental error. Strangely, the data are quantitatively in good accord with $\chi_{//}$ rather than with χ_p. $\chi_{//}$ exhibits a broad maximum at $kT_{max}=J$; thus, it is found that $J/k=-2.3$ K for $T_{max}=2.3$ K. Using the values of $g=2.66$ and $J=-2.3k$, the theoretical curve of $\chi_{//}$ is shown against T as a solid curve, together with the data shown in Fig. 5. The agreement is very good. The Weiss constant is expressed as $\theta=(2/3)zS(S+1)(J/k)$. By substituting the values of $\theta=-3$ K, $z=2$ and $S=1/2$, it is found that $J=-3k$, which is consistent with the value of $J=-2.3k$ rather than with that of $J=-4.89k$.

These facts can not be understood well, but they may come from the fact that PcCo is not the ideal Ising spin system, since the anisotropy of g values is small compared with those of the usual Co(II) compounds of the Ising type.[20]

c) PcCu. The results are subjected to the Curie law in the temperature region where the measurements were carried out (1.8—77 K). This implies that the exchange interaction in the PcCu crystal is very small; thus, PcCu may not form a magnetic linear chain. The g value was determined as 2.07 from the slope of the $1/\chi_m-T$ plots; this value is consistent with those obtained from the ESR measurements ($g_{//}=2.18$, $g_\perp=2.05$).[21]

d) Exchange Interactions in PcMn, PcCo, and PcCu. Through their crystal structures are isomorphous, the exchange interactions in PcMn, PcCo, and PcCu are multifarious. Because the nature of the magnetic interaction is dependent on the electronic configuration of each molecule, it will be useful to comment on the characteristics of the electronic state of the present system. The phthalocyanine ring has a well-developed π-system and generally has been treated by the molecular orbital method. The central metal orbitals interact weakly with the π-system. Let us consider the orbitals occupied by the unpaired electrons. Based upon the discussion of the results calculated by Gouterman *et al.*[22] and the results observed experimentally by ESR measurements, *etc.*[1,4,18,21] for PcCu, PcCo, and PcMn, the features can be described as follows.

The ordering of energy levels may be identical for the three compounds, as is shown in Fig. 6. The rise in the d_{zx} and d_{yz} levels above the d_{xy} level originates in the π-bonding with the phthalocyanine molecular orbitals.[21] In PcCu, the $d_{x^2-y^2}$ orbital is occupied by the unpaired electron which spreads into the molecular plane and has a σ-characteristic. In PcCo, the unpaired electron is localized in a d_{z^2} orbital which is almost pure. This orbital has a characteristic of an out-of-plane spreading. In PcMn, three unpaired electrons occupy the d_{z^2}, d_{zx}, and d_{yz} orbitals. The unpaired electrons in the d_{zx} and d_{yz} orbitals can spread

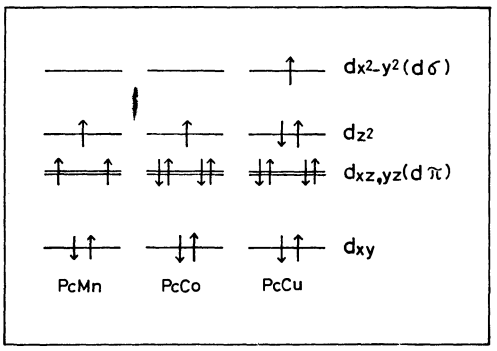

Fig. 6. Schematic representation of electronic structures of PcCu, PcCo, and PcMn.

on the liganding phthalocyanine ring *via* the π-bonding.

In our previous report[2] on PcMn, the paramagnetic shifts of hydrogens were observed by means of proton magnetic resonance measurements (12 MHz) in the liquid-hydrogen-temperature region. These maesurements showed that the unpaired electrons in PcMn are spreading on the ligand. On the other hand, in PcCo and PcCu, only one nonshifted absorption is observed down to 1.8 K in the helium temperature range (PcCo: the linewidth is 9—10 G at 30 MHz; PcCu: the linewidth is 15—18 G at 17 MHz). These results support the above description of the electronic states.

The exchange interaction originates from an overlap of the wave function of the unpaired electrons. The nearest vertical distance between adjacent parallel molecules is 3.38 Å and may ensure a weak overlap of the out-of-plane orbitals. In PcCu, the $d_{x^2-y^2}$ unpaired orbital has a σ-characteristic; hence, the overlap of the wave function between adjacent molecules may be very small. Both PcCo and PcCu have out-of-plane unpaired orbitals; therefore, the overlap may be present. In PcCo, since the unpaired orbital d_{z^2} is almost pure, the overlap may be attributed to the direct one between the d_{z^2} orbitals of adjacent molecules. On the other hand, in PcMn there exists a delocalization of the unpaired spins onto the molecular plane *via* the π-bonding. This may enhance the overlap and afford the possibility of an exchange interaction between the nonparallel molecules (interchain interaction). However, for the nonparallel molecules, the metal-metal distance is 10.3 Å and the orbitals are at right angles to each other. Accordingly, the overlap of the wave functions between nonparallel molecules may be smaller than that between the parallel molecules.

The author is much obliged to Professor Yasuo Deguchi and Dr. Hiroaki Ohya-Nishiguchi for their continuous encouragement throughout this work, and also to Professor Mamoru Mekata, Dr. Yoshitami Ajiro, and the other members of his laboratory for their illuminating discussions. Thanks are also due to Professor Ikuji Tsujikawa and Dr. Hanako Kobayashi for offering him a chance to use the Hartshorn bridge apparatus.

Ultrasonic Study on Solute-Solvent Interaction in Aqueous Systems of Ethers

Nobuo TAKENAKA and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received July 12, 1973)

Ultrasonic velocity and absorption were measured for binary mixtures of water and ethers (1,2-dimethoxyethane, bis(2-ethoxyethyl)ether, bis(2-methoxyethyl)ether, ethylether, diethoxymethane, 1,1-diethoxyethane and 1,2-diethoxyethane) in the frequency range 15—45 MHz at 10—30 °C. Vibrational relaxation was observed in the pure liquid of 1,2-dimethoxyethane. For each solution of 1,2-dimethoxyethane and bis(2-methoxyethyl)-ether, the maximum absorption at the intermediate composition was ascribed to the formation of dihydrate and trihydrate, respectively. The difference between the behavior of ethyl group in water and that of methyl group was discussed from the absorption data.

It has been accepted that hydrocarbon-water interaction (hydrophobic interaction) plays an important role in the conformation of biopolymers in aqueous solutions. For the elucidation of the nature of the interaction, we have studied the aqueous solutions of polyethyleneoxide,[1] dioxane,[2,3] alkyl-substituted urea,[4] amino acid,[5] diamine,[6] tetraalkylammonium salt[7] *etc.* in relation to the structure theory of water.[8-10]

Ultrasonic studies of the aqueous solution of polyethyleneoxide have been carried out by several workers.[1,11-15] It was concluded that "the local water structure formation around the polymer consists of water molecules hydrogen-bonded to oxygen atoms of the chain and hydrophobic water structure around the $-CH_2CH_2-$ groups",[12] and also that it is the origin of the ultrasonic relaxation in the MHz region in the solution. From a study on the aqueous solution of dioxane,[2,3] the presence of dioxane dihydrate was proposed. It was concluded that, concerning the water structure, the structure-breaking ability due to two etheral oxygens is diminished in part by the structure-forming ability due to two $-CH_2CH_2-$ groups.

Many problems concerning the interaction between water and alkyl groups with polar groups remain nusolved.

An ultrasonic measurement is one of the most useful methods for studying the structure of liquids and solutions.[16-18] We have undertaken a comprehensive study of aqueous solutions of ethers by means of an ultrasonic pulse technique with the intention to investigate ethyleneoxide-water and alkyl group-water interactions.

Experimental

Apparatus and Procedures. The ultrasonic pulse method was used for the measurement of absorption coefficient and velocity. The apparatus and procedures were described previously.[1,19] The sound velocity and absorption coefficient were measured at 5 MHz and in the frequency range 15—45 MHz, respectively at temperatures 10—30 °C. The data of the absorption coefficient were reproducible within ±2% and sound velocity data ±1 m/s.

Samples. The samples of ethers were obtained from Wako Pure Chemical Ind. Co. Ltd. (Table 1). Before purification, ethylether was treated with a saturated potassium permanganate solution containing 5% sodium hydroxide, with 50% sulfuric acid and then with water.[20] To bis(2-ethoxyethyl)ether and bis(2-methoxyethyl)ether, a small amount of water was added and the mixture was distilled. Impurities such as xylene were azeotropically removed.

All the samples were refluxed over potassium–sodium alloy after desiccation with potassium hydroxide, and then fractionally distilled through a Widmer column. Distillation was carried out under reduced pressure for 1,2-diethoxyethane and bis(2-ethoxyethyl)ether and for bis(2-methoxyethyl)ether under nitrogen atomsphere. The boiling points observed are given in Table 1.

Results

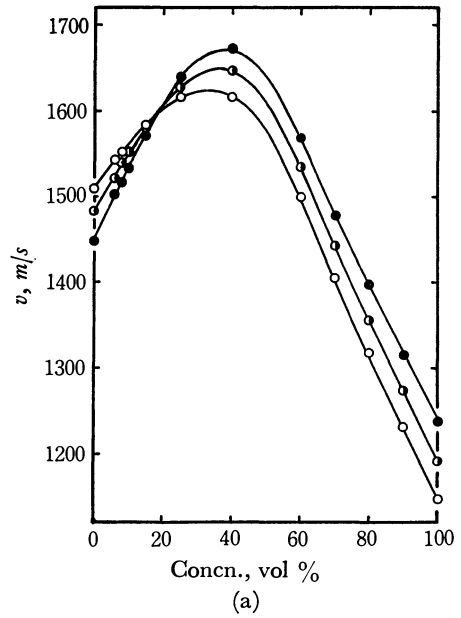
Sound Velocity. 1,2-Dimethoxyethane, bis(2-ethoxyethyl)ether and bis(2-methoxyethyl)ether are miscible with water in all compositions, while other ethers are partially miscible at room temperature. The aqueous solution of bis(2-ethoxyethyl)ether has a lower critical solution temperature (L.C.S.T., 28 °C, 63.5% ether).[25] The sound velocity *vs.* concentration curves for aqueous solutions of 1,2-dimethoxyethane, bis(2-ethoxyethyl)ether and bis(2-methoxyethyl)ether are shown in Figs. 1(a)—(c), where the concentration is given in vol %.[26] The sound velocity data for dilute aqueous solutions of ethylether, diethoxymethane,

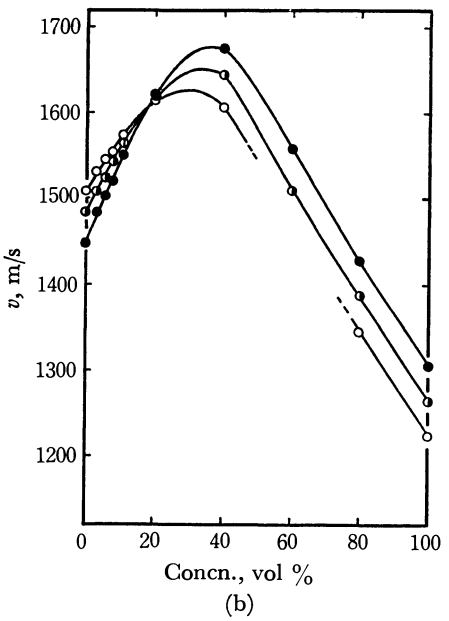
Table 1. Boiling points of ethers

Sample		Bp (°C) Present work	Ref.
Ethylether	$C_2H_5OC_2H_5$	34.4	34.55[20]
Diethoxymethane	$C_2H_5OCH_2OC_2H_5$	87.9	87.9[21]
1,1-Diethoxyethane	$(C_2H_5O)_2CHCH_3$	103.5	103.6[20]
1,2-Diethoxyethane	$C_2H_5OC_2H_4OC_2H_5$	43.5 (47.5 mmHg)	
Bis(2-ethoxyethyl)ether	$(C_2H_5OC_2H_4)_2O$	70.9 (10 mmHg)	
1,2-Dimethoxyethane	$CH_3OC_2H_4OCH_3$	85.1	85.2[22] 84.6[23]
Bis(2-methoxyethyl) ether	$(CH_3OC_2H_4)_2O$	163.0	162[24]

1,1-diethoxyethane and 1,2-diethoxyethane at 20 °C are shown in Fig. 2, including those for 1,2-dimethoxyethane, bis(2-ethoxyethyl)ether and bis(2-methoxyethyl)ether solutions. We see that the velocity *vs.* concentration relation is similar to each other in dilute aqueous solutions of all these materials, and that the relation is represented by a single curve for all the solutions.

Ultrasonic Absorption. Ultrasonic absorption, α/f^2, where α is absorption coefficient and f frequency, is plotted against temperature for pure 1,2-dimethoxyethane, bis(2-ethoxyethyl)ether and bis(2-methoxyethyl)ether (Fig. 3). In the frequency range studied, no relaxation was observed. The absorption of bis(2-ethoxyethyl)ether and bis(2-methoxyethyl)ether decreases and that of 1,2-dimethoxyethane increases with temperature rise. This indicates the presence of a vibrational relaxation mechanism in the pure liquid of 1,2-dimethoxyethane like dioxane.[2)]





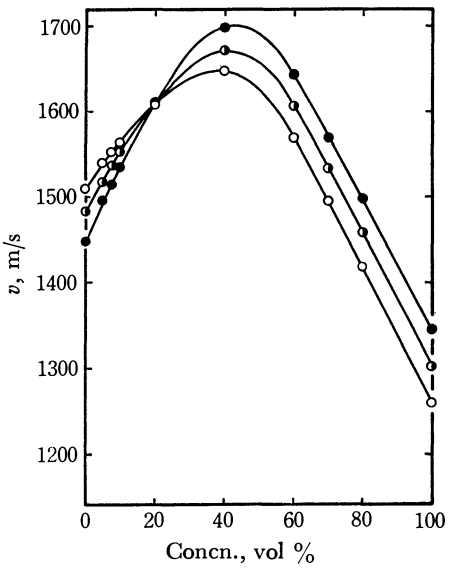


Fig. 1. The plot of ultrasonic velocity *vs.* concentration of ethers (vol %) in aqueous systems of ethers, (a): 1,2-dimethoxyethane, (b): bis(2-ethoxyethyl)ether, (c): bis(2-methoxyethyl)ether, ●: 10 °C, ◑: 20 °C, ○: 30 °C.

The absorptions of aqueous solutions of these ethers at 15 MHz are plotted against concentration (Figs. 4(a)—(c)). They are also plotted at various frequencies at 20 °C for the 1,2-dimethoxyethane–water system (Fig. 5). The absorption *vs.* concentration curves have a peak at about 60—80 vol %. The maximum value decreases with increasing frequency. In the aqueous solutions of 1,2-dimethoxyethane and bis(2-methoxyethyl)ether, the maximum value decreases with increasing temperature, while in the solutions of bis(2-ethoxyethyl)ether it increases. In Fig. 6, the absorption of the aqueous solutions of 1,2-dimethoxyethane and that of bis(2-methoxyethyl)ether at 10 °C and at 35 MHz are plotted against concentration

relations in these solutions are classified into two groups, each of which is represented by a single curve. The upper curve is for the ethers with ethyl groups at each end of a molecule, the lower curve for those with methyl groups at each end.

Partial molar volume has been calculated graphically[28] from the density data obtained for the bis(2-ethoxyethyl)ether-water system and is plotted in Fig. 8.

Discussion

The Origin of the Maximum in Ultrasonic Absorption. A marked peak appears at an intermediate composition in each absorption *vs.* composition curve. The behavior of the curve for bis(2-ethoxyethyl)ether (Fig. 4(b))

differs from that for other ethers (Figs. 4(a) and (c)), the temperature dependence of absorption near the maximum being the reverse of that at each side. This is ascribed to the presence of L.C.S.T. It is well-known that ultrasonic absorption increases rapidly near L.C.S.T.[29]

In the aqueous solution of 1,2-dimethoxyethane and bis(2-methoxyethyl)ether the maximum of the ultrasonic absorption could be attributed to other sources. At the composition of each maximum (Figs. 4(a), (c), and 6) the molar ratio between ether and water is 1 : 2 and 1 : 3 for 1,2-dimethoxyethane and bis(2-methoxyethyl)ether, respectively. Thus, the molar ratio between etheral oxygen and water becomes 1 : 1 exactly at the composition for both ethers, because each ether has two and three etheral oxygen atoms per molecule, respectively. In the case of the dioxane-water mixture a similar feature was found and the formation of dioxane dihydrate was proposed.[2] Thus it is tentatively assumed that the origin of the maximum absorption is mainly attributed to the presence of hydrates (1,2-dimethoxyethane dihydrate and bis(2-methoxyethyl)ether trihydrate).

Absorption vs. Composition Curves for Low Concentrations. A deep minimum is found in the partial molar volume of the solute *vs.* composition curve for the bis(2-ethoxyethyl)ether-water system (Fig. 8), similar to other aqueous solutions of organic substance.[22,24,30] The composition of the minimum is about 2.5 mol % (about 20% by volume).

The sound velocity *vs.* concentration curves at various temperatures shown in Figs. 1(a)—(c) have a crossing point, where sound velocity is independent of temperature. The solute concentration at the point is about 15—20 vol % for every ether (Fig. 1). As to the ultrasonic absorption, each curve for the absorption *vs.* concentration relation has a flat region at low concentrations (below about 15—20 vol %) (Figs. 4, 5, and 7). The concentration at which the rapid increase of absorption begins is the same as that at the crossing point of velocity *vs.* concentration curves and nearly the same as that at the minimum of partial molar volume. This suggests that all these features are related to some common molecular process in dilute aqueous solutions. As regards the aqueous solutions of dioxane and other substances,[3] we proposed an explanation of a similar feature in absorption *vs.* concentration curves, based on a model of water structure. The underlying molecular process has been assumed to be the "cooperative formation" of the short-lived "ice-like structure" in liquid water.[10]

Difference between the Behavior of Ethyl and Methyl Groups in Water. As seen in Fig. 7, the absorption *vs.* concentration relation for ethers with ethyl groups at each end of a molecule is represented by a single curve (upper curve), and that for ethers with methyl group by another single curve (lower curve).

The difference between the upper and lower curves could be ascribed to the different behavior of ethyl and methyl groups in water. A methyl group at the end of a molecule is considered to rotate almost freely in water at room temperature.[31] Thus, from the

large absorption of ethers with ethyl in comparison with that of ethers with methyl, the ethyl group at the molecular end is supposed to be hindered in its motion by the formation of the water structure about itself. The formation of "water structure" about ethyl group and its disruption by the direct contact of the hydrocarbon is considered to be the origin of "hydrophobic interaction" between hydrocarbons in general with exception of the methyl group.[10,32]

Isomerization of 2-Pinene Catalyzed by Solid Acids

Ryuichiro OHNISHI, Kozo TANABE,* Shinsuke MORIKAWA,* and Tadao NISHIZAKI

Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received July 13, 1973)

The isomerization of 2-pinene (I) and 2(10)-pinene (II) in the liquid phase has been studied at 50 °C over solid acid catalysts such as silica–alumina, aluminum phosphate, nickel sulfate and zinc sulfide which have different acid strengths. The primary reaction products were camphene (III), 1,7,7-trimethyl-tricyclo[2.2.1.$0^{2,6}$]-heptane (IV) and *p*-mentha-1,8-diene (VI). The catalytic activities increased with increasing acid strength and acid amount of the catalysts. The selectivities for the formation of III+IV and VI from I were about 90 and 10% respectively over $NiSO_4$, but about 10 and 70% respectively over SiO_2–Al_2O_3 and $AlPO_4$. Those for the formation of I, III+IV and VI from II also depended on the acid strength. In the isomerization of VI, *p*-mentha-1,4(8)-diene (VII) was formed predominantly over $NiSO_4$ and *p*-cymene (IX) over SiO_2–Al_2O_3. From these results together with those of the isomerizations of III and IV, a reaction mechanism is proposed which consists of two parallel reactions proceeding *via* a common intermediate between I and II: one which gives monocyclic terpenes and the other bi- and tricyclic terpenes.

The isomerization of 2-pinene (I) over solid catalysts in the liquid phase was first reported by Gurvich in 1915.[1] Since then, a number of studies have been made on the isomerization and the following reaction products have been reported: bi- or tricyclic terpenes such as 2(10)-pinene (II), camphene (III), 1,7,7-trimethyl-tricyclo[2.2.1.$0^{2,6}$]heptane (IV), bornene (V) *etc.*, monocyclic terpenes such as *p*-menthadienes (VI, VII, VIII *etc.*), *p*-cymene (IX) and polymers[2,3] (See Fig. 4 for structures of the compounds).

Catalysts used for the isomerization were mineral clay, active carbon, silica–alumina, titanium oxide, magnesium sulfate *etc.* which can be classified as solid acids. It was reported recently that alumina, a strong acid, showed a tendency to give monocyclic terpenes, while alkali poisoned aluminas, weak acids, form bi- or tricyclic terpenes in vapor phase reactions.[4] However, no systematic work has been done on the correlation between acidic property of solid acids and their catalytic activity or selectivity. In the present work, the correlation was examined by employing as catalysts nickel sulfate which has moderate acid strength and whose acidity can be easily changed by calcination,[5–7] silica–alumina and aluminum phosphate which have high acid strength and zinc sulfide which has weak acid strength[8] in liquid phase.

On the basis of the observed results, the reaction paths and intermediates of the isomerization are discussed.

Experimental

Reagents and Catalysts. 2-Pinene was purified from turpentine oil (Wako Pure Chemical Co.) by distillation over sodium, passage through a preparative gas chromatography (Perkin–Elmer F-21) with a 3 m×8 mm column containing 20% polyethylene glycol 1500 on Chromosorb W and distillation again over sodium under a stream of nitrogen. The purified material was stored in sealed ampoules. 2(10)-Pinene and camphene (Takasago Perfumery Co.) and 1,7,7-trimethyl-tricyclo[2.2.1.$0^{2,6}$]heptane, synthesized from camphor according to the method of Meerwein and Emster,[9] were purified similarly to 2-pinene.

Nickel sulfate catalysts were prepared by calcining the heptahydrate (guaranteed reagent, Kanto Chemical Co.) in the temperature range 150—550 °C in air, grinding after cooling and calcining again at the original temperature for 3 hr. Aluminum phosphate, prepared from H_3PO_4 and $AlCl_3 \cdot 6H_2O$,[10] was calcined in air at 450 °C for 3 hr. Silica–alumina (15 wt. % Al_2O_3, Nikki Chemical Co.) and zinc sulfide (guaranteed reagent, Nakarai Chemical Co.) were calcined in air at 600 and 450 °C respectively. All catalysts were stored in sealed ampoules.

Acidity and Kinetic Measurements The acid amounts at various acid strengths of the catalysts were measured by *n*-butylamine titration using various indicators,[5] or by the ultraviolet spectrophotometric method.[11] The indicators used for the titration method were phenylazonaphthylamine ($pK_a = +4.0$), *p*-dimethylaminoazobenzene (+3.3), dicinnamalacetone (−3.0) and anthraquinone (−8.2). 2,6-Dichloro-4-nitroaniline ($pK_a = -3.27$) was used for the spectrophotometric method.

The reaction was carried out under helium gas since it is sensitive to air. The reaction temperature was 50 °C unless otherwise stated. Reaction products were analyzed by a gas chromatograph with FID (Hitachi-Perkin-Elmer F-6D), using a 45 m capillary column of Ucon LB-500-X. The amount (mole %) of each product was obtained by measuring each peak area with an integrator (DISC Co.) and by multiplying by the respective correction coefficient.

Results

Acidity of Catalysts. The acid amounts at various strengths of the catalysts are shown in Table 1. Silica–alumina and aluminum phosphate have high acid strength ($pK_a = -8.2$), while zinc sulfide has a weak one ($pK_a = +4.0$). The acid strength of the nickel sulfates was moderate. The acid amount increased with the rise in calcination temperature, attaining a maximum value at 350 °C, and then decreased at higher temperatures.[5]

Isomerization of Camphene (III), 1,7,7-Trimethyl-tricyclo-[2.2.1.$0^{2,6}$]heptane (IV) and p*-Mentha-1,8-diene (VI).* Before the reaction of I, the isomerization of III, IV, and VI, main reaction products of I, was studied. The products of the isomerization of III (or IV) were IV (or III) and a small amount of V over nickel sulfates. Over silica–alumina and aluminum phosphate which

have high acid strength, considerable amounts of polymers were obtained in addition to the above products. The isomerization to I did not occur on any of the catalysts.

The equilibrium constants between III and IV, obtained from the mole % ratio of III to IV in equilibrium, are listed in Table 2. The values above 200 °C were cited from literature.

The main reaction products of VI were p-mentha-1,4(8)-diene (VII), p-mentha-1,3-diene (VIII) and p-cymene (IX). From initial slopes of the plots of VI, VII, and IX against reaction time the selectivity for the formation of VII and IX was obtained (Table 3). VII was formed predominantly over metal sulfates which have moderate acid strength, while IX was formed predominantly over strong solid acids, where polymers were also found.

Isomerization of 2-Pinene. The % conversion of 2-pinene (I) plotted against reaction time is shown in Fig. 1a. Since the isomerization did not obey the rate equation of a first- or second- order reaction, the initial rate per unit weight of catalyst was taken as the catalytic activity. The activities of various catalysts are given in Table 4. Because of high activity of silica–alumina, the reaction over the catalyst was carried out at ambient temperature. High activities were found for silica–alumina and aluminum phosphate and a low activity for zinc sulfide as expected from their acid strengths (Table 1). Calcined nickel sulfates showed intermediate activity, varying with changes in the calcination temperature. A correlation exists between the activity and the acid amount or strength.

It should be noted that the rate of isomerization is considerably affected by the presence of air. The reaction rate in the presence of air was too slow to measure at 50 °C but became measurable at 150 °C, at which temperature the reaction in the absence of air was too fast to follow. Thus, the unusual curve

a) Values at room temperature.

of % conversion *vs.* reaction time in Fig. 1a is considered to be due to the poisoning effect of a very small amount of oxygen or moisture in the reaction system.

In order to see the selectivity of this reaction, % of I remaining at reaction time t was plotted against % of III+IV formed at time t in Fig. 1b.[12] The plots fell on a straight line. This indicates that there is no backward reaction to I and that III and IV are not converted into any other compounds under the reaction conditions, in accordance with the results of the reactions of III and IV. This indicates that III and/or IV are primary products of I. A linear relation was also found between I and VI, indicating that there is no backward reaction from VI to I.

The selectivities for the formation of III+IV and VI from I, calculated from the slopes of the straight lines over various catalysts, are shown in Table 4. The selectivity did not change much over nickel sulfates calcined at various temperatures, 80—90% of bicyclic terpenes (III+IV) and about 10% of monocyclic terpene (VI) being formed. On the other hand, a high selectivity (about 70%) for VI was found for silica–alumina and aluminum phosphate which have high acid strength. This is in agreement with the result which showed that monocyclic terpenes are formed more readily over alumina than over alkali poisoned alumina;[4] it also explains the result observed by Okada and Fushizaki where the yield of camphene was increased by the addition of magnesium oxide to mineral clay used as a solid acid,[13] since magnesium oxide, recently recognized to be a strong solid base,[14,15] is considered to weaken the acid strength of a mineral clay catalysts.

The relation between III and IV which were formed from I is shown in Fig. 2, where the catalyst used was nickel sulfate calcined at 300 °C. The slope of IV/III increased with the progress of reaction and finally reached the equilibrium value, the plots of I *vs.* III+IV falling on a straight line until the end of the reaction (Fig. 3a). The results suggest that the isomerization between III and IV takes place during a later stage of the reaction. It is shown in Fig. 3b that limonene (VI) is also converted into other compounds during a later stage of the reaction. Similar results observed

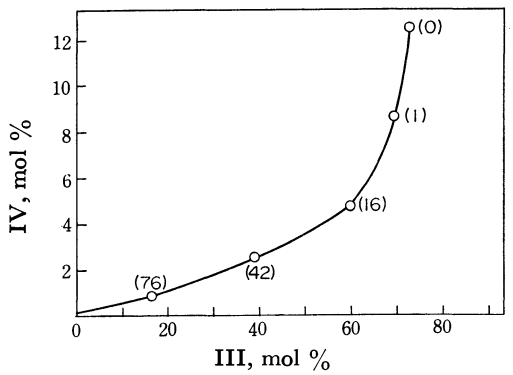

Fig. 2. Mol % of 1,7,7-trimethyl-tricyclo[2.2.1.$0^{2,6}$]heptane (IV) *vs.* mol % of camphene (III). Catalyst: nickel sulfate calcined at 300 °C, Figures in parentheses show the mol % of 2-pinene (I).

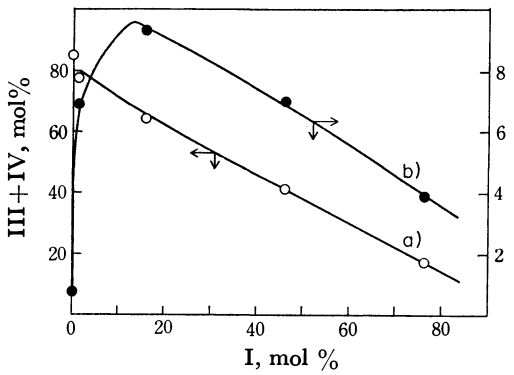

Fig. 3. Mol % of III+IV and *p*-mentha-1,8-diene (VI) *vs.* mole % of I. Catalyst: the same as in Fig. 2.

by Rudakov *et al.* for titanium oxide[16] indicate that both III and IV are primary products.

Isomerization of 2(10)-Pinene (II). The isomerization products of II were the same as those of I. The plots of III+IV *vs.* II, VI *vs.* II and I *vs.* II gave straight lines in the range 100—20 mol % of II as in Fig. 3. This indicates that III and/or IV, VI, and I are the primary products of II and that there is no backward reaction to II. This is in line with the result by Ivanova *et al.* which showed that I, III, and VI are not readsorbed on silica–alumina to react further until the concentration of II becomes less than 20—30%.[17] The selectivities for the formation of III+IV, VI and I from II, calculated from the slopes of the straight lines, are shown in Table 5, where the activity of various catalysts for the isomerization is also given. The values in parentheses, which show the selectivity recalculated by using the formula, selectivity of III+IV from II/(1−selectivity of I from II), can be compared with the selectivity values for the reactions from I given in Table 4, since II is not formed from I. The values are in fairly good accord with those in Table 5 except for silica–alumina, suggesting that III, IV, and VI are formed through a common intermediate from both.

Discussion

The maximum acidity of nickel sulfate was observed when the sulfate is calcined at 350 °C (Table 1). It is known that the acidity as measured by titrating with *n*-butylamine is the sum of Brönsted and Lewis acidity.

According to the infrared study on pyridine adsorbed on nickel sulfates, maximum Brönsted acidity appears at 250 °C and maximum Lewis acidity at 400 °C.[21] The fact that, in the isomerization of 2-pinene (I), maximum activity was observed when the sulfate was calcined at 400 °C seems to indicate that Lewis acid sites are active for the reaction. However, the isomerization of I is not catalyzed by Lewis acids such as BF_3, $AlCl_3$, $TiCl_4$ *etc.*, in the presence of an aprotic solvent such as benzene although polymers including dimer *etc.* were formed during the course of reaction.[22] The isomerization took place, however, in the presence of protic solvents such as alcohols which have proton donating ability.[23] Ozaki and Kimura reported that Lewis acid sites were converted into Brönsted acid sites by the adsorption of olefin and that the converted sites were active for olefin isomerization.[24] Thus, it can be said that the number of Lewis acid sites are correlated with the catalytic activity for the isomerization, but the actual active sites under the reaction conditions are all Brönsted acids.

Important results obtained are summarized as follows. 1) III, IV, and VI are formed through a common protonated intermediate from I and II. 2) There is no reverse reaction to I or II from III, IV, and VI. 3) VI is formed through a reaction path differing from that which III and IV are formed. 4) III, IV, and VI are not readsorbed on catalysts to react further in the presence of I or II, but turn to other compounds when the amount of I or II becomes small. 5) Over strong acid catalysts, VI is formed predominantly as compared with III and/or IV, polymers being formed from III and IV. 6) The reaction between III and IV is reversible, if I is absent. 7) The main products in the isomerization of VI are VII and IX, the latter being formed predominantly over strong solid acids.

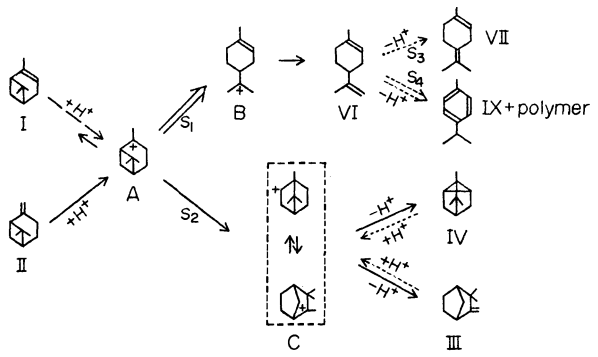

Fig. 4. Reaction scheme.

A, B, C: reaction intermediates.

⟶ steps taking place independently of the amount of I.

⟶ a step taking place when the amount of II becomes small.

⇢ steps taking place when the amounts of both I and II become small.

Steps S_1 and S_4 take place more predominantly than steps S_2 and S_3, respectively, as the acid strength of catalyst becomes higher.

These results lead us to the reaction scheme shown in Fig. 4, where the inferred structures of the reaction intermediates are also given. It is considered that the structures of intermediate A and an intermediate between VI and VII or IX change depending on the acid strength of catalyst.

The authors wish to thank Professor K. Miyahara and Professor T. Masamune for their helpful discussions.

Studies on the Mechanism of Methanol Oxidation on Zinc Oxide by Dynamic Treatments of Chemisorbed Species under the Reaction Conditions

A. C. HERD, Takaharu ONISHI, and Kenzi TAMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 4, 1973)

The mechanism of methanol oxidation on zinc oxide was studied by quantitatively observing the dynamic behaviour of the surface species during the course of the reaction. It was concluded that the mechanism was similar to that of the decomposition reaction, with an additional step, the oxidation of the carbon monoxide formed. As a key step in the oxidation of methanol, the decomposition of adsorbed methoxide groups in the presence of oxygen at temperatures between 140 and 180 °C has been studied by infrared spectroscopy. The methoxide groups decompose to formate ions until a maximum surface concentration is reached. The rate of decomposition at first increases with methoxide concentration, then decreases as the surface coverage approaches saturation. The observed kinetics can be explained by a mechanism which postulates that negatively charged surface species repel electrons from the surface of the zinc oxide, thus inhibiting decomposition of the methoxide groups.

In order to elucidate the mechanisms of heterogeneous catalytic reactions, it is advantageous to be able to quantitatively observe the dynamic behaviour of the surface species during the course of the reaction.[1] Infrared spectroscopy provides a means of achieving this, but progress has been limited, mainly because of experimental difficulties.[2]

Recently, a paper from this laboratory[3] elucidated the mechanism of methanol decomposition on zinc oxide, by the use of simultaneous infrared and kinetic measurements. It was shown that methanol is adsorbed as methoxide and hydroxide groups. At temperatures above approximately 150 °C, the methoxide groups decompose to give formate ions, which at temperatures above 200 °C and in the absence of methanol vapour, decompose to give carbon monoxide.

Because of this successful application of quantitative infrared spectroscopy, it was felt that it would be profitable to extend this work to a detailed study of the individual reaction steps of a similar system. The oxidation of methanol was chosen because the presence of oxygen decreases the infrared absorption by zinc oxide. Experiments showed that the mechanism was similar to that of the decomposition reaction, with an additional step, the oxidation of the carbon monoxide formed. This paper reports on the decomposition of surface methoxide groups on zinc oxide in the presence of oxygen.

Experimental

The zinc oxide, Kadox 25, a product of the New Jersey Zinc Co., was the same as that used in the previous work,[3] and had a B.E.T. surface area of 10 $m^2 g^{-1}$. It was pressed into self-supporting disks (ca. 0.1 g cm^{-2}) and a single disk placed in a previously described infrared cell,[4] part of a conventional closed circulating system. The infrared spectrometer employed was a JASCO 402G Grating Spectrometer (Japan Spectroscopic Co.), and the spectra of the adsorbed species were studied within the 4000 to 900 cm^{-1} range.

Before each experiment, the catalyst disk was given the following outgassing treatment at 400 °C. Evacuation (*ca.* 10^{-5} Torr) for three hours, followed by 5 minutes in 1 cmHg of oxygen, a further 1 hour evacuation, 30 minutes in 1 cmHg of oxygen, and finally cooled to the reaction temperature (usually 150 °C) under oxygen. During the oxygen treatments, the gas phase was circulated through the infrared cell and a liquid nitrogen trap in order to remove any CO_2 that had desorbed from the catalyst surface. This treatment gave a highly oxidised catalyst, and the residual hydroxyl and carbon dioxide peaks were reduced to a satisfactory level.

The reactions were carried out in the absence of gas phase methanol, under 1 cmHg of oxygen. Methoxide groups are strongly bound to the zinc oxide surface, and at the temperatures studied, the rate of desorption was small, especially at lower coverages.

Results

Oxidation of Methanol and Decomposition of Methoxide Groups. The spectra observed for the methoxide, hydroxide and formate surface species on zinc oxide in the presence of oxygen, were the same as those reported by Ueno *et al.*[3] on reduced zinc oxide, with the addition of a methoxide band overlapping the ZnO band at 1070 cm^{-1}, which is assigned to C–O stretching.

At temperatures above 150 °C in vacuum, ZnO slowly loses oxygen,[5] giving an increase in the number of conduction electrons. This causes a marked decrease in the background transmission, and affects the optical density of the absorption bands due to adsorbed

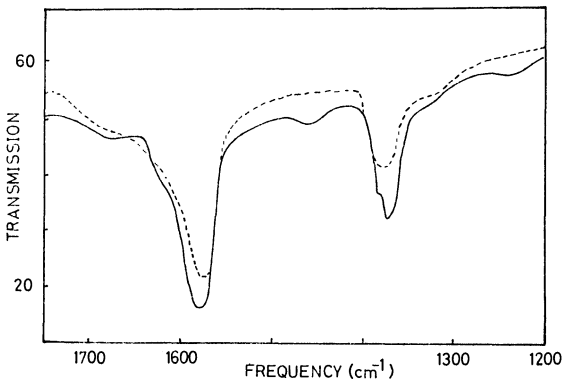

Fig. 1. The effect of adsorbed methanol on the spectrum of formate ions on ZnO.
------ the spectrum of adsorbed formic acid, —— the same spectrum after the addition of methanol.

species, especially those at lower frequencies. This loss of lattice oxygen appears to be enhanced by the adsorption of methanol. In the presence of oxygen, however, the background transmission is greatly improved, and the intense formate O–C–O asymmetric stretching band at 1570 cm^{-1} can be used for quantitative measurements.

It was found that the band shape and optical density of the formate 1570 cm^{-1} band were affected by the presence of other surface species as illustrated in Fig. 1. Therefore, for this band, the integrated optical density was used, as this was shown to be independent of the presence or absence of the other surface species occurring in this work.

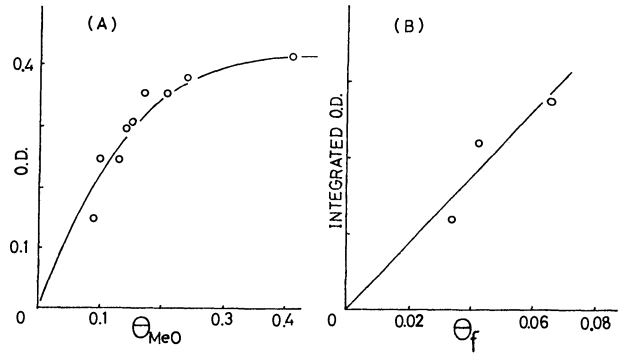

Fig. 2. Calibration curves. (A) Optical density of the 2830 cm^{-1} methoxide band *versus* methoxide group coverage. (B) Integrated optical density of the 1570 cm^{-1} formate ion band *versus* formate ion coverage.

The calibration curves for the methoxide group and formate ion shown in Fig. 2 were determined by measuring the 2830 and 1570 cm^{-1} bands when measured amounts of methanol and formic acid respectively were adsorbed at 100 °C. The concentration of surface sites on the zinc oxide was assumed to be 10^{15} cm^{-2}.

It is of significant interest to note that methanol oxidation proceeds in the presence of oxygen in a manner similar to that of methanol decomposition in the absence of oxygen, with an additional step, the oxidation of the carbon monoxide formed.

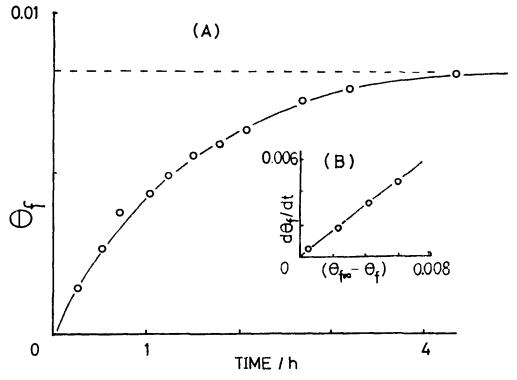

Fig. 3. Formate ion formation at 150 °C and $\theta_{MeO}=0.095$

When methanol was adsorbed on zinc oxide at 150 °C, the methoxide groups decomposed to give formate ions, until the surface formate ion coverage, θ_f, reached a saturation value, $\theta_{f\infty}$, which increased with increasing temperature. A typical result is shown in Fig. 3(A). It was found that the results, when plotted as $d\theta_f/dt$ against $(\theta_{f\infty}-\theta_f)$, as in Fig. 3(B), gave a straight line, and hence could be expressed as

$$d\theta_f/dt = k(\theta_{f\infty}-\theta_f).$$

Although the limited accuracy of the experimental results does not exclude other expressions, this form was found to be useful in defining a first order rate constant k, and in cases where the reaction was very slow, in estimating $\theta_{f\infty}$.

When formic acid was preadsorbed on the catalyst disk at 150 °C, to give a coverage of $\theta_f=0.01$, the integrated optical density of the 1570 cm^{-1} band remained constant with time, and did not change even when methoxide groups were introduced onto the surface. This showed that the methoxide groups did not decompose in the presence of this surface coverage of formate ions, and that the rate of formate ion decomposition at 150 °C is negligible.

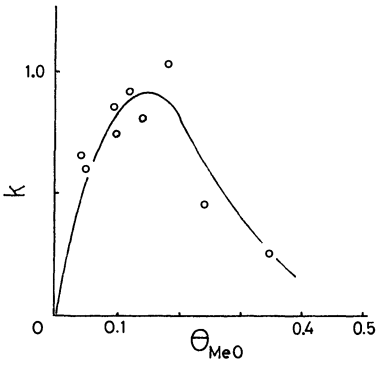

Fig. 4. The dependence of k on the methoxide group coverage.

Figure 4 shows the dependence of k on the methoxide surface coverage, θ_{MeO}. As $\theta_{f\infty}$ was always small compared to θ_{MeO}, the methoxide coverage was approximated as being constant during each run, although the gradual desorption of methanol may lead to errors of up to 10% in the value of θ_{MeO} at higher coverages. The results from Fig. 4 suggest that the rate equation for the reaction could be written as

$$d\theta_f/dt = k'(\theta_{f\infty}-\theta_f)\theta_{MeO}^{x}(1-\theta)^{y}$$

where θ is the total surface coverage. Although the scatter of the experimental points cannot justify putting exact values to x and y, it seems probable that $y \geq x \approx 1$.

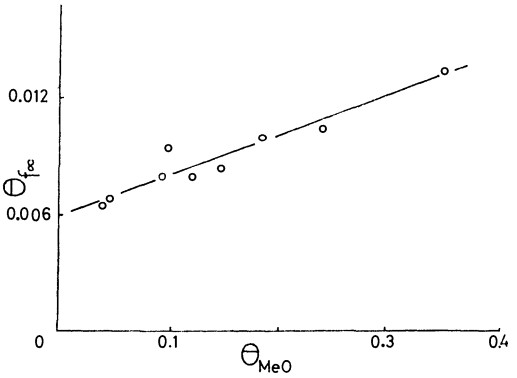

Fig. 5. The saturation formate ion coverage at 150 °C *versus* methoxide group coverage.

Support for the $(1-\theta)^y$ term was given by the results of an experiment in which the methoxide coverage was increased in the middle of a normal run. θ increased from 0.27 to 0.75 and the rate of formate ion formation was drastically reduced. As shown in Fig. 5, $\theta_{f\infty}$ depends linearly on θ_{MeO}.

It was found that there was no measureable dependence of either $\theta_{f\infty}$ or k on oxygen pressure in the range 1 to 12 cmHg. At oxygen pressures of less than about 0.5 cmHg, the zinc oxide appeared to lose oxygen, and the formate ion coverage was impossible to measure quantitatively.

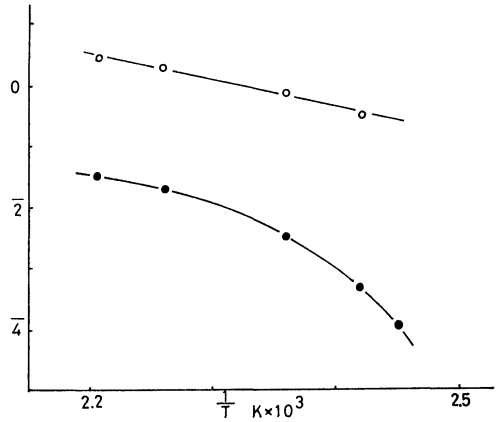

Fig. 6. Arrhenius plots of k —●—, and the initial rate of formate ion formation —○—.

Arrhenius plots of k and the initial rate of formate formation, for constant $\theta_{MeO}=0.16$, are shown in Fig. 6. The slope of the straight line given by $\log_{10} k$ against $1/T$ is equivalent to an activation energy of 85 kJ·mol^{-1}.

Preadsorbed Carbon Dioxide. The effect of CO_2 on the rate of the formate ion decomposition and on $\theta_{f\infty}$ was also investigated. CO_2 was admitted onto the zinc oxide in the presence of oxygen at 150 °C, then the circulated gas phase was trapped with liquid nitrogen. Figure 7 shows the spectrum immediately after the CO_2 was removed from the gas phase, and after a further 40 min trapping. The addition of methanol caused a large proportion of the remaining carbon dioxide to desorb.

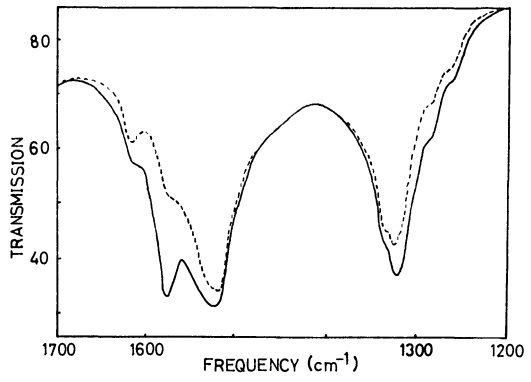

Fig. 7. The spectrum of CO_2 adsorbed on ZnO at 150 °C.
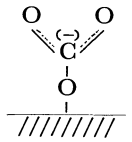
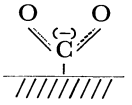
—— immediately after trapping the gas phase CO_2.
---- after 40 minutes trapping.

Despite a considerable amount of literature, the assignment of the infrared bands of CO and CO_2 adsorbed on metals and metal oxides remains very uncertain.[2] However, it seems probable that the two strong bands at 1530 and 1325 cm^{-1} should be assigned to the asymmetric and symmetric O–C–O stretching vibrations of



because of the close correlation with the spectrum of $Na_2[Cu(OCO_2)_2]\cdot 3H_2O$, which has bands at 1529 and 1326 cm^{-1}.[6] The unstable species absorbing at 1575 and probably 1325 cm^{-1} is possibly.[7]



Although it is difficult to determine exactly the amount of chemisorbed carbon dioxide species, it was found that the chemisorption of an estimated θ_{CO_2} of 0.02 halved the formate ion coverage at saturation. This effect is obviously too great to be attributed solely to the $(1-\theta)^y$ term.

Discussion

It appears unlikely that the apparent saturation of the formate ion is caused by its simultaneous decomposition, because the rate of decomposition of formate ions was shown to be negligible at 150 °C, and because this explanation would predict a linear Arrhenius plot for the initial rate.

A possible explanation for the results arises from the observation that negatively charged surface ions such as adsorbed CO_2 and formate ions appear to inhibit the decomposition of the methoxide groups. If the methoxide group must capture an electron from the zinc oxide before it can decompose,

$$CH_3O(a) + e \rightleftharpoons CH_3O^-(a) \quad (1)$$

$$CH_3O^-(a) + \text{free surface sites} \longrightarrow HCOO^-(a) + 2OH(a) \quad (2)$$

and it is assumed that the concentration of $CH_3O^-(a)$ is small, and that the latter reaction is rate controlling, we can write

$$d\theta_f/dt = k''(1-\theta)^a[CH_3O(a)][e_s]K \quad (3)$$

where e_s is the concentration of free electrons at the surface of the zinc oxide and K is the equilibrium constant for Eq. (1). The concentration of electrons at the surface can be written as[8]

$$[e_s] = N_c \exp\{-(\mu + eQ^2/2N_d\varepsilon\varepsilon_0)/kT\} \quad (4)$$

where N_c is the number of free electrons, μ is the energy difference between the Fermi level and the bottom of the conduction band in the bulk, N_d the donor density, ε the dielectric constant of the ZnO, ε_0 the permittivity of the ambient gas, and eQ^2 the surface charge arising from charged surface species ($HCOO^-(a)$, $CO_2^-(a)$, and $O^-(a)$). Substitution of this term into Eq. (3) gives a rate equation similar to the experimentally derived rate equation, except that the $(\theta_{f\infty}-\theta_f)$ term

has been replaced by an expression for the surface electron concentration which is exponential in $-eQ^2$. It is very unlikely that the experimental results could distinguish between these two forms, especially in view of the approximations of constant θ_{MeO} and θ, and the lack of information about chemisorbed oxygen. The proposed mechanism therefore suggests that the slowing down of the reaction is caused by the negatively charged layer of surface formate ions (or adsorbed CO_2^-) repelling electrons from the surface.

The increase of $\theta_{f\infty}$ with increasing temperature and increasing θ_{MeO} can be explained by their effects on the amount of chemisorbed O^-. Both would tend to decrease [O^-(a)] thus decreasing the number of negatively charged species at the surface. Although no oxygen pressure dependence was found at oxygen pressures above 1 cmHg, it is possible that the surface is virtually saturated with O^-(a) below this pressure. In support of this, increasing the oxygen pressure from 1 to 12 cmHg had little effect on the background ZnO infrared absorption. Further, values of $\theta_{f\infty}$ (ignoring formate ion decomposition) in the absence of gas phase oxygen, calculated from the results of Ueno *et al.*[3] are approximately 10 times larger than those found in this work.

Doping of the zinc oxide should also affect $\theta_{f\infty}$, though not to the same extent as changes in the surface charge, and this may help to explain the direct relationship between the electrical conductivity of zinc oxides and their activities for the decomposition of methanol.[9]

A New Technique Using the Polynomials Approximation and Trapezoidal Average Method for Estimating Kinetic Rate Constants in Systems of Linear or Nonlinear Differential Equations

Katsutoshi OHKUBO, Kohji TSUCHIHASHI, and Hiroyuki SAKAMOTO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received August 9, 1973)

A new technique using the polynomials approximation and the trapezoidal average method, has been proposed for estimating kinetic rate constants. It is implemented by minimizing the error of the concentration (of a product) obtained from the polynomial-approximated least square-error analysis of the observed concentrations during the initial reaction stage relative to that obtained theoretically from the trapezoidal average of the calculated concentration (of a product) on the basis of the law of mass action. The technique is useful for easily and exactly estimating the rate constants in systems of linear or nonlinear differential equations. A kinetic model, $A \longrightarrow B \rightleftarrows C$, was used to illustrate and develop the present technique.

In usual kinetic studies of chemical-reaction mechanisms, we often find it difficult to estimate exactly the kinetic rate constants of the elementary steps of the reaction. Some numerical integration methods, such as the Runge-Kutta integration,[1] Taylor's series expansion,[2] and Picard's method,[3] are usually used to estimate the rate constants. These methods, however, require a precision fit to dense data or much computation time.

The new technique presented in this paper requires only a few kinetic data (usually concentrations) about the species participating in the reaction. It is based on the polynomial approximation of the given kinetic data and the trapezoidal average of the minute change in the concentration of the species (typically, that of a product). The following kinetic model was used to illustrate and develop the present technique:

$$A \xrightarrow{k_1} B \underset{k_3}{\overset{k_2}{\rightleftarrows}} C \qquad (1)$$

where A=reactant; B=intermediate; C=product; k_i= rate constant i, and i=1, 2, and 3. The type of reaction depicted by Eq. (1) is found in such an organic reaction progress as chlorosulfonation:

$$RH \xrightarrow{ClSO_2OH} RSO_2OH + HCl \overset{ClSO_2OH}{\rightleftarrows} RSO_2Cl + H_2SO_4 \quad (R=\text{alkyl or aryl}).$$

Computation Method

The kinetic model illustrated by Eq. (1) can be described by the following differential equations drawn from the law of mass action:

$$d(A)/dt = -k_1(A) \qquad (A)_0 \neq 0 \qquad (2a)$$

$$d(B)/dt = k_1(A) - k_2(B) + k_3(C) \qquad (B)_0 = 0 \qquad (2b)$$

$$d(C)/dt = k_2(B) - k_3(C) \qquad (C)_0 = 0 \qquad (2c)$$

where the parentheses denote concentrations and where the subscript zeros stand for the initial concentrations of the species.

We will now explain the computation method of the present technique for estimating the rate constants, basing on the above differential equations. According to Eqs. (2a—c), the increments for the three components, A, B, and C, at the reaction time of t, $D(A)_t$, $D(B)_t$, and $D(C)_t$, are defined as:

$$D(A)_t = -k_1(A)_t dt, \quad (A)_{t+dt} = (A)_t + D(A)_t \qquad (3a)$$

$$D(B)_t = k_1(A)_t dt - k_2(B)_t dt + k_3(C)_t dt, \quad (B)_{t+dt} = (B)_t + D(B)_t \qquad (3b)$$

$$D(C)_t = k_2(B)_t dt - k_3(C)_t dt, \quad (C)_{t+dt} = (C)_t + D(C)_t \qquad (3c)$$

where the notations of $(\text{Component})_t$ and $(\text{Component})_{t+dt}$ indicate the concentrations of the components at t and $t+dt$ respectively.

The concentrations of the components at $t+mdt$ (m=1,2,3,$\cdots$), $(\text{Component})_{t+mdt}$ are, then, defined by:

$$(\text{Component})_{t+mdt} = (\text{Component})_t + \sum_{p=1}^{m} D(\text{Component})_{t+(p-1)dt} \qquad (4)$$

The $D(\text{Component})_{t+(p-1)dt}$ values in Eq. (4) are evaluated by the following trapezoidal average:

$$\begin{aligned} D(\text{Component})_{t+(p-1)dt} &= (D(\text{Component})_{t+(p-1)dt} + D(\text{Component})_{t+pdt})/2 \\ &= 1.5D(\text{Component})_{t+(p-1)dt} - 0.5D(\text{Component})_{t+(p-2)dt} \end{aligned} \qquad (5)$$

where $D(\text{Component})_{t+(p-1)dt}$ is defined by

$$D(\text{Component})_{t+(p-1)dt} = (D(\text{Component})_{t+pdt} + D(\text{Component})_{t+(p-2)dt})/2.$$

We will use the product of C as the Component and assume that p=2. Then, the above relationships can be rewritten as:

$$\begin{aligned} D(C)_{t+dt} &= (D(C)_{t+dt} + D(C)_{t+2dt})/2 \\ &= 1.5D(C)_{t+dt} - 0.5D(C)_t \end{aligned} \qquad (5')$$

where $D(C)_{t+dt}=(D(C)_{t+2dt}+D(C)_t)/2$.

In the evaluation of the $D(C)_{t+dt}$ values, the rate constants, k_i, are supplied by:

$$k_t = \min k_t + \sum^{n} 10^{(\gamma-\beta)} \min k_t, \quad \gamma = \text{gauss}\left[\frac{n-1}{9\alpha}\right] \qquad (6)$$

(n=1, 2, 3, $\cdots$, β=0, 1, 2, $\cdots$, $\alpha=10^{\beta}$)

where min k_i=lower limit of k_i ($1.0\times10^{\delta}$; δ=constant); γ=integral number; β=constant; α=parameter determining the number of significant figure for k_i (*viz.*, k_i=(β+1) significant figures at $\alpha=10^{\beta}$).

On the other hand, the time conversion of the observed concentration of C, $(C)_{t,obsd}$, is represented by the following series of polynomials, resulting from the least square-error analysis of the $(C)_{t,obsd}$ values:

$$(C)_{t,obsd} = a_0 + a_1 t + a_2 t^2 + a_3 t^3 + \cdots + a_n t^n \quad (n=0, 1, 2, \cdots) \tag{7}$$

where a_n (n=0,1,2,$\cdots$) denote coefficients. The average increment observed at $t+dt$, $D(C)_{t+dt,obsd}$, is, then, defined as:

$$D(C)_{t+dt,\,obsd} = (C)_{t+2dt,\,obsd} - (C)_{t+dt,\,obsd} \tag{8}$$

where the $(C)_{t+2dt,obsd}$ and $(C)_{t+dt,obsd}$ values are calculated by Eq. (7).

The best rate constants are estimated by minimizing the following relative error, ε:

$$\varepsilon = |D(C)_{t+dt} - D(C)_{t+dt,\,obsd}| / D(C)_{t+dt,\,obsd} < \delta\varepsilon \tag{9}$$

where $\delta\varepsilon$ is the error norm for converging the computation. In the evaluation of the ε value, the iteration procedure is necessary: that is, the rate constants, k_j (j=1, 2, or 3), are changed in turn until one gets the smallest ε value while the other constants, $k_{i(i\neq j)}$, are fited.

The $D(C)_{t+dt}$ values in Eq. (9) are computed by the following equation, derived from Eqs. (3c), (4), and (5′):

$$\begin{aligned} D(C)_{t+dt} = {} & [k_2((A)_0 - (A)_{t+dt}) - (k_2+k_3)(C)_{t+dt})]dt \\ & + 1.5[k_2(k_1+k_2+k_3)(A)_{t+dt} \\ & + (k_2+k_3)^2(C)_{t+dt} - k_2(k_2+k_3)(A)_0]dt^2 \end{aligned} \tag{10}$$

In Eq. (10), the following approximation is taken for simplicity of computation:

$$(A)_{t+dt} \approx (A)_t \tag{11}$$

In order to avoid any technical error caused by the above approximation, a very small dt value should be used for the computation. However, it is better to discard the above approximation when the $(A)_{t+dt}$ value can be evaluated from the time conversion of (A).

The conditions used throughout in this paper are dt=0.01—0.1, min k_i=1.0×10^{-5}, n=1—991, β=1, and α=10.

Computed Results and Discussion

Table 1 shows the kinetic data, $(Component)_{t,obsd}$, obtained by the simulation[4] of the kinetic model with specifications of $(A)_0$=10.0, $(B)_0=(C)_0$=0, k_1=0.1, k_2=0.6, k_3=0.2, and dt=0.001. We used the simulation data as the given kinetic data, because the preliminarily known k_i values facilitate the checking of the accuracy of the estimated rate constants, $k_{i,estimated}$. The coefficients (a_n) of the polynomials of Eq. (7) were, then, determined by the least square-error analysis of the $(C)_{t,obsd}$ values at t=0, 1, 2, $\cdots$, n in Table 1 (n corresponds to the subscript n of a_n in the highest-order term of Eq. (7)). Table 2 lists the a_n values,

a) See Ref. 5 ($(A)_0=10.0$; $(B)_0=(C)_0=0$; $k_1=0.1$; $k_2=0.6$; $k_3=0.2$; $dt=0.001$).

and Table 3 shows the $(C)_{t+dt,obsd}$ and $(C)_{t+2dt,obsd}$ values evaluated by the polynomial approximation.

Now, let us examine the effect of the dt values on the estimation of the rate constants. The rate constants for the kinetic model were estimated using the polynomials ($n=10$) with the following specifications: $(A)_0=10.0$; $(B)_0=(C)_0=0$; $dt=0.01$—0.1; $(C)_t=(C)_{1.0}$; $(C)_{t+dt}=(C)_{1.0+dt}$; $(C)_{t+2dt}=(C)_{1.0+2dt}$. Table 4 shows the change in the $k_{i,estimated}$ values due to the dt values, together with the relative errors of ε and ε_i ($i=1$, 2, and 3), defined by Eq. (9) and (12) respectively:

$$\varepsilon_i = |k_{i,estimated}-k_{i,given}|/k_{i,given} \quad (12)$$

where $k_{i,given}$ stands for the exact k_i values (*viz.*, $k_1=0.1$, $k_2=0.6$, and $k_3=0.2$). It may be seen from Table 4 that the smaller the dt value becomes, the more the ε_i values are lowered. Since the best k_i values should be given by the $k_{i,estimated}$ values, which are not appreciably influenced by the dt value, it is desirable to establish the following relationship:

$$|(A)_{t+dt}-(A)_t|/(A)_t \approx 0 \quad (13)$$

where the $(A)_{t+dt}$ and $(A)_t$ values are, respectively, obtained from Eq. (3a) and Table 1.

It is of interest here to compare the $k_{i,estimated}$ values presented in Table 4 with those calculated by means of the following equation:

$$\begin{aligned} D(C)_{t+dt} &= (C)_{t+2dt}-(C)_{t+dt} \\ &= [k_2((A)_0-(A)_{t+dt})-(k_2+k_3)(C)_{t+dt}]dt \\ &\quad + [k_2(k_1+k_2+k_3)(A)_{t+dt}+(k_2+k_3)^2(C)_{t+dt} \\ &\quad -k_2(k_2+k_3)(A)_0]dt^2 \end{aligned} \quad (14)$$

where $(A)_{t+dt}$ is approximated by $(A)_t$. The $k_{i,estimated}$ values evaluated by Eq. (14) were found to be inaccurate in some measure as compared with those listed in Table 4; for example, $k_1=0.14$, $k_2=0.60$, $k_3=0.20$, and $\varepsilon=0.221\%$ at $dt=0.1$, and $k_1=0.13$, $k_2=0.60$, $k_3=0.20$, and $\varepsilon=0.028\%$ at $dt=0.01$ under the specifications mentioned before. It may be deduced, therefore, that the trapezoidal average method depicted by Eq. (5′) is superior to the usual technique illustrated by Eq. (14) for estimating the rate constants.

Next, let us notice the effect of the order (n) of the polynomial approximation on the evaluation of the $k_{i,estimated}$ values. Table 5 lists the $k_{i,estimated}$ values

Table 4. Effect of the dt value on the estimation of rate constants

dt	k_i			$\varepsilon_i(\%)$			$\varepsilon(\%)$
	k_1	k_2	k_3	ε_1	ε_2	ε_3

0.02	0.098	0.60	0.20	2.0	0.0	0.0	0.004
0.01	0.10	0.60	0.20	0.0	0.0	0.0	0.029

Computations were carried out with the polynomials of $n=10$. (Iteration=2; Computation time with FACOM 230-25=1.7 min in every case.)

obtained by the trapezoidal method using the polynomials of $n=2$, 3, 4, 5, 6, and 10. As we expected, the increase in the n value of the polynomials decreases the ε_i ($i=1$—3) values as defined by Eq. (12), and the polynomials of $n=10$ offer the exact rate constants. The present technique requires a polynomial approximation involving a relatively high order of terms, because it takes the rough approximation depicted by Eq. (11).

Table 5. Estimated rate constants and relative errors

n	k_i[a]			$\varepsilon_i(\%)$			$\varepsilon(\%)$
	k_1	k_2	k_3	ε_1	ε_2	ε_3	
2	0.01	0.55	0.19	90.0	8.33	5.0	0.0494
3	0.010	0.59	0.19	90.0	1.67	5.0	0.187

(Received August 10, 1973)

The crystal structure of the cyclic tetramer of formaldehyde, 1,3,5,7-tetroxocane, has been determined by the X-ray diffraction method. The unit cell is monoclinic, with $a=11.455$, $b=4.160$, $c=12.232$ Å, and $\beta=108.4°$. The space group is C2/c, and there are four molecules per unit cell. The structure was solved by using a molecular transform method and was refined by the block-diagonal least-squares method to a final R factor of 0.051, using 728 reflections measured with an automated four-circle diffractometer. The molecules in the crystal are of the so-called crown form, with an approximate C_{4v} symmetry but an exact C_2 symmetry. The torsion angles about the four independent C–O bonds appear in two distinguishable values: two bonds with 83.7 and −83.6°, and the other two bonds with 93.6 and −94.1°. The average C–O bond length is 1.403 Å, while the average C–O–C and O–C–O bond angles are 116.6 and 113.8° respectively. The deformation from a regular crown form by taking the two distinguishable torsion angles and the increase in bond angles is favorable to compensating for the intramolecular H···H repulsions; the close H···H distances in the deformed crown form are 2.16 and 2.20 Å.

The cyclic tetramer of formaldehyde, 1,3,5,7-tetroxocane $(-CH_2-O-)_4$, presents two interesting problems which can be investigated by X-ray study. One is the molecular conformation of this eight-membered cyclic compound, and the other is the radiation-induced solid-state polymerization of tetroxocane, by which tetroxocane molecules in the crystal are converted into highly crystalline linear polyoxymethylene $(-CH_2-O-)_n$.[1] Studies along similar lines have been performed on some cyclic oligomers of formaldehyde: 1,3,5-trioxane $(-CH_2-O-)_3$,[2] 1,3,5,7,9-pentoxecane $(-CH_2-O-)_5$,[3,4] and 1,3,5,7,9,11-hexoxecane $(-CH_2-O-)_6$.[5] As for tetroxocane, a structural study of the solid-state polymerization has already been reported,[6] in which the crystal structure of this substance has been shown; also, it has been stated that the molecular conformation in the crystal is of a crown form. On the other hand, the presence of two conformations is suggested by the study of the temperature dependence of the NMR spectra of the tetroxocane in solutions:[7,8] one has a boat-chair or a distorted boat-chair conformation, and the other, preponderant at low temperatures, presumably has a crown form which was expected to be found in the crystal. The present paper will describe the crystal structure of tetroxocane in detail.

Experimental

The tetroxocane was synthesized by the method of Staudinger and Luthy.[9] The melting point of tetroxocane is 114 °C. Recrystallization from a benzene solution or sublimation yielded prismlike crystals elongated along the b axis. Because of its high vapor pressure, single crystals were sealed in thin-walled Lindemann glass capillaries. The cell dimensions were determined from Weissenberg photographs and from θ values as measured with a single-crystal diffractometer. Crystal data:

1,3,5,7-Tetroxocane, $(-CH_2-O-)_4$
Molecular weight 120.1
Monoclinic $a=11.455\pm0.007$ Å
$b=4.160\pm0.006$
$c=12.232\pm0.009$
$\beta=108.4\pm0.1°$
$Z=4$
Volume of the unit cell: $V=553.0$ Å^3
Density, calculated: $D_x=1.442$ g/cm^3; measured: $D_m=1.435$ g/cm^3
Number of electrons per unit cell: $F(000)=256$
Absorption coefficient for $\lambda_{MoK\alpha}$(=0.7107 Å): $\mu=1.40$ cm^{-1}

The systematic extinctions occur for hkl with $h+k$ odd, for $h0l$ with either h or l odd, and for $0k0$ with k odd. The space group is, therefore, either Cc or C2/c, of which the latter was adopted on the basis of the plot of the intensity distribution.[10,11]

The intensity measurements were performed using a Rigaku-Denki automated four-circle diffractometer. The crystal used for the intensity measurements was $0.4\times0.4\times0.5$ mm^3 in size. The integrated intensities were measured using the $\theta-2\theta$ (moving-crystal, moving-counter) technique for all the reflections in the sphere of the $\sin\theta/\lambda<0.70$ Å^{-1} radius, with MoKα radiation. The scanning speed was 2°/min, and the scan range was calculated by this formula:

$$\text{scan range}=(0.8+1.0\tan\theta)\text{ degrees.}$$

The background counts were measured at the beginning and at the end of the scan range for a period of 20 seconds and corrected for the time factor. No correction was made for absorption. The F values of 52 out of the 780 non-equivalent reflections within the sphere were set as equal to zero, since the F values were smaller than the estimated standard deviation of the values, and were not included in the refinement. In a previous paper[6] solid-state polymerization by X- or γ-irradiation was reported. The yield of the polymer depends upon the irradiation temperature. The present measurements were performed at 19 °C; judging from the approximate constancy of the intensities of the three reference reflections measured every 25 reflections, such a polymerization was almost suppressed, the gradual decrease in the observed F values being 2% at the end of the measurements (the total exposure was 42 hours). Therefore, the correction for the time dependence was made for the observed F values. It was also noticed that the diffraction spots of tetroxocane crystal were not altered in location and remained fairly sharp in spite of the polymerization.

Structure Determination

b-Projection. There are eight equivalent general positions in the C2/c space group, while the number of molecules in the unit cell is four. Therefore, the molecules in the unit cell must be situated at one of the twofold positions. There are, in this space group, four sets of centers of symmetry and a set of twofold rotation axes along the b axis. In the b-projection, however, these two kinds of symmetry elements are not distinguishable, and a smaller cell with one molecule can be chosen. The shortness of the b dimension (4.160 Å) indicates that there can be no superposition of atoms in the b-projection, and the eight-membered rings are oriented almost perpendicularly to the b axis. On the b-projection, we could assume a regular octagonal ring as a gross structure of the projected molecule, although the molecular conformation was still uncertain. Accordingly, as a first step, the molecular transform of a regular octagonal ring of the tetroxocane molecule was calculated, taking the polar coordinates (r, ϕ) and (R, ψ) in the real space and the reciprocal space respectively. On the regular octagonal model, there is a fourfold rotation symmetry. The molecular transform, F_m, thus can be written by analogy with the molecular transform of a helix proposed by Cochran, Crick, and Vand:[12]

$$F_m(R, \psi) = 4\sum_n\sum_j f_j J_n(2\pi R r_j) \exp\{in(\psi-\phi_j+\pi/2)\},$$

where J_n is the Bessel function of the n-th order. In the present case, only $n=0$, ±4 and ±8 need be considered in the range of $\sin\theta/\lambda<0.70$ Å^{-1}, and the ϕ_j's for the reference oxygen and carbon atoms are 0 and $\pi/4$ respectively. By using this expression, the molecular transform was evaluated very fast by handwork. A satisfactory fitting of the squares of the molecular transform, F_m^2, to the weighted reciprocal lattice points, as is shown in Fig. 1a, was obtained when the oxygen atom was oriented at an angle of 27° from the c axis (Fig. 1b). The signs of all the observed $F(h0l)$'s except for a few weak ones were determined from the molecular transform. By two cycles of two-dimensional Fourier syntheses, the atomic coordinates were refined up to the discrepancy factor, $R(=\sum||F_o|-|F_c||/\sum|F_o|)$, of 0.12 without hydrogen atoms.

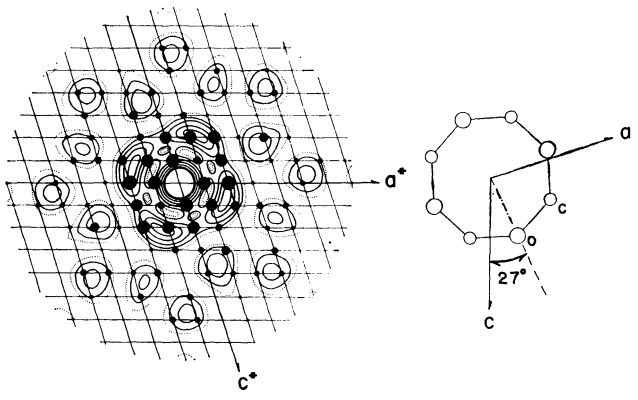

Fig. 1. (a) Contour map of $F_m^2(R, \psi)$ of the regular octagonal shape model of tetroxocane molecule and the weighted $(h0l)$ reciprocal lattice points. (b) Orientation of the model in the crystal lattice.

Three-dimensional Structure. A good agreement of F_o and F_c was obtained when the molecular conformation was a crown form with a twofold rotation axis and when the center of gravity of the molecule was at approximate $y=0.25$. Further refinement was made using the block-diagonal least-squares method.[13] The R value was reduced to 0.14 by using isotropic thermal factors. The anisotropic thermal factors were then introduced, and the R value dropped to 0.09 after six cycles. Hydrogen atoms were located at this stage from a difference Fourier synthesis (Fig. 2) and were included in the least-squares refinement with isotropic thermal factors. In the last stage, the 002 and $\bar{1}11$ reflections were excluded from the least-squares calculation because they appeared to be seriously affected by extinction. The $\sum w(F_o-kF_c)^2$ quantity was minimized, where w is the weight function and k is the scale factor. At the final stage of the refinement, the following weighting scheme was employed: $w=(4F_{min}/F_o)^2$ if $F_o\geq4F_{min}$, $w=1$ if $4F_{min}>F_o\geq F_{min}$, and $w=0.2$ if $F_o<F_{min}$, where $F_{min}=2.0$. The R value dropped to 0.048 for all the observed reflections except 002 and $\bar{1}11$, and to 0.051 including these two reflections. The atomic scattering factors used for the carbon and oxygen atoms were those in the International Tables for X-ray Crystallography, Vol. III,[14] while for hydrogen the values of Stewart *et al.*[15] were used. The final atomic coordinates and thermal parameters are listed in Table 1. A comparison of the observed and calculated structure factors is given in Table 2.

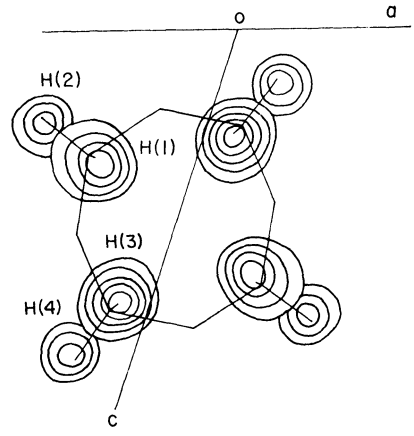

Fig. 2. Sections of three-dimensional difference Fourier synthesis through the atomic centers parallel to the (010). The contours are at intervals of 0.1 e/Å^3, starting with 0.2 e/Å^3.

Results and Discussion

The molecular dimensions derived from the final atomic coordinates are shown in Table 3 and Fig. 3. The molecular conformation of tetroxocane in the crystal was established to have a crown form, like that of methaldehyde[16] and sulphur,[17] though 1,3,5,7-tetrathiocane $(-CH_2-S-)_4$[18] was found to exist not in

O(1)–C(1)–H(1)	111(1)	O(1′)–C(2)–H(4)	105(1)
Torsion angles (°)			
C(2′)–O(1)	83.7	C(1)–O(2)	93.6
O(1)–C(1)	−83.6	O(2)–C(2)	−94.1
Intramolecular H···H distances (Å)			
H(1)···H(3)	2.20(3)	H(1)···H(3′)	2.16(3)

Estimated standard deviations shown in parentheses refer to the last decimal positions.

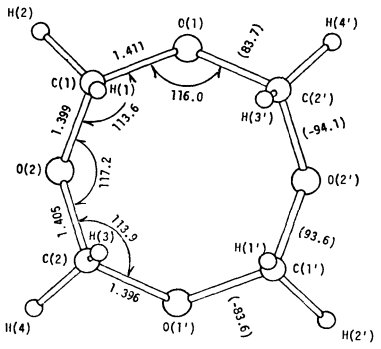

Fig. 3. Bond lengths, bond angles and torsion angles (shown in parentheses) of tetroxocane molecule.

a crown form but in a boat-chair form in the crystalline state. On a closer examination, the molecular conformation of tetroxocane in the crystal is found to depart from the regular crown form: the molecular shape has an approximate C_{4v} symmetry but an exact C_2 symmetry. That is, the crown is elongated in the direction of O(1)···O(1′) (3.448 Å) and is shrunk along the direction of O(2)···O(2′) (3.190 Å). The difference, 0.258 Å, is significant. The torsion angles about the four independent C–O bonds thus appear in two distinguishable values: two bonds with 83.7 and −83.6°, and the other two bonds with 93.6 and −94.1°. The average C–O bond length is 1.403 Å, and the average C–O–C and O–C–O bond angles are 116.6 and 113.8° respectively. This deformation from the regular crown form with the tetrahedral angle may be due to the steric effects of the hydrogen atoms. If a regular crown form is constructed from the normal bond lengths and the tetrahedral angle, the torsion angle is calculated to be 96°58′ and the H···H distances become 1.90 Å, while the actual short H···H distances in the distorted crown form were found to be 2.16 and 2.20 Å. Table 4 shows the molecular dimensions of the cyclic oligomers of formaldehyde from trimer to hexamer. The average C–O bond length in the tetroxocane is the shortest. This may be partly due to the thermal motions. Except for trioxane, the C–O–C bond angles are larger than the O–C–O bond angles, but all the C–O–C and O–C–O bond angles are evidently larger than the tetrahedral angle, 109°28′. The increase in the bond angles, especially those of the C–O–C bond angles, may compensate for the intramolecular steric hindrances. The bending force constant of C–O–C is smaller than that of O–C–O. Therefore, the larger increase in the C–O–C bond angles might be favorable in terms of the conformation energy.

Table 5 lists the root-mean-square vibration am-

plitudes along the principal axes of the thermal ellipsoids and the angles between the principal axes and the crystallographic a, b, and c* axes. The thermal motion of each skeletal atom is predominant in the direction perpendicular to the plane formed by the atom and both neighboring atoms. Such a feature has previously been found in the cases of pentoxecane[22] and hexoxecane.[5] In the case of hexoxecane, a rigid body approximation[23,24] was undertaken for the molecule of the $\bar{3}$ symmetry, but no reasonable result could be obtained. These facts might imply that, besides the translational and vibrational motions, intramolecular motions, *e.g.*, torsional and bending motions, are also appreciable in these cyclic oligomers. Since we do not yet know the mode of the intramolecular motions, corrections of bond lengths and bond angles for the thermal motions were not made.

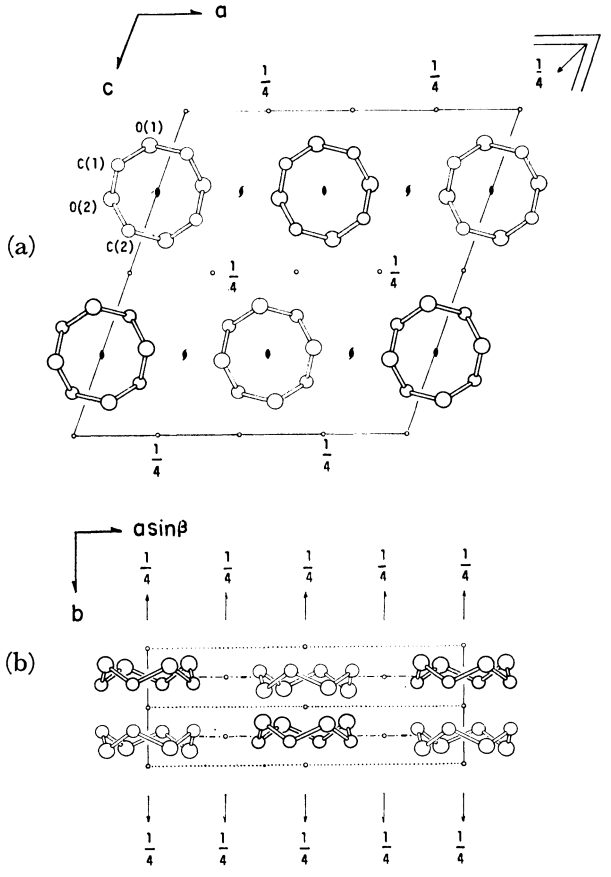

Fig. 4. (a) Crystal structure viewed along the b axis. (b) Crystal structure viewed along the c axis.

Table 6. Intermolecular atomic distances

C···O (Å)		C···C (Å)	
C(1,a)···O(1,b)	3.86	C(2,a)···C(2,f)	3.54
C(1,a)···O(2,b)	3.77	C(2,a)···C(2,g)	3.92
C(2,a)···O(2,b)	3.77	C(1,a)···C(1,h)	4.18
C(2,a)···O(1,c)	3.86	C(1,a)···C(2,h)	3.98
C(2,a)···O(1,d)	3.75	C(2,a)···C(1,h)	3.98
C(2,a)···O(1,e)	3.53	C(1,a)···C(1,i)	3.96
C(1,a)···O(2,h)	3.25		
C(1,a)···O(1,i)	3.79		

a: x, y, z; b: $x, 1+y, z$; c: $-x, 1+y, 1/2-z$; d: $x, 1-y, 1/2+z$; e: $x, -y, 1/2+z$; f: $-x, 1-y, 1-z$; g: $-x, -y, 1-z$; h: $-1/2-x, 1/2+y, 1/2-z$; i: $-1/2-x, 1/2-y, -z$.

The molecular packing is shown in Fig. 4. The ring molecules are piled up along the b axis. The shortest intermolecular (between centers of gravity) distance of 4.16 Å is in the b direction, along which the dipole moment vectors of all the molecules in a row are parallel. Some short intermolecular atomic distances are shown in Table 6. The closest C···O distance is 3.25 Å. The C···C distances are longer than 3.92 Å except for the 3.54 Å of C(2,a)···C(2,f).

The authors wish to thank Professor H. Tadokoro of Osaka University for his interest in the work and his constant encouragement.

Proton Nuclear Magnetic Resonance Spectroscopy of Partially-deuterated *n*-Pentanes

Masahiro KONDO, Isao ANDO, Riichirô CHÛJÔ, and Atsuo NISHIOKA

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 24, 1973)

The proton NMR spectra of some partially deuterated *n*-pentanes were observed under both proton-deuteron (H–D) spin-coupled and -decoupled conditions. With using the spectrum-simulation method, it was confirmed experimentally that the chemical shift of the $CH_2(3)$ protons appears at a higher field than that of the $CH_2(2)$ protons.

It is well known[1] that, in the case of molecules with rotational isomers, in which rotation about the C–C bond is very quick, the observed NMR chemical shift is averaged with the statistical weight for each isomer. *n*-Pentane can take seven preferred isomeric forms[2] (TT, TG, GT, TG', G'T, GG, G'G'), while GG' and G'G conformations are ignored because of the steric hindrance or the so-called "pentane effect." In a previous paper,[3] the proton NMR chemical shift of *n*-pentane has been calculated theoretically, taking into account the above conformations, and then the energy difference between *trans* and *gauche* conformations and the magnetic anisotropy of the C–C bond was estimated. According to the results obtained there, the $CH_2(3)$ proton peak would appear at a field higher than that of the $CH_2(2)$ proton by 0.03—0.04 ppm.

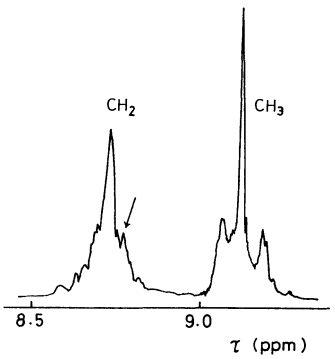

Fig. 1. The proton NMR spectrum of non-deuterated *n*-pentane in CCl_4 solution at 22.5 °C. The chemical shift of methyl protons appears at 9.125τ. The shoulder of the $CH_2(3)$ proton is indicated by an arrow.

As is shown in Fig. 1, the observed spectrum of the methylene groups in *n*-pentane has a weak shoulder at a higher field in the main peak. This shoulder was previously tentatively assigned to the $CH_2(3)$ protons, and the main peak, to the $CH_2(2)$ protons.[3] Such an assignment, however, was made without taking into account the effect of the nuclear spin-spin coupling. Since the difference in the chemical shift between the $CH_2(2)$ and $CH_2(3)$ protons is very small, it may be considered that the spin-spin coupling plays an important role in determining the pattern of the spectrum. Hence, we attempted to confirm whether the previous assignment is true or not. In doing this, we may encounter inconvenience due to the large number of protons. Therefore, we prepared some partially-deuterated *n*-pentanes and made spectrum-simulation in order to determine whether or not the chemical shift of the $CH_2(3)$ protons appears at a field higher than that of the $CH_2(2)$ protons.

Experimental

Materials. The partially-deuterated *n*-pentanes, (II)—(V), used here are as follows:

$CH_3CH_2CH_2CH_2CH_3$ (I)

$CH_2DCH_2CH_2CH_2CH_2D$ (II)

$CHD_2CH_2CH_2CH_2CHD_2$ (III)

$CD_3CH_2CH_2CH_2CD_3$ (IV)

$CH_3CH_2CD_2CH_2CH_3$ (V)

They were prepared by the method to be described below.

Preparation. $CD_3CH_2CH_2CH_2CD_3$: Dimethyl glutarate (25 g) was added, drop by drop, to a well-stirred solution of lithium aluminum deuteride (7 g) in dry ether (150 ml). After this addition and stirring for 2 hr, the excess lithium aluminum deuteride was carefully decomposed with water to give a product like white clay. 1,5-Pentanediol-1,1,5,5-d_4 (12 g) was extracted from the product with ether by using a Soxhlet extractor for 2 days. The ether was then evaporated, and the resulting alcohol was treated with potassium iodide (50 g) in a mixture of phosphoric anhydride (12 g) and 85% phosphoric acid (40 ml) to give 1,5-diiodopentane-1,1,5,5-d_4. After drying, it was converted to *n*-pentane-1,1,1,5,5,5-d_6 with heavy water by the usual Grignard reaction. This product (*ca.* 1 ml) was separated from ether by washing with cold, concentrated sulfuric acid, and then distilled. The NMR spectrum of the deuterated *n*-pentane showed the absence of methyl protons.

$CH_3CH_2CD_2CH_2CH_3$: Diethyl ketone (25 g) was reduced with lithium aluminum deuteride (3 g) in dry ether (100 ml) in the usual way to give 3-pentanol-3-d_1 (14 ml). A mixture of this alcohol and freshly-distilled methanesulfonyl chloride in methylene chloride (70 ml) was treated with pyridine (15 ml) below −5 °C. After having been stirred for 1 hr in an ice-salt bath, the mixture was stored in a refrigerator for 24 hr and then poured into dilute sulfuric acid. The washed and dried organic layer was evaporated at room temperature, and the residue was pumped for several hours to yield 3-penthyl-3-*d* methanesulfonate (13 ml). This product was added, drop by drop, to a solution of lithium aluminum deuteride (4 g) in dry ether (100 ml). A mixture of *n*-pentane-3,3-d_2 and ether was distilled, and the deuterated *n*-pentane (2 ml) was separated from ether by washing with cold concentrated sulfuric acid. According to the NMR spectrum of this product, the deuterium content was more than 95%.

Method: The proton NMR spectra of partially-

deuturated *n*-pentanes were measured by means of a JEOL PS-100-type spectrometer at 100 MHz, in a solution of carbon tetrachloride at room temperature. Tetramethylsilane (TMS) was used as the internal standard. The deuteron spin decoupling (D-decoupling) was done using JNM SD-HC (hetero spin decoupler) equipment.

Calculations of the NMR spectra were carried out by means of the HITAC 5020E of the Computer Centre of the University of Tokyo, using a LAOCOON III program.

Results and Discussion

The observed spectra of some deuterated *n*-pentanes are shown in Figs. 2, 3, 4, and 5, where (a) and (b) were obtained under proton-deuteron (H–D) spin-coupled and -decoupled conditions respectively. The following features may be noted: In *n*-pentane-1,5-d_2, $CH_2DCH_2CH_2CH_2CH_2D$ (II), each line of the methyl proton triplet, moreover, splits into a triplet (Fig. 2(a)) as a result of the geminal H–D spin-spin coupling, the constant of which is $J_{H\text{-}D}^{gem}=1.9$ Hz. In *n*-pentane-1,1,5,5-d_4, $CHD_2CH_2CH_2CH_2CHD_2$ (III), it splits into a quintet (Fig. 3(a)). While Fig. 4(a) shows only a single methylene proton peak, which is somewhat broad because of the vicinal H–D spin-spin coupling,

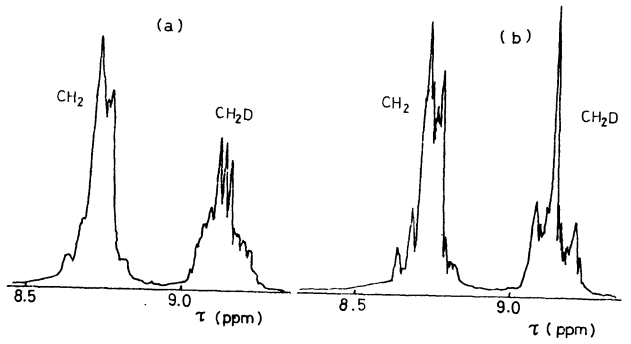

Fig. 2. The proton NMR spectrum of *n*-pentane-1,5-d_2 in CCl_4 solution at 22.5 °C. The chemical shift of methyl protons appears at 9.141τ.
(a) Taken under H–D spin-undecoupled condition.
(b) Taken under H–D spin-decoupled condition.

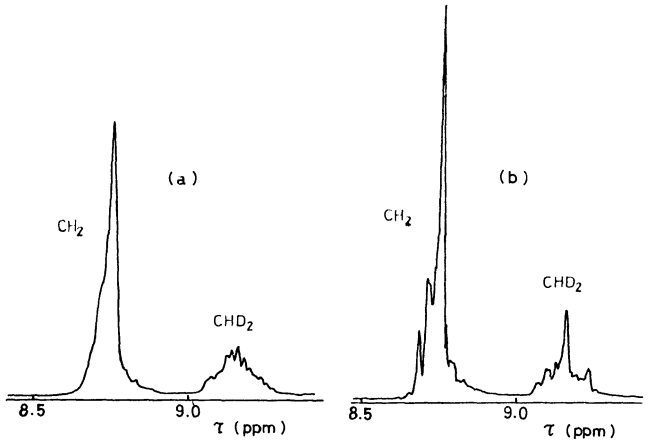

Fig. 3. The proton NMR spectrum of *n*-pentane-1,1,5,5-d_4 in CCl_4 solution at 22.5 °C. The chemical shift of methyl protons appears at 9.158τ.
(a) Taken under H–D spin-undecoupled condition.
(b) Taken under H–D spin-decoupled condition.

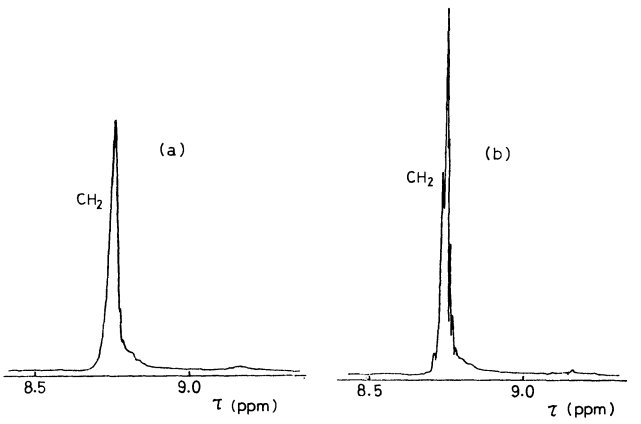

Fig. 4. The proton NMR spectrum of *n*-pentane-1,1,1,5,5,-5-d_6 in CCl_4 solution at 22.5 °C.
(a) Taken under H–D spin-undecoupled condition.
(b) Taken under H–D spin-decoupled condition.

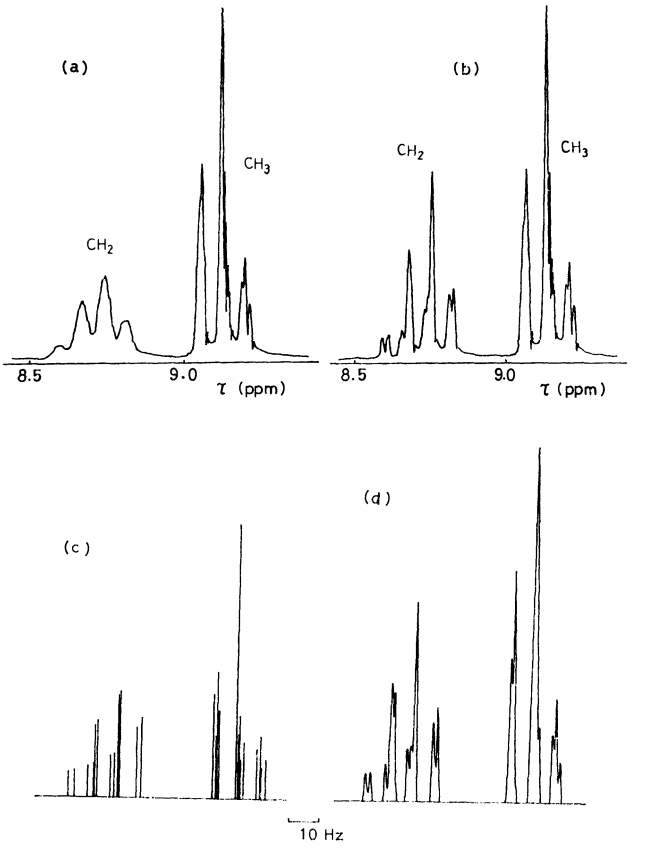

Fig. 5. The proton NMR spectrum of *n*-pentane-3,3-d_2 in CCl_4 solution at 22.5 °C. The chemical shift of methyl protons appears at 9.127τ.
(a) Taken under H–D spin-undecoupled condition.
(b) Taken under H–D spin-decoupled condition.
(c) Calculated "Stick" spectrum.
(d) Calculated spectrum in Lorentzian line shapes. with half-height-width of 0.4 Hz.

the D-decoupled spectrum (Fig. 4(b)) shows a fine structure, which may be expected to come from the chemical-shift difference between the methylene protons in *n*-pentane-1,1,1,5,5,5-d_6, $CD_3CH_2CH_2CH_2CD_3$ (IV). *n*-Pentane-3,3-d_2, $CH_3CH_2CD_2CH_2CH_3$ (V), gives a A_3B_2-type spectrum of the five-spin system (Fig. 5(b))

if the deuteron is irradiated. As is shown in Fig. 5(a), line broadening occurs in the methylene proton quartet because of the vicinal H–D spin-spin coupling, the constant of which is probably about 1 Hz, but the methyl proton triplet remains sharp. This means that the long-range H–D spin-spin coupling separated by more than four bonds is negligibly small.

As we have stated above, we are mainly concerned with the problem of the chemical-shift difference between the $CH_2(2)$ and $CH_2(3)$ protons, which was previously predicted by means of theoretical calculations.[3] Thus, let us first compare the spectra of the partially-deuterated *n*-pentane measured under two different conditions, in which one was under undecoupled conditions and the other, under D-decoupled conditions. As for Sample (II), a comparison between Figs. 2(a) and 2(b) shows the following features: the shoulders which appear on the down-field side of the methylene peak in Fig. 2(a), which may be expected to come from the line broadening due to the vicinal H–D spin-spin coupling, change into rather sharp peaks upon D-decoupling, as is shown in Fig. 2(b) but there is almost no significant difference on the up-field side. Also, in the case of Sample (III), similar features are noted in comparing the spectra shown in Figs. 3(a) and 3(b). The $CH_2(2)$ protons are placed on the vicinal position against the deuterium atom in the methyl group, while the $CH_2(3)$ protons are on the position of four-bond separation from the deuterium atom. We may, therefore, conclude qualitatively that the chemical shift of the $CH_2(2)$ protons should appear at a lower field than that of the $CH_2(3)$ protons: this is in agreement with the previous results.

Table 1. The parameters used in doing the spectrum simulation of deuterated *n*-pentanes

$CH_3CH_2CD_2CH_2CH_3$	
	$\delta_{CH_3(1)-CH_3(2)}=0.415$ ppm
	$J^{gem}_{CH_3(1)-CH_3(1)}=J^{gem}_{CH_3(2)-CH_3(2)}=12.4$ Hz
	$J^{vic}_{CH_3(1)-CH_3(2)}=7.4$ Hz
$CD_3CH_2CH_2CH_2CD_3$	
	$\delta_{CH_3(3)-CH_3(2)}=0.05$, 0.03, and -0.03 ppm
	$J^{gem}_{CH_3(2)-CH_3(2)}=J^{gem}_{CH_3(3)-CH_3(3)}=12.4$ Hz
	$J^{vic}_{CH_3(3)-CH_3(2)}=7.4$ Hz
	$J^{long}_{CH_3(2)-CH_3(4)}=1$ Hz

Next, let us examine the spectrum of Sample (IV) by the aid of the spectrum-simulation method. Before doing this, though, we shall preliminarily simulate the spectrum of Sample (V) in order to estimate the vicinal coupling constant. The simulated spectra shown in Figs. 5(c) and 5(d) were obtained by using the "stick" type and the Lorentzian line shape respectively. When the parameters listed in Table 1 are used, the spectrum fairly well fits the observed one except that the calculated methylene part is somewhat sharper than the observed one: this may come from the neglect of the long-range coupling between the $CH_2(2)$ and $CH_2(4)$ protons. Although these parameters are not necessarily the best-fitting ones, they seem to be reasonable. In doing the spectrum simulation of Sample (IV) we

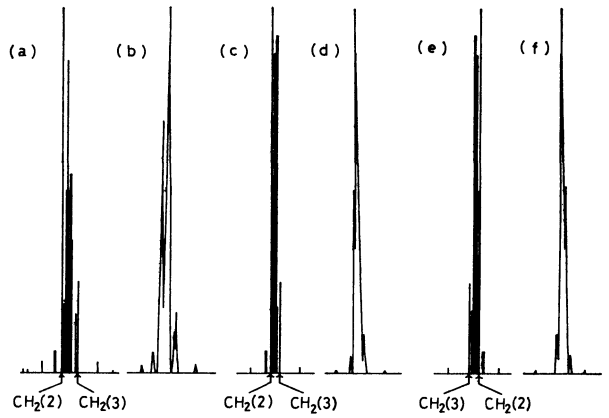

Fig. 6. The calculated spectra of *n*-pentane-1,1,1,5,5,5-d_6 for various values as the chemical shift difference between the $CH_2(3)$ and $CH_2(2)$ protons ($\delta_{CH_3(3)-CH_3(2)}$).
(a), (c), (e):
Calculated "stick" spectra using the values of 0.05, 0.03, and -0.03 ppm as $\delta_{CH_3(3)-CH_3(2)}$, respectively. The input chemical shifts of the $CH_2(3)$ and $CH_2(2)$ protons are indicated by the arrow.
(b), (d), (f):
Calculated spectra in Lorentzian line shapes with half-height-width of 0.4 Hz corresponding to (a), (c) and (e), respectively.

will tentatively use the parameters obtained above, that is, the vicinal coupling constant of 7.4 Hz and the long-range coupling of 1 Hz, since we cannot decide the detailed parameters because of the lack of characteristic peaks in Fig. 4(b). These values are, then, approximated such that the coupling constant between the $CH_2(2)$ and $CH_2(3)$ protons is nearly equal to that between the $CH_3(1)$ and $CH_2(2)$ protons: the long-range coupling constant may be somewhat overestimated. Figure 6 shows the calculated spectra of Sample (IV) with the various values for the chemical-shift difference between the $CH_2(2)$ and $CH_2(3)$ protons. As the observed spectrum (Fig. 4(b)) shows a rather sharp shoulder on the lower-field side of the main peak, we shall compare the calculated spectra with the observed one with regard to this shoulder. As is shown in Figs. 6(e) and 6(f), when the chemical shift of the $CH_2(2)$ protons is at a higher field than that of the $CH_2(3)$ protons, the calculated spectrum shows a shoulder on the higher-field side of the main peak: this is in disagreement with the observed spectrum. On the contrary, when the chemical shift of the $CH_2(3)$ protons is at a higher field, the shoulder in the calculated spectrum (Figs. 6(a), (b), (c), and (d)) appears on the lower-field side: this agrees with the observed spectrum. As the difference in chemical shift between the $CH_2(2)$ and $CH_2(3)$ protons becomes large, this shoulder moves away from the center of the main peak and becomes a resolved peak. When the value of 0.03 ppm is used as the chemical shift difference, a better-fitting spectrum seems to be obtained. From the "stick" spectrum (Fig. 6) it is found that the shoulder can be assigned to the $CH_2(2)$ protons, while a weak peak at the foot of the higher-field side, which is hardly shown in the observed spectrum because

of wiggle, can be assigned to the $CH_2(3)$ proton, and that the position of the main peak corresponds to something like the mean value of the chemical shifts between the $CH_2(2)$ and $CH_2(3)$ protons. Thus, we obtained results in accordance with the previous ones[3] by means of the simulation method for Sample (IV) as well as for Samples (II) and (III).

It is well known[4] that the replacement of a hydrogen atom by a deuterium atom causes a small up-field shift in the proton NMR: this is called the isotope shift. We shall examine this effect upon the deuterated *n*-pentanes, since we are concerned with a slight difference in the chemical shift between the methylene protons. The observed isotope shifts of the methyl protons in the deuterated *n*-pentanes are tabulated in Table 2. As has been reported in methane and other molecules by Bernheim *et al.*[5] and Barfield *et al.*[6] it was noted that the magnitude of the isotope shift is proportional to the number of the geminally isotopic substitution. We could not measure the isotope shift of the methylene protons, for we could not decide the exact chemical shifts of the $CH_2(2)$ and $CH_2(3)$ protons in deuterated *n*-pentanes. However, we can expect a very small isotope effect between the $CH_3(1)$ and $CH_2(3)$ groups, because the observed isotope shift of the methyl proton in Sample (V) is very small. Further, if we assume that the isotope effect of the vicinally isotopic substitution is smaller than that of the geminally one, it may not be because of the isotope shift, but because of the difference in the original chemical shift, that the $CH_2(3)$ protons appear at a field higher than the $CH_2(2)$ ones by *ca.* 0.03 ppm in the deuterated *n*-pentanes. Though we could not obtain any information on whether or not the shoulder on the higher-field side of the main peak in the non-deuterated *n*-pentane (Sample (I)) was the signal of the $CH_2(3)$ protons, we obtained experimental results which were in accordance with the theoretically-predicted ones.[3]

TABLE 2. ISOTOPE SHIFTS OF METHYL PROTONS OF *n*-PENTANE IN CCl_4 SOLUTION FOR VARIOUS AMOUNTS OF DEUTERIUM SUBSTITUTION (22.5 °C)

Sample	Isotope shift (ppm)
$CH_3CH_2CH_2CH_2CH_3$	0
$CH_2DCH_2CH_2CH_2CH_2D$	0.016
$CHD_2CH_2CH_2CH_2CHD_2$	0.033
$CH_3CH_2CD_2CH_2CH_3$	0.002

The authors wish to thank Dr. Tsuneo Hirano of the University of Tokyo for the use of the LAOCOON III program. Their thanks are also due to Mr. Masao Kambe of our laboratory for his kind assistance in the D-decoupling technique.

Phase Equilibria of the Systems Containing Silver Iodide and Alkali Iodide. II.† AgI-NaI-H_2O System

Norio NISHIMURA and Tatsuo HIGASHIYAMA*

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700
**College of Liberal Arts, Okayama University, Tsushima, Okayama 700*

(Received September 10, 1973)

Phase diagrams were constructed for the equilibria of the AgI–NaI–H_2O system at temperatures 0—70 °C. A compound $AgI \cdot NaI \cdot 3H_2O$ was isolated, and the compound was found by means of X-ray analysis to belong to the orthorhombic system with cell constants $a=8.78$, $b=33.5$, and $c=6.48$ Å.

The formation of a series of compounds, probably of the type $K_n[AgI_{1+n}]$, was recognized for the binary system of AgI and KI.[1-4] They can be formed by a solid state reaction at high temperatures or by mixing the components with a small amount of water or from a concentrated aqueous solution. This type of compound often crystallizes with a solvent of crystallization. Marsh and Rhymes[5] described a series of crystalline compounds such as $2AgI \cdot KI \cdot 2C_3H_6O$, where C_3H_6O denotes acetone. The present authors[6] have studied the phase equilibria of the AgI–KI–H_2O system and reported the formation of a new compound $2AgI \cdot KI \cdot 2H_2O$.

The phase equilibria of the AgI–NaI–H_2O system at 25 °C were studied by Krym.[7] His phase diagram, however, is obviously incomplete, since he did not notice the existence of the solid phase of $NaI \cdot 2H_2O$. The present paper deals with an investigation of this system over a wide temperature range together with an X-ray study of a compound formed in this system.

Experimental

Materials. Silver iodide of extra pure grade was used. It was found by means of X-ray powder method to be γ-AgI (cubic), containing a small amount of β-AgI(hexagonal). Sodium iodide of extra pure grade was dried at 110—120 °C to a constant weight.

Determination of Composition. Desired amounts of AgI, NaI and water were introduced into a stoppered flask and thermostated for various periods of time depending on the experimental temperature (*ca.* 3 hr(70 °C)—24 hr(0 °C)). After the equilibrium had been attained, the solution was pipetted out and weighed, and then dried to a constant weight. The loss in weight was regarded to correspond to the quantity of the water involved. A large amount of water was added to the residue. After complete precipitation of AgI, the supernatant solution was carefully removed. The NaI in the residue was removed completely by repeating the procedure several times. It was confirmed that recovery of AgI was over 99%.

At temperatures below 40 °C, the formation of a crystalline compound, other than the components, was observed in a range of appropriate proportions of the components. As this compound crystallized from very concentrated solutions, supersaturation of the solutions often occurred. In the determination of the number of the water of crystallization, high temperature and humidity were avoided as far as possible, since the crystal is unstable in air and easily decomposes to the components even at room temperature. The crystals were washed with a small amount of acetone and dried quickly on a sheet of filter paper and weighed. The weight percentage of each component of the crystal was determined by the same method as that for solutions.

X-Ray Analysis. For the determination of the cell constants of the crystal, a single crystal was inserted into a thin-walled Pyrex glass capillary with a small amount of the mother liquid and sealed off. X-ray oscillation and Weissenberg photographs were taken using Ni-filtered Cu$K\alpha$ radiation. The density measurement was carried out with a picnometer of *ca.* 5 cm^3 and liquid paraffin.

Results and Discussion

The overall compositions of the AgI–NaI–H_2O system and the compositions of the liquid phases in equilibrium with solid phases are given in Table 1.

Table 1. Compositon of the AgI–NaI–H_2O system

Temp. (°C)	Overall composition (wt%) AgI	Overall composition (wt%) NaI	Composition of liquid phase in equilibrium with solid phase (wt%) AgI	Composition of liquid phase in equilibrium with solid phase (wt%) NaI	Solid phase

a) Solubility of NaI.[8)] b) AgI·NaI·3H$_2$O.

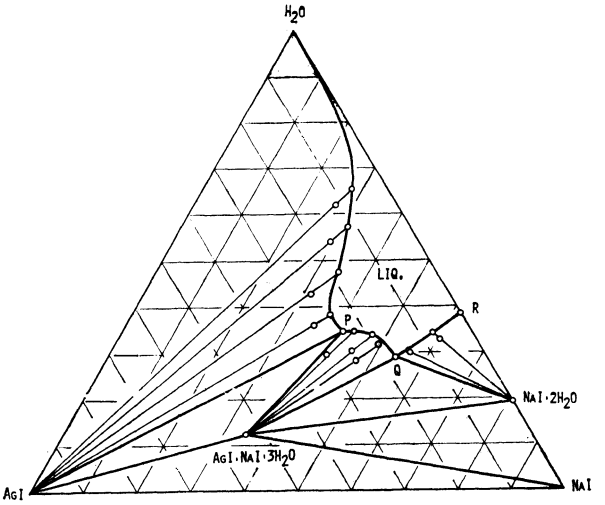

Fig. 1. Phase diagram of the AgI–NaI–H$_2$O system at 0 °C (wt%).

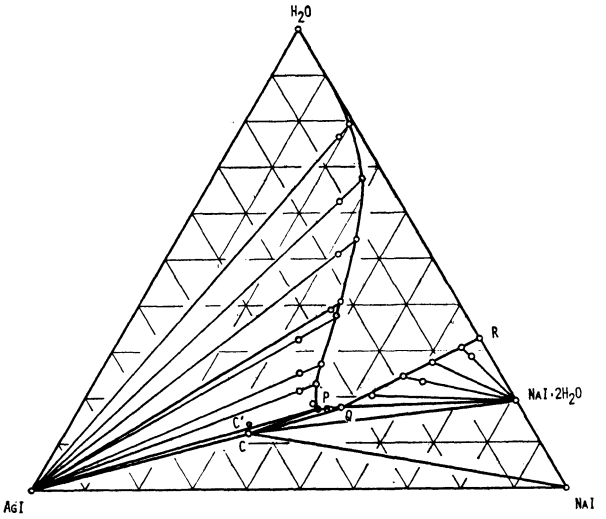

Fig. 2. Phase diagram of the AgI–NaI–H$_2$O system at 40 °C (wt%).

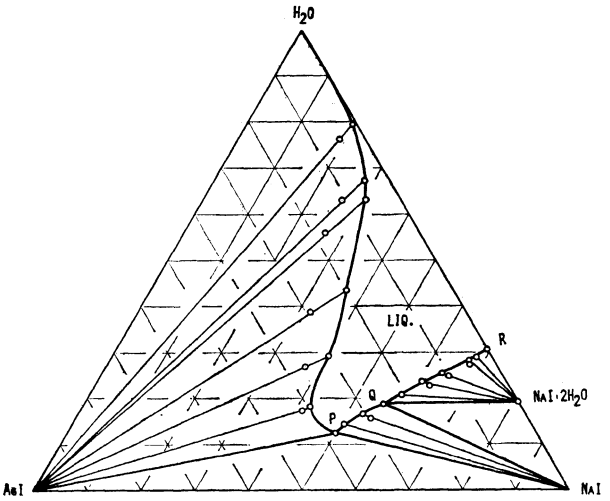

Fig. 3. Phase diagram of the AgI–NaI–H$_2$O system at 50 °C (wt%).

The weight percentages of the components were plotted on an equilateral triangle. Examples are shown in Figs. 1—3. Each corner of the triangle represents pure components. Points P and Q in these figures are invariant points, and R denotes the solubility of NaI in pure water.

A compound containing all the three components crystallizes under appropriate conditions. It should be identical with the one Krym[7] found in his study of the AgI–NaI–H_2O system at 25 °C, and to which he gave the formula $AgI \cdot NaI \cdot 3.5H_2O$. The compound was analyzed and the results are given in Table 2.

Table 2. Chemical composition (wt%)

	AgI	NaI	H_2O
	50.7	36.2	13.1
	52.3	34.9	12.8
	51.4	35.7	12.9
	52.5	34.7	12.8
Mean	51.7	35.4	12.9
Calcd as $AgI \cdot NaI \cdot 3H_2O$			
	53.5	34.2	12.3
Calcd as $AgI \cdot NaI \cdot 3.5H_2O$			
	52.4	33.5	14.1

It is evident that the mole ratio of AgI to NaI is 1:1, but the number of water of crystallization is not clear. It seems to be a $3H_2O$ rather than a $3.5H_2O$ compound.

An alternative way to presume the chemical formula is the Schreinemaker plot. In the region in which the compound coexists with solution, total composition–solution composition tie lines should converge on the point which represents the true composition of the compound. However, from the data at 0 °C as well as at other temperatures, no decisive conclusion has been drawn, since the experimental points have uncertainties due to errors in the chemical analysis. Nevertheless, a $3H_2O$ compound is considered more plausible on the following grounds. The invariant point P (filled circle) in Fig. 2 represents the average composition of the solution in equilibrium with both the solid AgI and the compound (see Table 1). The position of C′ ($3.5H_2O$ compound) is incompatible with the positions of P and AgI, making it impossible to construct the phase diagram at 40 °C. On the other hand, if the $3H_2O$ compound is assumed, no inconsistency is found in constructing the phase diagrams at 40 °C and other temperatures.

King *et al.*[9] studied the dependence of the solubility of AgI in water on the common ion concentration and indicated the existence of anionic and cationic complex ions in solution. Greenslade and Symons[10] measured the UV spectra of the solutions containing AgI and KI in various solvents. They assigned the band at 43800 cm^{-1} to AgI_2^-. The existence of this band was also confirmed by us. Thus the compound is considered to be a complex with the formula $Na[AgI_2] \cdot 3H_2O$.

The complex is a colorless, needle-like crystal. It loses the water of crystallization on exposure to dry air, deliquescing and at the same time decomposing in contact with water vapor. The crystal data of this compound are given in Table 3.

Table 3. Crystal data

Formula	$AgI \cdot NaI \cdot 3H_2O$
Molecular weight	438.7
Melting point	42—43 °C; decompose
Crystal system	Orthorhombic
a	8.78 Å
b	33.5 Å
c	6.48 Å
V	1908 Å^3
d_m	3.11 g cm^{-3}
d_c	3.05 g cm^{-3}
Z	8
Absent spectra	$0kl$ when k is odd and $h0l$ when l is odd
Possible space group	Pbcm or $Pbc2_1$

It is interesting to note that the solubility curves of AgI are s-shaped and almost independent of temperature. On the other hand, the solubility of NaI is temperature dependent and the extrapolated point to zero concentration of AgI agrees with the solubility of NaI in pure water at each temperature.[8]

According to the phase rule, no more than three phases can coexist in this system. In a region where all three phases are solid, AgI and $NaI \cdot 2H_2O$ can never coexist. Other sets of solids were observed to coexist depending on conditions. Identification of these solids was made by visual observation and the X-ray diffraction method: silver iodide was of yellow powder or thin yellow flakes; NaI white powder or brilliant flakes; $NaI \cdot 2H_2O$ large transparent plates, and the complex transparent needle-like crystals or white spherulites.

Figure 4 was constructed on the basis of the phase diagrams at each temperature. We see that the liquid phase is surrounded with four kinds of surfaces (S_1—S_4), the edges of which are shown with heavy solid lines. Surfaces S_1, S_2, S_3, and S_4 consist of the points repre-

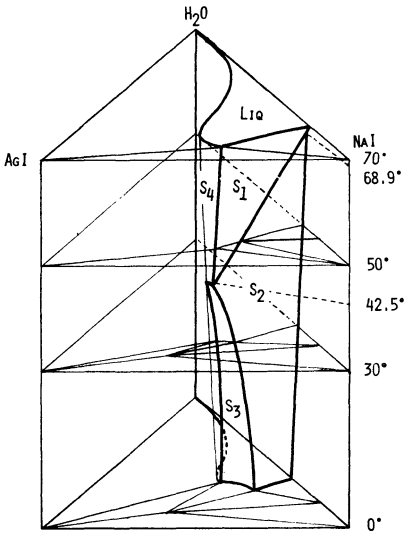

Fig. 4. Three-dimensional representation of the AgI–NaI–H_2O system (wt%).

senting the compositions of the liquid phase in equilibrium with the solids NaI, $NaI \cdot 2H_2O$, $Na[AgI_2] \cdot 3H_2O$, and AgI, respectively. The edges of the surfaces consist of the invariant points. Surfaces S_1 and S_2 are almost flat; S_3 is curved and S_4 is waved. Surface S_3 disappears above the melting point of the complex, and surface S_2 above 68.9 °C[8] (or 68.1 °C[11]), the decomposition point of $NaI \cdot 2H_2O$. It is not certain whether S_1 is in contact with S_3 or not, since it is difficult to make a study of the phase equilibria in the vicinity of the melting point of the complex. No ambiguity other than this seems to remain in Fig. 4 from the viewpoint of the phase rule.

An ESR Study of Nitric Oxide Adsorbed on Silica Gel

Masamoto IWAIZUMI, Shozo KUBOTA, and Taro ISOBE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980

(Received October 1, 1973)

Nitric oxide adsorbed on silica gel was investigated by ESR. It was found that there are at least two adsorption sites for nitric oxide; one of them is on the silica gel which has been pretreated at low temperatures (below *ca.* 500 °C) (Site L), while the other is predominantly on the silica gel which has been pretreated at high temperatures (above *ca.* 500 °C) (Site H). The crystal-field splitting of the π_X^* and π_Y^* states, which are originally degenerate, was determined to be 0.26 eV for the nitric oxide adsorbed on Site L and 0.52 eV for the nitric oxide on Site H. The temperature dependence of the ESR spectrum was also examined, and the average crystal field acting on nitric oxide was found to decrease with an increase in the temperature.

Previously, the magnetic properties of nitric oxide adsorbed on silica gel surfaces have been studied by Solbakken *et al.*[1] by the measurement of the magnetic susceptibility. They reported that, at 181 and 193 K, nitric oxide is adsorbed entirely in a state with a magnetic moment the same as in the excited $^2\Pi_{3/2}$ state, while at 273 and 293 K it is adsorbed in the same average magnetic state of $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$as in the gas phase. On the other hand, the ESR of nitric oxide adsorbed on solid surfaces has been observed in several adsorbent systems at the temperature of liquid nitrogen and at −180 °C.[2-10] In the ESR studies, it has been shown that, when nitric oxide is adsorbed on the solid surfaces, the orbital degeneracy of the $2p\pi^*$ level, which an odd number of electron occupy, is lifted by the surface field and the orbital angular momentum is quenched; that is, the ESR of nitric oxide in the adsorbed state can be explained by a spin-only paramagnetism and well reflects the nature of the interaction with the surfaces. A few attempts have been made to observe the ESR of nitric oxide adsorbed on the silica-gel surface.[5,7] However, no successful observation has yet been reported, although the ESR investigation of nitric oxide in the silica-gel system seemed to be interesting in connection with Solbakken's work and also for purposes of comparison with other adsorbent systems. In the course of studies of radicals trapped on solid surfaces, we could observe the ESR of nitric oxide adsorbed on silica gel. In this paper we will present the ESR observed for nitric oxide on silica gel and will discuss the interaction of nitric oxide with the surface.

Experimental

The nitric oxide was obtained commercially from the Takachiho Chem. Ind. Co., Ltd., and was dried with P_2O_5. The silica gel used was a Tokyo Chem. Ind. Co. product for chromatography, with a surface area of 422 m^2/g. The gel was heated *in vacuo* at 10^{-6} Torr overnight prior to the adsorption of nitric oxide. The heating *in vacuo* was attempted at several temperatures between 300 °C and 600 °C. After the pretreatment of the silica gel, the nitric oxide was adsorbed onto the silica gel at −60 °C and at pressures ranging from 2 to 60 Torr. When the silica gel was evacuated at low temperatures (below 450 °C), an appreciable decrease of radical concentration was observed when the sample was left standing at room temperature. All the samples for ESR measurements, therefore, were immediately immersed in the liquid nitrogen after the nitric oxide had been adsorbed and the sample tube had been sealed off from the vacuum line.

The measurements of the ESR were carried out with a Hitachi model 771 ESR spectrometer with 100 kHz field modulation. The number of nitric-oxide molecules responsible for the ESR was determined by using a freshly-crystallized $CuSO_4 \cdot 5H_2O$ crystal as the standard.

Results and Discussion

The ESR of nitric oxide observed at −196 °C are shown in Fig. 1. The hyperfine pattern observed is similar to those observed for the other adsorbent systems,[2-10] except that the linewidth is rather broader and the nitrogen hyperfine splitting is observed only as a shoulder. In Fig. 1, the sharp line with a *g*-value of 2.004 (indicated by A) is a background spectrum of silica gel which is produced by heating *in vacuo*. When the silica gel is preheated at temperatures higher than 550 °C, as Fig. 1b shows, a new additional absorption is observed on the low-field side of the nitric oxide spectrum (marked with B). This new absorption may be considered to be due to a paramagnetic center produced on the surface by the reaction with nitric oxide.

The ESR absorption due to nitric oxide changes appreciably with the preheating temperature of the silica gel. As Fig. 1 shows, when the silica gel is

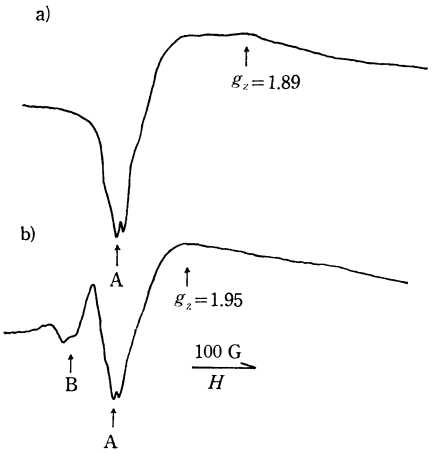

Fig. 1. ESR spectra, recorded at −196 °C, of nitric oxide on silica gel preheated at 500 °C (a), and at 600 °C (b).

pretreated at low temperatures (below *ca.* 500 °C), nitric oxide shows a spectrum with g_z value of 1.89,[11] whereas when the silica gel is pretreated at temperatures above *ca.* 500 °C, the signal intensity at the absorption maximum corresponding to the g_z value weakens appreciably and the maximum appears on the low-field side corresponding to $g_z=1.95$. These facts indicate that there are at least two different adsorption sites for nitric oxide on the silica-gel surface; one of the sites is on the silica gel which has been preheated at low temperatures (Site L), while the other is predominantly on the silica gel preheated at high temperatures (Site H). However, it is imagined that there may still be some small variety in these two adsorption sites, since the spectra show broad absorption bands.

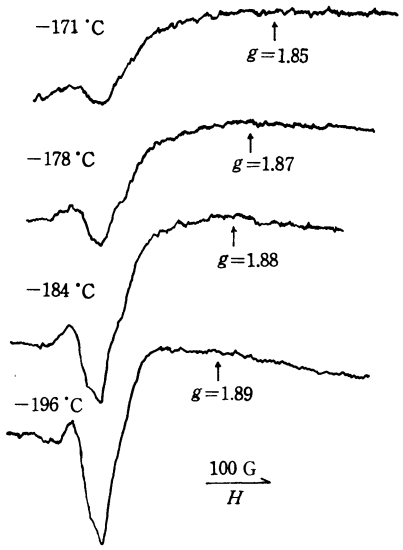

Fig. 2. Variation of ESR spectra of nitric oxide on silica gel with temperature. The silica gel was preheated at 550 °C.

When the ESR are measured at temperatures higher than −196 °C, the ESR absorption extensively broadens, losing its intensity, and above *ca.* −160 °C no ESR absorption attributable to the adsorbed nitric oxide can be detected. However, it was observed that, as the temperature increases, the absorption maximum in the g_z region gradually shifts toward the high-field side (Fig. 2). In a way similar to that reported by Kanzig *et al.* for the O_2^- molecule,[12] the following expression is derived for the g_z-value of nitric oxide:

$$g_z = g_e - 2\left(\frac{\lambda^2}{\lambda^2+\Delta^2}\right)^{1/2}. \quad (1)$$

Here, λ is the spin-orbit coupling constant and is estimated to be ~0.01 eV from the interval between the $^2\Pi_{3/2}$ and and $^2\Pi_{1/2}$ states, while Δ is the crystal-field splitting of the Π_x^* and Π_y^* states. According to the equation, the increase in the g_z value with the elevation of the temperature indicates that the effective surface field acting on the nitric oxide molecule weakens as the temperature is elevated and as the molecular motion becomes more active, implying that the orbital angular momentum, quenched by the interaction with the surface, recovers as the temperature is elevated. The marked linewidth broadening observed with the elevation of the temperature may be attributed to the large spin-orbit coupling, the magnitude of which is modulated with the fluctuation in the interaction of nitric oxide with the surface by the thermal agitation of nitric oxide.

Recetnly, Huang and Van Vleck tried to explain Solbakken's magnetic-susceptibility measurements by theoretical calculations.[13] They showed that Solbakken's observation may be explained by assuming that the average crystal field per molecule increases as the temperature is elevated. Our observation indicates, however, that the average crystal field acting on nitric oxide, rather, decreases as the temperature is elevated. It seems likely that the average magnetic moment of nitric oxide at low temperatures in the adsorbed state is much higher than that of nitric oxide in the gas phase at the same temperature, because the orbital angular momentum is quenched by the interaction with the surface and the molecule in the ground state, $^2\Pi_{1/2}$, which originally has no magnetic moment because of the cancellation of the orbital magnetic moment and the spin magnetic moment, comes to show paramagnetism due to electron spin.

Table 1. Values of Δ for nitric oxide

Solid	(eV)	Ref.
Silica gel { site L	0.26	This work
Silica gel { site H	0.52	This work
MgO	0.30	2
ZnS	0.33	3
ZnO	0.50	3
Silica–alumina	0.60	5
Silica–magnesia	0.33, 0.60	5
γ-Alumina	0.75	5

The crystal-field splitting of the Π_x^* and Π_y^* states, Δ, was evaluated as 0.26 eV for nitric oxide on Site L and 0.52 eV for nitric oxide on Site H by means of Eq. (1). These Δ values are compared with those obtained in the other systems in Table 1. It should be noticed here that the value relates to the field gradient in the X or Y direction of the nitric oxide molecule;[9] therefore, it relates also to the adsorbed structure of nitric oxide. It is not necessarily proportional to the field strength primarily existing on the surface if there is any difference in the adsorbed structure in the solid systems.

The maximum concentration of nitric oxide responsible for the ESR absorption was obtained for the sample pretreated at temperatures higher than 500 °C as 0.9×10^{18} spin/g, which corresponds to 2×10^{11} spin/cm^2, with an error of ±30%, while for the sample pretreated at *ca.* 300 °C the spin concentration was much less (1/3~1/4), suggesting that the sites for adsorption were produced by the loss of a hydroxyl group, such as a siloxane group. The presence of the two adsorption sites, Site L and Site H, may be due to a difference in the surroundings of the two sites; Site L may be the siloxane group, with silanol groups

surrounding it, while Site H may be the siloxane group, with no silanol groups surrounding it. The increase in the pressure of nitric oxide over 30 Torr at the adsorption process in the sample preparation did not seem to result in any appreciable increase in the radical concentration. This may be mainly due to the formation of the diamagnetic dimer of nitric oxide, N_2O_2, on the surface.

The authors wish to express their thanks to Dr. Hiroshi Utsuki for his help in the measurement of the surface area of silica gel and also for his valuable discussions.

A New Method for Determination of Self-diffusion Coefficients in Solid Solutions

Seiichi KURIHARA, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received October 8, 1973)

A new method for obtaining the self-diffusion coefficients of A in the AY–BY solid solution has been proposed. In this method, the tracer diffusion of A* and the interdiffusion between AY and BY are carried out simultaneously, and the self-diffusion coefficients are determined as a function of composition over the whole range of composition in a similar way as the Boltzmann-Matano analysis. Since this method employs a diffusion couple consisting of single crystals of AY and BY, one can avoid troubles and errors due to segregation and/or phase separation which are often encountered in experiments using solid solutions as specimens. In order to confirm the validity of the proposed method, D_{Cl}* in the TlCl–TlBr system and D_{Ag}* and D_{Na}* in the AgBr–NaBr system have been determined at 400 °C by this method and compared with the results obtained by the conventional method. A good agreement has been found between them.

Self-diffusion coefficients in solid solutions are usually determined as a function of composition by using single crystals of various compositions. However, segregation occurs during solidification of melts and segregated crystals cannot be easily homogenized by annealing. Sometimes, phase separation occurs with lowering temperature and the single crystal changes into a polycrystal. In such a case, it is difficult to obtain self-diffusion coefficients by the conventional method.

The purpose of this paper is to propose a new method for obtaining self-diffusion coefficients in solid solutions as a function of composition. In this method, the tracer diffusion of an element and the interdiffusion between the component salts are carried out simultaneously, and the concentration profiles are analysed in a similar way as the Boltzmann[1]-Matano[2] method which is usually used to obtain interdiffusion coefficients. Employment of this new method can avoid experimental difficulties due to the segregation and/or the phase separation.

Theoretical

1. Flux and Mass Balance Equations. Let us assume that ionic crystals AY and BY form a solid solution. If pure AY and BY containing a small amount of A*, a radioactive isotope of A, are in contact with each other and allowed to diffuse mutually, the concentration curve for A including both radioactive and stable isotopes and that for A* would be as shown in Fig. 1. Denoting the fluxes of A and A*, relative to one end of the specimen, by J'° and J'^{*} and those relative to the local lattice by J° and J^{*}, respectively, we obtain

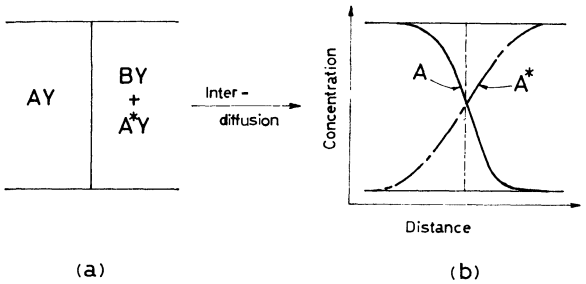

Fig. 1. Schematic diagram for interdiffusion in AY–(B,A*)Y system.

$$J'^{\circ} = J^{\circ} + c^{\circ}v \tag{1}$$

$$J'^{*} = J^{*} + c^{*}v, \tag{2}$$

where v is the velocity of the local lattice relative to one end of the specimen and c is the molar concentration. Symbols ° and * express the quantities with respect to A and A*, respectively. Neglecting cross terms, we have the following phenomenological equations,

$$J^{\circ} = -\frac{D^{*}c^{\circ}}{RT}\frac{\partial\tilde{\mu}^{\circ}}{\partial x} \tag{3}$$

$$J^{*} = -\frac{D^{*}c^{*}}{RT}\frac{\partial\tilde{\mu}^{*}}{\partial x}, \tag{4}$$

where x is the distance, D^* is the self-diffusion coefficient of A and $\tilde{\mu}$ is the electrochemical potential. $\tilde{\mu}^{\circ}$ and $\tilde{\mu}^{*}$ are written as follows:

$$\tilde{\mu}^{\circ} = \mu^{\circ} + ZF\phi \tag{5}$$

$$\tilde{\mu}^{*} = \mu^{*} + ZF\phi, \tag{6}$$

where μ, ZF and ϕ are the chemical potential, electric charge per mole and electric potential, respectively. μ° is the chemical potential of A in the system of (A, B)Y and μ^{*} is that of A* in the system of (radioactive A, stable A, B)Y which has the same concentration of B as the former system.

Because A* atoms have the same chemical properties as stable A atoms, A* atoms are expected to be distributed in stable A atoms with complete randomness and to interact with others in a quite same manner as stable A atoms. Therefore, μ^{*} is expressed as

$$\mu^{*} = \mu^{\circ} - T\bar{S}_c, \tag{7}$$

where $\bar{S}_c$ is the partial molal configurational entropy of A* in both radioactive and stable A atoms. $\bar{S}_c$ is written as

$$\bar{S}_c = R\ln(c^{\circ}/c^{*}). \tag{8}$$

Combination of Eqs. (7) and (8) gives

$$\mu^{*} = \mu^{\circ} + RT\ln(c^{*}/c^{\circ}). \tag{9}$$

Combination of Eqs. (5), (6), and (9) yields

$$\tilde{\mu}^* = \tilde{\mu}^\circ + RT\ln(c^*/c^\circ). \quad (10)$$

Substituting Eq. (10) into Eq. (4) and comparing Eq. (4) with Eq. (3), we obtain

$$J^* = \frac{c^*}{c^\circ}J^\circ + D^*\left(\frac{c^*}{c^\circ}\frac{\partial c^\circ}{\partial x} - \frac{\partial c^*}{\partial x}\right). \quad (11)$$

Substitution of Eq. (11) into Eq. (2) and comparison of Eq. (2) with Eq. (1) results in

$$J'^* = \frac{c^*}{c^\circ}J'^\circ + D^*\left(\frac{c^*}{c^\circ}\frac{\partial c^\circ}{\partial x} - \frac{\partial c^*}{\partial x}\right). \quad (12)$$

Assuming that the molal volume of the AY–BY solid solution is independent of the composition, we obtain

$$J'^\circ = -\tilde{D}\frac{\partial c^\circ}{\partial x} \quad (13)$$

where $\tilde{D}$ is the interdiffusion coefficient of the AY–BY system. Equation (13) gives the mass balance equation,

$$\frac{\partial c^\circ}{\partial t} = \frac{\partial}{\partial x}\left(\tilde{D}\frac{\partial c^\circ}{\partial x}\right). \quad (14)$$

Substituting Eq. (13) into Eq. (12) we obtain the flux equation of A* as follows:

$$J'^* = -\frac{c^*}{c^\circ}\tilde{D}\frac{\partial c^\circ}{\partial x} + D^*\left(\frac{c^*}{c^\circ}\frac{\partial c^\circ}{\partial x} - \frac{\partial c^*}{\partial x}\right). \quad (15)$$

The mass balance equation of A* is

$$\frac{\partial c^*}{\partial t} = \frac{\partial}{\partial x}\left\{\frac{c^*}{c^\circ}\tilde{D}\frac{\partial c^\circ}{\partial x} - D^*\left(\frac{c^*}{c^\circ}\frac{\partial c^\circ}{\partial x} - \frac{\partial c^*}{\partial x}\right)\right\}. \quad (16)$$

Equations (14) and (16) give the concentration curves in such a system where the interdiffusion and the tracer diffusion proceed simultaneously.

2. Equation for Determination of D.* The concentration of A obtained experimentally is not c° but the mole fraction N. Also, the normalized A* concentration n^* which is defined as the ratio of $c^*(x,t)$ to the initial value of c^* in BY, is obtained experimentally as the concentration of A*. Therefore, equations for N and n^* are required for the purpose of application, instead of Eqs. (14) and (16). Since Eqs. (14) and (16) are linear with respect to c° and c^* and the molar volume of the solid solution is assumed to be independent of composition, they are rewritten in the following forms:

$$\frac{\partial N}{\partial t} = \frac{\partial}{\partial x}\left(\tilde{D}\frac{\partial N}{\partial x}\right) \quad (17)$$

$$\frac{\partial n^*}{\partial t} = \frac{\partial}{\partial x}\left\{\frac{n^*}{N}\tilde{D}\frac{\partial N}{\partial x} - D^*\left(\frac{n^*}{N}\frac{\partial N}{\partial x} - \frac{\partial n^*}{\partial x}\right)\right\}. \quad (18)$$

If the initial conditions for Eq. (17) are described in terms of the Boltzmann variable $\eta \equiv x/(2\sqrt{t})$, N is a function of η only and Eq. (17) can be transformed into an ordinary differential equation,

$$-2\eta\frac{dN}{d\eta} = \frac{d}{d\eta}\left(\tilde{D}\frac{dN}{d\eta}\right). \quad (19)$$

Similarly, if the initial conditions for n^* in addition to those of N are described as a function of η, Eq. (18) is rewritten as

$$-2\eta\frac{dn^*}{d\eta} = \frac{d}{d\eta}\left\{\frac{n^*}{N}\tilde{D}\frac{dN}{d\eta} - D^*\left(\frac{n^*}{N}\frac{dN}{d\eta} - \frac{dn^*}{d\eta}\right)\right\}. \quad (20)$$

Assuming that the mole fraction of A*Y is very small, we can describe the initial conditions in Fig. 1 as follows:

$$N = 0, \quad n^* = 1 \quad \text{for } \eta = +\infty$$
$$N = 1, \quad n^* = 0 \quad \text{for } \eta = -\infty.$$

Integrating Eqs. (19) and (20) with respect to η and rearranging them, we obtain the following expressions for D^*,

$$-D^*(N_m) = \frac{2N_m\int_0^{n_m^*}\eta dn^* - 2n_m^*\int_0^{N_m}\eta dN}{N_m\left(\frac{dn^*}{d\eta}\right)_{\eta=\eta_m} - n_m^*\left(\frac{dN}{d\eta}\right)_{\eta=\eta_m}}$$
$$= \frac{N_m\int_0^{n_m^*}x dn^* - n_m^*\int_0^{N_m}x dN}{2t\left\{N_m\left(\frac{\partial n^*}{\partial x}\right)_{x=x_m} - n_m^*\left(\frac{\partial N}{\partial x}\right)_{x=x_m}\right\}}, \quad (21)$$

where N_m and n_m^* are N and n^* at $\eta_m\{=x_m/(2\sqrt{t})\}$, respectively and $D^*(N_m)$ is the self-diffusion coefficient of A in a homogeneous solid solution of composition N_m. The so-called Matano interface is taken as the origin of η or x. If the concentration profiles of both interdiffusion and tracer diffusion are obtained experimentally, we can determine the self-diffusion coefficients of A and B in the AY–BY solid solution by means of Eq. (21).

Experimental

In order to confirm the results of the aforementioned theory experimentally, the self-diffusion coefficients of Cl in the TlCl–TlBr system and those of Ag and Na in the AgBr–NaBr system were determined by the new method and compared with the results obtained by the conventional method.

1. TlCl–TlBr System. Single crystals of TlCl and TlBr were prepared in a similar way as reported previously.[3] Disks, 2 mm in thickness and 10 mm in diameter, were cut from these crystals. A few drops of aqueous TlCl*(^{36}Cl) solution were applied to both ends of the disk. After the drying, the disk was sealed in an evacuated Pyrex-glass ampoule and annealed at about 400 °C for several days to distribute Cl* uniformly in the disk. Then, the disk was finished to obtain flat end surfaces. The doped disk was coupled with an undoped one as follows:

Couple A: TlCl(Cl*)/TlBr

Couple B: TlCl/TlBr(Cl*)

where TlCl(Cl*) and TlBr(Cl*) are ^{36}Cl-doped disks, and TlCl and TlBr are undoped disks. Couple A was used for obtaining the interdiffusion profile, because the concentration of Cl* is proportional to the concentration of Cl. Couple B was employed for determining the profile of tracer diffusion accompanied by interdiffusion. The couple was sealed in a Pyrex-glass ampoule evacuated to 10^{-3} Torr and annealed at 400 °C. Then, the couple was taken out and sectioned serially from one end. The procedures of diffusion annealing and sectioning are described elsewhere.[3,4] The weight and radioactivity of each sectioned layer were measured. Mole fraction of TlCl of each layer was determined from the radioactivity. Density of the layer was calculated from the mole fraction and lattice constant of this system.[5] The thickness of each layer was determined from the weight, the cross sectional area and the density. As the interface between

the disks acts as a natural marker during the interdiffusion, it was taken as the standard plane for determining the distance. In this way, the mole fraction of TlCl was determined as a function of distance from the interface.

The relation between radioactivity and weight per cross sectional area was also obtained for couple B. As the annealing time required for couple A was different from that for couple B, the weight per cross sectional area for couple A was multiplied by the square root of the ratio of the annealing time for couple B to that for couple A, to obtain the corresponding profiles of self-diffusion and interdiffusion. The mole fraction of TlCl in couple B was determined from the corresponding profiles with the same origin of distance, and the normalized concentration of Cl* was calculated as a function of distance from the interface.

2. AgBr–NaBr System. According to the results by previous investigators, the self-diffusion coefficients of this system depend on the purity of crystals in a composition range rich in NaBr.[6] Therefore, in the present study the experiment was carried out in a composition range from $N_{AgBr}=0.4$ to 1.0. Commercially obtained AgBr of G. R. grade was further purified in an evacuated and sealed Pyrex-glass tube by the zone refining technique. The refining operation was repeated 30 times so that the concentration of impurity might decrease to the order of 10 ppm. NaBr of Merck's Suprapur grade (99.9995% pure) was used.

Single crystals were prepared by the Bridgeman method, and cut into disks, 2 mm in thickness. Radioisotope ^{110m}Ag or ^{22}Na was applied to the disks of $Ag_{0.4}Na_{0.6}Br$, which were then annealed at about 410 °C for 20 days in an evacuated ampoule in order to homogenize the composition and distribute the radioisotopes uniformly in them. Concentration profiles were obtained by using the following couples,

Couple C: $AgBr/Ag_{0.4}Na_{0.6}Br(Na^*)$

Couple D: $AgBr/Ag_{0.4}Na_{0.6}Br(Ag^*)$

Couple E: $AgBr(Na^*)/Ag_{0.4}Na_{0.6}Br$.

Couples C, D and E were used for obtaining the concentration profiles of interdiffusion, tracer diffusion of Ag* and tracer diffusion of Na*, respectively. Annealing was carried out at 400 °C, and the determination of concentration profile was performed in a similar way as the TlCl–TlBr system.

Results and Discussion

1. TlCl–TlBr System. The profile of the interdiffusion obtained by using couple A, is given in Fig. 2 as a plot of N_{TlCl} *vs.* distance. The diffusion profile of tracer Cl* is shown in Fig. 3, as a plot of n_{Cl}^* *vs.* distance. In both figures, the interface between the crystals was taken as the origin of the distance and are shown by symbol B. Figure 4 shows the profiles of self-diffusion and interdiffusion, expressed as a plot of concentration *vs.* η. Plane A in the figure indicates the Matano interface and it was taken as the origin of the distance.

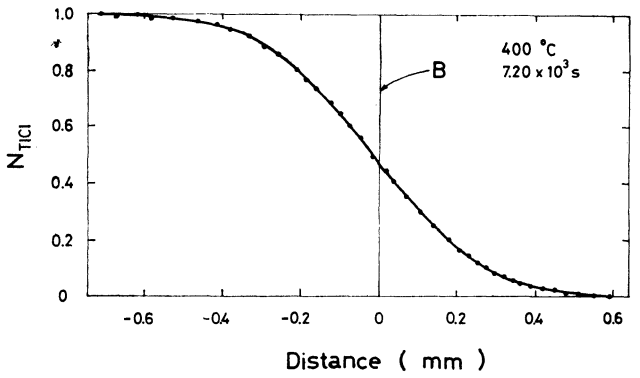

Fig. 2. Interdiffusion profile for TlCl–TlBr system.

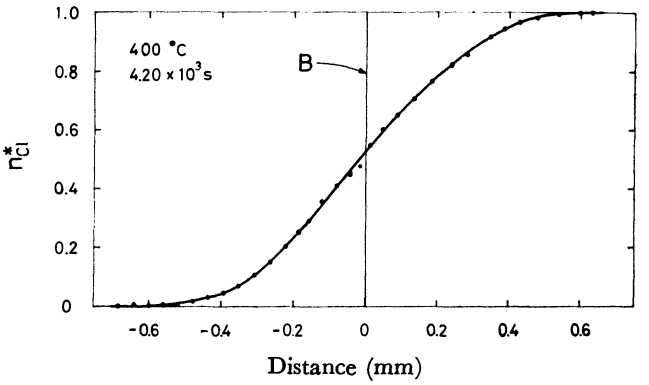

Fig. 3. Tracer diffusion profile of Cl* in TlCl/TlBr interdiffusion couple.

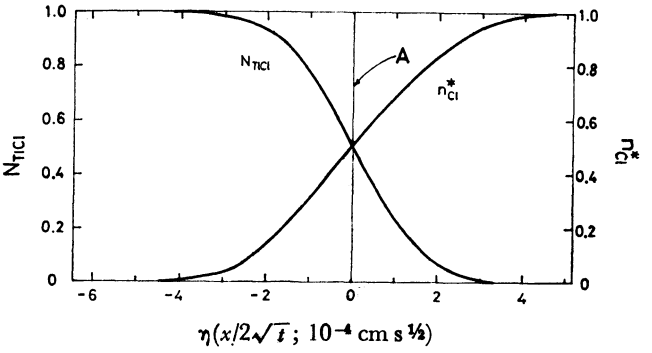

Fig. 4. Concentration profiles of TlCl and Cl* at 400 °C.

The self-diffusion coefficients of Cl, D_{Cl}^*, at 400 °C were calculated from the curves given in Fig. 4 by using Eq. (21). The results are shown by solid circles in Fig. 5. For comparison, the values of D_{Cl}^* obtained by the conventional method[4] are shown by open circles in the same figure. Agreement between them is fairly good. The maximum difference is only 15% of D_{Cl}^*.

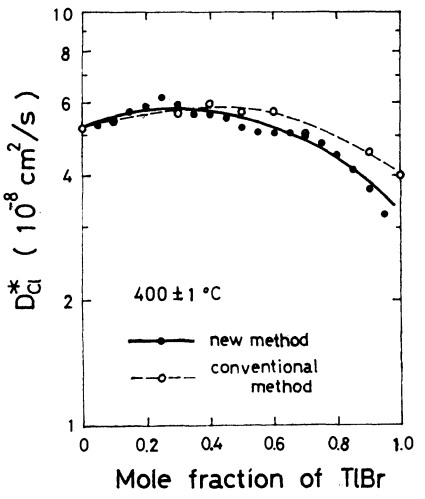

Fig. 5. D_{Cl}^* in TlCl-TlBr system.

2. AgBr–NaBr System. Figure 6 shows N_{AgBr} and n_{Ag}* as functions of η. These profiles were obtained from couples C and D, by assuming that Vegard's law holds for molar volume of the solid solution. D_{Ag}* at 400 °C were calculated from the curves shown in Fig. 6 by using Eq. (21). The results are shown by solid circles in the upper part of Fig. 7. D_{Na}* at 400 °C was calculated from the results for couples C and E. They are given by solid circles in the lower part of Fig. 7. The values of D_{Ag}* and D_{Na}* obtained by the conventional method are also shown in Fig. 7. Self-diffusion coefficients obtained by the new method well agree with those by the conventional method.

It is concluded that self-diffusion coefficients in solid solutions can be obtained by the method proposed in this paper.

Summary

(1) A new method has been proposed to obtain self-diffusion coefficients of A in AY–BY solid solution as a function of composition.

(2) D_{Cl}* in TlCl–TlBr system and D_{Ag}* and D_{Na}* in AgBr–NaBr system at 400 °C have been obtained by the new method and compared with the values obtained by the conventional method. A good agreement was found between them.

(Received October 15, 1973)

Triplet-triplet absorption, phosphorescence, and ESR spectra have been measured on the 1,3,5-tricyanobenzene complexes with toluene, mesitylene, durene, and hexamethylbenzene. Four triplet-triplet absorption bands were commonly observed in the wave number region of 10000—30000 cm^{-1} for all the complexes. The observed phosphorescence and T-T absorption spectra could be understood systematically by considering the interaction among zero-order charge-transfer triplet states and zero-order locally (within the acceptor) excited triplet states. From an analysis of the zero-field splitting values obtained from the observed ESR spectra, the contribution of the zero-order charge-transfer triplet state to the lowest triplet state was determined to be 76, 65, 25, and 9% for the 1,3,5-tricyanobenzene complexes with hexamethylbenzene, durene, mesitylene, and toluene, respectively. From the consideration on the results obtained for various polycyanobenzene complexes, the phosphorescence lifetime was found to decrease remarkably for the complexes with the charge-transfer character higher than 50% in their lowest triplet states.

The triplet states of electron donor-acceptor (EDA) complexes have been studied in detail through measurements of the phosphorescence and ESR spectra.[1-7] In particular, concerning the TCNB complexes with benzene and methyl substituted benzenes, the nature of their lowest triplet states was investigated quantitatively and the appearance of the charge-transfer (CT) phosphorescence characteristic of the electron donor-acceptor interaction was confirmed.[4,5]

Triplet-triplet (T-T) absorption spectra have been measured with some EDA complexes.[8-12] The analysis of the results on the TCNB complexes with methyl substituted benzenes supports the conclusions obtained from the phosphorescence and ESR spectra.[10,12]

In the present paper, for the purpose of studying the effects of the electron accepting ability and molecular symmetry of the acceptor upon the triplet states of EDA complexes, we have undertaken a study of the phosphorescence, ESR, and T-T absorption spectra of the 1,3,5-tricyanobenzene complexes with toluene, mesitylene, durene, and hexamethylbenzene.

Experimental

1,3,5-Tricyanobenzene (TRCNB) used as electron acceptor was prepared and purified by the method described in literature.[13,14]

Hexamethylbenzene (HMB), durene, mesitylene, and toluene were used as electron donors. HMB and durene were recrystallized from ethanol. Mesitylene was shaken with concentrated sulfuric acid, washed with water, dried over calcium chloride, and finally distilled. Toluene (Dotite spectrosol grade) was used without further purification.

T-T absorption spectra were measured at 77 K for the TRCNB–toluene complex in a toluene–ethyl ether (1:1) mixed solvent and for the other TRCNB complexes in an ethyl ether–isopentane (1:1) mixed solvent (EP). The samples were excited by a 500 W super-high pressure mercury lamp combined with a Toshiba UV-D 25 filter. The details of the measurement were described in a previous paper.[12]

The electronic absorption spectra as shown in Fig. 2 were measured with a Cary recording spectrophotometer model 14M. Phosphorescence spectra were measured with a phosphoroscope and a grating monochromator (Spex 1700-111) attached with an EMI 9558 QB photomultiplier, and excitation of the samples was effected with a 100 W high pressure mercury lamp.

ESR spectra of the phosphorescent states were measured in rigid solutions at 77 K with a JEOL ME 3X spectrometer (9225.9 MHz, 100 kHz magnetic field modulation), the samples being excited with a 500 W super-high pressure mercury lamp. The microwave magnetic field was perpendicular to the external field.

Theoretical

In order to assign the observed T-T absorption spectra and clarify the nature of the triplet states of the complexes, theoretical studies were made by considering the interaction among the zero-order CT triplet states and the zero-order locally (within TRCNB) excited (LE) triplet states. The details of the method were described in the previous paper.[12] In actuality, we took six zero-order CT triplet states and three zero-order LE triplet states shown in Table 1.

The molecular orbitals of TRCNB were calculated by the Pariser-Parr-Pople SCF MO method,[15,16] the same parameters as those used for TCNB[17] being adopted. The results are shown in Table 2. The zero-order CT triplet states in Table 1, ${}^3\Phi_{CT_1}({}^3\Phi_{CT_2})$, ${}^3\Phi_{CT_3}({}^3\Phi_{CT_4})$, and ${}^3\Phi_{CT_5}({}^3\Phi_{CT_6})$, correspond to the electron transfer from the highest occupied orbital of the donor, $\theta_2(\theta_3)$, to the lowest three vacant orbitals of TRCNB, ϕ_7, ϕ_8, and ϕ_9, respectively. The zero-order LE triplet states, ${}^3\Phi_{LE_1}$, ${}^3\Phi_{LE_2}$, and ${}^3\Phi_{LE_3}$ are represented as follows:

$$
\begin{aligned}
{}^3\Phi_{LE_1} = {} & -0.64638\,{}^3\Psi_{6\to7} + 0.64719\,{}^3\Psi_{5\to8} + 0.00040\,{}^3\Psi_{5\to9} \\
& - 0.00081\,{}^3\Psi_{4\to8} + \cdots \\
{}^3\Phi_{LE_2} = {} & 0.52383\,{}^3\Psi_{6\to7} + 0.52037\,{}^3\Psi_{5\to8} + 0.33223\,{}^3\Psi_{5\to9} \\
& - 0.31785\,{}^3\Psi_{4\to8} + \cdots \\
{}^3\Phi_{LE_3} = {} & -0.02656\,{}^3\Psi_{6\to7} - 0.02695\,{}^3\Psi_{5\to8} - 0.44357\,{}^3\Psi_{5\to9} \\
& + 0.31901\,{}^3\Psi_{4\to8} + \cdots
\end{aligned}
$$

* One of the benzene rings is rotated about the z axis by 30° from the other.

The geometrical structure of this complex is not yet known. Therefore, the actual calculation was made with five tentative geometrical models shown in Fig. 1. The separation between the two benzene rings was fixed to 3.4 Å. The off-diagonal elements of the total electronic Hamiltonian representing the interactions between the zero-order CT triplet states and the zero-order LE triplet states were taken to be $\beta=-kS_{ij}$, where the parameter k was assumed to be 10[17] and the overlap integral $S_{ij}=\int\theta_i(1)\phi_j(1)d\tau$ was calculated by the use of the SCF MO's. The energies of the zero-order triplet states were determined by the procedures described in the previous paper.[12] The result on the TRCNB–HMB complex is shown in Table 1.

Results and Discussion

Electronic Absorption Spectra. The donors used in the present study show absorption bands in the wavelength region shorter than 280 nm.[18] The acceptor, TRCNB, exhibits the longest wavelength band at 300 nm. Methanol solutions containing TRCNB as an electron acceptor and HMB or durene as an electron donor exhibit a weak CT band in the 300—360 nm region. TRCNB in mesitylene also shows a CT band at 290 nm. The CT band of the TRCNB–HMB complex, as an example, is shown in Fig. 2. No CT band could be observed with TRCNB in toluene.

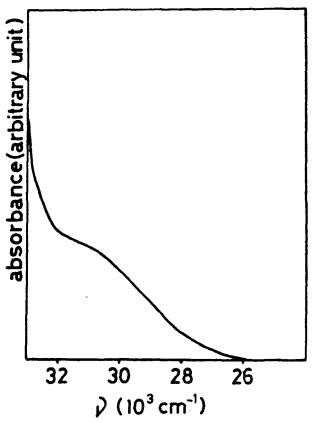

Fig. 2. The electronic absorption spectrum of the methanol solution of the TRCNB–HMB complex.

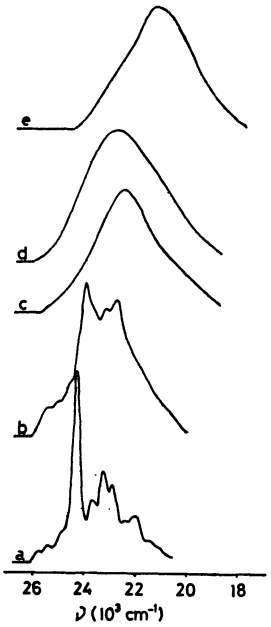

Fig. 3. Phosphorescence spectra of TRCNB and its Complexes in EP at 77 K. (a) TRCNB (b) TRCNB–toluene (c) TRCNB–mesitylene (d) TRCNB–durene (e) TRCNB–HMB.

It is expected to appear around 270 nm and may be covered with the strong absorptions of the component molecules.

The Phosphorescence Spectra. The phosphorescence spectra of the TRCNB complexes were measured by use of a Toshiba UV-D2 filter so that the excitation was effected only in the CT bands. The observed phosphorescence spectra are shown in Fig. 3, together with that of TRCNB. Their peak positions are shown in Table 3, together with the phosphorescence lifetimes. The characteristics of the phosphorescences of the TRCNB complexes are as follows: (1) the vibrational structures appearing in the phosphorescence spectrum of TRCNB disappear or become obscure in the spectra of the CT complexes; (2) the phosphorescence spectra shift to the longer wavelengths for the complexes than for the acceptor; (3) the phosphorescence lifetimes are slightly shorter for the complexes than for the acceptor. These characteristics are similar to those observed for the TCNB complexes[4] and suggest that the lowest excited states of the complexes under consideration have the CT character to some extent.

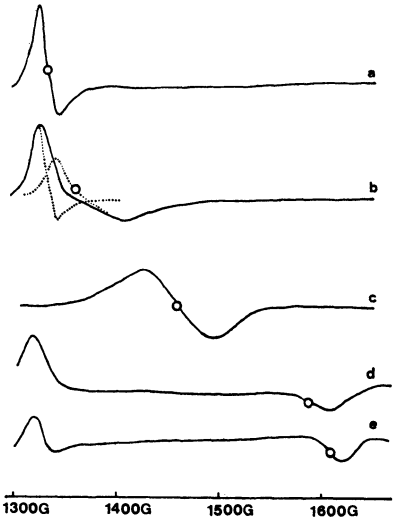

Fig. 4. ESR spectra ($\Delta m=\pm 2$) observed with the ternary solutions containing TRCNB and various donors in EP at 77 K. (a) TRCNB (b) TRCNB–toluene (c) TRCNB–mesitylene (d) TRCNB–durene (e) TRCNB–HMB. Open circles denote the position of H_{min} The signal due to the TRCNB was not observed for curve (c) because of the high concentration of mesitylene. The signals due to the complex and the TRCNB are close to each other in curve (b). The H_{min} value in this case was obtained with the curve corrected for the contribution from the TRCNB.

The ESR Spectra. In order to discuss the character of the lowest triplet state quantitatively, we measured ESR spectra for TRCNB and its complexes. ESR spectra due to the $\Delta m=\pm 2$ transitions of the lowest triplet states were observed for the EP solutions of the CT complexes and of the acceptor itself by steady irradiation with the 500 W mercury lamp through a UV-D25 filter. The observed spectra are shown in Fig. 4. The lowest possible resonance fields (H_{min}) were determined as the midpoint between the maximum and minimun of each of the observed derivative curves. From the H_{min} value, the zero-field splitting constant, D^*, was evaluated by the following equation:[19]

$$D^* = \left\{\frac{3}{4}(h\nu)^2 - 3(g\beta H_{min})^2\right\}^{1/2}$$

where $D^*=(D^2+3E^2)^{1/2}$. D, E, ν, g, and β have their conventional meanings. The g value was assumed

Table 4. The observed D^* values and the CT characters

to be 2.003 and 2.000 for the acceptor and the complexes, respectively.[5] From the D^* values obtained for the complexes we evaluated the degree of CT, x(%), in the lowest triplet state for the molecular complexes by the following equation.[5]

$$D^* = xD_{CT}^* + (1-x)D_A^*$$

Here D_A^* is the observed valueof TRCNB itself (0.1567 cm^{-1}) and D_{CT}^* is the theoretical value of the zero-order CT triplet state. By considering the electron spin dipolar interaction, D_{CT}^* was calculated to be 0.0243, 0.0228, 0.0229, and 0.0250 cm^{-1} for the zero-order CT triplet states represented by Φ_{CT_1}, Φ_{CT_2}, Φ_{CT_3}, and Φ_{CT_4}, respectively. Since they are close to one another, the average value, 0.0238 cm^{-1} was used as D_{CT}^*. The D^* and x values are given in Table 4, together with those for the TCNB complexes.

The results show that the CT character of the lowest triplet state increases for the TRCNB complexes with the decreasing I_p of the donor. This tendency was also found for the TCNB and dicyanobenzene complexes. Table 4 shows that the lowest triplet state is mainly contributed by the CT structure in the TRCNB complexes with HMB and durene, whereas by the LE structure in those with mesitylene and toluene.

T-T Absorptions of the TRCNB Complexes with Methyl Substituted Benzenes. The T-T absorption spectra observed for the TRCNB complexes with HMB, durene, mesitylene, and toluene are shown in Fig. 5. The spectrum of each complex apparently consists of four bands, bands A and B in 10000—15000 cm^{-1}, and bands C and D in >20000 cm^{-1}.[20] Neither TRCNB

$^3\psi_8 = 0.8659\,{}^3\Phi_{CT_5} + 0.5002\,{}^3\Phi_{CT_6}$

$^3\psi_9 = -0.4078\,{}^3\Phi_{CT_5} + 0.7061\,{}^3\Phi_{CT_6} + 0.5712\,{}^3\Phi_{LE_3}$

nor the donors show any T-T absorption in these wave number regions. The observed absorption bands for the respective complexes decay at the same rate as the corresponding phosphorescences. Therefore, we can safely assign them to the T-T absorption bands of the complexes. The observed band positions are given in Table 5.

Assignment of the T-T Absorptions. We interpreted the observed absorption spectra considering the calculated transition energies and oscillator strengths, the TRCNB–HMB complex being taken as an example. The observed and the calculated transition energies for this complex are shown in Table 6. The calculations were made with five geometrical models shown in Fig. 1. In Table 6 are also shown the calculated oscillator strengths for three of the models.

The calculated band positions and intensities vary considerably with the choice of models. Model 1 (face-to-face model) is rather favorable from the comparison between the observed and calculated transition energies, but the calculated intensities for this model can not explain even qualitatively the observed ones; particularly the intensity predicted for band B is too weak. The transition energies calculated for models 3 and 4 become too low compared with the observed data (particularly for band A). As a whole, the overall feature of the observed spectrum (the appearance of the two pairs of bands with comparable intensities) seems to be reproduced by model 2.[21]

The wave functions calculated for model 2 are given in Table 7.[22] Since the lowest four zero-order CT triplet states (3.0 eV) and the lowest zero-order LE triplet state (3.2 eV) are close to each other in the TRCNB–HMB complex, they mix with each other efficiently and give rise to the five states, T_1—T_5. The bands corresponding to the transitions from T_1 to T_2—T_4 are expected to be too weak to be observed. A fairly strong band due to the transition between T_1 and T_5 is expected to appear in the lowest energy region. Therefore, we assign band A in the near-infrared region to the $T_5 \leftarrow T_1$ transition. As is clearly seen in Table 6, bands B, C, and D can reasonably be assigned to the transitions from T_1 to T_6, T_8, and T_9, respectively.[23]

From the wave functions given in Table 7, it is found that T_1 is mainly contributed by the zero-order CT triplet states, while the main components of T_5 and T_6 are $^3\Phi_{LE_1}$ and $^3\Phi_{LE_2}$, respectively. Therefore, bands A and B are assigned to the LE←CT transitions.

The $T_8 \leftarrow T_1$ and $T_9 \leftarrow T_1$ transitions may be interpreted as due to the local excitations within the TRCNB anion. The T_8 and T_9 states arise mainly from the interaction between the $^3\Phi_{CT_5}$ and $^3\Phi_{CT_6}$ structures. This means that the $T_8 \leftarrow T_1$ and $T_9 \leftarrow T_1$ transitions correspond to the strong absorption of the TRCNB anion appearing at 18500 cm^{-1}.[24] The shifts to the higher frequencies (5300 and 6500 cm^{-1}) caused by the complex formation may partly be due to the stabilization of the lowest zero-order triplet state.

Effect of Electron Donors. The calculated (model 2) and observed triplet levels are shown in Fig. 6, in which the triplet-state energies of the complexes are plotted against the ionization potentials of the donors,

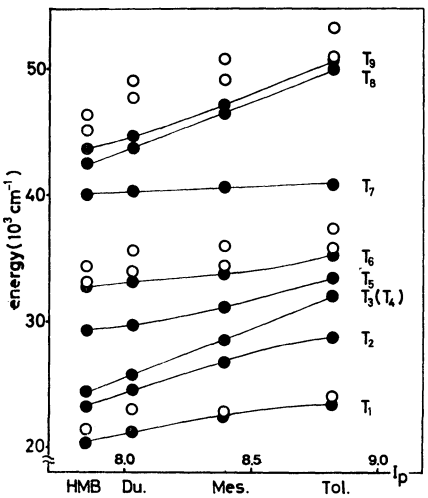

Fig. 6. The triplet state energy diagrams calculated (model 2) and observed for the TRCNB complexes. ○: observed, ●: calculated.

TABLE 8. CT CHARACTERS (%) ESTIMATED FOR THE TRIPLET STATES OF THE TRCNB COMPLEXES (MODEL 2)

Donor	T_1[a]	T_2	T_3	T_4	T_5	T_6	T_7	T_8	T_9
Toluene	25 (9)	42	100	100	76	76	4	100	96
Mesitylene	37 (25)	72	100	100	57	34	8	100	92
Durene	53 (65)	86	100	100	42	21	19	100	80
HMB	60 (76)	89	100	100	36	16	32	100	67

a) The values in parentheses are estimated from the ESR spectra.

I_p. The calculated energy levels, though they are commonly about 0.25 eV smaller for the T_5, T_6, T_8, and T_9 states of all the complexes than the observed values, can well explain the observed energy dependences upon I_p.

The calculated contributions of the zero-order CT triplet states to the $T_1 \sim T_9$ states of the complexes are given in Table 8. The character of T_1 is mainly of the CT triplet for the complexes with HMB and durene and mainly of the LE triplet for those with mesitylene and toluene. A similar tendency was found for the TCNB complexes with these methyl substituted benzenes. The contributions of the zero-order CT triplet states to T_1 are 60, 53, 37, and 25% for the TRCNB complexes with HMB, durene, mesitylene, and toluene, respectively. This estimation is semi-quantitatively consistent with the results of the ESR study. The CT characters of the T_5 state are 36, 42, 57, and 76% for the TRCNB complexes with HMB, durene, mesitylene, and toluene. Consequently, it is confirmed that the character of band A is of the LE←CT transition for the TRCNB–HMB and TRCNB–durene complexes, and of the CT←LE transition for the TRCNB–mesitylene and TRCNB–toluene complexes.

Band B is comparatively insensitive to the electron donors. The calculation shows that the energies of the upper and lower states of this band, T_1 and T_6, change almost in parallel with each other by changing the electron donor from toluene to HMB. This is a reason why band B does not shift remarkably from donor to donor.

Bands C and D shift toward the higher frequencies with the increasing I_P of the donor. The upper states of these bands, T_8 and T_9, are mainly of the CT character and their energies increase more steeply than that of the T_1 state.

Comparison among Polycyanobenzene Complexes. Table 9 shows the observed values of $\Delta\nu_p = \nu_{00}^A - \nu_{max}^C$, x, and τ_C/τ_A for the phthalonitrile (PN), TRCNB, TCNB complexes with various donors. Here ν_{00}^A and ν_{max}^C are the phosphorescence 0-0 band frequency of

Toluene		1.0	1.0

a) Taken from Ref. 6. b) Taken from Ref 4.

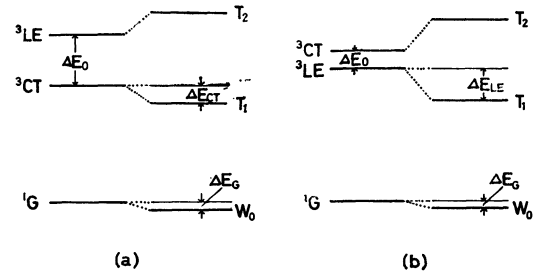

Fig. 7. Schematic energy diagrams of the lower triplet states of the HMB complexes with (a) TCNB or TRCNB; (b) PN.

the acceptor and the phosphorescence maximum frequency of the complex, respectively, x is the CT character of the phosphorescent state of the complex obtained from the ESR spectrum, and τ_A and τ_C are the phosphorescence lifetimes obtained for the acceptor and the complex, respectively.

As clearly seen in Table 9, $\Delta\nu_p$ and x increase, while τ_C/τ_A decreases, for a fixed acceptor with the decreasing I_p of the donor. This holds for all the complexes under consideration. On the other hand, for a fixed donor, $\Delta\nu_p$ is the largest for the TRCNB complex. For example, taking HMB as donor, $\Delta\nu_p$ is 4500, 4400, and 3600 cm^{-1} for the TRCNB, TCNB, and PN complexes, respectively. The phosphorescent states are mainly of the CT character for the TCNB and TRCNB complexes and of the LE character for the PN complex. As is seen in Fig. 7, $\Delta\nu_p$ is expressed as follows;

$$\Delta\nu_p = \Delta E_0 + \Delta E_{CT} - \Delta E_G \quad \text{for the TCNB and TRCNB complexes}$$

$$\Delta\nu_p = \Delta E_{LE} - \Delta E_G \quad \text{for the PN complex.}$$

The energy difference between the zero-order CT and LE triplet states, ΔE_0, is estimated to be 2480 and 1600 cm^{-1} for the TCNB and TRCNB complexes, respectively. The stabilization energy of the ground configuration, ΔE_G, is estimated to be 240—480 cm^{-1} for the TCNB complex,[17] and is expected to be smaller for the TRCNB and PN complexes. Thus, the stabilization energy of the lowest zero-order CT or LE triplet state (ΔE_{CT} or ΔE_{LE}, respectively), is expected to be the greatest for the PN complex and the smallest for the TCNB complex. This is reasonable in view of the fact that the ΔE_0 value is the greatest for the TCNB complex and the smallest for the PN complex (160 cm^{-1}).

According to Table 9, the x values for a fixed donor decrease in the following order of acceptors; TCNB> TRCNB>PN. This is consistent with the expectation that the electron affinities of the acceptors decrease in the same order.

Finally let us consider the relation between the phosphorescence lifetime of a complex and the CT character in its lowest triplet state.[4] The τ_C/τ_A values are plotted *versus* x in Fig. 8. The figure shows that τ_C/τ_A decreases with the increasing x, and the decrease becomes appreciable, in particular, in the region of x>50%. This may suggest that such phosphorescence quenching processes as ion-pair formation and ioniza-

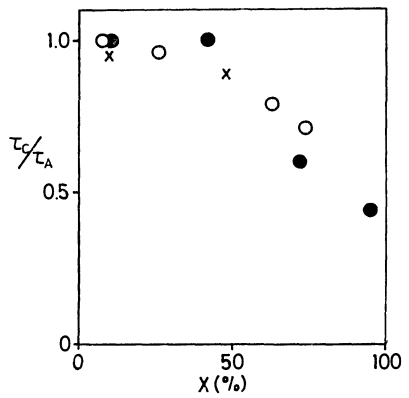

Fig. 8. Plots of τ_C/τ_A *versus* x for the complexes.

tion become important in that region of x.

The authors express their sincere thanks to Professor Jiro Higuchi, Yokohama National University, for his kindness in putting the ESR spectrometer at their disposal.

20) We could observe no T-T absorption band for the complexes in the region below 10000 cm^{-1}.
21) The overlap integral between the highest occupied orbital of the donor and the lowest vacant one of the acceptor, and consequently the stabilization energy of the ground state, is larger for models 2, 3, and 4 than for model 1. Thus, the former models favor the formation of a stable complex.
22) The calculated energy levels have a general tendency to be about 2000 cm^{-1} lower than the observed ones. This tendency was also seen to some extent in the TCNB complexes.[12] These discrepancies may originate from the underestimation of the interaction term. As the interaction is expected to increase in the excited state, the constant k should be taken to be greater than 10.
23) We did not assign band C to the $T_7 \leftarrow T_1$ transition. The $T_7 \leftarrow T_1$ transition is predicted to show a red shift with the increasing I_p of the donor, while as shown in Fig. 6, band C shifts to the higher frequencies with the increasing I_p.

Metachromasy. II.* Interaction between Sodium Polyphosphates and Crystal Violet with Special Emphasis on the Effect of Chain Lengths of the Polymer on the Metachromasy Band

Kiwamu YAMAOKA, Mineo TAKATSUKI, Kunio YAGUCHI,** and Masaji MIURA
Faculty of Science, Hiroshima University, Hiroshima 730
(Received October 22, 1973)

The interaction of crystal violet with sodium polyphosphate in aqueous solutions at neutral pH has been investigated by means of visible absorption spectroscopy and electric conductivity. The mixing ratio of polymer residue to dye was varied from 0.1 to 10000. The metachromasy band at 506 nm was found to fully develop between 3 and 10, whereas conductometric titration showed that crystal violet saturates the polymer site. Emphasis was placed on the effect of the polymer chain length on the metachromasy band. To study this effect, 17 fractionated and 13 refractionated polymer samples with degrees of polymerization extending from 4 to 300 were utilized. A critical range of the degree of polymerization from the metachromasy band exists between 7 and 20. The effect of small ions on metachromasy was also studied using sodium phosphates. An increase in Na^+ ions tends to suppress the metachromasy band. This effect is more pronounced with shorter polymer lengths. In order to explain the observed metachromasy phenomena, two mechanisms were postulated; one attributes metachromasy to the flexibility of the polymer backbone when dye is present, and the other deals with specific interaction of dye and polymer site.

A characteristic change of color is exhibited by certain cationic dyes in aqueous solutions, as their concentration is increased or the temperature is lowered. A similar change occurs when such dyes are bound to certain polyelectrolytes with anionic groups in low concentrations where the dyes alone obey Beer's law. This is the phenomenon of *metachromasy*, as originally termed by Ehrlich, in contrast with *orthochromasy* which signifies the relative lack in such a color change of basic dyes at higher concentrations or when bound to polyelectrolytes.[2] The metachromatic change, which is most pronounced in the visible spectrum, is frequently characterized by the appearance of a new absorption band (or bands)—metachromasy band—or prominent shoulders in the wavelength region shorter than the original band of a pure dye. The change has been interpreted as due to the formation of various aggregates of the bound dye molecules on the polymer sites.[3]

Such metachromatic changes are frequently specific rather than general and constitute an experimental basis of histo- and cytochemical applications. For a particular dye the metachromatic behavior is characteristic of the polyelectrolyte species and its conformation under given experimental conditions.[3-5] For a particular polymer species it often depends on the specific substituents attached to the dyes even if they belong to a class of the same chemical structure.[6,7] The differentiation of nucleic acids between themselves or from proteins *in vitro* as well as *in vivo* is based on the delicate color shades of a bound metachromatic dye.

A simple polymeric model of nucleic acids is indisputably polyphosphoric acid which is one of the simplest polyelectrolytes with ionizable phosphate groups in the polymer chain. The interactions between polyphosphates and metachromatic cationic dyes have been studied and the results compared with the interaction with nucleic acids. Dyes studied so far are toluidine blue,[8] 4,5,4′,5′-dibenzo-3,3′-diethyl-9-methylthiacarbocyanine,[9] acridine orange,[3,10-14] and proflavine.[10] Polyphosphates utilized in these studies were randomly chosen from small oligomeric samples to very high polymeric Kurrol's salts. Few attempts, however, have been made to find the relation between the critical polymer dimension and metachromasy.

In this paper we present, for the first time, detailed results of the effect of the length of polymer chain on induction of metachromasy and, in particular, evidence for the existence of a critical range of the chain lengths. We prepared a large number of fractionated polyphosphate samples with degrees of polymerization in the range 4—300. As a metachromatic dye we chose crystal violet, purer and more representative of triphenylmethane dyes, instead of acridines. The optical properties of crystal violet have been studied to the same extent as acridine orange or proflavine both in the absence [15-17] and presence of various polyelectrolytes.[6,7,18-20,25,26] Crystal violet is particularly suitable, since, under certain conditions, it exhibits a new, well-defined metachromasy band at 506 nm separated from its principal band, when bound to polyphosphate.[1]

Experimental

Materials. Sodium polyphosphate (NaPP) was synthesized from sodium dihydrogen phosphate used as a monomer by the method of pyropolymerization.[1] The degree of polymerization of each preparation was controlled by adding an appropriate amount of disodium hydrogen phosphate, as a chain terminator, to the monomer. The reactants were mixed and preheated in a platinum crucible below 200 °C to dryness and then heated at 800 °C in an electric furnance for about 8 hr. The melt was then quickly solidified in a liquid nitrogen bath.

Eight NaPP preparations were each fractionated into five to eight fractions of approximately equal volume by the method of fractional precipitation from aqueous solution (ca. 7%) with acetone. Each fraction was separated from the mother liquor by decantation, redissolved in water, lyophilyzed, and dried *in vacuo* at room temperature and then at 57 °C. Samples were stored in a desiccator over

* Part I of this series is Ref. 1.

phosphorus pentoxide. The number-average degree of polymerization, $\bar{n}$, of the total fifty fractions was determined by the method of end-group titration with sodium hydroxide and found to be in the range 4—300. In order to prepare better-defined samples with respect to molecular weight distribution, a mixture of four fractions, whose $\bar{n}$'s were in the neighborhood of 11, was refractionated into eight fractions. Another mixture of two fractions with $\bar{n}$'s of approximately 120 was also refractionated into eight fractions.

Crystal violet (CV) in the chloride form (Chroma Gesellschaft, Schmid & Co.) was purified by recrystallization from hot water and dried to be anhydrous at 80 °C *in vacuo*.[1] The purity of CV was tested by thin-layer chromatography (1: 4 methanol–chloroform mixed solvent as an eluent). The vacuum-dried dye sample was weighed as anhydrous chloride to prepare a stock solution, which was stored in the dark at room temperature. All glassware was equilibrated with a concentrated dye solution and rinsed thoroughly with water before use to avoid the undesirable adsorption of dye. The maximum molar extinction coefficient at 592 nm was 94000 at 1.12×10^{-5}M.

Procedures. An anhydrous polymer sample was dissolved in distilled water to prepare a stock solution which was stored in the cold. Just prior to measurements, one part of the dye stock solution was added dropwise to one part of the polymer solution, while the mixture was being stirred. The dye–polymer solution was then equilibrated for about 15 min. This order of mixing was observed throughout. The final concentration of dye in the dye–polymer solution was maintained at a fixed value of 1.12×10^{-5}M, unless otherwise stated. The ratio of monomer residue (or anionic site) to dye, P/D, was defined as before.[4]

The buffered dye–polymer solution was prepared by using the Na_2HPO_4–NaH_2PO_4 buffer system, the components of which are both monomeric units of NaPP. One part of the buffer solution was first added to one part of the polymer solution, followed by two parts of the dye solution. The pH of buffered dye–polymer solutions was adjusted to about 6.5. Part of this solution was saved for pH determination. The final buffer concentration was kept at five times higher than that of NaPP, except for the study of the effect of concentration of added salt (Na_2HPO_4–NaH_2PO_4) on the dye–polymer complex formation.

Measurements. A Hitachi Model EPS-3T recording spectrophotometer was used together with a matched pair of 1 cm long quartz cells. The temperature was controlled at 25 °C by circulating regulated water through a cell holder. The solution was always equilibrated for 5—10 min before the measurement of an absorption spectrum which was scanned at least twice to ascertain reproducibility. Conductometric titration was carried out on a Jones type 1000-Hz bridge.[21,22] The electrodes of a conductivity cell with a cell constant of 0.0333 were made of bright platinum to avoid the adsorption of NaPP. No time dependence of the cell resistance was observed in the presence of the solution of NaPP or CV. 1 ml of a 1.3×10^{-3}M NaPP solution was added (0.04 ml at a time) through a burette to 25 ml of a 2.26×10^{-5}M CV solution in the cell. The mixture was stirred and allowed for about 2 min each time for equilibration before reading the resistance.

Results

Spectra of Crystal Violet in the Presence of NaPP in Aqueous Solutions. The visible absorption spectra of CV in the presence of a high molecular weight NaPP are shown in Fig. 1. The values of P/D were varied by adjusting the polymer concentration at a fixed CV concentration. The absorption maximum of CV at 592 nm decreases with an increase in P/D values up to 3 by the addition of NaPP, while its absorption at 506 nm increases steadily to a distinct band—a metachromasy band. There is an isosbestic point at 639 nm in the longer wavelength side in a family of the NaPP–CV spectra at P/D values less than unity. The spectral trend reverses very slowly at first and then gradually, as the polymer concentration is increased to about 100 in terms of P/D. At exceedingly high P/D values, the 592 nm band regains its intensity, whereas the metachromasy band at 506 nm diminishes. Thus, the overall spectrum becomes almost the same as that of pure CV. An isosbestic point also appears at 636 nm in the spectra of NaPP–CV systems at P/D values higher than 100. It should be noted that in the spec-

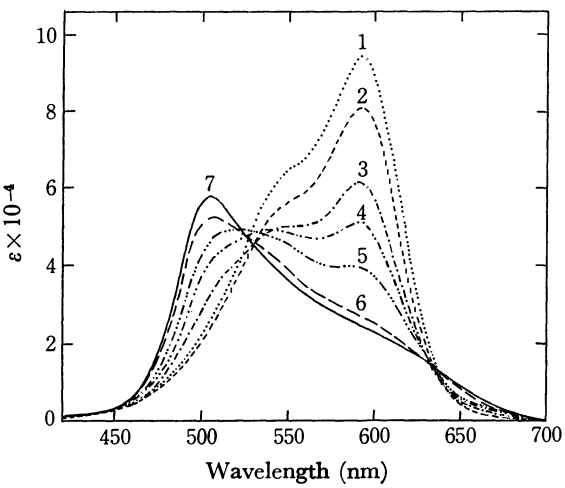

Fig. 2. Spectra of CV in the presence of NaPP with various chain lengths at a P/D value of 3 in aqueous solutions.
(1) Pure CV (P/D=0) for comparison, (2) $\bar{n}$=7.77, (3) $\bar{n}$=12.9, (4) $\bar{n}$=15.6, (5) $\bar{n}$=24.4, (6) $\bar{n}$=63.0, (7) $\bar{n}$=154.

trum of CV there is a weak, probably forbidden band between 340 and 380 nm which is also affected by the presence of NaPP.[1] No quantitative analysis of this band is given because of the small changes in intensity and band position.

The effect of the chain length of NaPP on the visible absorption spectra of CV is shown in Fig. 2. The P/D value is held at 3 which is one of the most favorable values for the appearance of the metachromasy band. The spectra for $\bar{n}$ values less than about 5 are essentially the same as the pure CV spectrum. As the values of $\bar{n}$ increase, the principal band intensity at 592 nm decreases, while the metachromasy band intensity increases for the NaPP samples. A sharp transient region of $\bar{n}$ lies approximately between 7 and 20. The intensities of both bands become unchanged as $\bar{n}$ exceeds 20. It is interesting to note that the spectral behavior shown in Fig. 2 is closely related to that shown in Fig. 1. This indicates that, with respect to the 506 nm metachromasy band, some correlation exists between changes in P/D values at a given $\bar{n}$ and changes in $\bar{n}$ at a given P/D value. All results are hereafter described in terms of absorptions at the 592 and 506 nm bands with which the metachromasy of CV can be characterized most conveniently.

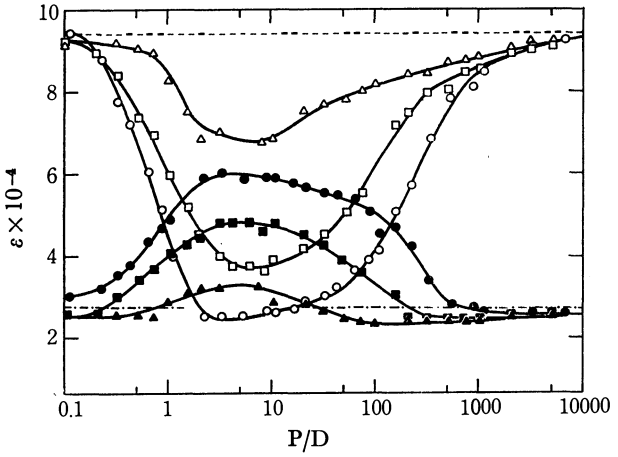

Fig. 3. The dependence of metachromasy on the P/D values for NaPP–CV systems with different chain lengths in aqueous solutions.
Open symbols are the molar extinction coefficients of CV at 592 nm and filled ones are those at 506 nm. -○- and -●- for $\bar{n}$=154, -□- and -■- for $\bar{n}$=24, -△- and -▲- for $\bar{n}$=11.

Effect of the P/D Values on the Absorption of NaPP–CV Complexes with Various Degrees of Polymerization. In Fig. 3, the molar extinction coefficients of CV at 592 and 506 nm in the presence of three different NaPP samples ($\bar{n}$=154, 24, and 11) are plotted against P/D on a logarithmic scale. The effect of P/D is such that, at both low and extremely high P/D values, the molar extinction coefficients at 592 and 506 nm are about the same as those of pure CV. The 506 nm band becomes most outstanding and the 592 nm band is diminished to a minimum for each NaPP sample at P/D values between about 3 and 10. The extreme values of the extinction coefficients differ with the chain length of NaPP. This indicates that, while the metachromasy is developed to be maximum for each NaPP sample in this P/D range, the magnitude of the 506 nm metachromasy band is affected by the polymer chain length. The three NaPP samples were so chosen that the metachromasy band is induced to a small ($\bar{n}$=11), medium ($\bar{n}$=24), or large ($\bar{n}$=154) extent.

Effects of the Chain Length and Fractionation of NaPP on the Absorption of NaPP–CV Complexes at Various Values of P/D. The effects of chain length and frac-

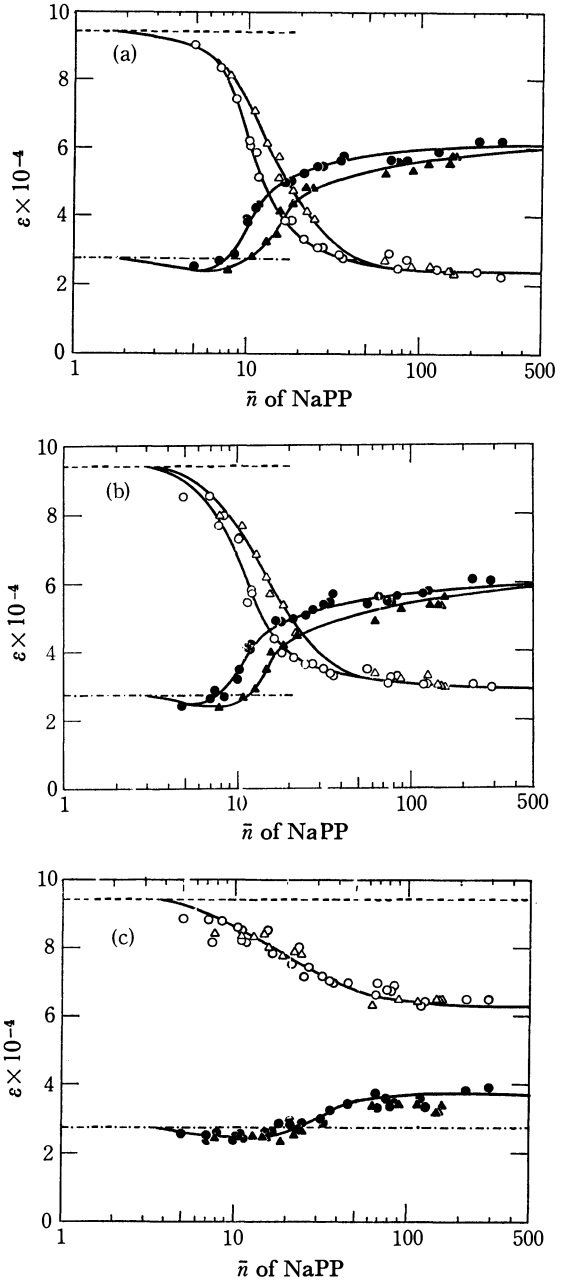

Fig. 4. The dependence of metachromasy on the chain lengths of fractionated and refractionated NaPP samples at (a) P/D=3, (b) P/D=30, and (c) P/D=300 in aqueous solutions.
In each figure, open symbols are the molar extinction coefficients of CV at 592 nm and filled ones are those at 506 nm. -○- and -●- for fractionated NaPP, and -△- and -▲- for refractionated NaPP.

tionation on the induction of metachromasy band are shown in Figs. 4a—4c, where the molar extinction coefficients of the NaPP–CV system are plotted against the chain length of both fractionated and refractionated NaPP samples on a logarithmic scale. The concentration of each NaPP sample is so chosen that the metachromasy is most distinctive (P/D=3), medium (P/D=30), or very weak (P/D=300). At P/D values of 3 and 30 the principal band at 592 nm decreases, while the metachromasy band at 506 nm increases, very sharply in a narrow range of the chain length 7—20. Both band intensities then level off, as $\bar{n}$ reaches about 100. The midpoints of these sigmoidal changes in ε_{506nm} and ε_{592nm} correspond to $\bar{n}=17$ and 14 (P/D=3), and $\bar{n}=18$ and 16 (P/D=30), respectively, for refractionated samples. The midpoint is slightly displaced to $\bar{n}=30$ and 20 at a P/D value of 300, which indicates that a longer chain length is required for metachromasy. In any case, it is evident that metachromasy is dependent on the polymer chain length and is critically associated with the oligomeric dimensions.

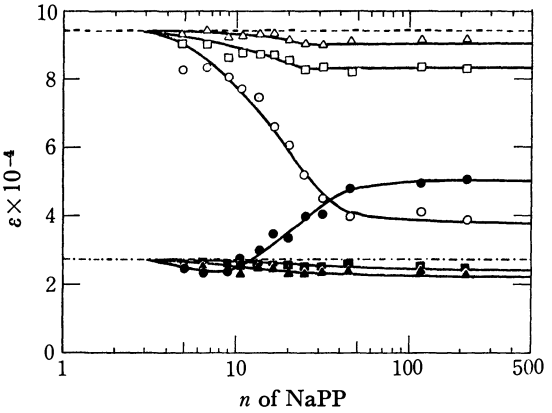

Fig. 5. The dependence of metachromasy on the chain lengths of NaPP at various P/D values and at fixed pH's.
Open symbols are the molar extinction coefficients of CV at 592 nm and filled ones are those at 506 nm. -○- and -●- for P/D=5 at pH=7.0, -□- and -■- for P/D=50 at pH=6.8, -△- and -▲- for P/D=500 at pH=6.5.

The pH value of NaPP in aqueous solutions varies slightly with the chain length at a given value of P/D and the polymer concentration at a given value of $\bar{n}$. An attempt was made to examine the effect of $\bar{n}$ on metachromasy at a constant pH using a sodium phosphate buffer five times more concentrated than NaPP (Fig. 5). As the data in Figs. 4a—4c and 5 indicate, the optical behavior is all the same except that the development of the metachromasy is somewhat suppressed in the buffered solution. This is, not a direct consequence of maintaining pH at a fixed value*,

* The slight variation of pH in the neutral region is due to the fact that the degree of ionization of end-groups of a polymer chain (other phosphate residues are all ionized in this pH region) depends on the chain length. For a given NaPP sample, the metachromasy is confirmed to be independent of pH between 5.5 and 9 for CV.

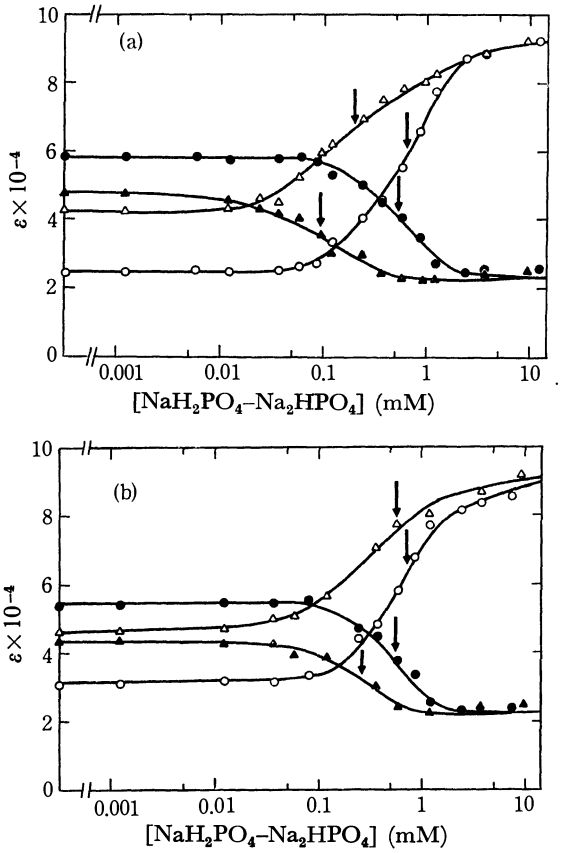

Fig. 6. The effect of small electrolytes on metachromasy at (a) P/D=3, and (b) P/D=30.
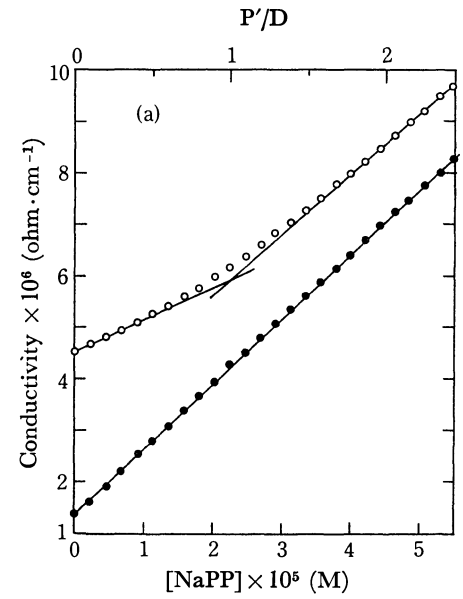
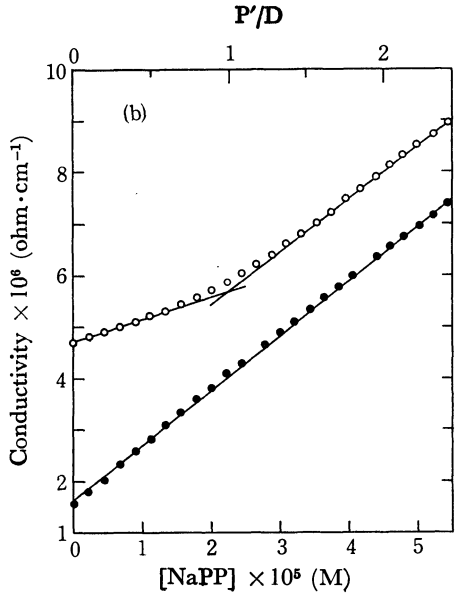
Open symbols in each figure are the molar extinction coefficients of CV at 592 nm and filled ones are those at 506 nm. -○- and -●- for NaPP with n=154, and -△- and -▲- for NaPP with n=24. Arrows indicate the mid-points of the changes in ε.

but due to the effect of the ionic strength of the buffering small ions on metachromasy (*vide infra*).

Effect of Addition of Small Electrolytes on Metachromasy. The effect of small ions on the absorption bands at 592 and 506 nm is shown for two NaPP samples ($\bar{n}$=154 and 24) at P/D values 3 and 30, respectively (Figs. 6a and 6b). At each P/D the effect of the concentration of the added small ion on metachromasy is insignificant up to about 1×10^{-5} M, a concentration comparable with that of CV. However, a further increase in the salt concentration gives rise to a gradual decrease in metachromasy. The absorptions at 592 and 506 nm become indistinguishable with those of pure CV at salt concentration higher than 10^{-2} M, up to which the pure CV spectrum is independent of the amount of added salts. The chain length effect on this process, which has been attributed to the competitive binding between CV^+ cations and Na^+ ions toward polymer sites,[1,19] reflects the prevailing relationship between molecular weight of polymer and metachromasy. The 506 and 592 nm sigmoidal curves for the higher $\bar{n}$ sample are clearly displaced to the right. More small ions are required to dissociate the bound dye. The arrows in Figs. 6a and 6b indicate the midpoints of either increasing or decreasing curves of molar extinction coefficients.

Conductometric Titration of CV with NaPP of Three Different Chain Lengths. In order to establish the relation between the binding of CV to polymer site and the chain length of NaPP, conductometric titrations of CV with representative NaPP samples were carried out. The results are shown in Figs. 7a—7c, where each corresponding blank titration is also plotted. In the absence of CV the conductivity of each NaPP sample increases with the increase of the concentration, although the slope depends on the chain length. In the presence of CV, however, the conductivity of the titrated solution increases in two steps on the dropwise addition of the NaPP titrant. A sharp break always appears at a P/D value of about unity (1.01, 1.01, and 1.02) for each NaPP sample ($\bar{n}$=11, 24, and 154) as shown by an intersection of two interpolated lines (Figs. 7a—7c). This indicates that, regardless of the chain length of NaPP, *i.e.*, either oligomeric or polymeric sample, CV binds to the NaPP site at most up to a one-to-one ratio at a total CV concentration of 2.26×10^{-5} M. After the P/D=1 break, a further addition of NaPP increases the conductivity of the NaPP–CV solution practically in parallel with the increase in conductivity of a pure NaPP solution.





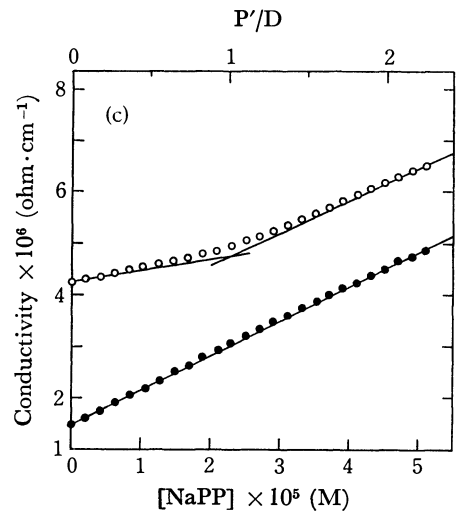


Fig. 7. Conductometric titration of CV with NaPP with various chain lengths (a) n=11, (b) n=24, and (c) n=154.
—●— for blank solution titrated with NaPP for comparison. The concentration of NaPP is corrected for volume increase. P′ is the concentration of the ionized group of the polymer and corrected as equal to $P(1+1/n)$ where P is the residue concentration. Other conditions are given in Experimental.

Discussion

Effects of Mixing Ratio and Polymer Chain Length on Metachromasy. The fact that an abrupt change in metachromasy of CV occurs in the presence of NaPP with chain lengths in the range 7—20 at P/D values of 3 and 30 (Figs. 4a—4b) should be taken as evidence that a certain degree of polymerization is required for a polyphosphate to show metachromasy in a dilute concentration range of 10^{-5} M. This finding newly confirms the previous incomplete reports[8,11,12] and definitely establishes the existence of a critical range of polymer chain lengths for metachromasy. It is not known at present why the polyelectrolyte should have a certain degree of polymerization to induce metachromasy, or why such a critical range should lie in the relatively short oligomeric dimensions. However, there can be no doubt that some action of water on the NaPP–CV complex is involved. The conformation of the complex in aqueous media can be strongly affected by factors such as dielectric constant, hydration and dissociation. Such effects may vary with the chain length of polymer—less pronounced in the case of higher molecular weight. Gekko reported a sudden change in the second virial coefficients of dextran oligomers in aqueous solutions.[23] He attributes the sharp break, which occurs at a degree of polymerization close to 12, to the conformational transition from uncoiling stretched-form for lower molecular weight to random-coil form for higher molecular weight

oligodextrans. Goodman *et al.* have also demonstrated that a critical range exists between $\bar{n}=7$ and 9 for γ-methyl-L-glutamate oligomers forming a helix in dimethylformamide.[24]

The effect of the refractionation of NaPP samples is apparent from Figs. 4a—4c. From the data which show that the sigmoidal curves of the samples are shifted toward the higher $\bar{n}$ relative to the fractionated ones, each refractionated sample should have a narrower molecular weight distribution. This is because the ability of inducing the metachromasy band is unproportionally high with the longer chain length components, which conceivably are included in larger proportions in once-fractionated oligomeric samples than in the twice-fractionated ones. We have studied competitive interactions between a higher ($\bar{n}=154$) and a lower ($\bar{n}=11$) molecular weight NaPP toward the binding of CV. The presence of the small amount (10%) of the higher NaPP in the mixture is sufficient to produce spectra identical with those of the higher NaPP–CV complex at several P/D values. The molecular weight distributions have thus been estimated to be reasonably narrow enough for establishing the critical range of the chain lengths.

Comparison of Optical Titrations with Conductometric Titrations. The optical titration curves in Fig. 3 can be divided into two parts; the region of P/D smaller than unity, where CV in solution is in excess of NaPP residues, and the rest of P/D, where the situation reverses. This option can be justified particularly for polyphosphates, since the only functional group is ionizable phosphates. The first region represents, at a fixed dye concentration (1.12×10^{-5} M), the state of equilibrium between free and bound dyes in solution. This is manifest when the pure CV spectrum is compared with any one of NaPP–CV spectra at very low P/D. They are essentially superimposable. The 592 and 506 nm band intensities are restored almost linearly with P/D between approximately unity and zero. An isosbestic point exists at 639 nm. Hence, it is unlikely that any strong interaction is involved between unbound and bound CV molecules.

With regard to the transition from the first to the second region, the present results (Fig. 3) corroborate the fact that not only the magnitude of metachromasy but also the break at a P/D value near unity depends on the chain lengths of oligomeric polyphosphates ($P/D=1.3$, 1.6, and 2.0 with the uncertainty of about $\pm20\%$ for $\bar{n}=154$, 24, and 11 in this order). The conductometric data (Figs. 6a—6c) show a sharp break at a P/D value of about unity for each NaPP sample. The break is almost independent of the chain length (P/D=1.01, 1.01, and 1.02 with the uncertainty of about $\pm5\%$ for $\bar{n}=11$, 24, and 154 in this order). The unexpected conductometric finding may be taken to be an indication that CV can bind to the phosphate residue of the polymer up to the 1 : 1 ratio at maximum, *i.e.*, the saturation of sites irrespective of the polymer chain length; thus a simple electrostatic binding between cationic CV moiety and anionic phosphate residue should not be the direct cause for the generation of metachromasy. If such an electric charge neutralization by the Coulombic force were sufficient to give rise to metachromasy, then the fact that the metachromasy is less developed for smaller NaPP samples could not be correctly explained without modifying the interpretation of the conductometric data.

Critical Views of the Origin of Metachromasy. As regards the restoration of the 592 nm band intensity observed at higher P/D portion of the second region where polymer sites are in large excess of dye, Bradley *et al.* proposed a mechanism in which metachromasy is generated as a result of the interaction between adjacent bound dyes on the sites of a polymer of infinite length.[3] As the number of the polymer sites becomes in great excess of dye molecules, the bound dyes are unstacked from the adjacent sites and tend to redistribute themselves on the sites and, consequently, they are separated from one another by some vacant sites on a single polymer. Or they are transferred to the isolated sites of other polymer molecules. Pal and Chaudhuri have considered the interaction between adjacent bound dyes to be of hydrophobic nature.[25] According to the original stacking theory, however, the magnitude of metachromasy induced by CV bound to NaPP should remain practically constant over a wide P/D range (particularly between 1 and 10) irrespective of the polymer chain length. This conclusion apparently contradicts the present experimental results.

We alternatively offer two possible but tentative views on the origin of metachromasy, recognizing in both the important role of solvent water molecules. The first view is a modified version of the stacking theory which associates metachromasy with the conformation, more specifically flexibility, of the polymer backbone to which dyes are bound. Since the high molecular weight NaPP is more flexible, the sparsely bound dyes may approach one another while being shielded from hydrophilic environments even in a relatively high P/D range. The forces are thus exerted between the approaching dyes sufficiently to induce metachromasy. Low molecular weight oligomers are too short to be flexible. Because of the stiffness of the short chain, the bound dyes can hardly be enclosed so that they are adjacent. When all the polymer sites are filled with dye molecules (P/D=1), the chain of either short or long polymer would have to be elongated stiffly rather than compactly coiled because of the geometric constraint of the dye-bound moiety. Therefore, the development of metachromasy is optimum in the P/D range 3—10 rather than near unity. One drawback is the difficulty of explaining the fact that the metachromasy band position at 506 nm remains independent of P/D values over almost the entire range while only its intensity varies, and that CV shows a metachromasy band with NaPP, but malachite green does not.[1]

The second view is the dye-site interaction theory which emphasizes the local and specific binding resulting from the dye-site interaction more than the general effect of gross polymer conformations and bound dye-bound dye interactions. The theory attaches primary importance to the following factors: the specific chemical

structure and symmetry of a dye, alteration of the electronic states of dye and site upon formation of a bond which is more than a pure Coulombic one, and the distortion of the bond by some steric perturbation which should increase as more dye molecules are bound in a given crowded area (the lower P/D region). When the bonding between dye and site is purely electrostatic with little orbital overlapping and unsheathing of hydrated water, no metachromasy band should be expected (higher P/D region). In this case, the overall electronic structures of the excited and ground states of the bonding site probably closely resemble those of the pure CV in organic solvents. The second theory does not exclude contributions, to metachromasy, of the flexibility of the polymer chain, which should increase the steric constraints on the bound dye as the chain length increases (high $\bar{n}$ samples), and of the bound dye-bound dye interaction which is probably affected by the conjugated π-electron system of triphenylmethane skeleton. These factors are not to be sufficient for elucidating metachromasy; thus, the first view may be considered to be supplementary to the second.

Closing Remarks. The primary importance should be the class and functional substituent of triphenylmethane dyes for metachromatic behavior. While malachite green with a C_{2v} symmetry, which is short of a substituted amino group as compared with CV, behaves very similarly in the presence of NaPP but shows no metachromasy band under the closely related conditions, ethyl violet and parafuchsin, both of which are homologs of CV with a point symmetry of D_{3h}, show the metachromasy band. In this connection, systematic work relating the development of metachromasy to the chemical structures of triphenylmethane and acridine dyes is highly desirable.[6]

Dielectric Relaxation and Molecular Structure. IX. Dielectric Behavior of 1-Propanol and 1-Butanol in a Variety of Solvents

Taro KOSHII, Eiji ARIE,* Masahiko NAKAMURA, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, Waseda University, Shinjuku, Tokyo 160

(Received November 22, 1973)

The dielectric constants and losses of 1-propanol and its mixtures with benzene, chlorobenzene, 1,4-dioxane or pyridine, and 1-butanol and its mixtures with benzene or pyridine have been measured in the frequency range of 0.35—2.1 GHz at 25.0 °C. Concentrations of alcohols are 1—0.6 mol fraction of the mixtures. Densities and refractive indices have also been determined. The dielectric data were used to calculate the relaxation times of the alcohols. The Cole-Cole plots for these systems showed Debye-type semicircles in lower frequencies where the principal relaxation of alcohols dominates. Deviations from the semicircle, however, have been observed in the region of upper frequencies, where the second dispersion of alcohol, the dispersion of solvent itself and of hydrogen-bonded species between alcohol and solvent may occur. The principal relaxation times of alcohols calculated from the data of lower frequencies change with concentration in two different manners by solvents, and this difference is due to whether the solvent has hydrogen-bonding capacity or not, and does not depend upon the dielectric constant and/or the polarity of the solvent.

Since Mizushima published his measurements on a number of liquid alcohols in 1926,[1] the monoalcohols have been considered to provide an example with which the Debye dispersion of polar molecules occurs in the liquid state. Later, Smyth *et al.*[2] studied ten normal alcohols from propyl through dodecyl in a wide frequency range up to 150 GHz, and established that the dielectric dispersion of primary aliphatic alcohols in the liquid state is characterized by three relaxation regions the most important (the principal relaxation) being at the lower frequency region, and that the principal relaxation cannot be accounted for as arising from rotation of single alcohol molecules. Although a number of dielectric investigations have been made on alcohols since, the precise mechanism of the principal relaxation is still unknown.

In this report the dielectric behavior of normal alcohols has been investigated in the frequency range in which the principal relaxation occurs. Several solvents having different properties in the dielectric constant, the dipole moment and the hydrogen-bonding capacity were added to alcohols and the effect of this addition on the principal relaxation was examined.

Experimental

Materials. All the samples were of the best grade available from commercial sources. They were dehydrated by the usual methods and fractionally distilled prior to their use. The observed refractive indices at 25.0 °C: 1-propanol $n_D=1.3830$, 1-butanol $n_D=1.3968$ are in agreement with the literature values[3].

Apparatus. The apparatus (UHF Material Characteristics Test Assembly) is a coaxial-slotted line type, manufactured by Rohde and Schwarz Co. Ltd., (München, Germany). The principle of the measurement is the standing-wave method, that is, if there is any attenuation in the dielectrics there will be a reduction in the voltage standing-wave ratio (E_{max}/E_{min}), since all the incident wave intensity would not be reflected. A water-jacket surrounding the cell allows for the temperature control of samples within 0.05 °C during a run.

Densities were determined with a Lipkin type pycnometer calibrated with pure water. Refractive indices for sodium D line were measured with a Pulfrich type refractometer.

Evaluation of data. Dielectric constants and losses were calculated as follows. The measured value of the standing-wave ratio E_{max}/E_{min} is mathematically related to the propagation constant γ of the wave along the coaxial line within the sample in the following equation.

$$\frac{\tanh \gamma d}{\gamma d} = -j\left(\frac{\lambda}{2\pi d}\right)\frac{\frac{E_{min}}{E_{max}} - j\tan\left(\frac{2\pi x}{\lambda}\right)}{1 - j\frac{E_{min}}{E_{max}}\tan\left(\frac{2\pi x}{\lambda}\right)} \quad (1)$$

where x is the distance from the first electric field strength minimum of the standing-wave to the surface of the sample, d the specimen length and λ the wavelength along the coaxial line outside the sample. A graphical solution of Eq. (1) has been given by von Hippel[4] in the charts of the following equation.

$$Ce^{j\zeta} = \frac{\tanh Te^{j\delta}}{Te^{j\delta}} \quad (2)$$

where $T\exp(j\delta)$ is the polar form of γd and $C\exp(j\zeta)$ is the polar form of the right hand side of Eq. (1). The charts given in Ref. 4 are limited in range. A computer solution of Eq. (2) was used in order to extend the range. Then the dielectric constant and loss factor are calculated by the following equation.

$$\varepsilon' - j\varepsilon'' = -\left(\frac{\lambda}{2\pi d}\right)^2(\gamma d)^2 \quad (3)$$

When the value of E_{min}/E_{max} is large enough (more than 0.7), it can be measured directly. If the value is small, the distance between the points of twice minimum power Δl is measurable and it connects with E_{max}/E_{min} as follows.

$$\frac{E_{max}}{E_{min}} = \frac{\sqrt{2-\cos^2\left(\frac{\pi\Delta l}{\lambda}\right)}}{\sin\left(\frac{\pi\Delta l}{\lambda}\right)} \quad (4)$$

If the dielectric constant of the sample is approximately

* Present address: Mitsubishi Monsanto Chemical Company, Iwatsuka, Nakamura, Nagoya 453.

known, the optimum length d is given by the condition that d should be at least a quarter wavelength in the material[5], that is,

$$d = \frac{\lambda}{4\sqrt{\varepsilon'}} \tag{5}$$

To determine the relaxation time τ, the distribution parameter α and the high-frequency dielectric constant ε_∞, the Cole-Cole equation[6]

$$\varepsilon' - j\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + (j\omega\tau)^{1-\alpha}} \tag{6}$$

was fitted to the data by an iterative method using an electronic computer.

Results and Discussion

The dielectric constants and losses of alcohols and their mixtures obtained in this experiments are recorded in Table 1. Dielectric spectra for 1-propanol–benzene and 1-butanol–pyridine mixtures are shown in Fig. 1. (See also Fig. 1 of the preceding letter[7] regarding those for 1-propanol–pyridine mixtures.) It is found for all the mixtures that with increasing amount of solvent the intensity of the maximum absorption decreases and the critical frequency shifts to the higher frequency side. The shift of the frequency is more pronounced in the 1,4-dioxane and in the pyridine mixtures than those in the benzene and in the chlorobenzene mixtures.

The high frequency intercepts of the Cole-Cole plots (ε_∞) for pure alcohols are always much larger than the square of refractive indices for sodium D line (Table 2). It suggests that the second and the third dispersions of alcohols exist in higher frequency range. Values of ε_∞ for the pyridine and chlorobenzene mixtures increase with increasing concentration of solvent, (see *e.g.* Fig. 2-a), while those of ε_∞ for the 1,4-dioxane and benzene mixtures do not change with an increase in the concentration, (see *e.g.* Fig. 2-b). The above difference is due to whether the dispersion of polar solvent contributes to this effect or not. Deviation from the Debye-type semicircle was observed in the frequency range higher than 1 GHz for pure alcohols. For pyridine mixtures the deviation in higher frequency range increases with increasing amount of solvent, while such is not observed for benzene mixtures as in Fig. 2-a and 2-b. The above trend is an indication for the existence of the dispersions of polar solvent, of interaction species between solute and solvent, of second dispersion of the alcohol, *etc.*

Using Eq. (6) the distribution parameter α of the Cole-Cole plot and the relaxation time τ were evaluated

the Debye dispersions observed in the frequency range lower than 1 GHz are of the principal relaxation.** The values of principal relaxation times of normal alcohols are thus determined from (1) and compared with those of the literature in Table 2.

The principal relaxation times of 1-propanol and 1-butanol against the molarity of the alcohols are plotted in Fig. 3. With increasing alcohol molarity, τ increases; in other words, decrease in τ is accompanied with decrease in the molarity, *i.e.*, with increasing amount of solvent added. It will be seen that this decrease in τ is more pronounced when hydrogen-bonding solvent, pyridine or 1,4-dioxane, is added to 1-propanol. And the plots of τ *vs.* molarity fall into the same curve A for these two solvents inspite of the fact that pyridine has a large dipole moment 2.25 D and high dielectric constant (ε=12.3)*** and 1,4-dioxane

▲: Pyridine, □: Pure alcohol

is non-polar and has a low dielectric constant (ε=2.21). In sharp contrast to this, the same plots for the addition of two non-hydrogen-bonding solvents, benzene or chlorobenzene, give the identical curve B in which the degree of decrease in τ is much smaller with decreasing molarity. Again the dipole moments μ and the dielectric constants ε differ greatly in benzene (μ=0.0 D, ε=2.27) and in chlorobenzene (μ=1.70 D, ε=5.62).

The principal relaxation time of 1-butanol is studied with addition of hydrogen-bonding pyridine and non-hydrogen-bonding benzene. Again the decrease in τ is more pronounced in pyridine mixtures (curve A) than benzene mixtures (curve B).

The dependence of relaxation time upon the concentration in highly concentrated mixture of alcohols has been reported by Sarojini[9)] and Hanna *et al.*[10)] Both of these authors observed that the relaxation time did not change monotonously with the concentration. A minimum in τ was observed in 1-propanol mixture with pyridine,[9)] while a maximum was detected in 1-butanol mixture with carbon tetrachloride and with other viscous non-polar solvents.[10)] These results are inconsistent with ours. Perhaps their choice of the frequency range was inadequate for determining the pure principal relaxation, that is, they failed in eliminating the effects from other dispersions.

We wish to present our sincere thanks to Professor Mansel Davies of University College of Wales for his helpful suggestions and also correcting English in the manuscript. We also thank Toray Science Foundation for the financial aids.

** Errors due to the losses of polar solvents, *viz.* pyridine and chlorobenzne, were estimated and the relaxation times with this correction were found to be almost identical with those calculated without the correction. The relaxation times reported in the preceding letter[7)] were those of calculated from the method (2). New relaxation times calculated by use of the Debye equation (α=0) are employed in the present paper.

*** The dielectric constants cited here are those at 25.0 °C.

Dielectric Relaxation and Molecular Structure. X. Dielectric Behavior of 2-Propanol, 2-Methylpropanol, and 2-Butanol in a Variety of Solvents

Taro KOSHII, Eiji ARIE,* Masahiko NAKAMURA, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, Waseda University, Shinjuku, Tokyo 160

(Received November 22, 1973)

The dielectric constants and losses of 2-propanol and its mixtures with benzene, chlorobenzene, 1,4-dioxane or pyridine and 2-methylpropanol or 2-butanol and their mixtures with benzene or pyridine have been measured in the frequency range of 0.35—2.1 GHz at 25.0 °C. Concentrations of alcohols are 1—0.6 mol fractions of the mixtures. The principal relaxation times and the Kirkwood correlation factor g were evaluated. Variation of the principal relaxation times against the concentrations of these branched alcohol mixtures is not much different from that of normal alcohol mixtures. The g factor decreases almost monotonously with increasing amount of solvent exception being found in case for propanol–benzene mixtures.

Smyth *et al.*[1] have made dielectric measurements on several isomeric octanols in non-polar solvent (*n*-heptane). For those isomers in which a methyl group is attached to the same carbon atom as the hydroxyl group or to the adjacent carbon, the dielectric absorption is characterized by two relaxation times and the principal relaxation does not appear at the concentrations employed. However, the isomers containing a relatively less shielded hydroxyl group exhibit an additional low-frequency relaxation at the higher alcohol concentrations. Crossley *et al.*[2] have made dielectric investigation on several isomeric butanols with various solvents in a wide concentration range. He found that the basicity of the solvent plays an important role in determining the extent of self association of alcohol, that is, cyclohexane was regarded as an inert solvent and the other three solvents had a disassociating effect which increases in the order of *p*-xylene$\leq$mesitylene$<$1,4-dioxane.

We have made dielectric measurements on branched-alcohol mixtures with solvents having various properties such as different dipole moments, dielectric constants or hydrogen-bonding capacities. The side chain of those alcohols is expected to have an effect on the relaxation mechanism. The relaxation time observed in our frequency range was the principal (long) relaxation time and its variation with the concentration of solvents was examined.

Experimental

The purification of the samples has been given in the previous paper[3]. The observed refractive indices: 2-propanol n_D=1.3750, 2-methylpropanol n_D=1.3932, 2-butanol n_D=1.3945 at 25.0 °C are in agreement with the literature values[4]. The dielectric constants and losses were measured by use of the method previously described[3]. Viscosities were measured with an Ostwald type viscometer.

The Kirkwood correlation factor g is represented in the following equation[5].

$$g = \frac{9kT(\varepsilon_0-\varepsilon_\infty)(2\varepsilon_0+\varepsilon_\infty)}{4\pi N\varepsilon_0(\varepsilon_\infty+2)^2\mu_0^2} \quad (1)$$

where μ_0 is the dipole moment of the molecule, N the number of molecules per unit of volume, k the Boltzmann constant and T the absolute temperature. ε_0 and ε_∞ are the static and the high frequency dielectric constants, respectively. We used the values of ε_0 and ε_∞ obtained from the low and the high frequency intercepts of the Debye-type semicircle, respectively and μ_0 from the values in the gaseous state.[6] The values of ε_0 obtained above are compared with those measured at the frequency of 10 kHz; both are generally in good agreement.

Results and Discussion

The measurements in dielectric constants and losses are recorded in Table 1. The dispersion and absorption curves of branched-alcohol mixtures are similar to those observed in normal-alcohol mixtures. (See Fig. 1 of Ref. 3).

The principal relaxation times were calculated by the method previously employed[3] and are plotted against the concentration in Fig. 1. The trend similar to normal-alcohol mixtures is observed, that is, the plots can be grouped into two groups (curves A and B). The relaxation times of 2-propanol depend very little upon the polarity of the solvent; the dipole moments of pyridine, chlorobenzene, 1,4-dioxane, and benzene are 2.25, 1.70, 0.4, and 0.0 D in gaseous state, respectively. They are also independent of the dielectric constant (ε for pyridine, chlorobenzene, 1,4-dioxane, and benzene are 12.3, 5.62, 2.21, and 2.27 at 25 °C, respectively) and depend only upon the hydrogen-bonding capacity. These facts strongly suggest that the principal relaxation times of the alcohol may be mainly dominated by hydrogen bonding of alcohol molecules.

A similar study on the relaxation times for 2-butanol dioxane mixture was reported by Sakellaridis and Hinopoulos.[7] Their relaxation times are, however, much lower than those of our experiment: possibly it may come from their measurement at the single frequency of 9.3 GHz.

The separation between curves A and B is not the same for all the alcohols. This separation is more pronounced in 1-propanol** than in 2-propanol, while

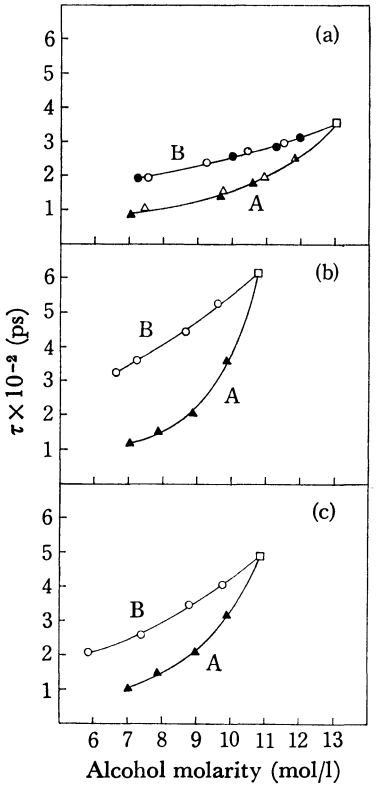

Fig. 1. Relaxation time τ *vs.* concentration for (a) 2-propanol, (b) 2-methylpropanol and (c) 2-butanol mixtures with solvent.
Solvent:
○: Benzene, ●: Chlorobenzene, △: *p*-Dioxane,
▲: Pyridine, □: Pure alcohol

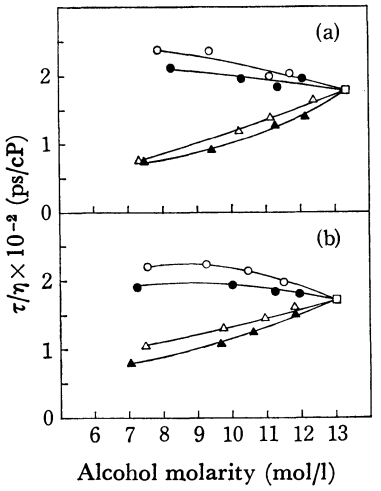

Fig. 2. Reduced relaxation time τ/η *vs.* concentration for (a) 1-propanol and (b) 2-propanol mixtures with solvent. Same notations as in Fig. 1.

for 1-butanol** and 2-methyl propanol it is similar to each other, being much diminished in 2-Butanol Thus, the relaxation process of normal alcohols is more strongly effected by hydrogen-bonding capacity of solvents than that of *iso* and *secondary* alcohols in which hydrogen bonding of the hydroxyl group is hindered by the screening effect of side chains.

The reduced relaxation time τ/η in which τ is the relaxation time and η is the viscosity of the mixture is considered. Plots of τ/η against the molarity are shown in Fig. 2. We find four curves in Fig. 2 instead of two curves A and B in Fig. 1. Again in the pyridine and 1,4-dioxane mixtures the decrease in τ/η, which represents the volume of rotating units in the Stokes assumption, is sharper with increasing amount of solvent than that in the benzene and chlorobenzene mixtures.

Figure 3 shows the Kirkwood correlation factor g against the concentration of mixture. The values of g were calculated by means of Eq. (1). A large value of g, a parameter for the self association, is found in the pure liquid alcohols, and the value of g decreases with increasing amount of solvent (see Fig. 3). At infinite dilution, or, for free molecules g is equal to unity.[2] Small g values less than the unity found *e.g.*, in pyridine mixtures, might reveal the formation of multimers having smaller dipole moments than the free monomer. Further, if the g factor represents the short-range interaction of molecules, the observed decrease in g would suggest that the degree of this interaction decreases in dilution. It will be seen that the decrease is sharpest in case of the mixture with hydrogen-bonding pyridine (ε=12.3, μ=2.25 D) and followed by

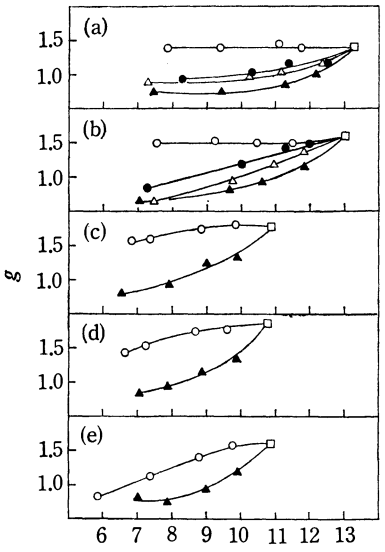

Fig. 3. Kirkwood correlation factor g *vs.* concentration for (a) 1-propanol, (b) 2-propanol, (c) 1-butanol, (d) 2-methylpropanol and (e) 2-butanol mixtures with solvent. Same notations as in Fig. 1.

another hydrogen-bonding 1,4-dioxane (ε=2.21, μ=0.4 D), non-hydrogen-bonding chlorobenzene (ε=5.62, μ=1.7 D) and benzene (ε=2.27, μ=0.0 D). This order of decrease in g agrees with that in reduced relaxation time in Fig. 2. This would suggest that the multimer is associated with the volume of rotating unit. The fact that g is almost independent of the concentration in propanol–mixtures with benzene would indicate that the interaction between alcohol and solvent molecule does not change with dilution.

We wish to present our sincere thanks to Professor Mansel Davies of University College of Wales for his helpful suggestions and also for correcting English in the manuscript. We also thank Toray Science Foundation for the financial aids.

Vibrational Structures in the He(I) Photoelectron Spectra of Carboxylic Acids

Iwao WATANABE, Yu YOKOYAMA, and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received August 17, 1973)

The first and the second bands of the photoelectron spectra of acetic, propionic, and isobutyric acids were recorded, and the vibrational structures in the spectra were studied by comparing with the results of formic acid. The first band exhibits a $\nu_{C=O}$, a δ_{OH}, and a ρ_{COOH} vibrational progression, and this implies that an oxygen lone pair orbital, from which the first band of the spectra originates, contributes not only to a C=O bonding and the bonding between carbonyl oxygen and hydroxyl hydrogen, but to the settling of carboxyl group in the molecular plane. The second band exhibits a $\nu_{C=O}$, a ν_{C-O}, and a δ_{OCO} vibrational progression with very high frequency for the $\nu_{C=O}$ as observed in the case of formic acid. Thus the vibrational features of the second band are consistent with the ionization of an antisymmetric π orbital localized mainly on carbonyl and hydroxyl oxygen atoms. Since the 0-0 vibrational transitions for the second ionization are out of the Franck-Condon region, the second adiabatic ionization potential was estimated by comparing the vibrational fine structures of the spectra with that of formic acid. The second adiabatic ionization potential of acetic acid so determined is 11.63 eV.

It is predicted from theoretical calculations that the most easily ionized orbitals, from which the first and the second bands of photoelectron spectra of aliphatic carboxylic acids originate, are an oxygen lone pair (n_o) and an antisymmetric π (π_2) orbital.[1-3] It is reasonable to expect that these bands have quite similar appearances among these molecules, since the calculations predict that the n_o orbital is localized mainly on a carbonyl oxygen and the π_2 on carbonyl and hydroxyl oxygens. In other words, if some features in the photoelectron bands are found which are common in all carboxylic acids, they must be the features intrinsic to the carboxyl group.

In the previous report,[3] the vibrational structures in the spectra of formic acid and its deuterium derivatives have been studied in detail, and the most interesting phenomenon found in the spectra of formic acid is the extraordinarily strengthened C=O bond by the ionization of the π_2 orbital. If the n_o and the π_2 orbitals are really the intrinsic orbitals localized on the carboxyl group, similar vibrational structures to those of formic acid should be revealed in the spectra of acetic acid and/or higher carboxylic acids, too.

The only vibrational structures reported in the spectrum of acetic acid are a $\nu_{C=O}$ (C=O stretching vibration) mode in the first band, and a 1050 cm^{-1} mode unassigned in the second.[4,5] Any other vibrational structures in the second or deeper bands for acetic or higher carboxylic acids have not been reported.

This paper deals with the first and the second bands of improved resolution spectra of acetic, propionic, and isobutyric acids together with the comparison of their fine structures with those of formic acid to find intrinsic features in the photoelectron spectra of carboxylic acids.

Experimental

The photoelectron spectra were measured with an apparatus already reported[6] and a modified helium resonance lamp. The new lamp has a shorter collimating capillary of wider inner diameter and two hollow electrodes aligned in the optical axis of the lamp. The modification increased the intensity of the exciting light (He(I) 584 Å), and better performance was attained.

All samples were of G. R. grade and used without any further purification. Variations of appearance potentials of photoelectron peaks for carboxylic acids during measurements were so large that preliminary mixing of reference gas, xenon, into the sample gas was essentially needed to measure the ionization potentials accurately. Usually the spectra were measured after running of sample gas more than 30 minutes, since shift of the kinetic energy of photoelectron to lower energy side with the elapse of time was always noticed. The measurements were repeated many times for more than five hours until it was confirmed that the differences between consecutive runs were not detected.

The point which an attention should be paid to is the dependence of the resolving power of this apparatus on the sample pressure. The spectra of acetic acid at high and low pressures have very different appearances. The spectrum at low sample pressure has adequate signal intensity and very similar appearance to the expanded spectrum reported by Sweigart *et al.*[4] On the other hand, the high pressure spectrum has sharper bands with finer vibrational structures. To study whether the association of sample molecules or the change of sample density in an ionization chamber gives rise to the phenomenon, the sample gas was mixed with xenon gas and the spectra of the sample were measured with varying the xenon gas pressure while the partial pressure of the sample gas remained constant. It was found that by introducing the xenon in relatively high pressure the spectrum features resemble those of the high pressure spectrum, and that the resolving power strongly depends on the gas density in the ionization chamber. The similar phenomena have been noticed in the cases of other molecules. The factors influencing the variation of the electron kinetic energy[6] can cause the broadening of the photoelectron peaks. It was found that the degree of the photoelectron spectrum degradation by the broadening depends on the character of the sample gas, the gas density in the ionization chamber, and the history of the apparatus, that is, the sample flowed just before the measurement, the period of the apparatus left at rest in vacuum or in air, and so on.

Results and Discussion

The First Bands. The expanded spectra of the first band of acetic, propionic, and isobutyric acids are

shown in Figs. 1, 2, and 3, respectively, and their vibrational frequencies are summarized in Table 1. The spectra of other aliphatic carboxylic acids do not exhibit clear vibrational structures and are not shown.

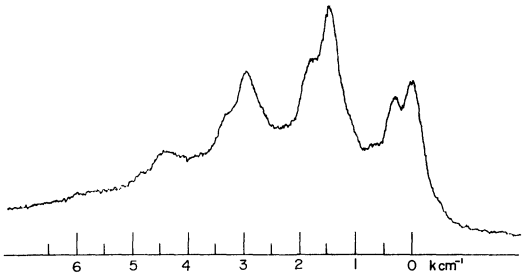

Fig. 1. The first band of the photoelectron spectrum of acetic acid.

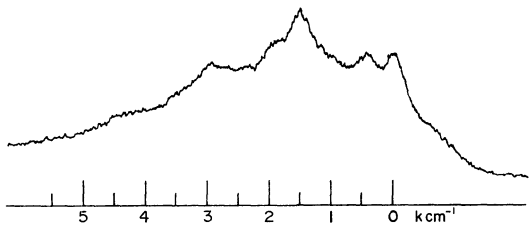

Fig. 2. The first band of the photoelectron spectrum of propionic acid.

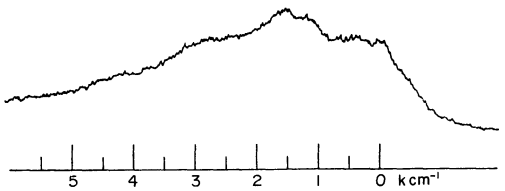

Fig. 3. The first band of the photoelectron spectrum of isobutyric acid.

For comparison the fundamental vibrational frequencies of the ground molecular state of acetic acid are taken from the work by Berney *et al.*,[7] which utilized an inert-gas matrix method and are included in Table 1. The usual gas phase IR spectra of the monomers of carboxylic acids have been measured at a high temperature, 150 °C, to decrease dimer equilibrium ratio and thus the appearance of their IR spectra becomes broad and complex. The matrix-isolation technique at temperatures near 4 K sharpens the absorption peaks, removes hot bands, and allows an accurate determination of the band origins.

Obviously the first ionization is accompanied by the excitation of not only a $\nu_{C=O}$ mode but some other vibrational modes in all carboxylic acids. The main spacings (*ca.* 1500 cm^{-1}) of the $\nu_{C=O}$ present in all molecules almost agree with that of formic acid (1486 cm^{-1}).[3]

The frequencies for the next strongest vibrational progression are 310, 420, and 360 cm^{-1} in acetic, propionic, and isobutyric acid, respectively. This structure has not been reported yet. It is difficult to find a fundamental mode of acetic acid corresponding to such a low vibrational frequency and thus the two possibilities are considered to interpret this low frequency component by attributing to one of the vibrational frequencies of dimer molecule. (1) The photoelectron spectra of dimers of carboxylic acids have the same profiles as those of monomers with the ionization potential blue shifted by *ca.* 38 meV (~300 cm^{-1}). The orbital energies, obtained from the *ab initio* MO calculations performed by Ady *et al.*,[8] of the highest occupied σ orbital of monomer and dimer molecule of formic acid are −0.4510 and −0.4526 (in atomic units) and the difference is about the same as the observed ionization potential shift. (2) The adiabatic ionization potentials of monomers and dimers are almost or just the same and thus the peaks separated

a) From C. V. Berney, R. L. Redington, and K. C. Lin, Ref. 7.

from the main progression by 300—400 cm^{-1} correspond to the vibrational components of dimer ions.

Although low frequency modes are easily found in the IR or Raman spectra of dimers,[9-11] both explanations mentioned above are based on the assumption of very near or almost equal ionization potentials for monomer and dimer molecules and this is unlikely if the photoelectron experiment of carboxylic acid dimers performed by Thomas[5] is considered. His spectra for dimers are very broad and structureless and he has concluded that the ionization potentials of dimers are 0.2—0.3 eV lower than those of the corresponding monomers. The peaks observed in the present spectra should have been broadened if the peaks were attributed to the dimers, because of many low frequency hydrogen bond vibrations of dimer ions and the thermal population of the low frequency vibrational states of the dimer molecules.

Therefore above-mentioned two models are discarded and the low frequency mode is more likely to be attributed to the monomer ions. The present experiments in which the pressure of ionization chamber was changed by introducing inert gas strongly support that the spectra obtained are from monomers.

This low frequency structure is not observed in the spectrum of formic acid, and then should originate from the vibration accompanying the geometrical alteration of methyl group. With regard to a ν_{17} (γCOOH wagging) or a ν_{18} (τ_{CH_3}, CH_3 torsion) among the modes in an a'' block their doubled frequencies are too high or too low[12] compared with 310 cm^{-1} and it is unlikely that the vibrational mode of a'' symmetry is so strongly excited by the ionization of the n_o orbital.

It is concluded, therefore, that the most reasonable assignment is a ν_{12} (ρ gear, COOH rocking or CCO angle deformation). Other modes in an a' block are thought to arise from vibrations involving more rigid bonds and are too high frequencies. This ν_{12} mode excitation in acetic acid could be considered to be an evidence supporting the assignments that the first band of formic acid exhibits not only a δ_{OH} but a δ_{CH} vibrational component.[3]

Another structure observed in all spectra of the three carboxylic acids is *ca.* 1100 cm^{-1} vibration and this mode could be assigned as a δ_{OH} by analogy with the case of formic acid.[3] The peaks appear weakly as shoulders on the slopes of the $\nu_{C=O}$ progression in formic and acetic acid, and are separated from the peaks of the $\nu_{C=O}$ progression by the deuterium substitution of hydroxyl hydrogen in the formic acid molecule.

The remaining vibration unassigned, 700—900 cm^{-1}, could be attributed either to a ν_{CC}, a ρ_{CH_3} (CH_3 rocking), or a ν_{C-O}.

A broad band in Figs. 2 or 3 at the lower ionization potential region than a 0-0 peak might be attributed to the ionization of corresponding dimer, since the appearance is quite similar to that of the mixture of monomer and dimer molecules reported by Thomas.[5]

The Second Bands. The appearances of the second band spectra of acetic, propionic, and isobutyric acids are quite different from that of formic acid, but the three spectra resemble each other. At least six vibrational peaks are clearly distinguishable in the spectrum of acetic acid. The vibrational analysis assuming the first or the second peak as arising from an adiabatic ionization process have not led to any reasonable vibrational assignments.

Then, for the identification of the position of the 0-0 peak, namely, the adiabatic ionization potential, the second band spectrum of acetic acid has been superimposed on that of formic acid and the best fit obtained is shown in Fig. 4, together with the bands of propionic and isobutyric acids. It is shown in Fig. 4 that the vibrational fine structures in the spectra of the three acids are quite the same as that of formic acid, and that the 0-0 transition for acetic and higher carboxylic acids is out of the Franck-Condon region.

The adiabatic ionization potential of the second band of acetic acid so determined is 11.63 eV and is included in Table 2 with other ionization potentials determined by the same procedures.

The vibrational assignments are summarized in Table 3. The frequencies measured in practice are the peak separations from the postulated 0-0 peak and therefore the small differences of the frequencies of formic acid

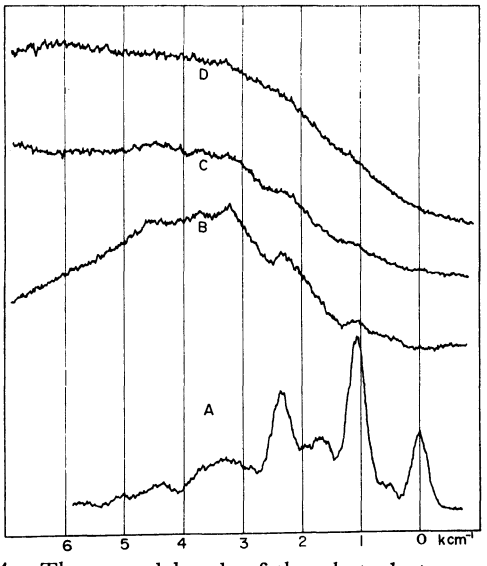

Fig. 4. The second bands of the photoelectron spectra of A; formic acid, B; acetic acid, C; propionic acid, and D; isobutyric acid.

Table 2. Ionization potentials for n_o and π_2 orbitals of some carboxylic acids (eV)

		Acetic	Propionic	Isobutyric

	Vertical	12.02 ±0.01	11.91	12.80

TABLE 3. VIBRATIONAL FREQUENCIES IN THE SECOND BAND OF ACETIC ACID SPECTRUM (cm^{-1})

Frequencies from 0—0 peak (postulated)	Assignments
510	δ_{OCO}
1050	ν_{C-O}
2320	$\nu_{C=O}$
3260	$\nu_{C-O}+\nu_{C=O}$ (3370)
3760	$\nu_{C-O}+\nu_{C=O}+\delta_{OCO}$ (3770)
4500	$2\nu_{C=O}$ (4640)

from those of acetic or other carboxylic acids do not have any significance.

The spectra in Fig. 4 become broad and structureless as the substituted alkyl group becomes larger, but still the band structures seem to correspond well to those of formic acid.

Thus the vibrational modes appearing in the second band for the molecules from formic to isobutyric acid are a $\nu_{C=O}$, a ν_{C-O}, and a δ_{OCO}, and are all fundamental modes intrinsic to the main framework of carboxyl group.

Conclusion

The technique of photoelectron spectroscopy provides the information about the structures of various ions produced by the ionization of one of the electrons in the corresponding molecule. This capability of the technique could be described in other way that the technique is able to give the information how each electron plays a role in the molecule.

From the study of the photoelectron spectra it is concluded that the n_0 and the π_2 orbitals have a number of inherent properties common to all the carboxylic acids studied.

1. The photoelectron spectra of carboxylic acids have a characteristic band, n_0, of carboxyl group corresponding to the first ionization and the n_0 orbital is so separated in energy from other deeper orbitals that the corresponding photoelectron band always appears as a strong isolated band overlapped by no other bands and easily identified from the spectrum. Such bands exhibiting vibrational structures as those originating either from the n_0 or π_2 orbital for carboxylic acids can be directly assigned without the aid of theoretical calculations.

2. The photoelectron peak corresponding to an adiabatic ionization from the n_0 orbital is always detected and this fact implies that the n_0 orbital is almost of "non-bonding" character; the ionization from the n_0 orbital does not alter the geometry of the molecule greatly.

3. The n_0 orbital is strongly localized on the carbonyl oxygen atom. The loss of an electron from this orbital excites a $\nu_{C=O}$ vibration and weakens the C=O bond slightly. The orbital also contributes to bonding of hydroxyl hydrogen to carbonyl oxygen. It is further conceived that the orbital plays an important role in settling the carboxyl group in a molecular plane as it is, since the ionization of the n_0 orbital is accompanied by the excitation of a δ_{CH} mode in formic acid and a ρ_{COOH} mode in acetic and higher carboxylic acids.

4. The second band of carboxylic acids is verified to originate from the π_2 ionization by inspecting vibrational structures. It is found from a study of formic acid and its deuterium derivatives, that the second band has an unexpected feature, *i.e.*, the extraordinarily high frequency for the $\nu_{C=O}$ mode of the ion, and it is the case for other higher carboxylic acids, also.

Thus it is concluded that the characteristic properties of the π_2 orbital are the anti-bonding character with regard to the C=O bond, and that the π_2 orbital contributes to settling the geometrical structure of carboxyl group, since the ionization of the π_2 orbital excites only the $\nu_{C=O}$, a ν_{C-O}, and a δ_{OCO} modes which are all intrinsic vibrational modes within the carboxyl group.

5. The lack of a 0-0 peak for the second band of acetic and higher carboxylic acids corresponding to the π_2 ionization implies that the equilibrium geometry of the corresponding ions is out of the Franck-Condon region and that the ions considerably change in geometry from the neutral molecules.

12) However, there is a possibility that the ν_{18} mode has a frequency of about a half of 310 cm^{-1}, since the frequency of 93 cm^{-1} for the ν_{18} of acetic acid has not been experimentally determined but is a theoretically predicted value. See Ref. 7.

Molecular Structure of *N*-Methylformamide as Studied by Gas Electron Diffraction

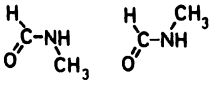
Mitsuo KITANO and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 6, 1973)

The bond distances (r_g) and angles (r_α) in *N*-methylformamide $HCONHCH_3$ have been determined by gas electron diffraction as follows: N–C(methyl) = 1.459±0.006 Å, C(carbonyl)–N = 1.366±0.008 Å, C=O = 1.219±0.005 Å, C–H(methyl) = 1.114±0.025 Å, ∠N–C=O = 124.6±0.5° and ∠C–N–C = 121.4±0.9°, where uncertainties represent estimated limits of experimental error. Systematic trends are observed among the skeletal structures of formamide, acetamide, *N*-methylformamide and *N*-methylacetamide. A conformer with the C(carbonyl)–H and N–C(methyl) bonds *trans* to each other is found to be dominant in the gas phase. The presence of a small fraction of the *cis* conformer is suggested, but the experimental evidence is not conclusive.

The present work is a part of our systematic study of simple amide structures by gas electron diffraction. In the preceding studies of formamide,[1] acetamide,[2] and *N*-methylacetamide,[3] significant differences in the C′–N[4] and C′=O distances and in the N–C′=O angles were observed. The question was then raised whether the skeletal structure of *N*-methylformamide (Fig. 1), which has never been reported,[5] conforms to these trends.



trans *cis*

Fig. 1. *N*-methylformamide.

As for the possibility of rotational isomerism about the C′–N bonds, Phillips[6] observed a single methyl-proton NMR spectrum and reported that only one of the two possible conformers (*trans* and *cis* relative to the C′–H and N–C bonds) was present. Jones[7] remarked that the general character of the infrared spectrum in the vapor phase was more consistent with the *cis* model and that the rotation about the C′–N bond was severely hindered. However, his assignment was questioned by Miyazawa[8] and Suzuki,[9] who interpreted the spectrum as that of the *trans* conformer, though a small fraction of the *cis* conformer could exist. The abundance ratio of the *cis* form in a dilute solution of carbon tetrachloride was estimated from the N–H stretching bands to be about 5% by Russell and Thompson.[10]

Experimental

A commercial sample was heated to about 130 °C by a high-temperature nozzle,[11] and diffraction photographs were taken with 40 kV electrons[12] at camera distances of 112.30 mm (short) and 246.86 mm (long). The scale factors of the diffraction patterns were calibrated to within 0.10% with reference to the r_a (C=O) distance of carbon dioxide (1.1646 Å).[12] The densities of four plates taken at each camera distance (D=0.82—0.25) were measured by a digital microphotometer.[13] Other experimental conditions are described elsewhere.[11-14]

Molecular intensities in the ranges s=2.2—15.7 and 9.4—37.7 Å^{-1} were obtained[15] from the long and short distance data, respectively, by use of hand-drawn backgrounds.

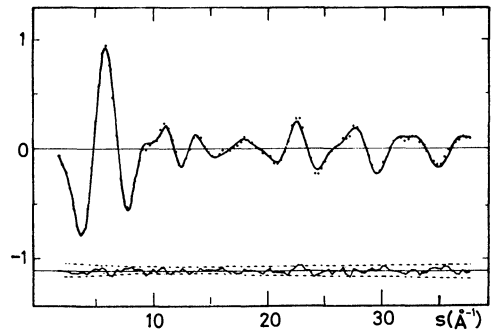


Fig. 2. Experimental and theoretical molecular intensities for *N*-methylformamide. Typical observed $sM(s)$ values are shown in dots, and the best-fit theoretical intensity based on a mixture model of 83% *trans* and 17% *cis* conformers is shown in the solid curve. The lower solid and broken curves represent the residual and the error limits in the $sM(s)$ to a fractional error of 1×10^{-3} of the original photocurrent, respectively. A 100% *trans* model gives residuals of nearly equal magnitude.

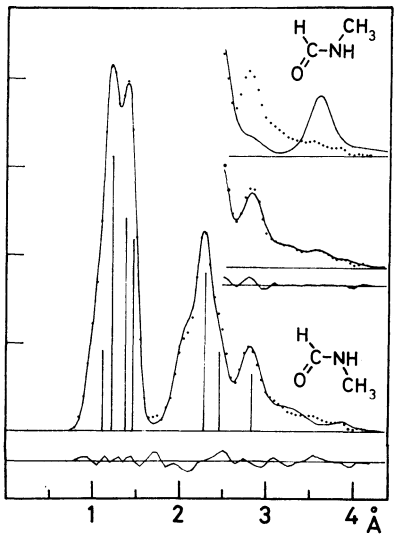

Fig. 3. Experimental (dots) and theoretical radial distribution curves for 100% *cis* (top), 83% *trans* and 17% *cis* (middle), and 100% *trans* (bottom) models. Vertical bars represent principal atom pairs. A damping factor, $\exp(-0.0016\,s^2)$ is used. Residuals are shown below.

Since they agreed with each other in the overlapping region within experimental error (about 0.03 in the absolute $sM(s)$ scale), they were joined at $s=12.7$ Å^{-1} (Fig. 2). The corresponding radial distribution curve, shown in Fig. 3, confirmed that the dominant conformer has the C'–H and N–C bonds *trans* to each other. Most of the calculations were carried out on a HITAC-5020E and a HITAC-8800 in the Computer Centre of the University of Tokyo.

Analysis

Skeletal Structure. The skeletal parameters were determined by a least-squares analysis of molecular intensities with conventional diagonal weights[16] under the following assumptions:

1) All the atoms except for two hydrogen atoms in the methyl group are coplanar.

2) The C'–H and N–C bonds are *trans* to each other.

3) The *N*-methyl group is in the staggered conformation with the C'–N bond.[17]

4) The methyl group has local C_{3v} symmetry and has no tilt.

5) The H–C–H angle (r_α defined in Ref. 18) is equal to that in dimethylamine,[19] 108.6°.

6) The r_g(C'–H) and r_g(N–H) distances are equal to the corresponding distances in formamide,[1] 1.125 and 1.027 Å, respectively.

7) The C'–N–H and N–C'–H angles (r_α) are equal to the corresponding angles in formamide,[1,20] 118.7 and 112.7°, respectively.

8) The barriers hindering the skeletal and methyl torsions, V_2 and V_3, are 20 kcal/mol[21] and 1 kcal/mol, respectively.

9) The asymmetry parameters κ for the bonded C–H and N–H distances are 1.8×10^{-5} Å^3, and the rest of the κ parameters are zero.[22]

Mean vibrational amplitudes and vibrational corrections for shrinkage effects (r_a-r_α)[18,23] were calculated by use of the modified Urey-Bradley force constants reported by Suzuki[9] with a number of additional force constants for out-of-plane displacements for *N*-methylacetamide reported by Itoh,[24,25] both determined from frequencies observed in the liquid phase. The results are given in Table 1. Contributions to the vibrational corrections from the skeletal and methyl torsions were estimated in the way described in a previous paper[3] by use of assumption 8. All the mean amplitudes except for those of the C'=O and C'–N bonds were fixed to the values listed in Table 1.

TABLE 1. MEAN AMPLITUDES AND VIBRATIONAL CORRECTIONS FOR *N*-METHYLFORMAMIDE (in 10^{-4} Å)

X_5					45	12	6	13	−11	−20
X_6						35	5	10	−11	65
l_1							12	9	−12	52
l_2								18	−10	−42
k_1									110	−77
k_2										458

a) X_1=C′–N, X_2=N–C, X_3=C′=O, X_4=C–H, X_5=∠C–N–C′, X_6=∠N–C′=O, l_1=l(C′=O), l_2=l(C′–N), k_1, k_2= indices of resolution for long and short distance data (0.98 and 0.97), respectively. Units ($\times 10^{-4}$) for the distances and mean amplitudes are Å, those for the angles are rad, and those for the indices are dimensionless.

The r_g distances and the r_α angles derived from the least-squares analysis are listed in Table 2 with limits of error estimated from random and systematic errors.[16,26,27)] The skeletal parameters are not sensitive to any of the above assumptions 1—9, and systematic errors caused by uncertainties in the assumptions are included in the quoted error limits. The error matrix[28)] is given in Table 3.

Skeletal Torsion. The observed radial distribution curve shown in Fig. 3 seems to have a small hump around 3.6 Å, which can be assigned to the O···C (methyl) distance in a *cis* conformer. Though the hump is almost comparable with the noise level of the observed radial distribution curve, the peak is reproducible, and a fraction of about 17% is suggested. Accordingly, the molecular intensity was further examined by a least-squares analysis. The system was assumed to be a mixture of *trans* and *cis* conformers with identical frame structures, and their fractions were taken as an additional variable. The analysis gave identical structural parameters and 17±10% for the *cis* fraction, corresponding to a free energy difference ΔG of about 1.3 kcal/mol. This estimate is compatible with the spectroscopic prediction by Miyazawa.[8)] This model was also acceptable according to a further analysis of background functions[29,30)] based on a criterion of their smoothness. However, a 100% *trans* model was equally acceptable in this criterion within experimental error. Furthermore, the *cis* fraction derived from the least-squares analysis mentioned above was found to have strong correlation with the assumptions about the methyl conformation and the methyl torsional barrier. The *cis* fraction decreased to 11± 10% when the methyl torsion was assumed to be essentially free. In further consideration of the uncertainties in the experimental molecular intensity and in the above-mentioned assumptions made in the analysis, it was im possible to unambiguously demonstrate the presence of the *cis* conformer. Further precise spectroscopic or diffraction experiments are necessary for a definite confirmation of the rotational isomerism.

Methyl Torsion. Theoretical radial distribution curves were calculated with different conformations of the methyl hydrogens and with different barrier heights for the methyl torsion. When the V_3 value was assumed to be less than 1 kcal/mol, theoretical curves based on any equilibrium position agreed with the observed curve within the range of experimental error. The agreement became worse when the barrier height was increased, and for $V_3 \simeq 3.8$ kcal/mol, which corresponds to a methyl torsional frequency of about 242 cm^{-1} assigned by DeGraaf and Sutherland,[31)] only a model with a dihedral angle of about 30° between the C′–N and one of the C–H bonds remained acceptable. Consequently, it seems to be the case that either the barrier is lower than those in methylamine,[32)] 2.0 kcal/mol, and in dimethylamine,[33)] 3.2 kcal/mol, or the equilibrium dihedral angle is about 30°.

The theoretical molecular intensity and radial distribution curves based on the most probable structure are compared with the corresponding observed curves in Figs. 2 and 3, respectively.

Discussion

In comparison with the skeletal structures of formamide, acetamide, and *N*-methylacetamide listed in Table 2, the following trends are observed:

1) The C(carbonyl)–N bond lengths in formamide and *N*-methylformamide are essentially equal to each other and are about 0.01 Å shorter than those in acetamide and *N*-methylacetamide.

2) The N–C=O angles in formamide and *N*-methylformamide are nearly equal to each other and are about 3° larger than those in acetamide and *N*-methylacetamide. As remarked in Ref. 1, this trend conforms to the similar trends observed in other systems, where X–CH=Y angles are consistently larger than the corresponding X–C(CH_3)=Y angles by about 3°.

3) On the other hand, the C=O bond lengths in *N*-methylformamide and acetamide are nearly equal to each other and are slightly longer than that in formamide and slightly shorter than that in *N*-methylacetamide.

4) The N–C(methyl) bond length in *N*-methylformamide appears to be shorter than that in *N*-methylacetamide.

5) The C–N–C angle in *N*-methylformamide is larger than that in *N*-methylacetamide.

The authors are indebted to Professor R. K. Bohn for his critical reading of the manuscript and to Professor R. H. Schwendeman for his communication of his microwave data prior to publication.

The Chemistry of Americium. II. The Behavior of Am(III), Am(V), and Am(VI) in Column Chromatography, with Bis(2-ethylhexyl)phosphoric Acid Used as the Extractant

Mitsuo HARA and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-chome, Sendai 980

(Received January 5, 1973)

The behavior of Am(III), Am(V), and Am(VI) in column chromatography with bis(2-ethylhexyl)phosphoric acid(HDEHP) used as the extractant were investigated in comparison with that of Np(IV), Np(V), and Np(VI). When the solution of Am(VI) was submitted to the column chromatography, it was found that Am(VI) was rapidly reduced to Am(V) and partially to Am(III) by HDEHP, irrespective of the conditions, such as the flow rate, the acidity, and the composition and temperature of the influent. The optimum conditions for the separation of Am(V) and Am(III) and for the preparation of the Am(V) solution were established by utilizing the difference in the adsorbability on the column bed between Am(III) and Am(V). When a freshly-prepared Am(V) solution was submitted to column chromatography, it was found that Am(V) was also reduced to Am(III) as well as Am(VI) by HDEHP. The percentage of the Am(V) fraction eluted strongly depended on the conditions in the column chromatography, but it was found to be constant within the limits of experimental error under definite conditions as long as the same column was used. This fact was applied to the determination of the Am(V) content in the mixed solution of Am(III) and Am(V). The content of Am(V) decreased slowly in the nitrate, acetate, sulfate, and perchlorate solutions at lower temperatures, but it rapidly decreased in the chloride, iodide, sulfite, and hydrogen peroxide solutions even at 0 °C. The content of Am(V) decreased more rapidly at higher temperatures, and the kinetic analysis showed that the reduction of Am(V) apparently followed the first-order kinetics in the acetate solutions.

Americium is the heaviest of the actinoid element which are known to have penta- and hexa-valent states. In the solution involving higher concentrations of americium, the disproportionation reaction of Am(V) is remarkable, but it is negligible at lower concentrations of americium. The α-decay of ^{241}Am leads to the radiolytic reduction of both Am(V) and Am(VI) at rates of 1.2 and 3.1%/h respectively, irrespective of the concentration of ^{241}Am.[1] Therefore, the stabilities of Am(V) and Am(VI) must be discussed in connection with the participation of these reactions.

It is well known that Am(VI) is relatively stable in strongly acidic solutions,[2] but Stokely and Moore have reported that the addition of an acetate buffer to a cooled solution of Am(VI) causes the reduction of Am(VI) to Am(V).[3] It has also been reported that Am(VI) in a dilute nitric acid solution not containing silver ion was rapidly reduced to Am(V) in the absence of such stabilizing anions as fluoride.[4] Zangen investigated the solvent extraction of Am(VI) with several extractants such as HDEHP in CCl_4 from nitric acid solutions containing $(NH_4)_2S_2O_8$ and $AgNO_3$ as holding oxidants, but he gave no information about the stability of Am(VI) during the extraction.[5]

The standard potentials for the Am(III)–Am(V) and Am(V)–Am(VI) couples are 1.74 and 1.60 volts respectively.[6] It can be expected from these potentials that Am(V) and Am(VI) are powerful oxidants and that they are easily reduced by normal reductants and organic materials. Our information concerning the instabilities of Am(V) and Am(VI) in both the aqueous and organic phases is rather poor, especially at lower concentrations of americium. Only a little information was obtained by the previous work in which the rates of reduction of Am(V) in several media were investigated by means of solvent extraction with 2-thenoyltrifluoroacetone(TTA).[7]

In this work the behavior of Am(III), Am(V), and Am(VI) in column chromatography, using HDEHP as an extractant, has been studied in comparison with that of neptunium in various valency states. Furthermore, the instabilities of Am(V) and Am(VI) with respect to reduction by HDEHP and by some coexisting materials have been investigated.

Experimental

Reagents. The nuclides used in this study were ^{241}Am (433 y), ^{243}Am(7400 y), ^{237}Np(2.14×10^6 y), and ^{239}Np (2.355 d); their radiochemical purities were certified by γ-ray and α-particle spectrometry. The solutions of Am(III) and Am(VI) were prepared in a manner which has been described before using ^{241}Am,[7] and the concentration of americium was adjusted to about 10^{-6}M. $^{243}AmO_2$, obtained from the Oak Ridge National Laboratory, was dissolved in concentrated nitric acid, and a 10M nitric acid solution of ^{243}Am was used for the tri-*n*-octylamine (T-*n*-OA) extraction to isolate ^{239}Np,[8] which was a daughter of ^{243}Am and which was used as a tracer of neptunium. ^{237}Np in a 1M nitric acid solution, obtained from the Radiochemical Centre, Amersham, England, was purified by the TTA extraction method[9] and was used as a carrier of neptunium within two hours after the purification in order to minimize the interference from its daughter. The solutions of Np(IV), Np(V), and Np(VI) were prepared by the literature methods.[10-12]

HDEHP, obtained from Tokyo Kasei, was purified by the solvent extraction method[13] and diluted with distilled acetone. The TTA, T-*n*-OA, and other chemicals were of a G. R. grade. Celite 545, obtained from Jones–Mannville, was used as a supporting medium for the extractant. It had been washed with acid, treated with dimethyldichlorosilane, and sized in 80—100 meshes.

Apparatus. A Kobe Kogyo Model PS-500 flat-type NaI(Tl) scintillation probe connected with a Toshiba 800-channel pulse-height analyzer was used for the measurement of the γ-ray spectra, while an Osaka Dempa Gridded Ioniza-

tion Chamber connected with the same pulse-height analyzer was used for the measurement of the α-particle spectra. The γ-ray assay was performed by the use of the scintillation probe connected with a Kobe Kogyo Model SA-400 scaler.

A Toa-Dempa-Kogyo pH meter Model PE-2 was used for the pH measurements. A Shimadzu Ozone Generator was used to bubble ozone gas through the testing solutions in order to eliminate the reducing materials as much as possible. Most of the column chromatographic experiments were performed at a temperature determined with an accuracy of ±0.5 °C in an Ohishi Netsu-Kagaku thermostatted box.

Procedure. Column Preparation: 5 grams of Celite 545 and 20 ml of 1M HDEHP–acetone were mixed in a beaker. The mixture was allowed to settle overnight, and then the excess solution was decanted. After air drying at room temperature, the powder was suspended in distilled water; the mixture was then added to a glass tube plugged with glass wool to the desired height. The column was subsequently washed with a 2M nitric acid solution and with water.

Column Chromatography: 50—100 μl portions of sample solutions were fed onto the top of the column bed, which had preliminarily been washed with the influent. The column was operated by the usual chromatographic procedures. Suitable aliquots of the effluent were put in polyethylene test tubes or on aluminium dishes for γ-ray measurements.

If the separation of Am(III) and Am(V) was desired, it was done as follows: Am(V) was eluted from the column with a few milliliters of an influent whose acidity was lower than 0.1M; then the Am(III) was eluted with a few milliliters of a 2M nitric acid solution. After the measurement of the total γ-ray activity in both the Am(V) and Am(III) fractions, the percentage of Am(V) was calculated.

Results and Discussion

Elution of Am(III), Am(VI), Np(IV), Np(V), and Np(VI). The Am(III), Am(VI), and Np(V) in the nitric acid solutions were fed onto the top of a column bed and then eluted with nitric acid solutions of various acidities. Some typical elution curves are shown in Fig. 1. The peak of Np(V) in the elution curve did not shift in the 10^{-4}—0.5 M acidity range; Np(V) passed through the column without adsorption. On the other hand, the peak of Am(III) shifted remarkably with the change in the acidity of the influent. In the case of the Am(VI) sample solution, the major part of the americium was eluted within two column volumes of the influent, while the minor part was eluted with the same volume of the influent as Am(III); the major peak did not shift in the 10^{-4}—0.5 M acidity range like the peak of Np(V), and the minor peak showed the same behavior as that of Am(III).

The Np(IV) and Np(VI) fed onto the column bed could not be eluted with the nitric acid solution in the 0.01—2 M acidity range. However, Np(VI) was gradually eluted with influents of acidities higher than 5 M, though Np(IV) was not eluted at all with the nitric acid solution of the acidity up to 10 M adsorbed tightly on the column bed.

It is known that the actinoid(III, IV, VI) ions are adsorbed tightly on the column bed containing HDEHP.[4] Therefore, it may be concluded that the species which passed through the column without adsorption in the elution of the Am(VI) sample solution was Am(V), since it showed a behavior in the column chromatography similar to that of Np(V) among the various valency states of neptunium.

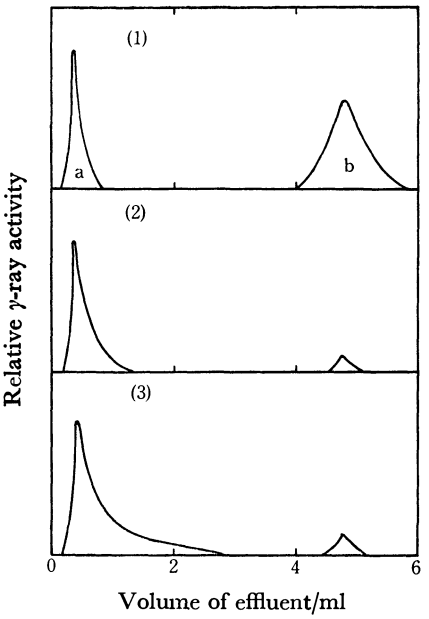

Fig. 1. Behaviors of Am(III), Am(VI) and Np(V) in column chromatography.
Column: 5 mmφ × 30 mm, Influent: 0.2 M HNO_3, Flow rate: 80 μl/min
1. a) Np(V), b) Am(III). 2. Am(VI) sample solution. 3. Am(VI) sample solution (Influent: 0.2 M HNO_3, 0.1 M peroxydisulfate, trace $AgNO_3$).

Reduction of Am(VI) during the Column Chromatography. Before the Am(VI) sample solution was submitted to the column chromatography, the valency state of americium had been confirmed as hexavalent by means of the LaF_3 coprecipitation method.[14] Therefore, it is clear that Am(VI) was rapidly reduced to Am(V) during the column chromatography. It is well known that Am(VI) is relatively stable in the presence of such holding oxidants as $(NH_4)_2S_2O_8$ with an $AgNO_3$ catalyst and without any contact with organic materials.[14] In the elution curve with an influent containing the holding oxidant (Fig. 1(3)), the peak corresponding to Am(V) had a tail. The rate of reduction decreased somewhat in the presence of the holding oxidant, but it was found that most of the americium was eluted in the pentavalent state.

As causes of the reduction of Am(VI), two factors are possible: the supporting medium and the extractant (HDEHP) in the column bed. In the preliminary experiments, it was confirmed that the powder used as the supporting medium was inert to the redox reaction of americium. Thus, the Am(VI) was probably reduced by the extractant even though the holding oxidant was added. The rapid reduction of Am(VI) by the extractant was also observed in the column chromatography with the Am(VI) solutions of acetate, sulfate, perchlorate, bromate, chloride and hypochlorite in the acidity range of 10^{-4}—0.1 M.

○: Am(III) ●: Am(V)

Reduction of Am(V) during the Column Chromatography. The log-log plot of the retention volume (the volume of the effluent at the peak position in the elution curve) *vs.* the acidity of the influent is shown in Fig. 2, where the retention volume, subtracted by one column volume (V_c), is expressed in V_c units. The difference between Am(III) and Am(V) in their adsorbability on the column bed suggests that the recommended procedure for the separation of Am(V) from Am(III) should be as follows: using a column more than 1 ml in bed volume, the Am(V) should be eluted with an influent with an acidity of less than 0.1 M and a volume of less than two column volumes, and the Am(III) should be rapidly stripped with a 2 M nitric acid solution.

Table 1. Elution of Am(VI) sample solution with 0.1 M nitrate solution

pH	Temperature °C	Am(V) fraction %	
2.0	0	86.5±0.8[a)]	
2.5	0	85.1±0.8	
3.0	0	84.1±1.0	
3.5	0	84.7±0.8	
2.0	0	89.8±0.8[b)]	77.7[c)]
2.0	10	87.8±1.0	70.5
2.0	20	88.9±1.0	69.5
2.0	30	87.4±1.0	68.6
2.0	40	80.8±1.0	61.0

Oxidant a) and b): $(NH_4)_2S_2O_8+AgNO_3$ c): $(NH_4)_2S_2O_8$
Column a): 6 mmϕ×30 mm b) and c): 6 mmϕ×25 mm

Following the procedure described above, Am(VI) sample solutions were eluted with nitrate solutions under various conditions and the percentage of the Am(V) fraction was determined radiometrically. As is postulated in Table 1, the percentage of the Am(V) fraction was almost constant in the 2.0—3.5 pH range at 0 °C, but it decreased with a rise in the temperature at a constant acidity. The percentage of the Am(V) fraction did not reach 100% even at 0 °C. These findings are probably the result of the instability of Am(V) during the column chromatography.

Table 2. Elution of Am(V) sample solution with 0.01 M nitrate solution (pH 2.5) at 0 °C

Bed volume mmϕ, mm	Flow rate ml/min	Am(V) fraction %
8×50	0.1	3.0
8×40	0.4	15.1
8×35	1.0	42.4
8×30	1.1	60.3
8×30	1.6	64.8
10×20	2.0	91.5
10×15	2.5	95.0

The Am(V) solution freshly prepared by the elution of the Am(VI) solution was submitted to column chromatography, and the percentage of the Am(V) fraction was measured with respect to the different volume of the column bed. It is clear from the results presented in Table 2 that the bigger the column bed, the smaller the percentage of the Am(V) fraction. These results can be explained easily in connection with the duration of passing over the column bed: Am(V) was obviously reduced by the extractant to Am(III) just like Am(VI). The percentage of the Am(V) fraction depended on the conditions of the column chromatography, such as the temperature, the flow rate, the composition of the influent, and the volume of the column bed. However, it was found that the percentage of the Am(V) fraction was constant within limits of experimental error, as is shown in Fig. 3, when the same column was used in the elution

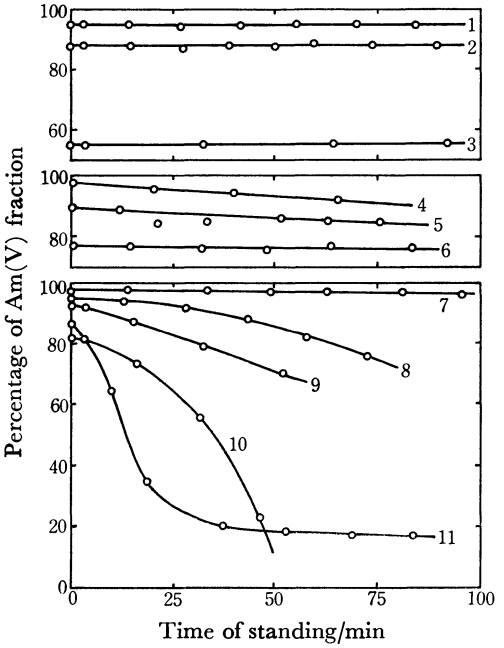

Fig. 3. Time-dependence of percentage of Am(V) fraction in 0.1 M solutions of pH 2.5 at 0 °C
1–3: Nitrate, 4: Acetate, 5: Sulfate, 6: Perchlorate, 7: Peroxydisulfate, 8: Chloride, 9: Hydrogen peroxide, 10: Potassium bromate, 11: Peroxydisulfate freshly prepared (The different column was used except for two couples, 1–8 and 2–11)

of Am(V) in a 0.1 M nitric acid solution. This finding suggests that Am(V) is stable in the nitrate solutions and that the rate of Am(V) decreased by the column chromatography is constant so long as the same column is used. Thus, the content of Am(V) in the mixed solution of Am(III) and Am(V) can be determined by a simple correction for the percentage of the Am(V) fraction obtained by the column chromatography under definite conditions using the same column.

Stability of Am(V) in Several Kinds of Solutions.

Aliquots of an Am(V) solution kept at various temperatures were submitted to column chromatography at 0 °C in order to investigate the dependence of the percentage of the Am(V) fraction on the standing time. Some of the results are shown in Fig. 3. The percentage of the Am(V) fraction in the perchlorate, sulfate, acetate, and aged peroxydisulfate solutions decreased slowly, but it readily decreased in the chloride, iodide, sulfite, hydroxylamine, hydrogen peroxide, bromate, and freshly-prepared peroxydisulfate solutions, even at 0 °C. The unexpected results with the common oxidant, the bromate, and the freshly-prepared peroxydisulfate solutions can be explained in terms of the following phenomena: the bromate obviously eluted a portion of the extractant and the peroxydisulfate formed bubbles in the column bed. The decreases in the percentage of the Am(V) fraction in the solution kept at lowered temperatures did not result from the oxidation of Am(III) and Am(V), but from the reduction of Am(V) to Am(III) because of the higher redox potentials for two couples, Am(III)–Am(V) and Am(V)–Am(VI).

Then, the dependence of the content of Am(V) in the acetate solutions on the standing time was investigated at various temperatures. As is shown in Fig. 4, the semilog arithmic plot of $[Am(V)]_t/[Am(V)]_0$ *vs.* the standing time showed a linearity, where $[Am(V)]_0$ and $[Am(V)]_t$ were the concentrations of Am(V) at the standing times of 0 and t respectively. The slope of the straight line somewhat increased with an increase in the pH in the 2—3 range examined at the same temperature. Consequently, the reduction of Am(V) in an acetate solution apparently follows the first-order kinetics. The reduction rate of Am(V) to Am(III) decreased to as low as a few percentages per hour at 0 °C, though the radiolytic reduction rate of 1.2%/h should remain even at sufficiently lowered temperatures. Therefore, the experiments using Am(V) solutions have to be performed at lower temperatures and have to be finished within a few hours after the preparation of Am(V) solutions in order to minimize the interference from Am(III).

ESR of Copper(II) Complexes in Magnetically Non-dilute Crystals. II. Polycrystals of Various Bis(amino acidato)copper(II) Complexes

Hiroshi Yokoi

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received February 24, 1973)

The molecular g values of several bis(amino acidato)copper(II) complexes in crystals, whose crystal structures with two molecules per unit cell are known, have been estimated from the crystal g values by considering the effect of the spin-exchange interaction between the dissimilar copper(II) ions. All the crystal g values have been determined here from the powder K-band ESR spectra. Many other complexes with unknown crystal structures have also been dealt with in a similar way. The results have indicated that most of the complexes probably have a tetragonal or nearly tetragonal copper(II) ion environment in crystals, and a tendency for the estimated $g_{//}$ value to decrease with an increase in the energy of the visible absorption peak in crystals have been noted. A discussion about the correlation between an axial molecular g tensor and the two copper-ligand bond lengths of Cu–O and Cu–N has been given.

In previous papers,[1,2] it has been suggested that the copper(II) ion environment in most bis(amino acidato)-copper(II) complexes in crystals may be rhombically distorted because of two different kinds of atoms (O and N) directly coordinating to the metal ion. This has been supported by the fact that almost all the powder ESR spectra of the complexes show three different principal g values.[1] On the other hand, however, it has been reported that some bis(amino acidato)copper(II) complexes in magnetically diluted crystals and almost all the complexes in frozen aqueous methanolic solutions are of an axial symmetry in their g values.[1-3] Recently, an ESR study of bis(L-alaninato)copper(II) in undiluted single crystals has also revealed that a tetragonal molecular g tensor can be estimated from the observed rhombic g tensor of the crystal bulk by considering the crystal structure and the effect of the spin-exchange interaction between the dissimilar copper(II) ions.[4] Therefore, it seems necessary at present to reinterpret the powder ESR results previously reported after giving thought to the spin-exchange interaction in magnetically non-dilute crystals.

The purpose of this paper is to estimate the molecular g values from the crystal values for various bis(amino acidato)copper(II) complexes in crystals in view of the above-mentioned spin-exchange effect, and to discuss the correlation among the estimated molecular g values, the crystal structures, and the ligand-field properties.

Experimental

The K-band ESR spectra were measured in a polycrystalline state at room temperature with a Hitachi ESR spectrometer, Model-4001. The principal crystal g values (the principal g values of the crystal bulk) were determined from the powder ESR spectra by the use of the approximation of Kneubühl.[5]

The copper(II) complexes of amino acids employed in the present ESR measurements were as follows: bis(α-amino-isobutyrato)copper(II), bis(L-threoninato)copper(II) monohydrate, bis(*N*,*N*-dimethylglycinato)copper(II) trihydrate, and bis(L-hydroxyprolinato)copper(II) monohydrate (abbreviated as $[Cu(Aib)_2]$, $[Cu(L\text{-}Thr)_2]\cdot H_2O$, $[Cu(Dmg)_2]\cdot 3H_2O$, and $[Cu(L\text{-}Hypro)_2]\cdot H_2O$ respectively). They were all prepared according to the usual method,[6] using commercial G.R.-grade α-amino acids, were recrystallized from water, and were identified by elemental analysis. The visible absorption spectra for these complexes in a polycrystalline state were measured using the opal-glass method previously described.[1] Only the absorption peak positions (λ_{max}) will

be reported here, with an error of ±4 nm.

Bis(β-alaninato)copper(II) hexahydrate is known to effloresce in air at room temperature. After the powdered hexahydrate complex had been allowed to stand in air at room temperature for several hours (resulting in Compound (I)), its powder K-band spectrum was measured; then, the K-band spectrum also was measured for the complex obtained by heating Compound (I) *in vacuo* at 120 °C for two hours (resulting in Compound (II)).[7] Recently, Misumi *et al.* determined the hydration degree for each of the complexes obtained in the course of the dehydration of the hexahydrate complex; they also measured the powder X-band ESR spectra of the complexes.[8] By a comparison between the ESR spectra reported by them and those shown in this paper, Compounds (I) and (II) can be regarded as $[Cu(\beta\text{-Ala})_2]\cdot 2H_2O$ and $[Cu(\beta\text{-Ala})_2]\cdot 0\text{—}1H_2O$ respectively. $[Cu(L\text{-Pro})_2]\cdot 2H_2O$ was also dehydrated *in vacuo* at 120 °C for two hours (the degree of hydration for this complex, which is abbreviated as $[Cu(L\text{-Pro})_2]\cdot 0\text{—}1H_2O$, was not checked here). The powder ESR spectrum of $[Cu(DL\text{-Pro})_2]\cdot 2H_2O$ was again measured after repeated recrystallizations from water. All the powder ESR spectra measured in this work are shown in Fig. 1. $[Cu(\beta\text{-Ala})_2]\cdot 6H_2O$, $[Cu(L\text{-Pro})_2]\cdot 2H_2O$, and $[Cu(DL\text{-Pro})_2]\cdot 2H_2O$ are the complexes which had been prepared in previous works.[1,2] The abbreviations for the other bis(amino acidato)copper(II) complexes cited in this paper are the same as have been reported previously.[1,2]

Results and Discussion

Estimation of Molecular g Values. We will now consider the case of a unit cell containing only two sets of crystallographically non-equivalent axial molecules, whose principal g values are represented by $g_{//}$ and $g_\perp$ ($g_{//}>g_\perp$). Let the two principal axes of the molecules be inclined at an angle of 2γ. In the condition of $2J>(g_{//}-g_\perp)\beta H$, the three principal crystal g values ($g_1\leq g_2\leq g_3$ for $0°\leq\gamma\leq 45°$) are expressed as follows:[9]

$$g_1 = g_\perp \tag{1}$$

$$g_2 = \sqrt{g_\perp^2+(g_{//}^2-g_\perp^2)\sin^2\gamma} \tag{2}$$

$$g_3 = \sqrt{g_\perp^2+(g_{//}^2-g_\perp^2)\cos^2\gamma} \tag{3}$$

where the g_3 and g_2 axes are directed to the internal and external bisectors respectively of the axes normal to the two non-equivalent molecular planes, and where the g_1 axis is perpendicular to both the g_2 axis and the g_3 axis. The powder ESR line shape of a reverse-type ($g_1<g_2=g_3$) is observed for any one of the complexes, with $\gamma=45°$ in crystals. Strictly speaking, Eqs. (1)—(3) are incorrect for the above-described system, since g_2 and g_3 must be expressed as $g_\perp+(g_{//}-g_\perp)\sin^2\gamma$ and $g_\perp+(g_{//}-g_\perp)\cos^2\gamma$ respectively, because of the following form of the Zeeman term in the effective spin Hamiltonian under such a spin-exchange field: $(\beta/2)(\boldsymbol{S}^1+\boldsymbol{S}^2)(\boldsymbol{g}_a+\boldsymbol{g}_b)\boldsymbol{H}$, where the two paramagnetic species are denoted by a and b and where the electrons are denoted by 1 and 2.[10] However, as the anisotropy in the molecular g tensor for copper(II) complexes is not so large, Eqs. (1)—(3) can be used in numerical calculations without any serious errors in this work; so can Eq. (4), which will be discussed later.

Equations (1)—(3) were successfully applicable to the case of $[Cu(L\text{-Ala})_2]$ in crystals. The results alone are presented in Table 1. The $g_{//}$ and $g_\perp$ values of $[Cu(Pen)_2]$ in crystals were determined from Eqs. (1)—(3), using the γ value determined by X-ray analysis so as to minimize the equation of $(g_2^{ob}-g_2^{calc})^2+(g_3^{ob}-g_3^{calc})^2$.[11] The results are listed in Table 1. The values of g_2^{calc} and g_3^{calc} for this complex are in agreement with the experimentally-determined values of g_2^{ob} and g_3^{ob} respectively within the limits of experimental error. $[Cu(DL\text{-}\alpha\text{-}NH_2but)_2]$ and $[Cu(DL\text{-Met})_2]$, whose γ values are not known,[12,13] show powder ESR line shapes similar to those of $[Cu(L\text{-Ala})_2]$ and $[Cu(Pen)_2]$; the values of $g_{//}$, $g_\perp$, and γ for the former two complexes were tentatively calculated from Eqs. (1)—(3) using the observed crystal g values. The γ values thus calculated were close to those of the latter two complexes, as is shown in Table 1. This result can be well understood from the point of view of crystal structure; all these four complexes are monoclinic, with a space group of the $P2_1$ type, and all may be expected to have almost the same inter-molecular interaction in crystals. The molecular g values thus estimated, therefore, may be substantially correct.

The powder ESR spectrum of $[Cu(L\text{-Ser})_2]$ has a typical reverse-type line shape ($g_1^{ob}<g_2^{ob}\fallingdotseq g_3^{ob}$), as has been shown previously.[2] The γ value of this complex was determined by X-ray analysis to be close to 45°.[14] Its observed crystal g values, therefore, can be qualitatively explained from Eqs. (1)—(3) using such a large γ value as is listed in Table 1. The powder ESR line shape of $[Cu(DL\text{-Pro})_2]\cdot 2H_2O$ is also of a reverse-type, as is shown in Fig. 1. Its reverse-type line shape alone can be qualitatively explained in terms of the fact that its γ value is close to 45°. Some other complicated factors, however, must be considered in order to explain the complexity of its line shape.

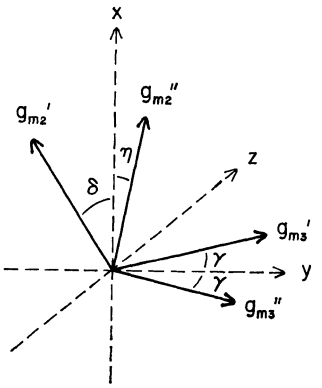

Fig. 2. A coordinate system for two non-axial molecules per unit cell.

The possibility, however, can not be denied that certain complexes might have non-axial molecular tensors. The equations corresponding to Eqs. (1)—(3) are complicated for this non-axial case;[15,16] besides γ, they require two new angles (δ and η), which will be defined below. The three principal molecular g values are denoted by g_{m1}, g_{m2}, and g_{m3} in order of increasing magnitude. The y and z axes are defined so as to bisect the angle between the two non-equivalent molecular axes (the two g_{m3} axes) internally and ex-

a) All the complexes have two molecules per unit cell except [Cu(β-NHbut)$_2$]·2H$_2$O, which has one molecule per unit cell. b) See Ref. 4. c) Experimental errors in g factors were $\pm$ 0.003. d) Larger errors may be expected in the two large crystal g values, because the powder ESR line shape of this complex deviates slightly from a complete reverse-type. e) See the text. f) The assumed values are expressed in parentheses (see the text).

ternally respectively, while the x axis is defined as perpendicular to the plane containing the two molecular axes (Fig. 2). In this coordinate system, δ and η specify the inclination of the two sets of g_{m2} axes to the x-axis. In general, the relation of $\delta=180°-\eta$ holds, since molecules are often related by screw-diad axes, as in the case of the complexes in Table 1. Accordingly, the elements of the g^2 matrix in this coordinate system may be expressed as follows:

$$g_{xx}^2 = g_{m1}^2 + (g_{m2}^2-g_{m1}^2)\cos^2\delta$$
$$g_{yy}^2 = g_{m2}^2\cos^2\gamma + g_{m3}^2\sin^2\gamma - (g_{m2}^2-g_{m1}^2)\sin^2\gamma\cos^2\delta$$
$$g_{zz}^2 = g_{m3}^2\sin^2\gamma + g_{m2}^2\cos^2\gamma - (g_{m2}^2-g_{m1}^2)\cos^2\gamma\cos^2\delta$$
$$g_{xz}^2 = (1/2)(g_{m2}^2-g_{m1}^2)\cos\gamma\sin 2\delta \qquad (4)$$

Here, g^2_{yz} and g^2_{xy} are reduced to zero by the relation of $\delta=180°-\eta$. The observed principal crystal g values (g_a, g_b, and g_c) are obtained by diagonalizing the above matrix; in this case, the following convenient equations can be derived:

$$g_a^2 = g_{yy}^2$$
$$g_a^2 + g_c^2 = g_{xx}^2 + g_{zz}^2$$
$$g_a^2\cdot g_c^2 = g_{xx}^2\cdot g_{zz}^2 - (g_{xz}^2)^2 \qquad (5)$$

There have been almost no data concerning the δ except for a few copper(II) complexes. The crystal g values (g_a, g_b, and g_c) for each of the properly-assumed

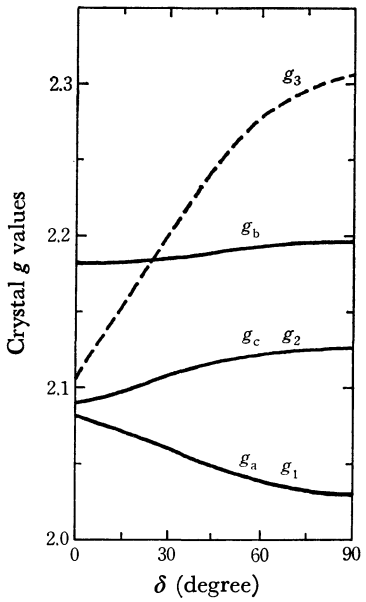

Fig. 3. The three principal crystal g values (g_a, g_b, and g_c; they are expressed as solid lines) derived from Eqs. (4) and (5) using $g_{m1}=2.030$, $g_{m2}=2.090$, $g_{m3}=2.230$, and $\gamma=30°$. The dashed line represents the g_3 value derived from Eq. (3) on the assumption of $g_1=g_a$ and $g_2=g_c$ in Eqs. (1) and (2).

sets of the g_{m1}, g_{m2}, g_{m3}, γ, and δ values were calculated from Eqs. (4) and (5). Then, it was examined whether or not the g_1, g_2, and g_3 values derived from Eqs. (1)—(3) using a proper set of the $g_{//}$ and $g_{\perp}$ values and the same γ value could be fitted to the g_a, g_b, and g_c values calculated above. Some of the results are shown in Fig. 3. This figure indicates that the g_a, g_b, and g_c values calculated for $\gamma=30°$, $g_{m1}=2.030$, $g_{m2}=2.090$, and $g_{m3}=2.230$ are not equal to the g_1, g_3, and g_2 values respectively except for the case of $\delta=25°$ (an intersection of solid and dashed lines in this figure). Furthermore, it became apparent that such an intersection varies over a wide range of δ according to the g_{m1}, g_{m2}, g_{m3}, and γ values. Since it is very rare for an actual case to correspond to the case of such an intersection, it is highly probable that the g tensors of copper(II) complexes in crystals are of an axial or nearly axial symmetry, if their crystal g values, as calculated from Eqs. (1)—(3) using proper sets of the $g_{//}$ and $g_{\perp}$ values, can be fitted to the observed values within the limits of experimental error. Accordingly, there is very little doubt that [Cu(Pen)$_2$] in crystals has an axial g tensor as well as [Cu(L-Ala)$_2$], as has been mentioned above. On the other hand, it was found that, when γ is close to 45°, g_b becomes close to g_c for any value of δ; accordingly, it is difficult to judge whether the observed crystal g values of a reverse-type ($g_1^{ob}<g_2^{ob}=g_3^{ob}$) correspond to the g_a, g_b, and g_c values or to the g_1, g_2, and g_3 ones. In this case, another method for judging whether or not the $g_{//}$ and $g_{\perp}$ values tentatively estimated from the observed g values are correct is required.

Support for the view that all the $g_{//}$ and $g_{\perp}$ values listed in Table 1 are close to the true molecular g values comes also from the fact that the tendency for the $g_{//}$ value to decrease regularly with an increase in the energy of λ_{max}, as is shown by full circles in Fig. 4, is consistent with the same tendency previously recognized for a great numer of copper(II) complexes in frozen solutions.[21]

The values of $g_{//}$, $g_{\perp}$, and γ for a number of bis-

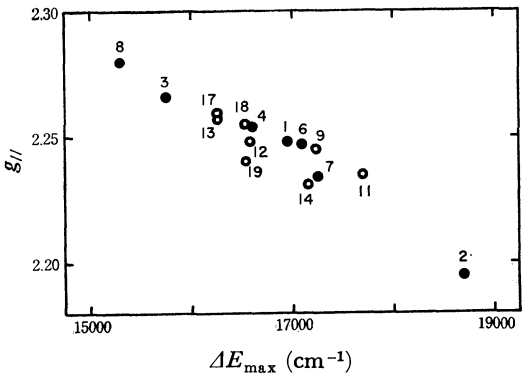

Fig. 4. A plot of $g_{//}$ against ΔE_{max} (numbers correspond to the complexes in Tables 1 and 2; open circles correspond to the complexes with unknown crystal structures listed in Table 2).

(amino acidato)copper(II) complexes whose crystal structures are not known were determined from the observed crystal g values using Eqs. (1)—(3), on the assumption that all these complexes have axial g tensors in crystals; the results are listed in Table 2. All the reverse-type crystal g values observed for several complexes led to the result of $\gamma=45°$. The fact that all the determined γ values of the anhydrous complexes in Table 2 are close to 30° is consistent with the fact noted for the anhydrous complexes in Table 1. There is also a slight tendency for the $g_{//}$ value thus estimated to decrease with an increase in the energy of λ_{max} in crystals, as is shown by open circles in Fig. 4. The molecular g values listed in Table 2 may, therefore, be substantially correct.

The ESR spectra of the hydrated copper(II) complexes generally show drastic changes in line shape when the complexes are dehydrated to a varying extent, as is shown by some examples in Fig. 1. It seems unnatural, however, that the molecular g values of the hydrates are markedly altered only by such a dehydration. For instance, [Cu(β-Ala)$_2$]·6H$_2$O and [Cu(DL-Ala)$_2$]·H$_2$O showed almost no marked changes in the

a) Experimental errors in g factors are ±0.003. b) The observed crystal g values can be calculated from Eqs. (1)—(3) using the assumed γ and molecular g values. c) Since the absorption spectrum is composed of two broad bands (about 525 and 610 nm), the mean was adopted for convenience.

estimated molecular g values upon dehydration, as is shown in Table 2, nor were there any remarkable accompanying color changes. It is of interest that the reverse-type powder ESR line shape of [Cu(L-Pro)$_2$]·2H$_2$O changed into a nearly symmetric one when this complex was dehydrated to a certain degree, as is shown in Fig. 1(f). It is more likely that the molecular g values for this complex also are not markedly altered upon dehydration, and that the symmetric powder ESR line shape is due to a special type of molecular packing in crystals; for instance, such a symmetrical line is observed if the four axial molecules are arranged with their molecular axes pointing towards the corners of a tetrahedron.[16]

Symmetry of the Ligand Field. Recently, many ESR studies have indicated that the molecular g tensors of the copper(II) complexes with different coordinating atoms in the molecular plane are of an axial or nearly axial symmetry. Almost all of the mixed-ligand complexes of copper(II) in solution so far examined have shown ESR line shapes of an axial type.[22] It is a well-known fact that the ability of some familiar ligand atoms to coordinate to the copper atom is in the order of S>N>O. The copper(II) chelates of monothio-β-diketones also have nearly axial g and A tensors in various magnetically-diluted states.[23] These facts suggest that, especially in solution, most copper(II) complexes generally tend to be of an axial or nearly axial symmetry in the g and A tensors, even if their coordinating atoms are different in kind.

Most of the complexes listed in Table 1 also have axial or nearly axial molecular g tensors in crystals; it is worthy of special attention that all the Cu–O bonds of these complexes are shorter by 0.03—0.07 Å than the Cu–N ones. On the other hand, the Cu–O bonds of [Cu(β-NH$_2$but)$_2$]·2H$_2$O are slightly longer than the Cu–N ones, and its molecular g tensor is clearly rhombic. [Cu(L-Ser)$_2$] is known to adopt a *cis*-configuration. The Cu–O bonds of this complex also are shorter by 0.020 Å (the mean) than the Cu–N ones. In general, the *cis*-complexes of copper(II), whose four coordinating atoms take a planar conformation of C_{2v} symmetry, as is approximately the case with [Cu(L-Ser)$_2$], tend to have axial or nearly axial g tensors, since even the possible lateral distortions (a distortion type of $Y_{1,3}^1$ in the crystal-field theory) in such *cis*-complexes do not destroy the axial symmetry in the molecular g tensor.[24]

Let us now consider the above-mentioned relation between the coordinate bond lengths and the axial g tensor. An axial molecular g tensor roughly means that $2-2\lambda_0(\alpha^2\mu^2/\Delta E_{xz})=2-2\lambda_0(\alpha^2\nu^2/\Delta E_{yz})$, where λ_0 represents the spin-orbit coupling constant for the free copper(II) ions, where $\Delta E_{xz}=E_{x^2-y^2}-E_{xz}$ and $\Delta E_{yz}=E_{x^2-y^2}-E_{yz}$, and where α, μ, and ν are the coefficients of the metal $3d$ atomic orbitals in the following antibonding molecular orbitals: $\phi_\alpha=\alpha d_{x^2-y^2}-\alpha'\phi_\alpha^{\mathrm{L}}$, $\phi_\mu=\mu d_{xz}-\mu'\phi_\mu^{\mathrm{L}}$, and $\phi_\nu=\nu d_{yz}-\nu'\phi_\nu^{\mathrm{L}}$ (ϕ^{L}s express the proper ligand orbitals).[25] One of the conditions which satisfy the equation of $(\alpha^2\mu^2/\Delta E_{xz})=(\alpha^2\nu^2/\Delta E_{yz})$ for the *trans*-complexes is as follows: the energy levels of ϕ_μ^{L} and ϕ_ν^{L} are close to each other, and, in addition, the square values of the overlap integral in the ϕ_μ and ϕ_ν molecular orbitals are almost equal.[26] Although the oxygen $2s$ and $2p$ atomic orbitals generally lie at lower energy levels than the respective nitrogen ones, it can reasonably be considered that the oxygen energy levels in the complexes of amino acids are raised to a great extent because of the oxygen atoms coordinated to the metal atom as a part of negatively-charged carboxyl anions.[27]

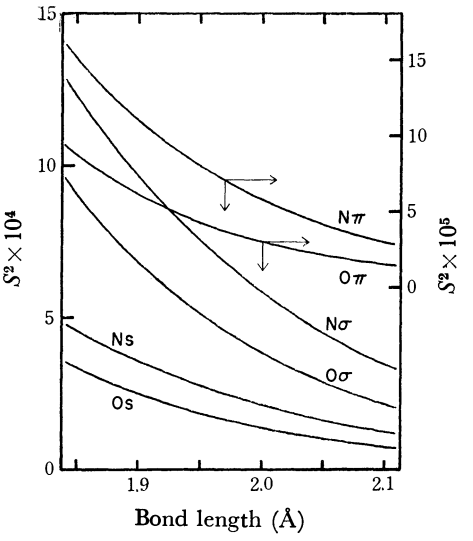

Fig. 5. Variations of the squares of overlap integrals with bond length (Ns, Nσ, and Nπ represent [S(3dσ–2s)]^2, [S(3dσ—2pσ)]^2, and [S(3πd—2pπ)]^2 respectively for the Cu–N bond, and Os, Oσ, and Oπ do so for the Cu–O bond).

The square values of the overlap integral, S, for the Cu–O and Cu–N bonds were calculated from the Slater atomic orbitals by the use of the single-ζ exponent values given by Clementi and Raimondi,[28] assuming that the copper and nitrogen atoms are electrically neutral and that the oxygen atom is negatively charged by a half unit; for the oxygen $2s$ and $2p$ orbitals, $\zeta=\zeta_n-0.35\ (q/n)$, where ζ_n represents the ζ value of electrically-neutral oxygen atoms, where 0.35 means the shielding constant, and where q is the charge, and n, the principal quantum number ($q=1/2$, $n=2$).[29] The numerical calculations were carried out on the NEAC-2200 Model-700 (TSS) computer at Tohoku University. The results are shown in Fig. 5. This figure indicates that the square values of S(3dσ-2s), S(3dσ-2pσ), and S(3dπ-2pπ) for the Cu–O bonds become equal to those for the respective Cu–N bonds when the Cu–O bonds are shorter than the Cu–N ones by about 0.07 Å for the former two S's and by about 0.09 Å for the latter. This result can qualitatively explain the above-mentioned fact that it is required for an axial g tensor that the Cu–O bonds are shorter by about 0.05 Å than the Cu–N ones. This result is also almost consistent with the concept of covalent bond radii; the covalent radius of N is larger by 0.04 Å than that of O.[30]

It may be concluded from all the experimental results listed in Tables 1 and 2 that almost all bis(amino acidato)copper(II) complexes in crystals, except for

a small number, are of an axial or nearly axial symmetry in the copper(II) ion environment.

The author is grateful to Professor Taro Isobe for his encouragement throughout this work.

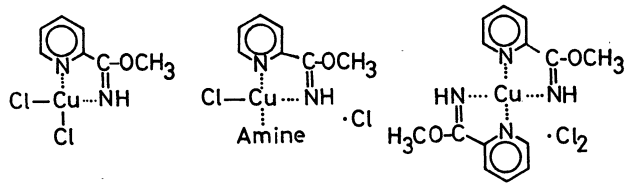
(Received April 12, 1973)

On treatment of bis(2-pyridinecarbonitrile)copper(II) chloride with various amines in methanol, the alkoxylation of the nitrile group in the complex took place; in some cases, the alkoxylation and the ligand substitution of the complex occurred at the same time. The reaction products were classified into three types depending on the amines used; two of the types consisted of new complexes. The complexes of $CuCl_2$(MeOpy)(Amine) (MeOpy: *O*-methylpyridine-2-carboximidate), were obtained on the addition of ammonia, methylamine, dimethylamine, ethylamine, benzylamine, or piperidine to a methanol solution of bis(2-pyridinecarbonitrile)copper(II) chloride. On the other hand, the addition of trimethylamine, diethylamine, or triethylamine afforded the complex of $CuCl_2$-$(MeOpy)_2$. These types of complexes were not obtained by the use of aniline or pyridine; but the previously known complex, $CuCl_2$(MeOpy), was obatined in this case. It has been assumed that the formation of the three types of complexes is essentially the result of both the basicities and the steric factors of the amines.

It has been reported that 2-pyridinecarbonitrile readily gives the chelates of 2-pyridinecarboxamide or *O*-methylpyridine-2-carboximidate(MeOpy) upon heating with transition-metal ions, *e.g.*, Cu(II) or Ni(II), in water[2,3] or methanol[3] respectively. Although 2-pyridinecarbonitrile coordinates *via* the nitrogen atom of the pyridine ring to the metal ions, the nitrile group in the 2-position is presumed to have an interaction with the metal ions and to be easily attacked by the nucleophilic reagents, water or alcohols.

The amination of the nitrile group in $PtCl_2(CH_3CN)_2$ has been reported by Stephenson.[4] We tried the addition of amines to bis(2-pyridinecarbonitrile)copper(II) chloride in methanol. However, no amination products but the following three types of copper(II) complexes were obtained (Fig. 1); the complexes of Type



$CuCl_2$(MeOpy), Type I — $CuCl_2$(MeOpy)(Amine), Type II — $CuCl_2(MeOpy)_2$ Type III

Fig. 1. Three types of copper(II) complexes.

II and III were new ones. A brief note has been already reported.[5] In this paper, the relationship between the cause of the formation of the different types of complexes and their structures will be discussed.

Experimental

Preparation of Bis(2-pyridinecarbonitrile)copper(II) Chloride. Commercial 2-pyridinecarbonitrile was purified by recrystallization from ether; mp 26.5—27.5 °C. A dry methanol solution of 2-pyridinecarbonitrile(2 mol) was added to a dry methanol solution of copper(II) chloride dihydrate (1 mol) at 0 °C. The mixture was stirred vigorously to yield deep blue crystals. The crystals were immediately collected by filtration, and washed with ether. They were then dried over phosphorus pentoxide *in vacuo*. Found: C, 42.04; H, 2.48; N, 15.99; Cu, 18.45% Calcd for $CuCl_2(C_5H_4NCN)_2$: C, 42.06; H, 2.36; N, 16.35; Cu, 18.54%.

Reaction of Bis(2-pyridinecarbonitrile)copper(II) Chloride with Methanol and Various Amines. Bis(2-pyridinecarbonirile)-copper(II) chloride was suspended by stirring it in dry methanol at 0 °C, and then a methanol solution of an amine (1 or 2 mol) was immediately added to it. After the mixture had been stirred for 45—60 min at 0 °C, ether was added until bluish green crystals were precipitated; these crystals were then separated by filtration. They were instantly washed with ether several times and dried over silica gel *in vacuo*. All the products were obtained quantitatively. For recrystallization, the precipitates were dissolved in methanol, and ether was added until fine crystals were deposited. Since the recrystallization of ethylamine complex was not easy, its methanol solution was kept overnight at room temperature. The various complexes thus obtained are shown in Table 1, while the analytical data of the new complexes are given in Table 2.

$CuCl_2(NH_3)$(MeOpy)–No. 2– was also synthesized by means of the following method. At room temperature, ammonia gas was bubbled into 50 ml of a methanol solution containing 1.0 g of $CuCl_2$(MeOpy), No. 1. The reaction occurred immediately, and the color of the reaction mixture changed from bluish green to violet. Then the reaction mixture was concentrated to about 15 ml. The violet precipitates of the tetraamminecopper (II) chloride which had been initially deposited were filtered off, and pale blue $CuCl_2(NH_3)$-(MeOpy), crystals were obtained by adding ether to the filtrate. It was recrystallized from methanol ether mixture three times.

Instraments. The electronic and infrared spectra were obtained with Hitachi Recording Spectrophotometers, ESP-3T and EPI-G-2 respectively.

Results and Discussion

Absorption Spectra. The absorption spectra of the complexes synthesized are listed in Table 3. All the copper(II) complexes have d-d bands in the 12900—15000 cm^{-1}, $\log \varepsilon = 1.8$—2.0, while the bands of $\log \varepsilon = 3.85$ in the ultraviolet region (36600 cm^{-1}) are mainly due to the pyridine ring in the ligand. As for the infrared spectra of all the complexes, the bands of the

a) Ref. 2.

N–H stretching vibrations of amines or of the imidate group appeared at 3000—3300 cm^{-1}. The C–N stretching and antisymmetric C–O–C stretching vibrations of the imidate group appeared at about 1650 and 1380 cm^{-1} respectively.

The Formation of the Type I Complex. The complex of Type I, which is prepared by heating equimolar amounts of 2-pyridinecarbonitrile and copper(II) chloride in methanol, has already been reported by Barnard.[3] In our studies, it was also prepared easily when aniline or pyridine was added to a methanol solution containing an equimolar amount of bis(2-pyridinecarbonitrile)copper(II) chloride. However, by adding an excess of amine —but less than two moles—, a mixture of the Type I complex and the copper(II) complex of aniline or pyridine was obtained.

The Formation of the Type II Complexes. The complexes of Type II (Nos. 2—7, Table 1) were obtained by adding amines to a methanol solution of bis(2-pyridinecarbonitrile)copper(II) chloride. The amines used are shown in Table 1. The amount of amines employed was 1—2 mol for bis(2-pyridinecarbonitrile)copper(II) chloride. On the contrary, each aminecopper(II) complex was formed by employing more than two moles of amines. The difference in the composition of the Type II complexes from that of the other types is observed in the absorption spectra data (d-d bands, λ_{max}=14600—15000 cm^{-1}) in Table 3. In particular, the d-d band of No. 2 (Type II) was shifted to the range of shorter wavelengths and increased in its absorption intensity as compared with that of No. 1. This indicates the coordination of ammonia in the No. 2. From the infrared spectral data in Table 3, the bands of C–N stretching vibrations of the imino group (Nos. 2—7) are known to be shifted to the range of lower wave numbers than that of the Type I complex (1658 cm^{-1}). Accordingly, it is presumed that these shifts may be attributed to the coordination of various amines in the complexes.

The Formation of the Type III Complexes. The addition of trimethylamine, diethylamine, or triethylamine to bis(2-pyridinecarbonitrile)copper(II) chloride in methanol always afforded a complex of Type III, $CuCl_2(MeOpy)_2$. With regard to the ultraviolet absorp-

tion bands due to the ligand, MeOpy (in Table 3), the absorption intensity of No. 8 is about twice that of No. 1, hence, No. 8 obviously contains two molecules of MeOpy.

The Effect of Amines. It was concluded that 2-pyridinecarbonitrile coordinated to the copper(II) ion underwent alkoxylation and/or ligand-exchange reaction in the presence of various amines. However, the complex formations of the different types, from I to III, are mainly dependent on the basicities and steric factors of the amines used.

In the case of Type I complex formation, in the presence of a weaker base, such as aniline or pyridine, the interaction of the amine with the metal ion is not strong enough to form a mixed-ligand complex such as Type II. However, when a large excess of the amine was employed, only an amine complex was obtained by the ligand exchange (*e.g.* an aniline or pyridine copper-(II) complex).

It is conceivable that the distinction between the formation of Types II and III complexes is due mainly to steric effects between amines and the MeOpy group. The basicities of the amines belonging to Types II and III are similar (Table 1, pK_a). The amines which afford the complexes of Type II have little steric hindrance and easily coordinate to the metal ion by means of the ligand exchange. On the other hand, the amines which have bulky alkyl groups, *e.g.*, trimethylamine, diethylamine, and triethylamine, do not afford amine complexes by the steric hindrance; they only act as catalysts for the alkoxylation (Type III). In order to prepare a Type III complex without amines, it is necessary for the reaction mixture to be refluxed more than 5 hr.

Syntheses of *N,N'*-Bis(1-acetonylethylidene)ethylenediamine Complexes of Rare Earth Perchlorates

Norifumi YOSHIDA, Akira MATSUMOTO, and Jiro SHIOKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 28, 1973)

N,N'-Bis(1-acetonylethylidene)ethylenediamine(AEH_2) complexes were prepared by the reaction of hydrous rare earth perchlorates with AEH_2 in methanol. Elemental analysis, X-ray powder diffraction analysis, pH titration, IR and luminescence spectrometries indicated that the complexes of the lighter rare earths were $Ln(AEH_2)_4(ClO_4)_3$, where Ln are La, Pr, Nd, and Sm, while the complexes of the heavier rare earths were hydroxocomplexes, $Ln(AEH_2)_2(ClO_4)_2(OH)\cdot H_2O$, where Ln are Gd, Dy, and Er. Anhydrous gadolinium perchlorate was reacted with AEH_2 in methanol under anhydrous conditions to give $Gd(AEH_2)_4(ClO_4)_3$. It was possible that a water molecule played an important role in the complexation of rare earth perchlorates with AEH_2 in methanol. The formation of the hydroxocomplexes with AEH_2 was related to the low coordinating ability of the perchlorate ion and to the charge densities of the rare earth ions as well as to the basicity of AEH_2.

A number of the rare earth complexes with neutral ligands have been prepared in organic solvents to avoid the coordination of the water molecule.[1,2] In the case of highly basic ligands such as amines,[3,4] the complexes have been prepared under anhydrous conditions to prevent hydrolysis. The number of the given ligands attached to rare earth ions depends on the ionic radii of the rare earth ions and on the coordinating abilities of the anions.

N,N'-Bis(1-acetonylethylidene)ethylenediamine-(AEH_2) complexes have previously been prepared from the hydrous rare earth salts, such as chlorides, nitrates, and thiocyanates, in ethanol[5] or in a methanol–acetone mixture,[6] while the AEH_2 complexes of rare earth perchlorates have not been reported. The present paper will deal with the preparation of the complexes obtained by the reaction of AEH_2 with hydrous rare earth perchlorates and anhydrous gadolinium perchlorate in methanol. The AEH_2 complexes of the lighter rare earth perchlorates include more ligand molecules attached to the metal ion than those[5,6] of the lighter rare earth salts. The complexes obtained from hydrous, heavier rare earth perchlorates were hydroxocomplexes. Scarcely no hydroxocomplexes with neutral ligands are found in the literature.

Experimental

Materials. Rare earth oxides of a 99.9% purity were obtained from the Shin-etsu Chem. Ind. Co., Ltd. The hydrous rare earth perchlorates were prepared by dissolving a known amount of oxide in dilute perchloric acid and by then evaporating the mixture carefully on a hot plate. Anhydrous gadolinium perchlorate was obtained by heating the hydrate slowly up to 250 °C *in vacuo*.[3] The AEH_2 was prepared by the method shown in the literature.[7]

Preparation of Complexes Using Hydrous Rare Earth Perchlorates. The complexes were prepared by adding 10 ml of methanol containing an appropriate amount of AEH_2 (7 mM or 14 mM) to 15 ml of a methanol solution of rare earth perchlorate (3 mM). Lanthanum and praseodymium complexes were precipitated immediately. In the case of the other rare earths, the mixed solution was stirred for a few minutes and then allowed to stand overnight at room temperature to precipitate crystalline complexes.

Preparation of a Complex Using Anhydrous Gadolinium Perchlorate. The procedure was carried out in a dry nitrogen atmosphere. Anhydrous gadolinium perchlorate (*ca.* 3 mM) was dissolved in 15 ml of methanol, and then a small amount of the insoluble residue was filtered off. The filtrate was added to 10 ml of methanol including 14 mM of AEH_2, and the mixture was allowed to stand overnight at room temperature to give a crystalline product.

All the products were filtered, washed with methanol, and then dried *in vacuo*.

Elemental Analysis. A known amount of the complex was dissolved in dilute hydrochloric acid. The rare earth elements were determined gravimetrically.[8] The perchlorate ion was determined spectrophotometrically.[9]

Measurements. The IR spectra were recorded with a Perkin-Elmer 225 and a Hitachi EPI-L spectrophotometer. X-ray powder diffraction patterns were obtained with a Rigaku Denki diffractometer "Geiger-flex", using Ni-filtered Cu$K\alpha$ radiation. The luminescence spectra of the complexes and AEH_2 in the solid state excited at 260 nm were measured with a Hitachi MPF model 3 spectrophotometer. The pH was measured by a Hitachi-Horiba F-7 pH meter.

Results and Discussion

The analytical data listed in Table 1 indicate that the complexes obtained may be classified into two types—the 'D' type[6] including the complexes obtained from the hydrous, lighter rare earth (La, Pr, Nd, and Sm) and anhydrous gadolinium perchlorates, and the 'E' type including the complexes obtained from the hydrous, heavier rare earth (Gd, Dy, and Er) perchlorates. The formulas are estimated to be $Ln(AEH_2)_4(ClO_4)_3$ for the 'D' type and $Ln(AEH_2)_2(ClO_4)_2(OH)\cdot H_2O$ for the 'E' type on the basis of the analytical data and the data to be described hereinafter. The X-ray diffraction spectra shown in Fig. 1 also support the above classification into two types.

The pH titration curves for the two types of complexes are compared in Fig. 2. The pH value of the aqueous solution of the praseodymium complex (the 'D' type) varied little from the initial pH value upon the addition of a standard acid solution. On the other hand, the titration curve of the erbium complex (the 'E' type) shows a pH break which corresponds to *ca.* one equivalence of the acid. When the titration was continued, the pH titration curves of both 'D'- and

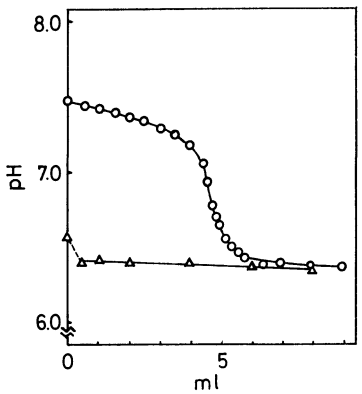

Fig. 2. Titration curves of complexes with 0.012 M HCl. —△—: Pr complex ('D' type), —○—: Er complex ('E' type).

'E' types leveled off at a pH value of *ca.* 6.4. An odor of acetylacetone was also detected; it seems to be caused by a decomposition of AEH_2 into acetyl-

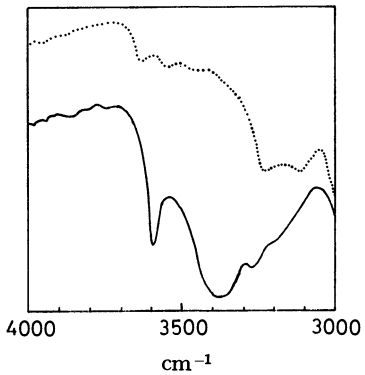

Fig. 3. Infrared spectra of gadolinium complexes in the OH and NH stretching region. ---------: 'D' type, ———: 'E' type

acetone and diazepine.[10,11] The results of the pH titration are considered to indicate that 'E'-type complexes contain a hydroxyl group.

The presence of the hydroxyl group in the 'E'-type complexes is also suggested by the IR absorption spectra. The IR absorption spectra of gadolinium complexes in the 3000—4000 cm^{-1} region are shown in Fig. 3. For the 'E'-type complex of gadolinium, a sharp band is observed at 3594 cm^{-1}. The corresponding bands are also observed at 3596 cm^{-1} for the dysprosium complex and at 3600 cm^{-1} for the erbium complex. These sharp bands are assignable to the OH stretching of the hydroxyl group. In other reports, a similar assignment has been made for the sharp absorption bands of the rare earth hydroxo-compounds, *e.g.*, at 3600—3610 cm^{-1} (hydroxides),[12] 3585—3620 cm^{-1} (hydroxo-oxides),[12] 3425—3550 cm^{-1} (hydroxocarbonates)[13] and 3588 cm^{-1} (neodymium azide).[14] The broad band at 3380 cm^{-1} of the 'E' type might arise from the OH stretching vibration of the inherent water of the complex.[15,16] On the other hand, the 'D'-type complex of gadolinium shows no absorption bands due to hydroxyl and water molecule.

In Fig. 3, the broad band at 3100—3300 cm^{-1} observed in both 'D'- and 'E'-type complexes indicates that hydrogen-bonded O–H···N or O···H–N groups are present in the complexes.[5,17] The IR absorption bands of the complexes in the region of the C=O, C=N, and C=C stretching vibrations[17] are summarized in Table 2. In the case of the thorium(IV) complex[18]

Table 2. Characteristic infrared absorption bands (cm^{-1}) of complexes and ligand

Ln	Type	(C=O)	(C=C) or (C=N)
La	D	1605s 1593sh	1542s 1496m

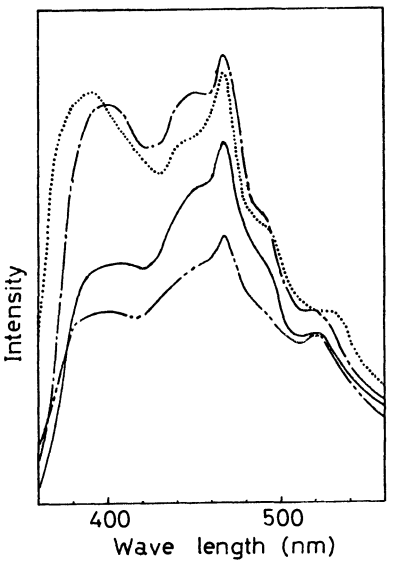

Fig. 4. Luminescence spectra of gadolinium complexes and AEH_2.
----: 'C' type complex, — — —: 'D' type complex, ———: 'E' type complex, ·····: AEH_2.

containing both neutral and ionic ligands, $Th(AEH_2)(AE)(NO_3)_2$, the absorption intensity of $\nu_{(C=O)}$ at 1600 cm^{-1} is rather weaker than those of $\nu_{(C=N)}$ and $\nu_{(C=C)}$. Since the absorption bands $\nu_{(C=O)}$ of both 'D'- and 'E'-type complexes are very strong, these complexes seem not to contain an ionic ligand such as AEH^- or AE^{2-}.

Furthermore, the luminescence spectra in the solid state of AEH_2 and three gadolinium complexes with AEH_2 were recorded in the 360—560 nm range. The results are shown in Fig. 4. The fluorescence of the terpositive gadolinium ion could not be observed in the visible region because of the ^6P level of Gd^{3+} being in the ultraviolet region (—32 kK).[19] The luminescence spectra of the three gadolinium complexes are quite similar to that of AEH_2. The close similarity in the luminescence spectra suggests that the ligand molecules in the 'D'- and 'E'-type complexes of gadolinium are neutral, as are those in the 'C'-type complex of gadolinium.

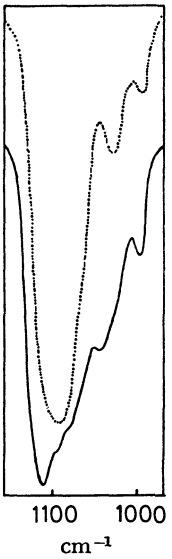

Fig. 5. Infrared spectra of complexes in the region of perchlorate absorption.
------: Pr complex ('D' type), ——: Dy complex ('E' type).

In Table 2, the $\nu_{(C=O)}$ bands of the 'D'-type complexes are found to split weakly into two peaks; this is not observed for the 'A'-, 'B'-, 'C'-, and 'E'-type complexes. The splitting suggests that the ligands in the 'D'-type complexes are coordinated and/or not coordinated with oxygen atoms.[20]

Figure 5 presents the IR absorption spectra assigned to perchlorate ions in the praseodymium and dysprosium complexes. The praseodymium complex shows two peaks in the 1100 cm^{-1} region. The perchlorate ion in the 'E'-type complexes appears to be coordinated weakly with the rare earth ions.[21]

Table 3. Metal-ligand stretching vibrations (cm^{-1})

Type	La	Pr	Nd	Sm	Gd	Dy	Er
D	418	418	418	422	422		
E					429	430	432

The bands assignable to the metal-ligand stretching vibrations[6] are listed in Table 3. The absorption frequencies of these bands increase in the order of the atomic numbers of the rare earths.

The number of the ligand molecules attached to a metal ion in the 'D'-type complexes is more than those of the AEH_2 complexes of the other lighter rare earth salts, such as chlorides, nitrates, and thiocyanates.[5] The increasing of the ligand molecules is probably due to the low coordinating ability of the perchlorate ion.[2]

Gadolinium perchlorate forms a 'D'-type complex under anhydrous conditions, while it forms an 'E'-type complex under hydrous conditions. Therefore, it is obvious that a water molecule plays an important role in the formation of hydroxo complexes ('E' type). Since the hydroxo complexes with AEH_2 are obtained only from the hydrous, heavier rare earth perchlorates, the increase in the charge densities of rare earth ions and the low coordinating ability of the perchlorate ion are considered to result from the formation of the hydroxide ion. The hydroxide ion, which has a strong tendency to coordinate toward rare earth ions,[2] seems to be produced from a water molecule in the complex cation of heavier rare earths, $[Ln(H_2O)_x(Solvent)_y]^{3+}$. Actually, the perchlorate ion is present in the outer coordination sphere, and the other anionic species are present in inner coordination sphere of rare earth ions in alcohol,[22,23] though the coordination of the perchlorate ion in the 'E'-type complexes can not be explained.

Consequently, it may be presumed that the formation of the hydroxo complexes ('E' type) is related to the low coordinating ability of the perchlorate ion and the charge densities of the rare earth ions as well as to the basicity of AEH_2.

(Received June 27, 1973)

The thermal decomposition of $[Cr(NH_3)_6](SCN)_3$, $[Cr(NCS)(NH_3)_5](SCN)_2$ and *cis*-$[Cr(NCS)_2(NH_3)_4]SCN$ in solid state was studied by isothermal as well as continuous temperature-rise methods. Under isothermal heating at 140 °C, $[Cr(NH_3)_6](SCN)_3$ changed stepwise to *cis,trans*-$[Cr(NCS)_3(NH_3)_3]$ through *trans*-$[Cr(NCS)_2(NH_3)_4]$-SCN, $[Cr(NCS)(NH_3)_5](SCN)_2$ turning to the *cis-trans* complex over the *trans* complex in the same manner as $[Cr(NH_3)_6](SCN)_3$. Under the continuous temperature-rise, $[Cr(NH_3)_6](SCN)_3$, $[Cr(NCS)(NH_3)_5](SCN)_2$ as well as *trans*-$[Cr(NCS)_2(NH_3)_4]SCN$ were found to be directly converted into *cis,trans*-$[Cr(NCS)_3(NH_3)_3]$.

The thermal decomposition of various chromium(III) compiexes has been extensively investigated.[2] As regard the thermal decomposition of several hexaamminechromium(III) halides, Wendlandt and Chou[3] reported that decomposition is initiated by the substitution reaction of a coordinated ammonia by halide ion in outer sphere, but gave no discussion on the structure of the decomposition products. Tanaka and Nagase carried out kinetic studies of the thermal decomposition reaction of $[Cr(NH_3)_6]Cl_3$, $[CrCl(NH_3)_5]Cl_2$, and *cis*-$[CrCl_2(NH_3)_4]Cl$ in solid state,[4] and proposed the following possible pathway for the deamminationanation reaction of these chromium(III) ammine complexes:

$[Cr(NH_3)_6]Cl_3$

↓

$[CrCl(NH_3)_5]Cl_2$

↓

trans-$[CrCl_2(NH_3)_4]Cl \overset{\text{isomerization}}{\rightleftharpoons}$ *cis*-$[CrCl_2(NH_3)_4]Cl$

↓

cis, trans-$[CrCl_3(NH_3)_3] \overset{\text{isomerization}}{\longleftarrow}$ *cis, cis*-$[CrCl_3(NH_3)_3]$

Recently, they made it clear that *trans*-$[CrCl_2(NH_3)_4]Cl$ is reversibly isomerized to the corresponding *cis*-form.[5]

So far systematic pathways for the thermal decomposition of the chromium(III) ammine isothiocyanato complexes are not known. Werner and Halben[6] obtained a pale rose insoluble product $[Cr(NCS)_3(NH_3)_3]$ by isothermal heating of $[Cr(NCS)(NH_3)_5](SCN)_2$ at 130—140 °C, but its geometrical structure has not been identified.

In order to examine the structural changes along with the thermal reaction pathways of the ammine chromium(III) thiocyanate, we have studied the decomposition reactions of $[Cr(NH_3)_6](SCN)_3$, $[Cr(NCS).(NH_3)_5](SCN)_2$, and *cis*-$[Cr(NCS)_2(NH_3)_4]SCN$ in solid state by the isothermal and the continuous temperature-rise methods. The structures of the decomposition products obtained upon heating were clarified by the measurement of their infrared and electronic spectra. Possible reaction pathways in the thermal reaction of these chromium(III) ammine complexes were proposed.

Experimental

Preparation of Complexes. Hexaamminechromium(III) thiocyanate, $[Cr(NH_3)_6](SCN)_3$, was prepared by adding potassium thiocyanate to the corresponding chloride obtained by the method in literature.[7]

Isothiocyanatopentaamminechromium(III) thiocyanate, $[Cr(NCS)(NH_3)_5](SCN)_2$, and *cis*-diisothiocyanatotetraamminechromium(III) thiocyanate, *cis*-$[Cr(NCS)_2(NH_3)_4]$-SCN, were prepared by the method given by Werner and Halben[6] and by Kyuno *et al.*[8] All the complexes were identified by elemental analysis and absorption spectral measurement.

trans-Diisothiocyanatotetraamminechromium(III) thiocyanate, *trans*-$[Cr(NCS)_2(NH_3)_4]SCN$, was prepared by the isothermal heating of $[Cr(NH_3)_6](SCN)_3$ at 140 °C for 10 min.

cis, trans-Triisothiocyanatotriamminechromium(III), *cis, trans*-$[Cr(NCS)_3(NH_3)_3]$, was prepared by the isothermal heating of $[Cr(NH_3)_6](SCN)_3$ at 140 °C for seven hours and was prepared by the known method.[6]

Isothermal Measurement. Isothermal measurement for these complexes was carried out in a Toyo Roshi Air Oven, the temperature of the sample being controlled within ±1 °C at 140 °C. In each run a 500 mg sample smaller than 200 mesh in size was weighed.

Continuous Temperature-rise Measurement. The continuous temperature-rise measurement was carried out with a Metrimpex Derivatograph Type-OD-102 and a Tokyo Koki thermobalance. Derivatographic measurement was made in a nitrogen stream under heating rate of 1 °C/min, 500 mg of the sample being used in each run. TG curve was obtained with the thermobalance in an open system under the heating rate of 1 °C/min for 500 mg of the sample. The results obtained by the above two instruments were in good agreement with each other.

Apparatus for Measurement. Molar conductivity, electronic and IR absorption spectra and X-ray diffraction were measured with a Yanagimoto conductivity-measuring equipment, a Hitachi EPU-2A spectrophotometer, a JASCO IR spectrophotometer DS-301 and with a Toshiba EO-60B X-ray Analyser, respectively.

Results and Discussion

Thermal Reaction of $[Cr(NH_3)_6](SCN)_3$ under Isothermal Heating at 140±1 °C. The starting yellow complex liberated two moles of ammonia in the initial stage of 10 min heating, turning to reddish orange. The molar conductivity of the product in a 5×10^{-3} M aqueous

Table 1. IR spectral bands of ammine-isothiocyanato chromium(III) complexes

	ν_{CH}	δ_{aNH_3}	δ_{SNH_3}	ρ_{NH_3}
$[Cr(NH_3)_6(SCN)_3]$	2050	1600	1310	766
$[Cr(NCS)(NH_3)_5](SCN)_2$	2050	1605	1290	730

$[Cr(NCS)_2(NH_3)_4]SCN$[a]	2050	1588	1263	722
$[Cr(NCS)_3(NH_3)_3]$	2050[b]	1599[b]	1270[b]	722[b]

δ_a: degenerate deformation, δ_S: symmetric deformation, ρ: rocking

a) Obtained from $[Cr(NH_3)_6](SCN)_3$ by isothermal heating. b) These values were in agreement with those obtained from $[Cr(NH_3)_6](SCN_3)$ by the continuous temperature-rise method.

solution was 125 ohm^{-1} cm^2/mol. This value corresponds to that of 1:1 valency type complex. Found: N, 33.13; C, 12.07; H, 4.06%. Calcd for $[Cr(NCS)_2(NH_3)_4]SCN$: N, 33.01; C, 12.24; H, 4.11%. The product is soluble in acetone, differing from *cis*-$[Cr(NCS)_2(NH_3)_4]SCN$ insoluble.

The wave numbers of some IR spectral bands are listed in Table 1 for the ammine-isothiocyanato chromium(III) complexes. We see that the thermal reaction product $[Cr(NCS)_2(NH_3)_4]SCN$ gives the absorption band assigned to the NH_3 symmetric deformation vibration at 1263 cm^{-1}, while the corresponding *cis*-form complex gives the corresponding band at 1292 cm^{-1}. The X-ray diffraction pattern of this compound was found to differ from that of *cis*-$[Cr(NCS)_2(NH_3)_4]SCN$.

The electronic spectral data of a series of ammine-isothiocyanato chromium(III) complexes are shown in

Table 2. Absorption maxima of chromium(III) complexes

$[Cr(NCS)_3(NH_3)_3]$[b]	19.3 (2.02)	25.5 (1.96)	30.9 (3.82)
$[Cr(NCS)_3(NH_3)_3]$[d]	19.3 (2.02)	25.5 (1.96)	30.8 (3.82)
$[Cr(NCS)_3(NH_3)_3]$[e]	19.3 (2.02)	25.5 (1.97)	30.8 (3.84)

a) obtained from $[Cr(NH_3)_6](SCN)_3$ by isothermal heating. b) obtained from $[Cr(NCS)(NH_3)_5](SCN)_2$ by isothermal heating. c) obtained from $[Cr(NH_3)_6](SCN)_3$ by continuous temperature-rise method. d) obtained from $[Cr(NCS)(NH_3)_5](SCN)_2$ by the continuous temperature-rise method. e) obtained from a) by the continuous temperature-rise method.

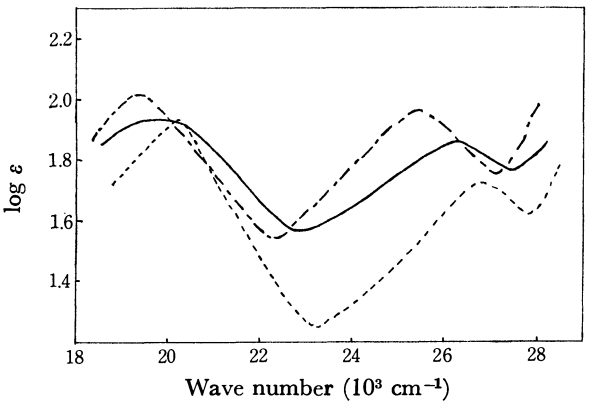

Fig. 1. The electronic spectra of $[Cr(NCS)_2(NH_3)_4]SCN$ (——) and $[Cr(NCS)_3(NH_3)_3]$ (– – –) obtained from $[Cr(NH_3)_6](SCN)_3$ by the isothermal heating along with that of cis-$[Cr(NCS)_2(NH_3)_4]$ SCN (------).

Table 2. The spectra of $[Cr(NCS)_2(NH_3)_4]SCN$ and $[Cr(NCS)_3(NH_3)_3]$, obtained by the isothermal heating of $[Cr(NH_3)_6](SCN)_3$ are given in Fig. 1 together with that of *cis*-$[Cr(NCS)_2(NH_3)_4]SCN$. It is seen that the spectra of $[Cr(NCS)_2(NH_3)_4]SCN$ specimens obtained from $[Cr(NH_3)_6](SCN)_3$ and $[Cr(NCS)(NH_3)_5](SCN)_2$ are in complete agreement with each other, and that they differ from the spectrum of *cis*-$[Cr(NCS)_2(NH_3)_4]SCN$.

It is concluded that the geometrical configuration of the thermal product formed by liberating two moles of ammonia from $[Cr(NH_3)_6](SCN)_3$ is *trans*-$[Cr(NCS)_2(NH_3)_4]SCN$.

The starting hexaammine complex liberated three moles of ammonia after seven hours heating with a color change to reddish purple. The product is soluble in acetone but not in water. Found: N, 30.67; C, 12.63; H, 3.34%. Calcd for $[Cr(NCS)_3(NH_3)_3]$: N, 30.30; C, 12.99; H, 3.25%. No composition change

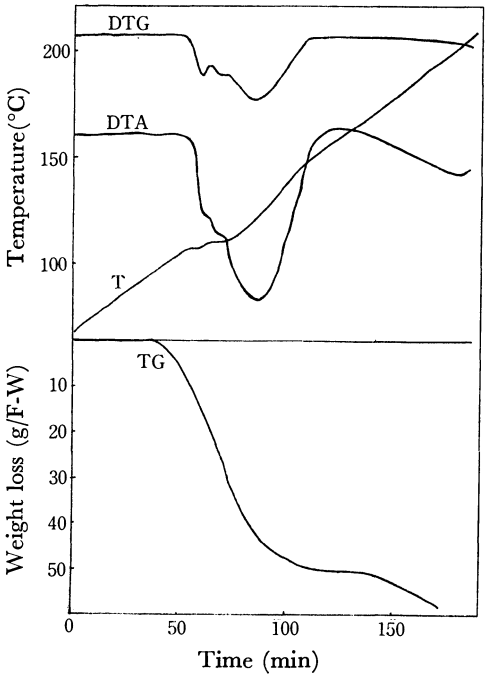

Fig. 2. The derivatogram for $[Cr(NH_3)_6](SCN)_3$.

took place even after heating for 11 hr. As the geometrical isomers of this product, either *cis-trans* or *cis-cis* configuration is possible. However, since the product at the first thermal decomposition step has a *trans*-configuration, it is likely that the product at the second step is *cis,trans*-$[Cr(NCS)_3(NH_3)_3]$. It is reasonable to consider that the *cis,cis*-configuration is less stable than the *cis,trans* one from the viewpoint of the steric hindrance, as has been reported by Tanaka and Nagase.[4]

Thermal Reaction of $[Cr(NH_3)_6](SCN)_3$ *under Continuous Temperature-rise.* The derivatogram of $[Cr(NH_3)_6](SCN)_3$ is shown in Fig. 2. The TG curve shows that the weight loss starts at 110 °C, and the weight remains almost constant untill 170 °C. The DTA curve gives an endothermic peak with two shoulders. The DTG curve also shows a similar feature to that of the DTA curve. The weight loss in the TG curve corresponds to the loss of three moles of ammonia. The analytical data of the product are as follows: Found: N, 29.68; C, 12.61; H, 3.33%. Calcd for $[Cr(NCS)_3(NH_3)_3]$: N, 30.30; C, 12.99; H, 3.25%.

The data listed in Tables 1 and 2 support the view that the product has *cis,trans*-configuration. It is obvious from the spectral data that *cis,trans*-$[Cr(NCS)_3(NH_3)_3]$ produced in the derivatograph is identical with the final product obtained by isothermal heating at 140 °C. The X-ray diffraction pattern also supports this conclusion. The shoulders and the peak in DTA can be attributed to the liberation of one and two moles of ammonia from the starting material, respectively. However, it can not be confirmed whether $[Cr(NCS)(NH_3)_5](SCN)_2$ is formed in the intermediate step or not.

Thermal Reaction of $[Cr(NCS)(NH_3)_5](SCN)_2$ *under Isothermal Heating at 140±1 °C.* The starting complex seems to change to *trans*-$[Cr(NCS)_2(NH_3)_4]SCN$ after eight minutes heating and finally to *cis,trans*-$[Cr(NCS)_3(NH_3)_3]$ as judged by the weight loss. But the stoichiometry was not complete. Even after 18 hr heating, the weight loss amounted to only 98% of two moles of ammonia. Werner and Halben[6] reported that $[Cr(NCS)_3(NH_3)_3]$ was obtained from $[Cr(NCS)(NH_3)_5](SCN)_2$ by isothermal heating (at 130—140 °C) for 30—40 hr. The results we obtained are not contradictory to theirs.

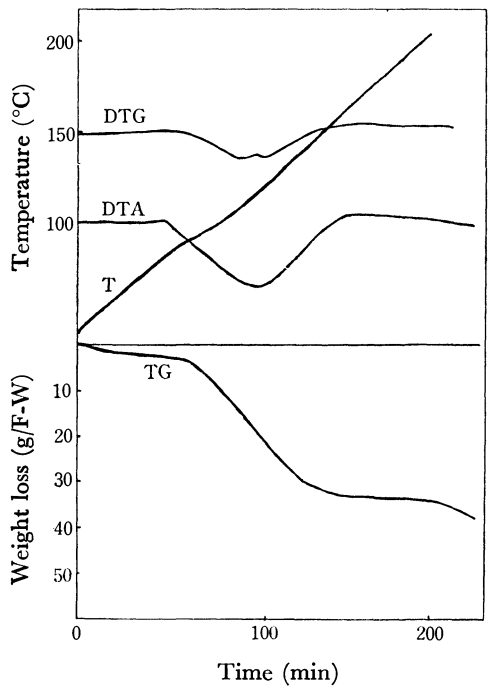

Fig. 3. The derivatogram for $[Cr(NCS)(NH_3)_5](SCN)_2$.

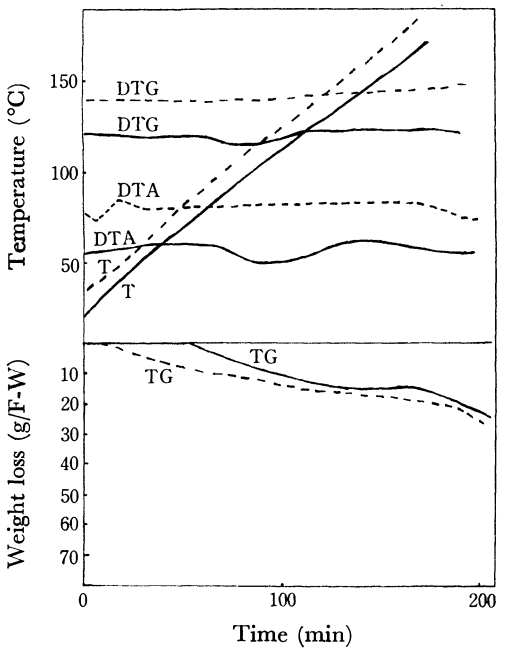

Fig. 4. The derivatograms for *trans*-$[Cr(NCS)_2(NH_3)_4]SCN$ obtained from $[Cr(NH_3)_6](SCN)_3$ by the isothermal heating (——) and *cis*-$[Cr(NCS)_2(NH_3)_4]SCN$ (------).

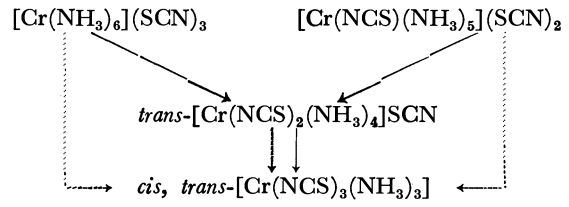
Thermal Reaction of $[Cr(NCS)(NH_3)_5](SCN)_2$ *under Continuous Temperature-rise.* The derivatogram of this complex is shown in Fig. 3. The TG, DTA, and DTG curves support an endothermal reaction one step. The weight loss corresponds to only 90% of two moles of ammonia. The result suggests that the reaction in the derivatograph is not completely stoichiometric and is similar to the isothermal reaction. The main product was confirmed to have a *cis,trans*-configuration from the spectral measurements.

Thermal Reaction of trans- *and* cis-$[Cr(NCS)_2(NH_3)_4]SCN$ *under Continuous Temperature-rise.* The derivatograms of these complexes are shown in Fig. 4. The thermal product obtained from the *trans* complex was identified by electronic spectra to be *cis,trans*-$[Cr(NCS)_3(NH_3)_3]$, whereas the configuration of the product obtained from the *cis* complex was difficult to be determined. For the *cis* complex, the derivatogram showed no distinct plateau corresponding to the weight loss of one mole of ammonia. The product obtained at the heating step by the thermobalance was not pure due to its hygroscopic character. The decomposition process of the *cis* complex must be a complicated one and the isomerization could not be clearly observed in both the isothermal measurement as well as the con-



(——) The isothermal reaction (at 140°±1°C)
(------) The continuous temperature-rising reaction (1 °C/min)

Fig. 5. The possible reaction processes of isothiocyanato-ammine chromium(III) complexes.

tinuous temperature-rise method. The results differ remarkably from those in the decomposition processes of *cis*-$[CrCl_2(NH_3)_4]Cl$ reported by Tanaka and Nagase.[4]

Possible decomposition reaction processes of a series of isothiocyanato-ammine chromium(III) complexes can be represented as shown in Fig. 5.

Infrared Spectra of Nitrosylplatinum (^{14}NO and ^{15}NO) Complexes

Eiichi Miki, Kunihiko Mizumachi, Tatsujiro Ishimori, and Hisateru Okuno
Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima, Tokyo 171
(Received September 3, 1973)

The ^{15}NO-complexes for *trans*-$[PtCl(NH_3)_4(NO)]Cl_2$, *trans*-$K_2[PtCl(NO_2)_4(NO)]$ and $M_2[PtX_5(NO)]$ (M=K and Cs, X=Cl and Br) were prepared. The effect of ^{15}N-substitution on infrared spectra indicated that the weak absorption band at *ca.* 290 cm^{-1} is assigned to the Pt-(NO) stretching vibration and the absorptoin band in the region 530—570 cm^{-1} to the Pt-(NO) bending vibration.

For transition-metal nitrosyl compounds, the isotopic effects of ^{15}N in the NO group on infrared spectra were measured. The isotopic shifts observed were compared with those calculated by a three-body model of the metal and the NO group. This method is found to be useful for assigning the skeletal vibrations between the metal and the NO group; the isotopic shift of the metal–(NO) stretching vibration is smaller than that of the metal–(NO) bending vibration.[1]

We have measured the isotopic shifts for ^{15}NO-substitution in *trans*-$[PtCl(NH_3)_4(NO)]Cl_2$, *trans*-$[PtCl(ND_3)_4(NO)]Cl_2$, *trans*-$K_2[PtCl(NO_2)_4(NO)]$ and $M_2[PtX_5(NO)]$ (M=K and Cs, X=Cl and Br). The Pt-(NO) binding states are discussed on the basis of the following: comparison of the infrared spectra with those for ammine- and chloro-complexes of Pt(II) and Pt(IV), the approximate force constant for the Pt-(NO) stretching vibration and the isotopic shift of the N–O stretching vibration upon ^{15}NO-substitution.

Experimental

Preparation of Nitrosylplatinum Compounds. The complexes were prepared by the method of Griffith *et al.*[2] Their ^{15}NO-complexes were prepared in a vacuum line with the use of ^{15}NO, ^{15}NO–$^{15}NO_2$, or $^{15}NOCl$ derived from 3—10 mmol of $K^{15}NO_3$ (^{15}N atom %=95—99.7). Nitrosyl chloride was prepared from nitric oxide and potassium chloride by the method of Ratcliffe.[3] The elementary analyses and IR spectra showed that the desired products were obtained.

trans-$[PtCl(NH_3)_4(NO)]Cl_2$: (A) By cooling with liquid nitrogen, 3 mmol of NO gas was trapped into a reaction vessel containing 0.3 mmol of $[Pt(NH_3)_4]Cl_2 \cdot H_2O$ in 10 ml of 6M hydrochloric acid. The reaction vessel was shaken in running water until the frozen solution was molten. Air was then introduced into the reaction vessel to instantly give green precipitates with shaking. The products were filtered out and dried under vacuum. $\chi_g = -0.27 \times 10^{-6}$ (c.g.s.). Found: Pt, 48.9; N, 17.5; H, 4.3; Cl, 25.2%. Calcd for $[PtCl(NH_3)_4(NO)]Cl_2$: Pt, 48.82; N, 17.53; H, 3.03; Cl, 26.62%. (B) Finely powdered $[Pt(NH_3)_4]Cl_2 \cdot H_2O$ (0.3 mmol) was stirred with 5 mmol of NOCl in 5 ml of freshly distilled chloroform for 70 hr at about 0 °C. Found: Pt, 49.5; N, 16.3; H, 2.9; Cl, 26.9%.

trans-$[PtCl(ND_3)_4(NO)]Cl_2$: 3 mmol of NO gas was trapped into a reaction vessel containing a solution prepared by adding 5 ml of concentrated hydrochloric acid to 0.3 mmol of $[Pt(NH_3)_4]Cl_2 \cdot H_2O$ in 5 ml of D_2O. Green products were obtained by the same produre as for *trans*-$[PtCl(NH_3)_4(NO)]Cl_2$. The IR spectra showed that deuteration was accomplished by hydrogen exchange with D_2O.

trans-$K_2[PtCl(NO_2)_4(NO)]$: This compound was synthesized with NOCl in a similar procedure to that for $[PtCl(NH_3)_4(NO)]Cl_2$. Found: K, 14.3; Pt, 36.7; N, 11.0%. Calcd for $K_2[PtCl(NO_2)_4(NO)]$: K, 14.96; Pt, 37.32; N, 13.40%.

$K_2[PtCl_5(NO)]$: $K_2[PtCl_4]$ (0.3 mmol) was stirred with 5 mmol of NOCl in 5 ml of freshly distilled chloroform for 50 hr at about 0 °C to convert it into olive green products. The products were washed with chloroform and dried under vacuum. Found: K, 16.3; Pt, 41.1; Cl, 38.5; N, 2.7%. Calcd for $K_2[PtCl_5(NO)]$: K, 16.57; Pt, 40.45; Cl, 36.75; N, 2.91%.

$Cs_2[PtCl_5(NO)]$: An aqueous solution of $K_2[PtCl_4]$ (1 mmol in 5 ml) was passed through a 5 cm column (1 cm diameter) of cation exchange resin, Diaion SK#1, in hydrogen form. CsCl (2 mmol) in 5 ml of H_2O was added to the effluent. NO–NO_2 gas was bubbled into the solution to give dark brown products. $\chi_g = -0.08 \times 10^{-6}$ (c.g.s.). To prepare the ^{15}NO-complex, 0.5 mmol of $K_2[PtCl_4]$ and 3 mmol of ^{15}NO–$^{15}NO_2$ gas were used. Found: Cs, 39.9; Pt, 29.3; N, 2.1; Cl, 26.4%. Calcd for $Cs_2[PtCl_5(NO)]$: Cs, 39.78; Pt, 29.20; N, 2.10; Cl, 26.53%.

$K_2[PtBr_5(NO)]$ (*contaminated with a large amount of* $K_2[PtBr_6]$): 5 mmol of NO gas was trapped with liquid nitrogen into a reaction vessel containing 1 mmol of $K_2[PtBr_4] \cdot 2H_2O$ in 3 ml of 1M hydrobromic acid. After the frozen solution was melted in running water, the solution was stirred for *ca.* 6 hr. $K_2[PtBr_6]$ formed was removed by filtration and the filtrate was added to 25 ml of ice-cooled ethyl alcohol to give dark brown powder. The product was washed with ether and dried in air. Stirring of NO with $K_2[PtBr_4] \cdot 2H_2O$ in hydrobromic acid over a long period gave only $K_2[PtBr_6]$. Found: N, 1.3; Br, 57.8%. Calcd for $K_2[PtBr_5(NO)]$: N, 1.99; Br, 56.85%.

The synthetic procedure for the complexes shows the possibility that nitro-complex contaminates the nitrosyl complex. However, infrared spectra showed no characteristic absorption bands of nitro-complex.

Apparatus. Infrared spectra were measured in the region 200—4000 cm^{-1} as Nujol mull and hexachlorobutadiene mull in sodium chloride and in polyethylene plates. The spectra at room temperature were recorded on JASCO DS-402G and JASCO model IR-F infrared spectrophotometers. The spectra of *trans*-$[PtCl(NH_3)_4(NO)]Cl_2$ and $K_2[PtCl_5(NO)]$ at liquid nitrogen temperature were measured *in vacuo* as Nujol mull on KRS-5 plates in the range *ca.* 300—600 cm^{-1} on a Hitachi EPI-L infrared spectrophotometer. The wave numbers of the observed bands were calibrated with polystyrene film, 1,2,4-trichlorobenzene and water vapour. The magnetic susceptibility was measured by the Gouy method.

$[PtCl(NH_3)_4(NO)]Cl_2$ prepared with the use of $NO-NO_2$ gas were almost the same as those prepared with NOCl.

Pt–NH_3 stretching vibration was expected in the region where the skeletal vibrations between the metal atom and the NO group are usually observed. This absorption band for *trans*-$[PtCl(NH_3)_4(NO)]Cl_2$ was ascertained on the basis of considerable isotopic shifts upon deuterium substitution and no isotopic shifts upon ^{15}NO-substitution. It was found that the band did not overlap with the bands due to the PtNO skeleton.

The wave numbers, isotopic shifts and assignments of infrared absorption bands due to the PtNO group of the examined complexes are shown in Table 1. The N–O stretching vibrations were observed in the region 1680—1730 cm^{-1}, the isotopic shifts upon ^{15}NO-substitution being 20—40 cm^{-1}.

Of the absorption bands in the region 200—700 cm^{-1}, only strong ones in the region 530—570 cm^{-1} shifted downwards by 10—15 cm^{-1} upon ^{15}NO-substitution for all the compounds. For $K_2[PtCl(NO_2)_4(NO)]$, the absorption bands in this region were broad and the isotopic shifts could not be measured exactly.

The infrared spectra at liquid nitrogen temperature showed that the bands in the region 530—570 cm^{-1} shifted downwards but did not split; the band at 575 cm^{-1} shifted to 565 cm^{-1} for $[PtCl(NH_3)_4(NO)]Cl_2$, that at 570 to 555 cm^{-1} for $[PtCl(ND_3)_4(NO)]Cl_2$, and that at 565 to 552 cm^{-1} for $K_2[PtCl_5(NO)]$. In the region other than 530—570 cm^{-1}, no isotopic shifts could be observed for $[PtCl(NH_3)_4(NO)]Cl_2$, $[PtCl(ND_3)_4(NO)]Cl_2$, and $K_2[PtCl(NO_2)_4(NO)]$. On the other hand, for $M_2[PtX_5(NO)]$ (M=K and Cs, X=Cl and Br) the weak absorption bands at about 290 cm^{-1} shifted downwards by 2—4 cm^{-1} (Table 1 and Fig. 1). Such absorption bands for the examined complexes except for $M_2[PtX_5(NO)]$ could not be observed because of the overlapping with the strong absorption bands due to the H_3N–Pt–NH_3 bending and the NO_2 rocking vibrations.

The IR study on $[MCl_5(NO)]^{n-}$ anion (M=Ru, Os, and Ir) by Cleare *et al.*[4] has shown that two or three M–Cl stretching, two or three Cl–M–Cl bending and (ON)–M–Cl bending vibrations are observed in the regions 280—340 cm^{-1}, 120—185 cm^{-1}, and 70—90 cm^{-1}, respectively. For $[MBr_5(NO)]^{n-}$ anion (M=Ru, Os, and Ir), M–Br stretching, Br–M–Br bending and (ON)–M–Br bending vibrations are observed in the regions 180—260 cm^{-1}, 120—140 cm^{-1}, and 60—90 cm^{-1}, respectively. No isotopic shifts upon ^{15}NO-substitution are shown for all of the absorption bands. The possibility of assigning the *ca.* 290 cm^{-1} bands to the (ON)–Pt–halogen bending vibrations can be excluded. Thus the weak bands at *ca.* 290 cm^{-1} and the strong bands at 530—570 cm^{-1} are considered to be assigned to the skeletal vibrations between the platinum and the NO group. The strong absorption band at 339 cm^{-1} with a shoulder at *ca.* 330 cm^{-1} and the broad 212 cm^{-1} band for $K_2[PtCl_5(NO)]$ can be assigned to the Pt–Cl stretching and the Cl–Pt–Cl bending vibrations, respectively. The 240 cm^{-1} band for $K_2[PtBr_5(NO)]$ can be assigned to the Pt–Br stretching vibration.

Calculation of Isotopic Shifts. No structural study on monomeric nitrosylplatinum complex has been reported. IR studies for the examined complexes show that the oxidation state of the platinum atom is considered to be IV and that of the NO group −I. X-ray diffraction studies on several nitrosyl complexes formulated as NO^- complexes have shown that the metal–(NO) bond angle is almost equal to 120° and the N–O bond distance is 1.1—1.2 Å.[5] The Pt–(NO) bond distance is considered to be 1.9—2.0 Å.[6]

Calculation of the ^{15}N-isotopic shifts by means of the three-body model of the metal atom and the NO group is useful for determining the coordination atom of the NO group and for assigning distinctly the skeletal vibrations between the metal and the NO group, when the metal atom and the ligands other than the NO group are much heavier than nitrogen and oxygen.[1] Thus the calculation is considered to be useful in the case of $K_2[PtCl_5(NO)]$ as well as $K_2[RuCl_5(NO)]$. The isotopic shifts were calculated with two angular three-body models, Pt–N–O and Pt–O–N (the metal–(NO) bond angle is 120°) and by assuming that the N–O distance is 1.1 Å and the Pt–(NO) distance 2.0 Å. The force constants f_{12} and f_{13} were assumed to be 0.2 mdyn/Å[1] (Table 2). The calculation was carried out with a Hitachi 5020E at the Computer Centre of the University of Tokyo.

The observed isotopic shifts, calculated ones and the force constants for $K_2[PtCl_5(NO)]$ are shown in Table 2. The wave numbers and isotopic shifts calculated from the bent Pt–N–O model were almost the same as those from the bent Pt–O–N one. Application of ^{15}NO-substitution to determine the coordinating atom of the NO group in the case of the NO^- complexes seems to be useless even though metal and ligands are much heavier than nitrogen and oxygen. From a comparison of the observed isotopic shifts with the calculated ones, the absorption bands observed in the region 530—570 cm^{-1} can be assigned to the Pt–(NO) bending vibration, and the *ca.* 290 cm^{-1} bands which could be observed on $M_2[PtX_5(NO)]$ (M=K and Cs, X=Cl and Br) to the Pt–(NO) stretching vibration. The *ca.* 290 cm^{-1} band is in the same region as that of the 259 cm^{-1} band which was assigned to the Co–(NO) stretching vibration for $Co(NO)(S_2CN(CH_3)_2)_2$.[1] The calculation shows that the isotopic shift for the Pt–(NO) stretching vibration is smaller than that of the Pt–(NO) bending vibration for the nitrosylplatinum complexes as observed on other nitrosyl complexes.[1]

Discussion

IR studies on ammine- and chloro-complexes have shown that the NH_3 rocking and the Pt–Cl stretching vibrations are sensitive to the oxidation state of the metal atom.[7,8] The NH_3 rocking vibrations of Pt(II)- and Pt(IV)-ammine complexes are observed in the region 810—840 cm^{-1} and *ca.* 940 cm^{-1}, respectively. The Pt–Cl stretching vibrations of Pt(II)- and Pt(IV)–chloro complexes are observed at *ca.* 320 and 340 cm^{-1}, respectively. For *trans*-$[PtCl(NH_3)_4(NO)]Cl_2$, the NH_3 rocking vibration and the Pt–Cl stretching vibration were observed at 918 and 350 cm^{-1}, respectively. The Pt–Cl stretching vibration of $K_2[PtCl_5(NO)]$ was observed at 339 cm^{-1}. This seems to support the view that the oxidation state of the platinum atom is IV and that of the NO group −I.

For $Ir(NO)Cl_2(P(C_6H_5)_3)_2$ and $[Co(NO)(NH_3)_5]Cl_2$ formulated as NO^- complexes, two skeletal vibrations between the metal and the NO group were observed in the region 560—620 cm^{-1}.[1] The Pt–(NO) bending vibration was observed in this region but the Pt–(NO) stretching vibration was observed at extraordinarily low wave numbers. An X-ray diffraction study on nitrosyl complexes by Mingos and Ibers[5] has shown that the N–O bond distance for nitrosyl complex formulated as NO^- complex is almost equal to that formulated as NO^+ complex, a multiple bond character existing in the NO group of the NO^- complex. This might reflect the suggestion that the Pt–(NO) bending vibration is left behind in the region 530—570 cm^{-1} where the skeletal vibrations between the metal and the NO

group would have been observed even though the Pt–(NO) stretching vibration shifts to *ca.* 290 cm^{-1}. The same phenomenon has been observed on octahedral cyanides. IR studies on $[M(CN)_6]^{n-}$ and $[M(CN)_5L]^{m-}$ have shown that bands at *ca.* 460—590 cm^{-1} and at *ca.* 340—420 cm^{-1} are assigned to metal–(CN) bending and metal–(CN) stretching vibrations, respectively, and that the stretching vibrations are in a lower region than the bending vibrations by *ca.* 50—150 cm^{-1}.[8]

If another possibility of overlapping of the Pt–(NO) stretching vibration with the strong absorption band assigned to the Pt–(NO) bending vibration exists, the *ca.* 290 cm^{-1} band might be assigned to one of the Pt–Cl stretching vibrations for $[PtCl_5(NO)]^{2-}$ anion, but a reasonable explanation cannot be given to the *ca.* 290 cm^{-1} band for $[PtBr_5(NO)]^{2-}$ anion.

Our recent study has shown that the isotopic shifts observed on the N–O stretching vibration for the NO^- complexes are smaller than those for the NO^+ complexes which are almost equal to those calculated by assuming the linear metal–N–O model.[1] Thus the extent of isotopic shift for N–O stretching vibration might be used as a measure for determining the oxidation state of the NO group. The isotopic shifts of the N–O stretching vibrations observed on the examined complexes are in the region 20—30 cm^{-1}, and the shift calculated by assuming a linear Pt–N–O model is 38 cm^{-1}. This seems to suggest a bent Pt–N–O linkage. The isotopic shift observed on $K_2[PtBr_5(NO)]$ was 43 cm^{-1}. The abnormally large value may be attributed to the change of Pt–(NO) bond angle due to the great size of the bromide ion in $[PtBr_5(NO)]^{2-}$ anion. However, no details can be given.

The force constants of the metal–(NO) stretching vibrations calculated by means of the three-body model are in the region 4—7 mdyn/Å. The approximate force constant of the Pt–(NO) stretching vibration for $K_2[PtCl_5(NO)]$ was calculated to be 1.3 mdyn/Å. This is considered to reflect the suggestion that the metal–(NO) bond distances for the NO^- complexes are generally longer than those for the NO^+ complexes.[5] The force constant for the Pt–(NO) stretching vibration is considered to be comparable to the force constants for the Pt–NH_3 stretching vibrations; for the Pt(II) and the Pt(IV)-ammine complexes, the force constants of the Pt–NH_3 stretching vibrations have been reported to be 1.92 and 2.13 mdyn/Å, respectively.[9]

For $M_2[PtX_5(NO)]$ (M=K and Cs, X=Cl and Br), the effects of outer sphere cations and halide ions on IR spectra were observed on the absorption bands due to the Pt–(NO) skeleton. The wave numbers of the N–O stretching, Pt–(NO) bending and Pt–(NO) stretching vibrations increase in the order Br and Cl for the potassium salts, and the wave numbers of the N–O stretching and Pt–(NO) stretching vibrations increase in the order Cs and K for the chloro-complexes. These tendencies were similar to those observed on the absorption bands due to the Ru–(NO) skeleton for $M_2[RuX_5(NO)]$ (M=K, Rb, and Cs; X=Cl, Br, and I).[10]

The authors wish to express their appreciation to Prof. Ichiro Nakagawa of Tohoku University and Mr. Yoshiyuki Morioka of the University of Tokyo for measurement of the IR spectra at liquid nitrogen temperature, and to Dr. Shigeru Nagashima and Mr. Akira Tamura for their technical assistance. The present work was supported in part by a Grant for Scientific Research from the Ministry of Education.

Derivatographic Studies on Transition Metal Complexes. XIII.[1] Thermal Decomposition of $[Ni(N_2H_4)_6]X_2$ Complexes[2]

Ryokichi TSUCHIYA, Masaaki YONEMURA,* Akira UEHARA, and Eishin KYUNO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received November 10, 1973)

The thermal decomposition of $[Ni(N_2H_4)_6]X_2$ (X=Cl, Br, I) in solid phase was investigated by means of derivatography and IR spectral measurement. It was found from the derivatography that the decomposition of the chloride and bromide proceeded *via* tris-, bis-, and mono-hydrazine complexes as metastable reaction intermediates, while tetra-hydrazine complex was produced in the decomposition of the iodide instead of the tris-one which appeared in the chloride and bromide. IR spectra showed that, although the hexa-hydrazine complex as a starting material contains only unidentate hydrazine coordinated by either one of terminal nitrogen atoms, all the reaction intermediates have bidentate one bridging between two nickel ions. In particular, it was of much interest that the decomposition of these hydrazine complexes was remarkably exothermic, a part of the reasons being discussed.

Systematic studies on thermal decomposition in solid phase for [Ni(II)N_6]-type complexes seem to be still rare except for $[Ni(NH_3)_6]X_2$.[3] Tanaka *et al.*[4] proposed from the thermogravimetry for hexaammine-nickel(II) complexes that it decomposed in two or three steps through lower ammine intermediates $NiX_2 \cdot n NH_3$: n=2, 1 for X=Cl; n=2 for X=Br, I and n=4 for X=NO_3.

Because of d^8 electronic configuration in nickel(II) ion, the tendency of the complex formation of either octahedral (O_h symmetry) six-coordinated, square planar (D_{4h}) or tetrahedral (T_d) four-coordinated structure apparently could exist depending upon the changes in trivial steric hindrance or the nature of surroundings for the central metal ion.[5,6] In the thermal decomposition of hexaamminenickel(II) complexes described above, however, the latter two forms, square planar and tetrahedral, could not be found, but the intermediates were presumed to be polymers from the diffuse reflectance spectral measurement in which nickel ions were octahedrally coordinated with ammonia molecules and bridging halogen atoms.

Hydrazine (NH_2NH_2), in general, behaves either as unidentate ligand coordinated by either one of terminal nitrogen atoms or as bidentate one bridging between two metals[7-9] because of the difficulty of the formation of bidentate coordination with a same metal ion owing to its short N–N distance despite of keeping two nitrogen atoms capable of coordinating to metal in one hydrazine molecule itself.

From these standpoints, hydrazine may be expected to form the complex like [NiN_6]-type. On the other hand, the thermal decomposition of the complexes of nickel(II),[10] iron(II),[11] and cobalt(II)[12] oxalates with hydrazine had been investigated.

Thus, as the object of the present work, it was undertaken to find whether or not the nickel(II) complexes with hydrazine undergo the analogous structural transformation to that of hexaamminenickel(II) complexes in the course of thermal decomposition, and whether or not any unique changes can be found in terms of the peculiar behavior of hydrazine to coordination form as described above.

* Present address: Matsushita Denki Sangyo Co. Ltd., Yamato-koriyama, Nara.

Experimental

Preparation of Complexes. Complexes $Ni(N_2H_4)_6X_2$ (X=Cl, Br, I) were prepared in the similar manner to that described in the literature.[13] Compounds of $Ni(N_2H_4)_3X_2$ type as well as $Ni(N_2H_4)_2X_2$ type were also obtained by the known method[8] to identify the corresponding intermediates in the thermal reaction of hexehydrazinenickel(II) complexes. Their chemical formulae were determined by elemental analysis and spectral measurement.

Derivatographic Measurements. The derivatograms were obtained with a MOM Derivatograph Typ-OD-102. All the measurements were carried out in a constant flow of nitrogen stream under the heating rate of 1 °C/min. In each run 0.4 or 0.5 g sample was used. The thermal functions, activation energies (E_a) and enthalpy changes (ΔH), were calculated in each step of thermal reaction by analyzing the DTA curves in the derivatograms obtained.[14]

Spectral Measurements. In order to examine the structural change or bonding feature of the reaction intermediates during the course of the thermal decomposition, the reaction intermediates were taken out of a furnace at various desired temperatures during the continuous heating by a Shimadzu TM-1A thermobalance and their electronic and infrared absorption spectra were measured with a Hitachi EPS and EPU-2A spectrophotometers in both solution and powder state and with a JASCO Model IR-E spectrophotometer in mull state, respectively.

Magnetic Measurements. The effective magnetic moments of the samples as well as the reaction intermediates were evaluated from the magnetic susceptibilities of the sample corrected by applying the Pascal's constant of the elements involved.

X-Ray Powder Diffraction. X-ray powder diffraction patterns of the sample and its thermal reaction intermediates were obtained with a Rigaku-denki Geiger-flex X-ray Analyzer.

Results and Discussion

Derivatography. When $Ni(N_2H_4)_6X_2$ (X=Cl, Br) was heated in solid phase, the decomposition accompanying the liberation of hydrazine took place stepwise with some color changes. Figure 1 shows the derivatograms for the chloride and bromide.

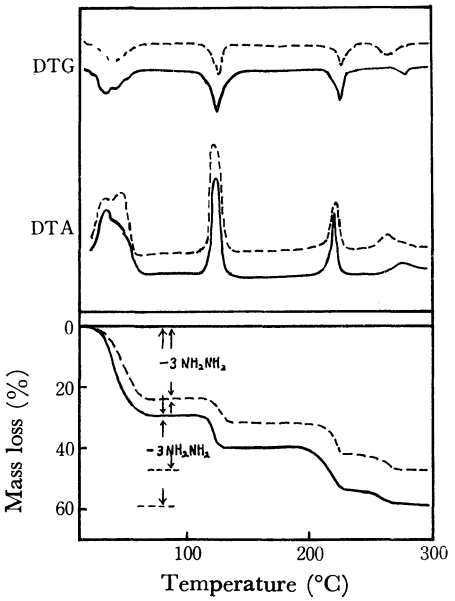

Fig. 1. Derivatograms for $Ni(N_2H_4)_6Cl_2$ (——) and $Ni(N_2H_4)_6Br_2$ (------).

As seen in this figure, two reaction intermediates formed as the result of the evolution of three and four moles of hydrazine are obviously detected successively in the TG curves up to 60 °C and in the temperature range of 100—140 °C, respectively, being confirmed to have the compositions, $Ni(N_2H_4)_3X_2$ (X=Cl, Br) and $Ni(N_2H_4)_2X_2$, by the electronic and IR spectra which will be described in the later sections. The further heating of these compounds leads to the decomposition to nickel(II) halides as the final products at 240—320 °C *via*, as a whole, the formation of monohydrazine complexes, $Ni(N_2H_4)X_2$ (Cl, Br), at 190—230 °C as the third reaction intermediates.

The DTA curves show one broad and two sharply exothermic peaks in the three decomposition steps, $Ni(N_2H_4)_6X_2$ to $Ni(N_2H_4)_3X_2$, $Ni(N_2H_4)_3X_2$ to $Ni(N_2H_4)_2X_2$ and $Ni(N_2H_4)_2X_2$ to $Ni(N_2H_4)X_2$, and a small exothermic peak in the last step of the decomposition to nickel(II) halides.

Although the evolution of ammonia or water molecules in the thermal decomposition of aquo or ammine cobalt(III) or chromium(III) complexes gives, in general, endothermic peak,[14,15] an appearance of exothermic peaks as mentioned above is of much interest. Such a phenomenon will be attributed to the characteristic properties of hydrazine, and the discussion concerned will be briefly made in the later section.

In the case of the iodide, on the other hand, the tetrahydrazine complex was found in place of tris(hydrazine) complex in the case of chloride and bromide, and bis(hydrazine) complex undersent the complete decomposition without the formation of monohydrazine complex as shown in Fig. 2: the two decomposition steps, hexa-to-tetra and tetra-to-bis complex, appear at about 30—85 °C and at 100—135 °C, respectively, and the final decomposition occurs at 240—290 °C. The most striking difference between the chloride, bromide and iodide is that, in the former two, the final decomposition product is nickel(II) halides, whereas the iodide finally decomposes without the formation of nickel(II) iodide. It may be in part due to the essential decomposition with iodine liberation.

Magnetic Susceptibilities. The effective magnetic moments evaluated from the magnetic susceptibilities of the hexahydrazine complexes and their thermal reaction intermediates are listed in Table 1 together with their colors.

The complexes $Ni(N_2H_4)_6X_2$ (Cl, Br) did not give a constant value on account of the sensitivity of the composition in air exposure, and hence are expressed as paramagnetic. That the complexes, $Ni(N_2H_4)_3X_2$ and $Ni(N_2H_4)_2X_2$, give the magnetic moments corresponding to the electronic structure with two free spins suggests that their structures are not, at least, the square planar. The values for the iodide could not be obtained because of the comparative instability against the chloride and bromide.

Electronic Spectra. In order to clarify the coordination structures of the hexahydrazinenickel(II) complexes, $Ni(N_2H_4)_6X_2$, and their thermal reaction intermediates, their electronic spectra were measured in the powdered state by the diffuse reflectance method, which are shown in Fig. 2 for the chloride, in Fig. 3 for the bromide and in Fig. 4 for the iodides.

As seen in these figures and in Table 1, tris(hydrazine)nickel(II) chloride, $Ni(N_2H_4)_3Cl_2$, and the bromide, $Ni(N_2H_4)_3Br_2$, and tetra-hydrazine iodide, $Ni(N_2H_4)_4I_2$, as well as the hexahydrazinenickel(II)

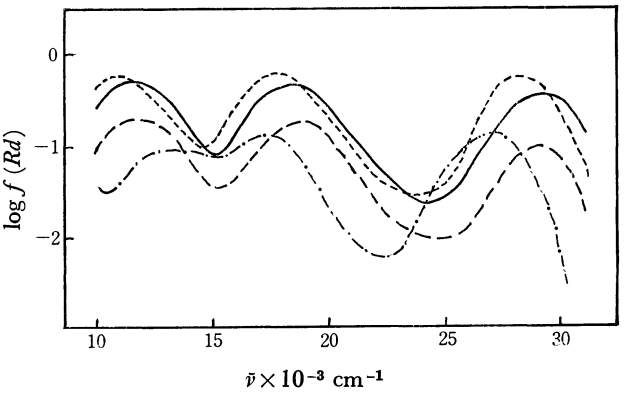

Fig. 2. Electronic spectra of $[Ni(N_2H_4)_6]Cl_2$ (——), $Ni(N_2H_4)_3Cl_2$ (– – – –), $Ni(N_2H_4)_2Cl_2$ (— – —), and $[Ni(NH_3)_6]Cl_2$ (-------).

Table 1. Magnetic moments (25 °C) and colors of $[Ni(N_2H_4)_n]X_2$

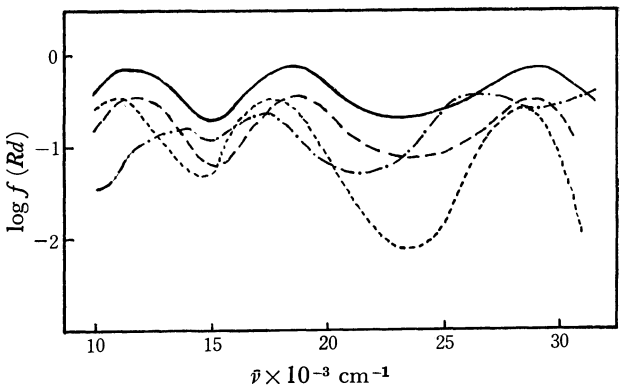

Fig. 3. Electronic spectra of $[Ni(N_2H_4)_6]Br_2$ (——), $Ni(N_2H_4)_3Br_2$ (----), $Ni(N_2H_4)_2Br_2$ (— — —) and $[Ni(NH_3)_6]Br_2$ (-------).

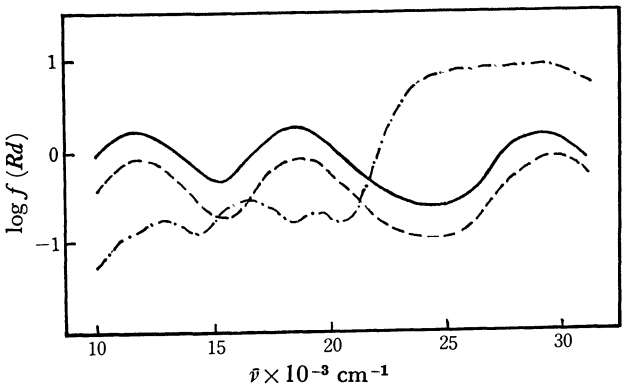

Fig. 4. Electronic spectra of $[Ni(N_2H_4)_6]I_2$ (——), $Ni(N_2H_4)_4I_2$ (----) and $Ni(N_2H_4)_2I_2$ (— — —).

complexes as the starting materials are all pale violet in color, and their spectra are in approximate agreement with each other in the chlorides, bromides and iodides, respectively. These facts exhibit that these complexes have commonly the same $[NiN_6]$-type coordination structure.

In the bis-type complexes, $Ni(N_2H_4)_2X_2$, on the other hand, the spectra assigned to $^3T_{2g}\leftarrow{}^3A_{2g}$, $^3T_{1g}\leftarrow{}^3A_{2g}$, and $^3T_{1g}(P)\leftarrow{}^3A_{2g}$ are found to slightly shift to the longer wavelength region than that of hexahydrazine complexes without the remarkable change of the spectral form. These shifts are understood to be attributed to the substitution of the ligand hydrazine by halide ions in the lower position of the spectrochemical series, and they support the color change to pale blue for the chloride, grayish blue for the bromide and yellowish green for the iodide from yellow in the starting complexes upon heating, in a similar manner in the case of heating $Ni(NN\text{-}deen)_2Cl_2\cdot 2H_2O$(NN-deen=*N*,*N*-diethylethylenediamine), where two chloride ions existing as a counter ion anate by entering the coordination sphere after the liberation of water.[5]

IR Spectra. Closely related to the structural determination from electronic spectra, it may be very important to know whether the hydrazine coordinates as unidentate or as bidentate ligand bridging between two nickel ions from IR spectral measurement in the course of thermal reaction. Above all, the strikingly decisive factor for the above informations is the N–N stretching vibration, ν_{N-N}.

It is well known that the vibration ν_{N-N} in the hydrazine coordinated as unidentate ligand by either one of terminal nitrogen atoms appears in the 920—940 cm^{-1} region with considerably high intensity, whereas in the hydrazine coordinated as bidentate ligand bridging between two metal ions, the ν_{N-N} frequency is expected to shift to higher wave number side, lying in the 960—985 cm^{-1} region.[8,9] Therefore, the ν_{N-N} frequency mentioned above is thought to be the most immediately useful identification method which type of coordinated hydrazine are contained in the complexes.

The IR spectra of the hexahydrazinenickel(II) complexes and their thermal reaction intermediates were given in Fig. 5.

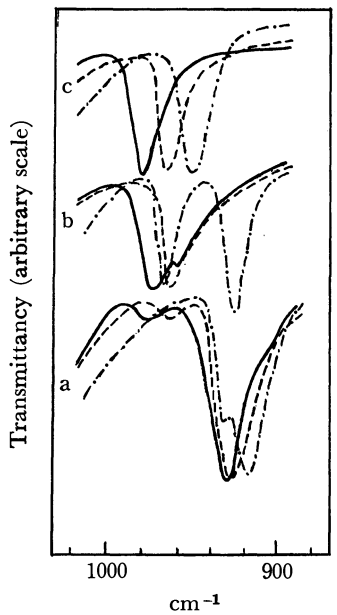

Fig. 5. IR spectra of (a) $[Ni(N_2H_4)_6]X_2$, (b) $Ni(N_2H_4)_4X_2$ (X=I) and $Ni(N_2H_4)_3X_2$ (X=Cl, Br) and (c) $Ni(N_2H_4)_2X_2$.
—— chloride, ---- bromide, — — — iodide

As seen in this figure, the N–N stretching vibration are found at around 932, 928, and 936(sh)—915 cm^{-1} for the chloride, bromide and iodide of $[Ni(N_2H_4)_6]X_2$ complexes as starting materials, respectively. These facts indicate that all the hydrazine molecules coordinate to central nickel(II) ion as unidentate ligand with either one of terminal nitrogen atoms in these type complexes. In $Ni(N_2H_4)_3X_2$ type complexes of the first reaction intermediates, on the other hand, the ν_{N-N} band is shifted to 968 cm^{-1} for the chloride and 966 cm^{-1} for the bromide, respectively.

Upon heating $[Ni(N_2H_4)_6]I_2$, the original peak, 936—915 cm^{-1}, is diminished gradually and a new peak at 966 cm^{-1} grows strong until $Ni(N_2H_4)_4I_2$ is formed, with the liberation of two moles of hydrazine. These facts suggest that tris(hydrazine)nickel(II) chloride and bromide contain bidentate bridging hydrazine alone, while the tetrahydrazinenickel(II) iodide does both unidentate terminal and bidentate bridging hydrazine as ligands.

In the bis(hydrazine)nickel(II) chloride and bromide as the second reaction intermediates, the ν_{N-N} band is observed at around 980 and 966 cm^{-1}, respectively, as the same as the corresponding tris complexes, and in the bis(hydrazine)nickel(II) iodide, only the band at 966 cm^{-1} remains, the band at a around 930 cm^{-1} being quenched. These results indicate that all the hydrazines are the bidentate bridging ligand.

It was concluded, therefore, from the information shown by IR spectra as above along with no color change in the first reaction step for $[Ni(N_2H_4)_6]X_2$ to tris(hydrazine)nickel(II) chloride and bromide or to tetrahydrazinenickel(II) iodide that these processes are "Dehydrazination-Bridging" reaction, and from the electronic spectra that the second step reactions are "Dehydrazination-Anation."

X-Ray Powder Diffraction Pattern. The structural determination of $[Zn(N_2H_4)_2]Cl_2$ has been done by X-ray diffraction method.[16] The powder patterns of $Ni(N_2H_4)_2Cl_2$ and $Ni(N_2H_4)_2Br_2$ obtained in the present work were similar to that of the corresponding Zn(II) complex, as shown in Fig. 6. Therefore, they seem to have isostructure, which is also supported by the spectral measurements.

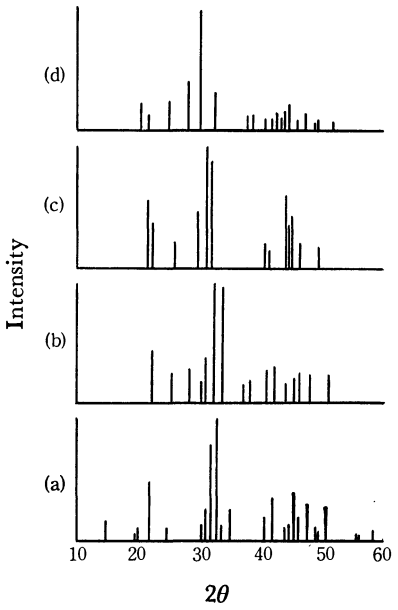

Fig. 6. X-ray diffraction patterns of (a) $ZnCl_2(NH_2-NH_2)_2$, (b) $NiCl_2(NH_2NH_2)_2$, (c) $NiBr_2(NH_2NH_2)_2$ and (d) $NiI_2(NH_2NH_2)_2$.

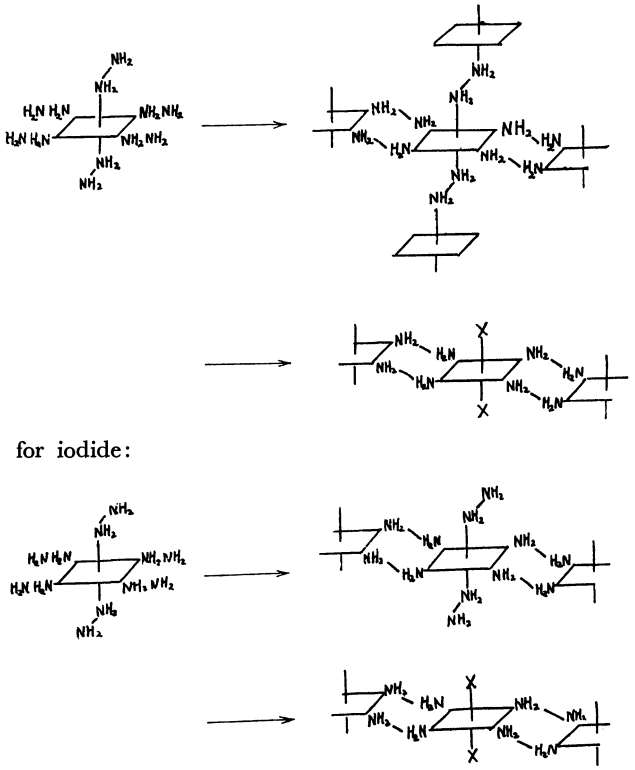
In the case of $Ni(N_2H_4)_2I_2$, however, the powder pattern may be somewhat different from those of the chloride and bromide. Although details on the structure except by the informations in the electronic and IR spectra are still unknown the tetra-, tris-, and bis-(hydrazine) type complexes probably have polymer structures.

Summarily, on the basis of the experimental results obtained above, the thermal reactions of hydrazine complexes are presumed to be portrayed by the following schemes:

for chloride and bromide:



for iodide:

Thermochemical Functions. The values of the enthalpy changes (ΔH) and the activation energies (E_a) were calculated from the derivatograms, which are summarized in Table 2, along with the temperatures of each decomposition step.

As shown in derivatograms and in Table 2, the striking feature appearing in the hydrazine complexes treated in the present work is great exothermicity in the dehydrazination in contrast to the endothermicity in the general dehydration. This abnormal character may be considered to be in part attributed to the following reaction predicted to occur in the dehydrazination process.

Table 2. Thermochemical functions for decomposition of $[Ni(N_2H_4)_6]X_2$ (X=Cl, Br)

Decomposition step		Complex	
		$[Ni(N_2H_4)_6]Cl_2$	$[Ni(N_2H_4)_6]Br_2$
$Ni(N_2H_4)_6X_2$ to $Ni(N_2H_4)_3X_2$	T(°C)[a]	−60	−50
	ΔH[b]	−20.5	−18.6
	E_a[c]	—	—
$Ni(N_2H_4)_3X_2$ to $Ni(N_2H_4)_2X_2$	T(°C)	100—140	110—140
	ΔH	−19.6	−13.7
	E_a	46.5	43.8
$Ni(N_2H_4)_2X_2$ to $Ni(N_2H_4)X$	T(°C)	190—230	190—230
	ΔH	−16.8	−8.5
	E_a	26.3	33.7
$Ni(N_2H_4)X_2$ to NiX_2	T(°C)	240—320	250—310
	ΔH	−16.7	−8.6
	E_a	—	—

a) Decomposition temperature. b) kcal per one mole of hydrazine liberated. c) kcal per one mole of complexes.

If hydrazine is decomposed by the following mode,

$$NH_2NH_2\,(g) = 4/3NH_3\,(g) + 1/3N_2\,(g),$$

the enthalpy change is expected as $\Delta H_1 = -36.77$ kcal/mol.[17] On the other hand, the enthalpy change of deammonation in the reaction,

$$Ni(NH_3)_6Br_2\,(s) = Ni(NH_3)_2Br_2\,(s) + 4NH_3\,(g),$$

is known as $\Delta H_2 = 15.79$ kcal/mol,[18] which is assumed to be equal to the energy required to break the bond between nickel(II) ion and four nitrogen atoms.

$$Ni(NH_2NH_2)_3Br_2\,(s) = Ni(NH_2NH_2)_2Br_2\,(s) + 4/3NH_3\,(g) + 1/3N_2\,(g),$$

Therefore, for example, the enthalpy change of the thermal decomposition of tris(hydrazine)nickel(II) bromide is calculated as $\Delta H = \Delta H_1 + 2\Delta H_2 = -5.19$ kcal/mol. Although this value is relatively lower than the observed value, $\Delta H = -13.7$ kcal/mol in Table 2, the exothermicity can be, to some extent, explained by the results calculated as above.

Reactions of Bis(acetylacetonato)palladium(II) with Triphenylphosphine and Nitrogen Bases

Shigeru BABA, Tetsuya OGURA, and Shinichi KAWAGUCHI*

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi, Osaka 558

(Received November 12, 1973)

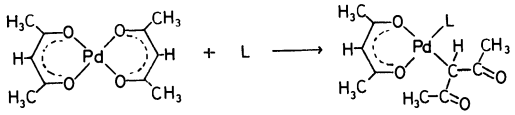
Bis(acetylacetonato)palladium(II) reacts with triphenylphosphine and nitrogen bases such as pyridine, diethylamine, and *N*-methylbenzylamine to transform one of the chelating ligands into the carbon-bonded state. The product complexes of the type $Pd(acac)_2L$ have been isolated in high yields and characterized by IR and NMR spectra. Several reactions of $Pd(acac)_2PPh_3$ and $Pd(acac)_2py$ were also examined.

Acetylacetone is a very versatile ligand showing various modes of bonding to metal atoms.[1] Most usually the acetylacetonate anion coordinates to a metal atom *via* the two oxygen atoms, forming a six-membered chelate ring.[2] The unidentate linkage *via* the central carbon atom is also well known for platinum(II) and other rather soft metal ions,[3] but no example of carbon-bonded palladium(II) complexes of acetylacetone has yet been reported.

The complex $K[PtCl(acac)_2]$ was prepared by Werner[4] in 1901 by the reaction of $K_2[PtCl_4]$ with potassium acetylacetonate in aqueous solution, and was shown by X-ray crystal analysis[5] to have one carbon-bonded and one oxygen-bonded ligands. On the other hand, similar reactions of $K_2[PdCl_4]$ with acetylacetonate anions under various conditions produce only the simple chelate $Pd(acac)_2$.[3] However, in our study of the reaction between $Pd(acac)_2$ and triphenylphosphine in benzene to prepare $Pd(PPh_3)_4$, the carbon-bonded acetylacetonate complex $Pd(acac)_2(PPh_3)$ was obtained as a stable intermediary product.[6] This paper reports the preparation and characterization of several palladium(II) complexes containing the carbon-bonded acetylacetonate ligand.

Results and Discussion

Preparation. Bis(acetylacetonato)palladium(II), $Pd(acac)_2$, reacts with excess triphenylphosphine in benzene at room temperature to produce $Pd(PPh_3)_4$ or $PdO_2(PPh_3)_2$ in the absence or presence of oxygen, respectively. However, an equimolar amount of triphenylphosphine gave a carbon-bonded acetylacetonate complex, $Pd(acac)_2(PPh_3)$ [**1a**], in a high yield. Nitrogen bases such as pyridine, diethylamine, and *N*-methylbenzylamine also reacted with $Pd(acac)_2$ to transform one of the chelating ligands into the carbon-bonded state (Eq. (1)). The analytical data of the products are summarized in Table 1.



(1)

L=PPh_3[**1a**], Py[**1b**], $NHEt_2$[**1c**], or $NH(Me)CH_2Ph$[**1d**]

Triphenylarsine and benzonitrile did not react with $Pd(acac)_2$. Either twice as many moles of triphenylphosphine or excess nitrogen bases did not afford the palladium(II) complex containing two carbon-bonded acetylacetonate ligands, but resulted in the compounds **1** alone. The bidentate bases such as 1,2-bisdiphenylphosphinoethane, 2,2′-bipyridine, 1,10-phenanthroline, ethylenediamine, and *N*,*N*′-dimethylethylenediamine did not produce the aimed compounds, either. It is not yet clear why the palladium(II) complex containing two carbon-bonded acetylacetonate ligand can not be obtained, but the existence of one acetylacetonate chelate ring might be necessary to stabilize the carbon-bonding of the other acetylacetonate ligand.

Infrared and NMR Spectra. The characteristic stretching vibrations in the carbon-bonded acetylacetonate complexes are summarized in Table 2. The ν(C=O) and ν(C=C) bands of the chelating acetylacetonate ligand appear in the 1500—1600 cm^{-1} region, and the absorption bands in the 1600—1700 cm^{-1} region which are not observed for $Pd(acac)_2$ can be unequivocally assigned to the ν(C=O) vibrations of the carbon-bonded acetylacetonate ligand.[7] The strong band which is observed in the 500—550 cm^{-1} region

can be attributed to the ν(Pd–C) vibration.

The coexistence of one oxygen-chelating and one carbon-bonded acetylacetonate ligands in the complexes **1a**—**1d** is clearly revealed by the proton NMR spectra listed in Table 3. The NMR spectra of platinum(II) complexes containing the carbon-bonded acetylacetonate ligand have been studied extensively by Lewis and his co-workers,[8] and are referred to here in assigning the present spectra.

In a spectrum of $Pd(acac)_2PPh_3$ [**1a**] three methyl-proton signals are observed each as a singlet at 8.46, 7.96, and 7.86 τ with the intensity ratio of 1 : 1 : 2. The lowest-field peak is assigned to the two methyl groups of the carbon-bonded acetylacetonate ligand, indicating

Table 3. NMR data recorded at 60 MHz in $CDCl_3$ (τ Values relative to internal TMS)[a]

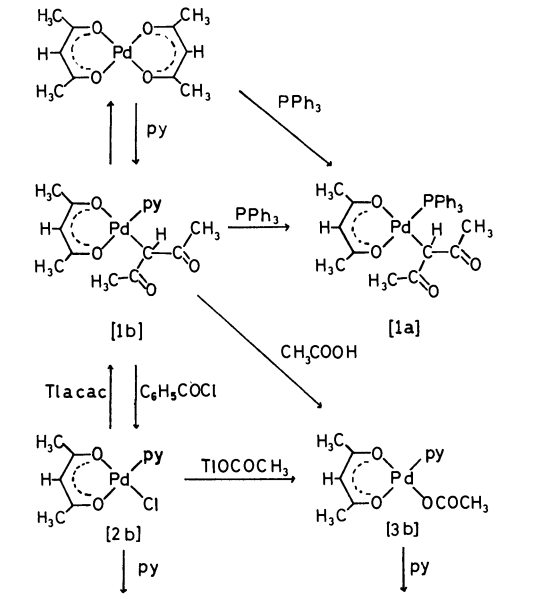
b) Doublet, J_{P-H}=6.3 Hz.

that the two methyl groups are equivalent on account of free rotation of the ligand around the Pd–C bond. The two peaks of equal intensity at 8.46 and 7.96 τ are attributed to the two methyl groups of the chelating acetylacetonate ligand. As is noticed in Table 3, the highest-field signal is shifted appreciably when triphenylphosphine is replaced by other ligands, while the lower-field one is not sensitive to the nature of L. Such an anisotropic shielding effect of the triphenylphosphine ligand is expected to be experienced by the methyl group nearer to this ligand, and thus the highest-field signal is assigned to the acetylacetonate-methyl group in the *cis* position of L. Similar situations have also been found for PtCl(acac)L complexes containing various tertiary phosphines and other bases as L.[8,9]

It has been well established for the platinum(II) complexes[10] that the methine proton of the carbon-bonded acetylacetone absorbs at higher field in comparison with that of the chelating acetylacetone. This assignment holds also for the palladium(II) complexes, and the methine proton signal of the carbon-bonded acetylacetone in the phosphine complex **1a** appears as a doublet because of coupling with the phosphorus nucleus (J_{P-H}=6.3 Hz).

Reactions of Pd(acac)$_2$L. The compound **1a** reacts with more than three mole equivalents of triphenylphosphine to produce tetrakis(triphenylphosphine)palladium(0). Benzoyl chloride reacts with **1a** in benzene at room temperature to replace the carbon-bonded acetylacetonate ligand with a chloride anion, affording $PdCl(acac)PPh_3$ [**2a**]. The loss of the carbon-bonded acetylacetone is clearly evidenced by the IR and NMR spectra (Tables 2 and 3). The compound **2a** can be transformed again to **1a** by the reaction with thallium(I) acetylacetonate. **2a** also reacts with thallium(I) acetate to form $Pd(OCOCH_3)(acac)PPh_3$ [**3a**], which can alternatively derived from **1a** by the direct reaction with acetic acid. It should be noted that $Pd(acac)_2$ does not react with acetic acid, but the carbon-bonded acetylacetonate group in **1a** can be easily displaced by the reaction with acetic acid.

The mechanism of the reaction of **1a** with acetic acid or benzoyl chloride is not clear at the present stage of investigation, but the oxidative addition of the reactant to **1a** might have occurred, being followed by the reductive elimination of acetylacetone or its benzoyl derivative.



Scheme

As is summarized in the Scheme, similar reactions are also observed for the compound **1b** to produce PdCl(acac)py [**2b**] and $PdOCOCH_3$(acac)py [**3b**]. The compound **1b** was prepared by the reaction of $Pd(acac)_2$ with pyridine, but the reaction can be reversed. When **1b** was dissolved in benzene, refluxed for about one hour, and the solvent was distilled off under reduced pressure, $Pd(acac)_2$ was recovered. The ligand pyridine can also be replaced by triphenylphosphine to give **1a**.

It is very interesting that the compound **2b** reacts with pyridine to produce *trans*-$PdCl_2py_2$ and $Pd(acac)_2$-py [**1b**]. These products correspond to the disproportionation of **2b** to form $PdCl_2py_2$ and $Pd(acac)_2$ followed by the reaction of $Pd(acac)_2$ with pyridine to give **1b**. However such a disproportionation reaction of **2b** does not occur spontaneously, but needs pyridine as a trigger reagent. The acetate complex **3b** also reacts with pyridine to afford *trans*-$Pd(OCOCH_3)_2py_2$ and **1b**.

The mechanism of this kind of interesting reaction is not yet clear, but the reaction proceeds quite readily and offers a useful and convenient route for the synthesis of *trans*-$Pd(OCOCH_3)_2py_2$. Bis(acetylacetonato)-palladium(II) readily reacts with pyridine and acetic acid in benzene at room temperature to form *trans*-$Pd(OCOCH_3)_2py_2$ in a high yield.

Experimental

Reactions of $Pd(acac)_2$ with Bases. A mixture of $Pd(acac)_2$ (0.272 g, 0.89 mmol) and PPh_3 (0.240 g, 0.91 mmol) was stirred in benzene (6 ml) at room temperature until the solution became transparent. Then petroleum ether (bp 30 —60 °C) was added to separate the product. Yield 0.473 g, 87%. Yellow-orange crystals of $Pd(acac)_2PPh_3 \cdot \frac{1}{2}C_6H_6$ were obtained by recrystallization from benzene–petroleum ether, but those recrystallized from chloroform did not involve the lattice solvent.

A mixture of $Pd(acac)_2$ (0.290 g, 0.95 mmol) and pyridine (5 ml) was warmed at about 80 °C until a clear solution resulted. Petroleum ether was added to precipitate $Pd(acac)_2py$. Yield 0.332 g, 91%. Yellow-green crystals were obtained by recrystallization from benzene–petroleum ether. $Pd(acac)_2NH(Me)CH_2Ph$ was also prepared by a similar reaction in a yield of 90%.

A mixture of $Pd(acac)_2$ (0.353 g, 1.15 mmol) and $NHEt_2$ (5 ml) was stirred at room temperature until a clear solution was obtained. Then the amine was evaporated spontaneously to leave the product $Pd(acac)_2NHEt_2$, which was recrystallized from cyclohexane. Yield 0.39 g, 87%.

The Reaction of $Pd(acac)_2PPh_3$ with Excess Triphenylphosphine. The complex $Pd(acac)_2PPh_3$ (0.202 g, 0.35 mmol) was allowed to react with triphenylphosphine (0.380 g, 1.45 mmol) in benzene at room temperature in an atmosphere of nitrogen. Petroleum ether was added to the dark red solution to separate out the product $Pd(PPh_3)_4$. Yield 0.335 g, 81%.

The Reactions of $Pd(acac)_2PPh_3$ and $Pd(acac)_2py$ with Benzoyl Chloride. A mixture of $Pd(acac)_2PPh_3$ (0.205 g, 0.35 mmol) and benzoyl chloride (2 ml) was stirred in benzene (5 ml) at room temperature until a reddish orange solution resulted. Petroleum ether was then added to precipitate the product $PdCl(acac)PPh_3$. Yield 0.172 g, 95%. Reddish orange crystals were obtained by recrystallization from benzene–petroleum ether. Orange crystals of PdCl(acac)py were similarly prepared in a yield of 85%.

The Reactions of $PdCl(acac)PPh_3$ and PdCl(acac)py with Thallium(I) Acetylacetonate. Thallium(I) acetylacetonate (0.015 g, 0.05 mmol) was added to a solution of $PdCl(acac)$-PPh_3 (0.024 g, 0.05 mmol) in chloroform (10 ml) and the mixture was stirred at room temperature for 30 min. Thallium(I) chloride was filtered off and the filtrate was concentrated by evaporation under reduced pressure to separate out $Pd(acac)_2PPh_3$. Yield 0.024 g, 88%. $Pd(acac)_2py$ was also derived from PdCl(acac)py by a similar procedure in a yield of 90%.

Reactions of $Pd(acac)_2py$ to $Pd(acac)_2$ and $Pd(acac)_2PPh_3$. A solution of $Pd(acac)_2py$ in benzene was refluxed for 1 hr and the solvent was distilled off. $Pd(acac)_2$ was recovered. In another experiment, triphenylphosphine (0.300 g, 0.12 mmol) was added to a solution of $Pd(acac)_2py$ (0.348 g, 0.11 mmol) in benzene. After stirring for 10 min, the solution was concentrated to separate out $Pd(acac)_2PPh_3$. Yield 0.500 g, 90%.

Preparations of $PdOCOCH_3(acac)PPh_3$ and $PdOCOCH_3(acac)py$. To a solution of $PdCl(acac)PPh_3$ (0.162 g, 0.32 mmol) in methylene chloride (10 ml) was added thallium(I) acetate (0.102 g, 0.39 mmol), and the mixture was stirred for 30 min at room temperature. Thallium(I) chloride was filtered off, and the filtrate was concentrated by evaporation under reduced pressure to separate out $PdOCOCH_3(acac)PPh_3$. Yield 0.167 g, 97%.

The corresponding pyridine complex $PdOCOCH_3(acac)py$ was similarly prepared from PdCl(acac)py in a yield of 86%. The acetate complex was also prepared by the direct reaction of $Pd(acac)_2py$ (0.167 g, 0.04 mmol) with acetic acid (2 ml) in benzene. The solution was stirred for 3 hr at room temperature. After the evaporation of benzene and acetic acid under reduced pressure, the residue was recrystallized from

benzene–petroleum ether. Yield 0.125 g, 84%.

The Reactions of PdCl(acac)py and PdOCOCH$_3$(acac)py with pyridine. Pyridine (2 ml) was added to a solution of PdCl(acac)py (0.114 g, 0.36 mmol) in benzene (10 ml). The reaction occurred rapidly to precipitate *trans*-PdCl$_2$py$_2$ (yield 0.054 g, 44% on the basis of palladium). Petroleum ether was added to the concentrate of the filtrate to separate out Pd(acac)$_2$py (yield 0.067 g, 48%).

Pyridine (2 ml) was added to a solution of PdOCOCH$_3$-(acac)py (0.139 g, 0.41 mmol) in benzene (10 ml). After stirring for 3 hr at room temperature the solution was concentrated to yield precipitates. Concentration to separate out precipitate was repeated further twice. Resultant yield of *trans*-Pd(OCOCH$_3$)$_2$py$_2$·H$_2$O was 0.075 g, 46%. From the final filtrate Pd(acac)$_2$py was obtained in a yield of 0.059 g, 38%.

Preparation of trans-*Pd(OCOCH$_3$)$_2$py$_2$ from Pd(acac)$_2$.* When pyridine (2 ml) and acetic acid (2 ml) were added to a suspension of Pd(acac)$_2$ (0.241 g, 0.79 mmol) in benzene (12 ml), the mixture became transparent immediately and changed its color from red to pale yellow. After stirring for 20 min petroleum ether was added to the solution to yield *trans*-Pd(OCOCH$_3$)$_2$py$_2$. Yield 0.300 g, 94%. White needles were obtained by the recrystallization from methylene chloride–petroleum ether. Found: C, 42.00; H, 4.63; N, 7.08%. Calcd for Pd(OCOCH$_3$)$_2$py$_2$·H$_2$O: C, 41.96; H, 4.52; N, 6.99%. The ν(C=O) absorption is observed at 1600 cm^{-1}, and the CH$_3$–proton signal at 8.16 τ.

Measurements. Infrared absorption spectra in the 4000—600 cm^{-1} region were measured with a JASCO IR-E spectrophotometer and those in the 700—200 cm^{-1} region with a Hitachi grating infrared spectrophotometer EPI-L. The NMR spectra were recorded at 60 MHz with tetramethylsilane as the internal reference on a C-60 HL spectrometer of Japan Electron Optics. The molecular weight was determined in dichloromethane at 25 °C by the method of vapor pressure osmometry with an apparatus manufactured by Knauer, Germany.

We are indebted to Mr. J. Gohda and Miss M. Iwao for the elemental analyses and NMR measurements. Financial aid by the Ministry of Education and the kind supply of acetylacetone by the Daicel Co., Ltd. are also acknowledged.

Proton Magnetic Resonance Spectra of Metal Ammine Complexes. I. Cobalt(III) Pentammine Series

Hayami YONEDA and Yoshiaki NAKASHIMA*

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received December 21, 1973)

The proton magnetic resonance spectra have been measured in dimethylsulfoxide on some cobalt(III) complexes of the type $[CoX(NH_3)_5]$. Ammine protons show two peaks, except in a complex with $X=NO_2^-$. The major peak, due to *cis* NH_3, appears downfields and the minor one, due to *trans* NH_3, upfields as compared with the shift in $[Co(NH_3)_6]^{3+}$. In the case of $X=CN^-$, the shift pattern is reversed. For $[Co(NO_2)(NH_3)_5]^{2+}$, the spectrum is a single peak. This chemical shift behavior is explained by a simple model based on Ramsay's theory for chemical shift. It is concluded that the behavior arises primarily from paramagnetic anisotropy of the central cobalt(III) ion. The model used in this work is shown to be applicable also to the assignment of the PMR spectra for complexes of the types *cis*-$[CoX_2(NH_3)_4]$ and *cis*-$[CoX_2(en)_2]$.

Only a few works have been made on the proton magnetic resonance (PMR) spectra of metal–ammine complexes. This is partly due to the paucity of suitable solvents. Cliffton and Pratt[1] may be the first, to our knowledge, to show that the PMR spectra of cobalt(III) ammine complexes can be obtained when dissolved in acidified heavy water. Recently, Jolly and co-workers[2,3] have measured the PMR spectra of pentammine complexes of cobalt(III), rhodium(III), and iridium(III) in sulfuric acid. It is reported that two peaks with an intensity ratio of 4 to 1 can be obtained for cobalt(III) complexes while single peaks are observed in rhodium(III) and iridium(III) complexes. They have suggested that two-peak patterns in cobalt complexes may be explained by taking into consideration the contribution to the proton shift from the paramagnetic anisotropy of the central cobaltic ion. They have not made, however, even qualitative order-of-magnitude estimations and further no clear-cut explanation has been given to the fact that $[Co(CN)(NH_3)_5]^{2+}$ has *trans* ammine protons shifted to lower field than *cis* protons. Other complexes have reversed shift patterns with *trans* protons shifted to higher field.

We have measured the PMR spectra of some pentammine complexes of cobalt(III) in dimethyl sulfoxide. Herein reported are the shift patterns for these complexes and a simple explanation is given to the shift behavior. The model is based on Ramsay's theory of chemical shift. The major contribution to the proton shift is attributed to the anisotropy of temperature-independent paramagnetism of cobalt(III) ion. This model can account for the change in proton chemical shifts of $[CoX(NH_3)_5]$ when X is varied along the spectrochemical series. Further, some applications are given to the assignment of the PMR spectra of *cis*-$[CoX_2(NH_3)_4]$ and *cis*-$[CoX_2(en)_2]$ (en=ethylenediamine).

Experimental

The complexes used in this work are $[Co(NH_3)_6](NO_3)_3$, $[Co(H_2O)(NH_3)_5](NO_3)_3$, $[Co(CN)(NH_3)_5](NO_3)_2$, and $[CoX(NH_3)_5](NO_3)_2$ ($X=NO_2^-$, OH^-, Cl^-, Br^-, HCO^-, $CH_3CO_2^-$, $CH_2ClCO_2^-$, and $CCl_3CO_2^-$). These complexes are prepared after the well-established methods.[4]

All the spectra are recorded on a Varian A-60 spectrometer. Dimethyl sulfoxide of spectrograde or deuterated dimethyl sulfoxide (Merck) as the case may be is used as solvent. Chemical shifts are measured relative to an internal standard of sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS).

Results

As illustrated in Fig. 1, the observed PMR spectra of cobalt(III)–pentammine complexes may be grouped into three categories. Category A; most of the complexes investigated belong to this category. The major peak, due to *cis* NH_3, appears downfields and the minor one, due to *trans* NH_3, upfields as compared with the shift of $[Co(NH_3)_6]^{3+}$. Category B; the spectrum of $[Co(NO_2)(NH_3)_5]^{2+}$ is an example. The shift difference between *cis* and *trans* ammine protons is not observed. The single peak lies slightly upfields relative to the hexammine complex. In trifluoroacetic acid, it also shows a single peak. Category C; the spectrum of cyanopentammine complex belongs to this group. The spectrum pattern is reversed in that the major peak is situated at higher field than the minor one.

The PMR data are summarized in Table 1. Note

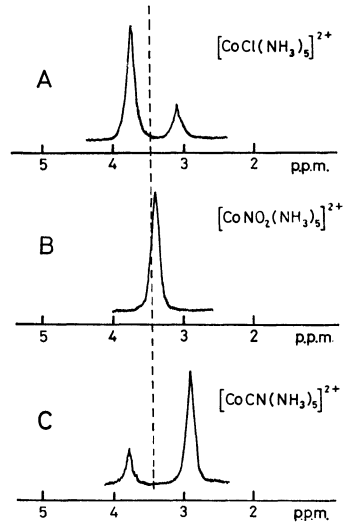

Fig. 1. Three types of PMR spectra for pentammine cobalt(III) complexes. Shift values are relative to DSS internal standard.

* On leave from Wakayama University.

TABLE 1. CHEMICAL SHIFTS (in Hz) OBSERVED FOR PENTAMMINE COBALT(III) COMPLEXES IN DIMETHYLSULFOXIDE SOLUTION

Measurements have been made at 60 MHz with DSS internal standard.

X	*trans* NH_3	*cis* NH_3
CN^-	227	174
NO_2^-	205 (singlet)

$[Co(NH_3)_6]^{3+}$	207	

a) Overlapped with the methyl signal of dimethylsulfoxide.

that all X's in $[CoX(NH_3)_5]$ of Category A are observed to lie lower in the spectrochemical series than NH_3. Further, the lower in the spectrochemical series the ligand X lies, the greater the shift difference between *cis* and *trans* ammine protons. In $[Co(CN)(NH_3)_5]^{2+}$ of Category C, CN^- is a representative of strong-field ligands and lies highest in the spectrochemical series.

The Model

We assume that three protons of each ammine group are situated at an average position, *i.e.*, at one of the points indicated by open circles in Fig. 2. Figure 2 defines the coordinate axes x, y, and z for complexes $[CoX(NH_3)_5]$. Chemical shift of specific ammine protons of a complex in solution is characterized by

$$\sigma = \frac{1}{3}(\sigma_{xx}+\sigma_{yy}+\sigma_{zz}). \quad (1)$$

Here, σ_{xx}, σ_{yy}, and σ_{zz} are the shielding constants for protons of interest when the magnetic field is applied along the x, y, and z axes, respectively, defined in Fig. 2. These constants consist of two contributions, namely the so-called paramagnetic and diamagnetic terms. It can be shown,[5] however, that diamagnetic terms are at least two orders of magnitude smaller than paramagnetic ones. Thus, we attribute the chemical shift behavior in pentammine cobalt complexes to the paramagnetic shielding constant, σ^P.

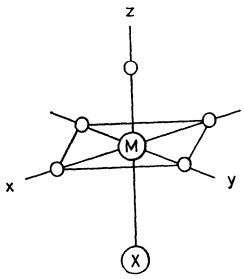

Fig. 2. The definition of the frame of reference for $[CoX(NH_3)_5]$-type complexes. Open circles are assumed to represent the position of ammine protons.

Calculation of the paramagnetic shielding constant for complexes of C_{4v} symmetry has been made by Buckingham and Stephens.[6] They have discussed the PMR spectra of hydride complexes of cobalt and iron. We will follow their procedure. They have modified Ramsay's formula for chemical shift of protons in C_{4v} cobalt complex to the form

$$\sigma^P_{xx} = -\frac{e^2}{2m^2c^2}\frac{1}{E_E-E_{A1}}[\langle {}^1A_1|\sum_j L_{xj}|{}^1E_x\rangle\langle {}^1E_x|\sum_k L_{xk}/r_k^3|{}^1A_1\rangle + \langle {}^1A_1|\sum_k L_{xk}/r_k^3|{}^1E_x\rangle\langle {}^1E_x|\sum_j L_{xj}|{}^1A_1\rangle], \quad (2)$$

and

$$\sigma^P_{zz} = -\frac{e^2}{2m^2c^2}\frac{1}{E_{A2}-E_{A1}}[\langle {}^1A_1|\sum_j L_{zj}|{}^1A_2\rangle\langle {}^1A_2|\sum_k L_{zk}/r_k^3|{}^1A_1\rangle + \langle {}^1A_1|\sum_k L_{zk}/r_k^3|{}^1A_2\rangle\langle {}^1A_2|\sum_j L_{zj}|{}^1A_1\rangle]. \quad (3)$$

We have retained paramagnetic terms only. In the above, $|{}^1A_1\rangle$, and $|{}^1A_2\rangle$ and $|{}^1E_x\rangle$ are the ground and the excited states of the central cobalt(III) ion and E_{A1}, E_{A2}, and E_E are the corresponding energies, respectively (see Fig. 3). L_{xj} and L_{zj} are the x and z components of orbital angular momentum operator for j-th electron of cobalt ion. The distance from protons in question to k-th electron is denoted by r_k. The summation is over all 3d electrons of cobalt. Operators subscripted with M and H are on the metal and proton centers, respectively.

Figure 3 shows the ground and the low-lying excited states of Co(III) ion under C_{4v} symmetry. Wave functions associated with these levels are given in Table 2. $|{}^1E_x\rangle$ and $|{}^1E_y\rangle$ are degenerate. To a first approximation, we neglect hybridization of 3d with 4s and 4p orbitals and covalency with ligand orbitals.

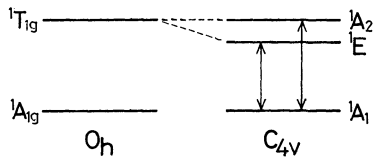

Fig. 3. The ground and the low-lying excited states of Co(III) ion under crystal fields of O_h and C_{4v} symmetries.

TABLE 2. WAVEFUNCTIONS ASSOCIATED WITH THE GROUND AND THE LOW-LYING EXCITED STATES OF Co(III) ION UNDER C_{4v} CRYSTAL FIELD

Superscripts 2, and + and − refer to the fully occupied orbital and orbitals with up and down spins, respectively.

$\|{}^1A_1\rangle$	$\|d_{yz}^2 d_{zx}^2 d_{xy}^2\|$
$\|{}^1A_2\rangle$	$\frac{1}{\sqrt{2}}[\|d_{yz}^2 d_{zx}^2 d_{xy}^+ d_{x^2-y^2}^-\| - \|d_{yz}^2 d_{zx}^2 d_{xy}^- d_{x^2-y^2}^+\|]$
$\|{}^1E_x\rangle$	$\frac{1}{\sqrt{2}}[\|d_{yz}^+ d_{y^2-z^2}^- d_{zx}^2 d_{xy}^2\| - \|d_{yz}^- d_{y^2-z^2}^+ d_{zx}^2 d_{xy}^2\|]$
$\|{}^1E_y\rangle$	$\frac{1}{\sqrt{2}}[\|d_{yz}^2 d_{zx}^+ d_{z^2-x^2}^- d_{xy}^2\| - \|d_{yz}^2 d_{zx}^- d_{z^2-x^2}^+ d_{xy}^2\|]$

Further, contributions can be shown small to be neglected from levels into which T_{2g} state in O_h symmetry is split under the influence of the crystal field of C_{4v} symmetry. Under these simplifying assumptions, calculation of Eqs. (2) and (3) renders Eqs. (4) and (5) for *cis* and *trans* ammine protons, respectively.

$$\sigma_C^P = \frac{1}{3}(\sigma_{xx}^P+\sigma_{yy}^P+\sigma_{zz}^P) = \frac{4e^2\hbar^2}{3m^2c^2}\frac{1}{R^3}\left(\frac{1}{E_{A2}-E_{A1}}-\frac{1}{E_E-E_{A1}}\right). \quad (4)$$

$$\sigma_T^P = \frac{1}{3}(2\sigma_{xx}^P+\sigma_{zz}^P) = \frac{8e^2\hbar^2}{3m^2c^2}\frac{1}{R^3}\left(\frac{1}{E_E-E_{A1}}-\frac{1}{E_{A2}-E_{A1}}\right). \quad (5)$$

Quantities subscripted with C and T refer to *cis* and *trans*, respectively. R is the distance between the protons of interest and the cobalt nucleus. If R and excitation energies are measured in units of a.u. and cm^{-1}, $\sigma_C{}^P$ and $\sigma_T{}^P$ are expressed as dimensionless quantities.

$$\sigma_C^P = \frac{4}{3}\times 11.7\frac{1}{R^3}\left(\frac{1}{E_{A2}-E_{A1}}-\frac{1}{E_E-E_{A1}}\right). \quad (6)$$

$$\sigma_T^P = \frac{8}{3}\times 11.7\frac{1}{R^3}\left(\frac{1}{E_E-E_{A1}}-\frac{1}{E_{A2}-E_{A1}}\right). \quad (7)$$

The above result may be visualized in the following way (see Fig. 4).

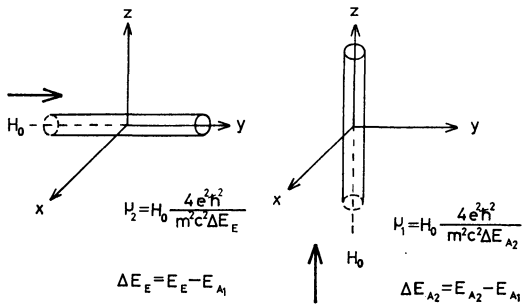

Fig. 4. The schematic presentation of induced paramagnetic moments. All notations have their usual singnificance.

On applying the magnetic field along the, say, x direction, magnetic moment will be induced. This induced moment, μ_2, is known as second-order paramagnetism and in magnetism as temperature-independent paramagnetism or the highfrequency term. This is given by

$$\mu_2 = H_0\frac{4e^2\hbar^2}{m^2c^2}\frac{1}{E_E-E_{A1}}. \quad (8)$$

Induced moments when the magnetic field is applied along the y and z directions are depicted in Fig. 4. These induced moments will be sensed by protons of interest as dipolar fields. Summing up over these dipolar fields, the same result as in Eqs. (6) and (7) is obtained. These reasoning is equivalent to regarding the shift as caused by the anisotropy in paramagnetic moment of Co(III) ion.

Comparison with Experiment

We first note that the energy E_E changes upon substitution of X, while the energy E_{A_2} is unaffected by substitution because the latter energy corresponds to the transition from d_{xy} to $d_{x^2-y^2}$. The ordering of the ligand field levels is determined, from spectroscopic and spectrophotometric studies,[7] as $E_E<E_{A_2}$ except for strong-field ligands such as CN^- and NO_2^-, for which the ordering is reversed. Therefore, σ_C^P is generally positive and σ_T^P is negative, which means that *trans* ammine protons are shifted to high fields and *cis* protons to low fields (from the shift of hexammine cobalt(III) ion). This corresponds to the case of Category A. Further, the weaker spectrochemically the ligand X is, we can expect the smaller E_E, and hence, the bigger shift difference between *cis* and *trans* protons. This trend is consistent with experimental results already mentioned. In contrast, when X is a strong-field ligand, *e.g.*, $X=CN^-$, we can expect the shift pattern reversed to that in Category A, as has the case really been observed. So far so good.

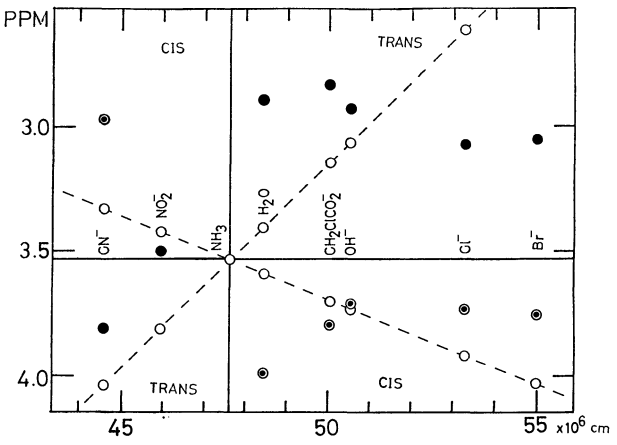

Fig. 5. Comparison of the calculated shift values (○) with observed values (⊙ and ●). Shift values are from DSS internal standard and the abscissa is the reciprocal of the excitation energy E_E-E_{A1}.

If we examine more closely the correlation between the experimental results and Eqs. (6) and (7), agreement is not so satisfactory. Setting $R=5.7$ a.u.[8] and using reported values for excitation energies,[9] we can plot the calculated shift values against the reciprocal of the energy difference E_E-E_{A1}. Figure 5 shows the comparison of the calculated and the observed shift values. As seen in Fig. 5, shift patterns of Categories A, B, and C appear to be roughly explained. It seems difficult to explain by using only metal 3d orbitals that the complex with $X=NO_2^-$ goes into Category B.

The model used in this work is applicable also to the interpretation of the PMR spectra of *cis*-$[CoX_2(NH_3)_4]$ and *cis*-$[CoX_2(en)_2]$. For these complexes, *trans* (to ligand X) ammine or NH_2 protons and *cis* protons have the same intensity. The assignment is therefore not straightforward. We assume, after Yamatera,[10] that three electronic transitions comprising the first absorption band are approximated, irrespective of the symmetry of the complex in question, by the following transitions under O_h symmetry.

$$d_{xy}\rightarrow d_{x^2-y^2},\ \frac{1}{2}\delta+\Delta \quad (9)$$

$$d_{yz} \rightarrow d_{y'z'},\ \frac{1}{4}\delta+\Delta \quad (10)$$

$$d_{zx} \rightarrow d_{z'x'},\ \frac{1}{4}\delta+\Delta \quad (11)$$

To the right are given the corresponding transition energies.

δ is the splitting factor defined by Yamatera and Δ the transition energy of the first absorption band in $[Co(NH_3)_6]^{3+}$ or $[Co(en)_3]^{3+}$ [11] as the case may be. Substitution of these energies into Eqs. (4) and (5) yields

$$\sigma^P(5,6) = -2\left(\frac{4e^2\hbar^2}{3m^2c^2}\frac{1}{R^3}\right)\left(\frac{1}{\Delta+\delta/2}-\frac{1}{\Delta+\delta/4}\right), \quad (12)$$

$$\sigma^P(2,3) = +\left(\frac{4e^2\hbar^2}{3m^2c^2}\frac{1}{R^3}\right)\left(\frac{1}{\Delta+\delta/2}-\frac{1}{\Delta+\delta/4}\right). \quad (13)$$

Shielding constants $\sigma^P(5,6)$ and $\sigma^P(2,3)$ are for *cis* and *trans* NH_3 or NH_2 protons, respectively. For complexes with weak-field ligand X, δ is negative by definition, rendering $\sigma^P(5,6)$ negative and $\sigma^P(2,3)$ positive. Therefore, we can expect, except for strong-field ligands, that 5- and 6-protons are shifted to low fields and 2- and 3-protons to high fields. For strong-field ligands, such as X=CN⁻, the situation may be the reverse of the above.

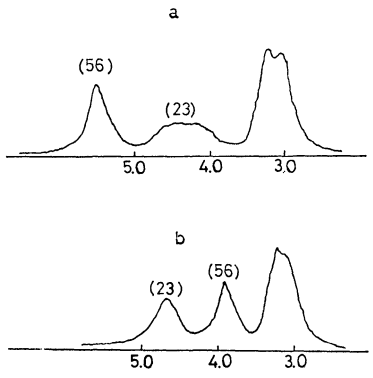

Fig. 6. The PMR spectra of (a) $[CoCl_2(en)_2]^+$ and (b) $[Co(CN)_2(en)_2]^+$ in trifluoroacetic acid. Shift values are from an internal standard of tetramethylsilane. Numbers in parentheses represent the proposed assignments (see text).

Let us illustrate how this result works in actual cases. Figure 6 depicts the PMR spectra of *cis*-$[CoCl_2(en)_2]^+$ and *cis*-$[Co(CN)_2(en)_2]^+$ in trifluoroacetic acid. Chloride ion is a representative of weak-field ligands. Thus, the broader peak situated around 4.4 ppm is assigned as *trans* NH_2 protons and the lowest-field peak as *cis* NH_2. Since CN^- is strong-field ligand, the assignment given in Fig. 6-b will hold.

Conclusion

The PMR spectra of pentammine cobalt(III) complexes can be explained primarily by the paramagnetic anisotropy of the central cobalt(III) ion. The results derived in this work may be summarized as the following rules (see Fig. 7).

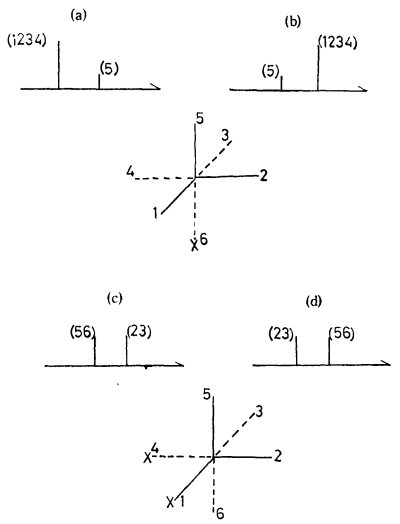

Fig. 7. The predicted behavior of the PMR spectra for $[CoX(NH_3)_5]$ and *cis*-$[CoX_2(NH_3)_4]$ or *cis*-$[CoX_2(en)_2]$. (a) and (b) are for pentammine complexes with weak- and strong-field ligands, respectively. (c) and (d) are for the *cis*-type complexes with weak- and strong-field ligands, respectively.

For $[CoX(NH_3)_5]$;

(1) If X is spectrochemically lower than NH_3, ammine protons *trans* to X appear at high fields (Fig. 7-a).

(2) If X is a strong-field ligand, the reverse is expected (Fig. 7-b).

For *cis*-$[CoX_2(NH_3)_4]$ or *cis*-$[CoX_2(en)_2]$;

(1) If X is a weak-field ligand, the high-field peak is due to 2- and 3-protons (Fig. 7-c).

(2) If X is strong, protons situated at 5- and 6-positions will appear at higher field (Fig. 7-d).

The Cyclopolymerization of Triallyl Citrate

Akira MATSUMOTO, Tetsuji OHATA, and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received June 12, 1973)

The radical polymerization of triallyl citrate was carried out at 60 °C, benzoyl peroxide being used as the initiator and benzene as the solvent; here it has been considered kinetically in terms of cyclopolymerization. Thus, the kinetic equations for the polymerization of the triallyl ester were first derived by an extension of the kinetic treatment for the cyclopolymerization of the diallyl ester. Next, they were applied to the polymerization of triallyl citrate. In consequence, the following results were obtained: (i) the rate of polymerization, R_p, was not proportional to either the square root or first power of the initiator concentration, [I]; rather, $R_p/[I]^{1/2}$ and $[I]^{1/2}$ had a linear relationship, (ii) the relation between the rate of polymerization over the degree of polymerization, $R_p/\bar{P}_{n,o}$, and the monomer concentration, [M], was also linear, and (iii) the ratio of the unimolecular cyclization reaction to the bimolecular propagation reaction of the uncyclized radical, K_c, was estimated to be 4.5 mol/l from the dependence of the residual unsaturation on the monomer concentration.

In our previous papers,[1-4] the polymerizations of various diallyl esters of dicarboxylic acids have been kinetically discussed in detail in terms of cyclopolymerization and allyl polymerization, including the degradative chain transfer[5] characteristic of allyl compounds.

The present paper will be concerned with the polymerization kinetics of triallyl citrate; the kinetic treatment for the polymerization of the diallyl ester involving the intramolecular cyclization reaction is developed for application and the radical polymerization results are discussed in detail.

Experimental

Materials. The triallyl citrate was prepared by the esterification of citric acid with allyl alcohol according to the literature[6]; bp 130 °C/0.005 mmHg, d_4^{20} 1.135 (lit. bp 207—208 °C/12 mmHg, d_4^{17} 1.1358). The purity of triallyl citrate was confirmed further by spectral and chemical analyses.

The benzoyl peroxide (BPO) was purified by repeated precipitations from a chloroform solution with methanol.

The benzene was distilled over metallic sodium after purification by the usual method.

Polymerization Procedure. Measured amounts of triallyl citrate, BPO, and benzene were placed in a glass ampoule (10—50 ml capacity), which was then evacuated under reduced pressure and flushed with nitrogen. The ampoule was then sealed under a vacuum and put into a thermostat regulated at 60±0.1 °C.

After a definite reaction time, the polymer thus produced was precipitated by pouring the reaction mixture into more than a tenfold volume of cooled petroleum ether. The polymer thus obtained was then washed repeatedly with petroleum ether and dried *in vacuo* until a constant weight was obtained. The percentage conversion was calculated from the weight of the polymer isolated. The polymer was then purified by dissolving it in acetone and by subsequent reprecipiation with petroleum ether.

Analyses of the Polymer. The unreacted pendant allyl groups of the purified polymer were determined by the method of Simpson *et al.*[7] The polymer was dissolved in methanol and saponified in excess potassium hydroxide, and then the free allyl alcohol was determined by the bromide–bromate technique. The residual unsaturation of the polymer was then expressed as percentages of the corresponding pure triallyl citrate.

The number-average molecular weight of the polymer was measured with a Hewlett-Packard 302 vapor pressure osmometer in acetone at 37 °C.

Results and Discussion

Kinetics. The polymerization mechanism of triallyl citrate must be virtually equivalent to that of the diallyl ester.[1] Thus, the following reaction scheme can be presented for the polymerization of triallyl citrate; in the scheme it is assumed that the three allyl groups of triallyl citrate behave equivalently and that the possibility of a bicyclo-intramolecular propagation[8] accompanying the formation of a bicyclic ring is negligible, as will be discussed later.

Decomposition: $I \longrightarrow 2R\cdot$	$2k_d[I]$
Initiation: $R\cdot + M \longrightarrow M\cdot$	$3k_i[R\cdot][M]$
Cyclization: $M\cdot \longrightarrow M_c\cdot$	$2k_c[M\cdot]$
Propagation: $M\cdot + M \longrightarrow M\cdot$	$3k_p[M\cdot][M]$
$M_c\cdot + M \longrightarrow M\cdot$	$3k_{cp}[M_c\cdot][M]$
Chain transfer: $M\cdot + M \longrightarrow P + M\cdot *$	$3k_{t1}[M\cdot][M]$
$M_c\cdot + M \longrightarrow P + M\cdot *$	$3k_{t2}[M_c\cdot][M]$
Re-initiation: $M\cdot * + M \longrightarrow M\cdot$	$3k_i'[M\cdot *][M]$
Stabilization: $M\cdot * + M\cdot * \longrightarrow M*\text{–}M*$	$k_{t3}[M\cdot *]^2$

where I denotes an initiator; M, a triallyl citrate monomer; P, the polymer; R·, the initiator radical; M·, the initial radical derived from the attack of a radical on M (the uncyclized radical); $M_c\cdot$, the radical formed by the intramolecular cyclization of M· (the cyclized radical), and M·*, the radical derived from the abstraction of an allylic hydrogen of M by the growing polymer chain (the degraded radical).

If a steady state is assumed for the different types of radicals, Eqs. (1)—(4) can be obtained:

$$[R\cdot] = 2fk_d[I]/3k_i[M] \tag{1}$$

$$[M\cdot] = \frac{2fk_d[I] + 3k_i'(2fk_d[I]/k_{t3})^{1/2}[M]}{3k_{t1}[M] + 2k_ck_{t2}/(k_{cp}+k_{t2})} \tag{2}$$

$$[M_c\cdot] = \frac{\{2k_c/3(k_{cp}+k_{t2})[M]\}\{2fk_d[I] + 3k_i'(2fk_d[I]/k_{t3})^{1/2}(M)\}}{3k_{t1}[M] + 2k_ck_{t2}/(k_{cp}+k_{t2})} \tag{3}$$

$$[M\cdot *] = (2fk_d[I]/k_{t3})^{1/2} \tag{4}$$

where f denotes the efficiency of the initiation of chain radicals by R·.

In previous papers on the polymerization of diallyl esters,[1-3] the kinetic equations were derived for two cases. In one case, where the loss of a monomer by initiation, chain termination, and re-initiation reaction is not negligible compared with that by the propagation, the kinetic chain length is small. In the other case, where the propagation reaction is predominant, the kinetic chain length is quite large and the simplified kinetic equations can, therefore, be used instead of the elaborate ones. In the polymerization of triallyl citrate investigated in this paper, the degree of polymerization was quite large, as can be seen in Table 2: therefore, the polymerization of triallyl citrate is of the latter type, as for the diallyl esters of aliphatic dicarboxylic acids.[2,3]

Thus, the rate of polymerization is given by:

$$\begin{aligned} R_p &= 3k_p[M\cdot][M] + 3k_{cp}[M_c\cdot][M] \\ &= \{2fk_d[I] + 3k_i'(2fk_d[I]/k_{t3})^{1/2}[M]\} \\ &\quad \times \left\{ \frac{3k_p[M] + 2k_ck_{cp}/(k_{cp}+k_{t2})}{3k_{t1}[M] + 2k_ck_{t2}/(k_{cp}+k_{t2})} \right\} \end{aligned} \quad (5)$$

The initial degree of polymerization is also given by:

$$\begin{aligned} \bar{P}_{n,o} &= R_p/(3k_{t1}[M\cdot][M] + 3k_{t2}[M_c\cdot][M]) \\ &= \frac{3k_p[M] + 2k_ck_{cp}/(k_{cp}+k_{t2})}{3k_{t1}[M] + 2k_ck_{t2}/(k_{cp}+k_{t2})} \end{aligned} \quad (6)$$

The combination of Eqs. (5) and (6) gives:

$$R_p/\bar{P}_{n,o} = 2fk_d[I] + 3k_i'(2fk_d[I]/k_{t3})^{1/2}[M] \quad (7)$$

On the other hand, the rate of the formation of the pendant unreacted allyl groups in the polymer is given by:

$$d[allyl]/dt = 6k_p[M\cdot][M] + 3(1-\alpha)k_{cp}[M_c\cdot][M] \quad (8)$$

where α denotes the ratio of the non-consecutive cyclization as seen in the polymerization of diallyl terephthalate[4] to the consecutive intramolecular cyclization in the same monomer unit.

Equation (8) is true in the absence of crosslinking reactions, since these reactions will consume the pendant unreacted allyl groups in the polymer. However, in the early stage of polymerization, the loss of allyl groups by the crosslinking reaction should be small compared with that during propagation.

By using Eqs. (2) and (3), we obtain:

$$\begin{aligned} d(allyl)/dt &= \{2fk_d[I] + 3k_i'(2fk_d[I]/k_{t3})^{1/2}[M]\} \\ &\quad \times \left\{ \frac{6k_p[M] + 2(1-\alpha)k_ck_{cp}/(k_{cp}+k_{t2})}{3k_{t1}[M] + 2k_ck_{t2}/(k_{cp}+k_{t2})} \right\} \end{aligned} \quad (9)$$

Equatins (5) and (9) give:

$$\begin{aligned} -\frac{d[allyl]}{d[M]} &= 3R_{us} \\ &= \frac{6k_p[M] + 2(1-\alpha)k_ck_{cp}/(k_{cp}+k_{t2})}{3k_p[M] + 2k_ck_{cp}/(k_{cp}+k_{t2})} \end{aligned} \quad (10)$$

where R_{us} denotes the degree of unsaturation of the polymer.

From Eq. (10) we obtain:

$$(3R_{us})_{M\to 0} = 1 - \alpha \quad (11)$$

On the other hand, the rearrangement of Eq. (10) gives:

$$(2-3R_{us})^{-1} = \frac{1}{1+\alpha} + \frac{3(1+x)}{2(1+\alpha)} \cdot \frac{1}{K_c}[M] \quad (12)$$

where $x = k_{t2}/k_{cp} = (\bar{P}_{n,o})^{-1}_{M\to 0}$, $K_c = k_c/k_p$.

Polymerization Results. The bulk polymerization of triallyl citrate was investigated under different initiator concentrations at 60 °C; the initial rates of polymerization as calculated from the slope of the straight lines of the time-conversion curves, are summarized in Table 1; they are proportional neither to the square root nor to the first power of the initiator concentration, as was observed in the polymerization of diallyl esters.[1-4]

Table 1. Relation between the rate of polymerization and initiator concentration in the bulk polymerization of triallyl citrate at 60 °C

[I] (mol/l)	$R_p \times 10^5$ (mol/l·s^{-1})	$(R_p/[I]^{1/2}) \times 10^4$ (mol/l·s^{-2})$^{1/2}$	$(R_p/[I]) \times 10^3$ (s^{-1})
0.01	1.39	1.39	1.39
0.02	2.31	1.63	1.16
0.04	3.42	1.71	0.86
0.10	8.24	2.61	0.82

Table 2. Polymerization of triallyl citrate (60 °C, [BPO] = 0.02 mol/l, Solvent; benzene)

[M] (mol/l)	$R_p \times 10^5$ (mol/l·s^{-1})	$\bar{P}_{n,o}$	R_{us}
3.63	2.33	—	0.500
2.42	1.20	58.9	0.465
1.82	0.74	52.3	0.435
1.21	0.45	44.2	0.405
0.73	0.25	36.5	0.362
0.40	0.13	29.5	0.327

On the other hand, the influence of the monomer concentration on the rate of polymerization, the residual unsaturation, and the degree of polymerization was also examined at a constant initiator concentration at 60 °C. The results obtained are given in Table 2.

Figure 1 shows the relation between the residual unsaturation, R_{us}, and the monomer concentration; R_{us} tends to decrease with a decrease in the monomer con-

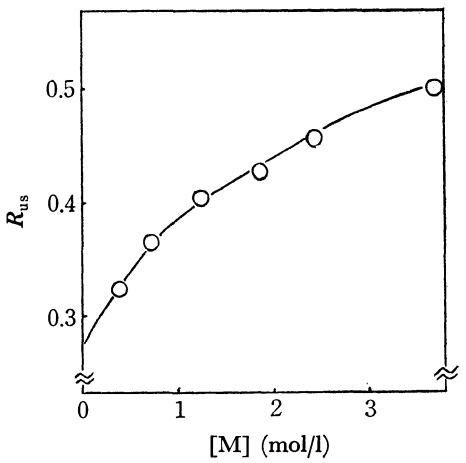

Fig. 1. Dependence of R_{us} on monomer concentration.

centration, and it reaches 0.284 by the extrapolation of the monomer concentration to zero. Thus, α is estimated from Eq. (11) to be 0.148.

Now, it should be noted that R_{us} must be 0.667 if neither cyclization nor crosslinking reaction occurs; conversely, it reaches zero in an infinitely diluted solution if the bicyclo-intramolecular cyclization reaction occurs completely. On the other hand, in the absence of the bicyclo-intramolecular cyclization, R_{us} approaches 0.333, assuming that the intramolecular cyclization reaction occurs only in the same monomer unit. Consequently, the result obtained above, *i.e.*, $(R_{us})_{M\to 0}=$ 0.284, may be understood by considering the absence of the bicyclo-intramolecular cyclization and the occurrence of the non-consecutive intramolecular addition reaction, as was observed in the polymerization of diallyl terephthalate.[4,9,10]

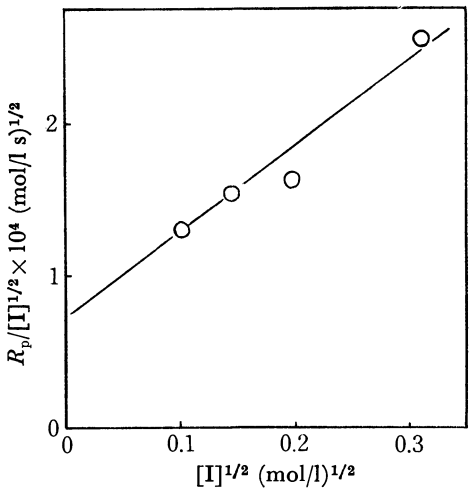

Fig. 2. Relationship between $R_p/[I]^{1/2}$ and $[I]^{1/2}$ based on Eq. (6).

Kinetic Evaluation. Figure 2 shows the relation between $R_p/[I]^{1/2}$ and $[I]^{1/2}$ based on the data of Table 1; there is a fairly good linear relationship, as can be expected from Eq. (5). Similarly, if the initiator concentration is kept constant and the monomer concentration is varied, a linear relationship between $R_p/\bar{P}_{n,o}$ and [M] can be expected from Eq. (7) (See Fig. 3). These results seem to demonstrate the validity

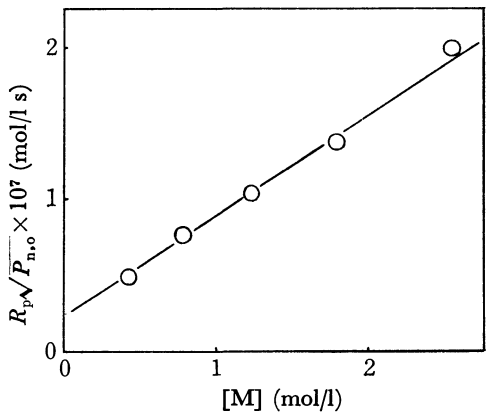

Fig. 3. Relationship between $R_p\sqrt{\bar{P}_{n,o}}$ and [M] based on Eq. (9).

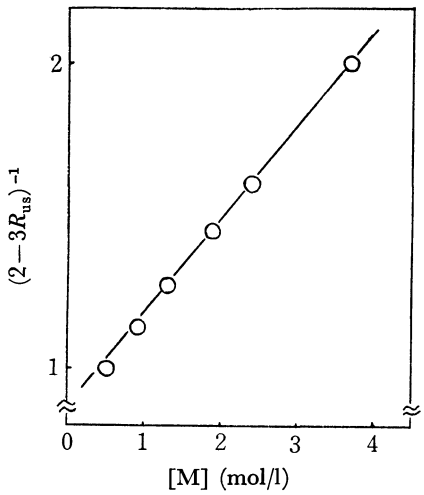

Fig. 4. Evaluation of K_c based on Eq. (14).

of the kinetics discussed in the previous section.

On the other hand, the ratio of the unimolecular cyclization reaction to that of the bimolecular propagation reaction of the uncyclized radical, K_c, can be obtained from the dependence of the residual unsaturation on the monomer concentration by employing Eq. (12), since, in the early stage of polymerization, the crosslinking reaction is negligible and the deviation of R_{us} from 0.667 can predominantly be attributed to the intramolecular cyclization reaction. Figure 4 shows the plot of $(2-3R_{us})^{-1}$ *vs.* [M]; there is a good linear relationship, and K_c was estimated to be 4.5 mol/l from the slope of the straight line. K_c is a critical factor determining the microstructure of the polymer; the monomer concentration required for obtaining the polymer carrying 50% of the cyclic recurring unit is 3.0 mol/l, which corresponds to around a 82.5% dilution of the pure monomer.

Now, it should be noted that the values of K_c for diallyl phthalate and diallyl succinate, which are considered to be diallyl esters structurally corresponding to triallyl citrate, are 7.5 mol/l[1] and 2.8 mol/l[3] respectively, in which the free rotation between the two ester groups is possible in diallyl succinate, whereas in diallyl phthalate it is impossible. Thus, the fact that the value of the K_c of triallyl citrate is intermediary between those of diallyl phthalate and diallyl succinate suggests a limited rotation among the three ester groups; we may imagine the structural feature of triallyl citrate to be that the three allyl groups are symmetrical about the hydroxide group. From such a standpoint, the equivalency of the three allyl groups of triallyl citrate mentioned above can also be understood.

Bromine Addition to Chloronorbornene Derivatives[1]

Yūji YANAGIDA, Hideo SHIGESATO, Masakatsu NOMURA, and Shōichi KIKKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received July 6, 1973)

The reaction of bromine with both *trans*-5,6-dichloro-2-norbornene (I) and *exo-cis*-5,6-dichloro-2-norbornene (III) in an acetic acid solution gave *trans*-adducts in a 100% yield, while the bromination of *endo-cis*-5,6-dichloronorbornene (II) afforded the *exo-cis* adduct in a *ca.* 100% yield. The latter observation was explained in terms of a sterical inhibition of the bromide ion's attack in the *endo*-direction by the two *endo*-chloro substituents. In the CCl_4 solution, however the reaction of I with bromine afforded the *exo-cis* adduct in a 64% yield, together with the *trans*-adduct (36% yield). Then, the reaction of I with bromine was carried out in several other solvents (CH_3OH, $Cl(CH_2)_2Cl$, $CH_3CO_2C_2H_5$, and CCl_4). As the polarity of the solvents (the E_T values are used here as a measure of the solvents' polarity) decreased, the formation of the *exo-cis* adduct became progressively more predominant, while the addition of bromide salt retarded the formation of the *exo-cis* adduct. Such results and the kinetic studies suggested that the *exo-cis* adduct was formed through the carbonium bromide ion-pair mechanism. The stereoisomers obtained in this study were assigned on the basis of the NMR spectra.

The authors have found, in a previous investigation,[2] that, under mild conditions, (in an acetic acid solution) favoring the polar mechanism rather than the free radical mechanism, the addition of bromine to *trans*-5,6-dicyano-2-norbornene gave the *exo-cis* adduct in a 24% yield, along with the *trans* adduct in a 76% yield. Such a formation of the *exo-cis* adduct could not be interpreted only in terms of the steric effects of cyano-substituents. In order to obtain further information on the nature of substituent effect on the *exo-cis* formation, we undertook a study of the addition of bromine to *trans*-5,6-dichloro-2-norbornene(I), *endo-cis*-5,6-dichloronorbornene(II), and *exo-cis*-5,6-dichloronorbornene(III). The chlorine atom was chosen as a substituent because of its similarity in steric environment[3] to the cyano group, but it has less inductive effect than that of the cyano group.

Experimental[4]

Starting Materials. The starting chlorides I and II. were prepared according to the procedure of Roberts[5] and were comfirmed to be the desired *trans-endo, exo*-5,6-dichloronorbornene (I) and *cis-endo*-5,6-dichloronorbornene (II) on the basis of the NMR spectral data. Their purities were above 99%, as determined by means of glc analysis. (I), mp 79—80 °C (from *n*-Hexane); yield, 11% (Found; C, 51.05; H, 5.03%). (II), bp 72.5—73 °C/15 mmHg; yield, 74% (Found; C, 51.33; H, 5.03%).

cis-exo-5,6-Dichloronorbornene was also isolated from the reaction mixture of cyclopentadiene with *cis*-dichloroethylene, along with I, in a yield of about 0.3% (bp 88 °C/20 mmHg); its identity was confirmed on the basis of NMR datum and elementary analysis (Found C, 51.56; H, 4.93%. Calcd C, 51.56; H, 4.95%), while glc analysis showed some (ca. 3%) contamination with the *endo*-isomer.

Bromination and Kinetic Study. The bromine addition reactions were carried out in the usual way in solutions of CCl_4, $CH_3CO_2C_2H_5$, CH_3CO_2H, $Cl(CH_2)_2Cl$, and CH_3OH. The addition products were isolated, according to their situation, by means of recrystallization (A), vacuum distillation (B) and preparative gas chromatography (C).[6]

The rate of addition was determined by the titration method described in the previous paper[2].

Results and Discussion

The brominations of the substrates, I, II, and III, in acetic acid were stereospecific, giving the *trans* adduct, the *exo-cis* adduct, and the *trans* adduct respectively. The stereochemistry of the addition products was confirmed on the basis of the NMR spectra. The results of microanalysis and the assignments of the NMR spectra of the adducts obtained in this investigation are listed in Tables 1 and 2 respectively.

Table 1. Results of micro analysis of adducts

Adducts	Bp or Mp	C%		H%	
		Calcd	Found	Calcd	Found
(I_t)	59—60 °C (C, A)[c] (*n*-hexane)	26.04	25.90	2.50	2.44
(I_c)[a]	57.5—58.5 °C (B)	26.04	26.14	2.50	2.43
(II_c)	164.5—165.5 °C (A) (cyclohexane)	26.04	26.14	2.50	2.49
(III_t)	83—85 °C/ 10^{-3} mmHg (C)	26.04	26.11	2.50	2.30
(I_m)[b]	(B)	35.07	35.01	4.05	4.16

a) The preparative gas chromatography of the reaction mixture of I with bromine in CCl_4 afforded the *exo-cis* adduct as a crystalline compound. b) The methoxy derivative was isolated as an oily product together with I_t by the preparative gas chromatography from the reaction mixture of I with bromine in methanol. Bp of the mixture of I_t and I_m was 60—75 °C/10^{-3} mmHg. c) Alphabet in brackets shows the preparative method described in Experimental part.

As to the orientation of bromine addition, the results for the substrates, I, II, and III, show an inclination to dicyanonorbornene derivatives similar to that described in the previous paper[2] except that the bromination of *endo*-2,*exo*-3-dicyanonorbornene gave *exo-cis* adduct in a 24% yield even in acetic acid, while the bromination of I gave stereospecifically the *trans* adduct (*ca.* 100% yield). Steric terms could not interpret the difference described above because the chlorine atom may be considered to have a bulkiness similar to that of the cyano group. Such results may presumably be explained in terms of the different inductive effects.

TABLE 2. NMR SPECTRAL DATA OF ADDUCTS[a)]

Adduct[g)]	H_2	H_3	H_1 and H_4	H_5	H_6	H_{7a}	H_{7b}

a) Chemical shifts are in ppm downfield from TMS (τ-units, in $CDCl_3$). b) Band width at half-height= 14 Hz. c) Chemical shifts in parentheses were measured in C_6H_6. This solvent was useful for separation of the overlapped signals. d) Measured in solution of $CDCl_3$ and $(CD_3)_2CO$ in the ratio of 1:1. e) Measured in solution in CCl_4. f) τ-Value for CH_3O was 6.57 ppm in CCl_4 solution. g) At first such numbering as shown in (I_t) were employed for convenience of stereochemical studies of bromine adducts. Stereochemistry of bromine atoms of adducts was elucidated by means of the magnitude of coupling constants between C_5 proton and C_6 proton and the presence of 4σ long range coupling between 7b proton and C_5 or C_6 *endo* proton (refer to assignments of lines in the previous paper[2)]). An example of the assignment of peaks in I_t is afforded here. The 100 MHz NMR spectrum of I_t shows two resonances equivalent to two protons at upfield positions. Based upon the discussion presented in the previous paper, the absorptions around τ 7.28 and 7.78 are assigned to the 1,4 protons and 7a, 7b protons, respectively. The absorptions around τ 5.72 and 5.60 exhibits a complicated AB pattern in which the upfield part is assigned to C_2 *exo* proton with great certainty compared with the chemical shift of C_2 *exo* proton in I_c. Spin decoupling experiments also revealed that the proton in I_t at τ 5.72 was coupled with the C_1 proton to the extent of 3 Hz, leading to the assignment of 3 Hz of the resulting doublet as the coupling between C_2 *exo* and C_3 *endo* protons. Irradiation of C_{7a} proton removes the 2.0 Hz coupling from the absorption at τ 5.60, confirming 2.0 Hz as a coupling of C_3 *endo* proton with C_{7a} proton. The complicated resonance at τ 5.50 is equivalent to two protons. The value of 5.0 Hz as band width at half-height may eliminate the presence of *cis* coupling between C_5 and C_6 protons. However, the presence of two stereoisomers would be possible with I_t adduct. This is the same with the *trans*-adduct I_t' of bromine to 5,6-dicyanonorbornene (I') obtained in the previous paper whose conformational assignment remained obscure. NMR spectra of these adducts (I_t and I_t') showed the formation of only one isomer of each two stereoisomers. With I_t', one of them, 5-*exo*,6-*endo*-dibromo, 2-*endo*, 3-*exo*-dicyanonorbornane which seemed to be least probable according to their intramolecular repulsion between C_6-*endo* bromine and C_2-*endo* cyano group, does not take place intramolecular lactonization on hydrolysis. Treatment of I_t' with 15% HBr solution under reflux conditions over a 30 min period, afforded a solid material which was recrystallized from hot 15% HBr solution. mp 228—230 °C. The IR spectrum (KBr disk) exhibited a strong absorption band at 1770 cm^{-1} (γ-lactone). The NMR spectrum (DMSO-d_6) gave signals at 5.34 (1H, C_{6exo}, $J_{6-exo-1}=4.8$ Hz), 5.33 (1H, C_{5exo}, $J_{5exo-4}=3.5$ Hz, $J_{6exo-5exo}=7.1$ Hz), suggesting this compound 3-*exo*-carboxy-5-*endo*-bromo-6-*endo*-hydroxybicyclo[2,2,1]heptane-2-*endo*-carboxylic acid lactone (Found: C, 40.85; H, 3.40; Br, 30.36%; Calcd: C, 41.40; H, 3.47; Br, 30.61%). As a chlorine atom is considered to have a bulkiness similar to that of cyano group from their van der Waals radii,[7)] I_t may be also assigned to a less strained structure shown in Table 2. (The structure of I_m was also considered to be that one listed in Table 2 in connection with those of I_t' and I_t).

Kinetic studies showed that the reactions of bromine with I and II in acetic acid follow the second-order rate equation (first-order in bromine concentration and first-order in substrate concentration); the rate constants observed in these studies are summarized in Table 3. The reaction of bromine with the III substrate was too fast to be determined by such a titration method ($k(25\ °C)>273\times10^{-3}$ mol/l·s).

Table 3 shows that the reactivity increased in the substrate order of III>I>II, indicating that the *endo*-chlorine atoms retarded the bromine addition reaction. Such results appear to be analogous to the reactivities reported in the previous paper[2)] with 2,3-dicyano-5-norbornene derivatives, although the rate constants are about six times larger than those of the corresponding 2,3-dicyano-5-norbornenes.

Unlike the results of the reaction of I with bromine in acetic acid, in a relatively nonpolar solvent such as CCl_4, the *trans*-adduct (I_t) and the *exo-cis* adduct (I_c) were obtained in 37 and 63% yields respectively; their

Table 3. Rate constants of bromine addition in acetic acid

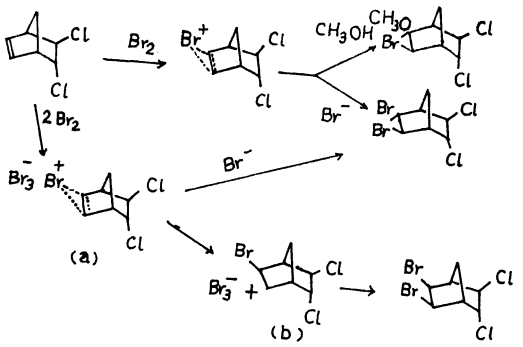
(II)	0.0301 (0.0483)	20.0	61.6	6.33
	0.0300 (0.0476)	24.7	60.1	7.58
	0.0400 (0.0475)	35.0	66.7	9.88

a) Values in brackets indicate the initial bromine concentration (mol/l).

compositions were estimated by glc.[9] As the compositions of these dibromides were estimated to depend upon the polarity of solvents, the addition of bromine to the substrate I was carried out in various solvents whose polarities had been evaluated in terms of the E_T value.[10]

Table 4 summarizes the approximate compositions of I_t and I_c obtained from the addition reaction, along with the E_T value of each solvent. Table 4 indicates that the addition became progressively less stereospecific and gave more and more *exo-cis* adduct as solvents of lower E_T values (relatively non-polar solvents) were used. Since free-radical addition has often been reported to lead to the *exo-cis* adduct[11,12] as the major product, the addition of bromine was carried out in the presence of nitrobenzene, which has been reported to be a radical inhibitor[13] (Runs No. 9 and 10), but as is shown in Table 4, no inhibiting effect by nitrobenzene was observed. The increase in the *trans*-adduct with Run No. 10 compared with that of Run No. 9 was observed. This may be considered to be the result of the increase in solvent polarity caused by the addition of nitrobenzene (polar media, E_T value=42.0). Such a finding may exclude the possibility of a radical mechanism in bromine addition in relatively non-polar solvents.

Kinetic studies showed that the addition reaction in CCl_4 followed the third-order rate equation ($dc/dt = k[Br_2]^2\times[\text{substrate}]$, $[Br_2]=0.0511$ mol/l, [substrate]=0.0309 mol/l, percentage of completion=64%, k(29.7 °C)$=5.86\times10^{-1}$ l²/mol²·s) rather than the second-order rate equation ($dc/dt=k\times[Br_2]\times[\text{substrate}]$). Such results suggest that the *exo-cis* adduct may be produced through the ion-pair mechanism shown in Scheme 1. Such an intermediate would be most stable in relatively nonpolar solvents. As the polarities of solvents increase, the ion-pair intermediate may become progressively less stable and be replaced by the bromonium-ion intermediate.



Scheme 1. Probable reaction mechanism.

The interpretation of the *cis* addition of bromine in terms of ion-pair mechanism was employed in Tamelen's report[14] with regard to the bromination of Dewar benzene in an octane solution. The formation of the *trans*-adduct from the ion-pair intermediate (b) or its precursor [(a) in Scheme 1, most probably] is possible, as is shown in Scheme 1. In order to confirm this possibility, additions were carried out with a bromide salt(tetra-*n*-butylammonium bromide) present (listed in Table 4).[15] The presence of bromide salt[16] as a source of bromide ions increases the ratio of the *trans* adduct in three different solvents ($Cl(CH_2)_2Cl$, $CH_3CO_2C_2H_5$, CCl_4), suggesting that the increase in the *trans* adduct compared with that in the absence of bromide salt may result from the bromide ion attack on this intermediate from the *endo* direction. Accordingly, the finding that the bromination of *trans*-

Table 4. Results of bromine addition to substrate I in different solvents

Run No.	Concentration of substrate (mol/l)	Solvent (ml)	Temp. (°C)	E_T-value[a]	I_t (%)	I_c[b] (%)
1	0.0188	MeOH (170)	30	55.5	100[d]	0

8	0.00316	CCl_4 (100)	30[c]		64.5	35.5
9	0.00619	CCl_4 (70)+$C_6H_5NO_2$ (6)	66—70		32.5	67.5
10	0.00619	CCl_4 (70)+$C_6H_5NO_2$ (18)			46.9	53.1

a) These values were taken from Ref. 10. b) Analyzed by means of glc. c) Addition of 1.6 g of tetra-*n*-butyl ammonium bromide. d) 6-Bromo-5-methoxy-1-*endo*, 2-*exo*-dichloronorbornane (refer to Tables 1 and 2) was also obtained along with *trans* dibromide, (I_t). e) Small amounts of (I_c) was detected by means of glc analysis.

5,6-dicyano-2-norbornene in acetic acid afforded the *exo-cis* adduct in a 24% yield, whereas the bromination of I gave the *trans* adduct stereospecifically, may be explained in terms of the coexistence of a carbonium bromide ion pair[17] along with the bromonium ion in the former reaction. With the bromonium ion as an intermediate, a full positive charge develops through olefin carbons, which may be destabilized to some extent by a stronger electron-attracting group such as the cyano group, while, in the ion-pair intermediate, where the bromide ion may remain associated with the carbonium ion, the above substituent will not exert such an influence on the destabilization of the ion pair as is imagined in the case of the bromonium ion. Therefore, in the bromination of *trans*-5,6-dicyano-2-norbornene in acetic acid, the bromonium-ion intermediate may be destabilized to the extent of permitting the coexistence of an ion pair by the more electronegative group (C≡N).

16) When tetra-*n*-butylammonium bromide is dissolved in a bromine solution, the equilibrium may be considered to involve bromine, monobromide salt, and tribromide salt. However, in the bromination by these salts, it is said that active species is bromine, so that the addition of monobromide in this experiment will exert little effect upon the stereochemical distribution of adducts.

Some Electrophilic Substitution Reactions of 2-Hydroxyazulene Derivatives[1]

Tetsuo Nozoe,* Toyonobu Asao,** and Masaji Oda
Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980
(Received July 18, 1973)

The bromination, chlorination, and nitration of 1,3-disubstituted 2-hydroxyazulenes were investigated. Bromination by bromine or NBS afforded 1-bromoazulan-2-one derivatives as kinetically-controlled products and 6-bromo-2-hydroxyazulene derivatives as thermodynamically-controlled products. Chlorination by NCS gave 1-chloroazulan-2-one derivatives, while that by chlorine afforded further chlorine addition products. Nitration afforded a mixture of 1-nitroazulan-2-one and 6-nitro-2-hydroxyazulene derivatives. The ultraviolet, infrared, and NMR spectra of the products were discussed.

It has been established[2,3] that the electrophilic substitutions of azulenes occur at the 1 and 3 positions; positions which coincide with the calculated positions[4] thought to have the highest electron density by theoretical considerations, and that the 5, 7, and 2 positions, with the next higher electron density, undergo the reaction in the case of 1,3-disubstituted azulenes.[5]

However, 1,3-disubstituted azulenes with strongly electron-releasing groups, such as an amino or a methylamino group, at the 2-position have been known to undergo facile bromination at the 6-position,[6] and 1,3-dicyano-2-hydroxy-5-isopropylazulene have also been known to afford 6,8-dibromo derivative by bromination.[7] These facts indicate that the strongly electron-releasing group at the 2-position governs the substitution at the 4, 6, and 8 positions.

In the present research, some electrophilic substitutions of 1,3-disubstituted 2-hydroxyazulenes were investigated; the results will be reported herein.

The bromination of diethyl 2-hydroxyazulene-1,3-dicarboxylate (I)[8] with 1.5 molar equivalents of bromine in acetic acid in the presence of sodium acetate afforded a reddish pink solid (II). When the solid was dissolved in ethanol, it gradually turned yellow; from it 90% of the starting azulene (I) and 5.5% of yellow needles (III) (mp 163 °C) were then obtained. Compound III, corresponding to the monobromide of I, shows an ultraviolet spectrum (Fig. 1) similar to that of I; its infrared spectrum displays an out-of-plane deformation band due to adjacent two hydrogens at 830 cm^{-1}. Furthermore, the NMR spectrum of III shows two doublets with the same coupling constant (J=11.8 Hz) at δ 7.86 and 8.93, each corresponding to two protons. These data clearly show that Compound III is diethyl 6-bromo-2-hydroxyazulene-1,3-dicarboxylate.

When the reddish pink solid (II) was washed with ether and then recrystallized from benzene–petroleum ether, a pure specimen of II was obtained as reddish prisms (mp 129 °C) in a yield of 68%. Compound II was also obtained by the reaction of I and NBS in CCl_4 in a 75% yield. Elemental analyses show that Compound II is also a monobromide of I; its UV spectrum (Fig. 1) is completely different from that of I or III, but rather similar to those of 1-oxaazulan-2-one (1*H*-1-oxaazulene-2-one) derivatives[9] or 8,8-dicyanoheptafulvene[10] in methanol.

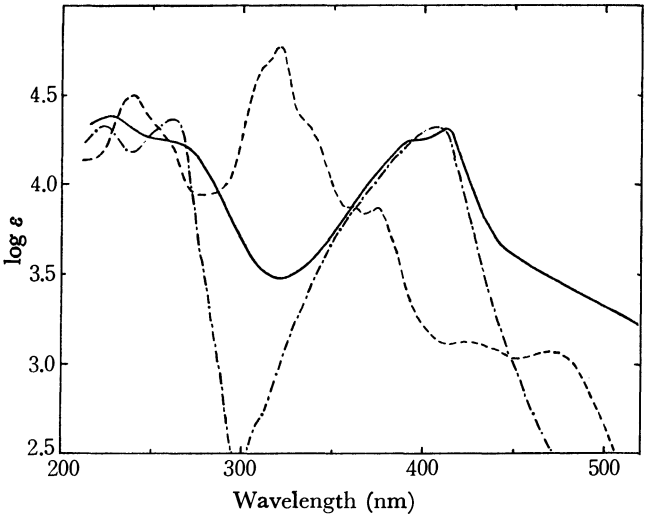

Fig. 1. UV spectra of II (——), III (----), and ethyl 1-oxa-2-oxo-azulane-3-carboxylate (— - —) in methanol.

The IR spectrum of II shows carbonyl bands at 1749 and 1689 cm^{-1}; the former one is comparable to that of 1-oxaazulan-2-one.[9] The NMR spectrum of II exhibits signals at δ 8.40 (bd, J=12 Hz, Ha), 6.7—7.2 (m, Hb–He), 4.31 (q), 4.20 (q), 1.36 (t), and 1.1 (t). From the above data, it is clear that II is diethyl 1-bromo-2-oxo-azulane-1,3-dicarboxylate (diethyl 1*H*-1,2-dihydro-1-bromo-2-oxoazulene-1,3-dicarboxylate), with a heptafulvenoid chromophore. The formation of II can be explained by considering that Compound I reacts as a β-keto ester form (Ia) under the present reaction conditions. The reactivity is similar to that of β-naphthol.[11]

It has been found that 2-hydroxyazulene (IV) exists in the enol form (IV) in methanol and in the keto form, 1,2-dihydroazulene-2-one (IVa), in $CHCl_3$ or water, and that the IR of 2-hydroxyazulene in KBr disk does not show any carbonyl band.[12] Meanwhile, Nozoe *et al.* have reported, in their azulene synthesis from the reactive troponoids with active methylene compounds, that there are three principal interme-

(A) X = O, NH (B) (C) X = O, NH

diates: "oxaazulanone" (A), "heptafulvene" (B), and "azulanone" (C).[13] However, the B and C intermediates are so unstable in the basic reaction conditions that they could not be isolated. Compound II is the first example of stable azulanone type compound obtained from azulene derivatives, and from the above view points, it is of interest to investigate the properties of II and the similar compounds obtained below.

Compound II is unstable to protic solvents, especially to bases, and in these solvents II liberates the bromine cation, which can easily be detected by the iodine-starch test, to give mainly I and a small amount of III at room temperature. Even on standing in air, II is gradually decomposed, presumably by moisture, to give I and III. Compound II immediately gave the sodium salt of hydroxyazulene (I) by the action of a sodium hydroxide solution, while the reaction with potassium iodide in acetone afforded potassium salt of I. The reaction of II with 2,4-dinitrophenylhydrazine or hydrazine yielded I and the hydrazine salt of I respectively.

On the other hand, the heating of II in DMF at 90 °C afforded 55% of I and 45% of III. When II was heated in DMF at 90 °C in the presence of an equimolar amount of dimethyl 2-hydroxyazulene-1,3-dicarboxylate (V),[10] dimethyl 6-bromo-2-hydroxyazulene-1,3-dicarboxylate (VI) (mp 210 °C) was obtained besides I, III, and V by intermolecular reaction. Therefore, it is clear that the bromination of I afforded at first the 1-bromo derivative (II) as a kinetically controlled product; then it afforded the 6-bromo derivative (III) as a thermodynamically controlled product under more severe reaction conditions. For the purpose of the direct synthesis of III, the bromination of I at an elevated temperature was attempted. Thus, the action of bromine on I in acetic acid–sodium acetate or in DMF–sodium acetate at 100 °C afforded III in yields of 45 and 70% respectively, besides I.

The bromination of the dimethyl ester (V) by bromine in $CHCl_3$ in the presence of sodium acetate at room temperature afforded 1-bromo compound (VII) as reddish prisms (mp 136 °C), whose UV and IR spectra are very similar to those of Compound II. When the reaction was carried out in DMF in the presence of sodium acetate and then the mixture was left standing at room temperature for 10 hr, the 6-bromo derivative (VI) was obtained in a 76% yield. Compound VI was also obtained by heating VII in DMF.

Similarly, the bromination of ethyl 1-cyano-2-hydroxyazulene-3-carboxylate (VIII)[13] with bromine in acetic acid–sodium acetate or with NBS in benzene afforded ethyl 1-bromo-3-cyano-2-oxo-azulane-1-carboxylate (IX) (mp 109 °C); the bromination of VIII in acetic acid–sodium acetate at 100 °C afforded ethyl 6-bromo-3-cyano-2-hydroxyazulene-1-carboxylate (X) (mp 207 °C).

The bromination of 1,3-dicyano-2-hydroxyazulene (XI)[13] by bromine in $CHCl_3$ in the presence of sodium acetate at room temperature afforded a reddish oily product (XII), which did not crystallize and which could not be purified because of its instability. The IR of XII exhibits a strong carbonyl band at 1724 cm^{-1} and a weak cyano band at 2215 cm^{-1}. The UV of XII shows a curve similar to that of II, with maxima at 290, 406, and 425 nm. From these data, the oil is assumed to be 1-bromo-1,3-dicyanoazulan-2-one (XII). When the solution of the oil (XII) in $CHCl_3$ was allowed to stand at room temperature for 30 min, it turned yellow and 50% of the 6-bromo-1,3-dicyano-2-hydroxyazulene (XIII) was obtained, besides XI. The structure of XIII was determined by means of the spectroscopic data.

When a solution of XI, 1.5 molar equivalents of bromine, and sodium acetate in acetic acid was allowed to stand at room temperature for 1 hr, the 6-bromo derivative (XIII) was obtained in a yield of 67% besides an unidentified yellowish-brown mixture. The reaction of XI with 3 molar equivalents of bromine in acetic acid in the presence of sodium acetate afforded 4,6,8-tribromo-1,3-dicyano-2-hydroxyazulene (XIV) besides XIII and an unidentified brown solid.

On the bromination of ethyl 2-hydroxyazulene-1-carboxylate (XV),[8] the unsubstituted 3-position was exclusively attacked, and ethyl 3-bromo-2-hydroxyazulene-1-carboxylate (XVI) was obtained in a good yield.

When the 6-bromo compound (III) was further

treated with NBS in benzene, the solution turned red, and the UV of the solution showed a curve similar to that of 1-bromide (II); therefore, the 1,6-dibromo compound (XVII) seems to be formed. However, the working-up of the solution afforded only the starting compound (III), and no XVII or 4,6-dibromo derivative could be isolated; such unreactivity may due to a steric interaction of ethoxycarbonyl groups at the 1 and 3 positions to the peri-position of the nucleus.

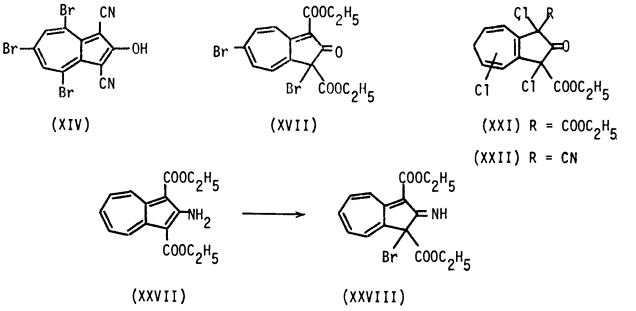
The reactions of I, V, and VIII with *N*-chlorosuccinimide (NCS) in benzene afforded three 1-chloro derivatives, XVIII (mp 98 °C), XIX (mp 161 °C), and XX (mp 132 °C), in good yields. The structures of these products were determined by their spectroscopic properties. These compounds are more stable than the corresponding bromides (II and VII), and do not change easily on standing in the air.

The reaction of I and VIII with chlorine in CCl_4 afforded two pale yellow oils (XXI and XXII respectively). The results of the analyses of these products almost accord with those of trichloride of the starting compounds, and their UV maxima appear only at 261 nm in both compounds. The IR of XXI displays bands at 1790 and 1767 cm^{-1}, while that of XXII shows them at 2205 (vw), 1975, and 1767 cm^{-1}. From these data, the structures of the compounds can tentatively be assigned as is shown in the figure. Compound XXI is quite stable; however, XXII gradually changes when allowed to stand at room temperature and gives a reddish solid, from which the 1-chloro compound (XX) is subsequently isolated in a 50% yield.

The nitration of I with concentrated nitric acid in acetic acid was carried out, and two kinds of mononitro derivatives, were isolated. One consisted of brown needles (XXIV) (41% yield), while the other consisted of reddish crystals (XXIII) with a low melting point (36% yield). Compound XXIV was determined to be diethyl 2-hydroxy-6-nitroazulene-1,3-dicarboxylate from its spectroscopic data; the UV is similar to those of azulenes, and the NMR in $CDCl_3$ shows A_2B_2-type doublets at δ 9.48 and 8.43, with the same coupling constant (J=12 Hz). From the similarity of UV and IR spectra of XXIII to those of II, Compound XXIII is assumed to be diethyl 1-nitro-2-oxo-azulane-1,3-dicarboxylate.

A similar nitration of VIII afforded 6-nitro derivative (XXVI) as brown crystals in a 39% yield and 1-nitro derivative (XXV) as reddish crystals in a 42% yield. In these nitrations of I and VIII, reddish powders were obtained in 10—15% yields; however, attempts to purify them were not successful.

As has been mentioned at the beginning, diethyl 2-aminoazulene-1,3-dicarboxylate (XXVII) undergoes a facile bromination by bromine at the 6-position in a $CHCl_3$ solution to give orange crystals with UV maxima at 473, 410, 332, 320, and 245 nm.[6] The UV spectrum of a solution of XXVII and NBS in benzene displays maxima at 395 and 375 nm characteristic of heptafulvene chromophore, therefore, the 1-bromoazulan-2-imine derivative (XXVIII) must be formed in the solution. However, the compound could not be isolated.



In order to synthesize the model compound (C; R′=R″=$COOC_2H_5$, R‴=CN or $CONH_2$) of the "azulanone" intermediate in the azulene synthesis,[13] the reaction of II with cyanogen bromide or urea was attempted. The reaction of silver salt of I with cyanogen bromide afforded II, III, and a small amount of a compound assumed to be diethyl 6-cyano-2-hydroxyazulene-1,3-dicarboxylate (XXIX). On the heating of I with urea in acetic acid in the presence of a few drops of sulfuric acid, reddish orange needles, which were assumed to be diethyl 1-carbamoyl-2-oxo-azulan-2-one-1,3-dicarboxylate (XXX), were obtained once in a 5% yield; also the starting azulene was recovered. However, the structure and the reactivity of XXX were not clarified because of the lack of a sample.

Experimental***

Bromination of Diethyl 2-Hydroxyazulene-1,3-dicarboxylate (I). (a) To a stirred solution of I (1 g) and sodium acetate (427 mg) in acetic acid (10 ml), a solution of bromine (834 mg) in acetic acid was added at room temperature. The solution turned deep red. After 2 hr, a 40 ml portion of water was added, thus giving a reddish oil, which was subsequently solidified by allowing to stand. The reddish pink solid that resulted was washed with ether, and 870 mg (68%) of reddish crystals were obtained. Recrystallization from benzene–petroleum ether gave II as reddish needles; mp 128—129 °C.

Found: C, 52.66; H, 4.29; Br, 22.00%. Calcd for $C_{16}H_{15}O_5Br$: C, 52.32; H, 4.12; Br, 21.76%.

λ_{max}^{MeOH} nm (log ε); 228 (4.39), 260 (4.24), 395 (4.24) and 414 (4.31).

By treating the filtrate with sodium hydroxide, sodium salt of I was recovered in a 25% yield.

(b) NBS (354 mg) was added to a stirred solution of I (500 mg) and sodium acetate in benzene (20 ml). After 15 min, the solvent was removed until the volume was about 10 ml, and then succinimide was removed by filtration. The filtrate was further condensed to about 5 ml, and petroleum ether was added to give reddish crystals (495 mg, 79%), which were subsequently washed with petroleum ether and recrystallized from benzene–petroleum ether to give red needles (mp 128—129 °C), whose infrared spectrum was superimposable upon that of II obtained by Procedure (a).

(c) A solution of I (1 g), sodium acetate (427 mg), and bromine (894 mg) in acetic acid was warmed on a water bath for 2 hr; then it was allowed to stand overnight at room temperature. The precipitate was filtered to give 490 mg

*** All melting points are uncorrected.

of yellow crystals; when water was then added to the filtrate to yield a reddish oil which was subsequently crystallized by the addition of ethanol, 80 mg of the same yellow crystals and 500 mg of the starting materials were obtained. The combined product was then recrystallized from ethanol to give III as yellow needles (470 mg, 73%); mp 162—163 °C

Found: C, 52.44; H, 4.32%. Calcd for $C_{16}H_{15}O_5Br$: C, 52.32; H, 4.12%.

λ_{max}^{MeOH} nm (log ε); 240 (4.50), 263^{sh} (4.23), 313^{sh} (4.67), 322 (4.78), 360 (3.87), 375 (3.87), 420 (3.13) and 470 (3.07).

$\lambda_{max}^{MeOH-0.1N\ NaOH}$nm (log ε); 247 (4.42), 275 (3.99), 320^{sh} (4.60), 334 (4.73), 420 (3.77) and 490 (3.72).

Methyl Ether: Methyl ether was obtained by the reaction of III with diazomethane; reddish orange needles; mp 124—125 °C.

Found: C, 53.39; H, 4.80%. Calcd for $C_{17}H_{17}O_5Br$: C, 53.55; H, 4.50%.

Ethyl Ether: Ethyl ether was obtained by the reaction of III with diazoethane; reddish orange needles; mp 109—110 °C.

Found: C, 54.53; H, 4.70%. Calcd for $C_{18}H_{19}O_5Br$: C, 54.71; H, 4.85%.

(d) A solution of I (200 mg), sodium acetate (85 mg), and bromine (166 mg) in dimethyl formamide (4 ml) was allowed to stand at room temperature for 2 days. When water (15 ml) was then added, 245 mg solid was obtained. The fractional recrystallization of the solid afforded 175 mg (68%) of III and 50 mg of I.

Thermal Reaction of Diethyl 1-Bromo-2-oxo-azulan-2-one-1,3-dicarboxylate (II). A solution of II (100 mg) in DMF (2 ml) was heated at 100 °C for 3 hr. When water was then added and the precipitate was fractionally recrystallized from ethanol, 45 mg (45%) of III and 40 mg (50%) of I were obtained.

Reaction of II and Dimethyl 2-Hydroxyazulene-1,3-dicarboxylate (V). A solution of II (200 mg) and V (142 mg) in DMF (6 ml) was heated at 100 °C for 3 hr. The crystals (80 mg) which were precipitated out were recrystallized from ethyl acetate to give 75 mg (40%) of pale yellow needles (mp 210 °C). The crystals were identified as dimethyl 6-bromo-2-hydroxyazulene-1,3-dicarboxylate (VI) by a mixed-melting-point comparison and by a comparison of the infrared spectra. The filtrate of the reaction was diluted with water and extracted with chloroform. When the extract was then evaporated, 215 mg of crystals were obtained. The crystals were proved to be a mixture of I, V, and a small amount of III by separation using thin-layer chromatography on silica gel.

Bromination of Dimethyl 2-Hydroxyazulene-1,3-dicarboxylate (V). (a) To a stirred solution of V (100 mg) and sodium acetate (42 mg) in chloroform (5 ml), a solution of bromine (80 mg) in chloroform was added at room temperature. After 15 min, the inorganic substance thus precipitated was filtered off, and to the filtrate petroleum ether was added to obtain reddish crystals. The crystals were then recrystallized from $CHCl_3$–petroleum ether to give VII as reddish prisms (25 mg); mp 136 °C.

Found: C, 49.49; H, 3.24%. Calcd for $C_{14}H_{11}O_5Br$: C, 49.60; H, 3.27%.

λ_{max}^{MeOH} nm (log ε); 227 (4.38), 270^{sh} (4.21), 395^{sh} (4.20) and 415 (4.26).

The treatment of the filtrate with sodium hydroxide afforded 70 mg of a sodium salt of V.

(b) A solution of V (200 mg), sodium acetate (77 mg), and bromine (148 mg) in DMF (5 ml) was allowed to stand at room temperature for 12 hr. Water (20 ml) was then added, and the crystals thus precipitated were washed with methanol and recrystallized from ethyl acetate to give VI (200 mg, 76%) as pale yellow needles; mp 210 °C.

Found: C, 49.39; H, 3.34%. Calcd for $C_{14}H_{11}O_5Br$: C, 49.60; H, 3.27%.

λ_{max}^{MeOH} nm (log ε); 240 (4.52), 264^{sh} (4.27), 310^{sh} (4.65), 321 (4.77), 335^{sh} (4.47), 374 (4.28), 420 (3.48) and 470 (3.30).

$\lambda_{max}^{MeOH-0.1N\ NaOH}$ nm (log ε); 247 (4.50), 280^{sh} (4.14), 325^{sh} (4.70), 333 (4.76), 415 (4.28) and 488 (4.18).

Bromination of Ethyl 3-Cyano-2-hydroxyazulene-1-carboxylate (VIII). (a) To a suspended solution of VIII (200 mg) and sodium acetate (88 mg) in acetic acid (20 ml) was added a solution of bromine (162 mg) in acetic acid at room temperature. After the solution had been stirred for 30 min, water (30 ml) was added and the solution was extracted with benzene. The extract was dried, the solvent was removed to a small volume, and petroleum ether was added to give reddish crystals (175 mg, 66%). Subsequent recrystallization from benzene–petroleum ether afforded ethyl 1-bromo-3-cyano-2-oxo-azulane-1-carboxylate (IX) as reddish prisms; mp 109 °C.

Found: C, 52.41; H, 3.15; N, 4.69; Br, 25.02%. Calcd for $C_{14}H_{10}O_3NBr$: C, 52.54; H, 3.40; N, 4.38; Br, 24.97%.

λ_{max}^{MeOH} nm (log ε); 225 (4.27), 258 (4.15), 395 (4.19) and 417 (4.25).

When the combined filtrates were treated with a sodium hydroxide solution, 55 mg of the sodium salt of VIII were recovered.

(b) To a stirred solution of VIII (500 mg) in benzene (25 ml), NBS (445 mg) was added at room temperature. After 20 min, the solvent was removed to about 10 ml and the precipitated succinimide was filtered off. A large amount of petroleum ether was then added to the filtrate, and 630 mg (95%) of reddish crystals were obtained. Recrystallization from benzene–petroleum ether afforded IX as reddish prisms; their infrared spectrum was superimposable on that of IX obtained by Procedure (a).

(c) A solution of VIII (300 mg), sodium acetate (154 mg), and bromine (298 mg) in acetic acid (15 ml) was heated at 100 °C for 3 hr. After the solution had stood overnight, 300 mg of crystals were obtained; they were recrystallized from ethyl acetate to give ethyl 6-bromo-3-cyano-2-hydroxy-azulene-1-carboxylate (X) (230 mg, 60%) as yellow needles; mp 206—207 °C. From the combined filtrate, VIII (60 mg) and X (20 mg) were obtained.

Found: C, 52.21; H, 3.30; N, 4.07%. Calcd for $C_{14}H_{10}O_3$-NBr: C, 52.54; H, 3.40; N, 4.38%.

λ_{max}^{MeOH} nm (log ε); 235 (4.54), 315^{sh} (4.74), 319 (4.82), 375 (3.93) and 450 (2.95).

$\lambda_{max}^{MeOH-0.1N\ NaOH}$nm (log ε); 247 (4.50), 270^{sh} (3.86), 320^{sh} (4.69), 332 (4.79), 422 (3.95) and 485 (3.77).

Bromination of 1,3-Dicyano-2-hydroxyazulene (XI). (a) To a suspended solution of XI (200 mg) and sodium acetate (127 mg) in $CHCl_3$ (10 ml), a solution of bromine (248 mg) in $CHCl_3$ was added. After 15 min, the precipitate was filtered off, a 50 ml portion of petroleum ether was added to the filtrate, and a reddish oil (200 mg, 70%) was obtained by decantation. The oil could not be crystallized or purified. A solution of the oil in $CHCl_3$ showed UV maxima at 290, 406, and 425 nm. The precipitate obtained from the reaction mixture was identified as a mixture of XI and the 6-bromo derivative (XIII) by a comparison of the infrared spectra.

(b) Bromine (620 mg) was added to a suspension of XI (500 mg) and sodium acetate (317 mg) in acetic acid (10 ml) at room temperature. After 1 hr, the crystals which were precipitated out were filtered and 470 mg of yellow crystals were obtained; these crystals were recrystallized from ethanol

to give 6-bromo-1,3-dicyano-2-hydroxyazulene (XIII) as yellow crystals; mp over 300 °C.

Found: C, 52.74; H, 2.02; N, 9.97%. Calcd for $C_{12}H_5ON_2Br$: C, 52.79; H, 1.85; N, 10.26%.

λ_{max}^{MeOH} nm (log ε); 228 (4.54), 250^{sh} (4.18), 315 (4.78), 328 (4.88), 426 (3.91) and 473 (3.63).

The filtrate obtained from the reaction mixture was diluted with water; a reddish brown solid, which could not be purified, was thus obtained.

(c) To a stirred suspension of XI (500 mg) and sodium acetate (640 mg) in acetic acid (15 ml), bromine (1.24 g) was added at room temperature. The suspension turned deep red, and yellow crystals began to precipitate after 20 min. After 3 hr, the crystals (480 mg) were filtered out and recrystallized from DMF to give 1,3-dicyano-2-hydroxy-4,6,8-tribromoazulene (XIV) (290 mg, 25%) as orange yellow crystals; mp over 300 °C.

Found: C, 32.47; H, 0.67; N, 5.87%. Calcd for $C_{12}H_3ON_2Br_3$: C, 33.43; H, 0.70; N, 6.50%.

λ_{max}^{MeOH} nm; 227, 283, 325, 338 and 440.

From the filtrate of the recrystallization, the 6-bromo derivative (XIII) (150 mg) was obtained. When water was then added to the filtrate of the reaction mixture, 410 mg of a reddish brown solid was obtained.

Ethyl 3-Bromo-2-hydroxyazulene-1-carboxylate (XVI). A solution of ethyl 2-hydroxyazulene-1-carboxylate (XV) (100 mg) and NBS (100 mg) in CCl_4 (4 ml) was gently heated for 20 min. Working up as usual sebsequently afforded XVI (110 mg) as deep orange needles; mp 106—107 °C after recrystallization from ethanol.

Found: C, 53.34; H, 3.82%, Calcd for $C_{13}H_{11}O_3Br$: C, 52.93; H, 3.76%.

λ_{max}^{MeOH} nm (log ε); 247 (4.36), 320 (4.53), 375 (3.75), 390^{sh} (3.77) and 408 (3.81).

$\lambda_{max}^{MeOH-0.1N\ NaOH}$nm (log ε); 245 (4.36), 320 (4.58), 369 (4.76) and 407 (3.70).

Chlorination of Diethyl 2-Hydroxyazulene-1,3-dicarboxylate (I), (a) A solution of I (250 mg), NCS (150 mg), and sodium acetate (100 mg) in $CHCl_3$ (10 ml) was gently heated for 30 min. The resulting reddish solution was washed with water, dried over anhydrous sodium sulfate, and chromatographed on silica gel column, using $CHCl_3$ as the solvent, to give 230 mg of reddish crystals. Subsequent recrystallization from benzene–cyclohexane afforded diethyl 1-chloroazulan-2-one-1,3-dicarboxylate (XVIII) as reddish prisms; mp 97—98 °C.

Found: C, 59.33; H, 4.60%. Calcd for $C_{16}H_{15}O_5Cl$: C, 59.54; H, 4.69%.

λ_{max}^{MeOH} nm (log ε); 225 (4.40), 258 (4.25), 395 (4.26) and 414 (4.30).

(b) To a stirred solution of I (250 mg) in $CHCl_3$, two molar equivalents of a solution of chlorine in CCl_4 were slowly added under gentle heating. The solution first turned red and then pale yellow. The solvent was then removed to give a pale yellow oil (XXI) which could not be purified further.

Found: C, 47.52; H, 3.81%. Calcd for $C_{16}H_{15}O_5Cl_3$: C, 48.85; H, 3.86%.

Dimethyl 1-Chloro-2-oxo-azulane-1,3-dicarboxylate (XIX). By the reaction of dimethyl 2-hydroxyazulene-1,3-dicarboxylate (V) with NCS, XIX was obtained in an 80% yield as reddish prisms (from benzene–cyclohexane); mp 160—161 °C.

Found: C, 57.49; H, 3.83%. Calcd for $C_{14}H_{11}O_5Cl$: C, 57.06; H, 3.76%.

λ_{max}^{MeOH} nm (log ε); 225 (4.38), 265 (4.20), 395 (4.25) and 415 (4.30).

Chlorination of Ethyl 3-Cyano-2-hydroxyazulene-1-carboxylate (VIII). (a) The reaction of VIII with NCS afforded ethyl 1-chloro-3-cyano-2-oxo-azulane-1-carboxylate (XX) as reddish prisms (from benzene–cyclohexane); mp 131—132 °C.

Found: C, 60.97; H, 3.95; N, 5.28%. Calcd for $C_{14}H_{10}O_3NCl$: C, 61.00; H, 3.95; N, 5.08%.

λ_{max}^{MeOH} nm (log ε); 222 (4.38), 255 (4.30), 395 (4.28) and 416 (4.31).

(b) To a solution of VIII (300 mg) in $CHCl_3$ (5 ml), a solution of chlorine in CCl_4 was added. The solution became pale yellow. The solvent was then removed to give a pale yellow oily product, which was assumed to be trichloride (XXII); however, it could not be purified. The oil was gradually decomposed to give a reddish solid. When a part (180 mg) of the solid was dissolved in $CHCl_3$ and chromatographed on silica gel, a compound (91 mg) (mp 132 °C) was obtained whose IR was superimposable upon that of XX obtained by Method (a).

Nitration of Diethyl 2-Hydroxyazulene-1,3-dicarboxylate (I). To a stirred solution of I (1 g) in acetic acid (10 ml), concentrated nitric acid (5 ml) was added at room temperature. A small amount of the solution was then placed in a test tube and heated until the solution turned deep red. The solution was then added to the original reaction mixture, and the mixture was stirred at room temperature. The mixture thereupon turned deep red; then it was cooled with ice. After 10 min, water (3 ml) was added and the precipitate was filtered and washed with ethanol to give 410 mg of brown crystals. The filtrate was diluted with water (50 ml) and extracted with $CHCl_3$. The extract was dried and chromatographed on silica gel, using $CHCl_3$ as the solvent. From the first effluent, 100 mg of the starting azulene (I) was obtained; the second effluent gave 420 mg of a reddish oil, which could not be crystallized or purified completely. The compound was considered to be diethyl 1-nitro-2-oxoazulane-1,3-dicarboxylate (XXIII) from the analytical results and the UV spectrum.

Found: C, 58.01; H, 4.90; N, 3.98%. Calcd for $C_{16}H_{15}O_7N$: C, 57.66; H, 4.54; N, 4.20%.

λ_{max}^{MeOH} nm; 225, 256, 395, and 416.

From the third effluent, 70 mg of brown crystals were obtained. The combined brown crystals (480 mg) were recrystallized from ethyl acetate to give diethyl 2-hydroxy-6-nitroazulene-1,3-dicarboxylate (XXIV) as brown needles; mp 219—220 °C.

Found: C, 57.44; H, 4.64; N, 4.13%. Calcd for $C_{16}H_{15}O_7N$: C, 57.66; H, 4.54; N, 4.20%.

λ_{max}^{MeOH} nm (log ε); 247 (4.54), 328 (4.64), 342 (4.59), 370 (3.98), 385 (3.95), 408 (3.92) and 465 (4.22).

$\lambda_{max}^{MeOH-0.1N\ NaOH}$nm (log ε); 243 (4.50), 342 (4.55), 382 (3.96), 405 (3.92) and 487 (4.41).

From the last effluent of the chromatography using ethanol as the solvent, 105 mg of a deep red powder were obtained.

Methyl Ether of XXIV: The methylation of XXIV with diazomethane afforded methyl ether as brownish green needles; mp 143.5—144.5 °C (from ethyl acetate).

Found: C, 58.47; H, 4.54; N, 4.25%. Calcd for $C_{17}H_{17}O_7N$: C, 58.79; H, 4.93; N, 4.03%.

λ_{max}^{MeOH} nm (log ε); 247 (4.49), 318 (4.78), 374 (3.84), 390 (3.86), 406 (3.89) and 470 (3.24).

Ethyl Ether of XXIV: Ethyl ether was obtained by the reaction of XXIV with diazoethane; green needles; mp 106—107 °C (from ethyl acetate).

Found: C, 60.23; H, 5.31%. Calcd for $C_{18}H_{19}O_7N$: C, 59.83; H, 5.30%.

Nitration of Ethyl 3-Cyano-2-hydroxyazulene-1-carboxylate (VIII). A solution of VIII (600 mg) and concentrated nitric acid (10 ml) in acetic acid (20 ml) was gently heated until a

reddish color appeared. When the solution was cooled and water was added 175 mg of brown crystals was obtained. The filtrate was then worked up as in the case of the nitration of I; 220 mg of reddish crystals (XXV), 100 mg of brown crystals, and 84 mg of a reddish powder were thus obtained. The reddish crystals (XXV) showed a mp of 105—108 °C and UV maxima at 225, 257, 397 and 417 nm, but they could not be purified further.

Found: C, 59.20; H, 3.60; N, 9.56%. Calcd for $C_{14}H_{10}O_5N_2$: C, 58.74; H, 3.52; N, 9.79%.

The combined brown crystals (275 mg) were recrystallized from ethyl acetate to give ethyl 3-cyano-2-hydroxy-6-nitroazulene-1-carboxylate (XXVI) as brown needles; mp 231—232 °C.

Found: C, 59.12; H, 3.38; N, 9.57%. Calcd for $C_{14}H_{10}O_5N_2$: C, 58.74; H, 3.52; N, 9.79%.

λ_{max}^{MeOH} nm (log ε); 236 (4.56), 325 (4.65), 340^{sh} (4.63), 370 (4.10), 385 (4.10) and 468 (4.16).

$\lambda_{max}^{MeOH-0.1N\ NaOH}$nm (log ε); 233 (4.55); 327 (4.51), 338 (4.54), 380 (4.02) and 476 (4.34).

Reaction of Silver Salt of I with Cyanogen Bromide. Silver salt of I was obtained by the reaction of I with silver oxide in ethanol and was used after drying under reduced pressure. To a stirred solution of silver salt of I (396 mg) in DMF (4 ml) at 100 °C, cyanogen bromide (400 mg) was added, whereupon the solution immediately turned red. After 30 min, the precipitated silver bromide was filtered off and washed with $CHCl_3$; the solvent was then removed under reduced pressure to leave a reddish oily product. A solution of the oil in $CHCl_3$ was chromatographed on silica gel. The crystals obtained from the reddish effluent was fractionally recrystallized from $CHCl_3$–petroleum ether; 120 mg of II, 20 mg of III, and 55 mg of reddish needles (XXIX) (mp 128—130 °C) were thus obtained.

Found: C, 64.95; H, 4.78; N, 4.19%. Calcd for $C_{17}H_{15}O_5N$: C, 65.23; H, 4.83; N, 4.48%.

λ_{max}^{MeOH} nm; 237, 262, 301, 312, and 410.

IR (KBr disk); 2242 and 1690 cm^{-1}.

NMR ($CDCl_3$); δ 1.52 (t), 4.53 (q), 7.92 (2H, d, J=8.6 Hz) and 10.03 (2H, d, J=8.6 Hz).

Reaction of I with Urea. A solution of I (400 mg) and urea (250 mg) in acetic acid (5 ml) was heated at *ca.* 90 °C for 4 hr in the presence of 5 drops of concentrated sulfuric acid. The solution was then diluted with water and extracted with $CHCl_3$, after which the extract was dried and chromatographed on a silica gel column. From the first effluent, 130 mg of the starting azulene (I) was recovered; the next effluent afforded 50 mg of a reddish oil, which was crystallized from benzene–petroleum ether, and also 10 mg of XXX as reddish-orange needles (mp 154—155 °C) was obtained (from benzene–petroleum ether).

Found: C, 63.55; H, 5.51%. Calcd for $C_{17}H_{17}O_6N$: C, 61.63; H, 5.17%.

Photo-Beckmann Rearrangements of Oximes of Androsterone and 13α-Androsterone[1]

Hiroshi SUGINOME and Tsutomu UCHIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 26, 1973)

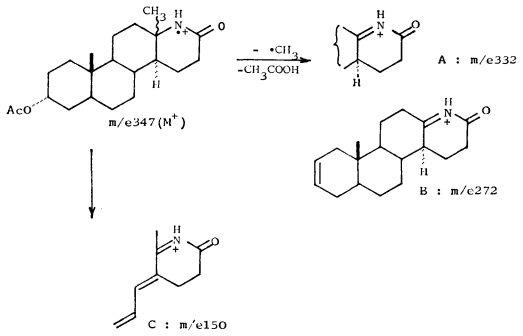
The photolysis of androsterone oxime and 13α-androsterone oxime affords isomeric lactams with and without the original configuration of the C-13 substituent of the starting oxime, although there were poor yields and no products due to photo-Beckmann fission. The formation of an epimeric pair of lactams from an oxime is at variance with our previous results on the photolysis of 5α- and 5β-cholestan-6-one oximes, in which the stereochemical integrity of the terminus of the migrating carbon in the photo-Beckmann rearrangement was observed. The implication of the present results for the migration step of the photo-Beckmann rearrangement is discussed.

In our previous papers it has been shown that in the photo-Beckmann rearrangement of steroidal oximes the bond migration of the oximes to amides proceeds in a stereospecific manner, the migration of carbon α to the oximino group occurring with the retention of the original configuration, and in these unsymmetrically α-substituted oximes the relative amounts of the two isomeric lactams due to the migration of the tri-substituted carbon (C_5) and the disubstituted carbon (C_7) are not significantly different.[2,3] This finding was subsequently confirmed by Just *et al.*[4] They showed that the photo-Beckmann rearrangements of menthone oxime and isomenthone oxime afforded the corresponding lactams with retention of the original configuration at carbon α to the oximino group of the starting oximes.

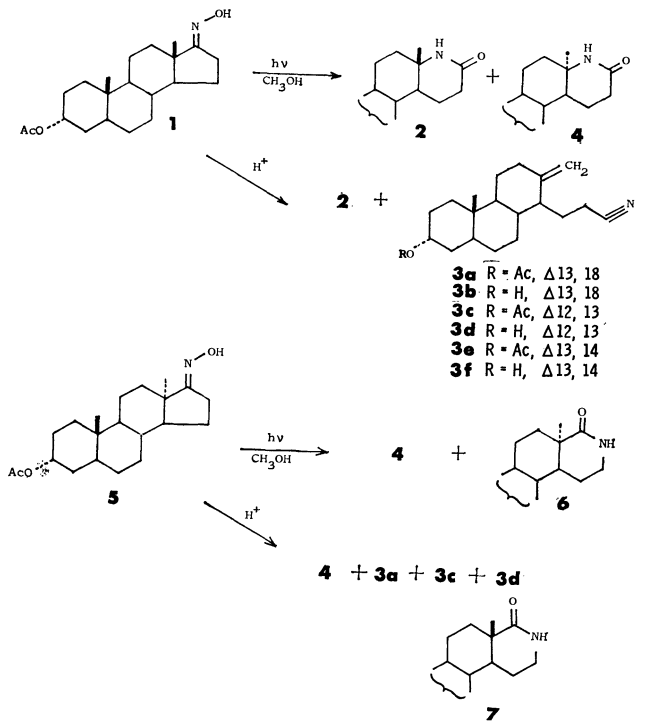
In this paper we wish to report on further results with respect to the stereospecificity of the migration stage in the photo-Beckmann rearrangement. In the present studies we used the title steroidal substrates in which one of the migrating carbons of the oximes is tetra-substituted and therefore, if any radical pair or ion pair is involved in the rearrangement, these species would be more stable and the original configuration of the migrating carbon would be lost more readily in the product lactams.

Results

The oximation of *O*-acetylandrosterone[5] was found to give a single oxime **1** as described previously.[6] The ground state Beckmann rearrangement of **1** has already been described by Regan and Hayes,[6] and later by Barton and his colleagues.[7] Our repetition of this Beckmann rearrangement with thionyl chloride led to a lactam, $C_{21}H_{33}O_3N$, mp 291—292 °C (50% yield), described by the previous investigators, and a mixture of olefins. The structure of the former was confirmed to be 17a-aza-*D*-homo-5α-androsterone **2** both by the NMR spectrum (no signal corresponding to methylene protons adjacent to the nitrogen) and by the mass spectrum in which distinct fragments were observed at *m/e* 347 (M^+), at *m/e* 332, at *m/e* 272, and at *m/e* 150. The respective fragments of the mass spectrum are attributable to the following fragments A, B, and C.[8] The olefins also obtained in a substantial



amount (31%) were amorphous. The elemental analysis and the mass spectrum of this was in accord with the molecular formula $C_{21}H_{31}O_2N$. The infrared spectrum of this revealed the characteristic bands at 2280, 1735, 1643, and 900 cm^{-1} attributable to C≡N stretching, acetoxy C=O stretching, C=C stretching and terminal methylene out-of-plane deformation vibrations. The NMR spectrum of this, however, showed it to be a mixture of 3α-acetoxy-13,17-seco-enoic nitriles, **3a**, **3c**, and **3e** with the double bond at 13, 18, at 12, 13 and at 13, 14. Thus, the NMR spectrum showed a broad singlet at τ 5.00, a couple of singlets of equal intensity at τ 5.23 and 5.54, two singlets at τ 7.96 and 9.29. These signals are safely assignable to the 3β-proton, the exocyclic methylene protons on a cyclohexane ring, the 3-*O*-acetyl group, and the C-10 methyl protons of **3a**. Besides these signals the spectrum showed a doublet at τ 4.38 (J=6.0 Hz) ascribable to the C-12-H of **3c** and a singlet at τ 9.26 ascribable to the 10β-methyl protons of **3c** and **3e**. Based on the peak areas the ratio of **3a**, **3c**, and **3e** were estimated to be 2:2:3. The hydrolysis of this mixture with methanolic KOH at room temperature resulted in the formation of a mixture of the corresponding 3β-ols. In the NMR spectrum two singlets at τ 5.25 and 5.56 and a broad singlet at τ 6.00 were observable and these are attributable to the exocyclic methylene protons and the 3β-proton of **3b**. No signal due to an olefinic proton at C-12 was observed but in the methyl part of the spectrum, in addition to the singlet at τ 9.33 ascribable to 10β-methyl protons of **3b**, another singlet at τ 9.29 and a doublet at τ 7.98 (J=2.4 Hz) were observable. We attribute this to the signal due to 10β-methyl protons and 13-methyl protons of **3f**. Based on the intensities of each signals the ratio of **3b** and



Scheme 1

3f was estimated to be approximately 3:2. The nitriles may be derived either by a second-order Beckmann rearrangement[9] of **1** or by the conversion of the lactam **2** under the reaction condition.[10] But the treatment of **2** in dioxane with $SOCl_2$ did not afford nitriles. Thus, it is certain that these are derived through a second-order Beckmann rearrangement of **1** and is not a secondary reaction product. It is noted that a product due to Beckmann fission of *cis*- and *trans*-8-methyl-1-hydrindanone oximes was a compound with an endocyclic double bond.[11] The obtaining of lactam **2** confirmed that the hydroxyl group is in *anti* position with respect to the C-13 methyl group.

The parallel experiments were then performed with 13α-androsterone oxime. 13α-Androsterone (lumiandrosterone) was first prepared by Butenandt and Poschmann by the photochemical isomerization of androsterone in 1944.[12] In the present study, the irradiation of 3-*O*-acetylandrosterone in dioxane afforded 3-*O*-acetyl-13α-androsterone, mp 122—124 °C, in *ca.* 21% yield. The oximation of this by the usual method afforded a single oxime **5**, mp 186—187 °C, and no isomeric oxime was formed as revealed by tlc. The Beckmann rearrangement of this oxime under the same condition as with androsterone oxime yielded a lactam **4**, mp 193—194 °C* and a mixture of olefins (57 mg) **3a**, **3c**, and **3e** in the ratio of approximately 2:5:3 as was judged by the NMR spectrum. The lactam **4** was isomeric with the lactam **2** and revealed IR bands at 1663 and 3200 cm^{-1} attributable to lactam C=O stretching and lactam NH stretching vibrations. The structure of the lactam **4** should be either 17a-aza-*D*-homo-5α,13α-androsterone or 17-aza-*D*-homo-5α, 13α-androsterone and the former was found to be correct by the NMR and mass spectra. The NMR spectrum of **4** revealed three three-proton singlets at τ 8.74, and at τ 7.96 ascribable to the C-10 methyl, the C-13 methyl and the 3-*O*-acetyl groups, and a three-proton singlet at τ 5.03 and a broad one-proton singlet at τ 3.52 (which vanished on the addition of D_2O), ascribable to the 3βH and the NH. Since no signals due to methylene protons attached to the lactam nitrogen are found, the structure of the lactam **4** should be 17a-aza-*D*-homo-5α,13α-androsterone. This structure was confirmed by the mass spectrum which showed qualitatively the same major fragmentation patterns with that of the lactam **2**. Therefore, the configuration of the hydroxyl group of **5** should be *anti* with respect to the C-13 methyl group.

The oxime **1** in methanol was photolyzed by a 15 W low pressure Hg arc lamp[13] for 30 hr under argon atmosphere to afford a product in which the presence of major four compounds was evidenced by the tlc analysis. Careful separation of the less polar lactam part by the preparative tlc afforded only two lactams, **2** (3%) and **4** (1%), which were identical with the lactams obtained by the ground state Beckmann rearrangements of **1** and **5**. Apart from these lactams a mixture of 3-*O*-acetylandrosterone and 3-*O*-acetyl-13α-androsterone[14] was obtained in 5% yield, together with the oxime **1** in 6% yield.

The photolysis of 3-*O*-acetyl-13α-androsterone oxime **5** was then studied under the same conditions as **1** and afforded a complex mixture of the products. Tlc analysis of this mixture indicated a similar pattern to that in the photolysis of **1** and disclosed the formation of the four major products. Careful preparative tlc gave the crystalline **4** (1%), a mixture of 3-*O*-acetyl-13α-androsterone and 3-*O*-acetylandrosterone (11%) and a gum **6** (3%), apart from the recovered starting oxime (6%). The product **4** was identical with the lactam obtained by the ground state Beckmann rearrangement of **5**. The NMR and IR spectra of the gum **6**, unobtainable in the pure crystalline form (although the near homogeneity of the material was revealed by the tlc examination), were taken and they revealed that gum **6** might be a 3-*O*-acetyl-17-aza-*D*-homo-5α,13α-androsterone. Thus, the mass spectrum of **6** revealed the M^+ peak at *m/e* 347, corresponding to $C_{21}H_{33}O_3N$, and a significant peak at *m/e* 288 due to the elimination of acetic acid from the parent ion. The IR spectrum of **6** revealed the NH band at around 3400 cm^{-1}, the OAc at 1733 cm^{-1} and the lactam C=O group at 1643 cm^{-1}. The NMR spectrum showed three three-proton singlets at τ 9.32, at τ 8.76, and at τ 7.97, a singlet at τ 5.05 and a multiplet from τ 6.2—7.0. These may be attributable to the C-10 methyl, the C-13 methyl, the 3-*O*-acetyl, the 3βH and the C-16-methylene protons.

Through the studies of these two photolyses, the lactam parts of the crude products were very carefully examined. However, none of **6** or **7** from the photolysis of **1**, and none of **2** or **7** from the photolysis of **5**, could be detected in the reaction mixture. Moreover, no nitriles stemming from the photo-Beckmann fission

* Described previously[1] as mp 180—182 °C.

were detected in the photolysates of **1** and **5**.

Discussion

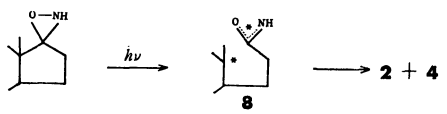
It is notable that while camphor oxime, in which the carbon α to the oximino group is in the bridgehead position and tetra-substituted and is comparable to the present system, gives solely nitriles due to the photo-Beckmann fission,[15] the photolysis of the oximes **1** or **5** does not give any nitriles on photolysis. It is interesting to speculate on the reason for this difference in the modes of photolysis between camphor oxime and steroidal 17-oximes.

One of the rationale for this difference would be the following. In camphor oxime the C_1–C_6 bond may cleave without the intervention of an oxaziridine intermediate since the oxaziridine, if it is formed, should be in the high energy state and would be unstable due to the interaction between the oxaziridine ring and both the C_1-methyl and the extra C_7-methyl. Therefore, the excited camphor oxime would prefer the lower energy reaction pathway, forming an imino radical instead of forming the corresponding oxaziridine ring.

In agreement with this, norcamphor oxime, in which the α-carbon is in bridgehead position but is tri-substituted and there are no C_1- and C_7-methyl groups, affords no cleaved products but the products due solely to normal photo-Beckmann rearrangements.[16]

On the basis of these considerations, we suggest that among several factors which result in the photo-Beckmann fission, the relative stabilities of the intermediate oxaziridine and the N–O bond cleaved species should be the crucial factor together with the strength of the C–C bond to be cleaved.

The formation of an epimeric pair of lactams from an oxime **1** is at variance with the mechanistic pattern on the breakdown of oxaziridine we previously suggested, although we were unable to isolate the lactam **2** from the photolysate of the oxime **5**.[2] The observed non-stereospecificity in the migration from the oxaziridine intermediate to the lactams cannot be due to secondary photolysis of the lactam **2**, which reveals UV absorption maximum at 207 nm (ε: 7300, CH_3OH), as **2** was found to be stable under the condition of the photolysis. The present results would, therefore, require the intervention of a radical or a charged intermediate species, such as **8**, in the rearrangement in liquid phases; in this intermediate[17] the C_{13}–C_{17} bond of the androsterone framework is broken and the C-17 end is released prior to bonding to the nitrogen. The failure in isolating **2** in the photolysis of oxime **5** can either be due to inadequacy of the analysis or due to some complicated origin.



8

With regard to the implication of the present results for the migration step of the photo-Beckmann rearrangement, on the basis of our results together with those of others, the following possibilities on the mode of the formation of lactam from oxaziridine may be considered.

The first would be a unifying mechanism for the whole saturated oximes involving the intervention of an intermediate in which the C–C bond between oxaziridine and the migrating α-carbon is released. If this is the case, our previous results on the oximes of cholestane series should be reinterpreted in terms of the involvement of an intermediate with the configurationally stable ion pairs or radical pairs.

Another possibility is dual mechanism for the saturated oximes. Oximes of cholestan-6-ones, menthone, isomenthone and norcamphor bear the tri-substituted migrating carbon whereas in the oximes of androsterone and 13α-androsterone, one of the migrating carbons is tetra-substituted. Thus we might suspect that the dual mechanisms are operative in the saturated oximes, depending on their structural features, particularly the immediate surrounding of the relevant oximino group, and the oxime which can afford stable ionic or radical species by the cleavage would be able to rearrange through an intermediate in which the migrating group becomes free of the migration terminus. In this instance, we cannot exclude the possibility of amide formation without an involvement of the intermediary oxaziridine although this seems less likely.

Between these, a unifying mechanism would have some difficulty in accommodating the fact that the two isomeric lactams are formed in nearly equal amounts in the case of cholestan-6-one oximes,[2] 3α,5-cyclo-5α-cholestan-6-one oxime,[3] unsymmetrically α-substituted cyclohexanone oximes[4] and norcamphor oxime.[16] Results in these oximes, would be better understandable if we assume both the migrating carbons of oxaziridines migrate to lactams without intermediate. Therefore, with reservation, the preference appears to be for the operation of the dual mechanism.

In the present experiments although we obtained only 17a-aza-*D*-homo-androsterones as the product lactam, the photolysis of the oxime **5** afforded 17-aza-*D*-homo-isomer in addition to 17a-aza-*D*-homo-androsterone.

In terms of the dual mechanism these results may be explicable as follows; in the oxime **5**, the C-13 end may rearrange through the open-chain intermediate such as **8** from oxaziridine but the C-16 end may still be able to migrate to lactam **6**, in this case, without intermediate.

This would mean that in the oxime **1** or **5** two mechanistic modes of the breakdown of oxaziridine appear to operate at the same time although we failed to isolate the lactam **7** in the photolysis of the oxime **1**. Further examination of the stereochemistry of the reaction on the various steroidal substrates will obviously be required to clear up the problem.

Experimental

All mp's were determined by a Yanagimoto type hot-stage and were uncorrected. Unless stated otherwise, IR was determined in Nujol using a Jasco model IR-E spectrophotometer. All NMR spectra were determined on a

Japan Electron Optics PS-100 high resolution NMR spectrometer in $CDCl_3$ solution using TMS as an internal reference. Wako gel B 5 for the preparative tlc was used. The progress of the reactions was followed by the tlc.

Beckmann Rearrangement of 3-O-Acetylandrosterone Oxime. Oxime **1** (300 mg) and thionyl chloride (0.1 ml) in dioxane were stirred for 10 minutes at room temperature. The reaction mixture was neutralized with aqueous 10% KOH and was extracted with chloroform. The solution was worked up in the usual manner. The residue (305 mg) revealed two spots on tlc and column chromatography (Mallinkrodt, silica gel 100 mesh, 3 g) afforded 88 mg of colorless gum and 154 mg of crystals **2**. The latter was recrystallized from acetone, yielding **2**, mp 291—292 °C. (lit., mp 280—284 °C).[7] IR; 3180 cm^{-1} (NH) 1747 cm^{-1} (OAc). 1678 cm^{-1} (lactam C=O). NMR; τ 5.01 (1H, 3β-H), τ 7.96 (3H, OAc), τ 8.86 (3H, C-13 methyl), τ 9.23 (3H, C-10 methyl). The colorless gum was proved to be a mixture of olefins **3a**, **3c**, and **3e** be the NMR spectrum. (See text.)

The Hydrolysis of 3a, 3c, and 3e. The gum above (88 mg) in 5% methanolic KOH (8 ml) was stirred for 5 hr at room temperature. The usual work-up of this reaction mixture afforded an unsaturated nitrile **3b** and **3f** (84 mg) in the ratio of 3: 2.

Photolysis of 3-O-Acetylandrosterone Oxime. Oxime **1** (960 mg) in dry methanol (400 ml) was irradiated by a 15-W low pressure Hg arc lamp under argon atmosphere at room temperature for 104 hours. The solvent was removed under reduced pressure and the residue showed four major spots on tlc. The reaction mixture was submitted to the preparative tlc. (chloroform–acetone 4: 1). Four fractions A, B, C and D were obtained in the order of their increasing polarity. The fraction A (157 mg) was recrystallized from ether, yielding the lactam **2** (57 mg) identical with the lactam **2** obtained by the ground state Beckmann rearrangement of **1**. The fraction B (84 mg) was recrystallized from ether, yielding the lactam **4**, mp 180—182 °C. The fraction C (157 mg) was recrystallized from acetone to yield the pure starting oxime (57 mg). The fraction D (215 mg) was a gum and the NMR spectrum of this showed it to be a mixture of 3-*O*-acetylandrosterone and 3-*O*-acetyl-13α-androsterone.

3-O-Acetyl-13α-androsterone. 3-*O*-Acetylandrosterone (1.27 g) in dioxane (400 ml) was irradiated for 5 hr by a 100 W high pressure Hg arc lamp. After the evaporation of the solvent, the residue was submitted to the preparative tlc. The separation of 3-*O*-acetylandrosterone and the 13α isomer with the similar R_f values could be achieved by twelve times developments of the thin-layer with a mixed solvent of petroleum ether and benzene with an increasing amount of the latter. The number of developments and the proportions of the volumes of petroleum ether and benzene are as follows; twice with 5 (petroleum ether): 1 (benzene), three times with 3: 1, once with 2: 1, twice with 1: 1, twice with 1: 1, twice with 1: 2 containing a few drops of ethyl acetate. Thus, 3-*O*-acetyl-13α-androsterone (263 mg, 21%) was obtained and showed mp 122—124 °C. Butenandt and Poschmann reported mp 121—122 °C for this compound. NMR τ 9.37 and τ 9.04 (C-10 methyl and C-13 methyl) τ 8.03 (OAc) τ 5.09 (3β-H). IR; 1740 cm^{-1} (OAc, five-membered ring ketone).

Oxime of 3-O-Acetyl-13α-androsterone. 3-*O*-acetyl-13α-androsterone (165 mg), hydroxylamine hydrochloride (180 mg) and sodium acetate (120 mg) in ethanol (7 ml) were stirred for 6 hours at room temperature and then were warmed for 17 hours at 50—60 °C. The usual work-up of the reaction mixture afforded the crude oxime **5** (129 mg). This was recrystallized from hexane, yielding 111 mg of the oxime **5**, mp 186—187 °C. Found: C, 72.71; H, 9.37; N, 3.88%; Calcd for $C_{21}H_{33}O_3N$: C, 72.58; H, 9.57; N, 4.03%. IR 3440 cm^{-1} (OH), 1710 cm^{-1} (OAc), 1665 cm^{-1} (C=N), Mass *m/e* 347 (M^+). NMR τ 9.34 and τ 8.96 (C-10 methyl and C-13 methyl) τ 7.97 (OAc), τ 4.97 (3β-H).

Beckmann Rearrangement of 3-O-Acetyl-13α-androsterone Oxime. To the solution of **5** (100 mg) in dioxane (1 ml) there was added thionyl chloride (0.5 ml). The solution was stirred for 20 min at room temperature. Work-up as was described in the case of the oxime **1** afforded a crude product (157 mg). This showed to be a mixture of nonpolar and polar substances by the tlc. Purification by the preparative tlc afforded a crude lactam **4** (40 mg) and a mixture of olefins. The former was recrystallized from a mixture of ether and hexane to yield the lactam **4**, mp 193—194 °C (25 mg). Found: C, 72.57; H, 9.62; N, 3.77%. Calcd for $C_{21}H_{33}O_3N$: C, 72.58; H, 9.57; N, 4.03%. IR 3200 cm^{-1} (NH), 1741 cm^{-1} (OAc), 1633 cm^{-1} (lactam C=O). Mass *m/e* 347 (M^+), *m/e* 332, 272, 150. The latter was a colorless gum and it was proved to be a mixture of the three olefinic nitriles **3a**, **3c**, and **3e** in the ratio of 2: 5: 3 as was judged by the NMR spectrum in the same manner as in the case of Beckmann rearrangement of **1**. The hydrolysis of this mixture (43 mg) afforded a mixture of **3b**, **3d**, and **3f** (33 mg) in a ratio of 2: 5: 3 as was judged by the NMR spectrum. The presence of **3d** was apparent by the presence of a broad doublet signal at τ 4.39 (J=4.5 Hz). The 10β-methyl protons of **3d** and **3f** appeared as a coincident singlet at τ 9.29. Moreover, there were two doublets at τ 7.98 (J=2.4 Hz) and at τ 8.05 (J=2.7 Hz), which are attributable to the 13-methyl protons of **3f** and **3d**. The observed small splittings are due to allyl couplings.

Phytolysis of 3-O-Acetyl-13α-androsterone Oxime. Oxime (500 mg) in dry methanol (200 ml) was irradiated by a 15-W low pressure Hg arc lamp under argon atmosphere at room temperature for 30 hr. The solvent was removed under reduced pressure and the residue showed four major spots on tlc. This reaction product was submitted to the preparative tlc. (chloroform–acetone 5: 1). The four fractions A. B, C and D in the order of increasing polarity were obtained. The fraction A (46 mg) was recrystallized from ether to yield 5 mg of the lactam **4** identical with lactam obtained by the ground state Beckmann rearrangement of **5**. The fraction B (30 mg) was purified again by the preparative tlc, yielding 13 mg of gum. It was not in a crystalline state, but the NMR and IR spectra of the gum showed it to be probably a crude lactam **6**. The fraction C (105 mg) was recrystallized from acetone to yield 31 mg of the starting oxime **5**. The fraction D (55 mg) was found to be a mixture of 3-*O*-acetyl-13α-androsterone and 3-*O*-acetylandrosterone from its NMR and IR spectra.

The authors are grateful to the Ministry of Education of Japan for financial assistance. We thank Mrs. Satoko Araki in this department for the measurements of 100 MHz NMR spectra. Microanalyses and the measurements of the mass spectra were carried out by the staffs of the laboratories of the Faculty of Pharmaceutical Sciences of this university, and we thank them for these measurements.

The Chlorination of Olefins with Antimony(V) Chloride[1]

Sakae UEMURA,* Akira ONOE, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received August 8, 1973)

Antimony(V) chloride was revealed to be a good reagent for the *cis*-chlorination of simple olefins in chlorinated hydrocarbon solvents, such as 1,2-dichloroethane, dichloromethane, chloroform, and carbon tetrachloride. The higher the reaction temperature or the solvent polarity was, the higher the selectivity for *cis*-chlorination became. From 1,3-butadiene, *cis*-1,4-dichloro-2-butene was formed together with the *trans*-1,4- and 1,2-dichloro isomers. In the cases of cyclopentene and norbornene, the *trans*-1,2-dichloride and other various dichlorides were obtained without any formation of the *cis*-1,2-isomer. Probable mechanisms for this chlorination are briefly discussed.

Although antimony(V) chloride has been used as a reagent for the chlorination of aromatic hydrocarbons[2] and alkanes[3] and as an active catalyst for chlorine molecule addition to olefins,[4-6] the direct chlorination of olefins with this reagent has not yet been studied except for only one case with α,β-dibromoethylene.[7] After we published our preliminary data[1] concerning a predominant *cis*-chlorination of certain olefins with antimony(V) chloride in carbon tetrachloride, an additional study of the same reaction in a more polar solvent, liquid SO_2, was described by Akiyama *et al.*[8] In this report, all the results of the chlorination of several kinds of mono-olefins and 1,3-butadiene in less polar solvents, mainly chlorinated hydrocarbons, will be described in detail. In contrast to other metal or metalloidal chlorides,[9] this chloride showed a striking product selectivity.

Results and Discussion

Reaction with Simple Olefins. When an olefinic hydrocarbon was added to a light-yellow homogeneous solution of antimony(V) chloride in carbon tetrachloride at room temperature, the reaction occurred exothermally to give the corresponding *vic*-dichloroalkane (**1**) in a good yield, occasionally together with small amounts

$$RCH{=}CHR' \xrightarrow[CCl_4]{SbCl_5} \underset{\mathbf{1}}{RCH(Cl)-CHR'(Cl)} + \underset{\mathbf{2}}{RCH_2-CHR'(Cl)} \quad (1)$$

of monochloride (**2**). Some typical data for several olefins are shown in Table 1. In contrast to the usual complete or predominant *trans*-addition in the chlorination using chlorine gas or other metal and metalloidal chlorides[9] (*e.g.*, PCl_5, $CuCl_2$, $AuCl_3$, and $TlCl_3$), a favorable *cis*-addition is the most remarkable feature of this chlorination.[10] Separate experiments revealed that no interconversion of *cis*- and *trans*-1,2-dichlorocyclohexanes occurred under the present reaction conditions. Moreover, as can be seen in Table 1, an elongation of the reaction time does not affect the ratio of *cis*- to *trans*-addition in the chlorination of *trans*-2-butene. Therefore, the observed ratio of *cis*- and *trans*-addition appears to be kinetically controlled. It should be noted that a rise in the reaction temperature resulted in a considerable increase in the *cis*-selectivity of this chlorination. The temperature dependence on the isomer ratio would indicate that both isomers may not arise from a common intermediate, as will be discussed later.

The reaction is clearly of an electrophilic nature,

because no reaction occurred with olefins having strong electron-withdrawing groups, such as acrylonitrile, ethyl maleate, ethyl fumarate, and tetrachloroethylene, even at the refluxing temperature in carbon tetrachloride, and all the olefins were recovered qualitatively. In a reaction with styrene or ethyl vinyl ether, a vigorous reduction of antimony(V) to antimony(III) occurred even at 0 °C, but only a resinous product was obtained; all attempts to isolate the dichlorinated compound were unsuccessful.

A radical pathway for the formation of **1** can be excluded by considering the following facts. First, no trace of 4-chloro-1-cyclohexene was found in the chlorination products from cyclohexene. Second, when the reaction was carried out in the presence of *m*-dinitrobenzene or oxygen, no change in the yield or in the *cis*/*trans* ratio of **1** was observed.

In order to ascertain the effect of solvents upon the stereoselectivity of the reaction, the chlorination of cyclohexene was carried out in several solvents. Some results are given in Table 2a. All the reaction mixtures were homogeneous. In chlorinated hydrocarbon solvents, the *cis*-dichloride generally predominated, and an increase in the ratio of *cis*- to *trans*-addition was observed when the dielectric constant of the solvent was increased. On the contrary, in a donor solvent such as carbon disulfide, a favorable *trans*-addition was observed. Certain polar solvents were not adequate for this chlorination; *i.e.*, when nitromethane was used as a solvent, only a slight amount of dichloride was formed from cyclohexene, and the reaction in acetonitrile afforded a tarry product. Alcohols, ethers (diethyl ether, 1,4-dioxane and tetrahydrofuran), dimethylformamide, and dimethyl sulfoxide could not be used as solvents because of a vigorous reaction or adduct formation between the solvent and antimony(V) chloride itself.

We should also consider briefly the source of hydrogen chloride, which gives **2** by addition to olefins. As the hydride-ion abstraction from triphenylmethane, 9,10-dihydroanthracene and cycloheptatriene with antimony(V) chloride has been established[11] to give hexachloroantimonate salts of stable carbonium ions, $SbCl_3$, and hydrogen chloride, it might be possible to assume that a similar abstraction may occur with olefins to produce hydrogen chloride. In fact, though we failed to isolate the corresponding antimonate salts or the hydrogen chloride addition product, α-chloroethylbenzene (**2**), because of the polymerization of styrene, the evolution of much hydrogen chloride was observed during the reaction of styrene. As the addition of hydrogen chloride is much easier to internal olefins than to terminal ones, **2** was not obtained from 1-octene and allyl chloride. Furthermore, the rate of the formation of **2** seems much slower than that of **1**; when the reaction was carried out using a smaller amount of cyclohexene than of antimony(V) chloride, the yield of chlorocyclohexane (**2**) became very low without affecting that of **1**. This may be a reason why **2** was not obtained from either *trans*- or *cis*-2-butenes, where the contact time of olefin and antimony(V) chloride is considered not to be very long. Another possible source of hydrogen chloride is the decomposition of antimony(III) chloride (formed through a reaction) or antimony(V) chloride by moisture.[12] However, even in the careful reaction under N_2 in a dried condition, the formation of **2** was observed, and so this possibility may be excluded.

Table 2. Chlorination of cyclohexene by antimony(V) chloride

(a) Effect of solvents on the isomer ratio [$SbCl_5$ 25 mmol, solvent 100 ml]

Cyclohexene mmol	Solvent (ε)	Temp. °C	Time min	1,2-Dichlorides Yield,[a] %	1,2-Dichlorides *cis*/*trans* Ratio

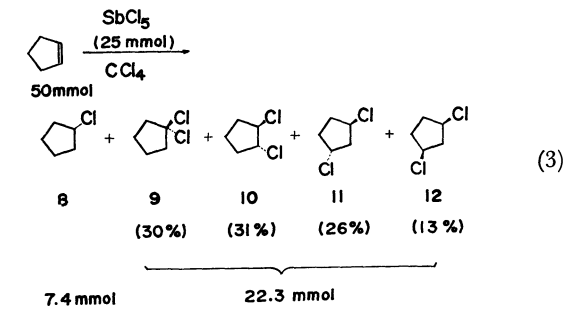
86	30	10	4.5	2.5	4.6	46	0.9	1.2	17
62	76	10	6.9	3.6	6.1	66	1.4	2.7	33

a) Based on $SbCl_5$. b) 3,4-Dichloro-1-butene. c) *cis*-1,4-Dichloro-2-butene. d) *trans*-1,4-Dichloro-2-butene. e) *dl*-1,2,3,4-Tetrachlorobutane. f) *meso*-1,2,3,4-Tetrachlorobutane.

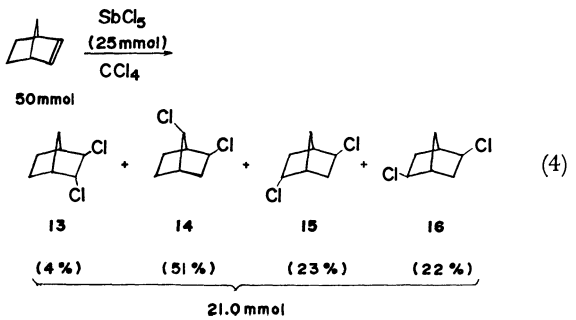
Reaction with 1,3-Butadiene. By passing 1,3-butadiene through a CCl_4 solution of antimony(V) chloride, the following compounds were obtained as products: 3,4-dichloro-1-butene (**3**), *cis*- and *trans*-1,4-dichloro-2-butenes (**4** and **5** respectively), and two stereoisomers of tetrachlorobutanes [**6** (*dl*) and **7** (*meso*)]. Some typical data are shown in Table 3. Separate experiments eliminated the possibility of the interconversion of **3**, **4**, and **5** under the present reaction conditions. At higher temperatures the formation of **6** and **7** became prominent; they were apparently formed by a further reaction of **3**, **4**, and **5** with antimony(V) chloride. A rather high proportion of **4** (21—22%) to all the products should be noted here, together with the results of chlorination using $TlCl_3 \cdot 4H_2O$[13] (11%) and $CuCl_2$[14] (5%), because **4** has never[15] or only slightly (1%)[16] been formed in chlorination with a chlorine molecule. This fact suggests the existence of a certain interaction between metal chloride and both terminal carbons of 1,3-butadiene.

$$CH_2{=}CH{-}CH{=}CH_2 \xrightarrow[CCl_4]{SbCl_5} \underset{\mathbf{3}}{CH_2{=}CHCHClCH_2Cl} + \underset{\mathbf{4}\ (cis)\ \&\ \mathbf{5}\ (trans)}{ClCH_2CH{=}CHCH_2Cl} + \underset{\mathbf{6}\ (dl)\ \&\ \mathbf{7}\ (meso)}{ClCH_2CHClCHClCH_2Cl} \quad (2)$$

Reaction with Cyclopentene and Norbornene. For cases of cyclopentene and norbornene, which might resist the *cis*-addition or *cis*-attack of the bulky species, the *trans*-1,2-dichloride and various unexpected dichlorides were obtained without the formation of the *cis*-1,2-isomer (Eqs. (3) and (4), where the figures in parentheses indicate a product distribution). All the dichlorides for each reaction seem to be formed by way of the corresponding carbonium ions, *i.e.*, the classical chlorocyclopentyl cation and the nonclassical chloronorbornyl cation, as will be discussed later. The reaction of cyclopentene with chlorine gas (neat or in CCl_4) has been reported[17] to yield only **10**; we found



(3)



(4)

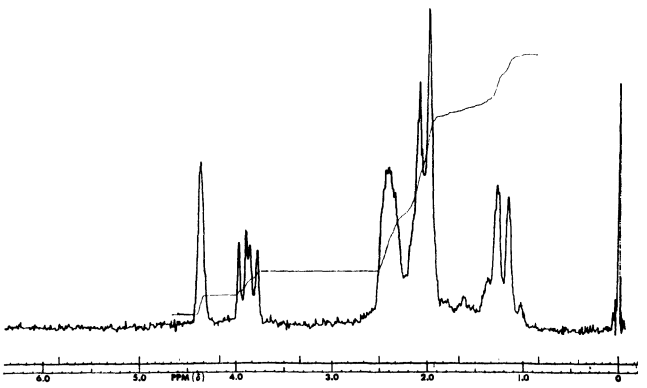


Fig. 1. NMR spectrum of **14** in CCl_4.

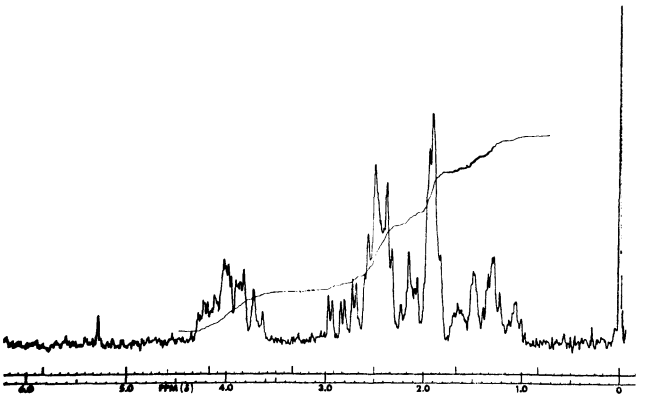

Fig. 2. NMR spectrum of **15** in CCl_4.

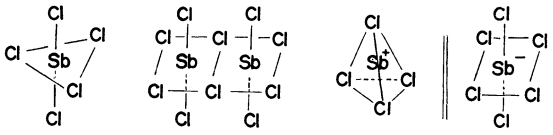
such a case also with copper(II) chloride (in acetonitrile). As to the chlorination of norbornene, the diversity of reaction products has previously been established. Thus, the chlorination with chlorine gas (in CCl_4) affords nortricyclyl chloride and *exo*-2-*syn*-7-dichloronorbornane, together with smaller amounts of *trans*-2,3- (**13**) and *exo*-*cis*-2,3-dichloronorbornane, by the ionic pathway,[18] and the reaction with gold(III) chloride (in cyclohexane) gives a mixture of *exo*-*cis*-2,5-dichloronorbornane (**16**), *exo*-2-*syn*-7-dichloronorbornane, and two unidentified isomeric dichlorides.[19] We have also confirmed that the chlorination with copper(II) chloride (in acetonitrile) yields mainly the *trans*-2,3- (**13**) and *exo*-*cis*-2,3-dichlorides, just as does the reaction with iodobenzene dichloride.[20]

Probable Reaction Mechanisms. The nature of antimony(V) chloride in solutions appears to depend on the polarity of the solvents. Thus, in acetonitrile (ε 37.5) the conductivity data have shown that $SbCl_5$ is in equilibrium with $SbCl_4^+$ and $SbCl_6^-$,[21] while in carbon tetrachloride (ε 2.23) it has been established that the vibrational spectra are consistent with the D_{3h} symmetry expected for covalent antimony(V) chloride; *i.e.*, the predominant species is the monomeric molecules.[22] In contrast to such thermodynamic data, Kovacic and Sparka have assumed the attack of the $SbCl_4^+$ moiety formed from two molecules of antimony(V) chloride (see Eq. (5)) in the reaction of benzene, toluene, and chlorobenzene with antimony(V) chloride (below 40 °C), where an excess aromatic component (ε 2.27—5.61) is used as the solvent.[2] Since the re-

action conditions of our chlorination and the electrophilic nature of the reaction are apparently similar to those of this aromatic chlorination, a similar participation of the ionic species—an initial attack of $SbCl_4^+$ on olefins, followed by a Cl^- transfer from $SbCl_6^-$ to give *trans*-dichlorides—might be expected, though the concentration of these species is believed to be very low. In this connection, a considerable decrease in the ratio of *cis*- to *trans*-addition was observed upon the addition of a strong Lewis acid (*e.g.*, $AlCl_3$ and SbF_3) to our chlorinating system (see Table 2b), where a complex formation of antimony(V) chloride with Lewis acid is to be expected (Eq. (6)).

$$2SbCl_5 \rightleftharpoons (SbCl_5)_2 \rightleftharpoons SbCl_4^+\|SbCl_6^- \quad (5)$$

17 **18** **19**

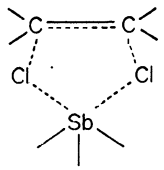


17 **18** **19**

$$SbCl_5 + MXn \rightleftharpoons SbCl_4^+\|MXnCl^- \quad (6)$$

20

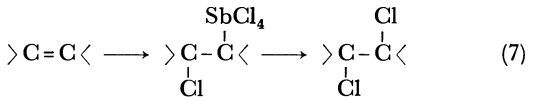
On the other hand, the formation of *cis*-dichlorides can presumably be explained by a concerted or near-concerted molecular addition of **17** or **18** to olefins, as has been proposed in connection with the chlorination of olefins by iodobenzene dichloride.[23] The distance



of any two chlorines is about 3.2—4.0 Å, assuming that the antimony-chlorine bond length of antimony(V) chloride is 2.29—2.34 Å[24] even in the liquid state; this is large enough for the interaction of two chlorines with two p-orbitals of simple olefins and even of 1,3-butadiene at the 1,4-position. The rather high proportion of *cis*-1,4-dichloro-2-butene (**4**) in the reaction products of 1,3-butadiene may be explained by assuming this interaction at the *s-cis*-conformation of 1,3-butadiene.

Since the ionization step in Eq. (5) is considered to be exothermic, like that of PCl_5,[25] the amount of **19** can be expected to increase when the temperature is lowered. The observed temperature effect on the isomer ratio in each solvent agreed with this expectation (see Table 2a). It is also anticipated that an increase in the solvent polarity would increase the proportion of ionized species. However, apparently a different trend was observed within a range of selected chlorinated hydrocarbon solvents (ε 2.23—10.37): namely, the higher the solvent polarity was, the higher the *cis*-selectivity became (see Table 2a). This may be explained by considering the large difference in the solvent effect on the rate between two chlorination reaction; *i.e.*, a change to a more polar solvent will increase the rate of the *cis*-addition (the reaction between two uncharged species) and will decrease that of the *trans*-addition (the reaction between uncharged and charged species).[26] The low *cis*-selectivity in carbon disulfide (ε 2.64) compared with that in carbon tetrachloride (ε 2.23) might be ascribed to the stabilization of **19** by solvation.

Another possible scheme for the chlorination is the addition of both chlorine and tetrachloroantimony species to olefin, followed by the displacement of antimony with chlorine (Eq. (7)), as has been established in the case of PCl_5.[27] However, the *trans* compound should be obtained preferably or exclusively by this scheme, as in the case of a reaction using PCl_5;[27] also, even careful experiments have failed to isolate the intermediate antimony compound. From these facts, this scheme can be excluded from consideration.



(7)

Finally, reasonable pathways to various unexpected chlorides derived from cyclopentene and norbornene were considered. If the *cis*-addition proceeds through a concerted or near-concerted transfer of chlorine between **17** or **18** and olefin, as has been described previously, quite a large steric hindrance would be unavoidable for both olefins and the attack of the $SbCl_4^+$ moiety of **19** may become important. In addition, an eclipsing effect at the Cl^--transfer step may affect the reaction products. In fact, the obtained 1,2-dichlorides consisted entirely of the *trans*-isomer. Further, the formation of 1,1- and 1,3-dichlorocyclopentanes from cyclopentene can be explained by assuming the deprotonation of the cation, **22** (Eqs. (8) and (9)). In the case of norbornene, the attack of $SbCl_6^-$ from a less crowding site upon each of the nonclassical

ions in equilibrium[28] may be expected, and all expected dichlorides were obtained except for those from **25** (Eq. (10)). The results seem to provide chemical evidence for the existence of such an equilibrium.

Experimental

Materials. Commercially-available *trans*-2-butene (contains 1% of the *cis*-isomer), *cis*-2-butene (contains 2.4% of the *trans*-isomer), and 1,3-butadiene were used without further purification, while $SbCl_5$ and all the other organic substrates and solvents were purified by distillation before use.

General Procedure. An appropriate amount of an olefinic hydrocarbon was added or bubbled into a homogeneous yellow solution of $SbCl_5$ (sometimes containing another Lewis acid salt as an additive) in a suitable solvent under stirring. The resulting black-red reaction mixture was cooled, aqueous NaOH was added, and the antimony(III) oxychloride or pentoxydichloride formed was filtered out.* The products in the filtrate sepatated from water were analyzed by glc with an appropriate internal standard material. The product composition was almost unchanged in the reverse reaction, *i.e.*, the drop-by-drop addition of $SbCl_5$ to a solution containing olefin.

a) 1,3-Butadiene: 1,3-Butadiene gas (4.6 g, 86 mmol) was bubbled into a CCl_4 (100 ml) solution of $SbCl_5$ (7.5 g, 25 mmol) at 30 °C for 10 min. The mixture was then treated as described above; the subsequent glc analysis of the CCl_4 layer showed the presence of these five components as products; 3,4-dichloro-1-butene (**3**; 0.56 g, 4.5 mmol), *cis*-1,4-(**4**; 0.31 g, 2.5 mmol) and *trans*-1,4-dichloro-2-butene (**5**; 0.58 g, 4.6 mmol), and *dl*-1,2,3,4- (**6**; 0.22 g, 1.2 mmol) and *meso*-1,2,3,4-tetrachlorobutane (**7**; 0.17 g, 0.9 mmol). A mixture of **4** and **5** (**4**: **5**=*ca.* 1: 2) was isolated by distillation (bp 51—53 °C/22 mmHg) from the reaction products of several runs. NMR (in $CDCl_3$) of the mixture; δ 6.05—5.7 (m, 2H), 4.2—4.0 (m, 4H). Found: C, 37.64; H, 4.72; Cl, 56.38%. Calcd. for $C_4H_6Cl_2$: C, 38.43; H, 4.84; Cl, 56.73%.

When 1,3-butadiene (3.5 g, 65 mmol) was passed into a CCl_4 (25 ml) solution of $SbCl_5$ (15 g, 50 mmol) at 76 °C for 10 min, a mixture of isomeric tetrachlorobutanes (**6** and **7**) was obtained as the main product (12.7 mmol, **6**: **7**=1: 2.7). Found: C, 24.53; H, 3.14; Cl, 72.33%. Calcd. for $C_4H_6Cl_4$: C, 24.52; H, 3.08; Cl, 72.39%. **7** was isolated as a solid and was revealed to be a *meso*-isomer; mp 72 °C from ethanol (lit.,[15] 72 °C).

b) Cyclopentene: The reaction of cyclopentane (3.4 g, 50 mmol) with $SbCl_5$ (7.5 g, 25 mmol) in CCl_4 (100 ml) at 25 °C for 5 min afforded a mixture of five products: **8** (7.4 mmol) and **9**—**12** (22.3 mmol, **9**: **10**: **11**: **12**=30: 31: 26: 13 by g.l.c.). A simple distillation gave 2.6 g, (18.7 mmol) of a mixture of **9**—**12**, which was revealed by analysis to be composed of isomeric dichlorocyclopentanes; bp 61—64 °C/42 mmHg. Found: C, 43.19; H, 5.97%. Calcd for $C_5H_8Cl_2$: C, 43.19; H, 5.80%. Further products, **9**, **10**, **11**, and **12**, were purely isolated by preparative glc, and comparisons of the NMR spectra and retention time on glc with those of the reported ones[29] revealed the compounds to be 1,1-, *trans*-1,2-, *trans*-1,3-, and *cis*-1,3-dichlorocyclopentane respectively. The chlorination of cyclopentene with a chlorine molecule in CCl_4[17] at room temperature afforded only **10** (by glc). **10** (1.2 g) could also be prepared by the reaction of cyclopentene (3.4 g) with $CuCl_2$ (3.4 g) in acetonitrile (25 ml) containing LiCl (1.1 g) at 80 °C for 3 hr; bp 50—51 °C/22 mmHg (lit.,[17] 53—53.5 °C/25 mmHg).

The reaction using 1,2-dichloroethane as a solvent at 84 °C for 10 min gave **9**, **10**, **11**, and **12** in the ratio of 18: 32: 30:: 20 (19 mmol).

c) Norbornene: The reaction of norbornene (4.7 g, 50 mmol) with $SbCl_5$ (7.5 g, 25 mmol) in CCl_4 (100 ml) at 26 °C for 10 min gave a mixture of four products (21 mmol, **13** : **14** : **15** : **16**=4 : 51 : 23: 22 by glc), all of which were revealed to be isomeric dichloronorbornanes by analysis; bp 92—98 °C/18 mmHg. Found: C, 50.72; H, 6.16%. Calcd for $C_7H_{10}Cl_2$: C, 50.93; H, 6.11%. After the fractional distillation of the mixture (a, bp 83—86 °C/13 mmHg; b, 86—87 °C/13 mmHg; c, 54—55 °C/2 mmHg), three products, **14**, **15**, and **16**, were purely isolated from Fraction a, b, and c respectively, by preparative glc. The NMR spectrum (in CCl_4) and the retention time on glc of **13** were identical with those of *trans*-2,3-dichloronorbornane, which was obtained from the reaction of norbornene (4.7 g) and $CuCl_2$ (13.4 g) in acetonitrile (200 ml) containing LiCl (4.2 g) at 84 °C for 3 hr; δ 4.3—4.1 (m, 1H), 3.7—3.6 (t, J=2 Hz, 1H) 2.6—2.3 (m, 2H), 2.1—1.1 (m, 6H). In the chlorination with $CuCl_2$, a slight formation of the *cis-exo*-2,3-dichloroisomer was also detected, together with **13** (yield, 6.7 g; *cis*: *trans*=*ca.* 1: 8). The NMR spectrum (in CCl_4) of **16** was identical with that of *exo-cis*-2,5-dichloronorbornane reported by Hüttel *et al.*;[19] δ 3.8—3.6 (t, J=5.5 Hz, 2H), 2.6—2.4 (m, 2H), 2.0—1.8 (m, 6H). The NMR spectra (in CCl_4) of **14** and **15** are shown in Figs. 1 and 2; **14**, δ 4.35 (s, 1H), 4.0—3.75 (m, 1H), 2.5—2.25 (m, 2H), 2.2—1.9 (m, 4H), 1.4—1.1 (m, 2H); **15**, δ 4.3—3.6 (m, 2H), 3.0—2.0 (m, 4H), 2.0—1.8 (m, 2H), 1.8—1.0 (m, 2H). The possibility of **14** and **15** being *cis-exo*-2,3- and *exo*-2-*syn*-7-dichloronorbornanes was eliminated, as well as the possibility of their being *cis-endo*-2,3-dichloroisomer (lit.,[18b] mp 70—72 °C), by a comparison of the retention time on glc and of the boiling point with the samples prepared by the reported method.[18a] Thus, **14** and **15** should be either *exo*-2-*anti*-7-, *trans*-2,5-, or *cis*- or *trans*-2,6-dichloronorbornane. In deuterated pyridine, a broad resonance near δ 2.4 of **14** in CCl_4 was split into two kinds of peaks, δ 2.15 (m) and 2.35 (m). Further, the sharp singlet peak at δ 4.35 of **14** can most reasonably be explained by identifying it as the *syn*-proton on C_7 bearing Cl. Thus, **14** is assigned to *exo*-2-*anti*-7-dichloronorbornane (lit.,[30] bp 77—81 °C/10 mmHg). A multiplet absorption at δ 4.3—3.6 in **15** shows the presence of both *exo*- (δ 4.3—4.0) and *endo*-(δ 4.0—3.6) protons; this appears to favor a *trans*-dichloride structure. If **15** is the *trans*-2,6-isomer, the peak of 2-*endo*-H can be expected to appear at a much lower field than usual because of the anisotropy of 6-*endo*-Cl. Thus, **15** can be assigned to *trans*-2,5-dichloronorbornane.

The reaction using 1,2-dichloroethane as a solvent at 84 °C for 10 min gave **13**, **14**, **15**, and **16** in the ratio of 5: 22: 40: 33 (20 mmol).

Attempted Isomerization of cis- *and* trans-*1,2-Dichlorocyclohexanes.* A mixture of the *cis*- and *trans*-dichlorides (2 g, *cis*/*trans*=1.6) was heated in 40 ml of CCl_4 containing 0.2 g of $SbCl_3$ and 0.3 g of $SbCl_5$ at a refluxing temperature (76 °C). Glc analysis after 2 hr gave an almost unchanged isomer ratio, *i.e.*, *cis*/*trans*=1.68.

Authentic Samples for glc. Both *meso*-2,3- (containing

* In separate experiments we have confirmed that the decomposition of $SbCl_3$ with water gave hydrogen chloride, which reacted easily with cyclohexene and 2-octene to afford monochloroalkanes (**2**) at room temperature. In order to avoid the formation of **2** by this route, the reaction mixture was treated with aqueous NaOH instead of water.

9.5% *dl*-isomer) and *dl*-2,3-dichlorobutane (containing 9.4% *meso*-isomer) were prepared by the reported method[31] by the reaction of *trans*- and *cis*-2-butenes with chlorine respectively at −40 °C. The *cis*-1,2-dichlorocyclohexane was obtained from the reaction of *trans*-2-chlorocyclohexanol with thionyl chloride in pyridine.[32] *trans*-1,2-Dichlorocyclohexane, 1,2-dichlorooctane, and *threo*-2,3-dichlorooctane were prepared by the reaction of the corresponding olefins with Cl_2 or $CuCl_2$.[33] The *erythro*-2,3-dichlorooctane was isolated by the reaction of *cis*-2-octene with $SbCl_5$; bp 77—79 °C/10 mm, Found: C, 52.33; H. 8.91; Cl 38.24%. Calcd. for $C_8H_{16}Cl_2$: C, 52.47; H, 8.81; Cl, 38.73%. The monochloroparaffins, 1,2,3-trichloropropane, 3,4-dichloro-1-butene, and *trans*-1,4-dichloro-2-butene were commercially available.

Analytical Instruments. The IR and NMR spectra were determined by the use of a Hitachi EPT-S2 apparatus and a Varian A-60 (CCl_4 or $CDCl_3$ solvent, with TMS as the internal standard) apparatus respectively. Gas chromatographies were carried out by the use of two Shimadzu apparatuses 5APTF and 4BMPF [PEG 20M (25%)-Shimalite (3 m), PEG 6000 (25%)-Chromosorb-W (3 m), Apiezon L (30%)-Celite (1 m) and DEGS (25%)-Shimalite (3 m) columns; carrier gas, He].

(Received August 20, 1973)

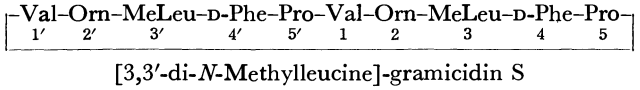
Two analogs of gramicidin S, *cyclo*(–Val–Orn–Leu–D-Phe–Pro–Val–Orn–MeLeu–D-Phe–Pro–), *i.e.*, [3-*N*-Methylleucine]–gramicidin S, and *cyclo*(–Val–Orn–MeLeu–D-Phe–Pro–Val–Orn–MeLeu–D-Phe–Pro–), *i.e.*, [3,3′-di-*N*-Methylleucine]–gramicidin S, were prepared in an attempt to investigate the contribution of the NH group of the leucine residue with regard to antibacterial activity. These analogs were almost as active as gramicidin S in the antibacterial test in reaction to microorganisms. The optical rotatory dispersions of these two analogs and of gramicidin S were measured in solvents of ethanol and 8 M aqueous urea. These studies suggested that both of the analogs containing *N*-methylleucine have a molecular conformation very similar to that of gramicidin S, and that the NH group of the leucine residues is not necessary for stabilizing the conformation in order to exhibit the biological properties.

In studies of the structure-activity relationship of gramicidin S, various analogs have been synthesized.[2] From these works and the optical rotatory dispersion (ORD) studies, it has been suggested that the biological activity of gramicidin S and its analogs has a close correlation to their conformation, and that a specific conformation may be necessary for a molecule to exhibit antibacterial activity.[3]

For the conformation of gramicidin S in the solid- and the solution-state, several models have been proposed. A possible model which was first suggested on the basis of X-ray studies by Hodgkin and Oughton is the intramolecular antiparallel β-form, with four hydrogen bondings between the valyl and the leucyl residues.[4] A similar structure was proposed by Schwyzer,[5] by Craig's group,[6] and by Urry's group.[7] These proposals prompted us to synthesize analogs which lack some of the four intramolecular hydrogen bondings in order to investigate to what extent these hydrogen bondings will stabilize the conformation.

The present paper will deal with the syntheses, antibacterial properties, and ORD measurements of two analogs of gramicidin S, [3-*N*-Methylleucine]- and [3,3′-di-*N*-Methylleucine]-gramicidin S, in which the leucyl residues in positions 3 and 3′ are replaced, singly or together, by *N*-methylleucine residues. These analogs are lacking in one or two of the four hydrogen bondings of the proposed model.

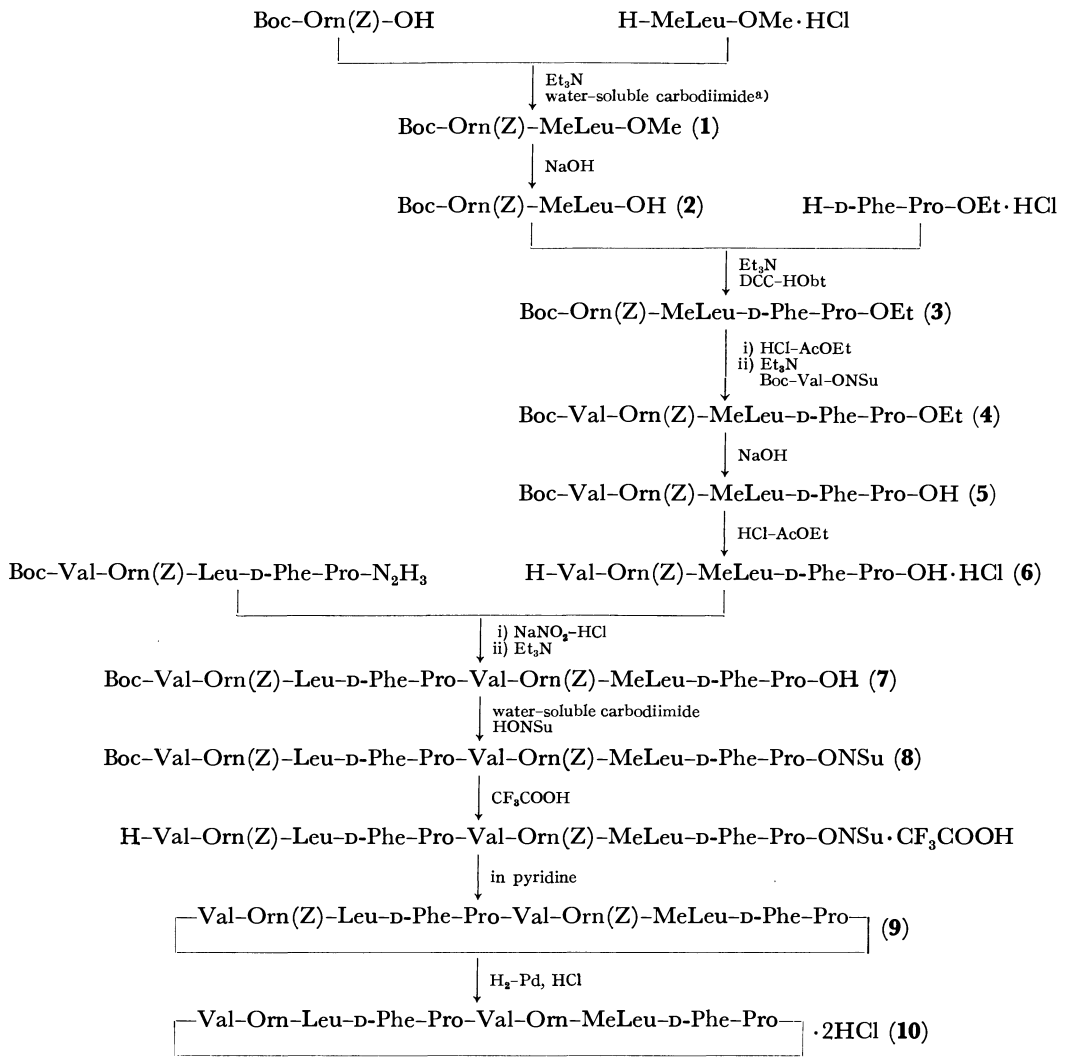
[3-*N*-Methylleucine]-gramicidin S



[3,3′-di-*N*-Methylleucine]-gramicidin S

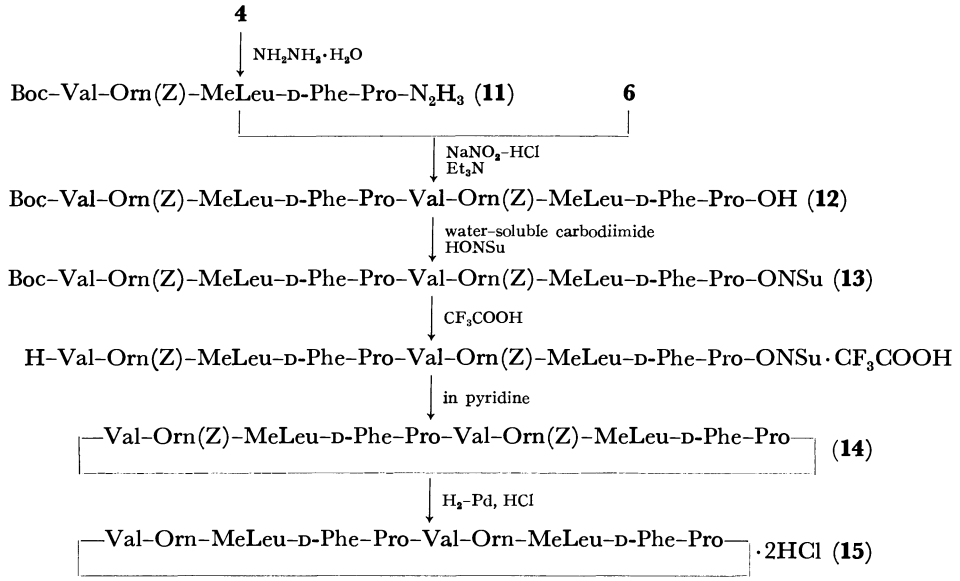
The synthesis of [3-*N*-Methylleucine]-gramicidin S is outlined in Scheme 1.[8] The strategy of the synthesis was chosen specifically to preclude the *N*-methylamino acid from the *N*- and *C*-terminus of the decapeptide, since acylation of the secondary amino group in *N*-methylamino acid residue and acylation by the activated carboxyl group in *N*-methylamino acid residue seems not to be favored.[9,10] Proline was chosen as the *C*-terminal residue in order to avoid racemization in the final cyclization step.

α-*t*-Butoxycarbonyl (Boc)-δ-benzyloxycarbonyl (Z)-ornithine was coupled with *N*-methylleucine methyl ester in the presence of dicyclohexylcarbodiimide (DCC) to yield the protected dipeptide, **1**, as an oil, together with the *N*-acylurea derived from the carboxyl component. All attempts at purification, such as crystallization and column chromatography, were unsuccessful. The corresponding reaction using the water-soluble carbodiimide gave the protected dipeptide, **1**, in a pure state in a 50% yield. The NMR evidence of the three *N*-methyl protons supported the proposed structure. Saponification of **1** easily gave the corresponding acid, **2**, as fine crystals. It was reported previously that, when the *C*-terminal amino acid residue of a carboxyl component was an *N*-methylamino acid residue, a system of DCC plus 1-hydroxybenzotriazole (HObt)[11] was a useful coupling agent;[10] therefore α-Boc-δ-Z-ornithyl-*N*-methylleucine was coupled with D-phenylalanylproline ethyl ester by the aid of DCC and HObt. The consequent yield of α-Boc-δ-Z-ornithyl-*N*-methylleucyl-D-phenylalanylproline ethyl ester (**3**) was nearly quantitative. After removal of the Boc group of **3**, the resulting tetrapeptide ester was coupled with Boc-valine *N*-hydroxysuccinimide ester to yield Boc-valyl-δ-Z-ornithyl-*N*-methylleucyl-D-phenylalanylproline ethyl ester (**4**) in an 80% yield; this ester was then converted to the corresponding acid **5** by saponification and subsequently to hydrochloride of valyl-δ-Z-ornithyl-*N*-methylleucyl-D-phenylalanylproline (**6**) by the action of hydrogen chloride in ethyl acetate. Condensation of the azide derived from Boc-valyl-δ-Z-ornithylleucyl-D-phenylalanylproline hydrazide with the pentapeptide, **6**, gave the acyldecapeptide acid, **7**, which was then isolated by column chromatography on silica gel. The acid, **7**, was then transformed into the Boc-decapeptide *N*-hydroxysuccinimide ester, **8**, by the reaction of *N*-hydroxysuccinimide (HONSu) and the water-soluble carbodiimide. After removal of the Boc group of **8** with trifluoroacetic acid, the decapeptide ester trifluoroacetate thus obtained was cyclized in pyridine at room temperature by the high-



a) 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide

Scheme 1.



Scheme 2.

dilution method.[12] Purification through ion-exchange columns, followed by fractionation on silica gel, gave the Z-substituted cyclic decapeptide, **9**, as colorless needles in a 56% yield. Hydrogenolysis of **9** afforded the desired [3-*N*-Methylleucine]-gramicidin S as a crystalline dihydrochloride, **10**.

[3,3'-Di-*N*-Methylleucine]-gramicidin S was prepared in a similar manner (Scheme 2). The Z-substituted cyclic derivative, **14**, was obtained in a 67.5% yield. These results indicate that the cyclization reaction is not affected by the *N*-methyl group. These two synthetic analogs gave satisfactory results in elemental and amino acid analyses, and were homogeneous by the criteria of paper electrophoresis and paper chromatography with various solvent systems.

Table 1. Antibacterial activity of the compounds
(Minimum inhibitory concentration, μg/ml)

Strain	Gramicidin S	[MeLeu³]-Gramicidin S (**10**)	[MeLeu³,³']-Gramicidin S (**15**)
Staphylococcus aureus	6.25 (1.56)[a]	6.25 (3.12)[a]	6.25 (6.25)[a]
Bacillus subtilis	3.12	3.12	3.12
Escherichia coli	100	50	50
Shigella flexneri	100	100	100
Candida albicans	50	50	25

a) ( ): Knight modified semisynthetic medium.

The results of the biological comparison of the two analogs to gramicidin S are shown in Table 1. In the antibacterial activities toward microorganisms, both of the analogs were almost identical with gramicidin S in potency. This indicates that the NH's of the leucine residues are not necessary for exhibiting the biological activity. Izumiya *et al.* have reported that the biologically-active gramicidin S analogs possess conformations similar to one another, irrespective of their primary structures.[3] Accordingly, we assume that these two

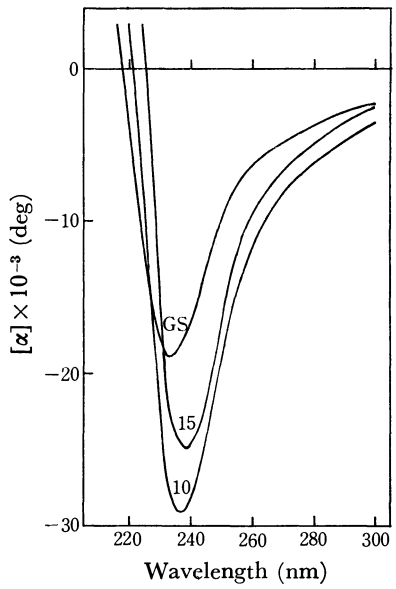


Fig. 1. ORD curves of [MeLeu³]-gramicidin S (**10**), [MeLeu³,³']-gramicidin S (**15**), and gramicidin S (GS) in ethanol, concentration 0.24 mg/ml.

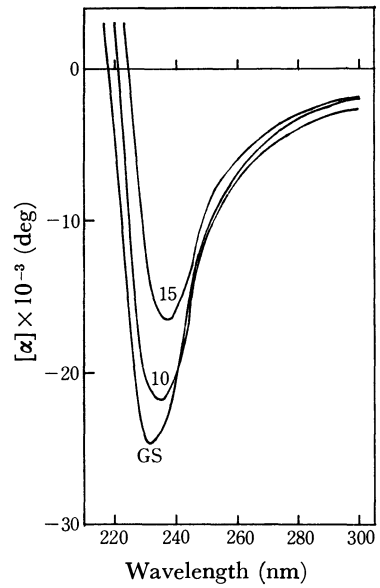

Fig. 2. ORD curves of [MeLeu³]-gramicidin S (**10**), [MeLeu³,³']-gramicidin S (**15**), and gramicidin S (GS) in 8 M urea, concentration 0.24 mg/ml.

analogs containing *N*-methylleucine also have conformations similar to that of gramicidin S. To confirm our assumption, ORD measurements were undertaken.

The ORD's of [3-*N*-methylleucine]- and of [3,3'-di-*N*-methylleucine]-gramicidin S in ethanol are shown in Fig. 1, along with that of gramicidin S. The shapes of the three ORD curves are very similar to each other. The troughs of the former two compounds are at 236—238 nm, whereas that of gramicidin S is at 232 nm. In a solvent of 8 M aqueous urea, which causes the denaturation of some polypeptides (*e.g.*, the biologically-inactive analogs of gramicidin S[12]), the positions of the troughs of the analogs (**10** and **5**) remained unchanged, as does that of gramicidin S (Fig. 2). In both solvents, their dispersions are different in their minimum rotations, and the positions of the troughs are slightly different, but the shapes of the curves are very similar even in 8 M urea, suggesting that all these three molecules have very similar and stable conformations. Judging from these results, two of the four hydrogen bondings in the β-type structure of gramicidin S proposed by several authors are not necessary for stabilizing the conformation. Furthermore, another model in which the NH's of the leucine residues do not participate in the intramolecular hydrogen bondings can be put forward. In this respect, as has been mentioned by Balasubramanian,[13] the Hodgkin-Oughton mixed α,β-structure and the Scheraga model can not be disregarded.[4,14] Further studies of this question are in progress.

Experimental

Thin-layer chromatography (tlc) was carried out on silica gel G (Merck) with the solvent systems: R_f^1, chloroform–methanol–acetic acid (95: 5: 3), R_f^2, acetone —28% aqueous ammonia (100: 5). The NMR spectra were recorded at 60 MHz, with tetramethylsilane as the internal standard and using a Hitachi R-20A apparatus. The optical rotations

were measured with a Perkin-Elmer polarimeter 141.

Boc-Orn(Z)-MeLeu-OMe (1). Into a solution of Boc-Orn(Z)-OH[15] (7.3 g, 20 mmol), H-MeLeu-OMe·HCl[10] (4 g, 20 mmol), and triethylamine (2.8 ml) in tetrahydrofuran (100 ml), was added 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide[16] (3.1 g, 20 mmol) at −5—0 °C over a period of 10 min. After the mixture had been stirred overnight at room temperature, the solvent was distilled off under reduced pressure and the residue was taken up in ethyl acetate. The ethyl acetate solution was then washed successively with M hydrochloric acid, 4% sodium bicarbonate, and water, and then dried over magnesium sulfate. The solvent was evaporated under reduced pressure to leave a colorless oil; yield, 5 g (50%); $[\alpha]_D^{25}$ −38.0° (*c* 1.5, methanol). NMR δ ($CDCl_3$): 1.45 (s, 9H, $(CH_3)_3C$–), 2.93 (s, 3H, CH_3N–), 3.65 (s, 3H, CH_3OCO–), 5.07 (s, 2H, $-C\underline{H}_2C_6H_5$), 7.30 (s, 5H, phenyl protons).

Boc-Orn(Z)-MeLeu-OH (2). A solution of compound **1** (4.7 g, 9.4 mmol) and 4M sodium hydroxide (2.5 ml) in methanol (18 ml) was stirred for 6 hr at 20—25 °C. The solution was then evaporated under reduced pressure below 40 °C to remove methanol, diluted with water (300 ml), and washed with ether. The aqueous solution was acidified with 2M hydrochloric acid, and the oil separated was repeatedly extracted with ether. The extract was washed with M hydrochloric acid and water. After drying over magnesium sulfate, the solution was evaporated to leave an oil which was subsequently crystallized in a refrigerator. The product was recrystallized from ether–*n*-hexane; yield, 3.4 g (73%); mp 95—97 °C; $[\alpha]_D^{25}$ −32.0° (*c* 1, methanol). Found: C, 60.62; H, 7.61; N, 8.50%. Calcd for $C_{25}H_{39}N_3O_7$: C, 60.83; H, 7.96; N, 8.51%.

Boc-Orn(Z)-MeLeu-D-Phe-Pro-OEt (3). To a stirred solution of **2** (9 g, 18 mmol), HObt (2.4 g, 18 mmol), HCl·H-D-Phe-Pro-OEt[17] (6 g, 18 mmol), and triethylamine (2.5 ml) in tetrahydrofuran (90 ml), DCC was added at −10—−5 °C. After the stirring had been continued for 2 hr at −5—0 °C, and for a further 2 hr at room temperature, the mixture was left to stand overnight. The mixture was then evaporated under reduced pressure, and the residue was diluted with ethyl acetate (500 ml). The solution which was separated from the dicyclohexylurea by filtration was washed successively with water, 4% sodium bicarbonate, and water, and then dried over magnesium sulfate. The solvent was distilled off under reduced pressure to leave an oil; yield, 13.4 g (98%); R_f^1, 0.44; $[\alpha]_D^{25}$ −82.1° (*c* 0.55, methanol). NMR δ ($CDCl_3$): 1.45 (s, 9H, $(CH_3)_3C$–), 2.87 (s, 3H, CH_3-N–), 5.10 (s, 2H, $-OC\underline{H}_2C_6H_5$), 7.17—7.35 (m, 10H, phenyl protons).

Boc-Val-Orn(Z)-MeLeu-D-Phe-Pro-OEt (4). Compound **3** (7.65 g, 10 mmol) was dissolved in 3M hydrogen chloride in ethyl acetate (100 ml) and allowed to react for 30 min at room temperature. The solvent was distilled off under reduced pressure to dryness. The tetrapeptide ethyl ester hydrochloride thus obtained was dissolved in chloroform (30 ml), neutralized with triethylamine (1.4 ml), and subjected to a reaction with Boc-Val-ONSu[18] (3.45 g, 11 mmol) overnight at room temperature. To this solution, a few drops of *N*-2-aminoethylpiperazine were added, and the mixture was allowed to stand for 30 min. The solution was then diluted with chloroform (200 ml), washed successively with M hydrochloric acid and 4% sodium bicarbonate, and dried over magnesium sulfate. The solvent was distilled off under reduced pressure, and the residue was crystallized by adding dry ether; yield, 7.7 g (80%); mp 88—99 °C; $[\alpha]_D^{25}$ −91.2° (*c* 0.25, methanol). Found: C, 63.74; H, 7.85; N, 9.73%. Calcd for $C_{46}H_{68}N_6O_{10}$: C, 63.86; H, 7.92; N, 9.71%.

Boc-Val-Orn(Z)-MeLeu-D-Phe-Pro-OH (5). To a solution of **4** (6.5 g, 7.5 mmol) in methanol (70 ml), M sodium hydroxide (15 ml) was added; the solution was then allowed to stand for 6 hr at room temperature. The solution was evaporated under reduced pressure to remove methanol, diluted with water (100 ml), and acidified with 2M hydrochloric acid. The oil thus separated was extracted with ethyl acetate, and the extract was washed with water and dried over magnesium sulfate. The solvent was distilled off under reduced pressure to yield an oily product; 6.4 g (100%); $[\alpha]_D^{25}$ −80.5° (*c* 1, methanol). Found: C, 61.71; H, 7.72; N, 9.37%. Calcd for $C_{44}H_{64}N_6O_{10}\cdot H_2O$: C, 61.80; H, 7.78; N, 9.82%.

H-Val-Orn(Z)-MeLeu-D-Phe-Pro-OH·HCl (6). Compound **5** (6.4 g, 7.5 mmol) was treated with 3M hydrogen chloride in ethyl acetate (80 ml) for 30 min at room temperature. The solution was then evaporated under reduced pressure, and the residue was triturated with dry ether. The product was collected by filtration, washed well with ether, and dried *in vacuo* over sodium hydroxide; yield, 5.8 g (100%).

Boc-Val-Orn(Z)-Leu-D-Phe-Pro-Val-Orn(Z)-MeLeu-D-Phe-Pro-OH (7). To a solution of Boc-Val-Orn(Z)-Leu-D-Phe-Pro-$NHNH_2$[12] (3.3 g, 4 mmol) and 3M hydrochloric acid (4 ml) in dimethylformamide (100 ml), was added a chilled solution of sodium nitrite (300 mg, 4.4 mmol) in water (1 ml) at −15 °C. After 15 min, the reaction mixture was neutralized with triethylamine (0.56 ml), and a solution of **6** (3 g, 4 mmol) and triethylamine (1.2 ml, 8 mmol) in dimethylformamide (40 ml) was added to the mixture. After 2 days at 3 °C, the solvent was evaporated under reduced pressure below 40 °C. The residue was added to 10% citric acid (50 ml), and the resulting oil was extracted with ethyl acetate. The ethyl acetate solution was washed successively with 10% citric acid and water and dried over magnesium sulfate. After removal of the solvent, the residue was subjected for purification to chromatography on a column of silica gel 60 (Merck), first with a mixture of acetone and 28% aqueous ammonia (100: 5). In this solvent system, the by-products (R_f^2, 0.9 and 0.8) were eluted; the main product (R_f^2, 0.1) was not eluted. The desired product was then removed with methanol. The fractions containing the product, as detected by tlc (R_f^1, 0.53), were pooled and evaporated to dryness. The residue was dissolved in ethyl acetate (200 ml), and the ethyl acetate solution was washed with 10% citric acid until the washings became acidic, and then with water. After drying over magnesium sulfate, the solvent was distilled off; yield of oil, 3.3 g (53%); $[\alpha]_D^{25}$ −96.9° (*c* 1, methanol). Found: C, 62.67; H, 7.77; N, 9.97%. Calcd for $C_{82}H_{116}N_{12}O_{17}\cdot 2H_2O$: C, 62.41; H, 7.66; N, 10.65%.

Boc-Val-Orn(Z)-Leu-D-Phe-Pro-Val-Orn(Z)-MeLeu-D-Phe-Pro-ONSu (8). To a solution of **7** (2.1 g, 1.3 mmol) in dimethylformamide (6 ml), HONSu (300 mg, 2.6 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (400 mg, 2.6 mmol) were added at 0 °C. After 12 hr at room temperature, the mixture was diluted with ethyl acetate (200 ml). The solution was washed with M hydrochloric acid, 4% sodium bicarbonate, and water. After drying over magnesium sulfate, the solvent was distilled off under reduced pressure. The crude product was reprecipitated from ethyl acetate–petroleum ether; yield, 2.0 g (95%); mp 105—111 °C; $[\alpha]_D^{25}$ −125.0° (*c* 0.6, ethyl acetate). Found: C, 62.21; H, 7.20; N, 10.92%. Calcd for $C_{86}H_{119}N_{13}O_{19}\cdot H_2O$: C, 62.33; H, 7.36; N, 10.98%.

cyclo(*-Val-Orn(Z)-Leu-D-Phe-Pro-Val-Orn(Z)-MeLeu-D-*

Phe–Pro–) (9). The decapeptide *N*-hydroxysuccinimide ester, **8** (400 mg), was dissolved in trifluoroacetic acid (15 ml). After 30 min, the solution was evaporated, and the residual powder was collected by filtration with the aid of dry ether and dried over sodium hydroxide *in vacuo*; yield, 340 mg. The *N*-hydroxysuccinimide ester trifluoroacetate thus obtained (340 mg) was dissolved in dimethylformamide (10 ml), and the solution was added, drop by drop, to pyridine (100 ml) at 30—40 °C over a period of 2 hr; stirring was then continued for an additional 2 hr at room temperature. The solvent was removed, and the residue was dissolved in a mixture of methanol (50 ml) and water (10 ml). The solution was passed through columns (1.9×40 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (500 ml), the combined effluent was evaporated, and the oil was extracted with ethyl acetate. The extract was dried over magnesium sulfate and evaporated to dryness. The oily product was further purified by a column (1.5×15 cm) with silica gel 60 (Merck). After the column had been washed with a mixture of ethyl acetate and benzene (1: 1) (200 ml), the desired product, as determined by tlc, was eluted with ethyl acetate (100 ml). The solvent was evaporated to leave an oil, which was subsequently crystallized by the addition of a mixture of ethyl acetate and petroleum ether; yield, 163 mg (56%); mp 212—214 °C; $[\alpha]_D^{25}$ −248° (*c* 0.31, methanol). Found: C, 63.45; H, 7.46; N, 11.71%; molecular weight 1450.[19] Calcd for $C_{77}H_{106}N_{12}O_{14}\cdot 2H_2O$: C, 63.35; H, 7.59; N, 11.51%; molecular weight 1460.

cyclo*(–Val–Orn–Leu–*D*-Phe–Pro–Val–Orn–MeLeu–*D*-Phe–Pro–)·2HCl ([3-*N*-Methylleucine]-gramicidin S Dihydrochloride) (10).* The protected cyclic decapeptide **9** (100 mg) was dissolved in 0.01M hydrogen chloride in methanol (20 ml), after which hydrogenation was carried out for 4 hr, using palladium black as a catalyst. After removal of the catalyst by filtration, the filtrate was evaporated under reduced pressure. The syrup which remained was treated with M hydrochloric acid (2 ml), and the crystals formed were filtered, washed in portions with M hydrochloric acid (2 ml), and dried *in vacuo* over sodium hydroxide; yield, 60 mg. Recrystallization from ethanol–M hydrochloric acid gave colorless crystals; yield, 50 mg; mp 237—239 °C; $[\alpha]_D^{25}$ −272° (*c* 0.05, ethanol). Amino acid ratios in acid hydrolyzate: Val 2.11, Orn 1.82, Leu 0.98, Pro 2.08, MeLeu 1.00, Phe 2.12.[10] Found: C, 57.89; H, 7.82; N, 13.23%. Calcd for $C_{61}H_{94}N_{12}O_{10}\cdot 2HCl\cdot 2H_2O$: C, 57.94; H, 7.97; N, 13.29%.

*Boc–Val–Orn(Z)–MeLeu–*D*-Phe–Pro–N_2H_3 (11).* A solution of **4** (8.56 g, 10 mmol) and hydrazine hydrate (15 ml, 300 mmol) in dimethylformamide (20 ml) was allowed to stand at 30 °C for 7 days. The solution was evaporated below 40 °C, and then ethyl acetate (200 ml) was added to the residue. The solution was washed with M hydrochloric acid, 4% sodium bicarbonate, and water. After drying over magnesium sulfate, the solution was evaporated to dryness; yield of oil, 8.6 g (100%); $[\alpha]_D^{25}$ −88.6° (*c* 1.5, ethyl acetate). Found: C, 60.74; H, 7.72; N, 12.44%. Calcd for $C_{44}H_{66}N_8O_9\cdot H_2O$: C, 60.80; H, 7.88; N, 12.89%.

*Boc–Val–Orn(Z)–MeLeu–*D*-Phe–Pro–Val–Orn(Z)–MeLeu–*D*-Phe–Pro–OH (12).* Compound **11** (2.9 g, 3.3 mmol), in a mixture of 3M hydrochloric acid (3.5 ml) and dimethylformamide (100 ml), was treated with sodium nitrite (280 mg, 4 mmol) as in the case of **7**. To the azide solution was added a solution of **6** (2.6 g, 3.3 mmol) in dimethylformamide (40 ml) containing triethylamine (1.8 ml). After the mixture had been stirred for 24 hr at 3 °C, the solvent was evaporated under reduced pressure. The residue was dissolved in ethyl acetate (500 ml), and the ethyl acetate solution was washed with 10% citric acid and water and dried over magnesium sulfate. After removal of the solvent, the residue was triturated with petroleum ether. The product was reprecipitated from ethyl acetate–petroleum ether; yield, 2.0 g (39%), mp 94—106 °C; $[\alpha]_D^{25}$ −115.0° (*c* 1, methanol). Found: C, 62.58; H, 7.30; N, 10.76%. Calcd for $C_{83}H_{118}N_{12}O_{17}\cdot 2H_2O$; C, 62.62; H, 7.72; N, 10.55%.

*Boc–Val–Orn(Z)–MeLeu–*D*-Phe–Pro–Val–Orn(Z)–MeLeu–*D*-Phe–Pro–ONSu (13).* The decapeptide acid **12** (1.55 g, 1 mmol) was converted to the active ester, **13**, by the method described for the preparation of **8**; yield, 1.27 g (77%); mp 95—110 °C; $[\alpha]_D^{25}$ −111.7° (*c* 0.5, ethyl acetate). Found: C, 63.01; H, 7.18; N, 10.88%. Calcd for $C_{87}H_{121}N_{13}O_{19}$: C, 63.21; H, 7.37; N, 11.01%.

cyclo*(–Val–Orn(Z)–MeLeu–*D*-Phe–Pro–Val–Orn(Z)–MeLeu–*D*-Phe–Pro–) (14).* Compound **13** (1.27 g, 0.77 mmol) was treated with trifluoroacetic acid (10 ml) as in the case of **9**. The decapeptide *N*-hydroxysuccinimide ester trifluoroacetate thus obtained (1.2 g) was dissolved in dimethylformamide (10 ml), and the solution was added to pyridine (700 ml). The solvent was removed, and the residue was dissolved in a mixture of methanol (50 ml) and water (10 ml). The solution was passed through columns (1.9×40 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (700 ml), the combined effluent was evaporated, and the oil was extracted with ethyl acetate. The extract was dried and evaporated. The oily product was further purified by column chromatography with silica gel 60 (Merck). After the column had been washed with a mixture of ethyl acetate and benzene (1: 1) (50 ml), the desired product, as determined by tlc (R_f^1, 0.5), was eluted with a mixture of chloroform, methanol, and acetic acid (95: 5: 3). The fractions (105—240 ml) containing the product were pooled and evaporated to an amorphous powder; yield, 770 mg (67.5%); mp 105—115 °C; $[\alpha]_D^{25}$ −173° (*c* 0.4, methanol). Found: C, 63.49; H, 7.18; N, 11.17%; molecular weight 1465.[19] Calcd for $C_{78}H_{108}N_{12}O_{14}\cdot 2H_2O$: C, 63.56; H, 7.65; N, 11.40%; molecular weight 1474.

cyclo*(–Val–Orn–MeLeu–*D*-Phe–Pro–Val–Orn–MeLeu–*D*-Phe–Pro–)·2HCl ([3,3′-di-*N*-Methylleucine]-gramicidin S Dihydrochloride) (15).* The protected cyclic derivative, **14** (340 mg, 0.23 mmol), was converted to **15** by the method described for the preparation of **10**; yield, 255 mg (85%); mp 233—235 °C; $[\alpha]_D^{25}$ −235.7° (*c* 0.05, ethanol). Amino acid ratios in acid hydrolyzate: Val 1.10, Orn 0.89, MeLeu 1.00, Phe 0.98, Pro 1.05.[10] Found: C, 57.47; H, 7.68; N, 12.78%. Calcd for $C_{62}H_{96}N_{12}O_{10}\cdot 2HCl\cdot 3H_2O$: C, 57.43; H, 8.08; N, 12.96%.

Paper Electrophoresis. To ascertain further the purities of the analogs of gramicidin S synthesized here, paper electrophoresis was carried out as has been described before.[20] Each peptide revealed a single spot, and the mobilities were comparable with that of gramicidin S.

Microbiological Assays. The minimum amounts of the compounds necessary for the complete inhibition of growth were determined by a dilution method, using a bouillon agar and a semisynthetic medium; the results are shown in Table 1.

ORD Measurements. The measurements were performed with a JASCO spectropolarimeter model ORD/UV-5, over the wavelength range from 210 to 300 nm. A cell with a path length of 0.2 cm was used, and the runs were made at an ambient temperature. Patterns in the solvents of ethanol and 8M aqueous urea are shown in Figs. 1 and 2 respectively.

The authors wish to express their thanks to Dr. I. Chibata of Tanabe Seiyaku Co., Ltd., for his encouragement in the course of this study. Thanks are also due to Associate Professor Y. Mukohata of Osaka University for his help in the ORD measurements, and to Dr. K. Enomoto of Tanabe Seiyaku Co., Ltd., for the biological assay.

Effect of Pressure on the Rate of Solvolysis. Formolysis of 1-(*p*-Substituted benzyl)ethyl Tosylates[1,2]

Akira SERA, Chisako YAMAGAMI, and Kazuhiro MARUYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 10, 1973)

The effect of pressure on the formolysis of 1-(*p*-substituted benzyl)ethyl tosylates was investigated, and the activation volumes, ΔV_o^* were estimated. The apparent values of activation volume were found to correlate nicely with σ^*. Because the present substrates were believed to be formolyzed through two separate processes, anchimerically assisted (k_Δ) and unassisted (k_s), the apparent values of activation volume were partitioned into the corresponding activation volumes, ΔV_Δ^* and ΔV_s^*. The dependence of ΔV_Δ^* and ΔV_s^* on the substituents was examined, and the correlation between the mechanisms of solvolysis and ΔV_Δ^* and ΔV_s^* was discussed.

In a previous paper we have shown the utility of the activation volumes as a diagnostic tool for studying solvolytic reaction mechanisms.[3]

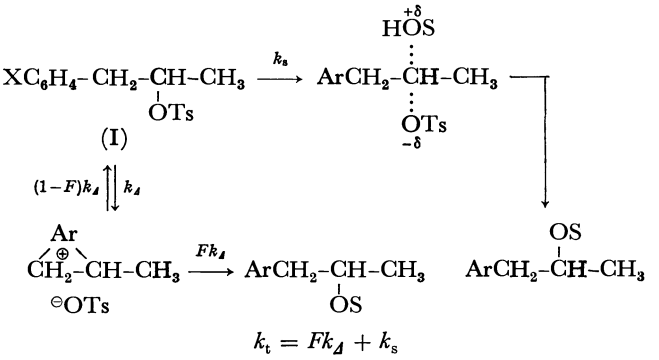
The activation volume, ΔV^*, defined as difference in the partial molal volumes between the transition and the initial states, can be determined experimentally from the rate data under pressure by means of the following equation;

$$\Delta V^* = -RT(\partial \ln k/\partial P)_T \qquad (1)$$

In general, solvolytic reactions of neutral substrates are characterized by activation volumes with a negative sign; that is, the rate constant increases by the application of pressure. This volume contraction is known to be caused mainly by the electrostrictive reorientation of the solvent molecules around the newly-charged transition state species.[4] The magnitude of activation volume is considered to reflect the charge density of the transition state species; a more delocalized charge yields a less negative value of ΔV^*. It may, then, be anticipated that the application of this concept to neighboring group participation reactions could provide a more comprehensive understanding of the carbonium-ion problem. le Noble and his co-workers studied the solvolysis of *exo*-2- and *endo*-2-norbornyl systems and showed that the less negative value of ΔV^* observed for the *exo*-epimer could be well reconciled with the σ-participation.[5] The aryl participations were also studied for primary substrates, and it was shown that the participation processes resulted in less negative activation volumes than the non-participation processes.[6]

However, little is known about the substituent effects on the activation volume for reactions proceeding through the participation mechanism. It seems that a series of β-arylalkyl compounds would be a suitable model for the investigation of this problem because the solvolytic behavior of β-arylalkyl arenesulfonates has been extensively studied[7] since the first proposal of phenonium-ion intermediate[7a] and because the presence of the aryl participation has been actually proved in some cases.[7c~e] Accordingly, we chose the formolysis of 1-(*p*-substituted benzyl)ethyl tosylates (System I) as our model reaction. It is now accepted that tosylates (I) are solvolyzed through two distinct pathways, the anchimerically assisted (k_Δ) and anchimerically unassisted (k_s) routes, as shown in Scheme 1.[7c,8]

In this paper, we shall describe an attempt to partition the activation volume (ΔV^*) of the reaction into the activation volume for the anchimerically assisted process (ΔV_Δ^*) and that for the anchimerically unassited process (ΔV_s^*) in order to obtain a further insight into the reaction mechanism in terms of the activation volume.



Scheme 1.

Results

The apparent activation volumes at atmospheric pressure, ΔV_o^*, for the formolysis of I and some typical secondary alkyl tosylates (System II) at 25.0 °C are summarized in Table 1, together with their rate constants at atmospheric pressure. These data were taken from our previous papers.[2,3] In order to examine the effect of an aryl moiety on the activation volume, the formolysis of γ-phenylalkyl tosylates (System III), a model possessing a non-participating aryl ring, was also studied (see Table 4). Their activation volumes, ΔV_o^*, were determined according to Eq. (1) by using the following first-order expression;

$$\ln k = a + bP \qquad (2)$$

The slope b was calculated by the method of least-squares in the range from 1 to 700 kg/cm^2, as has previously been described.[3] The results are given in Table 1.

As is shown in Table 1, the activation volume is dependent on the substituents in all systems. Figure 1 shows the correlations between ΔV_o^* and σ_{add}^*.[9] Two systems, I and II, were found to give approximately parallel correlation lines. The plot of ΔV_o^* against σ_{add}^* for System III gave another correlation line with a slope similar to the two others, whereas

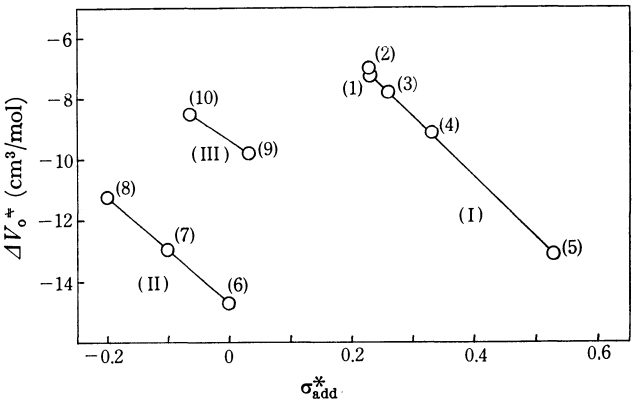

Fig. 1. Correlation of activation volume (ΔV_o^*) with σ^*_{add}. Roman numerals indicate system numbers and arabic numerals correspond to substrate numbers in Table 1.

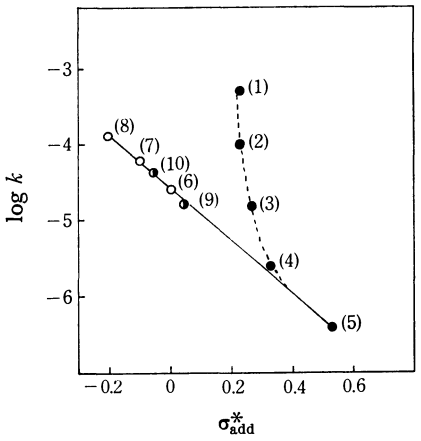

Fig. 2. Hammett-Taft plot of formolysis of secondary alkyl tosylates at atmospheric pressure.
●: $XC_6H_4CH_2CH(OTs)CH_3$, (system I); ○: $R_1CH(OTs)R_2$, (system II); ◑: $C_6H_5CH_2CH_2CH(OTs)R$, (system III). Numerals correspond to substrate numbers in Table 1.

the Hammett-Taft plot of log k against σ^*_{add} revealed a single correlation line including the points for System II (Fig. 2).

Partitioning of the Activation Volume. In order to partition solvolysis rates (k_t) for the β-arylalkyl system into anchimerically assisted (k_Δ) and unassisted (k_s) rate constants (Scheme 1), Schleyer and his coworkers[7c] have successfully utilized the deviation from the Hammett-Taft relation of the reaction rates for the substrates with activating substituents. The present method of partition of ΔV_o^* into ΔV_s^* and ΔV_Δ^* was essentially the same in principle. The plot of log k against σ^*_{add} (Fig. 2) shows that four substrates, **5**, **6**, **7**, and **8**, define a nicely correlated k_s line with the ρ*-value of −3.475.[8b] From this correlation line we estimated the k_s values for the other substrates with activating substituents. The values of Fk_Δ were then readily calculated from the relationship; $k_t = Fk_\Delta + k_s$. The same treatments of the rate-data at other pressures allow us to estimate the values of k_s and Fk_Δ at the given pressure. By knowing the values of k_s and Fk_Δ at each pressure, we can evaluate the magnitudes of ΔV_Δ^* and ΔV_s^* by means of the same method employed to determine the apparent ΔV_o^*. The representative results obtained for the unsubstituted compound (**3**) are presented in Table 2; the ρ*-value at each pressure is also given. Table 3 summarizes the activation volumes thus evaluated and the partitioned rate constants at atmospheric pressure for all the substrates. A set of parameters, ΔV_o^*, ΔV_Δ^*, and ΔV_s^*, allows us to calculate the fraction undergoing the k_Δ process, X_Δ, from the equation; $\Delta V_o^* = X_\Delta \cdot \Delta V_\Delta^* + (1 - X_\Delta) \cdot \Delta V_s^*$. The results are presented in the last column in Table 3. The rate ratio, Fk_Δ/k_t, is considered to be an alternative parameter providing the fraction of the contribution of the k_Δ-process. The excellent agreement of these two values (see Table 3) may confirm the reliability of the present analysis.

Table 2. Partitioning of formolysis rates for $PhCH_2CH(OTs)CH_3$ and ρ*-values under pressure at 25.0 °C

Pressure (kg/cm^2)	$10^5 k_t$ (s^{-1})	$10^5 k_s$ (s^{-1})	$10^5 Fk_\Delta$ (s^{-1})	ρ*[a]

Discussion

All the activation volumes shown in Table 1 are negative as had been predicted. Figure 1 shows that

a) Rate constant at atmospheric pressure, s^{-1}. (b) Activation volume at atmospheric pressure, cm^3/mol.
c) Calculated from $\Delta V_o^{\ddagger} = X_\Delta \cdot \Delta V_\Delta^{\ddagger} + (1-X_\Delta) \cdot \Delta V_s^{\ddagger}$.

all the systems presently studied exhibit a considerable dependence of the $\Delta V_o^{\ddagger}$ on σ_{add}^*. The conformity of $\Delta V_o^{\ddagger}$ to the Hammett-type correlation for II was previously discussed in terms of the k_c-k_s hybrid nature of the substrates.[3] The reaction of I is known to be accelerated more effectively by an electron-donating substituent. Accordingly, the shown trend that a less negative activation volume is associated with a more electron-donating substituent is in good accordance with the general concept that the transition state accompanying the neighboring group participation is sufficiently stabilized by the charge delocalization into the aryl moiety. The results of the partition of $\Delta V_o^{\ddagger}$ clearly indicate that the anchimerically assisted process (k_Δ) is characterized by a less negative activation volume (about −7 cm^3/mol) than the value (about −13 cm^3/mol) evaluated for the non-assisted process (k_s). This trend seems to correspond to the prediction that a k_Δ-process has a less negative activation entropy, $\Delta S^{\ddagger}$, than a k_s-process.[10] The difference of about 6 cm^3/mol observed between the two processes is noteworthy. This magnitude is thought to be large enough for us to distinguish these two reaction mechanisms.

It should be noted that the values of $\Delta V_\Delta^{\ddagger}$ and $\Delta V_s^{\ddagger}$ were found to be independent of the substituents in spite of the presence of a significant substituent effect on the apparent activation volumes, $\Delta V_o^{\ddagger}$. Since the $\Delta V_o^{\ddagger}$-σ^* correlation was observed for secondary alkyl tosylates,[3] the dissimilar features between Systems I and II will require some consideration. In the present treatments, the accumulation of errors causes the values of $\Delta V_o^{\ddagger}$ to be less precise. Hence, it is obscure whether $\Delta V_\Delta^{\ddagger}$ reveals a substituent effect or not.[11] Therefore, we will here discuss only the case of the non-assisted pathway. The independence of $\Delta V_s^{\ddagger}$ on the substituents for System I must result from the presence of the aryl ring in these substrates. As has been presented in Table 1 and Fig. 1, the substituent effect on $\Delta V_o^{\ddagger}$ for System III was actually observed. Accordingly, the possibility that the aryl moiety functions in some way effectively to exhibit a leveling effect on $\Delta V_s^{\ddagger}$ for System I could be excluded. Another effect induced by the presence of the aryl moiety is an inductive rate deceleration. Therefore, the most likely explanation of the insensitivity of $\Delta V_s^{\ddagger}$ to σ_{add}^* may be that the anchimerically unassisted reaction in the system under consideration actually undergoes a solvent assisted process, that is, a nearly pure k_s-process,[12] whereas simple alkyl tosylates are solvolyzed with some k_c-character.[3] The leveling effect on the activation volumes associated with the k_s-mechanism (solvent assisted) has already been discussed in the case of methanolyses.[3] The k_s-character (solvent assisted) of the non-participating process of β-arylalkyl system has been accepted by several workers;[7c,7e] another evidence can be supplied on the basis of activation volume parameters. We have suggested that, as a reaction mechanism shifts from a k_c- to k_s-process, its activation volume becomes more negative.[3,13] The study of the formolyses of *n*-propyl and isopropyl tosylates at 45.0 °C yielded the activation volumes of −16.5 cm^3/mol for the former and −15.6 cm^3/mol for the latter.[14] These two values agree well with each other within the limits of experimental error. These results lead us to conclude that the reaction of isopropyl tosylate, even in formolysis, has a sufficient k_s-character rather than a k_c-character.[15] It may, then, be reasonably predicted that the non-participating process of I, for all substituents, is actually nearly the pure k_s-process (solvent assisted) because the rate-retarding inductive effect of the aryl ring makes it more difficult for the reaction to proceed *via* a carbonium-ion intermediate (k_c-character).

As has been shown above, the apparent slope associated with System I (Fig. 1) does not reflect the substituent dependence of $\Delta V_\Delta^{\ddagger}$ and/or $\Delta V_s^{\ddagger}$. From Table 3, the value of X_Δ is seen to vary with the substituents. Therefore, it is the change in X_Δ which is responsible for the apparent substituent dependence of $\Delta V_o^{\ddagger}$. In other words, the slope of the correlation line for System I is determined by the change in the degree of the contribution of each process, k_Δ and k_s, to the over-all reaction. The fact that the correlation lines between $\Delta V_o^{\ddagger}$ and σ_{add}^* for Systems I and II show similar slopes is also of interest. In the discussion of the $\Delta V_o^{\ddagger}$-σ_{add}^* correlation for the formolysis of secondary alkyl tosylates, we have suggested the importance of the k_c-character of the reaction.[3] Therefore, it may be considered that the difference in the degree of the solvent assistance in contributing to the over-all reactions decides the correlation slope. The similarity of the slopes for Systems I and II implies that the change in the degree of the solvent assistance is controlled by the substituents in a similar manner in these two cases. This interpretation supports the k_c-k_s hybrid mechanism proposed for secondary alkyl tosylates.

The comparison of the activation volumes for System II with those for System III indicates that the introduction of a non-participating aryl substituent into the alkyl system results in an increase in $\Delta V_o^{\ddagger}$ by several cubic centimeters/mol (see Fig. 1). Since all the points for the substrates of System II and III fall on a single

Hammett-Taft correlation line (Fig. 2), it is hard to consider that the observed increase in ΔV_0^* is a result of a change in the mechanism. Accordingly, the presence of an aryl group is considered to result in the difference in solvation. The activation volume is represented as follows;

$$\Delta V^* = \bar{V}_t - \bar{V}_g \quad (3)$$

where $\bar{V}_g$ and $\bar{V}_t$ are the partial molal volumes of the initial and the transition sates respectively. The measurements of the partial molal volumes of the substrates can provide information on this problem.[16] A rough estimate of $\bar{V}_g$ in formic acid gave the values of 194.6 cm³/mol for (**6**) and 295 cm³/mol for (**10**).[14] These data indicate that, taking into account the molar volumes (V_m) of 188.2 cm³/mol for neat (**6**) and 287 cm³/mol for neat (**10**), the volume changes in the solvent system accompanied by the addition of the solute ($\bar{V}_g - V_m$) are nearly the same. Hence, the difference in ΔV_0^* between the two systems (II and III) can be thought to reflect the difference in $\bar{V}_t$ rather than that in $\bar{V}_g$. This means that, in the transtion state, System III reveals a less significant volume contraction than System II. An explanation is possible in terms of the steric effect; that is, the bulky aryl group exerts some effect in hindering the electrostrictive solvation. Unfortunately, unambiguous evidence supporting this interpretation is now lacking.

Experimental

Materials. Formic acid was purified as has been described previously.[3] All the tosylates were prepared from the corresponding alcohols in the usual way. The purity of all the tosylates was confirmed by NMR analysis. Tosylate (**10**) was found to contain a small amount of impurity, but it did not interfere with the kinetic measurements.

Rate Measurements. A high-pressure apparatus described previously[17] was used without further modification. The bath temperature was kept at 25.0±0.01 °C. The reactions were followed by a conductometric method described previously.[3] The rate constants of γ-phenyl tosylates at various pressures are given in Table 4.

Table 4. Formolysis rate constants of $PhCH_2CH_2CH(OTs)R$ under pressure at 25.0 °C

(Received September 13, 1973)

The natural-abundance ^{13}C NMR spectra of the *ortho*- or the *para*-halobiphenyls were obtained by the pulse Fourier transform NMR (FT-NMR). For the *para*-derivatives, the observed chemical shifts of the C_1, C_2, and C_3-positions gave an excellent linear dependence on the electronegativity of the substituents. The dependence for the C_4-position, which showed a deviation from the linear plot, may be due to the heavy atom effects. The additivity of the chemical shifts holds also for the *ortho*-derivatives except for the cases of the bridgehead carbons, the C_1 and C_1'-positions. In particular, the observed chemical shifts of the C_2, C_3, and C_4 positions for 2,2',6,6'-tetrachlorobiphenyl showed a good agreement with the predicted values, whereas a large discrepancy can be seen between the observed and the assumed values for the C_1 and C_1' positions. The effects on the chemical shifts due to the steric hindrance are discussed by comparison with the results of the hindered alkylbiphenyls. The temperature dependence of the spin-lattice relaxation time was investigated for 4,4'- and 2,2'-dichlorobiphenyls. The activation energies of the molecular reorientation are negligibly small at the C_1, and C_4-positions for the *para*-derivative, but the *ortho*-derivatives have higher values at these positions, indicating anisotropy for the molecular motion.

The recent greater facility of ^{13}C FT-NMR spectroscopy has promised to better results from structural and dynamic studies of organic molecules. In particular, the measurements of the spin-lattice relaxation time (T_1) can yield useful information about molecular motion.[2,3)] In the present work, ^{13}C FT NMR measurements were carried out on 4,4'-dihalobiphenyls, 4-halobiphenyls and several *ortho*-substituted chlorobiphenyls. The substituent effects of halogen atoms were studied in terms of the electronegativity of the substituents. The effects on the chemical shifts due to the steric hindrance were investigated on the basis of the additivity calculation and compared with the results of the previous works on the hindered alkylbiphenyls.[4)] The spin-lattice relaxation times of the ring carbons were measured for 4,4'-dichlorobiphenyl and 2,2'-dichlorobiphenyl, and the activation energies of the molecular reorientation were estimated from the temperature dependence of the spin-lattice relaxation time. The activation energies for the C_1 and C_4 positions were negligibly small, and those for C_2 and C_3 showed nearly the same value in the case of the *para*-derivative. This means that the molecule is likely to rotate around the long axis of biphenyl. In the case of the *ortho*-derivative, however the activation energy values increased at both C_1 and C_4 positions, suggesting that a molecular motion may be greatly hindered in the direction of the long molecular axis. The D_2O used for the NMR lock was also filled outside the spherical tube. The concentration of the samples used for the T_1 measurements was adjusted so as to make a 30% solution in THF. The reproducibility of the T_1 values was better than 10%.

Experimental

All the ^{13}C NMR spectra were recorded with a JEOL PS/PFT-100 spectrometer equipped with a Fourier transform operation at 25.15 MHz under a complete proton decoupling. Benzene was used as the external reference, and the chemical shifts were measured within limits of experimental error of about 0.1 ppm. The following materials were synthesized and recrystallized from ethanol (the physico-chemical indices are given): 4-fluorobiphenyl (mp 74.2—75 °C), 4-chlorobiphenyl (mp 72—72.5 °C), 4-bromobiphenyl (mp 79.5—80 °C), 4-iodobiphenyl (mp 112—113 °C), 4,4'-difluorobiphenyl (mp 88—89 °C), 4,4'-dichlorobiphenyl (mp 149—150 °C), 4,4'-dibromobiphenyl (mp 162—163 °C), 4,4'-diiodobiphenyl (mp 199—202 °C), and 2,2'-dichlorobiphenyl (mp 58—59 °C). The 2,2',6,6'-tetrachlorobiphenyl and 2,6-dichlorobiphenyl were purchased from the Japan chromatograph Co., Ltd. The purity of the material was checked by means of the proton NMR spectra. The samples were prepared as approximately a 10—30% solution in tetrahydrofuran (THF).

The measurements of the spin-lattice relaxation time (T_1) were carried out using the Inversion Recovery Method[5)] and the Progressive Saturation Method.[6)] The pulse width was 20 μs for 90° pulse in all the experiments. In these experiments, spherical tubes, which were placed in standard tubes, were employed to reduce the inhomogenity of the external field (H_0) and the rf field (H_1).

Results and Discussion

The ^{13}C NMR spectra of 4,4'-difluorobiphenyl and 4,4'-dichlorobiphenyl observed at room temperature are given in Fig. 1. The spectra can be easily analyzed on the basis of the predictions of additivity calculations.[7)] An extra splitting of the ^{19}F ($I=1/2$) nucleus can be seen in Fig. 1, where the magnitude of the spin-spin coupling constant alters as a function of the distance between the ^{13}C and ^{19}F nuclei. The calculated chemical shifts of 4,4'- and 4-halobiphenyls, summarized in Table 1, are in satisfactory agreement with the observed values. In order to study the substituent effects in the *para*-derivatives, plots were made between the observed chemical shifts and the electronegativity. As is shown in Fig. 2, the plots for C_1 and C_3 give straight lines, indicating that they are positive-dependent on the absolute value of the electronegativity, conversely, those for the C_2 and C_4 positions show a

negative-dependence. Similar alternative effects of the substituents, which were previously confirmed by the proton NMR of the 4,4′-dihalobiphenyl, have also been reported in ^{13}C NMR studies of the alkylbiphenyls. The plots of the C_4-position only revealed a remarkable deviation from the straight line. This can probably be attributed to the heavy-atom effects of the halogen atoms.[8)] It is of interest to compare the observed chemical shifts and predicted values in the *ortho*-derivatives, since the discrepancy between them may be attributed to the effect of a steric hindrance. In Table 2 we give the observed and the predicted ^{13}C

chemical shifts of 2,2'-dichlorobiphenyl, 2,6-dichlorobiphenyl, and 2,2',6,6'-tetrachlorobiphenyl. It is rather surprising that the additivity calculation gave more or less suitable results for the ring carbons, except for the values of the bridgehead C_1 and C_1' positions. Similar results for the proton NMR chemical shifts have previously been reported for 2,2'-dichlorobiphenyl.[9] This suggests that the anisotropic effect of the ring current is reduced by the large electronegativity of the halogen atoms. As can be seen in Table 2, however, the observed shifts of the C_1 and C_1' atoms show a remarkable deviation, shifting higher by about from 2.3 to 2.5 ppm in dichlorobiphenyl and by 7.7 ppm in 2,2',6,6'-tetrachlorobiphenyl, exceeding the calculated values by the additivity rule. A similar large discrepancy between the observed and the predicted C_1 chemical shifts has already been demonstrated for hindered alkylbiphenyl. One may consider several cooperative mechanisms[10] which modify the chemical shift for the *ortho*-derivatives. The first is the perturbation of the π-bond order between the central C_1–C_1' bond or that of the charge density on the bridgehead carbon atoms due to the steric hindrance. In the present case, however, the first effect is not important, because the observed chemical shifts of the other position (C_2, C_3, C_4) are nearly the value calculated for the planar biphenyl. Recently, the importance of the short-range interaction has been demonstrated between non-bonded atoms which are accessibly located in hindered molecules.[4,11,12] In such a case, a large higher shift (a so-called compression shift) has been observed for the carbon atoms bonded to the carbon interacting together this shift is due to the electronic repulsion. No such effect can be seen for the *ortho*-carbon atoms of the present derivatives. This suggests that the two phenyls are almost perpendicularly twisted in the hindered halobiphenyls.[13] In such a case, these anomalous discrepancies in the C_1-chemical shift may be considered to result from some interaction between the chlorine and $2p_z$ carbon atomic orbitals, but a more rigorous explanation will need further investigations.

Carbon-13 Spin-lattice Relaxation Time. When analyzing ^{13}C spin-lattice relaxation time, three possible relaxation mechanisms may be considered. One is the chemical-shift anisotropy (CSA), and another is spin-rotation (SR) and ^{13}C–^1H dipole-dipole interactions.[2,14,15] The third mechanism is expected to be predominant for the protonated carbons. It has been relatively easy to observe the ^{13}C relaxation under complete proton decoupling.[16] In this case, if the rotational reorientation of the molecule is isotropic, the ^{13}C–^1H dipole relaxation contributes to the $1/T_1$ of all the protonated carbons to the same extent. The ^{13}C–^1H dipole-dipole relaxation becomes:

$$1/T_1 = K\{f(\omega_H-\omega_C)+3f(\omega_C)+6f(\omega_H+\omega_C)\} \quad (3)$$

where:

$$f(\omega_i) = \tau_R(1+\omega_i^2\tau_R^2)^{-1} \quad (4)$$

$$K = \hbar^2\gamma_H^2\gamma_C^2 r^{-6} \quad (5)$$

The τ_R is the rotational correlation time, r is the C–H distance, and γ_H and γ_C are the gyromagnetic ratios of the proton and carbon nuclei respectively. For all cases, we have $(\omega_C+\omega_H)\tau_R \ll 1$, and Eq. (3) can be reduced to the familiar results;

$$1/T_1 = \hbar^2\gamma_H^2\gamma_C^2\tau_R r^{-6} \quad (6)$$

Equations (3)—(6) can be suitably modified, however, either when the rotational reorientation of the molecule is anisotropic or when an internal motion of the functional group must be considered.[15] If the anisotropic motion (τ_G) is much slower than the overall reorientation ($\tau_R(\tau_G \gg \tau_R)$), the relaxation time becomes identical to the suitably-modified Eq. (6). In this case, an internal motion has little effect on $1/T_1$, and τ_G can be estimated only with difficulty. On the other hand, however, if an anisotropic motion is much faster than the overall reorientation ($\tau_G \ll \tau_R$), the relaxation can be easily understood on the basis of Eqs. (3) and (6). One may thus expect that T_1 values do not depend on the correlation time for the overall reorientation, but will be affected by an internal motion. In the *para*-position, T_1 is shorter than those for the carbon atoms at the *ortho*- and the *meta*-positions as a result of the preferred rotation about the symmetry axis. The bulky substituents of benzene that are axially symmetric causes the T_1 *ortho*/T_1 *para* and T_1 *meta*/T_1 *para* ratios to become larger, while substituents without axial symmetry lead to these ratios approaching 1.0.[17] In rod-shaped molecules such as diphenyl diacetylene, the T_1 value for the *para*-carbons is five times shorter than the T_1 for the *ortho*- and *meta*-carbons.[2]

In order to see the motional anisotropy in the present biphenyl derivatives, the temperature dependence of the T_1 values was investigated for 4,4'-dichlorobiphenyl and 2,2'-dichlorobiphenyl.

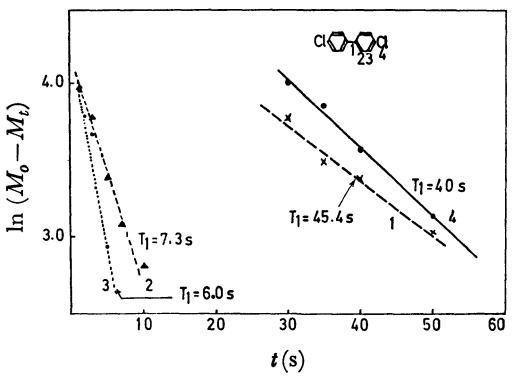

Fig. 3. Spin-lattice relaxation times of ^{13}C nuclei in proton decoupled 4,4'-dichlorobiphenyl.

The relaxation behavior of the ring carbons in 4,4'-dichlorobiphenyl is shown in Fig. 3.[18] The *ortho*-carbon relaxation of 4,4'-dichlorobiphenyl is nearly identical with that of the *meta*-carbons, since the anisotropic motion of this molecule dominates around the long biphenyl axis.

In general, the observed spin-lattice relaxation time T_1 can be divided into two contributions:

$$1/T_1 = (1/T_1)_D + (1/T_1)_0 \quad (7)$$

where the first term is the contribution of the dipole-dipole interaction and where the second term includes those of all the other mechanisms, in which the spin-rotation mechanism and the chemical-shift anisotropy

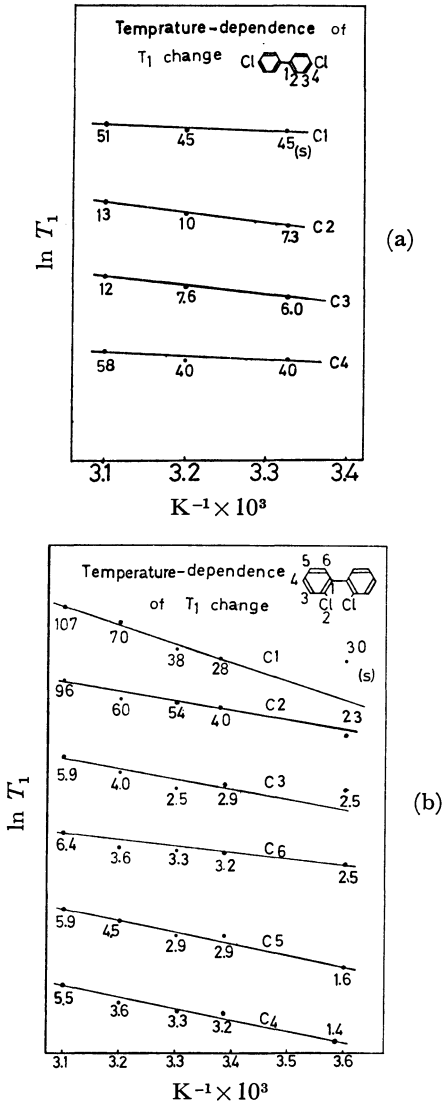

Fig. 4. Temperature dependence of the spin-lattice relaxation times for chloroderivatives.
a) 4,4′-dichlorobiphenyl, b) 2,2′-dichlorobiphenyl.

have been considered to be most important.[2] If the contribution of the spin-rotation relaxation is really important, the temperature dependence on the relaxation time will show a tendency opposite to those due to the other relaxation mechanisms.[14] At present, we have no strong experimental basis on which to characterize the relaxation mechanism of each carbon atom, but we have assumed that the dipole relaxation will be dominant for all carbon atoms; that is, $(T_1)_D \simeq T_1$, since the ^{13}C-resonance lines show nearly the same intensity ratio as that calculated from the numbers of the equivalent carbon atoms in the biphenyl ring. As is illustrated in Fig. 4, the T_1 curves show a temperature dependence of the Arrhenius type on the high-temperature side of their minima and the temperature dependence of τ_R is given by:

$$\tau_R = \tau_R^0 \exp(E_a/RT) \quad (8)$$

where E_a is the activation energy for the molecule reorientation. The apparent activation energy can be calculated from the slope of the plot, as is summarized in Table 3. The E_a values of the C_2 and C_3 positions are almost equal, but those for C_1 and C_4 positions are all negligibly small in the case of the *para*-derivative. This indicates that the rotation of the moecule is overwhelmingly dominant around the long axis of biphenyl. On the other hand, the E_a values of both C_1 and C_4 positions become much higher than those of the other positions in the *ortho*-derivative. This indicates that the partial motion of the phenyl would be greatly modified by the steric hindrance, in particular around the long axis of biphenyl.

Table 3. Activation energy (kcal/mol)

	C1	C2	C3	C4	C5	C6
4,4′-Cl	—	5.1	5.6	—		
2,2′-Cl	9.8	5.7	6.3	8.1	6.0	5.8

4,4′-Cl: 4,4′-dichlorobiphenyl.
2,2′-Cl: 2,2′-dichlorobiphenyl.

The temperature dependence of the C_1 and C_3 positions, which changes the slope at around 10 °C, suggests some contribution from the other relaxation mechanisms. The spin-rotational relaxation is most probable, but detailed investigations are now under way.

Radical Addition Reactions to the Carbonyl Group. I. The Reaction of Aliphatic Aldehydes with Di-*t*-butyl Peroxide

Kazuhiro MARUYAMA,* Mamoru TANIUCHI, and Shinzaburo OKA

**Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606*
Institute for Chemical Research, Kyoto University, Gokashō, Uji, Kyoto 611

(Received September 22, 1973)

The thermal decomposition of di-*t*-butyl peroxide in aliphatic aldehydes has been carefully examined. *n*-Aldehydes and β-substituted aldehyde gave appreciable amounts of *sec*-alcohols in the reactions. *sec*-Alcohol arose from the addition of the alkyl radical to the carbonyl group of aldehyde. α-Substituted aldehydes, however, did not give *sec*-alcohol, but instead gave considerable amounts of enol ether-aldehydes and dialdehydes. The addition of the alkyl radical to the carbonyl group and the decarbonylation of aldehydes were influenced remarkably by the structures of the aldehydes.

The cleavage reaction of the *t*-alkoxy radical to form ketone and the alkyl radical has been extensively studied. The relative ease of the bond scission of the *t*-alkoxy radical has been determined quantitatively by various methods.[1] On the other hand, only a few studies have been reported on the addition of the alkyl radical to the carbonyl groups of aldehyde and ketone, which is considered to be the reverse of the well-known cleavage reaction of the *t*-alkoxy radical.[2] However, no quantitative investigation has been published.

In this work, the formation of *sec*-alcohols by the reaction of aliphatic aldehydes with di-*t*-butyl peroxide has been examined in order to ascertain the possibility of the radical addition reaction to carbonyl groups.

Results and Discussion

The thermal decomposition of di-*t*-butyl peroxide in *n*-aldehydes yielded considerable amounts of *sec*-alcohols, accompanied by paraffin hydrocarbons and carbon monoxide. The yields of the reaction products were determined by gas chromatography. The reproducibility of the experimental results was fairly good: same typical experimental results are summarized in Table 1. The *sec*-alcohols, obtained in *ca.* 8% yields based on the aldehydes consumed (Table 1), were isolated by distillation and were identified by a comparison of the retention times in gas chromatography, and by a comparison of the IR, NMR, and mass spectra, with those of authentic samples. The main products obtained from the reaction of *n*-aldehydes with di-*t*-butyl peroxide can be explained by the mechanism shown in Eqs. (1)—(6):[2a]

$$(CH_3)_3COOC(CH_3)_3 \longrightarrow 2(CH_3)_3CO\cdot \quad (1)$$

$$(CH_3)_3CO\cdot + RCHO \longrightarrow (CH_3)_3COH + R\dot{C}O \quad (2)$$

TABLE 1. TYPICAL EXPERIMENTAL RESULTS OBTAINED IN THE REACTION OF ALDEHYDES WITH DI-*t*-BUTYL PEROXIDE (REACTION TIME 6 hr)

	Aldehyde used						
	Heptanal	Octanal	Nonanal	Decanal	2-Ethyl-heptanal	2-Methyl-octanal	3-Ethyl-heptanal[a]

a) Reaction was carried out in 4 hr.

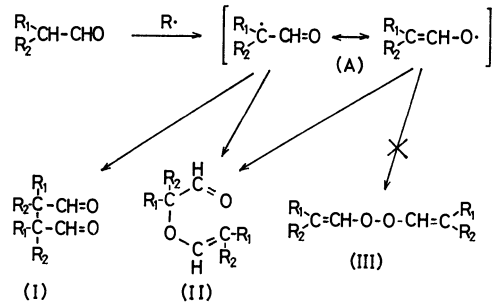
$$R\dot{C}O \longrightarrow R\cdot + CO \quad (3)$$

$$R\cdot + RCHO \longrightarrow R_2CHO\cdot \quad (4)$$

$$R\cdot + RCHO \longrightarrow RH + R\dot{C}O \quad (5)$$

$$R_2CHO\cdot + RCHO \longrightarrow R_2CHOH + R\dot{C}O \quad (6)$$

The main products—*t*-butyl alcohol, carbon monoxide, paraffin hydrocarbons, and *sec*-alcohols—are formed by Reactions 2, 3, 5, and 4—6 respectively. Reaction 4 implies the addition of the alkyl radical to the carbonyl group and is the reverse reaction of the decomposition of the *t*-alkoxy radical. Thus, the yield of *sec*-alcohol is a measure of the facility of the addition of the alkyl radical to the carbonyl group. β-Substituted aldehyde also yielded *sec*-alcohol, but its yield was considerably lower than those of *n*-aldehydes (Table 1). On the other hand, the reaction of α-substituted aldehydes with di-*t*-butyl peroxide led to the formation of enol ether-aldehydes and dialdehydes, much as in the oxidative coupling of α-substituted aldehydes by activated manganese dioxide.[3] In spite of our efforts, no *sec*-alcohol was detected in the products of these reactions. The formation of enol ether-aldehydes and dialdehydes may be explained by the following scheme:



α-Substituted aldehydes may suffer hydrogen abstraction on the α-carbon by a radical to a significant degree, thus giving the resonance-stabilized hybrid radicals (A). The hybrid radicals are considered to be fairly well stabilized by the hyperconjugation of two alkyl groups. However, with *n*-aldehydes and β-substituted aldehyde, an analogous conjugation would not be so important, because the radicals derived from α-hydrogen abstraction have only one alkyl group which contributes to such a stabilization. This would be the reason why the hybrid radical (A) plays an important role in the reaction of α-substituted aldehydes. Dialdehyde (I) and enol ether-aldehyde (II) can be produced through the dimerization of the radical (A). None of the other symmetrical coupling product, the divinyl peroxide (III), was found in the products. Moreover, 2-methyloctanal yielded quite large amounts of enol ether-aldehydes and dialdehyde compared with 2-ethylheptanal (Table 1). This can be explained by the greater capacity for the hyperconjugation effect of the methyl group, because it is well-known that this effect is much greater in the methyl group than in the ethyl group.[4] The lack of *sec*-alcohol may be interpreted in terms of steric factors. That is to say, the alkyl radicals derived from α-substituted aldehydes are *sec*-radicals, while the radicals from *n*-aldehydes and β-substituted aldehyde are prim-radicals. Thus, in adding to the carbonyl group, the radicals derived from α-substituted aldehydes are more sterically inhibited than those from *n*-aldehydes and β-substituted aldehyde. Similarly, the alkyl radical derived from β-substituted aldehyde is more sterically crowded than those from *n*-aldehydes. This would cause the lower yield of *sec*-alcohol in the reaction of β-substituted aldehyde (Table 1). As the other products, carbon monoxide was formed almost quantitatively except in the cases of α-substituted aldehydes, in which considerable amounts of enol ether-aldehydes and dialdehydes were formed: paraffin hydrocarbons were obtained in yields ranging from *ca.* 60 to 90%, depending on the structures of the aldehydes used. *t*-Butyl alcohol was obtained almost quantitatively with respect to the peroxide decomposed. Finally, in comparison with the rate of the decarbonylation of the three isomers of nonanal (Table 1), it was found that their rates were remarkably influenced by the structures of the aldehydes, decreasing in the following order: β-substituted aldehyde>*n*-aldehydes>α-substituted aldehydes. Therefore, the radical-induced decarbonylation of aliphatic aldehydes does not depend only on the structure of the attacking radical, but also on the structure of aldehydes.

Experimental

Materials. The heptanal, octanal, 2-ethylhexanal, nonanal, decanal, and di-*t*-butyl peroxide were all purchased from commercial sources. The 2-methyloctanal and 3-ethylheptanal were prepared by the Grignard procedure from the corresponding halides and ethyl orthoformate: 2-methyloctanal: bp 65—67 °C/18 mmHg; $n_D^{25.8}$ 1.4180: 3-ethylheptanal: bp 74—76 °C/18 mmHg; $n_D^{29.0}$ 1.4213. Their purities were confirmed by gas chromatography. The aldehydes were purified by vacuum distillation under nitrogen immediately before use.

Apparatus. The product analyses were performed by means of Yanagimoto Model GCG-220 and G-8 chromatographs equipped with thermal conductivity detectors. A Varian Model 920 aerograph was used in the preparations. The product identifications were carried out by a comparison of retention times in gas chromatography, and, if necessary, by a comparison of the IR spectra (Perkin-Elmer 521 spectrometer), the NMR spectra (Varian A-60 spectrometer), and the mass spectra (JMS-01SG spectrometer) of the products with those of authentic specimens.

Procedure. A three-necked reaction flask was equipped with a thermometer, a reflux condenser, and a gas inlet tube. The inlet tube was connected to a cylinder of nitrogen of 99.99 mol% purity. The reflux condenser was connected to a dry ice-acetone trap and then in turn to a water gas holder. A mixture of aldehyde and di-*t*-butyl peroxide was added to the reaction flask. The air in the reaction apparatus was then replaced by nitrogen prior to heating. The flask was heated to 120 °C in an oil bath. The reaction time was determined after the temperature of the oil bath had reached 120 °C. The gas liberated in the reaction was passed through the cold trap (−78 °C) and collected over water in the gas holder. The quantity of carbon monoxide was determined by means of the gaseous volume collected in the gas holder. At given time intervals, the oil bath was removed and the reaction flask was cooled by standing in air in order to quench the reaction. The reaction mixture in the flask and the volatile

products found in the cold trap were then combined. The resultant mixture was analyzed quantitatively by gas chromatography, using a suitable substance as an internal standard. The analyses of the products were mainly carried out, for lower-boiling materials by the use of a Model GCG-220 gas chromatograph equipped with a column (2.5 m) packed with 25% of Squalane on Firebrick C-22, 60—80 mesh, at 80 and 140 °C: for higher-boiling materials, we used a Model G-8 gas chromatograph equipped with a column (0.75 m) packed with 5.0% of Silicone Gum SE-30 on Chromosorb W, 60—80 mesh, at temperatures from 100 to 160 °C.

Preparation of Enol Ether-aldehydes and Dialdehydes by the Oxidative Coupling of α-Substituted Aldehydes. As a typical example, the procedure for the oxidative coupling of 2-ethylhexanal will be described. Activated manganese dioxide was prepared by a modified Attenburrow procedure[5] and activated by the azeotropic distillation of the excess water with benzene.[6] 2-Ethylhexanal (18.0 g) was added under nitrogen to a stirred mixture of activated manganese dioxide (69.5 g) in dioxane (150 ml). Then, the resultant mixture was heated for 24 hours at the reflux temperature of dioxane. The reaction mixture was subsequently filtered, and the filtrate evaporated. The residue was vacuum distilled under nitrogen. 2-Ethyl-2-(2'-ethyl-1'-hexenyloxy)hexanal (enol ether-aldehyde) and 2,3-diethyl-2,3-dibutyl-succinaldehyde (dialdehyde) were obtained in yields of 31 and 21% respectively. Essentially the same results were obtained from 2-methyloctanal.

The Unsensitized Photooxidation of (+)-Limonene, 1,2-Dimethylcyclohexene, and *endo*-Dicyclopentadiene

Tadashi SATO and Eigoro MURAYAMA

Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo 160

(Received November 9, 1973)

The unsensitized photooxidation of (+)-limonene (**1**), 1,2-dimethylcyclohexene (**2**) and *endo*-dicyclopentadiene (**3**) were carried out with Pyrex-filtered light. The singlet-oxygen oxidation was found to occur concurrently with the radical oxidation to the extent of 41% with **1** and 66% with **2**, but not at all with **3**. A reaction path *via* a complex was proposed.

Although sensitized photooxidation has been the subject of a number of recent investigations in connection with the reactivity of singlet oxygen, unsensitized photooxidation has attracted less attention. It has generally been accepted that, in unsensitized photooxidation, the light energy can be assumed to be used for the formation of a radical initiator, and that the reaction proceeds in the same reaction pattern as that of the radical-initiated oxidation.[1] In the present study, we observed that (+)-limonene (**1**), 1,2-dimethylcyclohexene (**2**), and *endo*-dicyclopentadiene (**3**), each possessing only isolated double bonds, suffered oxidation under the influence of the light of a longer wavelength (Pyrex-filtered light) to give results different from those obtained by the radical oxidation; an investigation was then undertaken in order to clarify the relation between the unsensitized photooxidation and the radical oxidation.

Results

(+)-Limonene (**1**), 1,2-dimethylcyclohexene (**2**), and *endo*-dicyclopentadiene (**3**) were oxidized with oxygen in three ways; Ox I—by heating a neat sample at 40—60 °C; Ox II—by irradiation with visible light in the presence of rose bengal (0.5 M in 1 : 1 *t*-butyl alcohol–methanol), and Ox III—by irradiation with Pyrex-filtered light in the absence of any sensitizer (0.5 M in 1 : 1 *t*-butyl alcohol–methanol). The products and product distribution after the reduction ($Na_2S_2O_3$+KI) of the primarily-formed hydroperoxide mixture are summarized in Tables 1—3. The product identification was carried out spectroscopically (see Experimental). The relative retention times on gas chromatography were also compared with those reported[2] in the case of the oxidation products of **1**.

It has been reported[3] that Compounds **10** and **11**, when obtained by the radical oxidation of **1**, are racemic, while both are optically-active when obtained by singlet-oxygen oxidation. In the latter case, Compounds **9** and **12** have also been known to be optically-active. The optical activities obtained in the present study are included in Table 1. It should be noted that the optical activities of **10** and **11**, obtained by Ox III, were reduced compared to those obtained by Ox II, whereas those of **9** and **12** were unchanged irrespective of the oxidation methods (Ox II or Ox III). We inferred from these facts that, in Ox III, some radical oxidation occurs concurrently with the singlet-oxygen oxidation. From the $[\alpha]_D$ values of **10** and **11**, it was estimated that the ratio of both reaction types is 41 : 59 (singlet-oxygen oxidation: radical oxidation). The product distribution also coincided

fairly well with the calculated values based on this ratio.*

It is evident from the results in Table 2 that, in the case of **2** also, the singlet-oxygen oxidation and the radical oxidation occur concurrently in Ox III, the ratio in the present case being 66: 34.** This ratio became larger as the reaction was carried out with a more dilute solution in the case of **2**, while it was almost independent of the concentration in the case of **1** (Tables 4 and 5).

Table 4. The ratio of singlet-oxygen participation as a function of concentration in case of **1** (after 20 hr)

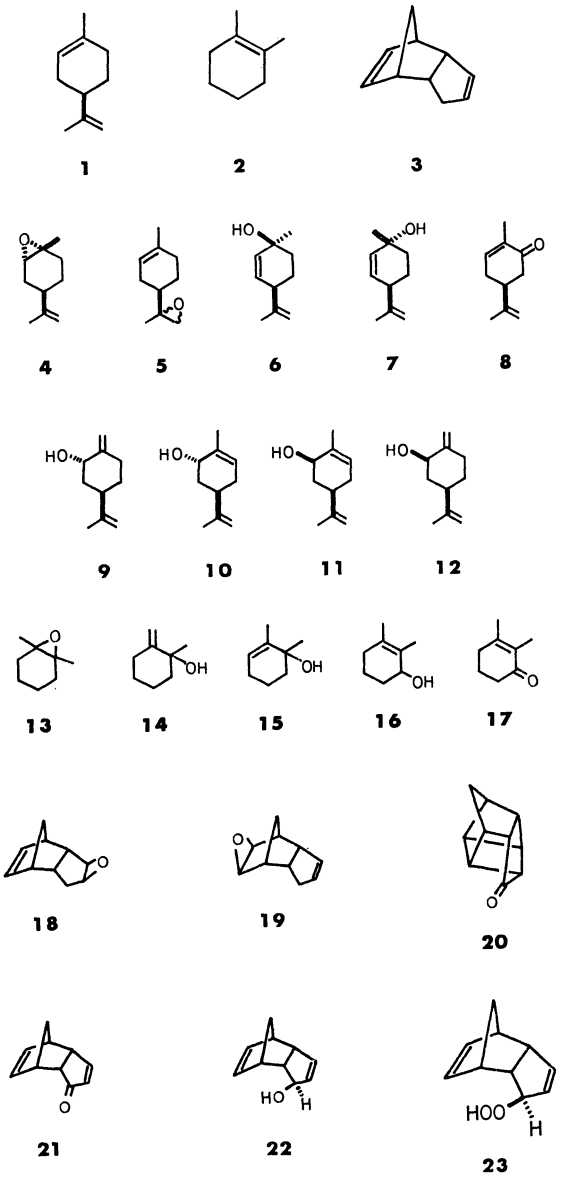
Concentration (M)	0.25	0.5	0.1	1.5	Neat
Percent of singlet-oxygen participation	39	41	40	35	26

Table 5. The ratio of singlet-oxygen participation as a function of concentration in case of **2** (after 5 hr)

Concentration (M)	0.19[a]	0.22	0.5	Neat[b]
Percent of singlet-oxygen participation	90	77	66	35

a) After 20 hr. b) Unfiltered or Pyrex-filtered light.

Contrary to the results obtained with the Ox-III oxidations of **1** and **2**, where singlet-oxygen oxidation constituted a considerable part of the reaction, only radical oxidation was observed in the Ox-III oxidation of **3** (Table 3). This conclusion was derived from the observation that the same product distribution as obtained by Ox III was obtained when Ox I and irradiation in the absence of oxygen were applied consecutively to **2**. Obviously, Ox III is essentially the same as the radical oxidation (Ox I) and the apparent differences in product distributions (with **18**, **20**, and **21**) in Ox I and Ox III may be assumed to arise from a secondary phototransformation of the primary products. This reasoning was supported by the facts that **21** afforded **20** on irradiation with Pyrex-filtered light[6] and that the hydroperoxide **23**, which is a presumable intermediate in the Ox-I oxidation of **3**, and which is actually obtained in an almost pure state by the singlet-oxygen oxidation of **3**, afforded **18**, in addition to **20**, under the irradiation.



Discussion

It was amusing that olefins which should not absorb the working light underwent photoreaction, and that the participation of singlet-oxygen oxidation was observed only in cases of **1** and **2**. Chien[7] has studied the mechanism of the initiation of the photooxidation of hydrocarbons in the wavelength region where there are no allowed transitions. He postulated, mainly on the basis of the kinetic data, two processes, the charge-transfer excitation and the oxygen-perturbed S–T ex-

* The unsensitized photooxidation of **1** has been reported by Schenck and his co-workers,[2] where a product distribution almost identical with that in the radical oxidation is obtained. This result contradictory to ours is conceivable since, under their reaction conditions (irradiation for 43 hr at 50 °C in a quartz vessel), the radical reaction would necessarily become more important than the inherent photochemical reaction of the olefin.

** The Ox-I and Ox-II oxidations of **2** have been reported by Foote.[4] Although results identical with ours have been obtained in case of Ox II, no description of **13** and **17** has appeared in the case of Ox I, in contrast to our results. This might be due to their over-reducing of the primary products by using $NaBH_4$ as a reducing reagent. Farmer and Sutton[5] have obtained a 1: 1 mixture of two hydroperoxides which are presumable precursors of **15** and **16** by the unsensitized photooxidation of **2**, and claimed an identity in mechanism between unsensitized photooxidation and radical oxidation. We traced the reaction under their reaction conditions (at 35 °C with a neat sample in a quartz vessel) and obtained **14** (38.6%) and **15** (32.8%) as the main products after the reduction of the hydroperoxide intermediates. The ratio of **16** was quite low (6%); it might be suspected that they were led to an erroneous conclusion as to the structure of the product deluded by the isomerization during the chemical-identification process of the products.

citation, as the most probable primary processes for this type of photooxidation. The possible formation of singlet oxygen has been suggested, but as a process of minor importance in the cases he studied.

We considered that singlet oxygen might be produced through a) sensitization by some impurities present in the reactants, b) sensitization by the primarily-formed radical oxidation products, and c) charge-transfer excitation.

The UV spectrum of **1** (1 cm path length, neat) showed a fine structure in the 250—270 nm region which was ascribable to some aromatics. The fine structure could not be removed by ordinary purification methods (distillation, column chromatography on alumina). *p*-Cymene, whose UV spectrum was very similar to the fine structure observed with the limonene sample, is the most probable candidate for the aromatic impurity. We, therefore, carried out the Ox-III oxidation of **1** in the presence of varying amounts of *p*-cymene, but the reaction pattern was unchanged in the *p*-cymene concentration region of 0—3.5 mg/8 ml. Thus, the Path a could be ruled out. As for the Path b, we considered that the most probable radical oxidation product which could sensitize the singlet-oxygen formation was carvone (**8**, λ_{max} 315 nm (ε 47)); therefore, Ox III with varying amounts of **8** was carried out. The results are shown in Fig. 1. Evidently **8** acted

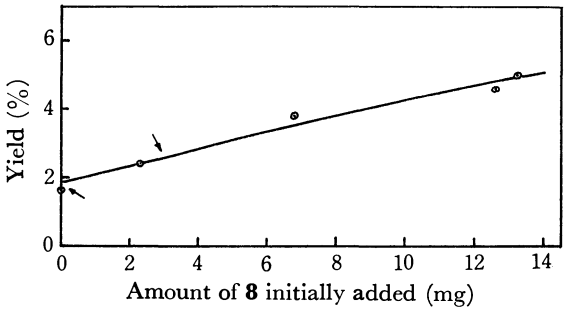


Fig. 1. Total yield of products from singlet-oxygen oxidation after 20 hr *vs.* amount of initially added **8** (mg in 8 ml of 0.5 M solution of **1** in 1 : 1 *t*-butyl alcohol–methanol).

as a sensitizer for the singlet-oxygen formation, but the following consideration revealed that this sensitization is not responsible for the total of the singlet-oxygen participation observed in Ox III. The amounts of **8** present in the reaction mixture obtained by the Ox-III oxidation of **1** with (3 mg) and without the initial addition of **8** are indicated by Lines I and II respectively in Fig. 2. The amount of **8** corresponding to the A area must be responsible for the extra singlet-oxygen participation of 0.7% (=2.6—1.9%; see arrows in Fig. 1), effected by the initial addition of **8**. The singlet-oxygen participation induced solely by the primarily-formed **8**, whose amount corresponds to the B area, should thus amount to 0.6% (=0.7%×(area B/areaA)), which corresponds to only one-third of the total singlet-oxygen oxidation observed in the Ox-III oxidation of **1**. A similar treatment was undertaken for the Ox-III oxidation of **2** by assuming **17** (λ_{max} 305 nm(ε 60)) as the possible sensitizer. From the

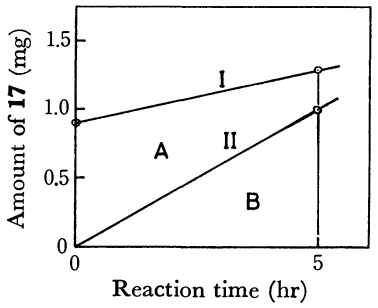

Fig. 4. Amount of **17** present in the reaction mixture as a function of time. (2 ml of 0.5 M solution of **2** in 1 : 1 *t*-butyl alcohol–methanol). I: With initial addition of 9 mg of **17**. II: Without initial addition.

results shown in Figs. 3 and 4, it was calculated that only one-third of the singlet-oxygen participation was ascribable to the sensitization by **17**. Further support that a mechanism other than unsaturated ketone sensitization for the singlet-oxygen formation was probably operating was obtained from the following observation. If the carvone sensitization were the sole path for the singlet-oxygen formation in the Ox III oxidation of **1**, then:

$$\{d[\text{singlet-oxygen products}]/dt\}_{t=0} = 0$$

and $\{d[\text{radical products}]/dt\}_{t=0} > 0$.

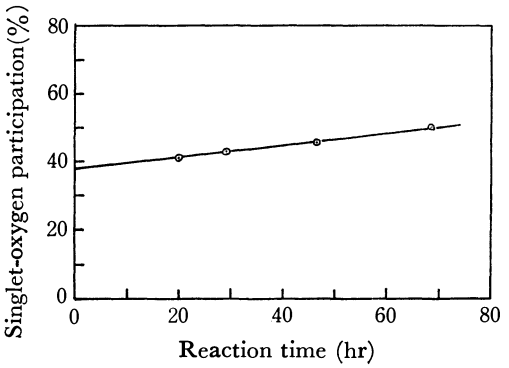

Fig. 5. Percent of singlet-oxygen participation as a function of time.

Therefore, the plots of

$$\frac{d[\text{singlet-oxygen products}]/dt}{d[\text{radical products}]/dt} \approx \frac{[\text{singlet-oxygen products}]}{[\text{radical products}]}$$

should extrapolate to zero at zero time. Such a plot is shown in Fig. 5, which does not intercept zero, in contrast to the above assumption. As another scheme for the singlet-oxygen formation, we considered a route *via* a C–T complex (Path c). When the UV spectra were measured with neat samples of **1**, **2**, and **3** which had been bubbled with 1 atom of oxygen for 5 min prior to the measurement, the end absorption moved to a wavelength longer by about 10 nm as compared with those of the oxygen-free samples. The original spectra were restored when the samples were bubbled with nitrogen. It might be reasonable, therefore, to assume that a C–T excitation is the primary step in Ox III, and that singlet oxygen would be formed by Reaction (1). With these arguments, we should consider why no singlet-oxygen participation was observed with **3**, in contrast to the observations with **1** and **2**. One is inclined to believe that only Path b is operative here, since this path would clearly explain the absence of singlet-oxygen participation in the case of **3** because of the photo-instability of the unsaturated ketone **21**, a potential sensitizer. However, we still persist in Path c for the following reason. Previous work[4] has shown that the reaction of singlet oxygen is quite sensitive to the electron density in the double bond of the olefin, and that the reactivity towards singlet oxygen increases with the number of alkyl groups attached to the double-bond carbon. Therefore, **1** and **2**, which have tri- and tetra-alkyl-substituted olefins respectively, would react with singlet oxygen more rapidly than **3**, disubstituted olefin. The situation is also clearly demonstrated by the fact that, with **1**, only trisubstituted olefin is attacked by singlet oxygen. If the rate of the reaction between singlet oxygen and **3** is fairly slow, the competing reactions of triplet species or Σ^1O_2, which are other products of Reaction (1) and possible initiators for the radical reaction, would become important and only radical-oxidation products would result. The dependence of the ratio of the singlet-oxygen participation on the concentration in the case of **2** (Table 5) would be another support for the involvement of the complex, since it is conceivable that the chain reaction would be easily terminated in a dilute solution, while the reaction through a complex would proceed as effectively in a dilute solution as in the more concentrated solution. However, the absence of a definite concentration dependence in the case of **1** can not be clearly interpreted.

$$\text{Olefin} + {}^3O_2 \xrightarrow{h\nu} (\text{Olefin-}O_2)^* \longrightarrow \text{Olefin} + {}^1O_2\ (\Delta \text{ or } \textstyle\sum) \quad (1)$$

In conclusion, we are inclined to favor the idea that the participation of charge-transfer excitation in the unsensitized photooxidation of olefin induces a competing singlet-oxygen oxidation and radical oxidation, but it remains uncertain, at this stage of the investigation, to what degree Path b is involved, particularly there is uncertainty as to the analyses of **8** or **17**; the possibility that compounds other than **8** or **17** could also serve as sensitizers for singlet-oxygen formation was also taken into account.

Experimental

The IR spectra were obtained in neat form with liquid samples and in KBr pellet form with solid samples. The NMR spectra were measured on a JEOL MH 60 (60 MHz) spectrometer with a CCl_4 solution; the chemical shifts are represented in δ values relative to the internal TMS standard. The mass spectra were measured on a Hitachi RMS-4 mass spectrometer.

Starting Materials. **1**: A commercial sample was passed through an alumina column. $[\alpha]_D^{26.5}=+112.6°$. Lit:[3] $[\alpha]_D^{20}=+122.4°$. **2**: A material prepared by the dehydration of 1,2-dimethylcyclohexanol[8] was purified by preparative gas chromatography. The sample could not be freed from 2,3-dimethylcyclohexene (5—7%), as revealed by the NMR spectrum. **3**: A commercial sample was fractionated through a packed column 80 cm in length.

General Methods of Oxidation. *Ox. I*: The sample was kept at 40—60 °C for 5—10 hr while oxygen was bubbled through. *Ox. II*: A 0.5M solution of the sample in *t*-butyl alcohol–methanol (1: 1) containing a small amount of rose bengal was irradiated at 18—20 °C with a tungsten lamp (200 W) for 10—20 hr, while oxygen was bubbled through. *Ox. III*: A 0.5M solution of the sample in *t*-butanol-methanol (1: 1) was irradiated at 18—20 °C with Pyrex-filtered light for 5—20 hr while oxygen was bubbled through.

The oxidized mixture obtained by each oxidation method was stirred vigorously with a solution containing KI (3 g) and $Na_2S_2O_3\cdot 5H_2O$ (4.5 g) in 10 ml of water for 40 hr. The organic material was extracted with ether, and the solvent was evaporated *in vacuo*. The residue was analyzed on a gas chromatograph, *p*-cymene being used as the internal reference. Although calibration curves were not obtained with all the oxidation products, we assumed that the relative sensitivities for the gas chromatographic detection did not deviate very much from each other; a calibration curve was obtained only with **10** in the case of **1** and with **14** in the case of **2**. Each product was obtained in a pure state by preparative gas chromatography.

A New Reagent for the Syntheses of *N*-Monoalkylated Hydroxylamines; *N*-Tosyl-*O*-2,4,6-trimethylbenzylhydroxylamine

Yoshikazu Isowa and Hideaki Kurita

Sagami Chemical Research Center, Nishionuma, Sagamihara, Kanagawa 229

(Received November 2, 1973)

The reactions of *N*-tosyl-*O*-2,4,6-trimethylbenzylhydroxylamine with primary alkyl halides yielded the protected hydroxylamines. The simultaneous cleavage of *N*-tosyl- and *O*-2,4,6-trimethylbenzyl groups with hydrogen bromide in acetic acid gave the corresponding *N*-monoalkylated hydroxylamines such as *N*-benzylhydroxylamine, 1-amino-3-hydroxyaminopropane and DL-3-hydroxyamino-2-aminopropionic acid.

Syntheses of naturally-occurring hydroxylamines,[1] which exist as hydroxamates or *N*-nitroso derivatives, have been accomplished using various methods including method A to E;

Method A: Zinc dust reduction of nitro group[2] in aqueous solution containing ammonium chloride.

Method B: Acid hydrolysis or hydrazinolysis of nitrone,[3] which is obtainable by the reaction of alkyl halides or acrylic acid derivatives with the appropriate aldoxime in the presence of base.

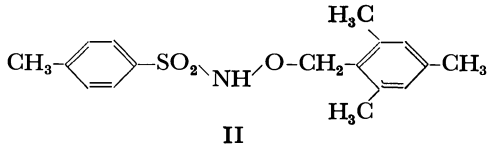
Method C: Direct conversion of alkyl halides[4] by hydroxylamine itself in the absence or presence of solvents.

Method D: Reduction of oxime.[5]

Method E: Hydrolysis of oxazirane,[6] which is obtained by the oxidation of Schiff's base.

In our previous papers, *N*-tosyl-*O*-benzylhydroxylamine (I) has been used for the syntheses of alanosine,[7] 5-*N*-hydroxy-L-ornithine,[8] rhodotorulic acid,[9] and ferrichrome.[10] The *N*-protecting tosyl group of I is always deprotected by the action of 36% hydrogen bromide in acetic acid, while the *O*-protecting benzyl group, after the *N*-acylation, is deblocked by the hydrogenation. In some cases,[8] *N*-tosyl and *O*-benzyl groups may be removed simultaneously by the treatment with 36% hydrogen bromide–acetic acid after long days, but in almost all cases, benzyl group remained intact with the action of this reagent.

In this paper, we describe a new reagent for the syntheses of *N*-monosubstituted hydroxylamines; *N*-tosyl-*O*-2,4,6-trimethylbenzylhydroxylamine (II). 2,4,6-Trimethylbenzyl group has been used for the first time by Stewart[11] for the masking of carboxyl groups in the peptide chemistry and is known to be acid-sensitive.



II

The reagent (II) was prepared according to the procedure[8] for the analogue (I); the tosylation of *O*-2,4,6-trimethylbenzylhydroxylamine, which was prepared by the 2,4,6-trimethylbenzylation of *N*-carboethoxyhydroxylamine and the subsequent alkaline hydrolysis, afforded II. Using this reagent, *N*-benzylhydroxylamine (III), 1-amino-3-hydroxyaminopropane (IV), and DL-3-hydroxyamino-2-aminopropionic acid (DL-V) were synthesized.

Synthesis of N-*Benzylhydroxylamine (III) and the Conditions of the Removal of the Protecting Groups.* Reaction of benzyl chloride and II in the presence of sodium methoxide gave *N*-benzyl-*N*-tosyl-*O*-2,4,6-trimethylbenzylhydroxylamine (VI).

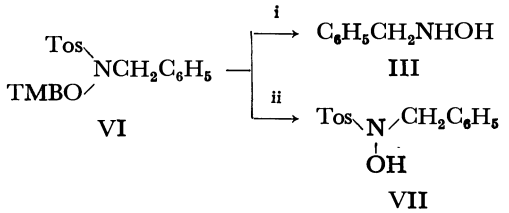


Fig. 1. Tos: tosyl, TMB: 2,4,6-trimethylbenzyl.
i: hydrogen bromide–acetic acid
ii: trifluoroacetic acid

The treatment of VI with 36% hydrogen bromide-acetic acid in the presence of phenol gave III. 18% Hydrogen bromide–acetic acid was also effective for the simultaneous removal of the two protecting groups. The use of trifluoroacetic acid as a deprotecting agent gave another result; only the 2,4,6-trimethylbenzyl group was removed and the *N*-tosyl group remained intact. The product was *N*-benzyl-*N*-tosylhydroxylamine, whose structure was determined by the elemental analysis, IR, and NMR spectra. Absorption of *N*-hydroxy group of VII appeared at 3360 cm^{-1} in IR and δ 10.19 in NMR.

Synthesis of 1-Amino-3-hydroxyaminopropane (IV). 1-Amino-3-hydroxyaminopropane (IV) is a component of schizokinen, an iron-transport compound from *Bacillus megaterium* and was synthesized by Neilands *et al.*[2a] by method A. The higher analogues of IV, 1-amino-4-hydroxyaminobutane[2c] and 1-amino-5-hydroxyaminopentane,[2d,e] were also synthesized previously by the same method. Condensation of 3-bromopropylphthalimide and II in the presence of sodium methoxide gave 1-phthalimido-3-(*N*-tosyl-*N*-2,4,6-trimethylbenzyloxy)aminopropane (VIII). VIII was converted by the action of hydrazine hydrate to 1-amino-3-(*N*-tosyl-*N*-2,4,6-trimethylbenzyloxy)aminopropane (IX), which was identified as the hydrochloride. The action of 36% hydrogen bromide-acetic acid on IX gave IV as the di-hydrobromide.

Synthesis of DL-*3-Hydroxyamino-2-aminopropionic Acid (DL-V).* First synthesis[4c,d] of DL-V was achieved by method C; condensation of methyl L- or DL-3-chloro-2-acetaminopropionate (X) with hydroxylamine in the absence of solvents and the subsequent acid

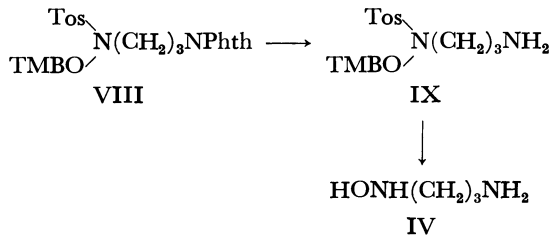

Fig. 2. Phth: phthalyl

hydrolysis gave DL-V. In recent years, improved synthesis[3g] of DL-V using method B was reported; the reaction of X with *anti*-benzaldoxime and the subsequent acid hydrolysis gave DL-V in excellent yield.

The higher homologues of DL-V, 5-*N*-hydroxy-DL-ornithine[2b,3e,f,4d] and 6-*N*-hydroxy-DL-lysine,[2b,3e,4d] were obtained by method A, B, or C.

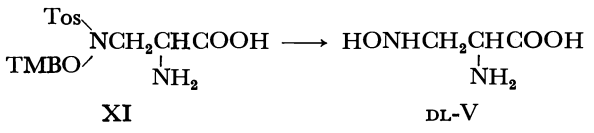

Fig. 3.

DL-2-Amino-3-(*N*-tosyl-*N*-2,4,6-trimethylbenzyloxy)-aminopropionic acid (XI) was synthesized, according to the procedure[7] for DL-2-amino-3-(*N*-tosyl-*N*-benzyloxy)aminopropionic acid, from ethyl 2,3-dibromopropionate and II as the starting materials. The protected amino-hydroxyamino acid (XI) was converted to DL-V by the treatment with 36% hydrogen bromide-acetic acid in the presence of phenol at room temperature.

Experimental

Melting points were determined with a Yanagimoto electric micromelting point apparatus, unless otherwise indicated and are uncorrected. Infrared spectra were recorded on a Hitachi EPI G-3 spectrophotometer as KBr disk. Nuclear magnetic resonance spectra were run on a Hitachi Perkin-Elmer R-20 High Resolution spectrometer, using tetramethylsilane as an internal standard.

N-*Carboethoxy*-O-*2,4,6-trimethylbenzylhydroxylamine.* To an ice-cooled solution of *N*-carboethoxyhydroxylamine (23.1 g, 0.22 mol) in methanol (50 ml) was added a solution of potassium hydroxide (12.3 g, 0.22 mol) in methanol (50 ml). After stirring for 30 min, 2,4,6-trimethylbenzyl chloride (33.7 g, 0.2 mol) in methanol (50 ml) was added at room temperature and the mixture was refluxed for 1 hr. The precipitated potassium chloride was removed and the filtrate was evaporated *in vacuo*. Ether (150 ml) and water (50 ml) were added. The organic layer was separated and dried. After evaporation of the solvent, the residue was distilled to give a pure product. Yield, 25.5 g (53.8%); bp 148—153 °C/0.9 mmHg.

Found: C, 65.40; H, 7.78%. Calcd for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.07%.

O-*2,4,6-Trimethylbenzylhydroxylamine.* A mixture of *N*-carboethoxy-*O*-2,4,6-trimethylbenzylhydroxylamine (47.5 g, 0.2 mol) and potassium hydroxide (45 g, 0.8 mol) in water (200 ml) was refluxed for 5 hr. After 12 hr, the crystallized substance was collected and washed with water. Yield, 23.6 g (70.6%). Recrystallization from ether–petroleum ether gave an analytical sample, mp 54—55 °C.

Found: C, 72.51; H, 8.95; N, 8.23%. Calcd for $C_{10}H_{15}NO$: C, 72.69; H, 9.15; N, 8.48%.

N-*Tosyl*-O-*2,4,6-trimethylbenzylhydroxylamine (II).* To an ice-cooled solution of *O*-2,4,6-trimethylbenzylhydroxylamine (16.5 g, 0.1 mol) in pyridine (80 ml) was added a solution of tosyl chloride (19.2 g, 0.101 mol) in pyridine (60 ml). Stirring was continued for another 5 hr at room temperature and then the solvent was evaporated *in vacuo*. Ethyl acetate (150 ml) was added to the residue and washed successively with 1M hydrochloric acid and water. The organic layer was dried over magnesium sulfate and evaporated *in vacuo* to give crystals. Yield, 26.8 g (84%); mp 132—134 °C. Recrystallization from ether–petroleum ether gave an analytical sample, mp 135—136 °C.

Found: C, 63.85; H, 6.67; N, 4.32%. Calcd for $C_{17}H_{21}NO_3S$: C, 63.92; H, 6.63; N, 4.39%.

N-*Benzyl*-N-*tosyl*-O-*2,4,6-trimethylbenzylhydroxylamine (VI).* To a stirred solution of sodium (1.2 g) in methanol (150 ml) were added II (14.8 g, 40 mmol) and benzyl chloride (6.3 g, 50 mmol) and then the mixture was refluxed for 3 hr. The deposited crystals were collected and washed successively with water and ether. Yield, 12.8 g (78.1%); mp 128—131 °C. Recrystallization from ethanol gave an analytical sample, mp 129—131 °C.

Found: C, 70.22; H, 6.64; N, 3.38%. Calcd for $C_{24}H_{27}NO_3S$: C, 70.38; H, 6.65; N, 3.42%.

N-*Benzylhydroxylamine (III).* *a*): A solution of VI (1.64 g, 4 mmol) in 36% hydrogen bromide–acetic acid (10 ml) containing phenol (1.5 g) was stirred for 20 hr and then concentrated *in vacuo*. To the residual oil was added ether (30 ml) and water (10 ml). The aqueous layer was separated, concentrated to a small volume, and adjusted to pH 8 with solid sodium carbonate. The crystals were collected, after the solution was stored in an ice box for 12 hr. Yield, 0.24 g (49%); mp 56—56.5 °C (lit,[18] mp 57 or 58 °C). Recrystallization from petroleum ether unchanged the mp. Triphenyltetrazolium test was positive. IR: 3255 and 3150 cm^{-1}.

b): III was also obtained from VI by the treatment with 18% hydrogen bromide- acetic acid. Yield, 32.7%.

N-*Benzyl*-N-*tosylhydroxylamine (VII).* A solution of VI (0.82 g, 2 mmol) in trifluoroacetic acid (5 ml) containing phenol (0.4 g) was stirred at room temperature for 20 hr. The deposits were collected. Yield, 0.43 g (79.5%); mp 171—173 °C. Recrystallization from ethanol gave an analytical sample, mp 175—177 °C. This compound gave negative ferric chloride and triphenyltetrazolium tests. IR: 3375, 1595, 1380 and 1170 cm^{-1}. NMR (d_6-DMSO): δ 2.45 (s, 3H), 4.02 (s, 2H), 7.33, 7.50 and 7.84 (9H), and 10.18 (s, 1H).

Found: C, 60.58; H, 5.45; N, 5.00%. Calcd for $C_{14}H_{15}NO_3S$: C, 60.63; H, 5.45; N, 5.05%.

*1-Phthalimido-3-(*N-*tosyl*-N-*2,4,6-trimethylbenzyloxy)aminopropane (VIII).* To a stirred solution of sodium (1.38 g, 60 mmol) in methanol (150 ml) were added 3-bromopropylphthalimide (13.4 g, 50 mmol) and II (15.95 g, 50 mmol). The mixture was refluxed for 3 hr and concentrated *in vacuo*. To the residue, water (50 ml) and ether (50 ml) were added and the mixture was stirred for 5 hr. Then crystals were collected, dried and recrystallized from *n*-propyl alcohol. Yield, 17.2 g (68.0%); mp 139—140 °C.

Found: C, 66.32; H, 6.17; N, 5.27%. Calcd for $C_{28}H_{30}N_2O_5S$: C, 66.38; H, 5.97; N, 5.53%.

*1-Amino-3-(*N-*tosyl*-N-*2,4,6-trimethylbenzyloxy)aminopropane (IX).* A suspension of VIII (2.53 g, 5 mmol) in ethanol (130 ml) was warmed at 60—65 °C. To the resultant solution, hydrazine hydrate (2.5 g, 50 mmol) was added.

After stirring for 6 hr at 60—65 °C, the mixture was adjusted to pH 5 with acetic acid and the precipitates were filtered off. The filtrate was concentrated *in vacuo* and water (50 ml) was added. Insoluble substance was removed and the filtrate was extracted with ethyl acetate (50 ml). The aqueous layer was evaporated. To the residual oil, ethanol (20 ml) was added and evaporated. This operation was repeated three times and finally water (30 ml) was added. The solution was adjusted to pH 8 with 7% aq. ammonia and extracted with ethyl acetate (50 ml×2). The organic layer was dried over sodium sulfate and concentrated *in vacuo* to give IX quantitatively as a colorless oil. IX was characterized as the monohydrochloride monohydrate. Recrystallization from methanol–ether gave an analytical sample. mp 99—102 °C.

Found: C, 55.87; H, 7.27; N, 6.50%. Calcd for $C_{20}H_{28}N_2O_3S \cdot HCl \cdot H_2O$: C, 55.73; H, 7.25; N, 6.50%.

1-Amino-3-hydroxyaminopropane Dihydrobromide (IV·2HBr). To the crude oil (IX), which was obtained from VIII (5 mmol) as described above, phenol (2 g) and 36% hydrogen bromide-acetic acid (10 ml) were added. After stirring for 24 hr at room temperature, dry ether (150 ml) was added. The deposited crystals were collected and washed with dry ether. Yield, 1.13 g (90%). Recrystallization from methanol–ether gave an analytical sample, mp 157—159 °C. Triphenyltetrazolium test was positive.

Found: C, 14.77; H, 5.02; N, 10.97%. Calcd for $C_3H_{12}N_2OBr_2$: C, 14.30; H, 4.80; N, 11.12%.

Ethyl 2-Bromo-3-(N-tosyl-N-2,4,6-trimethylbenzyloxy)aminopropionate. To a solution of sodium (2.8 g) in ethanol (500 ml) was added II (31.9 g, 0.1 mol). Then ethyl 2,3-dibromopropionate (29 g, 0.11 mol) was added dropwise at room temperature. After stirring for 12 hr, the deposited crystals were collected and washed with water. Yield, 18 g. The filtrate was concentrated *in vacuo* to a small volume to give 12 g of a second crop. Total yield, 30 g (60%). Recrystallization from ethanol gave an analytical sample, mp 98—99 °C. IR: 1740 cm^{-1}.

Found: Br, 15.65%. Calcd for $C_{22}H_{28}NO_5SBr$: Br, 16.03%.

2-Bromo-3-(N-tosyl-N-2,4,6-trimethylbenzyloxy)aminopropionic Acid. To a solution of the ester (12.5 g, 25 mmol), obtained as described above, in acetone (300 ml) was added M sodium hydroxide (40 ml) and the mixture was stirred at room temperature. After 72 hr, the solution was adjusted to pH 4 with M citric acid and then concentrated *in vacuo*. Ethyl acetate (300 ml) and water (100 ml) were added to the residue and the organic layer was dried over sodium sulfate. The solvent was removed to give a crystalline product. Yield, 8.1 g (69%). Recrystallization from carbon tetrachloride gave an analytical sample, mp 168—170 °C. IR: 1700 cm^{-1}.

Found: Br, 16.93%. Calcd for $C_{20}H_{24}NO_5SBr$: Br, 16.99%.

DL-*2-Amino-3-(N-tosyl-N-2,4,6-trimethylbenzyloxy)aminopropionic Acid (XI).* A solution of the bromide (9.4 g, 20 mmol), obtained as described above, in concd. aq. ammonia (500 ml) was stored at room temperature for 10 days and then concentrated *in vacuo* to a small volume. After acidified with acetic acid to pH 4, the crystals were collected and washed successively with water, hot methanol and water. Yield, 5.3 g (65%); mp 189—191 °C (decomp.).

Found: C, 58.97; H, 6.47; N, 6.84%. Calcd for $C_{20}H_{26}N_2O_5S$: C, 59.09; H, 6.45; N, 6.89%.

DL-*2-Amino-3-hydroxyaminopropionic Acid* (DL-*V*). A solution of XI (1.02 g, 2.5 mmol) in 36% hydrogen bromide–acetic acid (5 ml) containing phenol (1 g) was stirred at room temperature. After 45 hr, dry ether (70 ml) was added. The deposits were collected and dissolved in water. The aqueous solution was extracted with ether and concentrated *in vacuo*. The residue redissolved in a small quantity of water was adjusted to pH 8 with 7% aq. ammonia and ethanol was added until the solution was cloudy. The precipitated crystals were collected, after the solution was stirred in an ice box for 12 hr. Yield, 0.17 g (56.7%). Recrystallization from water–ethanol gave an analytical sample, mp 167—168 °C (decomp.) in an open capillary in a liquid bath (lit. mp 163—165 °C (decomp.)[4c,d] 180—181 °C (decomp.)[3g]). Triphenyltetrazolium test was positive. IR: 3275, 3250, 1635, 1585, and 1525 cm^{-1}.

Found: C, 29.97; H, 6.57; N, 22.91%. Calcd for $C_3H_8N_2O_3$: C, 30.00; H, 6.71; N, 23.33%.

Stable Crystalline Complexes of Diphenylcyclopropenone with Substituted Acetic Acids[1]

Israel AGRANAT* and Shmuel COHEN
Department of Organic Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel
(Received August 16, 1973)

Diphenylcyclopropenone (DCP) forms 1 : 1 stable crystalline complexes with dichloroacetic acid, phenylacetic acid, diphenylacetic acid, trichloroacetic acid and cyanoacetic acid. The physical properties of these complexes are consistent with a hydrogen-bonded complexation between the carbonyl oxygen of DCP and the acidic hydrogen of the substituted acetic acid.

Diphenylcyclopropenone (DCP) (I) has been shown to form stable solid complexes with Lewis acids (BF_3, $SbCl_5$),[2] water,[3] and acetylenic dialcohols;[3] with methanol, a complex was formed in solution.[4] We wish to report that DCP forms 1 : 1 stable crystalline complexes with substituted acetic acids. The physical properties of these complexes are consistent with a hydrogen-bonded complexation between the carbonyl oxygen of DCP and the acidic hydrogen of the substituted acetic acid.

Treatment of DCP with an equimolar quantity of dichloroacetic acid (II) in boiling cyclohexane solution afforded a crystalline adduct of DCP and (II), mp 88—89 °C, in 78% yield, which analyzed for $C_{17}H_{12}Cl_2O_3$. The properties of this adduct (III) indicated that it was a 1 : 1 complex of DCP and II. In the solid state, the infrared molecular bands of DCP (II)[5] were shifted to lower frequencies: (KBr) 1850 cm^{-1} (I)→ 1820 cm^{-1} (III); 1630 cm^{-1} (I)→1595 cm^{-1} (III). (Similar shifts were observed in nujol.) The NMR spectrum of the complex III in $CDCl_3$ solution (100 MHz, δ=7.59 (m, 6H, *meta*+*para*) and 7.98 ppm (m, 4H, *ortho*)) showed a downfield shift of the aromatic protons relative to the respective absorptions of DCP.[6] It is noteworthy that the extent of the shift of the *ortho* protons (8 Hz) was identical to that of the *meta*+*para* protons. Thus, these shifts cannot be rationalized as due to a greater contribution of the "aromatic" dipolar structure of the cyclopropenium type in the complex (III). The longest wavelength maximum in the UV spectrum of I in cyclohexane solution, at 362 nm (ε=960), was absent in the corresponding spectrum of the complex (III). Instead, only a tailing towards the visible was observed. It has previously been suggested, on the basis of the wavelength, the relatively low extinction and the response to solvent, that the 362 nm band was due to intramolecular charge transfer of the "aromatic" 1,2-diphenylcyclopropenium oxide type.[4] The behaviour of this band in the UV spectrum of the complex is consistent with this interpretation.

Most revealing is the mass spectrum of the complex (III). It is not simply a superposition of the mass spectra of DCP and dichloroacetic acid (II). Certain of its features originate from the complex. Whilst the molecular ion ($[C_{17}H_{12}{}^{35}Cl_2O_3]^{+\cdot}$, *m/e* 334) was absent, the mass spectrum contained a most intense signal at *m/e* 207 (36% relative to that of *m/e* 206 $[DCP]^{+\cdot}$). It is most probably due to the 3-hydroxy-1, 2-diphenylcyclopropenium ion (IV). Thus, the mass spectrum strongly supports the proposed structure of the complex (III).

It appears that the chlorine substituents in the acetic acid moiety are not a prerequistite for the complexation. The formation of such a 1 : 1 complex between DCP and a substituted acetic acid proved to be a general reaction (at least for acetic acids with $pK_a<$ 4.3). DCP reacts with phenylacetic acid, diphenylacetic acid, trichloroacetic acid, and cyanoacetic acid, in boiling cyclohexane solution to form, in each case, a 1 : 1 complex (see experimental section). The physical properties of these complexes closely resemble those of (III). The mass spectrum of each complex contained the prominent signal at *m/e* 207 representing the 3-hydroxy-1,2-diphenylcyclopropenium ion (IV). It should be noted that in solution, the complexation

a) (*ortho*) and (*meta*+*para*) refers to the chemical shifts of the center of the corresponding multiplets of the AB_2C_2 systems of the DCP residue.

could be effected directly by dissolving equimolar quantities of DCP and the substituted acetic acid in the appropriate solvent. Under such conditions, both the NMR spectra and the UV spectra were identical with those obtained from the respective solutions of crystalline complexes.

It is plausible to assume that the complexation involves a hydrogen bond between the oxygen of the polar carbonyl group of DCP and the acidic hydrogen of the substituted acetic acid. The shift to lower frequencies of the cyclopropenone bands in the infrared spectra in the solid state supports this hypothesis. Likewise, the strong signal in the mass spectra of the complexes at *m/e* 207 is consistent with the proposed structure. In solution (CH_2Cl_2), however, the infrared spectrum was, in each case, a superposition of the respective spectra of the two components. The exact structure of the complexes of DCP with the substituted acetic acids must await an X-ray-crystallographic determination.

Cl_2CHCO_2H

(II)

Experimental

Melting points were taken on a Unimelt Thomas and Hoover capillary mp apparatus and are uncorrected. IR spectra were recorded on a Perkin-Elmer 457 Spectrophotometer. UV spectra were recorded on a Unicam SP 800 spectrophotometer. NMR spectra were recorded at 100 MHz on a Varian HA-100 spectrometer in $CDCl_3$ solutions. ^1H chemical shifts are reported in parts per million, downfield from Me_4Si. Mass spectra were recorded on a Varian MAT-311 spectrometer operating at 70 eV.

The Reaction of DCP (I) with Dichloroacetic Acid (II). DCP (0.515 g, 2.5 mmol)[7] and dichloroacetic acid (0.32 g, 2.5 mmol) were dissolved in 50 ml of boiling cyclohexane; the solution was refluxed for 15 min and gradually cooled to room temperature. The complex (III) crystallized from the solution. It was obtained as colourless crystals, mp 88—89 °C (cyclohexane) (78% yield). Found: C, 61.13; H, 3.38; Cl, 21.20%. Calcd for $C_{17}H_{12}Cl_2O_3$: C, 60.92; H, 3.61; Cl, 21.15%. ν_{max} (KBr) 3050 (w), 3000 (w), 2895 (w), 2845 (w), 2450 (w), 1880(w), 1850 (s), 1820 (vs), 1745 (vs), 1620 (m), 1595 (vs), 1575 (s), 1560 (s), 1480 (w), 1450 (s), 1370 (vs), 1290 (s), 1210 (m), 1175 (s), 1000 (w), 925 (w), 810 (s), 790 (w), 767 (vs), 687 (s), 590 (m), 520 (m), 473 (m), and 440 (m) cm^{-1}. λ_{max} (C_6H_{12}) 218, 222, 237_{sh}, 249_{sh}, 253_{sh}, 266, 274, 280, 289, 298, and 314_{sh} nm (ε 18900, 17900, 7200, 8200, 9300, 17100, 19600, 25600, 20400, 24000, and 4600); λ_{max} (CH_3CN) 219, 226, 230_{sh}, 265_{sh}, 280, 288, 296, 310_{sh}, and 330 nm (ε 18800, 16900, 14400, 13000, 24000, 24400, 28000, 13500, and 1820).

The following complexes were prepared in a similar manner:

DCP-Phenylacetic Acid Complex. Mp 76—77 °C, 75% yield. Found: C, 80.73; H, 5.18%. Calcd for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30%. λ_{max} (C_6H_{12}) 217_{sh}, 222_{sh}, 227_{sh}, 249_{sh}, 267, 274_{sh}, 281, 289, 298, 314_{sh} and 356 nm (ε 23500, 20500, 15200, 6700, 15000, 18000, 22200, 19800, 22400, 7400, and 880).

DCP-Diphenylacetic Acid Complex. Mp 89—90 °C, 50% yield. Found: C, 83.56; H, 5.37%. Calcd for $C_{29}H_{20}O_3$: C, 83.23; H, 5.30%. λ_{max} (C_6H_{12}) 216_{sh}, 222_{sh}, 237, 249_{sh}, 266, 274, 281, 289, 298, 314_{sh}, and 344 nm (ε 36000, 28000, 9200, 10200, 19700, 21500, 27800, 19600, 24000, 1040, and 460).

DCP-Trichloroacetic Acid Complex. Mp 83—83.5 °C, 72% yield. Found: C, 55.33; H, 3.14; Cl, 28.43%. Calcd for $C_{17}H_{11}Cl_3O_3$: C, 55.24; H, 3.00; Cl, 28.77%. λ_{max} (C_6H_{12}) 219, 222, 227_{sh}, 266, 274, 281, 289, 298, and 314_{sh} nm (ε 18600, 18200, 14600, 14500, 17800, 21200, 18800, 22000, and 770).

DCP-Cyanoacetic Acid Complex. Mp 86—86.5 °C, 48% yield. Found: C, 73.94; H, 4.58; N, 5.03%. Calcd for $C_{18}H_{13}NO_3$: C, 74.22; H, 4.50; N, 4.89%. λ_{max} (C_6H_{12}) 221, 228, 290, 301, 314_{sh}, and 352_{sh} nm (ε 11500, 10900, 14100, 8200, and 440). For the preparation of this complex, a cyclohexane–benzene (50: 1) solution was employed.

The IR and the NMR spectra of the complexes are given in Tables 1 and 2.

We are deeply grateful to Professor Ernst David Bergmann of the Hebrew Universtiy of Jerusalem for his encouragement and his interest.

Implication of Diazonium Cations as Intermediates in the Photorearrangement of Azoxybenzenes

Nigel James BUNCE
Department of Chemistry, University of Guelph, Guelph, Ontario, Canada
(Received March 28, 1973)

Photolysis of azoxybenzene and 2,2′-azoxytoluene in the presence of 2-naphthol gives, in addition to *o*-hydroxyazocompounds, 1-arylazo-2-naphthols, sometimes as the major products. This implies that cleavage into diazonium ions may sometimes be a major pathway in the irradiation of aromatic azoxycompounds. A mechanism is proposed to account for the formation of azonaphthols as well as the various side products that have previously been obtained from these reactions.

The photorearrangement of azoxybenzene (**1a**) to *o*-hydroxyazobenzene (**2a**) is an intramolecular process in which the azoxy oxygen migrates to a free *ortho* position in the more distant aromatic ring.[1] Tanikaga showed[2] that the reaction involves the singlet π,π^* state of **1a** because, when the triplet excited state is populated by photosensitisation, oxygen migration is suppressed and photoreduction occurs instead. Iwata and Emoto[3] observed minor products additional to **2a** on photolysis of **1a** in chloroform solution; photoreduction concurrent with rearrangement occurred even in the absence of a photosensitiser, and *p*-hydroxyazobenzene (**3a**) was also formed. The authors speculated that photodissociation of **1a** into azobenzene and an oxygen atom might account for these minor products.

Side products have also been observed in irradiations of 2,2′-azoxytoluene (**1b**). Lewis and Reiss[4] observed the azocompounds (**3b**) and **4** in addition to expected product (**2b**), when ethanol was used as the solvent. Recently we have obtained **2b**, **4**, and the bis-azocompound **5** in our laboratory on photolysis of **1b** in benzene.[5] Similar behaviour was also observed with 2,2′-dibenzylazoxybenzene.

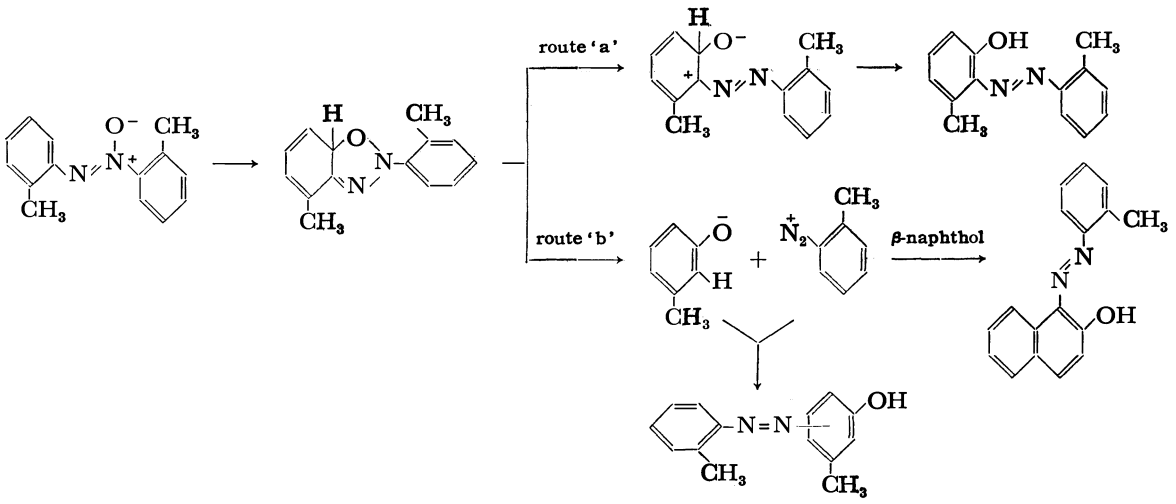
The abnormal products **3b** and **5** especially are reminiscent of the coupling products of a diazonium ion cation with an appropriate phenol; however, both we and Lewis and Reiss noted that **2b** is stable to the photolysis conditions and hence that the abnormal products do not arise as secondary products through the photochemical cleavage of **2b** into diazonium cations. By contrast, in this paper are reported observations which strongly implicate the participation of diazonium ion intermediates at some stage in the reaction. A modification of the widely accepted Badger and Buttery[6] rearrangement mechanism is proposed to account for the various side products that have been observed in the photolyses alluded to above.

Irradiation in ethanol of **1b** in the presence of 2-naphthol gave the usual rearrangement product **2b**, but the anomalous products **3**—**5** were suppressed. Instead there were obtained *m*-cresol and 1-*o*-tolylazo-2-naphthol (**6b**), the coupling product of an *o*-toluenediazonium cation with 2-naphthol. Photolysis of **2b** in the presence of 2-naphthol gave none of this compound. Observation of *m*-cresol and **6b** thus suggests that fragmentation of some intermediate is occurring, with one of the fragments being the *o*-toluenediazonium cation. The photostability of **2b** implies that such diazonium ions are formed not from **2b** but from one of its precursors. Tentatively, the accompanying reaction scheme is proposed to account for those observations. The Badger and Buttery cyclic intermediate **7** may either cleave the N–O bond to yield eventually **2b** as Badger and Buttery proposed; alternatively, the *o*-toluenediazonium ion may be expelled with the formation of a phenoxide anion. The diazonium ion reacts with the *m*-cresol or its anion, giving **3b** and **4**, or couples with preformed **2b**, when the bis-azocompound **5** results. In the presence of 2-naphthol the side products are suppressed because the diazonium ion is trapped by 2-naphthol.

An attractive feature of this proposal is that the ejection of the diazonium ion from **7** will be facilitated by the bulky alkyl group already in the 6-position of the intermediate. This is consistent with the fact that abnormal rearrangement products have only been observed during photolyses of 2,2′-disubstituted azoxybenzenes. It was thus anticipated that azoxybenzene **1a** itself, being sterically unencumbered, would afford



only small quantities of products arising from diazonium ion precursors. From an irradiation in ethanol, this was indeed the case, but unexpectedly, irradiation of **1a** and 2-naphthol in benzene gave 1-phenylazo-2-naphthol (**6a**) as the major product (60% based on reacted **1a**) together with 22% of **2a**. If formation of (**6a**) may be considered diagnostic of a diazonium ion precursor, it follows that, in this system at least, most azoxybenzene molecules photolyse by cleavage to a trappable diazonium cation. This implies that in the absence of 2-naphthol, even the normal product **2a** may arise, at least in part, by recombination of a geminate pair of diazonium cation and phenoxide ion (or phenol). Clearly the diazonium cation and the phenoxide anion never become free of each other, else *p*-hydroxyazobenzene would be a major product, since diazonium couplings invariably take place at an available *para* position.[7] The above implication opens up the question of whether aromatic azoxycompounnds in general photorearrange by the Badger and Buttery pathway (route 'a') or whether cleavage into diazonium ions (route 'b') can be a major, or even the exclusive, route to *o*-hydroxyazocompounds. Further work is in progress to test this possibility and to try to determine the cause of the marked change in product distribution observed when the solvent is changed from ethanol to benzene. Thus, photolysis of **1b** with 2-naphthol in benzene led to an increase in the proportion of the azonaphthol **6b** in the product mixture, analogous with the observations with **1a**.

An additional, minor product of the reaction of **1a** with 2-naphthol in benzene was an isomer of **6a** according to mass spectrometry, although insufficient material was obtained for complete identification. The isomer appears to be much too stable thermally to be the *cis* isomer of **6a**, aside from which, previous attempts to prepare *cis*-*o*-hydroxyazocompounds have been without success.[8] The new compound was not produced by photolysis of **6a** either alone or in the presence of either **1a** or 2-naphthol. It was felt that this could be a constitutional isomer of **6a** formed by a photochemical coupling reaction between a benzenediazonium cation and 2-naphthol. However, photolysis of sodium phenylazosulphonate (which gives diazonium ions on irradiation[9]) in the presence of 2-naphthol gave **6a**, but none of the other isomer, whose origin is therefore still a mystery.

The *p*-hydroxyazobenzene obtained by Iwata and Emoto may now be accounted for as the product of reaction of a separated diazonium ion with phenol. Their isolation of azobenzene however most likely involves a quite different mechanism, since Tanikaga[2] showed that, while **2a** derives from singlet excited **1a**, azobenzene is a triplet state product. Heavy atom solvents are well known to promote intersystem crossing, so it is likely that in chloroform solution intersystem crossing would occur more readily than in ethanol, and the resultant population of the triplet state of **1a** would allow a small amount of photoreduction to occur. On the scale of his experiments, Tanikaga did not observe any photoreduction in heavy atom solvents; perhaps the quantum yield for photoreduction is low.

TABLE 1. PHOTOREARRANGEMENT OF **1a** TO **2a** IN ETHANOLIC MIXTURES

Added solvent	**2a**, mg.	Recovered **1a**, mg	**2a**/**1a**
None	186	223	0.83
$CH_3CH_2CH_2Cl$	117	248	0.47
$CHCl_3$	112	252	0.44
$CH_3CH_2CH_2Br$	88	287	0.31
CCl_3Br	58[a]	252	0.23
CH_3CH_2I	78	296	0.26

a) Brominated *o*-hydroxyazobenzenes (61 mg) were formed in addition.

In support of a heavy atom effect, the photorearrangement of **1a** in ethanol has been found to be retarded considerably when halogenated compounds are added to the solvent (see Table 1) and the heavier the halogen concerned, the slower the reaction. On the scale of these experiments, azobenzene was again not formed in isolable quantities; nevertheless, the results are consistent with the idea of a heavy atom effect promoting intersystem crossing, with the consequent removal of some of the singlet excited **1a** molecules, making them unavailable for photorearrangement. In one solvent, ethanol/bromotrichloromethane, brominated *o*-hydroxy-

Table 2. Physical properties of brominated *o*-hydroxyazobenzenes

Compound	Mp	UV data: Conc. mg/100 ml	UV data: λ_{max} nm(A) in ethanol	UV data: λ_{max} nm(A) in ethanol/0.1 M KOH
Monobromide (photoreaction)	117—120°	0.9	376(0.43), 320(0.97)	462(0.44)

azobenzenes were formed additionally; these probably arise through photolysis of bromotrichloromethane to molecular bromine,[10] which brominates the **2a** already produced. Indeed, independent bromination of **2a** gave the same mixture of mono- and di-bromohydroxyazobenzenes, but isolation of pure compounds from these mixtures was difficult because of problems of separation (see Experimental section).

Experimental

Separation and analytical procedures have been described in detail previously.[5]

Irradiation of ***1b*** *with 2-Naphthol.* i) A solution of **1b** (0.650 g) and 2-naphthol (2.0 g) in ethanol (30 ml) was irradiated with an external source for 17 hr. After evaporation of the solvent, the residue was taken up in chloroform and extracted with 3 M sodium hydroxide solution. The organic phase was dried, evaporated, and separated by preparative tlc on silica gel (E. Merck No. 7747) (benzene: ligroin, 1:4) to give three bands, each of which was shown after extraction to be pure (tlc). Band 1 (129 mg) was **2b**, red needles from ethanol, mp 92—94 °C (lit,[5] 96 °C). Band 2 (81 mg) was an oil, which crystallised from ethanol, mp 50—52 °C, and was starting material. Band 3 (226 mg), red leaflets from ethanol, had mp 126—128 °C. Its mass spectrum, m^+/e 262 (M+ 74%), 245 (11), 234 (17), 171 (17), 144 (14), 143 (100), 128 (10), 115 (61), 107 (12), 106 (22), 91 (68), and mp were identical with those of an authentic sample of 1-(*o*-tolylazo-)-2-naphthol, **6b**, (lit, mp[11] 131 °C), obtained by coupling *o*-toluenediazonium chloride with 2-naphthol.

The sodium hydroxide extract of the crude photolysis mixture was acidified and extracted into chloroform, dried and evaporated. Vapour phase chromatography of the extract (10% SE30 on 30/80 Celite, 100°) showed a peak of retention time identical to that of *m*-cresol. The residue was distilled from a bulb using an oilbath at 260 °C to give *m*-cresol (99 mg) having IR spectrum identical to that of an authentic sample.

ii) A solution of **1b** (0.650 g) and 2-naphthol (2.0 g) in benzene (20 ml) was irradiated with an external source for 21 hr. After removal of most of the 2-naphthol by base extraction, the organic material was separated by preparative tlc as described above. The bands obtained were, in increasing order of polarity, **2b** (16 mg), recovered **1b** (0.26 g) and **6b** (133 mg), mp 128—129 °C. UV spectra of each of these compounds were identical with those of authentic samples.

Photolysis of **2b**. A solution of **2b** (26 mg) in benzene (2.0 ml) was irradiated for 6 hr in a 5 ml Pyrex flask equipped with reflux condenser, using an external source. Analytical tlc showed only one spot in the reaction mixture, and passage of the reaction mixture through a short column of silica gel, eluting with benzene, allowed recovery of **2b** (22 mg), mp 94—96 °C. Similar results were obtained in a 6 hr irradiation of **2b** (45 mg) in the presence of 2-naphthol (199 mg).

Irradiation of ***1a*** *with 2-Naphthol.* (i) A solution of **1a** (0.45 g) and 2-naphthol (2.0 g) in 95% ethanol (40 ml) was irradiated in a corked Pyrex test tube for 90 hr using an external source. After extraction with 0.5 M NaOH solution to remove most of the 2-naphthol, the residue was resolved by preparative tlc (benzene: ligroin, 1:9) affording **2a** (110 mg), mp 80—81 °C, recovered **1a** (322 mg), and **6a** (0.6 mg), estimated from its UV spectrum which was identical with that of an authentic sample (see below).

(ii) A solution of **1a** (0.40 g) and 2-naphthol (1.00 g) in dry benzene (20 ml) was irradiated for 12 hr in a stoppered Pyrex ampoule using a Hanovia 450 W medium pressure mercury arc. Analytical tlc on silica gel (benzene: ligroin, 1:4) showed three compounds besides starting materials. After removal of most of the 2-naphthol by extraction with 0.5 M NaOH, the organic residue was resolved by preparative tlc on silica gel.

The most mobile band was **2a** (43 mg), red needles from ethanol, mp 78—80 °C. Band 2 (213 mg) was recovered **1a**. Band 3 (19 mg) separated incompletely from band 2; fractional crystallisation from ethanol gave dark red needles (3 mg), mp 130—132 °C, softened at 117 °C. Mass spectrum (70 eV): m^+/e 248 (M+, 100%), 171 (18), 143 (90), 115 (52), 77 (42); UV (EtOH): λ_{max} 487 nm (log ε 4.6), 352 (4.5), 288 (4.6). The least mobile material on the tlc plate was **6a** (153 mg), mp 130—131 °C (lit,[6] 133 °C). Mass spectrum: m^+/e 248 (M+, 100%), 171 (25), 143 (98), 115 (72), 77 (49); UV (EtOH): λ_{max} 475 nm. (log ε 4.17), 413 sh (4.00), 309 (3.85), 258 sh (3.99), 251 (4.02) very similar to that reported.[6]

Despite the similarity of physical properties of bands 3 and 4, they were shown to be different as follows. Band 3 was a red spot (R_f 0.25) on analytical tlc whereas band 4 gave an orange spot (R_f 0.15). Band 3 was not converted to band 4 either by fusion at 150 °C or by heating in chlorobenzene to 160 °C for 21 hr. Likewise band 4 could not be converted to band 3 by photolysis either alone in benzene solutions of varying concentration, or by photolyses in benzene solution in the presence of either **1a** or 2-naphthol. In each case **6a** was recovered unchanged.

Irradiation of Sodium Phenylazosulphonate with 2-Naphthol. A solution of sodium phenylazosulphonate[9] (2.0 g) and 2-naphthol (1.0 g) in 100 ml ethanol and 225 ml water was irradiated in an immersion well apparatus with an unfiltered mercury arc for 1 hr by which time a suspension of a red substance was present. Extraction into chloroform gave a solution containing **6a**, unreacted 2-naphthol, and a tarry

residue, but no other products, according to tlc on silica gel (benzene: ligroin, 1: 9). Passage through a short column of alumina eluting with benzene: chloroform, 4: 1 gave **6a** (0.43 g), which crystallised as red needles from ethanol, mp 131—132 °C.

Irradiation of ***1a*** *in Mixtures of Ethanol and Halogenated Solvents.* Solutions of **1a** (0.40 g) in equal volumes of ethanol and the halogenated solvent (total volume 40 ml) were irradiated simultaneously for 100 hr using a Rayonet "Merry-go-round". The solvent was evaporated and each residue was separated by preparative tlc (benzene: ligroin, 1: 9), giving the quantities of **1a** and **2a** recorded in Table 1. When ethanol/bromotrichloromethane was the solvent the *o*-hydroxyazobenzene was obtained contaminated with other products. These could not be resolved on silica gel or by fractional crystallisation; partial separation was achieved by preparative tlc on alumina (J. T. Baker, Type 9F; developing solvent benzene, or benzene: ether, 9: 1), followed by repeated crystallisation from ethanol.

Physical characteristics of the purest samples obtained from both the photoreaction and from the bromination of **2a** in CCl_4 are given in Table 2. The identities of the products were established by mass spectrometry, but since the mass spectra of the monobromide always showed small amounts of the dibromide and *vice versa*, the raw UV absorbance data are recorded rather than the molar extinction coefficients. It seems most likely that the monobromide is 5-bromo-2-hydroxyazobenzene since its mp, mass spectrum, and UV correspond closely to those of authentic material, prepared in low yield by coupling benzenediazonium chloride with *p*-bromophenol. Also given for comparison are the physical properties of a second dibromohydroxyazobenzene, which crystallises from solution when **2a** is treated with a large excess of bromine.

The author thanks the National Research Council of Canada for generous financial support.

A Reinvestigation of the Normal Vibrations of Thioacetamide

Arabinda RAY and D. N. SATHYANARAYANA

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore, 560012 India

(Received January 30, 1973)

The normal coordinate treatments of thioacetamide and its seven isotopic molecules have been carried out using Urey-Bradley force constants refined by a least-squares procedure. The laser Raman spectrum of thioacetamide has also been recorded.

A satisfactory assignment of the infrared frequencies of thioacetamide (TAM) and its *N*-deuterated molecule was made by Suzuki[1] with the aid of a normal coordinate analysis using Urey-Bradley force field. Walter and Kubersky[2] reinvestigated the infrared spectra of TAM and its several isotopic molecules. They appear to doubt the applicability of the results of the normal coordinate treatment (of Suzuki) to the isotopic molecules of TAM and have proposed considerable revision of the assignments of the infrared spectrum of TAM. It is of particular interest that the C=S stretching frequency was assigned around 975 cm^{-1}, as was done by some earlier workers[3,4] instead of a band near 720 cm^{-1} as favoured by the normal coordinate treatment.[1] It was therefore considered worthwhile to reinvestigate the infrared spectral assignments of this simplest thioamide, the results of which could be of considerable interest for other molecules. We report here the results of the normal coordinate treatments of TAM and its seven isotopic molecules—CH_3CSND_2, CD_3CSNH_2, CD_3CSND_2, $CH_3CS^{15}NH_2$, $^{13}CH_3CSNH_2$, $^{13}CH_3CSND_2$, and $CH_3{}^{13}CSNH_2$. The laser Raman spectrum of TAM has also been recorded.

Experimental

Infrared Spectra: We recorded the infrared spectra of thioacetamide (E. Merck) and its *N*-deuterated molecule in the range 4000—250 cm^{-1}. The frequency data agree with those of Walter and Kubersky[2] within 2—3 cm^{-1}. In order to utilize the infrared data of other isotopes and for uniformity, the data from the latter were only employed in the calculations.

Raman Spectrum: The Raman spectrum of powdered TAM sealed in a capillary tube was taken on a Cary 81 Raman spectrophotometer using argon laser. The spectrum was kindly recorded for us by Dr. J. R. Scherer of the U. S. Department of Agriculture, Albany, California, to whom we are grateful for this help. The Raman bands are included in Table 2.

Normal Coordinate Treatment

The structural parameters and the internal symmetry coordinates were the same as those employed by Suzuki.[1] The NH and CH stretching modes, however, were retained in the calculations. The initial force constants were taken from Suzuki. Twelve of these force constants were refined by a least-squares technique[5] from 14 frequencies by keeping all stretching constants and three bending constants around the thioamide carbon fixed. The final force constants are given in Table 1. They are comparable to the initial set except for $F_{HNH}(=-0.33$ mdyn/Å). We have preferred keeping the force constants within the framework of Urey-Bradley field to the alternate method of keeping F_{HNH} as zero, and introducing a non Urey-Bradley term between two NH bonds, as was done in the case of acetamide and other molecules.[6-8] If the force constant F_{HNH} is kept zero, the NH_2 stretching frequencies deviate largely and the force filed does not converge satisfactorily. The frequencies of the isotopic molecules were calculated employing the refined force constants. All the numerical calculations were made on an IBM 360/44 computer.

Results and Discussion

The observed and calculated frequencies for TAM are given in Table 2, and for *N*- and *C*-deuterated TAM in Table 3, where the assignments obtained from the potential energy distribution (PED) are also shown. The agreement between the observed and calculated frequencies for TAM is excellent and that for isotopes of TAM listed in Tables 3 and 4 is fairly good. The calculated ND stretching frequencies deviate somewhat in the deuterated molecules. This may be attributed to the effects of hydrogen bonding.

The assignments given in Table 2 are practically the same as Suzuki's, and will therefore not be discussed. The satisfactory reproduction of the frequency shifts for several isotopic molecules of TAM (Tables 3 and 4) reflects the validity of the Urey-Bradley force constants and also the assignmtens derived therefrom. The revision of Suzuki's infrared assignments for TAM by Walter and Kubersky[2] therefore finds no support from isotopic molecules. When extensive coupling of the vibrations are involved, correlation by inspection of the frequency variations in the isotopic molecules with the assignments may be difficult as in the case of *N,N*-dimethylformamide.[9]

The C=S stretching mode has been attributed by Suzuki to a band at 720 cm^{-1} which has a mjaor contribution (approx. 60%) from the mode. This

A″ vibrations are tentatively assigned (*cf.* Table 3) a) From Ref. 2. b) From present investigation. n.i. denotes not investigated.

assignment is supported by the large red shift of the band, by 30—60 cm^{-1}, in metal complexes, where the thiocarbonyl sulfur is the donor[10,11] and the shift of the band to 675 cm^{-1} on *S*-methylation.[12] A comparison of the infrared spectrum of TAM with that of selenoacetamide ("Selenation") has also confirmed this assignment.[12] Thus the attribution of C=S stretching vibration to ~975 cm^{-1} frequency by Walter and Kubersky and others is not supported.[2-4,13] This band has, however, about ~10% C=S stretching mode and shows minor changes on complex formation, *S*-methylation and selenation.[10-12]

The C=S stretching vibration generally occurs as a split band in isotopic molecules. It appears at considerably lower wave numbers in deuterated molecules (Tables 3 and 4) depending on the nature of vibrational coupling.

Out-of-plane Vibrations. A tentative assignment for the seven A″ vibrations of TAM is given in Table 2.

The CH_3 out-of-plane rocking mode generally occurs at a higher frequency than CH_3 in-plane rocking and is of weaker intensity in amides. Accordingly, a weak broad band near 1130 cm^{-1} is attributed to CH_3 out-of-plane rocking in TAM, the band being slightly intensified in metal complexes.[10,11] Identification of CH_3 torsional mode is difficult since lattice modes

interfere in this region. A band at 162 cm^{-1} in Raman may be favoured to methyl torsion in comparison with that at 155 cm^{-1} in acetamide.[14]

Both the wagging and torsional vibrations of the NH_2 group in TAM were assigned[1] earlier to a fairly sharp band at 709 cm^{-1}. In the Raman spectrum also the corresponding band is sharp. Careful observation of the infrared spectrum of TAM shows a weak shoulder at 760 cm^{-1} to the main absorption at 720 cm^{-1}. In metal complexes of TAM, the 760 cm^{-1} band acquires intensity and is sometimes observed as a farily strong band as in the case of copper(I) and palladium(II) chloride complexes.[10,11] We favour therefore the weak band at 760 cm^{-1} in TAM to NH_2 torsion in comparison with that at 810 cm^{-1} (weak) in acetamide.[14] The intense band at 709 cm^{-1} is attributed to NH_2 wagging mode in agreement with the earlier assignment.[1] This is compatible with the NH_2 wagging in acetamide assigned[14] to a strong band at 700 cm^{-1}.

The remaining three A″ vibrations of TAM are easily assigned as indicated in Table 2. In the deuterated molecules CD_3 out-of-plane rocking is expected near *ca.* 1000 cm^{-1}, and the torsional and wagging modes of ND_2, respectively, around δ 550 and 500 cm^{-1}. It is satisfying to note that bands are observed in this region in deuterated molecules (Tables 3 and 4). For a more definite assignment of the A″ vibrations, a normal coordinate analysis would be helpful.

The authors wish to thank Prof. W. Walter for a copy of his paper, and Prof. C. C. Patel for helfpul discussions.

The Magnetic Circular Dichroism of Some Copper(II) β-Diketone Chelate Complexes in Various Media

Hajime KATÔ and Takahide KIMURA

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received May 15, 1973)

The magnetic circular dichroism (MCD) and absorption spectra of $Cu(acac)_2$, $Cu(bzac)_2$, $Cu(acest)_2$, $Cu(TFacac)_2$, and $Cu(HFacac)_2$ in benzene, chloroform, methylene chloride, 1,4-dioxane, pyridine, and piperidine are observed. The behavior of these spectra can be well explained by proposing this order of energy levels: d_{xz}, $d_{yz} < d_{x^2-y^2} < d_{z^2} < d_{xy}$. The MCD spectra in pyridine do not show any dispersion in the neighbourhood of the absorption peak which seems to correspond to the d_{xz}, $d_{yz} \rightarrow d_{xy}$ transition; this fact suggests that the B-term of the MCD parameters is dominant at room temperature. There is no serious difference between the MCD of $Cu(acac)_2$ and $Cu(bzac)_2$, or between $Cu(HFacac)_2$ and $Cu(TFacac)_2$. It appears that this lowering of symmetry is not important in interpreting the MCD spectra.

The magnetic circular dichroism (MCD) spectra of several Cu(II) complexes have been studied, and the B-term of the MCD parameters has been found to be dominant in the MCD of the Cu(II) complexes at room temperature.[1] The MCD spectrum of bis(acetylacetonato)copper(II), $Cu(acac)_2$, dissolved in chloroform was also studied.[2] The absorption spectra of $Cu(acac)_2$ in various media have been reported, and the positions and intensities have been shown to depend primarily upon the solvent basicity.[3] Therefore, MCD studies of the solvent effects are expected to yield a great deal of information about the assignments of the transitions and the properties of the MCD spectra. Furthermore, we have thought it worth while to investigate the MCD spectra for several substituted β-diketone complexes of copper(II). From this investigation, we expect to ascertain the effect of the lowering of symmetry around copper(II) upon the MCD and to ascertain the effect of various electron-withdrawing abilities of substituted acetylacetonates upon the MCD.

Experimental

Five copper(II) β-diketone chelate complexes, *i.e.*, bis(acetylacetonato)copper(II), bis(benzoylacetonato)copper(II), bis(ethylacetoacetato)copper(II), bis(trifluoroacetylacetonato)copper(II), and bis(hexafluoroacetylacetonato)copper(II) (abbreviated as $Cu(acac)_2$, $Cu(bzac)_2$, $Cu(acest)_2$, $Cu(TFacac)_2$, and $Cu(HFacac)_2$) were prepared and purified according to the methods described in the literature.[4-7] The absorption and MCD spectra of these compounds in the benzene, chloroform, methylene chloride, 1,4-dioxane, pyridine, and piperidine series of solvents were measured by the techniques described in an earlier paper.[1]

Results and Discussion

Figure 1 gives the MCD and absorption spectra of $Cu(acac)_2$ in the chloroform, methylene chloride, 1,4-dioxane, pyridine, and piperidine series of solvents. The MCD datum of $Cu(acac)_2$ in benzene was not available because of its poor solubility. Belford and his co-workers[3] have studied the absorption spectra, in the visible and near infrared region, of $Cu(acac)_2$ and bis(3-ethylacetylacetonato)copper(II) in various

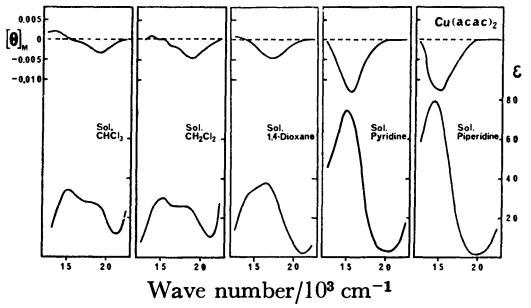

Fig. 1. The MCD (upper) and absorption (lower) spectra of $Cu(acac)_2$ dissolved in various solvents at room temperature.

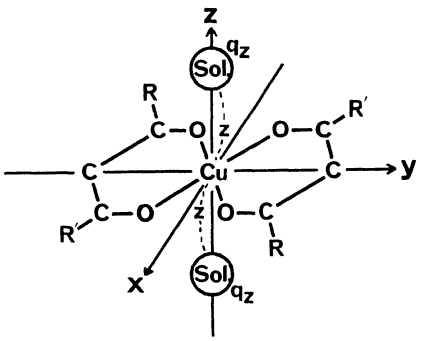

Fig. 2. The coordinate system and geometrical model for the calculation of solvent effects.

media. The behavior of these absorption bands upon the alternation of the solvent have been quite successfully explained in terms of the crystal field theory. Let us adopt the same model. The effect of the solvent is considered as two axial ligands (two charges, q_z, at (0, 0, z) and (0, 0, −z), as is shown in Fig. 2) are added to a square planar complex. $Cu(acac)_2$ molecule in a noninteracting solvent, chloroform, may be considered as an isolated square-planar complex. If we assign the bands at 18810 and 15190 cm^{-1} observed for $Cu(acac)_2$ in chloroform to the d_{yz}, $d_{yz} \rightarrow d_{yz}$ and $d_{x^2-y^2} \rightarrow d_{xy}$ transitions respectively,[3] the transition energies in the presence of an interacting solvent are given by:

$$\delta E_1(|xz\rangle, |yz\rangle \rightarrow |xy\rangle) = 18810 + (-9\langle r^2\rangle/z^2 + 5\langle r^4\rangle/z^4)2q_z e^2/21z,$$
$$\delta E_2(|x^2-y^2\rangle \rightarrow |xy\rangle) = 15190,$$
$$\delta E_3(|z^2\rangle \rightarrow |xy\rangle) = 14950 + (-12\langle r^2\rangle/z^2 - 5\langle r^4\rangle/z^4)2q_z e^2/21z \quad (1)$$

in units of cm^{-1}. The values of $\langle r^2\rangle$ and $\langle r^4\rangle$ are evaluated by using the analytical SCF function for Cu obtained by Clementi:[8] $\langle r^2\rangle_{Cu}=1.106\ a_0^2$, $\langle r^4\rangle_{Cu}=3.301\ a_0^4$. If we assume the distance, z, between the metal and the solvent charge, q_z, to be 2 A, then the excitation energies given by Eq. (1) are reduced to functions of q_z only. The results are shwon schematically in Fig. 3. $\delta E_2(|^2x-y^2\rangle \rightarrow |xy\rangle)$ displays little variation from solvent to solvent. $\delta E_1(|xz\rangle, |yz\rangle \rightarrow |xy\rangle)$ approaches $\delta E_2(|x^2-y^2\rangle \rightarrow |xy\rangle)$ as the solvent basicity is increased. The variation in the absorption bands upon the alternation of the solvent can be well explained by assuming the q_z values to be about 0.0, 0.1, 0.3, 0.7, and 0.9 for the spectra of $Cu(acac)_2$ in chloroform, methylene chloride, 1,4-dioxane, pyridine, and piperidine respectively. These values seem to be of a plausible order of magnitude.

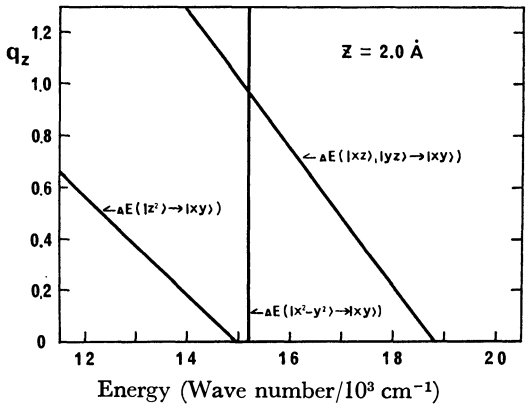

Fig. 3. Excitation energy diagram as a function of solvent charges q_z, which are assumed to be located axially to a square-planar complex at (0, 0, 2A) and (0, 0, −2A).

The interpretation of the polarized visible absorption spectrum of $Cu(acac)_2$ has been the subject of speculation and controversy as attempts have been made to remove the ambiguity of the assignment.[9-12] Unfortunately, however, the type of packing of molecules in the crystal was inadequate for the attempt.[13] Hitchman and Belford[13] studied the temperature-dependent polarized spectra of $Cu(bzac)_2$; they assigned the band at 18.1 kK to d_{xz}, $d_{yz} \rightarrow d_{xy}$, the band at 15.6 kK to $d_{x^2-y^2} \rightarrow d_{xy}$ and the band at 14.2 kK to $d_{z^2} \rightarrow d_{xy}$ on the basis of the temperature dependence and the relative polarization. This ordering of the d levels is the same as that suggested for bis(3-phenyl acethylacetonato)copper.[14] The positions of the d-d bands in $Cu(bzac)_2$ at 14.2, 15.6, and 18.1 kK, are very similar to those of the bands in $Cu(acac)_2$, at 14.5, 16.3, and 18.0 kK;[13] this suggests the same ordering of the d levels. Katô and Gohda[2] proposed the same order of energy levels (d_{xz}, $d_{yz} < d_{x^2-y^2} < d_{z^2} < d_{xy}$) for $Cu(acac)_2$ in chloroform on the basis of the MCD analysis.

The variation in the absorption bands upon the alternation of the solvent can be well explained by proposing this order of energy levels, as we have seen above. On the other hand, if we assign the bands at 18810 and 15190 cm^{-1} observed for $Cu(acac)_2$ in chloroform to the $d_{x^2-y^2} \rightarrow d_{xy}$ and d_{xz}, $d_{yz} \rightarrow d_{xy}$ transitions respectively, we can not explain the observed red shift of the bands as the basicity of the solvent increases. The energy for the $d_{x^2-y^2} \rightarrow d_{xy}$ transition should undergo little change from the variation in the basicity of solvent which coordinates axially to a square-planar complex. This property is due to the geometrical structure of the d_{xy} and $d_{x^2-y^2}$ orbitals and does not depend greatly on the model of the calculation.

The MCD spectra of $Cu(acac)_2$ display a remarkable change on going to a more basic solvent. This change can be explained on the basis of the above discussion about the transition energies and the previous analysis about the MCD of the Cu(II) complexes.[1] The d_{xz}, $d_{yz} \rightarrow d_{xy}$ transition, which shows an MCD with a positive B-term, approaches the $d_{x^2-y^2} \rightarrow d_{xy}$ transition band, which shows an MCD with a small positive B-term, as the solvent basicity is increased. The $d_{z^2} \rightarrow d_{xy}$ transition, which shows an MCD with a negative B-term, shifts to the lower frequency region, in which we can not measure the MCD spectra because of our instrumental restriction. Therefore, $Cu(acac)_2$ values in pyridine and piperidine display only a negative MCD in the region of 12.5—20.0 kK.

The MCD spectra of $Cu(acac)_2$ in 1,4-dioxane and pyridine do not show any dispersion in the neighbourhood of the absorption peak which seems to correspond to the d_{xz}, $d_{yz} \rightarrow d_{xy}$ transition. This fact strongly suggests that the B-term of the MCD parameters is dominant in the MCD of $Cu(acac)_2$ at room temperature. This conclusion is consistent with the theoretical prediction previously proposed by one of the present authors.[1]

The MCD and absorption spectra of $Cu(bzac)_2$, $Cu(acest)_2$, $Cu(TFacac)_2$, and $Cu(HFacac)_2$ in the benzene, chloroform, methylene chloride, 1,4-dioxane, pyridine, and piperidine series of solvents are shown in Figs. 4—7. In these spectra, the effect of changing the substituents is smaller than the effect of changing the solvent. However, the MCD and absorption spectra in the solvent with a weak basicity suggest a correla-

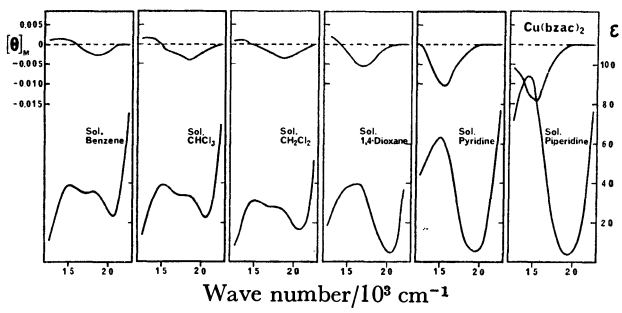

Fig. 4. The MCD and absorption spectra of $Cu(bzac)_2$ dissolved in various solvents at room temperature.

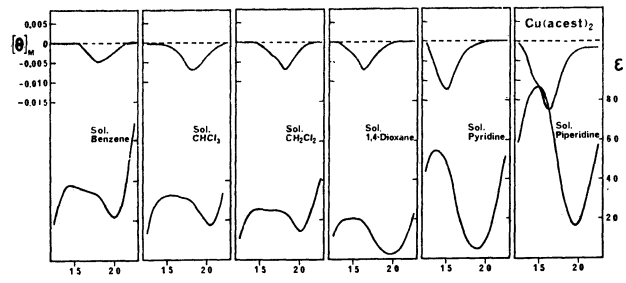

Fig. 5. The MCD and absorption spectra of Cu(acest)$_2$ dissolved in various solvents at room temperature.

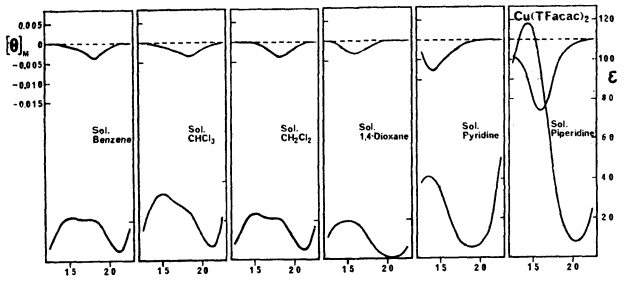

Fig. 6. The MCD and absorption spectra of Cu(TFacac)$_2$ dissolved in various solvents at room temperature.

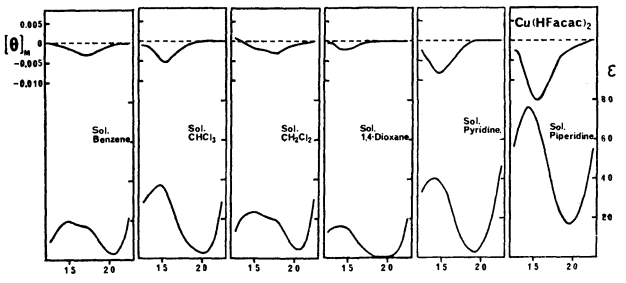

Fig. 7. The MCD and absorption spectra of Cu(HFacac)$_2$ dissolved in various solvents at room temperature.

tion between the relative electron-withdrawing ability of substituents and the energy levels of copper d electrons; the more electronegative the substituent, the smaller the energy separation. The order of electronegativity must be CF_3>OC_2H_5>Ph>H>CH_3. The MCD of the positive B-term of the d_{xz}, d_{yz}→d_{xy} transition would overcome the MCD of the negative B-term of the d_{z^2}→d_{xy} transition in Cu(acest)$_2$, Cu(TFacac)$_2$, and Cu(HFacac)$_2$.

Of course, the coordinating form and the steric effect of the solvent in each case is important. Kuska and Rogers[15] have reported that increasing the basicity of the solvent has the same effect on the d electron energy levels and on the unpaired electron density of copper as increasing the electronegativity of the substituents. To be sure, there are also similarities in the ESR parameters for Cu(HFacac)$_2$ in a chloroform solution and for Cu(acac)$_2$ in a pyridine solution, and the same similarity in the absorption and MCD spectra. However, the spectrum of Cu(HFacac)$_2$ in chloroform is rather a special case; the spectrum of Cu(HFacac)$_2$ in solvents of a weak basicity, benzene or methylene chloride, is similar to that of Cu(acac)$_2$ in chloroform. Chloroform would be an interacting solvent for Cu(HFacac)$_2$.

The symmetry of Cu(bzac)$_2$ or Cu(TFacac)$_2$ is lower than that of Cu(acac)$_2$ or Cu(HFacac)$_2$, but there is no serious difference between the MCD spectra of Cu(acac)$_2$ and Cu(bzac)$_2$ or between those of Cu(HFacac)$_2$ and Cu(TFacac)$_2$. It appears that this lowering of the symmetry is not important in interpreting the MCD spectra.

Hole-particle Formalism for the Electronic Spectra of Long Chain Polyenes

Sadhan BASU

Department of Chemistry, University College of Science, Calcutta-9, India

(Received June 15, 1973)

From the hole-particle description of the many-Fermion system of long chain polyenes it has been shown that the convergence limit in the electronic spectra may be accounted for by the electron-hole pairing interaction.

It is well-known that the wavelength of the lowest N–V transition of polyenes does not grow proportionately with the number n of the conjugated double bonds as is true for symmetrical cyanines, but tends to a limit as n becomes large.[1] Kuhn[2] related this behavior to the unequal length of single and double bonds, which generates a perturbing potential with a period of the bond length and thus introduces a Brillouin gap between the highest occupied and the lowest unoccupied level. Dewar[3] accounts for this phenomenon by assuming different exchange integrals for single and double bonds. On the other hand, simple free electron theory as well as molecular orbital theory predict a rapid equalization of bond lengths with increasing n and therefore invalidates the above reasoning. Further it has been found that mono- and dinegative ions of diphenyl polyenes show bond alternation,[5] although dinegative ions show convergence and mono-negative ions do not. Unequal bonds do not appear to lead to convergence. Araki[4] tried to correlate the convergence limit with the plasma oscillation in many-electron system, but it fails to explain different behavior of cyanines and polyenes.

In the usual treatment of many-Fermion problem each particle is supposed to move independently, the effect of the interaction between particles being simply replaced by an average field of force. This treatment does not take interparticle correlation into account. A step towards the improvement of the method so as to include correlation was taken by Euler,[6] who calculated the effect of interparticle interaction, which causes the correlation, by perturbation theory assuming the interaction to be small. The calculation of such a type is carried out in the following manner. In the zeroth approximation each particle is in some one-particle quantum state, which we consider a "level". Let us consider the lowest state for the sake of definiteness. In this state all levels up to some highest, which we call the Fermi maximum (λ), are each filled by the particles. The perturbation energy due to the interparticle force, has non-vanishing matrix elements which cause virtual transitions to states in which particles are excited to levels higher than the Fermi maximum. The state which results from the interparticle force is thus a superposition of zero order state and various excited states. Such a mixture of excited states gives rise to correlation between particles.

Accepting the above model we may approach the problem of π-electronic spectra of long chain polyenes in a different way. In the single-particle level scheme of "electron in a box" the levels up to λ (Fermi level) are occupied and the levels above it are unoccupied. The state obtained by exciting a particle from an occupied level to an unoccupied level is called a state of one hole-one particle type, because in this process of excitation a vacancy (hole) is left in the occupied level and a "particle" is produced, instead, in one of the unoccupied level. If we use single-particle creation operator and destruction operator in the treatment of many-body-Hamiltonian, then we will be able to get the elementary excitation energy of a hole-particle pair or a quasiparticle.

The physics and mathematics of quasiparticles have been rigorously developed and applied with great success in nuclear physics[8,8e] and in the theory of superconductivity.[7] In what follows we use this formulation in a simplified and somewhat approximate form.

Quasiparticle Hamiltonian

The second quantized version of the many-body Hamiltonian is given as[9]

$$H = \sum_{\alpha,\beta}\langle\alpha|T|\beta\rangle C_\alpha^+ C_\beta + \frac{1}{2}\sum_{\alpha,\beta,\gamma,\delta}\langle\alpha\beta|v|\gamma\delta\rangle C_\alpha^+ C_\beta^+ C_\gamma C_\delta \cdots, \quad (1)$$

$$\left(v = \frac{1}{r_{ij}}\right)$$

where C_α^+ is the creation operator for the state α and C_β, the destruction operator for the state β. The ground state $|\psi_0\rangle$contains a set of occupied single particle states h, h^1, $\cdots$ and hence it is impossible to create another particle in an occupied state h. Therefore

$$C_h^+|\psi_0\rangle = 0$$

The state $|\psi_0\rangle$ does not contain any of the unoccupied single particle states p, p^1 $\cdots$ and hence it is impossible to destroy any such state in

$$C_p|\psi_0\rangle = 0$$

If we now define a new destruction operator for the single particle state by the following relation;

$$b_i = C_i^+ \text{ when } i = h,$$
$$= C_i \text{ when } i = p.$$

Then we have

$$b_i|\psi_0\rangle = 0 \text{ for all } i.$$

We interpret the state $|\psi_0\rangle$ as the vacuum state for the new object which we created by b_i^+, such that

$$b_i^+ = C_i \text{ where } i = h,$$
$$= C_i^+ \text{ where } i = p.$$

We call these new-objects quasiparticles and the $|\psi_0\rangle$ state plays the role of vacuum state for these objects.

We now replace the Hamiltonian (1) by its expectation value with respect to ground state $|\psi_0\rangle$ and get

$$\langle H\rangle = \sum_{\alpha,\beta}\langle\alpha|T|\beta\rangle\langle C_\alpha^+ C_\beta\rangle + \frac{1}{2}\sum_{\alpha,\beta,\gamma,\delta}\langle\alpha\beta|v|\gamma\delta\rangle \times\{\langle C_\alpha^+ C_\beta^+\rangle\langle C_\gamma C_\delta\rangle + \langle C_\alpha^+ C_\gamma\rangle\langle C_\beta^+ C_\delta\rangle - \langle C_\alpha^+ C_\delta\rangle\langle C_\beta^+ C_\gamma\rangle\} \quad (2)$$

where the exceptation values $\langle C_\alpha^+ C_\beta\rangle$ *etc.* are pure numbers and is defined as density functions

$$\langle\beta|\rho|\alpha\rangle = \langle\psi_0|C_\alpha^+ C_\beta|\psi_0\rangle \quad (3)$$

With this definition the last two terms combine to give us the self-consistent potential V, made up of both Coulomb and exchange terms. We then get

$$\langle H\rangle = \sum_{\alpha,\beta}\langle\alpha|T+\frac{1}{2}V|\beta\rangle\langle\beta|\rho|\alpha\rangle + \frac{1}{2}\sum_{\alpha,\beta,\gamma,\delta}\langle\alpha\beta|v|\gamma\delta\rangle\langle C_\alpha^+ C_\beta^+\rangle\langle C_\gamma C_\delta\rangle \quad (4)$$

We notice that the energy expression contains an extra-potential term than what is present in Hartree-Fock state, so these states are called Hartree-Fock-Bogolyubov (HFB) states.[8] Now following (3) we define $\langle C_\delta C_\gamma\rangle = K_{\delta\gamma}$ a density function and following anticommutation of destruction operators we have $\langle C_\gamma C_\delta\rangle = -K_{\delta\gamma}$. We therefore write the second term in (4) as

$$\frac{1}{4}\sum_{\alpha,\beta,\gamma,\delta}\langle\alpha\beta|v|\gamma\delta\rangle K^*_{\beta\alpha}(K_{\delta\gamma}-K_{\gamma\delta}) = \frac{1}{2}\sum_{\alpha,\beta}\Delta_{\alpha\beta}K^*_{\beta\alpha}, \quad (5)$$

where $\Delta_{\alpha\beta}$ may be defined as a pairing potential. So we get

$$\langle H\rangle = \sum_{\alpha,\beta}\{\langle\alpha|T+\frac{1}{2}V|\beta\rangle\langle\beta|\rho|\alpha\rangle+\frac{1}{2}\Delta_{\alpha\beta}K^*_{\beta\alpha}\} \quad (6)$$

Variation of Calculation of Quasiparticle Energy

We now try to determine the ground state energy by a variational calculation,[8] *i.e.*, we try to minimise $\langle\psi_0|H-\lambda N|\psi_0\rangle$ where λ is the Lagrangian multiplier and N is the operator for total number of particles

$$N = \sum_\alpha C_\alpha^+ C_\alpha. \quad (7)$$

We now follow a two-step minimising procedure on $H(\lambda)=H-\lambda N$. We first omit the second term in (6) and define a single-particle state as

$$|i\rangle = \sum X_\alpha^i|\alpha\rangle \text{ and } H|i\rangle = \varepsilon_i|i\rangle$$

then the variation parameters X_α^i which makes $\langle H(\lambda)\rangle$ a minimum satisfy

$$\sum_\beta\langle\alpha|T-\lambda\mathbf{1}+\frac{1}{2}V|\beta\rangle X_\beta^i = (\varepsilon_i-\lambda)X_\alpha^i. \quad (8)$$

That is at this stage we now have single particles with energies $(\varepsilon_i-\lambda)$. In the next step we write $H(\lambda)$ using $|i\rangle$ as the basis

$$\langle H(\lambda)\rangle = \sum_{i,j}\langle i|T-\lambda\mathbf{1}+\frac{1}{2}V|j\rangle\langle j|\rho|i\rangle + \frac{1}{2}\sum_{ij}\Delta_{ij}K^*_{ij}, \quad (9)$$

Now we make a transformation[8]

$$b_i^+ = u_i C_i^+ + v_i C_{-i}, \quad (10)$$

where the coefficients u_i and v_i are the variation parameters. One can create a particle in a state if it is empty and destroy a particle if it is occupied. Therefore u_i^2 and v_i^2 are the probabilities of getting the state i empty and occupied respectively. We therefore have

$$u_i^2 + v_i^2 = 1,\ u_i = u_{-i},\ v_i = -v_{-i}. \quad (11)$$

Similarly we get

$$b_i = u_i C_i + v_i C_{-i}^+. \quad (12)$$

Inverting these relations we get

$$C_{-i}^+ = u_i b_{-i}^+ + v_i b_i,$$
$$C_i = u_i b_i - v_i b_{-i}^+. \quad (13)$$

With this transformations we have

$$\langle j|\rho|i\rangle = \langle C_i^+ C_j\rangle = \langle\psi_0|(u_i b_i^+ - v_i b_{-i})(u_j b_j - v_j b_{-j}^+)|\psi_0\rangle = \langle\psi_0|b_i b_j^+|\psi_0\rangle v_i v_j = v_i^2\delta_{ij}, \quad (14)$$

$$K_{ij} = \langle\psi_0|(u_i b_i - v_i b_{-j}^+)(u_j b_j - v_j b_{-j}^+)|\psi_0\rangle = -\langle\psi_0|b_i b_j^+|\psi_0\rangle u_i v_j = u_i v_{-i}\delta_{i,-j}. \quad (15)$$

Now b_i's in (10) and (12) are the creation and destruction operators for quasiparticles in the HFB[8] formulation and they differ from relations given for HF state because in HFB formulation the particle number is not conserved. In simplifying these relations we have used the Fermion anticommutation relations of quasiparticle operators

$$\{b_i, b_j\} = \{b_i^+, b_j^+\} = 0,$$

and

$$\{b_i, b_j^+\} = \delta_{ij}.$$

With these transformation we get

$$\langle H(\lambda)\rangle = \sum_i\langle i|T-\lambda\mathbf{1}+\frac{1}{2}V|i\rangle v_i^2 + \frac{1}{2}\sum_i\Delta_{i,-i}u_i v_{-i}. \quad (16)$$

We now minimise (16) by requiring $\delta H(\lambda)/\delta v_i=0$, using $u_i^2=1-v_i^2$, $v_{-i}=-v_i$ and we get

$$(\varepsilon_i-\lambda)2v_{-i}u_i+\frac{1}{2}\Delta_{i,-i}(u_i^2-v_i^2) = 0. \quad (17)$$

Putting $\cos\theta_i=u_i$ and $\sin\theta_i=v_{-i}$ we have

$$(\varepsilon_i-\lambda)\sin 2\theta_i = \Delta\cos 2\theta_i,\ \Delta = -\Delta_{i,-i}/2,$$

$$\text{or } \tan 2\theta_i = \frac{\Delta}{\varepsilon_i-\lambda},$$

$$2u_i v_{-i} = \sin 2\theta_i = \frac{\Delta}{\sqrt{(\varepsilon_i-\lambda)^2+\Delta^2}}, \quad (18)$$

$$u_i^2 - v_i^2 = \cos 2\theta_i = \frac{\Delta}{\sqrt{(\varepsilon_i-\lambda)^2+\Delta^2}}. \quad (19)$$

We set E_i equal to

$$E_i = \sqrt{(\varepsilon_i-\lambda)^2+\Delta^2}. \quad (20)$$

Significance of E_i

While simplifying the Eq. (1) we have used the product of the creation and destruction operator in the contracted form which gives us information about

the ground state only. Terms containing the normal products of the operator will give us informations about the states in which there are one, two, three, four, *etc.* pairs of creation and destruction operators. If we pick up only terms in which there is only one pair of creation and destruction operator, then we have

$$H_1(\lambda) = \sum_j(\varepsilon_j-\lambda)C_j^+C_j + \frac{1}{2}\sum_j \Delta_{j,-j}C_j^+C_{-j}^+. \quad (21)$$

Expressing the creation operators in terms of quasiparticle operators and following the algebraic procedure outlined in the proceeding section we get

$$\begin{aligned} H_t(\lambda) &= \sum_j[(\varepsilon_j-\lambda)(u_j^2-v_j^2)+\Delta_{j,-j}u_jv_{-j}]b_j^+b_j \\ &= \sum_j[(\varepsilon_j-\lambda)\cos 2\theta_j+\Delta_{j,-j}\sin 2\theta_j]b_j^+b_j \\ &= \sum_j E_jb_j^+b_j. \end{aligned} \quad (22)$$

The new Hamiltonian is thus

$$H = \langle H_0(\lambda)\rangle + \sum_j E_jb_j^+b_j. \quad (23)$$

Let us now consider a state i with one quasiparticle, *i.e.*, the state $b_i^+|\psi_0\rangle$. The energy of the state is given as

$$\begin{aligned} &\langle\psi_0|b_i\{\langle H_0(\lambda)\rangle+\sum_j E_jb_j^+b_j\}b_i^+|\psi_0\rangle \\ &= \langle H_0(\lambda)\rangle\langle\psi_0|b_ib_i^+|\psi_0\rangle + \sum_j E_j\langle\psi_0|b_ib_j^+b_jb_i^+|\psi_0\rangle \\ &= \langle H_0(\lambda)\rangle + E_i. \end{aligned} \quad (24)$$

The energy of the state ψ_0 is $\langle H_0(\lambda)\rangle$ and the energy of the state with one quasiparticle is $\langle H_0(\lambda)\rangle+E_i$. Hence we conclude that E_i is the energy carried by one hole-particle pair, *i.e.* a quasiparticle and it is given as

$$E_i = \sqrt{(\varepsilon_i-\lambda)^2+\Delta^2}, \quad \Delta^2 = \left(\frac{\Delta_{i,-i}}{2}\right)^2. \quad (25)$$

Exactly same expression has been obtained by solving HFB equation by Green function technique.[11] This partially justifies our assumption that Δ's are constant in variation calculation.

Significance of λ

From the relation

$$v_i^2 = \frac{1}{2}\left[1-\frac{\varepsilon_i-\lambda}{E_i}\right] \quad (26)$$

it is evident that when ε_i is much greater than λ, $v_i^2=0$ while when it is much less than λ, $v_i^2=1$ assuming Δ to be small. In the usual description of π-electron system the levels upto Fermi-maximum are occupied while those above it are all empty. So the occupation probability above Fermi-maximum is zero and below it is one. This suggests that λ is to be associated with ε_F, the energy of the Fermi-maximum. Hence the quasiparticle energy is given.

$$E_i = \sqrt{(\varepsilon_i-\varepsilon_F)^2+\Delta^2} \quad (27)$$

Convergence Limit and Δ

Equation (27) shows that when ε_i becomes equal to ε_F, the hole-particle energy is Δ and not zero and the minimum value of all quasiparticles is Δ. If the long-wavelength transition in linear polyene is associated with the electron jump from the top-most filled orbital to the first empty orbital, then in the quasiparticle scheme the energy should go over to Δ as the energy difference $\varepsilon_i-\varepsilon_F$ goes to zero, *i.e.*, as the length of the chain goes to infinity.

A Chemist's View of Δ

From the relation (18) we have

$$2u_iv_{-i} = \frac{\Delta}{\sqrt{(\varepsilon_i-\varepsilon_F)^2+\Delta^2}}.$$

Now for HF state we have

$u_i=1$ for a particle state
$=0$ for a hole state,
$v_{-i}=1$ for a hole state
$=0$ for a particle state.

In HFB case u_i and v_i will deviate from these unique values and will be somewhere between zero and one. This means that even for HFB case should be positive. So Δ must be a positive quantity. Now Δ has been set equal to $-(\Delta_{i,-i})/2$, which means that $\Delta_{i,-i}$ must be negative. $\Delta_{i,-i}$ is related to pairing potential which in the present formulation must be Coulombic in origin as $v=1/r_{ij}$. The Coulombic potential is negative if the interaction is between two particles of opposite charges. This suggests that we may associate this interaction with the attraction between a particle and a hole. This interaction is not taken into account at any stage in HF calculation.

If the Hamiltonian (1) is written out in full, then there will appear terms which can be correlated with interaction arising from hole-particle, particle-particle hole-hole, *etc.* These points have been thoroughly discussed in Random-Phase-Approximation Scheme.[10] Instead of going into details of that calculation we only state that whenever we go over to calculate energy values for states other than ground state we must take into account interactions arising from hole-hole, hole-particle terms in the Hamiltonian (1).

With this formulation we now proceed to analyse the case of cyanine. In the π-electron calculation on cyanines, the systems are considered to be open-chain systems like polyenes, but carry a positive charge *i.e.* a hole in Fermi sea. The interaction of this charge with the π-electrons is taken into account in the usual HF calculation. In the expression for quasiparticle energy

$$E_i = \sqrt{(\varepsilon_i-\varepsilon_F)^2+\Delta^2},$$

the Δ should be made up of two terms, the hole-particle attraction and the hole-hole repulsion, the terms which are not taken care of in HF calculation. It may not be too unfair to assume that these two terms will be nearly equal and cancel each other. The quasiparticle energy will then reduce to

$$E_i = (\varepsilon_i-\varepsilon_F),$$

and the system will not show any convergence limit as is actually the case.

While considering biphenyl-polyene dinegative and mononegative ions, we may consider the mononegative ion to be the same as dinegative ion with a formal hole in the Fermi sea. Consequently mononegative ion will show no convergence limit like cyanines, while dinegative ion will.

It appears that the hole-particle formulation with some chemical intuition can give a reasonable account for the convergence limit in π-electronic spectra of open-chain compounds.

Estimation of the Structures and Electronic States of Radicals Using the INDO-SCF MO Method. I. Alkoxyl Radicals

Katsutoshi OHKUBO and Futoshi KITAGAWA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received July 2, 1973)

Synopsis. The most energetically stable alkoxyl radicals take the following configuration: r(C–O)=1.36 Å, r(C–H)=1.12 Å, and ∠OCH=109°28′ for $CH_3O\cdot$, and r(C–O)=1.36 Å, r(C–C)=1.47 Å, and ∠OCC=108° for $C_2H_5O\cdot$. The pseudo π orbital is observed in the C–O bond.

Alkoxyl radicals (referred to as RO·) have been postulated as momentarily-living intermediates participating in the oxidation and polymerization reactions. Recently, they have been considered to play an important role in the air-pollution cycle:

$$-\underset{\text{H}}{\text{C}}=\text{C}-\text{C}- + {}^1\text{O}_2 \longrightarrow -\text{C}(\text{OOH})-\text{C}=\text{C}-$$

$$\xrightarrow{\text{dec.}} \text{Radicals such as RO}\cdot$$

$$\text{RO}\cdot + {}^3\text{O}_2 \longrightarrow \text{RO}_3\cdot$$

$$\xrightarrow{\text{NO}} \text{RO}_2\cdot + \text{NO}_2 \text{ (or } \text{RO}_3\text{NO)}$$

$$\text{RO}_2\cdot + \text{NO} \longrightarrow \text{RO}\cdot + \text{NO}_2$$

The molecular structures and electronic states of RO radicals, however, seem to be open to question, although some rough estimates of the said aspects of the radicals have been established by the iterative extended Hückel[1] and CNDO/2[2] treatments of some lower molecules.

In the present study, we will estimate the molecular structures and electronic states of RO radicals by means of the INDO-SCF MO method,[3] taking methoxyl and ethoxyl radicals as examples.

Method of Calculation

The following two systems were investigated in this work: (a) the methoxyl radical, $CH_3O\cdot$ and (b) the ethoxyl radical, $CH_3CH_2O\cdot$. The geometric parameters of the above species are shown in Fig. 1. In

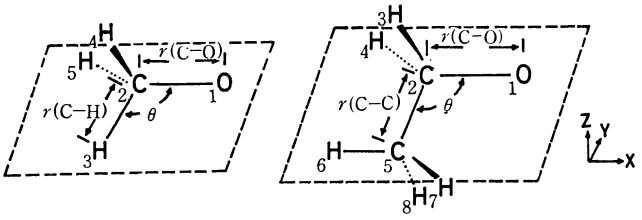

Fig. 1. Geometries used for calculations. (r(C–O), θ, r(C–H), and r(C–C) stand for geometric parameters.)

$CH_3CH_2O\cdot$, the interatomic distance of C–H and the valence angle of H–C–H of the CH_3 group were uniformly taken to be 1.09 Å and 109°28′ for the sake of simplicity.

The method of calculation was a semiempirical INDO, using the integrals and parametrization described in Ref. 3.

Results and Discussion

Methoxyl Radical. The INDO calculations were first performed on $CH_3O\cdot$ with two variables of the bond distances, r(C–O) and r(C–H), and one variable of the valence-bond angle, θ, by changing r(C–O), θ, and r(C–H) in turn.[4] As Table 1 indicates, the set of r(C–O)=1.36 Å, r(C–H)=1.12 Å, and θ=109°28′ give the lowest SCF total energy (E_{SCF}) of $CH_3O\cdot$. The bond angle of θ is in accordance with the usual sp^3 hybrid valence angle, while the bond lengths of r(C–O) and r(C–H) differ appreciably from those (r(C–O)≈1.44 Å[5] and r(C–O)≈1.09 Å[5]) of usual alcohols and carboxylic acids. In particular, the large estimated r(C–H) value of 1.12 Å is distinctive. It may also be seen in Table 1 that the formal charges (Q_A) of +0.240 for C and −0.178 for O give the dipole

Table 1. Changes in total energy and electronic state of $CH_3O\cdot$ as a function of three variables, r(C–O), θ, and r(C–H)

r(C–O)/Å	θ	r(C–H)/Å	E_{SCF}/a.u.	Q_A C	Q_A O	Odd-electron density	μ/D
1.35	109°28′	1.09	−26.6063	+0.242	−0.180	1.037	1.80
1.36	109°28′	1.09	−26.6064	+0.240	−0.180	1.035	1.81
1.37	109°28′	1.09	−26.6060	+0.236	−0.180	1.034	1.82
1.36	109°	1.09	−26.6063	+0.239	−0.181	1.075	1.81
1.36	109°28′	1.09	−26.6064	+0.240	−0.180	1.035	1.81
1.36	110°	1.09	−26.6063	+0.240	−0.179	1.238	1.81
1.36	109°28′	1.11	−26.6101	+0.240	−0.179	1.058	1.79
1.36	109°28′	1.12	−26.6106	+0.240	−0.178	1.056	1.78
1.36	109°28′	1.13	−26.6103	+0.240	−0.177	1.101	1.77

moment (μ) of 1.78 D, working mainly in the direction of the C–O bond axis.

The odd-electron (its density=1.056) is predominantly localized in the following occupied MO, ϕ_{occ}^{odd}:

$$\phi_{occ}^{odd} = 0.734Y_O + 0.112Z_O - 0.358Y_C + 0.456S_{3H} - 0.287S_{4H} - 0.167S_{5H}$$ [6]

while the lowest unoccupied MO, ϕ_{unocc}^{odd}, is also occupied strongly by the oxygen $2p_y$-orbital as:

$$\phi_{unocc}^{odd} = 0.849Y_O + 0.129Z_O + 0.174Y_O + 0.386S_{3H} - 0.248S_{4H} - 0.146S_{5H}$$ [6]

Here, let us illustrate the orbital contour maps of both MOs in Fig. 2 in order to aid understanding of the MOs.

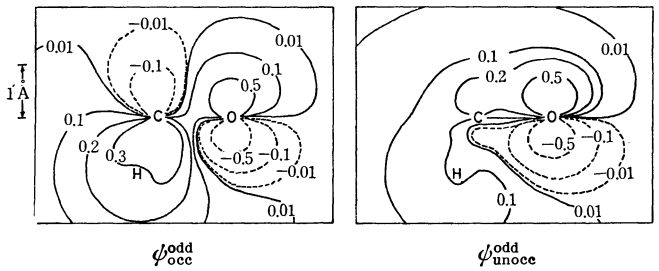

Fig. 2. Orbital Contour Maps of ϕ_{occ}^{odd} and ϕ_{unocc}^{odd} of $CH_3O\cdot$.
(x-y cross-section; solid and dotted curves are positive and negative MO signs respectively.)

Ethoxyl Radical. The INDO calculations were performed further on $CH_3CH_2O\cdot$ with three variables (r(C–O), θ, and r(C–C) in Fig. 1). The computation results with respect to the most energetically stable $CH_3CH_2O\cdot$ are shown in Table 2, together with the results from the CNDO/2 calculations. The bond angle of θ differs by 1°28′ from the sp^3 hybrid valence angle, and the r(C–C) of 1.47 Å is shorter than the usual single C–C bond (~1.54 Å). Moreover, the Q_A values of 2C and O atoms are more positively or negatively charged than those of $CH_3O\cdot$, although the magnitude of the odd-electron density (1.045) is weak in comparison with $CH_3O\cdot$.

With regard to the ionization energies (I_p), the INDO evaluations are relatively large, as we expected, for such open-shell molecules as the $CH_3O\cdot$ and CH_3-$CH_2O\cdot$ radicals as well as for the closed-shell molecules. The I_p values[7] of 0.526 a.u. for $CH_3O\cdot$ and 0.509 a.u. for $CH_3CH_2O\cdot$ differ considerably from those derived from experiments (0.339 a.u.[8] for the former and 0.337 a.u.[9] for the latter).

Finally, it is worthy of emphasis that, in the INDO calculations, the pseudo π orbital consisting of the $2p_z$-orbitals of the C and O atoms is observed in the C–O bond (for instance, see AO populations of the C and O and the bond-orders of the C–O bond in Table 2), as well as that in the iterative extended Hückel calculations.[1]

Very-high-dose-rate Radiolysis of *n*-Butane in the Gas Phase. The Effect of the Addition of Electron Scavengers

Yoshihiko HATANO, Satoshi TAKAO, Hideki NAMBA, Takumi UENO, and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro, Tokyo 152

(Received June 21, 1973)

Synopsis. The dose rate and its pulse-to-pulse reproducibility of very-high-intensity electron pulses have been measured. The effect of the addition of electron scavengers on the neutralization processes in the gas-phase radiolysis of *n*-butane has been examined by using this very high dose-rate electron pulse.

Several tests on the current waveforms of electron pulses from a high-intensity electron-pulse generator and on the pulse-to-pulse reproducibility of its intensity have been carefully undertaken. The results have shown that this pulsed-electron source gives very high dose rates of about 10^{27} eV g^{-1} s^{-1} with a good reproducibility. These high dose rates must cause some differences in the neutralization processes compared to those in the ordinary γ-radiolysis[1-3] of the lower dose rates. In this note, therefore, the effect of the addition of electron scavengers, SF_6 and N_2O, on the gas-phase radiolysis of *n*-C_4H_{10} under these very high dose rates has been examined. The results were compared with those of the γ-radiolysis.

Experimental

The electron pulses were obtained from a Febetron 706 with a model 5515 electron tube at a charging voltage of 27 kV and a nitrogen pressure of 14.4 atm in it. The current waveform of an electron pulse was measured directly using a Faraday cup bolted to the face of the Febetron electron window. The gap between the fringes of the electron window and of the Faraday cup was covered with aluminum foil to exclude the electromagnetic noise on the oscilloscope. A very small part of the electron beam was admitted through a collection aperture to strike the Faraday cup, which was coupled through a impedance matched attenuator and a cable to the 50Ω-input resistance of a 150 MHz oscilloscope (Tektronix 454 A MOD 163 D), equipped with a self-shield and self-filter for the electromagnetic noise. The signal cable was 4 m long and was equipped with a 50Ω feed-through terminator on each end to avoid any reflection. The display on the oscilloscope was photographed by means of an oscilloscope camera (Tektronix C-30A) equipped with an enhancer ($f=1.9$; image ratio, 0.7; shutter speed, 5 s) with Polaroid Land roll film, 10000 speed/type 410. The shape showed rather a sharp triangle with little noise. From this current shape, the value of 7.6 ns was obtained for the half-duration of the electron pulse, which is about twice as large as the nominal value. The rise time of this overall detection system is definitely less than 7.6 ns.

All the irradiations for dosimetry and pulse radiolysis were done in cylindrical vessels 20 cm long, 3 cm in o.d., 1 mm walls with a 80 μ thick aluminum window on one end, and equipped with an arm for the sample preparations. They were positioned to face the Febetron electron window. The aluminum windows were attached to the vessels by means of epoxy cement. The irradiation of these vessels caused the production of some gases in an amount less than 0.1 μmol. These were identified as H_2, N_2, and CO_2 by gas chromatography and mass spectrometry. These amounts, however, result in little error in this study; therefore, most of the irradiations were done with these vessels. This problem was overcome by soldering a thin film (20 μ) of stainless steel as a window material to a Kovar-to-glass seal. The dosimetry was based on a nitrogen yield of $G(N_2)=12.3$[4] in the radiolysis of N_2O at 800 mmHg. The absorbed dose in *n*-C_4H_{10} was calculated by an appropriate correction for the electron density. The gases were of a very high purity and were used without further purifications except for the usual degassing, the stated purities being *n*-C_4H_{10} (>99.7%), SF_6 (>98%), and N_2O (>99.9%). The products, H_2 and N_2, were measured by gas chromatography using a 5 m column of Molecular Sieve-5A at 60 °C.

Results and Discussion

The pulse-to-pulse reproducibility of an electron-pulse intensity has been examined by using the nitrous oxide dosimetry described above. The results are shown in Fig. 1. From the straight line in Fig. 1, the total dose in N_2O has been found to be $(1.45\pm0.07)\times 10^{19}$ eV g^{-1} $pulse^{-1}$. This corresponds to a mean dose rate of the order of 10^{27} eV g^{-1} s^{-1}. The pulse-to-pulse reproducibility is very excellent, with a maximum deviation of less than 5%; the additivity of the pulses is also excellent.

The fact that the dose rate of the above electron pulses is much higher than those in usual ^{60}Co-γ ray-irradiation facilities invites the following interest. Some new results might be obtained under these very high dose rates, especially in neutralization reactions. About 800 mmHg of *n*-C_4H_{10} has been pulse-radiolyzed at room temperature, and the effect of the addition of SF_6 on the hydrogen yield at the total dose of 8.5×10^{19} eV g^{-1} has been examined. The results are shown

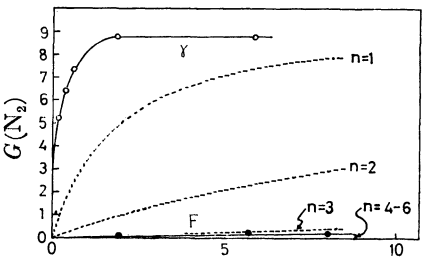

Fig. 4. The effect of the addition of N_2O in the gas-phase radiolysis of n-C_4H_{10}. The dotted lines correspond to the calculated results described in the text.

in Fig. 2, where the results for the same system obtained by γ-ray radiolysis[5] are also presented. The G-value of hydrogen from pulse-radiolyzed n-C_4H_{10} is 2.6, less than one-half of that in the γ-radiolysis of the same system. Figure 2 clearly shows the poor effect of SF_6 on $G(H_2)$, contrary to its very great effectiveness in the γ-radiolysis, where only 0.01 mol% of SF_6 is enough to suppress the neutralization completely. Following the reaction scheme accepted in γ-radiolysis,[1-3] the simple reaction scheme for the ionic processes for the hydrogen formation in the pulsed-electron radiolysis of n-C_4H_{10}–SF_6 mixtures may be depicted as:

$$n\text{-}C_4H_{10} \overset{D}{\rightsquigarrow} M^+ + e^-$$

$$M^+ + e^- \xrightarrow{k_1} H_2 \qquad (1)$$

$$SF_6 + e^- \xrightarrow{k_2} SF_6^- \qquad (2)$$

$$M^+ + SF_6^- \xrightarrow{k_3} \text{no } H_2 \text{ formation} \qquad (3)$$

where M^+ denotes the positive species in the system. Assuming that the steady-state treatment to be applied to this scheme, one may derive the following relation between the decrease in $G(H_2)$ in the presence of SF_6, $\Delta G(H_2)$, and the concentration of SF_6:

$$\frac{1}{\Delta G(H_2)} = \frac{1}{\Delta G_\infty(H_2)} \times \left(1+\frac{k_1[M^+]}{k_2[SF_6]}\right) \qquad (4)$$

with $[M^+]=(100^{-1}G(e^-)D/k_a)^{1/2}$, where $\Delta G_\infty(H_2)$ is the decrease in $G(H_2)$ at an infinite concentration of SF_6, where D is the dose rate in eV $cm^{-3}s^{-1}$, and where k_a is the averaged value of the neutralization rate constants, k_1 and k_3. Since no large significant difference has been observed[6] between them, it may be reasonable to use the k_a value. It can be expected from Eq. (4) to obtain the linear relation between $1/\Delta G(H_2)$ and $1/[SF_6]$ shown in Fig. 3. Good linearities were obtained in both cases, with a very large difference in the slopes. An almost zero slope was obtained in the case of γ-radiolysis. This large difference can be explained in terms of the large difference in the dose rates. If it is assumed in Eq. (4) that the rate constants and the other values are not very different from each other, then the ratio of the slopes is proportional to $D^{1/2}$. The ratio is calculated as high as 10^6, which may explain why the slope in γ-radiolysis is nearly equal to zero.

The effect of the addition of N_2O has also been examined (Fig. 4). Contrary to the large yields of N_2, which are well known in γ-radiolysis, very small yields of N_2 were observed in pulsed-electron radiolysis. This large difference can be explained as in the same way as in the addition of SF_6. The experimental results in Fig. 4 give good linear relationships between $1/G(N_2)$ and $1/[N_2O]$, as expected.[7] The slope in γ-radiolysis being multiplied by 10^n(n=1—6), one can obtain the dotted lines in Fig. 4. The observed yields in pulsed-electron radiolysis are at least below the curve at n=3, and might be near that at n=6. After the correction for the direct radiolysis of N_2O by using $G(N_2)=12.3$ from pure N_2O,[4] the slope becomes slightly less than zero. It is not easy to determine the curve which best fits them. More accurate and reasonable corrections for the direct radiolysis of N_2O are required, as has been suggested for the radiolysis of hydrocarbon solutions of N_2O,[8] in view of the small amount of N_2 formed. There remains, moreover, an important part unexplained—why $\Delta G_\infty(H_2)$ is not equal. More detailed experiments and discussions will be required to the clear and final understanding of the effect of very-high-dose-rate radiolysis.

The Effect of Copper(II) on the Formation and Thermal Change of Synthetic β-FeOOH

Katsuya INOUYE, Hiroyuki IMAMURA, Katsumi KANEKO, and Tatsuo ISHIKAWA

Department of Chemistry, Faculty of Science, Chiba University, Chiba 280

(Received July 10, 1973)

Synopsis. The effect of Cu(II) added to β-FeOOH in various ratios up to 6% Cu/Fe was examined by X-ray diffraction, electron microscope, BET surface area, DTA, TGA and chemical analyses. Differing from other cases reported previously, Cu(II) showed no effect, but thermal changes of the Cu-doped samples indicated a reinforcement of bonding by Cu.

In order to obtain a more definitive fundamental elucidation of the role of copper added to anti-weathering steels, which have been widely recognized to be appreciably anti-corrosive in atmospheric and, perhaps in a lesser extent, marine environments, the present authors have examined the effect of Cu(II) doped in every component of the corrosion product. These studies have covered the following cases: oxide-oxyhydroxide mixtures produced by the air oxidation of $Fe(OH)_2$,[1,2] magnetite from mutual interaction between $Fe(OH)_2$ and $Fe(OH)_3$ colloids,[3] magnetite from the self-decomposition of $Fe(OH)_2$[4] and α-FeOOH produced by the hydrolysis of a Fe(III)-sulfate solution.[5] The explanation of the phenomena observed as the copper effects is by no means simple, but it appears plausible to conclude that Cu(II) invariably impedes the formation and growth of those oxides and/or oxyhydroxides.

The present study is concerned with an examination of the similarly-expected copper effect on the crystallization of β-FeOOH, together with some thermal changes in Cu-doped β-FeOOH. It is interesting to note that β-FeOOH, as one of the corrosion products of iron-base alloys, is produced only when the Cl^- ion (or possibly other halide ions) is present and further, that the β-FeOOH crystal embraces chlorine as a genuine component.[6-8] It thus appears that the behavior of chlorine is an essential problem in any case involving the characteristics of β-FeOOH.

β-FeOOH was prepared from solutions of 0.2 M $FeCl_3$ added by 0.2 M $CuCl_2$ in 0, 1, 2, 3, 4, 5, and 6 Cu/Fe atomic % through hydrolysis with and without the addition of urea (30 g per 500 ml of a mixed solution) at 95—99 °C for 5 hr; up to this temperature range the solution was warmed at the rate of 1 °C/min. When aged, the suspension was kept at 30± 0.5 °C for various times up to 10, 20, 30, and 50 days. During the aging procedure, the pH values of the suspensions were kept at 7.5—8.0 with daily stirring. The suspensions were then filtered, and the crystals thus obtained were washed thoroughly with distilled water and dried at 80 °C for 2 hr.

The Fe, Cu, and Cl contents were conventionally determined after dissolving β-FeOOH in HCl by $K_2Cr_2O_7$ titration, by colorimetry in the presence of Cupferazone, and by Volhard method respectively, based on the crystal dried at 105—110 °C for 1 hr. Correction for the co-existing Cu(II) on Fe determination was done by means of a calibration curve. X-Ray diffraction, BET surface area determination, electron microscopy, differential thermal analysis (DTA), and thermal gravimetric analysis (TGA) were carried out by procedures similar to those described in preceding reports.[3-5,7,8]

It is noteworthy, first, that any Cu(II) over 6% Cu/Fe added to the original solution is excluded from the precipitates into medium during the course of hydrolysis, though the reason why 6% is the limit has not yet been understood.

The electron micrographs of each sample, with or without addition of Cu(II) and after aging at 30 °C for various durations, showed almost identical rod-like crystals approximately $1.8—1.9\times10^{-5}$ cm in length. The specific BET surface area measurements also gave almost identical values, ranging from 41 to 51 m^2/g. X-Ray diffraction patterns were exactly the same, irrespective of the variation in Cu content and aging time. There is no recognizable shift in any diffraction peak of the samples with different amounts of Cu present. The crystallite size calculated showed no appreciable variation with regard to the Cu content and aging time, giving values mostly in the range of 250—290 Å.

These results were inconceivable on the basis of our knowledge of previous experimental results, which indicated comprehensively that Cu is more or less destructive in the formation of oxyhydroxides or oxides. The disappearance of the Cu effect in the present case was thought at first to be possibly due to the presence of urea in the hydrolysis because of the homogeneous precipitation. The preparation of β-FeOOH without

Table 1. Chemical composition of β-FeOOH

the addition of urea under conditions otherwise the same was attempted in order to confirm the effect of urea. The X-ray diffraction patterns and other examinations of the resultant crystals showed them to be entirely identical with those which came out of suspensions upon the addition of urea.

The chemical analyses of each sample give us the Cu/Fe and Cl/Fe atomic ratios which are tabulated in Table 1. It seems that in crystals Fe is replaced by Cu at each intended ratio, except in the cases of 6% Cu/Fe, when only somewhat lower ratios were obtained. As for the Cl/Fe atomic ratio, values were observed in only the limited range of 8—9%, although a slight increase with the rise in the Cu/Fe ratio was observed. However, a constant Cl content was obtained by calculating Cl/(Fe+Cu). It is thus implied that Cl interacts not only with the Fe but also with the Cu included in the crystal.

According to Mackay,[6] β-FeOOH has the α-MnO_2 or hollandite ($BaMn_8O_{16}$) structure in a tetragonal system with a=10.48 Å and c=3.023 Å. Channels parallel to the *c*-axis are contained in crystals, where Cl^- and H_2O can be accomodated and sometimes mutually exchanged. In other words, the β-FeOOH structure is like a bundle of fine tubes, the walls of which are composed of O^- and OH^- ions surrounding the Fe^{3+}. Each Fe^{3+} is surrounded octahedrally by six (O^-, OH^-) ions. The octahedra are linked to form tubes parallel to the *c*-axis, sharing edges and some corners of the octahedra. In this context, therefore, it may be concluded that β-FeOOH crystals are so strongly stabilized by the presence of Cl^- that the destructive action of replacing Cu does not show up.

TGA curves in Fig. 1 on pure β-FeOOH and the 6% Cu/Fe sample illustrate the difference in the temperature region where the weight loss increases steeply, corresponding to the evolution of $FeCl_3$ sublimed, accompanied by a transformation of β-FeOOH to α-Fe_2O_3.[7,8] The shift in the "decomposition temperature" with the Cu indicates an increase in the bonding in the Cu-doped crystals. From the DTA curves in Fig. 2, we can conceive a bonding between the Cu added and the Cl constitutionally present. After the evolution of H_2O and the degradation of the β-FeOOH crystals to an amorphous state below 300 °C, a rather sudden recrystallization to α-Fe_2O_3 occurs at the temperatures characteristic of the Cu content; the recrystallization temperature corresponds to the sharp exothermic DTA peak, which shifts to higher temperatures proportionally with the increase in the Cu/Fe ratio. It is noted further that shallow endothermic DTA peaks appear in Fig. 2 just below 500 °C, presumably as a result of the melting of the resulting $CuCl_2$ (mp 498 °C).

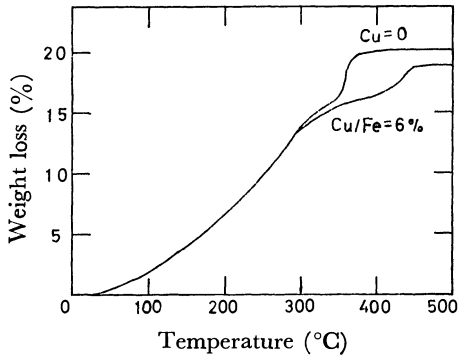

Fig. 1. TGA curves of β-FeOOH with 6% Cu/Fe and without addition of Cu.

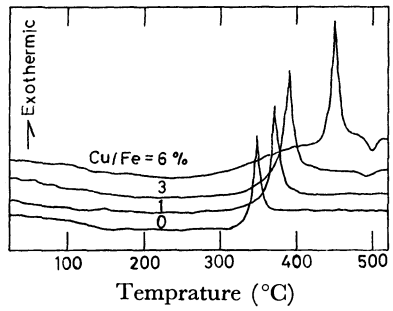

Fig. 2. DTA curves showing the shift of exothermic peaks.

All the facts observed seem to coincide with the unexpectedly high consistency of β-FeOOH crystals doped with Cu(II), if one accepts that it is likely to produce an interaction between Cu and Cl.

Flash-Spectroscopic Study of Phthalazine[1)]

Nobuaki KANAMARU,* Saburo NAGAKURA,** and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

***The Institute for Solid State Physics, The University of Tokyo, Minato, Tokyo 106*

(Received July 19, 1973)

Synopsis. The phthalazine triplet and the hydrogen-abstracted radical were obtained in ethanol *etc.* at room temperature, suggesting that the T_1 is of $n\pi^*$ type, whereas only the T–T absorption spectrum was obtained in acidic ethanol as reported in EPA glass at 77 K.

The lowest triplet states of hetero-cyclic aromatic compounds containing nitrogen are known to be mostly of the $\pi\pi^*$ type.[2)] Azobenzenes containing more than two nitrogen atoms, however, have been concluded to have the lowest excited triplet states of the $n\pi^*$ type from several spectroscopic studies on T←S transitions in gas phase as well as on phosphorescence in rigid glasses.[3)]

Hetero-polycyclic aromatic compounds containing nitrogen have also received much attention in connection with the assignment of the lowest excited singlet and triplet states.[2)] Phosphorescence and triplet-triplet (T–T) absorption studies[2,4–8)] of some hetero-polycyclic compounds in EPA glasses at 77 K have indicated that their lowest triplet states are of the $\pi\pi^*$ type at least in the 77 K EPA glasses. Phthalazine is one of typical examples in which a large interaction between two adjacent nitrogen atoms might cause the $^3n\pi^*$ state to be the lowest triplet. Recently, Baba *et al.*[7)] have concluded from phosphorescence and phosphorescence-polarization studies that the phosphorescent state of phthalazine should be of $^3B_2(\pi\pi^*)$ in EPA glass at 77 K. The $^3n\pi^*$ and $^3\pi\pi^*$ states of phthalazine are thought to be so close that the order of these two energy levels might be dependent on solvent and temperature. It is still unknown which state $^3n\pi^*$ or $^3\pi\pi^*$ is the lowest in solution at room temperature.

Since no flash photolysis studies have been reported for phthalazine in solution at room temperature, we have attempted to carry out flash photolysis experiments with a variety of solutions of phthalazine, with particular emphasis on studying the solvent effects of transient species.

Experimental

Flash experiments at room temperature were carried out with degassed solutions containing 10^{-4}—10^{-5} M phthalazine in ethanol, ether, *n*-hexane, benzene and acidic ethanol, 20 cm quartz cells being used. Low-temperature flash experiments were performed at 77 K in rigid glasses of a mixture of ether, isopentane and alcohol (EPA, 5 : 5 : 2) and a mixture of methylcyclohexane and isopentane (MP, 1 : 1) with a 1 cm quartz cell immersed in liquid nitrogen. The flash spectroscopic apparatus used here was the same as that described previously.[9)] Phthalazine was purchased from Aldrich Chemical Co. and purified by vacuum sublimation. Ethanol, ether, isopentane, *n*-hexane and benzene were purified by usual methods.[10)]

* Present address: Department of Chemistry, Wayne State University, Detroit, Michigan, U.S.A.

Results and Discussion

The transient absorption spectra obtained by the flash photolysis of phthalazine (10^{-4}—10^{-5} M) in ethanol, ether, *n*-hexane and benzene at room temperature are shown by curves a—d in Fig. 1 and that obtained for an acidic ethanol solution of 1×10^{-2} M phthalazine by curve e. The transient absorptions were observed only under degassed condition immediately after flash, a considerable amount of photoproducts being finally obtained. Each transient spectrum shown in Fig. 1 was obtained by subtracting the spectrum measured a few minutes after flash from that immediately after flash. The shorter wavelength parts of the spectra shown by broken lines are suffered from the absorption of the phthalazine molecule in the ground state. Thus, the absorption intensity in this region is somewhat smaller than the true value.

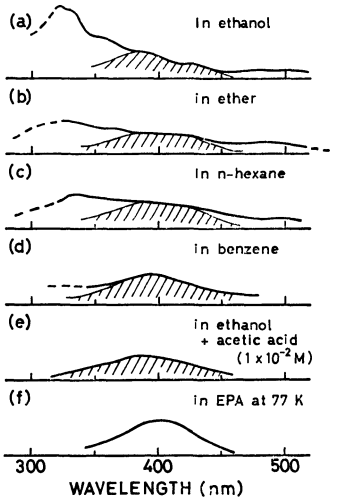

Fig. 1. Transient absorption spectra obtained for photoirradiated phthalazine. Curves a–e were obtained at room temperature under degassed condition with 20 cm quartz cells. Shaded portions indicate the absorption bands due to T-T transition. Concentrations of phthalazine: (a) 3×10^{-5}M; (b, c) 5×10^{-5}M; (d, e) 1×10^{-4}M. Curve f was obtained in EPA glass at 77 K, with a 1 cm quartz cell.

The flash photolysis of phthalazine in the EPA glass at 77 K gave rise to a transient spectrum shown by curve f in Fig. 1. In an MP glass at 77 K, the transient absorption was too weak to obtain a well-defined spectrum. The lifetime of the transient 390 nm band in the EPA glass was found to be roughly consistent with

the available phosphorescence lifetime of phthalazine (0.4 s).[7] Furthermore, the transient spectrum (curve f in Fig. 1) is in good agreement with the T–T absorption spectrum recently obtained by Alvarez and Hadley[11] in a rigid matrix of *n*-butanol and isopentane at 77 K and by Yamazaki and Baba[12] with a laser flash technique in EPA at 77 K. Therefore, there may be no doubt that the 77 K spectrum obtained here is due to the T–T transition of phthalazine.

As seen from Fig. 1, the transient spectra obtained in benzene and acidic ethanol solutions (spectra d and e) seem to differ considerably from those in ethanol, ether and *n*-hexane (spectra a—c), and are similar to the T–T spectrum of phthalazine (curve f). Thus, spectra d and e may be mainly due to the phthalazine triplet. As revealed from its shape, spectrum d may have a minor contribution of another transient species.

The transient spectra obtained with the ethanol, ether and *n*-hexane solutions at room temperature (curves a—c in Fig. 1) indicate the existence at least two sorts of transient species. The absorption intensities in the range 380 to 450 nm are independent of the solvents used, whereas those in the two ranges 300—380 and 450—520 nm considerably depend on the solvents. According to the time-resolved spectrophotographs obtained in the present study, the 380—450 nm bands decay much faster than the 300—380 nm and 450—520 nm bands: The 380—450 nm bands were detected only within several μs, whereas the 300—380 and 450—520 nm bands were observed until about 100 μs. Therefore, we may conclude that there exists another transient species in ethanol, ether and *n*-hexane, in addition to the triplet phthalazine.

The order of the yield of the transient species with the bands at 300—380 nm and 450—520 nm is:

$$n\text{-hexane} < \text{ether} < \text{ethanol}$$

This order seems to be correlated with the hydrogen-donating ability of the solvents. By adding acetic acid (1×10^{-2} M) to the ethanol solution, the ability of hydrogen abstraction of phthalazine is expected to be reduced significantly, since the nature of its lowest triplet excited state is changed by protonation from the $n\pi^*$ type to the $\pi\pi^*$ one. (It should be mentioned that the absorption spectrum of the ground state phthalazine in an acidic ethanol solution containing more than 10^{-3} M acetic acid shows no absorption corresponding to the $n\pi^*$ band of the ethanol solution of phthalazine appearing at about 330 nm, although this fact gives no direct information as to the triplet-state energy levels.) The $n\pi^*$ state of phthalazine is considered to have a greater ability of hydrogen abstraction than the $\pi\pi^*$ state, as is well known with carbonyl compounds.[13,14]

The experimental facts presented here concerning the second transient species may be explained by considering that this species is ascribed to the 2-hydrophthalazyl radical. It is interesting to note that the transient bands appearing at 330 and 480 nm resemble those of the naphthalene anion radical showing absorption maxima at 370 and 450 nm.[15] This fact strongly supports the assignment of the second species to the 2-hydrophthalazyl radical, which is isoelectronic to the naphthalene anion in π-electron structure. Judging from the short lifetimes (a few μs) of the T–T bands observed in ethanol, ether, *n*-hexane and benzene at room temperature, we may conclude that the lowest triplet states of phthalazine are of the $n\pi^*$ type but the lowest $\pi\pi^*$ and $n\pi^*$ triplet states are close to each other and mix to a considerable extent.

The present authors wish to express their sincere thanks to Professor H. Baba and Dr. I. Yamazaki for their helpful discussions.

Synopsis. Stability constants of zinc(II) mono- and biscomplexes with C_2 to C_6 dicarboxylic acids and with sulfate, thiosulfate and selenate ions determined at 25 °C by solvent extraction are described. The stability order of the dicarboxylate complexes decreases in an order of $C_2>C_3>C_4\simeq C_5\simeq C_6$ whereas that of the inorganic acids are nearly similar.

In previous papers of the present authors, the stability constants of zinc(II) with thiocyanate,[1] halide,[2] and monocarboxylate[3] ions in sodium perchlorate media at 25 °C have been determined. In the present paper, a further determination of the stability constants of zinc(II) complexes with several divalent anions has been made in 1 M sodium perchlorate media at 25 °C, using a chelate extraction method with β-isopropyltropolone (IPT).

Experimental

All the experiments were done in a thermostated room at 25±0.3 °C in a way similar to that described in the previous papers.[1-4] Ghe initial concentration of the zinc(II) in the aqueous phase was 1×10^{-6} M. Ghe aqueous phase in some experiments was buffered with acetate (the initial aqueous concentration was 0.01 M). It was confirmed that at this concentration the buffer has no effect on the extraction of zinc(II). Ghe dissociation constants of certain dicarboxylic acids were determined by the method described by Speakman.[5]

Results and Discussion

The statistical treatment of the experimental data was the same as in the previous papers.[1-3]

$$\beta_n = [ZnL_n^{2-2n}][Zn^{2+}]^{-1}[L^{2-}]^{-n} \quad (1)$$

The extraction of zinc(II) with IPT (HA) is generally written as:[6]

$$Zn^{2+} + 2HA(org) \rightleftarrows ZnA_2(org) + 2H^+ \quad (2)$$

$$ZnA_2(org) + HA(org) \rightleftarrows ZnA_2HA(org) \quad (3)$$

$$D_0 = ([ZnA_2]_{org}+[ZnA_2HA]_{org})/[Zn^{2+}] = K_{ex0}[HA]_{org}^2[H^+]^{-2}(1+K_{org}[HA]_{org}) \quad (4)$$

where K_{ex0} and K_{org} are the equilibrium constants for the reactions in Eqs. (2) and (3) respectively. When the concentration, $[HA]_{org}$, is kept constant in a series of experiments, Eq. (4) can be rewritten as:

$$D_0[H^+]^2 = K_0 \quad (5)$$

where $K_0=K_{ex0}[HA]_{org}^2(1+K_{org}[HA]_{org})$. It was confirmed that the value of K_0 is constant, at least when $D_0<10$ (K_0 is $10^{-11.76}$, $10^{-10.44}$, or $10^{-8.39}$ when $[HA]_{org}$ is 5.0×10^{-3} M, 2.0×10^{-2} M, or 1.0×10^{-1} M respectively). The distribution ratio when zinc(II) forms complexes with the L^{2-} is written as follows if the $[HA]_{org}$ value is also kept the same:

$$D = ([ZnA_2]_{org}+[ZnA_2HA]_{org})/([Zn^{2+}]+[ZnL]+[ZnL_2^{2-}]+\cdots) \quad (6)$$

and from Eqs. (1), (5), and (6):

$$D[H^+]^2K_0^{-1} = (1+\beta_1[L^{2-}]+\beta_2[L^{2-}]^2+\cdots)^{-1} \quad (7)$$

It was confirmed that the distribution ratio at a certain ligand concentration is proportional to $[H^+]^{-2}$ with all the ligands studied; thus, it was concluded that Eq. (7) can be used for the analysis of the experimental data.

Figures 1 and 2 show the decrease in the zinc(II) extraction as a function of the ligand-anion concentration in the aqueous phase. The ranges of the hydrogen-ion concentration in the aqueous phase were $10^{-6.1}$—$10^{-6.8}$ M (divalent carboxylate), $10^{-3.6}$—$10^{-3.7}$ M (sulfate), and $10^{-4.5}$—$10^{-5.2}$ M (selenate and thiosulfate), and the association of the ligand anion with protons in these hydrogen-ion concentration ranges was corrected by using the acid dissociation constants in Table 1 and in Ref. 8. Since the relative concentration of the HL^--type anion is rather low (the protonated species of oxalate and the inorganic ligand anions were negligible whereas the contributions of the HL^- and H_2L species were 7 and 0.2% respectively at the maximum for the other divalent carboxylate ligands), and since the stability constants of the complexes containing the HL^--form ligand may be much smaller than those for the ZnL and ZnL_2^{2-} complexes, as has been reported by, for example, Ostacoli and his co-workers,[9] the formation of such species as $ZnHL^+$ could be excluded from consideration. On these assumptions, the data in the figures were analyzed graphically and the stability constants listed in Tables 1(a) and 1(b) were obtained. The solid curves in the

Table 1. Stability constants

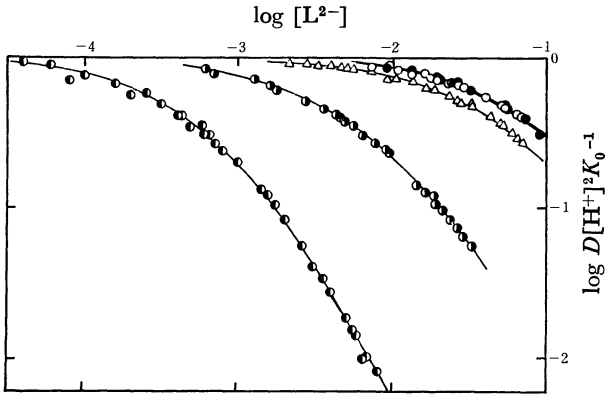

Fig. 1. Decrease in the IPT extraction of Zn(II) as a function of the ligand concentration. Org. phase: $CHCl_3$ containing 2×10^{-2}M IPT for oxalate and 5×10^{-3}M IPT for others. Aq. phase: 1M $Na(\frac{1}{2}L^{2-}, ClO_4^-)$ where L^{2-} is oxalate (◐), malonate (◑), succinate (△), glutarate (○), and adipate (●). The solid curves were drawn by using the following equation in which K_0 is defined by Eq. (5) and the values are given in the text; $\log D[H^+]^2K_0^{-1} = -\log(1+\beta_1[L^{2-}]+\beta_2[L^{2-}]^2)$.

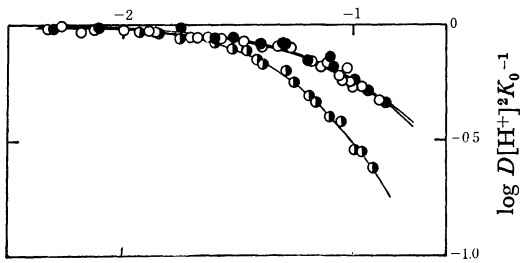

Fig. 2. Decrease in the IPT extraction of Zn(II) as a function of the ligand concentration. Org. phase: $CHCl_3$ containing 1×10^{-1}M IPT. Aq. phase: 1M $Na(\frac{1}{2}L^{2-}, ClO_4^-)$ where L^{2-} is sulfate (●), thiosulfate (◑), and selenate (○). The solid curves were drawn by using the following equation in which K_0 is defined by Eq. (5) and the values are given in the text; $\log D[H^+]^2K_0^{-1} = -\log(1+\beta_1[L^{2-}]+\beta_2[L^{2-}]^2)$.

figures were drawn by introducing these constants into Eq. (7).

There have been several literature values of the stability constants of zinc(II) complexes with these dicarboxylate ions,[9-15] but these stability constants were determined at lower ionic concentrations; furthermore, only a few data are available on the ZnL_2^{2-}-type.

Schwarzenbach and his co-workers[16-19] pointed out that the stability is the greatest with complexes having a five-membered chelate ring, it is less with those having a six-membered ring, and it reaches almost a constant value even when the member of the CH_2 group increases more. Such a tendency was also found with zinc(II) complexes with these divalent carboxylate ligands.[11-13]

This tendency may also be observed in the present results (Table 1(a)). It is remarkable that the same tendency can also be found among the second complexes, as may also be seen in Table 1(a). The β_2 values for the zinc(II) complexes with oxalate and malonate previously reported also show such a decrease with the increase in the member of the ring.[13] The tendency for the stabilities of the complexes with succinate, glutarate, and adipate to be similar to each other has been explained by previous workers[11,16-19] on the assumption that more members than seven is too large a number to form a stable chelate ring with the metal ion. The present results also seem to support this concept.

There have been some literature values of the stability constants of zinc(II) complexes with sulfate,[20] thiosulfate,[21,22] and selenate[23] ions. However, since the ionic concentrations in the literature (0 to 0.05 M) are different from that in the present study, a comparison of the values under different conditions is difficult.

The Migration of Electronic Excitation Energy in Copolymers of *N*-Vinylcarbazole with a Small Content of Styrene or Vinyl Acetate[1]

Kenichi OKAMOTO,* Akikazu YANO,** Shigekazu KUSABAYASHI,* and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received August 9, 1973)

Synopsis. The migration of electronic excitation energy in films of copolymers rich in *N*-vinylcarbazole has been studied by fluorescence quenching experiments using dimethyl terephthalate and perylene as guest molecules. The efficiency of the singlet exciton migration is almost the same for the copolymers and for poly-*N*-vinylcarbazole.

The present authors have reported on the significant decrease in the photocurrent in the copolymers of *N*-vinylcarbazole(VCz) with a small content of styrene (St) or vinylacetate(VAc).[1] For understanding this phenomenon, the efficiency of the migration of the electronic excitation energy in the copolymer films should be compared with the efficiency in a PVCz film.

The migration of the electronic excitation energy in a PVCz film has been studied by Schneider[2] and by Klöpffer.[3] Klöpffer has concluded that the energy transfer in a PVCz film occurs by means of the exciton migration mechanism.

Dimethyl terephthalate (DMTP) is a weak electron acceptor and interacts with a carbazole (Cz) chromophor to produce an exciplex which emits a broad fluorescence at 21000 cm^{-1}.[6] The single-step (dipole-dipole resonance) energy transfer from a Cz chromophor to a DMTP molecule is impossible, because DMTP has no absorption in the wavelength region longer than 300 mμ. DMTP is, therefore, expected to be useful in studying the efficiency of the singlet exciton migration.

Experimental

The polymers were prepared by a method similar to that described perviously.[1] The molecular weights of the polymers ranged from 7000 to 100000. DMTP and perylene were purified by repeated recrystallizations and then by vacuum sublimation. A spectrophotofluorometer was constructed using a high-intensity grating monochrometor equipped with a 1P 28 photomultiplier. The light from a 500W super-high-pressure mercury lamp was monochromatized by means of interference filters and then used for excitation. The emission spectra were measured with 90° excitation at 20 °C in the air and corrected using quinine sulfate and β-naphthol. A film (1 μ thick) was cast onto a quartz plate from a benzene solution and dried at 50 °C *in vacuo*.

Results and Discussion

Figure 1 shows the fluorescence spectra of the VCz–St copolymers in solution. The copolymers rich in VCz show almost the same fluorescence spectra as that of PVCz. With a decreasing VCz content, the excimer fluorescence (I_E) is reduced and the monomer fluorescence (I_M) is enhanced. The I_E/I_M ratio in the VCz–St copolymer is much smaller than that in the VCz–VAc copolymer with the same VCz content, as is shown in Fig. 2. From the monomer reactivity ratio,[5] the VCz sequence in the former is considered to be much shorter than that in the latter. Furthermore, the I_E/I_M value in the alternate VCz–fumaronitrile copolymer[6] is less than 0.1, as is shown by a cross mark in Fig. 2; this is much smaller than the corresponding value (0.4) in the VCz–St copolymer. These results suggest that excimer formation in a dilute solution of PVCz and of the VCz copolymers is mainly between nearest neighboring chromophores in a polymer chain rather than between far-distant neighboring ones.

The host-sensitized energy transfer in films of PVCz and of copolymers rich in VCz doped with DMTP or perylene was investigated. The fluorescence spectra of the films doped with DMTP are shown in Fig. 3.

According to the hopping model of exciton migration, the quenching factor of the host (monomer and excimer) fluorescence (Q_H) can be expressed by Eq. (1), in a way similar to that of the excimer fluorescence (Q_E) in Ref. 3, when that of the monomer fluorescence (Q_M) due to excimer-forming sites is much larger than unity:

$$Q_H = C/C_E \quad (1)$$

where C and C_E are the concentrations of the guest and the excimer-forming site (mol/mol VCz unit).

The values of Q_H were calculated from Eq. (2):[3]

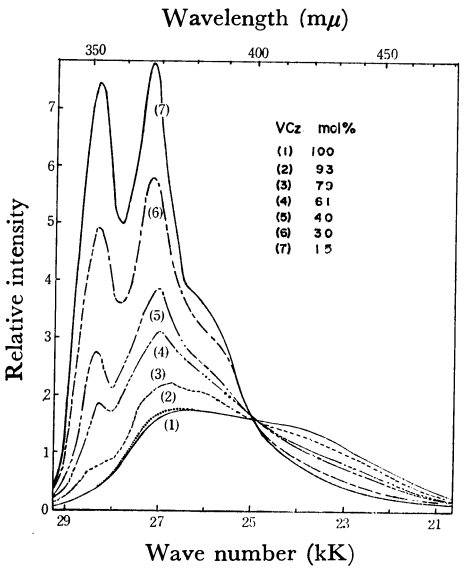

Fig. 1. Fluorescence spectra of VCz–St copolymers in benzene solution (1.5×10^{-4} mol VCz unit/l), 310 mμ excitation.

* Present address: Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube 755.

Table 1. Energy transfer by exciton diffusion process in polymer films

No	Host	Guest	η_H	η_G	$C_E \times 1000$ (mol/mol VCz unit)	$1/C_E$
1	PVCz	DMPT	0.03	0.036	2.9	350
2	VCz–St copolymer (VCz 93 mol%)	DMPT	0.03	0.036	3.3	300

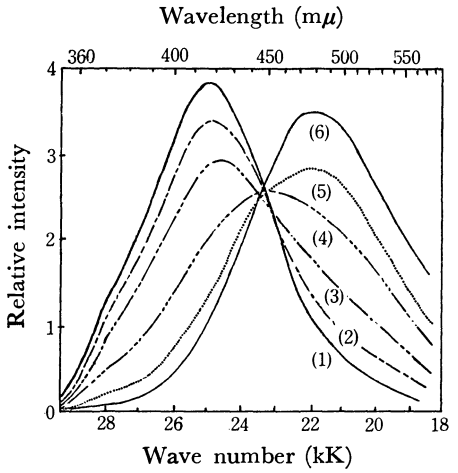

Fig. 3. Fluorescence spectra of PVCz films doped with DMTP, 334 mμ excitation. DMTP concentration; (1) 0, (2) 8×10^{-4}, (3) 2×10^{-3}, (4) 5×10^{-3}, (5) 1×10^{-2} and (6) 3×10^{-2} mol/mol VCz unit.

$$Q_H = (I_G/I_H)(\eta_H/\eta_G) \quad (2)$$

where I_H and I_G are the fluorescence intensities of the host and the guest and where η_H and η_G are quantum yields. The quantum yields of the exciplex fluorescence (η_G) between a Cz chromophore and DMTP in the films were determined from the exciplex fluorescence intensity in the heavy doping films (C=0.1) where no host fluorescence was observed.

Figure 4 shows the bilogarithumic plots of Q_H thus obtained and C. Straight lines with a slope of 1.0

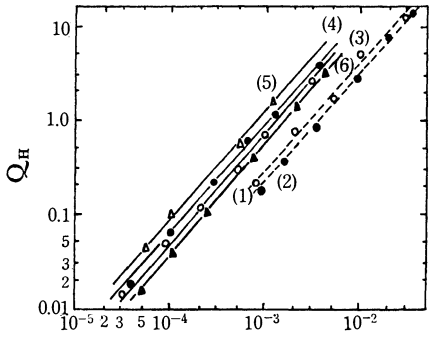

Fig. 4. Q_H *versus* C. See Table 1 as to the number in parentheses.

were obtained for every film as was to be expected from Eq. (1). In the films doped with DMTP, where the single-step energy transfer by the dipole-dipole resonance is impossible, the host fluorescence is quenched significantly by a small amount of DMTP, according to Eq. (1), as in the case of perylene doping. This indicates that the energy transfer both in a PVCz film and in films of copolymers rich in VCz occurs by means of the exciton migration mechanism. The values of C_E were obtained from Fig. 4: they are tabulated in Table 1. The values of C_E obtained from films doped with DMTP are somewhat larger than the values obtained from films doped with perylene. This may imply that in films doped with perylene the single-step energy transfer plays an important role when a singlet exciton comes close to a perylene molecule. In both doping systems, the values of C_E are, however, almost the same for PVCz and for copolymers.

Both in a PVCz film and in films of copolymers rich in VCz, the exciton migration is limited by excimer-forming sites, and the number of Cz rings covered by an exciton during the life-time is represented by $1/C_E$. This number is almost the same for a PVCz film and for copolymers films, it ranges from 400 to 900.

INDO Calculation of ^{13}C Chemical Shifts by the Finite Perturbation Method

Hiroyuki FUKUI

Kitami Institute of Technology, 165 Koencho, Kitami 090

(Received October 11, 1973)

Synopsis. The approximate SCF-MO calculation of ^{13}C nuclear magnetic shielding constants was performed using the finite perturbation method. The results indicated that the INDO finite perturbation method calculates ^{13}C chemical shifts in poor agreement with experiment.

The previous theories of the ^{13}C chemical shifts[1,2] have referred the shifts to the changes in the effective nuclear charge, the mobile bond order, and the average excitation energy and have given good results in many cases. However, in these semiempirical calculations, there is a certain degree of arbitrariness in the choice of an appropriate average excitation energy value. Especially the comparison of the shieldings between different types of molecules depends greatly on the choice of excitation energies. In the finite perturbation theory[3] this arbitrariness is eliminated. Ditchfield, Miller, and Pople[4] have presented *ab initio* results for the shieldings of small molecules using the finite perturbation method. The aim of this note is to examine the effectiveness of the finite perturbation calculation of ^{13}C chemical shifts in the simple molecular orbital method.[5]

In the finite perturbation theory, the shielding constant of the nucleus, A, in a liquid sample is expressed as:

$$\sigma^A = \sigma_d{}^A + \sigma_p{}^A,$$

$$\sigma_d{}^A = \frac{e^2}{3mc^2}\sum_{\mu\nu}P_{\mu\nu}(0)\langle\phi_\mu|r_A{}^{-1}|\phi_\nu\rangle,$$

$$\sigma_p{}^A = -\frac{1}{3}\sum_{\mu\nu}\sum_{\alpha}(H^{(0,1)}_{A\mu\nu})_\alpha(\partial/\partial H_\alpha[P^{Im}_{\mu\nu}(H_\alpha)])_{H=0},$$

$$(H^{(0,1)}_{A\mu\nu})_\alpha = (e\hbar/mc)\langle\phi_\mu|(r_A\wedge\nabla)_\alpha r_A{}^{-3}|\phi_\nu\rangle, \quad (\alpha=x, y, z), \tag{1}$$

where the gauge origin of the vector potential is set at the position of the nucleus, A. $P_{\mu\nu}(0)$ and $P_{\mu\nu}(H_\alpha)$ are the density-matrix elements without and with the magnetic perturbation, H_α, respectively. $P_{\mu\nu}(H_\alpha)$ is allowed to be complex to accommodate the purely imaginary nature of the perturbation, and $P_{\mu\nu}{}^{Im}(H_\alpha)$ represents its imaginary part. Then,

$$P_{\mu\nu}(H_\alpha) = 2\sum_i^{occ}C^*_{\mu i}C_{\nu i} = P^{Re}_{\mu\nu} + iP^{Im}_{\mu\nu}. \tag{2}$$

The LCAO coefficients, $C_{\mu i}$, are found by solving the Roothaan equation with the finite perturbation. The Fock matrix with the perturbation is given by:

$$F_{\mu\nu}(H_\alpha) = H^{core}_{\mu\nu} + iH_\alpha(H^{(1,0)}_{\mu\nu})_\alpha + \sum_{\lambda\sigma}P_{\lambda\sigma}(H_\alpha)[(\mu\nu|\lambda\sigma) - 1/2(\mu\sigma|\lambda\nu)],$$

$$(H^{(1,0)}_{\mu\nu})_\alpha = (e\hbar/2mc)\langle\phi_\mu|(r_A\wedge\nabla)_\alpha|\phi_\nu\rangle. \tag{3}$$

The equation used in the present calculation was simplified by means of the Alger, Grant, and Paul assumption[2] for the angular momentum operators. Then,

$$\langle\phi_\mu{}^A|\phi_\nu{}^B\rangle = \langle\phi_\mu{}^A|l_\alpha{}^A|\phi_\nu{}^B\rangle = 0,$$

$$\langle\phi_\mu{}^A|r_A{}^{-3}l_\alpha{}^A|\phi_\nu{}^B\rangle = \langle\phi_\mu{}^B|r_A{}^{-3}l_\alpha{}^A|\phi_\nu{}^B\rangle = 0,$$

$$l_\alpha{}^A = (r_A\wedge\nabla)_\alpha. \tag{4}$$

There is only one integral which survives the assumptions of Eq. (4) and that does not place all the orbitals on the A atom. It is the integral of the $\langle\phi_\mu{}^B|l_\alpha{}^A|\phi_\nu{}^B\rangle$ form, whose evaluation requires a translation of the coordinates, $l_\alpha{}^A = L_\alpha{}^{AB} + l_\alpha{}^B$. The term arising from the $L_\alpha{}^{AB}$ portion of $l_\alpha{}^A$ could be shown to be negligible; then:

$$\langle\phi_\mu{}^B|l_\alpha{}^A|\phi_\nu{}^B\rangle = \langle\phi_\mu{}^B|l_\alpha{}^B|\phi_\nu{}^B\rangle. \tag{5}$$

It was assumed here that the diamagnetic contribution, $\sigma_d{}^A$, is determined by the carbon 1s electrons. This assumption led to the value of 202.4 ppm for the diamagnetic contribution. The paramagnetic contribution, $\sigma_P{}^A$, was calculated from the INDO approximate molecular orbitals with Eqs. (1)—(5). The integral of $\langle\phi_\mu{}^A|r_A{}^{-3}l_\alpha{}^A|\phi_\nu{}^A\rangle$ in Eq. (1) reduces to the evaluation of $\langle r_A{}^{-3}\rangle_{2p}$. This was estimated by using the Slater 2p orbitals and by choosing the appropriate nuclear charge, Z_A. The effective nuclear charge was given by Eq. (6):

$$Z_A = 3.25 - 0.35(P_A - 4), \quad P_A = \sum_\lambda^A P_{\lambda\lambda}(0). \tag{6}$$

Since $P_{\mu\nu}{}^{Im}(H_\alpha)$ is an odd function of H_α, the derivatives in Eq. (1) are given approximately by:

$$(\partial/\partial H_\alpha[P^{Im}_{\mu\nu}(H_\alpha)])_{H=0} = P^{Im}_{\mu\nu}(H_\alpha)/H_\alpha. \tag{7}$$

The magnitude of H_α used was 5×10^6 Gauss; this gave about 10^{-3} a.u. as the perturbation energy. The diagonalization of the Hermitian matrix, F, was performed by means of a FACOM 230-60 computer in the Hok-

kaido University Computer Center, using a CDIAG program written by the author. The results are given in Table 1.

Although the approximation of the above calculation is of the same degree as that of Karplus and Pople[1b] or of Alger, Grant, and Paul's[2] semiempirical calculations, the estimated values of σ_p in Table 1 are about a half the values obtained by the latter average excitation approximation. Ditchfield, Miller, and Pople's *ab initio* calculation by the finite perturbation indicated an excellent agreement with the experimental values. However, the finite perturbation calculation in the simple molecular orbital method indicates rather poorer agreement with the experiment than does the average excitation method. This seems to be because the average excitation approximation cancels the neglect of the overlap integrals of the angular momentum operators. Recently Maciel *et al.*[5] have reported that he INDO finite perturbation calculation of ^{13}C chemical shifts with an altered set of parameters reproduced successfully the experimental results. However, they have not shown clearly why the standard INDO parameters should be altered.

Reactions of Tris(acetylacetonato)manganese(III) and -cobalt(III) with 1,10-Phenanthroline and α-Methylstyrene

Kyoji KAERIYAMA

Research Institute for Polymers and Textiles, Sawatari-4, Kanagawa-ku, Yokohama 221

(Received November 28, 1972)

Synopsis. Lower-valence-state compounds, bis(acetylacetonato)manganese(II) and bis(acetylacetonato)(1,10-phenanthroline)manganese(II), were prepared from tris(acetylacetonato)manganese(III). ESR spectra of manganese(II) compounds were shown. Bis(acetylacetonato)(1,10-phenanthroline)Co(II) was also prepared. The results were compared with activity for the initiation of radical polymerization.

In the course of studying the initiation reaction of radical polymerization by tris(acetylacetonato)manganese(III), $Mn(acac)_3$, and tris(acetylacetonato)cobalt(III), $Co(acac)_3$, the present author has found that these chelates react with α-methylstyrene and 1,10-phenanthroline to give anhydrous crystalline bis(acetylacetonato)manganese(II), $Mn(acac)_2$, bis(acetylacetonato) (1,10-phenanthroline)manganese(II), $Mn(acac)_2$-phen, and bis(acetylacetonato)(1,10-phenanthroline)-cobalt(II), $Co(acac)_2$phen.

The kinetic data of the polymerization can be explained by assuming that $Mn(acac)_3$ dissociats into $Mn(acac)_2$ and an acetylacetonyl radical on heating, and that $Mn(acac)_2$ and the acetylacetonyl radical recombine in the absence of a radical scavenger such as a vinyl monomer.[1] Bamford and Ferrar found that $Mn(acac)_3$/amine systes were much more active than $Mn(acac)_3$ and proposed a ligand-exchange mechanism.[2] In fact, Nishikawa, Nakanuma, and Kawaguchi obtained heterochelates of $Mn(acac)_2$ with primary amines from $Mn(acac)_3$ and $Mn(acac)_2(H_2O)_2$.[3] It was reported in previous papers that 1,10-phenanthroline accelerated the elimination of the acetylacetonyl radical from $Mn(acac)_3$.[4,5] In the present investigation, the effects of α-methylstyrene and 1,10-phenanthroline have been examined and discussed in connection with the activity of the initiation of radical polymerization.

A concentrated $Mn(acac)_3$ solution was heated in the presence of a radical scavenger, α-methylstyrene, which was not polymerized to a high polymer above room temperature. Crystalline $Mn(acac)_2$ was thus obtained in a high yield. This crystal remained anhydrous over a month under atmospheric conditions. Figure 1 shows its unique ESR spectrum. Its solution in pyridine gives a spectrum of six lines, as is shown in Fig. 2, although their separations are insufficient. They agree with the nuclear spin of Mn 5/2. These spectra may rise from the paramagnetic Mn(II) ion, which has a long relaxation time. Crystalline $Mn(acac)_2$ was also obtained in the presence of cyclohexanone. The $Mn(acac)_2$ gives the same ESR spectra as those shown in Figs. 1 and 2.

The reaction of $Mn(acac)_3$ with 1,10-phenanthroline resulted in the formation of heterochelate, $Mn(acac)_2$-phen, in a high yield. The chelate gives a symmetrical

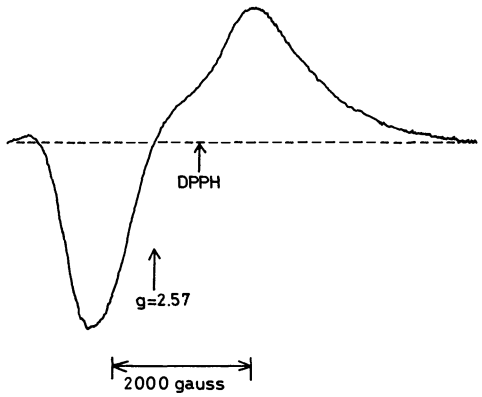

Fig. 1. ESR spectrum of $Mn(acac)_2$.

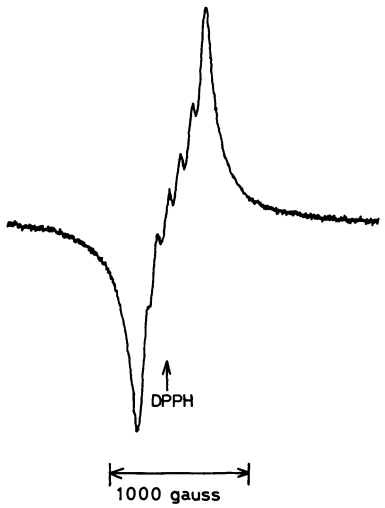

Fig. 2. ESR spectrum of $Mn(acac)_2$ solution in pyridine. $g = 2.0$

ESR spectrum, as is shown in Fig. 3. Its solution in pyridine gives the same spectrum as that shown in Fig. 2.

When a benzene solution of $Mn(acac)_3$ was heated without any such additives as α-methylstyrene, cyclohexanone, and 1,10-phenanthroline, no evidence of $Mn(acac)_2$ was obtained.

$Co(acac)_2$ could not be prepared from $Co(acac)_3$ in the presence of α-methylstyrene, but $Co(acac)_2$phen was obtained after the long heating of $Co(acac)_3$ in the presence of both α-methylstyrene and 1,10-phenanthroline. Although chromium and iron have the same two oxidation states as manganese and cobalt, it was impossible to get lower-valence-state chelates from their higher homologs.

$Mn(acac)_3$ is the most active for the initiation of radical polymerization, $Co(acac)_3$ is the second most

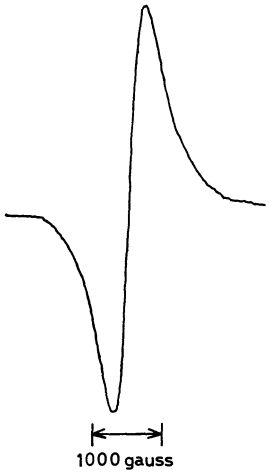

Fig. 3. ESR spectrum of 1,10-phenanthroline $Mn(acac)_2$.
$g = 2.0$

active, and $Fe(acac)_3$ and $Cr(acac)_3$ are inactive.[5] The same order of activity is observed in the present preparation of lower-valence-state compounds.

Experimental

A solution of 750 mg of $Mn(acac)_3$ in 5 ml of benzene and 5 ml of α-methylstyrene was heated for 40 hr at 70 °C under a high vacuum in a sealed tube. A yellow precipitate was thus separated. The solution was cooled to room temperature, and then the precipitate was collected on a sintered glass filter, washed with a small portion of benzene, and dried. Yield, 452 mg (84%). Found: C, 47.35; H, 5.35%. Calcd for $MnC_{10}H_{14}O_4$: C, 47.44; H, 5.57%.

Instead of α-methylstyrene, a 5 ml portion of cyclohexanone was used. The same procedure as that described above gave a yield of 231 mg (43%). Found: C, 48.34; H, 5.34%.

In 10 ml of benzene were heated 750 mg of $Mn(acac)_3$ (2.13×10^{-3} mol) and 422 mg of 1,10-phenanthroline (2.13×10^{-3} mol) for 22 hr at 70 °C. A yellow precipitate was thus obtained. Yield, 848 mg (92%). Found: C, 61.89; H, 4.68; N, 6.18%. Calcd for $MnC_{10}H_{14}O_4 \cdot C_{12}H_8N_2$: C, 60.97; H, 5.11; N, 6.47%.

A solution of 1.0 g of $Co(acac)_3$ and 587 mg of 1,10-phenanthroline in 5 ml of benzene and 5 ml of α-methylstyrene was heated for 5 days at 70 °C. $Co(acac)_2$ phen was thus precipitated from the solution. Yield, 717 mg (58.4%). Found: C, 60.53; H, 4.75; N, 6.85%. Calcd for $CoC_{10}H_{14}O_4 \cdot C_{12}H_8N_2$: C, 60.42; H, 5.07; N, 6.41%.

ESR measurements were made on samples in a capillary by using the JES-3BS-X apparatus of the Japan Electron Optics Laboratory. The frequency of the microwave was around 9450 Mc.

The author is grateful to Dr. M. Suzuki, Dr. S. Ueda, and Mr. Y. Shimura for their interest and encouragement during this work, and also to Dr. K. Someno for his useful suggestion with regard to the ESR spectroscopy.

The Synthesis of Crystalline Hydrated Double Carbonates of Rare Earth Elements and Sodium

Akihiko MOCHIZUKI, KOZO NAGASHIMA, and Hisanobu WAKITA*

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo 112

**Department of Chemistry, Faculty of Science, Fukuoka University, Fukuoka 814*

(Received June 25, 1973)

Synopsis. Crystalline hydrated double carbonates of rare-earth elements and sodium were obtained by adding sodium carbonate solutions to rare-earth chloride solutions. The formula of the precipitates was determined to be $LnNa(CO_3)_2 \cdot 6H_2O$ (Ln=La, Ce, Nd, Sm, Gd, Dy, and Y). The products have similar X-ray powder diffraction patterns, which were indexed assuming a tetragonal symmetry. The cell parameters of the products were calculated, they decrease linearly with the decrease in the ionic radii of the rare-earth elements.

In preceding papers,[1] the preparation, formation temperature, optical properties, infrared spectra, and TG data of crystalline hydrated oxocarbonates and crystalline hydrated normal carbonates of rare-earth elements were reported. One of the articles[1] also included the formation of the crystalline hydrated double carbonates of rare-earth elements and sodium (rare-earth element: sodium=1: 1). As for the double carbonates with a 1: 1 composition, though, very little has been known so far. Tselik *et al.*[2] reported the formation of Y: Na=1: 1 double carbonate by mixing solutions of sodium carbonate and yttrium chloride. It is not clear, however, whether their product is of a crystalline or an amorphous phase.

In this study, the synthesis of crystalline double carbonates of rare-earth elements and sodium was attempted at various temperature in order to make clear the formation temperatures of double carbonates. Some other properties of the products were also studied.

Experimental

To solutions of 0.05 M rare-earth chlorides we added acetic acid-sodium acetate buffer solutions of pH 5; then we vigorously stirred in excessive amounts of solutions of sodium carbonates. The solutions containing the precipitates were stored in an air bath kept at the temperatures of 20, 30, 40, 50, 60, 70, and 80 °C, for four days. The changes in the crystallinity of the product during the aging were checked by X-ray powder diffractometry. In the dry air, the precipitates are not stable and slowly change into another phase; therefore, studies such as chemical analysis, X-ray powder diffractometry, thermal analysis, infrared spectrometry, and the measurement of the refractive index were carried out immediately after filtration.

Results

Chemical Analysis. The rare-earth elements used for the preparation of the double carbonates were La, Ce, Nd, Sm, Gd, Dy, Y, Er, Yb, and Sc. The products of La, Ce, Nd, Sm, Gd, Dy, and Y were obtained in crystalline form, while those of Er, Yb, and Sc were obtained in amorphous form. The results of the chemical analysis of Gd and Y compounds are shown in Table 1. On the basis of these results, the chemical formulas for the synthesized double carbonates were determined to be $LnNa(CO_3)_2 \cdot 6H_2O$ (Ln=rare-earth elements).

Table 1. Chemical analysis of double carbonates

Rare earth element	M_2O_3 :	CO_2 :	H_2O :	Na_2O
Gadolinium	1.00	1.97	6.05	0.98
Yttrium	1.00	1.97	5.95	1.00

The formation temperatures of the double carbonates by means of the present procedure are shown in Fig. 1. The La and Ce precipitates were found to be mixtures of double carbonates and lanthanite-type carbonates, $Ln_2(CO_3)_3 \cdot 8H_2O$, while the Nd, Sm, Gd, Dy, and Y compounds were double carbonates showing the same X-ray powder diffraction pattern.

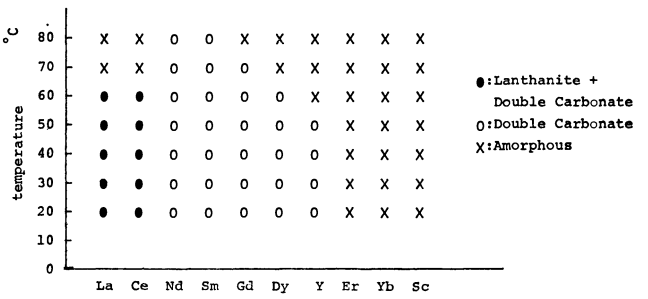

Fig. 1. Diagram showing the formation temperature of double carbonates.

X-Ray Data. The X-ray powder patterns were recorded on a Rigaku Denki Co., Ltd. The data of the synthesized crystalline, hydrated double carbonates of rare-earth elements and sodium are given in Table 2. The sample grains are too fine to be submitted to single crystal X-ray analysis. The indexing of the X-ray powder lines was done by the use of the indexing charts given by Bell *et al.*[3] The probable indices for the powder data, assuming a tetragonal symmetry, are listed in Table 2. The assumed tetragonal symmetry is consistent with the optical properties. Based on these indexings, the unit-cell dimensions and unit-cell volumes were calculated. The results are also shown in Table 2. The relations between the unit-cell parameters and the ionic radii of rare-earth elements are shown in Fig. 2. Using the cell parameters and measured density (2.31 g/cm^3 at 20 °C) for the Y compound, the number of formula units per unit cell was calculated as eight. Since all the reflexions of $h00$ are observed in the X-ray powder patterns, the space group of the materials may be one

c=9.93Å			c=9.85Å		c=9.77Å		c=9.69Å		c=9.65Å	
V=1706.7Å^3			V=1677.5Å^3		V=1648.6Å^3		V=1620.0Å^3		V=1605.8Å^3	

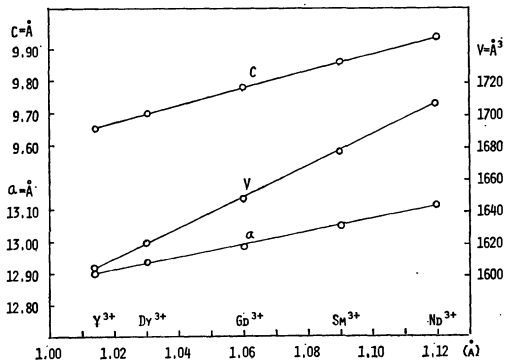

Fig. 2. Relationships between ionic radii of rare earth elements and unit cell parameters.

of P4 symmetries. These space groups have a four-fold axis in the unit cell, which is consistent with the fact that the materials have eight formula in a unit cell.

Refractive Indices. Under the microscope, the synthesized materials were very small rectangles and exhibited a straight extension. The refractive indices of the materials were determined by the immersion method. The immersion media were checked with an Abbe refractometer. The refractive indices of the Nd, Sm, Gd, and Dy compounds were found to have the same values of $\gamma=1.554$ and $\alpha=1.546$ within the limits of experimental error (± 0.001). The refractive indices of the Y compound are $\gamma=1.541$ and $\alpha=1.534$. The size of the crystals was so small that β and 2V could not be determined.

Infrared Absorption Spectra. The infrared absorption spectra were obtained by the KBr disk method. The absorption curve of the Nd compound is shown in Fig. 3 as an example. All the double carbonates of the rare-earth elements show spectra very similar as that in Fig. 3. The ν_1 band of CO_3^{2-} appears at 1070 cm^{-1} as a singlet absorption. On the other hand, the ν_2 and ν_3 band appears as doublet bands. The ν_2 band has peaks at 875 and 850 cm^{-1}, while ν_3 has its at 1530 and 1385 cm^{-1}. These splittings of ν_2 and ν_3 are rather common in rare-earth carbonates.[1] They may be due to the coupling between neighboring carbonate ions and/or to occupying two structurally different sites in the unit cell.

Thermal Analysis. The TG and DSC curves of Nd and Gd compounds are shown in Fig. 4. Based

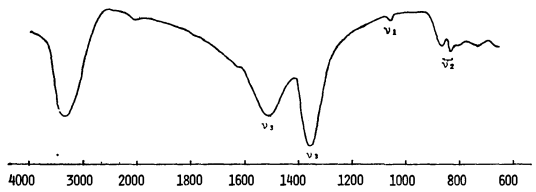

Fig. 3. Infrared absorption spectrum of double carbonate of neodymium and sodium.

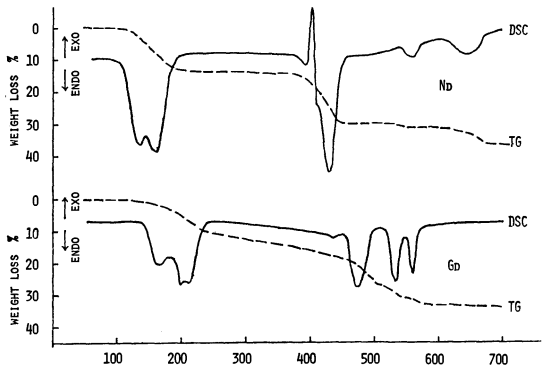

Fig. 4. TG and DSC curves of double carbonates.

on the TG data, the process of the thermal decomposition of each sample may be considered to take place in one of the following ways.

(1) $NdNa(CO_3)_2\cdot 6H_2O \xrightarrow[120\sim200°C]{} NdNa(CO_3)_2\cdot 3H_2O \xrightarrow[370\sim450°C]{} NdNa(CO_3)_2 \xrightarrow[650°C]{} NdNaO(CO_3)$

(2) $GdNa(CO_3)_2\cdot 6H_2O \xrightarrow[70\sim200°C]{} GdNa(CO_3)_2\cdot 2H_2O \xrightarrow[370\sim450°C]{} GdNa(CO_3)_2\cdot H_2O \xrightarrow[400\sim600°C]{} GdNaO(CO_3)$

The decomposition process of Sm carbonate is very similar to that of Nd carbonate, while the processes of Dy and Y carbonates are similar to that of Gd carbonate.

Studies on Preparation of High Purity Sulfur. II. Removal of Trace Amounts of Selenium and Tellurium in Sulfur by Means of Distillation with Silver

Hiroshi SUZUKI, Yasuaki OSUMI, Masanori NAKANE, and Yoshizo MIYAKE

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received June 30, 1973)

Synopsis. In the distillation without silver, most of the selenium and tellurium in crude sulfur appeared in the distillate. However, these impurities were removed by distillation using a column which was filled with silver and heated at 600—700 °C. The removal of them in the process was confirmed in a tracer experiment.

Selenium and tellurium are the main impurities in sulfur; however, few works have been published on the removal of trace amounts of these impurities.

Slepanov *et al.*[1] reported that 84.6% of the selenium in sulfur could be removed by treating molten sulfur in an aqueous magnesium chloride with nitric acid. Devyatykh *et al.*[2] reported that the removal of selenium was difficult during the purification of sulfur, by passing sulfur vapor through a high-temperature zone, because it formed a compound with sulfur. Nothing can be found in literature concerning the removal of tellurium in sulfur.

A method offers an investigation of distillation with silver as for the removal of selenium and tellurium in sulfur. A tracer experiment using ^{75}Se and ^{127m}Te has been undertaken in order to ascertain the effect of silver on the removal of trace amounts of the impurities.

Experimental

Determination of Selenium in Sulfur.[3] The sample solution was prepared by heating 5 g of sulfur with 15 ml of bromine and 60 ml of 30% nitric acid. To an aliquot of a sample solution (0.5 g sulfur), after neutralization, 12 g of ammonium chloride and 2 ml of 2 M formic acid were added and its pH was adjusted to 2—3. Ten ml of a 10% ethylenediaminetetraacetic acid solution and 2 ml of a 0.5% of diaminobenzidine solution were then added, the mixture was heated on a water both for 5 minutes and cooled, and its pH was adjusted to 6—7. The selenium complex in the solution was subsequently extracted in 10 ml of toluene, and its absorbance was measured at 420 nm.

Determination of Tellurium in Sulfur.[4] To an aliquot of a sample solution (1—4 g sulfur), about a 30 mg portion of ferric ions was added, precipitated with ammonia water, filtered, and washed with water. The solution obtained by dissolving the precipitate in 2 ml of 2 M hydrochloric acid and by then diluting the mixture to 10 ml with water was passed through an ion-exchange resin column (1 cm × 10 cm, Amberlite IR-120, H-form, 60 mesh). To the residue, obtained by evaporating the effluent and washing solution, 2.8 ml of water, 1 ml of a 40% ammonium citrate solution, and 2 ml of a 0.1% diethyldithiocarbamate solution were added, and the mixture was diluted to 10 ml with water. The tellurium complex in the solution was extracted in 5 ml of tributyl phosphate and measured at 400 nm.

Filling Material Containing Silver. The material, such as activated alumina, alumina ball, silica gel or a pumiceous substance, was digested in a silver nitrate solution. That containing silver was dried at 100 °C and then heated at 800 °C for 1 hr.

Preparation of Sulfur Containing ^{75}Se and ^{127m}Te. Into a flask of distillatory ^{75}Se (20 μCi, as Na_2SeO_3, 2.14 mCi/mg Se) and ^{127m}Te (450 μCi, as H_2TeO_3, 0.228 mCi/mg Te), 1 ml of hypophosphorous acid was added, and the mixture was dried at 100 °C. Into the flask a 30 g portion of sulfur was then taken, heated at 200 °C for 1 hr, and then distilled under a nitrogen atmosphere. The ^{75}Se and ^{127m}Te in the distilled sulfur were 41.5% and 92.6% respectively of these added to the flask.

Measurement of ^{75}Se and ^{127m}Te in Sulfur. In a 19-mmϕ aluminium dish, 0.5 g of sulfur was placed; then it was heated at 140 °C to melt and cooled slowly. The γ-rays from ^{75}Se and ^{127m}Te were simultaneously measured by the method described by Lee,[5] using a 100-channel scintillation spectrometer.

Distillation of Sulfur. The distilling apparatus used was the same as has been described in a previous paper.[6] The sulfur sample was distilled with a heated column, filled with filling material.

Results and Discussion

Table 1 shows the effect of silver on the removal of

a) Sulfur sample: Amount; 2 g, Se content; 3.00 ppm, Te content; 6.30 ppm, Se total activity; 293959 cpm, Te total activity; 47839 cpm. Column temperature: 600 °C. The bed of filling material was about 7 cm long. b) 8—12 mesh. c) Distillation without filling material.

selenium and tellurium. In the distillation without silver, most of the selenium and tellurium in crude sulfur appeared in the distillate. However, both the impurities were removed by distillation using a column filled with silver supported on a pumiceous substance or activated alumina. The effect of silver is related to the affinity of silver for selenium and tellurium. It has been established that silver has more affinity for selenium than for sulfur.[7] It seemes that silver reacts slowly with sulfur, but reacts rapidly with selenium and tellurium in the process. Consequently, sulfur passed through the column, while selenium and tellurium remained in the column.

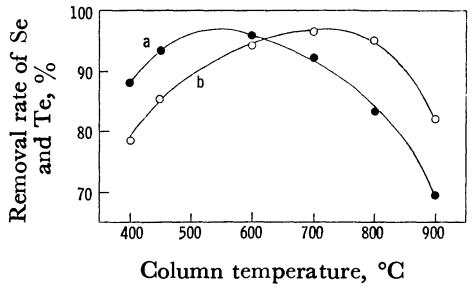

Fig. 1. The effect of temperature of column filled with silver on the removal of Se (a) and Te (b).
Sulfur sample: Amount; 10 g, Se content; 117 ppm, Te content; 56 ppm. The column was filled with 2 g of silver supported on 20 g of pumiceous substance (4—8 mesh) about 20 cm long.

Figure 1 shows the effect of the column temperature on the removal of the impurities. Both impurities were effectively removed with the column heated at 600—700 °C.

Figure 2 shows the effect of the amount of silver in the column on the removal of the impurities during the distillation of 10 g of sulfur. Effective removals of selenium and tellurium were shown when more than 1.7 and 1.0 g of silver respectively were present in the column. The reduction of the amount of silver in the column caused a decrease in the removal rates of the impurities; this was because the sulfuration of silver in the column progressed rapidly, while produced

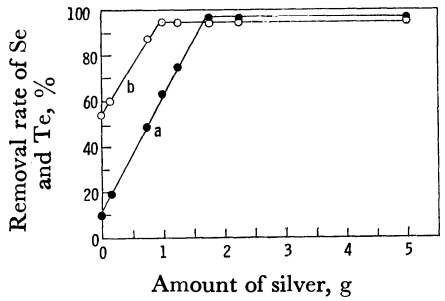

Fig. 2. The effect of amount of silver in column on the removal of Se (a) and Te (b).
Sulfur sample: Amount; 10 g, Se content; 117 ppm, Te content; 56 ppm. The columns were filled with various amounts of silver supported on 20 g of pumiceous substance (4—8 mesh) about 20 cm long. Column temperature: 600 °C.

sulfide did not react with selenium and tellurium.

The reproduction of the column in which silver had been converted into sulfide was easily carried out by passing air or oxygen through the column heated at more than 600 °C.

The removal of them was confirmed in a tracer experiment as shown in Table 2.

Studies on Preparation of High Purity Sulfur. IV. Effect of the Distillation with Adsorbent and Silver on the Removal of the Impurities in Sulfur[1)]

Hiroshi SUZUKI, Kunishige HIGASHI, and Yoshizo MIYAKE

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received July 16, 1973)

Synopsis. The distillation was shown to be effective in removing arsenic, selenium, tellurium, carbon, and common elements in sulfur. However, there was the disadvantage that trace amounts of common elements were not reduced further by the repetition of the distillation. This could be carried out by the zone refining.

In the course of studies of the preparation of high-purity sulfur, the removals of trace amounts of the main impurities, such as arsenic, selenium, tellurium, and carbon, have been separately presented in previous papers.[2-4)]

In order to remove the impurities simultaneously, a distillation of sulfur, using an adsorbent and silver, was proposed. In the distillation, the removal of the impurities was ascertained. Simultaneously, the ignition residue of the distilled sulfur and the common elements in the ignition residue were investigated.

The distillation was shown to be effective in removing various impurities in sulfur. At the same time it was found that trace amounts of the common elements remained in the distilled sulfur.

The zone refining of sulfur[5-8)] was carried out parallel with the distillation. The experimental results suggest that trace amounts of the common elements in the distilled sulfur can be further reduced by the technique.

Experimental

Distillation of Sulfur. The distilling apparatus and the silver supported on a pumiceous substance were the same as have been described in a previous paper.[3)] The column of the distilling flask, 50 cm long, was filled with the silver. In the flask, 50 g of a sulfur sample and 5 g of activated carbon (24—40 mesh) were then taken. The column was heated at 600 °C, the flask was heated below 500 °C, and the sulfur was distilled in a flow of inert gas.

Zone Refining. Sixty grams of sulfur were placed in a glass tube (15 mmϕ) and heated at 140 °C for several hours. After the atmosphere of the tube had then been replaced with nitrogen, the tube (30 cm long) was sealed. It was kept horizontal, heated to melt the sulfur, and then cooled slowly. A horizontal zone-refining apparatus was used. The conditions of the zone refining were as follows: zone width, 3 cm; speed of zoning, 1 cm per hour; pass of zone, 10 times.

Determination of the Impurities in Sulfur. The arsenic, selenium, and tellurium were separately determined by the spectrophotometric methods described in previous papers.[2,3)]

The common elements in the ignition residue of sulfur were determined by the spectrographic method. A sulfur sample was mixed with graphite powder in a proportion of 10: 1 in a platinum crucible and then heated to the melting point. Then, the graphite powder remaining in the crucible was heated at 650 °C for 3 hr; it was afterward transferred into a capsule and shaken sufficiently with the mixer mill. A weighed portion of this was used as the sample for measurements. The intensities of the spectral lines of the elements, such as Co, Si, Fe, Pb, Cu, Mg, Ca, Al, Cd, B, Bi, Ag, and Sn, were simultaneously measured by using a direct-reading emission spectrometer (Shimadzu, Ebert Grating Spectrometer GEM-340).

Results and Discussion

The distillation with an adsorbent and silver was compared with the distillations without them with respect to the removal of various impurities. The former distillation was more effective than the latter, as is shown in Table 1.

Arsenic was adsorbed to the activated carbon, and it remained in the flask. While sulfur vapor passed through the column, selenium and tellurium were caught in it, because they reacted rapidly with the heated silver in it. The removal rates of arsenic, selenium, and tellurium by the distillation were about 99, 95, and 95% respectively. The repetition of the

														24—30	3.2	79	20

* No detection.

distillation was effective in removing trace amounts of the impurities.

Although it is not shown in Table 1, most of the carbonaceous impurity was removed, and the halogen was removed somewhat. The carbonaceous impurity was decomposed rapidly and separated from the sulfur in the process, by which it was brought in contact with the heated silver in the column.

The common elements were effectively removed, too. Their contents in the sulfur were all reduced to the range of $n \times 10^{-1}$—10^{-2} ppm. However, there was the disadvantage that trace amounts of the common elements remaining in the distilled sulfur were not reduced further by the repetition of the distillation.

Table 2 shows the contents of various impurities in the fraction of sulfur traversed by molten zones. The results of the experiment showed that the contents of most of the common elements were reduced, and suggested that trace amounts of the impurities in sulfur could be reduced by zone refining. At the same time, it was found that the contents of arsenic, selenium, and tellurium could not be expected to be reduced, for the impurities in sulfur had unfavorable coefficients.

By the distillation, such impurities as arsenic, selenium, tellurium, and carbon were effectively removed, and the common elements were reduced to trace amounts. The further reduction of the common elements could be carried out by the zone refining.

The Extraction and Spectrophotometric Determination of Vanadium(IV) with Tiron[1]

Yoshinobu WAKAMATSU and Makoto OTOMO*

Department of Industrial Chemistry, Hachinohe Technical College, Hachinohe 031

**Department of Synthetic Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466*

(Received August 6, 1973)

Synopsis. The vanadium(IV)-Tiron chelate can be extracted into a mixed solvent of 1:4 isopentyl alcohol-chloroform in the presence of 1,3-diphenylguanidinium salt. Beer's law was obeyed up to 36 μg vanadium per 10 ml of the solvent.

Tiron reacts with vanadium(IV, V) to form water-soluble chelates. Tserkovnitskaya *et al.*[2] studied the complex formation between vanadium(IV) and Tiron in an aqueous solution. On the other hand, Sarma[3] and Nishikawa *et al.*[4] applied the vanadium(V)-Tiron chelate to the visible and ultraviolet spectrophotometric determination of vanadium(V) in an aqueous solution.

The present paper will describe the spectrophotometric determination of vanadium(IV), which is based on the extraction of the vanadium(IV)-Tiron chelate into a mixed solvent of 1:4 isopentyl alcohol–chloroform in the presence of excessive 1,3-diphenylguanidinium-(DPG) salt. The combining ratio of vanadium, Tiron, and DPG in the extracted species has also been determined by a spectrophotometric method.

Experimental

Reagents and Apparatus. A stock solution of vanadium (IV) (about 0.01 M) was prepared by dissolving a reagent grade vanadium(IV) sulfate in distilled water and then standardized against a standard EDTA solution, using Cu–PAN as the indicator.[5] All the other reagents and apparatus used were the same as those reported previously.[6]

Standard Procedure. To a sample solution containing up to 36 μg of vanadium in a 50 ml separatory funnel we added 1.0 ml of a 0.56 M ascorbic acid solution, 4.0 ml of a 0.2 M Tiron solution, and 10.0 ml of a 0.34 M DPG solution which had been adjusted to pH 3.5 with a 0.2 M monochloroacetic acid solution and a 0.2 M sodium acetate solution. The solution was diluted with water to 20.0 ml, allowed to stand for 20 min, and shaken for 10 min with 10.0 ml of a mixed solvent of 1:4 isopentyl alcohol–chloroform. The absorbance of the organic phase was then measured at 585 nm using a reagent blank as the reference.

Results and Discussion

Absorption Spectra. The absorption spectra of the vanadium(IV)-Tiron chelate in an aqueous solution and the ion association complex extracted into the solvent are shown in Fig. 1. The absorption maxima of the vanadium(IV) Tiron chelate and the ion-association complex are found at 565 and 585 nm respectively. Tiron is not extracted into the solvent, not even in the presence of DPG salt at pH 3.5.

The Effect of the pH. The effect of the pH of the aqueous phase on the extraction is shown in Fig. 2.

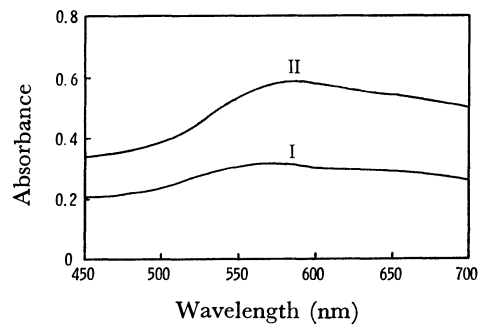

Fig. 1. Absorption spectra of the V(IV)-Tiron chelate in aqueous phase and the association complex in organic phase.
Tiron: 4.0×10^{-2}M, Ascorbic acid: 2.8×10^{-2}M, pH: 3.5, I: V(IV)-Tiron chelate, V(IV); 38.$_8$ μg, II: association complex, V(IV); 28.$_5$ μg, DPG; 0.17M.

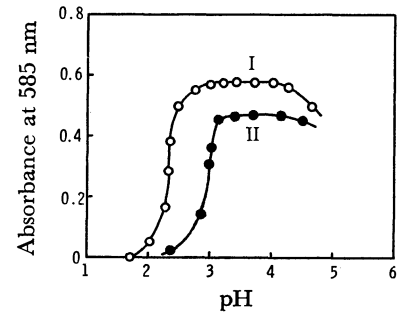

Fig. 2. Effect of pH on the extraction of V(IV)-Tiron-DPG.
V(IV): 28.$_5$ μg, DPG: 0.17M, Ascorbic acid: 2.8×10^{-2}M, Tiron: I; 4.0×10^{-2}M, II; 5.0×10^{-3}M.

The maximum extraction is reached at pH 2.9—4.1 when the association complex is extracted into the solvent from an aqueous solution containing 4.0×10^{-2} M Tiron. The wavelength of maximum absorption was independent of the pH of the aqueous phase.

The Effect of the Additives. The effect of the Tiron and the DPG concentrations on the extraction was investigated separately by varying the Tiron and the DPG concentrations respectively. It was found that the absorbances of the organic phase were essentially constant provided that the Tiron and the DPG concentrations in the initial aqueous phase were more than 3.0×10^{-2} M and 0.13 M respectively.

Choice of Solvent. The vanadium(IV)-Tiron-DPG association complex can be readily extracted into aliphatic alcohols; its extractability is analogous to those of the corresponding titanium complex.[6] A 1:4 mixed solvent of isopentyl alcohol and chloroform, which proved to give the highest absorbance, was chosen as the solvent.

The Effect of the Standing Time. The formation of the vanadium(IV)-Tiron chelate does not occur instantaneously in an aqueous solution, about 20 min being required to obtain the maximum absorbance. The absorbance of the organic phase remains almost constant for at least 5 hr if the vanadium(IV)-Tiron-DPG association complex is extracted into the solvent after the reaction mixture has been allowed to stand for 20 min.

The Effect of the Shaking Time. It was found that shaking for 5 min sufficed; for safety, though, a shaking time of 10 min was selected. The aqueous phase was colorless after one extraction, indicating that only one extraction is needed for the complete extraction of the association complex.

Calibration Curve. A calibration curve for the determination of vanadium(IV) was prepared under the optimum conditions. A good linear relationship was obtained over the concentration range from 0 to 36 μg of vanadium per 10 ml of the solvent. The molar absorptivity of the extracted species was approximately 1.03×10^4 at 585 nm, 1.4 times as high as that of the vanadium(V)-Tiron chelate at 310 nm.[4] The proposed method is comparable in sensitivity to the Methylthymol Blue method.[7]

Table 1. Effect of metal ions

V(IV): 2.8×10^{-5}M (28.5 μg), Tiron: 4.0×10^{-2}M, DPG: 0.17M, Ascorbic acid: 2.8×10^{-2}M, pH: 3.5

Metal ion	Amount added (μg)	V(IV) found (μg)
Fe(III)	30	28.5
	200	28.4
Al(III)	30	28.3
	200	28.8
Ti(IV)	60	28.3
	960	34.3
	960	28.2[a]
Th(IV)	200	29.0
U(VI)	200	28.9
W(VI)	30	28.4
	200	29.7
Mo(VI)	200	29.7

a) 2 ml of NaF (0.1M) was added.

The Effect of Diverse Ions. The effect of diverse ions on the determination of vanadium(IV) was examined. The effect of metal ions is summarized in Table 1. Divalent metal ions such as nickel, lead, cadmium, copper, calcium, and magnesium up to at least 200 μg do not interfere with the determination. Molybdenum(VI) and tungsten(VI), when present in large quantities, give positive errors. The interferences from iron(III) and titanium(IV) can be eliminated by the addition of ascorbic acid and sodium fluoride (0.01 M) respectively. Of the anions tested, chloride, sulfate, nitrate, phosphate, fluoride, and tartrate have no effect on the determination even when present in a molar concentration 500 times that of vanadium(IV). Chelating agents such as EDTA and CyDTA, however, interfere seriously.

The Composition of the Extracted Species. The combining ratios of Tiron and DPG to vanadium(IV) in the extracted species were deduced by a spectrophotometric method.[6] The number of moles of Tiron in the association complex was determined by plotting log(the distribution ratio of vanadium, D_v) against log(the total concentration of Tiron, $[H_2R]_t$). The pH and the total concentration of DPG were kept constant at 3.5 and 0.17 M respectively. The slope of the straight-line portion indicates that the vanadium: Tiron ratio is 1: 2. In the same manner, the number of moles of DPG in the association complex was determined by plotting $\log D_v$ against log(the total concentration of DPG, $[DPG]_t$), the pH and the total concentration of Tiron being kept constant. The slope of 6.1 suggests that one vanadium(IV)-Tiron chelate anion associates with six DPG cations to form an extractable neutral species. The pH dependence of the extraction was then examined by plotting $\log D_v$ against the pH value of the aqueous phase. The results are shown in Fig. 3. The slope of 4.1, which is calculated by the method of least-squares, indicates that four protons are concerned with the extraction process.

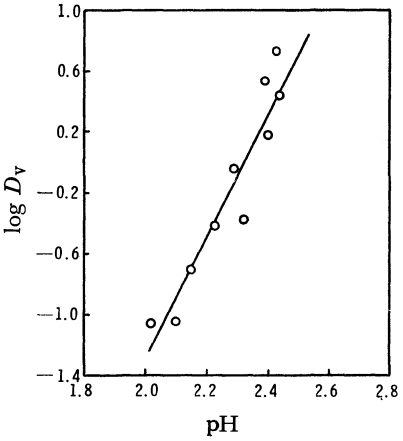

Fig. 3. Relationship between log D_v and pH for the V(IV)-Tiron-DPG system.
V(IV): 2.8×10^{-5}M, Tiron: 4.0×10^{-2}M, DPG: 0.17M, Ascorbic acid: 2.8×10^{-2}M.

From the foregoing observations, it seems natural to express the extraction equilibrium expression in the simplest form:

$$VO^{2+} + 2H_2R^{2-} + 6(DPG)^+ \rightleftarrows VO(R)_2(DPG)_6 + 4H^+$$

$$[VO(R)_2(DPG)_6] \rightleftarrows [VO(R)_2(DPG)_6]_0$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(3), 763—764 (1974)

A Novel Type of Penta-Coordinated Iron(III) Complex $FeCl[SSeCNR_2]_2$ ($R=CH_3$, C_2H_5)

Shunji NAKAJIMA and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received October 6, 1973)

Synopsis. The titled compounds were prepared, and the magnetic susceptibility and electronic spectrum were measured; the two weak bands observed in the near-infrared region are assigned as spin-forbidden d-d bands.

We have previously reported on some *N,N*-dialkylthioselenocarbamate complexes of tin(IV),[1] nickel(II), palladium(II), platinum(II),[2] and gold(III),[3] in which the thioselenocarbamate, $\left[\begin{matrix}S\\Se\end{matrix}\!\!\diagdown\!\!\!\!\diagup C{=}N\!\!\diagup\!\!\!\!\diagdown\begin{matrix}R\\R\end{matrix}\right]^-$ ($R=CH_3$, C_2H_5), coordinates through both the sulfur and selenium atoms. Recently, Heber *et al.*[4] prepared a variety of metal *N,N*-diethylthioselenocarbamates by the reaction of metal ions with $(C_2H_5)_2NH_2\cdot SSeCN(C_2H_5)_2$.

Our recent study has shown that the reaction of $FeCl_3$ with dimethylchlorotin(IV) *N,N*-dialkylthioselenocarbamate, $(CH_3)_2ClSn[SSeCNR_2]$ ($R=CH_3$ and C_2H_5), gave a novel type of penta-coordinate complex, $FeCl[SSeCNR_2]_2$. This paper will report the preparation and properties of this complex.

Experimental

Materials. Dimethylchlorotin(IV) *N,N*-dimethyl-[1] and *N,N*-diethylthioselenocarbamates,[2] $(CH_3)_2ClSn$(dmtsc) and $(CH_3)_2ClSn$(detsc) (dmtsc=$SSeCN(CH_3)_2$, detsc=$SSeCN(C_2H_5)_2$), were prepared as has been described elsewhere.

Preparation. An ethanol–ligroin (1 : 3 vol/vol) solution (20 ml) of $FeCl_3$ (1.2 mmol) was added, drop by drop, into $(CH_3)_2ClSn$(dmtsc) (3.7 mmol) in an ethanol–ligroin (1 : 5 vol/vol) mixture (100 ml) on an ice-bath, after which the solution was stirred for a further 30 min at 0 °C. The precipitate thus obtained was washed with chloroform several times and then dried *in vacuo* to give a black powder of $FeCl$(dmtsc)$_2$ (1.1 mmol) (mp >250 °C).

Found: C, 17.28; H, 3.15; N, 6.80%. Calcd for $C_6H_{12}N_2S_2Se_2ClFe$: C, 16.93; H, 2.81; N, 6.58%. ν(C=N) 1551 cm^{-1} and μ^{eff} 4.00 BM.

$FeCl(detsc)_2$ was similarly prepared by the reaction of $FeCl_3$ (6.2 mmol) with $(CH_3)_2ClSn$(detsc) (12—18 mmol). Recrystallization was done from a chloroform–ethanol mixture to give black crystals (3.0 mmol) (mp ~240 °C (decomp.)).

Found: C, 24.66; H, 4.36; N, 5.73%, mol wt, 487 in $CHCl_3$ by a vapor-pressure osmometer. Calcd for $C_{10}H_{20}N_2S_2Se_2ClFe$: C, 24.93; H, 4.19; N, 5.82%; mol wt, 482. ν(C—N) 1509 cm^{-1} and μ^{eff} 3.90 BM.

Physical Measurements. Magnetic susceptibility was measured for micro-crystalline materials by the Gouy method at room temperature. The infrared spectra were recorded in Nujol mulls on a Hitachi-Perkin Elmer 225 spectrophotometer, while the electronic spectra covering the near-infrared region were measured on a Hitachi EPS-03 or 124 spectrophotometer with a 1 cm quartz cell at 25 °C.

Results and Discussion

The reaction of $FeCl_3$ with $(CH_3)_2ClSn$(dmtsc) or its *N,N*-diethyl derivative at the mole ratio of 1 : 3 was carried out with a view to obtaining $Fe(dmtsc)_3$ or $Fe(detsc)_3$. We have not, however, been successful in isolating the tris-carbamate complex, even in several reaction conditions differing from that described in the Experimental section, such as at an elevated temperature and with prolonged stirring. Instead, the reaction yielded two complexes of a novel type, $FeCl(dmtsc)_2$ and $FeCl(detsc)_2$. This is in contrast with the results reported by Heber *et al.*,[4] who obtained $Fe(detsc)_3$ by the reaction of the Fe(III) ion with $(C_2H_5)_2NH_2$(detsc) in a methanol–water mixture.

Both the complexes obtained are somewhat sensitive to humidity in air. Molecular-weight determination indicates that the detsc complex is essentially monomeric in chloroform; the dmtsc complex is not sufficiently soluble in common organic solvents to determine the molecular weight.

The magnetic moments of the dmtsc and detsc complexes indicate the presence of three unpaired electrons. This may be compared with the results reported for halogenoiron(III) bis(*N,N*-dialkyldithiocarbamate), $FeX[S_2CNR_2]_2$ (X=Cl, R=CH_3, C_2H_5, and *sec*-C_4H_9; X=Br and I, R=C_2H_5),[5] the chloroiron(III) *N,N*-diethyl derivative of which has been reported to have an approximate square pyramidal structure, with the iron atom lying above the basal plane formed by the four sulfur atoms.[6] The electronic configuration suggested for these dithiocarbamates, $[(3d_{xy})^2(3d_{xz}3d_{yz})^2(3d_{z^2})^1(3d_{x^2-y^2})^0]$,[5] will be found in $FeCl(dmtsc)_2$ and $FeCl(detsc)_2$.

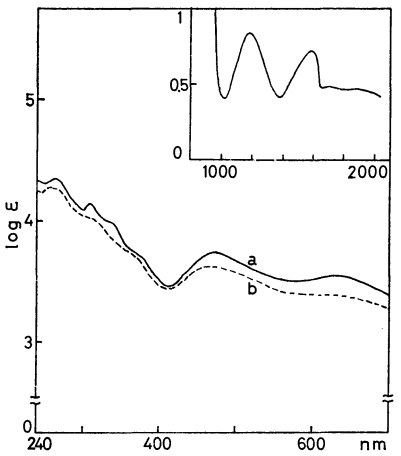

Fig. 1. Electronic spectra of $FeCl(detsc)_2$ (a) and $FeCl(dmtsc)_2$ (b) in dichloromethane.

Table 1. Electronic spectra in dichloromethane; band maxima (kK) and log ε (in parenthesis)

Complex	d-d band	CT band	Ligand band
$FeCl(dmtsc)_2$	16.0 (3.39)	26.5 (3.76)	32.3 (4.04)
	21.4 (3.62)	28.5 (3.82)	38.5 (4.27)
$FeCl(detsc)_2$	6.25 (0.72)	26.6 (3.72)	32.3 (4.14)
	8.40 (0.83)	29.9 (4.01)	37.6 (4.36)
	15.6 (3.54)		
	21.1 (3.75)		

Figure 1 depicts the electronic spectra of the Fe(III) complexes, while the data are listed in Table 1. The spectrum of $FeCl(detsc)_2$ is rich in absorption band and in appearance resembles the spectrum of $FeCl[S_2CN(C_2H_5)_2]$.[5] The bands observed above 25 kK have their origin in charge-transfer and intra-ligand transitions, while the two succeeding bands at around 21 and 16 kK arise from spin-allowed d-d transitions. These assignments seem reasonable in view of the fact that the bands around 20 and 16 kK of $M(detsc)_n$ ($n=3$ when M=Cr(III) and Co(III); $n=2$ when M=Ni(II)) have been identified as d-d transitions,[4] while the 15.9 kK band[7] of $Cu(detsc)_2$ is missing.[4] Moreover, the corresponding dmtsc complexes exhibit similar spectra.[7] There is, however, little information about the d-d bands of square pyramidal complexes,[8] and we have to await further studies of this type of complexes before we can make detailed assignments. It is noticed that there are two weak bands of $FeCl(detsc)_2$ in the near-infrared region. In view of the ε values, they are most likely to be spin-forbidden d-d bands, while the analogous weak bands of $FeCl[S_2CN(C_2H_5)_2]_2$ have been assigned as spin-allowed transitions.[5] No corresponding absorption has been observed in $FeCl(dmtsc)_2$, because of its limited solubility.

Notiz über neue $\overset{+}{S}$–$\overset{-}{N}$-Ylid-Komplexe von Platin(II)

Gen-etsu MATSUBAYASHI, Masaharu TORIUCHI, und Toshio TANAKA

Abteilung für Angewandte Chemie, Technische Fakultät der Universität Osaka, Yamadakami, Suita, Osaka 565

(Eingegangen den Oktober 12, 1973)

Synopsis. The reaction of $(CH_3)_2SNC(O)R$ (R= C_6H_5, $C_6H_4CH_3$-*p*)(Y) with K_2PtCl_4 in water gives a stable ylide complex, $PtCl_2(Y)(DMSO)$, in which Y coordinates to the Pt(II) *via* nitrogen and DMSO *via* the sulfur to form a *cis*-configuration.

In Rahmen einer Untersuchung der Komplexbildung von Yliden haben wir in früheren Mitteilungen über die stabilen $\overset{+}{S}$–$\overset{-}{C}$H Ylid-Komplexe[1] der Palladium(II)- und Platin(II)-dihalogenide und die isoelektronischen $\overset{+}{S}$–$\overset{-}{N}$ Ylid-Komplexe des Typs $PdCl_2 \cdot 2Y$, $PdCl_2 \cdot (Y)(P(C_6H_5)_3)$ und $PtCl_2 \cdot 2Y$ (Y=*S,S*-Dimethyl-*N*-benzoyl- oder *S,S*-Dimethyl-*N*-*p*-methylbenzoylsulfilimin) berichtet.[2] Für die letzten Komplexe wurde IR-spektrometrisch bestätigt, dass der negative Stickstoff gegenüber dem Metallatom als Donator wirkt.

Bei der Umsetzung des $\overset{+}{S}$–$\overset{-}{N}$ Ylids mit K_2PtCl_4 in Wasser beobachteten wir die Bildung eines neuen Komplexes, der Ylid und Dimethylsulfoxid als Liganden enthält.

Wäßrige Lösungen von K_2PtCl_4 wurden mit einem Überschluß an *S,S*-Dimethyl-*N*-benzoylsulfilimin mehr als 10 Stdn bei Raumtemperatur gerührt. Die Niederschläge wurden nach dem Abfiltrieren wiederholt mit Methylenchlorid gewaschen. Nach der Entfernung des Lösungsmittels kristallisiert *S,S*-Dimethyl-*N*-benzoylsulfilimin–dimethylsulfoxid–dichloroplatin (II) (i) als gelbe Nadeln aus Methylenchlorid/Petroläther. Schmpt. 129—131.5 °C. $C_{11}H_{17}Cl_2NO_2S_2Pt$. (Mol.-Gew. 525.4) Ber. C; 25.15, H; 3.26, N; 2.67. Gef. C; 25.46, H; 3.24, N; 2.85, (Mol.-Gew. osmometr. in Chloroform 508). *S,S*-Dimethyl-*N*-*p*-methylbenzoylsulfilimin–dimethylsulfoxid–dichloroplatin(II) (ii) wurde genauso wie (i) dargestellt. Schmpt. 135.5—137.5 °C. $C_{12}H_{19}Cl_2NO_2S_2Pt$. (Mol.-Gew. 539.4) Ber. C; 26.72, H; 3.55, N; 2.60. Gef. C; 26.90, H; 3.63, N; 2.84. (Mol.-Gew. osmometr. in Chloroform 534).

Das ungebundene Ylid hydrolysiert langsam in Wasser, wobei Benzamid und Dimethylsulfoxid entstehen.[3] Die zugleich im System befindlichen Platin(II)-Ionen beschleunigen die Spaltung der S-N-Bindung des Ylids. Dabei entsteht Dimethylsulfoxid, welches mit dem Metallion koordiniert. In der wäßrigen Lösung kann Benzamid oder *p*-Methylbenzamid nachgewiesen werden. In den hier in Frage kommenden Versuchen werden Bis(ylid)dichloroplatin(II) und Bis(dimethylsulfoxid)dichloroplatin(II) auch als in Methylenchlorid unlöslichen Niederschläge erhalten.

Die Daten der IR- und ^{1}H-NMR-Spektren der Ylid-Komplexe werden in Tabelle 1 wiedergegeben. Die Frequenz der C=O Streckschwingung liegt beim komplexierten Ylid um 81 bzw. 105 cm^{-1} höher als beim freien. Daraus ist zu schliessen, dass das Ylid mit dem Stickstoffatom an Platin gebunden wird, wie wir bereits für die Bis(ylid)-Komplexe gefunden haben.[2] Im freien Dimethylsulfoxid tritt ν(S–O) bei 1045 cm^{-1} auf, während bei den Komplexen eine langwellige Verschiebung dieser Bande nach 1118 bzw. 1120 cm^{-1} beobachtet wird. Das spricht für das Vorliegen einer Metal-Schwefel-Bindung. Dementsprechend erscheint ν(Pt–S) bei 437 bzw. 442 cm^{-1}, wie es ähnlich für $PtCl_2 \cdot 2DMSO$ beobachtet wurde.[4] Aus den ν(Pt–Cl)-Daten in der Tabelle wird auf eine *cis*-Konfiguration am Platinatom geschlossen, was in Übereinstimmung mit änderen Dihalogenidplatin(II)-Komplexen[4,5] steht.

Die ^{1}H-NMR-Spektren weisen auf eine erhöhte Abschirmung der Ylid- und Dimethylsulfoxidprotonen in den Addukten gegenüber den freien Liganden hin. Aus den Molgewichtsbestimmungen geht hervor, dass es sich um monomere Moleküle handelt, die ihrerseits in Chloroform keine Liganden abspalten. Im ^{1}H-NMR-Spektrum findet man dementsprechend nach Zusatz von überschüssigem Dimethylsulfoxid und Ylid für komplexierte und freie Liganden getrennte Signale. Das bedeutet, dass die Ylid-Metall-Bindung wesentlich

Benzo[*h*]quinolin-10-yl-*N* Iridium(III) Complexes

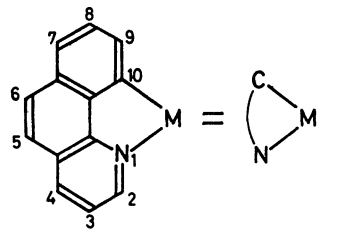
Matsuo NONOYAMA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

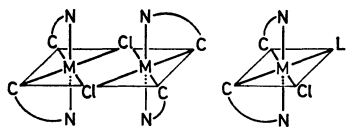
(Received November 5, 1973)

Synopsis. Benzo[*h*]quinoline(bhqH) is metallated with iridium(III) to give $[Ir(bhq)_2Cl]_2$ in which bhq is coordinated at 1-N and 10-C atoms. This complex reacts with a ligand(L) such as tri-*n*-butylphosphine and diethylsulfide to yield $[Ir(bhq)_2ClL]$.

The metallation reactions of organic nitrogen compounds with palladium(II) and platinum(II) to form a metal-carbon σ-bond have been studied widely, but the same reactions with other platinum metals have scarcely been investigated at all. A nitrogen heterocyclic base, benzo[*h*]quinoline(abbreviated as bhqH), has been reported[1] to form a π-complex with chromium hexacarbonyl, $Cr(CO)_3(bhqH)$. A different type of a benzo[*h*]quinoline complex has been prepared with palladium(II),[2,3] platinum(II),[3] and rhodium(III)[4] halides. In these complexes, the ligand loses one proton and coordinates to a metal ion through the carbon (10-C) and nitrogen (1-N) atoms, thus forming a five-membered chelate ring containing a metal-carbon σ-bond (Formula I). As a part of our studies of the metallation reactions of this ligand, the reaction of bhqH with $Na_3[IrCl_6]$ will be reported here.



I



II III

Experimental

The Reaction of bhqH with $Na_3[IrCl_6]$. To a solution of 0.5 g of $Na_3[IrCl_6]$ in 2-methoxyethanol (30 ml), we added 0.6 g of bhqH. The mixture was stirred for 8 hr at room temperature and then refluxed for 24 hr. A brownish-yellow precipitate was obtained. The crude product was washed with ethanol and extracted three times with 100 ml of chloroform. The extract was then concentrated to a small volume to give a yellowish-orange powder (0.3 g), $[Ir(bhq)_2Cl]_2 \cdot 2/3CHCl_3$, which decomposed above 305 °C.

Found: C, 50.80; H, 2.70; N, 4.54; Cl, 11.12%. Calcd for $Ir_2C_{52}H_{32}N_4Cl_2 \cdot 2/3CHCl_3$: C, 50.70; H, 2.64; N, 4.49; Cl, 11.37%.

When this chloroform adduct was recrystallized from benzene, an unsolvated complex, $[Ir(bhq)_2Cl]_2$, was obtained.

Found: C, 53.55; H, 2.92; N, 4.52%. Calcd for $Ir_2C_{52}H_{32}N_4Cl_2$: C, 53.47; H, 2.76; N, 4.80%.

In a similar manner, $Na_3[IrBr_6]$ gave yellowish-orange $[Ir(bhq)_2Br]_2 \cdot 1/2CHCl_3$.

Found: C, 47.80; H, 2.37; N, 4.31%. Calcd for $Ir_2C_{52}H_{32}N_4Br_2 \cdot 1/2CHCl_3$: C, 47.89; H, 2.49; N, 4.25%.

The Reactions of $[Ir(bhq)_2Cl]_2$ with Tri-n-butylphosphine and Diethylsulfide. To a chloroform suspension (20 ml) of 0.3 g of $[Ir(bhq)_2Cl]_2$, we added 0.1 g of tri-*n*-butylphosphine (PBu_3). The suspension became transparent, and upon the addition of *n*-hexane, a yellow powder, $[Ir(bhq)_2Cl(PBu_3)]$, was precipitated. It melted at 214—217 °C.

Found: C, 57.51; H, 5.29; N, 3.49; P, 3.44%. Calcd for $IrC_{38}H_{43}N_2PCl$: C, 58.04; H, 5.51; N, 3.56; P, 3.94%.

A similar reaction of $[Ir(bhq)_2Cl]_2$ with diethylsulfide (SEt_2) in benzene gave a yellow powder, $[Ir(bhq)_2Cl(SEt_2)]$, which decomposed above 300 °C.

Found: C, 53.18; H, 3.83; N, 4.11; S, 4.82%. Calcd for $IrC_{30}H_{26}N_2SCl$: C, 53.44; H, 3.89; N, 4.15; S, 4.76%.

Measurements. All the spectral measurements were carried out by the methods reported previously.[2,4]

Results and Discussion

The reaction of bhqH with iridium(III) halides requires more drastic conditions than that with rhodium(III) halides, which has been reported to proceed in boiling ethanol and to give a similar complex, $[Rh(bhq)_2Cl]_2 \cdot 1/4CHCl_3$.[4] This fact is consistent with the general inertness of iridium(III) compared with rhodium(III).

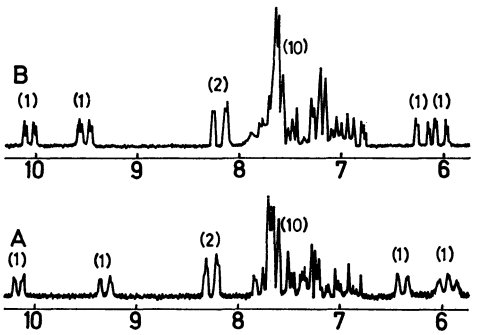


Fig. 1. 60 MHz PMR spectra of (A) $[Ir(bhq)_2Cl(PBu_3)]$ and (B) $[Ir(bhq)_2Cl(SEt_2)]$. Relative intensities of the signals are given in parentheses.

The iridium complex, $[Ir(bhq)_2Cl]_2$, is not sufficiently soluble in common solvents for precise PMR measurements. However, the gross features of the spectrum of its dilute deuterochloroform solution are similar to those of $[Rh(bhq)_2Cl]_2 \cdot 1/4CHCl_3$. Three isolated doublet-like signals were observed at $\delta = ca.$ 9.4, 8.3, and 6.0 ppm, and several overlapped peaks in the 6.7—8.0 ppm region. The former three signals are

assigned, respectively, to 2-H, 4-H, and 9-H of the metallated ligand on the basis of the assignments reported for the rhodium analogue.[4] The entire infrared spectrum of $[Ir(bhq)_2Cl]_2$ is very similar to that of the rhodium complex and shows ν_{Ir-Cl} at 219 and 240 cm^{-1}. The structure of the iridium complex seems, therefore, to be similar to that of the rhodium analogue (Formula II).

The PMR spectra of deuterochloroform solutions of $[Ir(bhq)_2Cl(PBu_3)]$ and $[Ir(bhq)_2Cl(SEt_2)]$ are shown in Fig. 1. The spectrum of the phosphine complex is very similar to that of the corresponding $[Rh(bhq)_2Cl(PBu_3)]$. In the spectra of the phosphine and sulfide complexes, the signals due to 2-H and 9-H of $[Ir(bhq)_2Cl]_2$ split into two components, implying that the two bhq moieties are not equivalent, while that of 4-H remains unsplit, probably because 4-H exists in a distant position from the donor atoms. One of the two components of the 9-H of the phosphine complex is a broad doublet at 6.39 ppm (J=6 Hz), and the other is a triplet at 5.95 ppm (J=6 Hz), while both of the sulfide complex are double doublets (at 6.22 and 6.04 ppm (J=6 and 1.5 Hz)). The triplet of the former complex may be due to the coupling of 9-H with the phosphorus atom (I=1/2), which is at the *trans*-position to the metallated carbon atom (10-C) (Formula III, L=PBu_3).

The signals due to 2-H are observed at 10.15 and 9.29 ppm for $[Ir(bhq)_2Cl(PBu_3)]$ and at 10.05 and 9.54 ppm for $[Ir(bhq)_2Cl(SEt_2)]$. The large splitting can be explained in terms of the proposed structure III, in which one proton is directed towards the coordinated chlorine atom and the other towards the phosphorus or sulfur atom. The two 2-H protons are, therefore, not equivalent.

The infrared spectrum of the phosphine complex is similar to that of the corresponding $[Rh(bhq)_2Cl(PBu_3)]$, and the band assignable to ν_{Ir-Cl} is observed at 247 cm^{-1}. The corresponding band, ν_{Ir-Cl}, for the sulfide complex is at 245 cm^{-1}. The low frequencies of these bands may be attributed to the fact that the chlorine atom is situated at *trans* position to a carbon atom with a high *trans*-influence (Formula III).[5] A new band observed for the phosphine complex at 397 cm^{-1} is tentatively assigned to δ_{CPC}.

Recently, the octahedral structure of acetatobis(2-(phenylazo)phenyl-*N*)rhodium(III) has been determined by X-rays;[6] the metallated carbon atoms have been found to be located mutually *cis*, and the nitrogen atoms *trans*, to each other. This is consistent with the structures proposed for the rhodium and iridium complexes of benzo[*h*]quinoline, and it is evident that the reaction of bhqH with $Na_3[IrCl_6]$ forms a carbon-iridium bond to give a five-membered metallocycle (Formula I).

Kinetic Studies of the Nickel Glycolate Complex Formation in Solution by the Pressure-Jump Method

Shoji HARADA, Yozo OKUUE, Haruki KAN, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 17, 1973)

Synopsis. The nickel glycolate complex formation reaction was studied by the pressure-jump method and the kinetic parameters were obtained. The rate-determining step of the reaction was revealed to be the chelate-ring formation process.

Glycolate ion makes a chelate complex with a metal ion where COO^- group and OH group are coordinated. The step-by-step model will be, then, proposed for the complex formation mechanism.[1,2] In the previous studies on the kinetics of the nickel lactate complex formation,[3] the authors showed that the rate-determining step is the chelate-ring closure and compared the results with those of the nickel glycolate. On the nickel glycolate complex formation reaction, a few kinetic data have been provided[4-6] but the detailed interpretations have not been reported. By obtaining the kinetic data on the nickel glycolate in the same procedures as that applied to the nickel lactate,[3] the authors aimed to study the ligand effects on the complex formation reaction.

Experimental

All of the chemicals used were of a reagent grade. Sample solutions were prepared in the same way as that described in the previous papers.[3,7] Kinetic studies were carried out by the pressure-jump method which has been described elsewhere.[3,7] The measurements were carried out at 10, 15, 20, 25, and 30 °C in the concentration range from 1.01×10^{-3} to 5.04×10^{-2} M of the nickel glycolate. Experiments were carried out at least five times for each solution and the quoted relaxation times were the mean values.

Results and Discussion

The concentration dependency of the relaxation times showed that the relaxation phenomena can be interpreted in terms of the following mechanism:

$$M^{2+} + L^- \underset{k_d}{\overset{k_f}{\rightleftharpoons}} ML^+ \qquad (1)$$

where M^{2+} is the metal ion, L^- is the ligand ion, ML^+ is the complex, k_f and k_d are the formation and the dissociation rate constants respectively. In Eq. (1), the relaxation time, τ, is related to the rate constants as follows:

$$1/\tau = k_f\gamma_M\gamma_L(C_M+C_L) + k_d\gamma_{ML} \qquad (2)$$

where γ is the activity coefficient, C is the equilibrium concentration of the species, and the subscripts indicate the corresponding species. Assuming that $\gamma_{ML}=\gamma_L$, Eq. (2) is converted to:

$$1/(\tau\cdot\gamma_{ML}) = k_f\gamma_M(C_M+C_L) + k_d \qquad (3)$$

If the stability constant, $K(=k_f/k_d)$, is given appropriately, the plot of $1/(\tau\cdot\gamma_{ML})$ *vs.* $\gamma_M(C_M+C_L)$ will be linear; then k_f and k_d can be obtained from the slope and the intercept of the straight line respectively. Here, the activity coefficients were calculated by the Davies equation.[8] Most probable plots at each temperatures are shown in Fig. 1. The rates and the stability constants obtained are summarized in Table 1. Activation parameters were calculated in the same way as that described in the previous papers.[3] They are listed in Table 2. Taking into account the differences of the experimental conditions and the method, the

a) The rate constants of the individual steps were calculated from the original data in the same way as that carried out in the nickel glycollate system.

stability constants in Table 2 are in good agreement with the literature values.[9-11] The rate constants at 25 °C are in fair agreement with the data of the nickel glycolate reported by Hoffmann.[6] The activation parameters are close, not only, to those of the lactate but also to the oxalate and the malonate.[12] These resembrances imply that the same step of the reaction, *e.g.*, chelate-ring closure, is responsible for the present relaxation phenomena.

The detailed model of the nickel glycolate complex formation can be expressed as follows:

$$\underset{\text{(I)}}{Ni^{2+} + L^-} \overset{K_0}{\rightleftharpoons} \underset{\text{(II)}}{Ni^{2+}O\begin{matrix}H\\ \diagdown\\ H\end{matrix}L^-} \overset{k_1}{\underset{k_{-1}}{\rightleftharpoons}} \underset{\text{(III)}}{Ni^+ - L} \overset{k_2}{\underset{k_{-2}}{\rightleftharpoons}} \underset{\text{(IV)}}{Ni^+ = L} \qquad (4)$$

where (I) is the free ions, (II) is the outer-sphere complex, (III) is the unidentated complex, (IV) is the chelate complex, and K_0 is the outer-sphere complex formation constant.

Assuming that the complex is stable as a chelate complex and the intermediate state (II) and (III) are in the steady state, the rate constants in Eq. (4) are related to k_f and k_d in Eq. (1) as follows:

$$k_f = K_0k_1\left(\frac{k_2}{k_2+k_{-1}}\right) \qquad (5)$$

$$k_d = k_{-1}\left(\frac{k_{-2}}{k_2+k_{-1}}\right) \qquad (6)$$

As that described in the previous paper,[3] K_0k_1 and k_{-1} can be estimated to be $1.5\times10^5\ M^{-1}\ s^{-1}$ and $9\times10^3\ s^{-1}$, respectively. Then, k_2 and k_{-2} can be obtained by Eqs. (5) and (6). They are listed in Table 3 along with the rate constants of the other nickel bidentate complexes.

In the nickel glycolate complex formation, the rate-determining-step is the chelate-ring closure step. The kinetic data are very close to those of the nickel lactate. This fact shows that the methyl group of the lactate ion does not give effective contributions to the kinetic values of the complex formation. In Table 3, the rate constants of the chelate-ring closure, k_2, are of the order of $\sim10^3\ s^{-1}$, which is about an order of magnitude smaller than the water exchange rate constant of the nickel ion. This fact means that the values of the rate constants of the chelate-ring rupture, k_{-2}, reflect the stabilities of the chelate complexes.

Micellar Effect of Lauryldimethylsulfonium Halides on the Hydrolysis of *p*-Nitrophenyl Decanoate

Tsuneo OKONOGI, Yumihiko YANO, and Waichiro TAGAKI

Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376

(Received July 23, 1973)

Synopsis. Micellar effects of lauryldimethylsulfonium chloride, bromide, and iodide on the hydrolysis of *p*-nitrophenyldecanoate were found to be very similar to those of the corresponding lauryltrimethylammonium halides.

Ester hydrolysis catalyzed by cationic micelles of quaternary ammonium salts has been extensively investigated in recent years.[1] In most cases, the rate of hydrolysis is first order with respect to hydroxide ion. Meanwhile, we have observed,[2] previously, that the rate of base catalyzed H–D exchange reaction of the methyl group of lauryldimethylsulfonium halides is non-linear with respect to the concentration of hydroxide ion under micellar conditions, but follows to a Michaelis-Menten type saturation kinetics, and we have suggested that the binding of hydroxide ion occurs on a cationic micellar surface prior to the hydrogen abstraction. Although such a difference in the behavior of hydroxide ion between ester hydrolysis and H–D exchange reaction is probably due to different ranges of hydroxide ion concentration which is much higher for the latter than for the former reaction, another possibility is due to some difference in micellar properties between ammonium and sulfonium salts. Incidentally, the micellar effects of sulfonium salts on the ester hydrolysis has little been investigated. Therefore we have compared the micellar effects of lauryltrimethylammonium and lauryldimethylsulfonium halides on the hydrolysis of *p*-nitrophenyl decanoate.

Results and Discussion

The rates of hydrolysis were followed by a conventional spectrophotometric determination of *p*-nitrophenol liberated. The dependency of the rates on detergent concentration is shown in Fig. 1. The Figure indicates typical micellar effects: 1) The rates increase rapidly by increasing detergent concentration near the CMC[1,3] and reach to a maximum, then decrease gradually by further increase of detergent. 2) The rates are affected markedly by the counter anion (X) and increase in the order of X=I<Br<Cl. These two trends are almost the same for each series of sulfonium and ammonium salts. The effects of added salts on the rates are shown in Table 1. The rate of sulfonium chloride observed in the absence of KI was reduced to one fifth by the addition of a half molar amounts of KI over the detergent concentration. The rate of the sulfonium iodide is also reduced by the addition of KCl, but the extent of rate reduction is very small. These salt effects appears to be essentially the same as observed in the micellar effects of quaternary ammonium salts.[4]

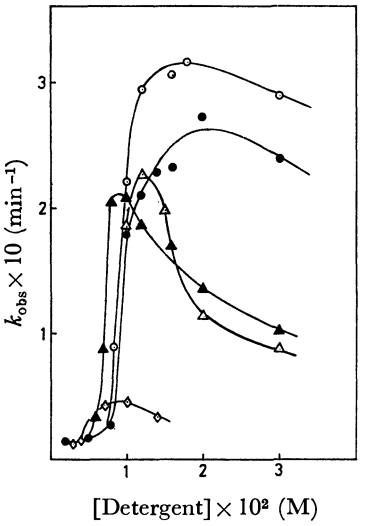

Fig. 1. Plots of k_{obs} *vs.* detergent concentration: Ester, 1×10^{-5}M; pH 10.1 (Na_2CO_3–$NaHCO_3$ buffer, 5×10^{-3}M), 25 °C.
○: *n*-$C_{12}H_{25}N^+(CH_3)_3Cl^-$, ●: *n*-$C_{12}H_{25}S^+(CH_3)_2Cl^-$,
△: *n*-$C_{12}H_{25}N^+(CH_3)_3Br^-$, ▲: *n*-$C_{12}H_{25}S^+(CH_3)_2Br^-$,
◇: *n*-$C_{12}H_{25}S^+(CH_3)_2I^-$.

Table 1. Salt effect on the hydrolysis of *p*-nitrophenyl decanoate (1×10^{-5}M) catalyzed by *n*-$C_{12}H_{25}S^+(CH_3)_2X^-$ (X=I; 1×10^{-2}M, X=Cl; 2×10^{-2}M): pH 10.1 (Na_2CO_3–$NaHCO_3$ buffer; 5×10^{-3}M), 25°

X=I		X=Cl	
KCl ($\times 10^2$M)	k_{obs} (min^{-1})	KI ($\times 10^3$M)	k_{obs} (min^{-1})
0	4.57×10^{-2}	0	2.73×10^{-1}
3	3.82×10^{-2}	2	1.90×10^{-1}
5	3.33×10^{-2}	4	1.58×10^{-1}
10	3.01×10^{-2}	10	5.06×10^{-2}

The dependency of the rates on hydroxide ion concentration was also examined. For all the salts shown in Fig. 1, the plots of log ($k_{obs}-k_o$) *vs.* log [OH^-] gave straight lines (slope=1.0) up to [OH^-]=10^{-2} M, and no saturation phenomenon as observed in the H–D exchange reaction was detected. It was difficult to use more higher base concentration as in the H–D exchange reactions ([OH^-]=0.1—0.2 M)[2] because the rates become too fast to measure by the present method.

The above results indicate that long chain alkyl sulfonium and ammonium salts behave quite similarly in the hydrolysis of *p*-nitrophenyl decanoate.

Experimental

Materials. *p*-Nitrophenyldecanoate was prepared by the method of Bodansky,[5] mp 35 °C (lit,[6] 35—35.7 °C).

Lauryldimethylsulfonium halides, $n\text{-}C_{12}H_{25}S^{+}(CH_3)_2X^{-}$, were reported previously:[2] iodide, mp 87 °C; bromide, mp 68—70 °C; chloride, mp 64—66 °C.

Lauryltrimethylammonium halides: bromide, mp 243 °C (lit,[7] 243—244 °C); chloride, mp 247 °C (lit,[8] 247 °C).

Kinetics were performed spectrophotometrically with Hitachi 124 spectrophotometer according to our previous method.[9] The pH of the reaction mixture was determined with Hitachi-Horiba pH meter (F-7DE).

The Reaction of Substituted Tropones with Diphenylketene

Toyonobu Asao, Noboru Morita, and Nobuo Iwagame

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received July 25, 1973)

Synopsis. The reaction of 2-methoxytropone and diphenylketene afforded (2+8)cycloadduct and 1-methoxy-8,8-diphenylheptafulvene which must be formed by the decarboxylation of the initially-formed (2+2)cycloadduct. 2-Dimethylaminotropone also gave the heptafulvene derivative. However, 2-chloro-, 2-cyano-, and 2,5-dimethoxytropone yielded only (2+8)cycloadducts.

The reaction of 4,5-benzotropone with diphenylketene has long been known to give diphenylbenzoheptafulvene[1] by the decarboxylation of the initially-formed (2+2)cycloadduct. The reactions of tropone with diphenylketene[2] and dichloroketene[3] have also been studied; two (8+2)cycloadducts (I and II respectively) were obtained. However, the reaction of tropone with activated isocyanates has been shown to give troponeimine derivatives; presumably they are formed by the elimination of CO_2 from the (2+2)cycloadducts.[4] Furthermore, we have recently found that 8-oxoheptafulvene, which has a cyclic conjugated ketene moiety, reacts with tropones to give (8+2)cycloadducts and heptafulvalenes and its derivatives, which are formed by the decarboxylation of the (2+2)cycloadducts; we have also found that the (8+2)cycloadducts might be the isomerization products of the (2+2)-cycloadducts.[5]

These results prompted us to investigate the reaction of substituted tropones and diphenylketene; this paper will describe the results of this study.

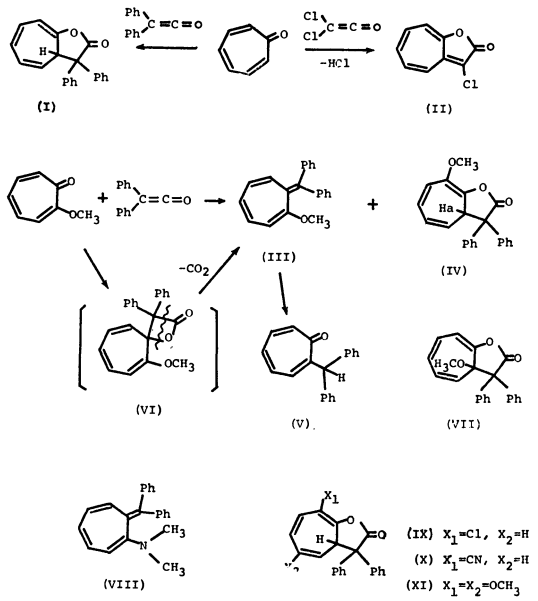
The refluxing of a mixture of 2-methoxytropone and diphenylketene (1: 1.2 molar ratio) in anhydrous benzene and subsequent chromatographic separation afforded two products, yellow plates (III) and colorless plates (IV), in 6.5 and 50% yields respectively.

Compound (III) was proved to be 1-methoxy-8,8-diphenylheptafulvene[6] from elemental analyses and its spectroscopic data, as well as by hydrolysis with hydrochloric acid which gave 2-benzhydryltropone (V). It is clear that Compound (III) is formed by the decarboxylation of the (2+2)cycloadduct intermediate (VI).

Compound (IV) was proved to be the (8+2)cycloadduct by the elemental analyses and by the spectroscopic data. The alternative structure (VII) for Compound (IV) could be excluded on the basis of the existence of a signal ascribable to Ha hydrogen in its NMR spectrum. This result is similar to that in the case of the (8+2)cycloadducts of 8-oxoheptafulvene with substituted tropones.[5]

The reaction of 2-dimethylaminotropone with diphenylketene afforded 1-dimethylamino-8,8-diphenylheptafulvene (VIII) and an unidentified product. However, the reaction of diphenylketene with 2-chloro-, 2-cyano-, and 2,5-dimethoxytropone afforded only (8+2)cycloadducts (IX—XI); no heptafulvene derivatives could be obtained.

It is clear that electron-releasing groups, such as a methoxy or dimethylamino group, stabilize 8,8-diphenylheptafulvene; however, the influence of the substituents of tropone on the mode of the reaction with diphenylketene is not clear.



Experimental

Reaction of 2-Methoxytropone with Diphenylketene. A solution of 2-methoxytropone (500 mg) and diphenylketene (800 mg) in anhydrous benzene (5 ml) was refluxed for 2 hr under a nitrogen atmosphere. The solvent was then removed and chromatographed on a silica-gel column, using $CHCl_3$ as the solvent. From the first effluent, 70 mg of yellow plates (III) (mp 115—116 °C (from ethanol)) were obatined. Compound (III) is stable when standing in the air at room temperature. λ_{max}^{MeOH} nm(log ε); 255^{sh} (3.48) and 333 (3.95). NMR ($CDCl_3$); δ 3.30 (OCH_3), 5.48 (1H, d, J=7.0 Hz), 5.8—6.4 (4H, m) and 6.8—7.4 (10H, m).

Found: C, 88.21; H, 6.40%. Calcd for $C_{21}H_{18}O$: C, 88.08; H, 6.34%.

From the second effluent, 646 mg of colorless plates (IV) (mp 122—123 °C (from ethanol)) were obtained. NMR ($CDCl_3$); δ 3.48 (Ha, d.d, J=4.5, 1.5 Hz), 3.75 (OCH_3), 4.62 (1H, d.d, J=10.0, 4.5 Hz), 5.8—6.5 (3H, m) and 6.9—7.6 (10H).

Found: C, 79.96; H, 5.59%. Calcd for $C_{22}H_{18}O_3$: C, 79.98; H, 5.49%.

Reaction of 2-Dimethylaminotropone with Diphenylketene. A solution of 2-dimethylaminotropone (750 mg) and diphenylketene (970 mg) in dry benzene (5 ml) was refluxed for 6 hr. The solution was then chromatographed on a silica-gel column and eluted with benzene; 117 mg (7.8%) of pale yellow needles (VIII) (mp 118—120 °C (from ethanol)), 246 mg of colorless needles (mp 131.5—132 °C,

(Found: C, 87.33; H, 5.97%, λ_{max}^{EtOH} nm; 249)), and 368 mg (49%) of the starting tropone were thus obtained. Compound (VIII) is also stable for standing in the air at room temperature. λ_{max}^{MeOH} nm(log ε); 246 (4.17), 310 (3.91), and 356 (4.03), NMR ($CDCl_3$); δ 2.42 ($N(CH_3)_2$), 6.6—7.5 (15H, m).

Found: C, 88.52; H, 7.22; N, 4.41%. Calcd for $C_{22}H_{21}N$: C, 88.25; H, 7.07; N, 4.68%.

Reaction of 2-Chlorotropone with Diphenylketene. A solution of 2-chlorotropone (560 mg) and diphenylketene (800 mg) in dry benzene (5 ml) was refluxed for 2 hr. The solvent was then removed, leaving colorless crystals; these crystals were subsequently recrystallized from ethanol to give 1.087 g (82%) of colorless prisms (IX) (mp 149—150 °C). NMR ($CDCl_3$); δ 3.72 (1H, d.d, J=4.5, 2.0 Hz), 4.66 (1H, d.d, J=10.0, 4.5 Hz), 5.90—6.65 (3H, m) and 7.18—7.50 (10H).

Found: C, 75.08; H, 4.50%. Calcd for $C_{21}H_{15}O_2Cl$: C, 75.34; H, 4.52%.

Reaction of 2-Cyanotropone with Diphenylketene. A solution of 2-cyanotropone (262 mg) and diphenylketene (450 mg) in dry benzene (15 ml) was refluxed for 1.5 hr. The solvent was then removed, and the residue was washed with $CHCl_3$ to give 530 mg of colorless crystals. Recrystallization from $CHCl_3$–ethanol gave X as colorless prisms; mp 175—176 °C. NMR ($CDCl_3$); δ 3.70 (1H, d.d, J=4.0, 2.0 Hz), 4.65 (1H, d.d, J=10.0, 4.0 Hz), 6.1 (1H, m), 6.60 (2H) and 7.15—7.5 (10H).

Found: C, 81.02; H, 4.58; N, 4.13%. Calcd for $C_{22}H_{15}O_2N$: C, 81.21; H, 4.65; N, 4.31%.

Reaction of 2,5-Dimethoxytropone with Diphenylketene. A solution of 2,5-dimethoxytropone (336 mg) and diphenylketene (400 mg) in dry benzene (8 ml) was refluxed for 1.5 hr. When the solution was then chromatographed on a silica-gel column, 697 mg of a colorless powder were obtained. Recrystallization from $CHCl_3$–ethanol afforded XI as colorless prisms; mp 125—126 °C. NMR ($CDCl_3$); δ 3.20 (OCH_3), 3.65—3.75 (OCH_3 and 2H), 6.07 (1H, d, J=11.5 Hz), 6.28 (1H, d, J=11.5 Hz) and 7.3 (10H).

Found: C, 76.43; H, 5.54%. Calcd for $C_{23}H_{20}O_4$: C, 76.65; H, 5.59%.

2-Benzhydryltropone (V). A solution of heptafulvene (III, 109 mg) in methanol (16 ml) and 3M HCl (3 ml) was refluxed for 25 min. The solvent was then removed, water was added, and the solution was extracted with $CHCl_3$. The subsequent removal of the solvent gave 90 mg of a pale yellow powder; recrystallization from $CHCl_3$–cyclohexane afforded V as pale yellow plates; mp 123—124 °C. λ_{max}^{MeOH} nm(log ε); 219^{sh} (4.46), 230^{sh} (4.36), and 313 (3.88). NMR ($CDCl_3$); δ 6.04 (1H, s) and 6.5—7.5 (16H, m).

Found: C, 88.27; H, 5.95%. Calcd for $C_{20}H_{16}O$: C, 88.20; H, 5.92%.

The Reaction of Isocyanates with Carboxylic Acids and Thiocarboxylic Acids

Shinichi MOTOKI, Takao SAITO, and Hiroaki KAGAMI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 27, 1973)

Synopsis. Thiocarboxylic acids reacted with isocyanates or acyl isocyanates to give the stable addition products. However, similar products obtained from benzoic acid and acyl isocyanates dissociated into their components in solution.

Isocyanates are known to react with carboxylic acids to give mixed carbamic carboxylic anhydrides (I).[1-3] These anhydrides are relatively unstable and decompose to give a mixture of amide, *sym*-substituted urea and carboxylic anhydride with evolution of carbon dioxide on heating.[2,3] Some of them dissociate into isocyanates and carboxylic acids in solution.[2,4] It appeared of interest to study the reactions of isocyanates and acyl isocyanates with carboxylic acids and thiocarboxylic acids.

Thiobenzoic acid was allowed to react with phenyl isocyanate in *n*-hexane at room temperature. The reaction proceeded immediately and benzoyl phenylcarbamoyl sulfide (IIa) was obtained as white precipitates. Though I* was readily decomposed on heating and difficult to be recrystallized, IIa was relatively stable and could be purified by recrystallization. Thus analogous sulfides (IIa)—(IIf) were prepared by a similar procedure. The results are summarized in Table 1. The IR spectra of II showed a N–H band at 3220—3250 cm^{-1}, two C=O bands at 1700—1730 cm^{-1} and 1675—1680 cm^{-1} and no absorption due to S–H in the region 2500—2600 cm^{-1}.** The reaction of phenyl isocyanate with thioacetic acid gave acetyl phenylcarbamoyl sulfide (IIg), mp 37—39 °C. IIg decomposed on standing for a few days. Elementary analyses were not in good agreement with the calculated values, but the structure was confirmed by IR spectra (3250 cm^{-1} (N–H), 1720, and 1680 cm^{-1} (C=O)) and NMR spectra (2.67 τ (5H, C_6H_5) and 7.66 τ (3H, CH_3)). The reaction of methyl isocyanate with thioacetic acid or thiobenzoic acid resulted in the corresponding decomposition products, *N*-methylacetamide and *N*-methylbenzamide.

Table 1. RNH–COSCO–R′ (II)

Compd	R	R′	Yield (%)	Mp (°C)
IIa	C_6H_5	C_6H_5	86	95—97
IIb	*m*-$O_2NC_6H_4$	C_6H_5	95	124
IIc	*m*-$O_2NC_6H_4$	CH_3	83	98
IId	C_6H_5	*p*-$O_2NC_6H_4$	76	125—126
IIe	C_6H_5	*p*-ClC_6H_4	81	118—120
IIf	C_6H_5	*p*-$CH_3C_6H_4$	93	109

* For the preparation of I, it is necessary to carry out the reaction in a very concentrated solution.[2]

** Wheeler, who examined the reaction of phenyl isocyanate and thiobenzoic acid, erroneously gave the structure *N*-benzoyl phenyl thiocarbamic acid to the product. (H. L. Wheeler, *J. Amer. Chem. Soc.*, **23**, 444 (1901)).

Table 2. RCONH–COSCO–R′ (III)

Compd	R	R′	Yield (%)	Mp (°C)
IIIa	C_6H_5	C_6H_5	93	75—76
IIIb	C_6H_5	*p*-ClC_6H_4	69	85—86
IIIc	C_6H_5	*p*-$O_2NC_6H_4$	74	82—83
IIId	C_6H_5	CH_3	85	59—61
IIIe	*p*-ClC_6H_4	C_6H_5	91	83—84
IIIf	*p*-$O_2NC_6H_4$	C_6H_5	89	105—106
IIIg	CH_2Cl	C_6H_5	81	107—109
IIIh	$CHCl_2$	C_6H_5	84	105—108
IIIi	CCl_3	C_6H_5	89	112—114

Acyl isocyanates reacted with thiocarboxylic acids also to give acyl acylcarbamoyl sulfides (IIIa)—(IIIi). The results are shown in Table 2. The IR spectra of III showed a broad N–H band at 3100—3400 cm^{-1} and three C=O bands at 1750—1790 cm^{-1}, 1660—1720 cm^{-1} and 1640—1660 cm^{-1}.

Table 3. RCONH–COOCO–R′ (IV)

Compd	R	R′	Yield (%)	Mp (°C)	Dissociation percent (25 °C) (0.5 mol/l)	
					$CHCl_3$	C_6H_6
IVa	C_6H_5	C_6H_5	82	62—65	100	100
IVb	CH_2Cl	C_6H_5	54	101—103	55	100
IVc	$CHCl_2$	C_6H_5	48	102—105	70	100
IVd	CCl_3	C_6H_5	80	70—73	80	100

Satisfactory analytical data (±0.3% for C, H, N, S) were obtained for all new compounds listed in Tables 1, 2, and 3.

The reaction of mono- or dichloroacetyl isocyanate with benzoic acid proceeded similarly to give carbamic benzoic anhydride (IVb) or (IVc). Treatment of benzoyl isocyanate or trichloroacetyl isocyanate with benzoic acid in ether at room temperature gave no precipitate of the product. However, the corresponding anhydride (IVa) or (IVd) was obtained in good yield by evaporation of the solvent. The results are shown in Table 3. The IR spectra of solid IVa—IVd were those of true anhydride (3200—3300 cm^{-1} (N–H), 1800—1820, 1740—1760, 1690—1720 cm^{-1} (C=O)). In $CHCl_3$, however, the spectra apparently consist of both of the absorption of the anhydride and its dissociated components, acyl isocyanate (2250 cm^{-1}

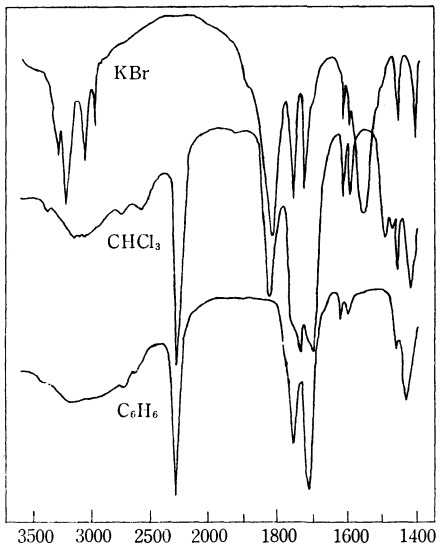

Fig. 1 IR spectra of IVb

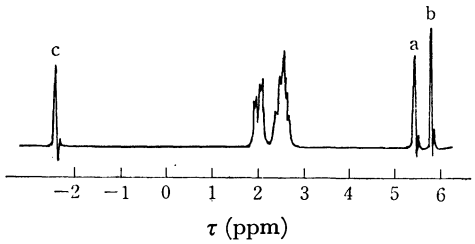

Fig. 2 NMR spectra of IVb ($CDCl_3$)

$ClCH_2CONHCOOCOC_6H_5 \rightleftharpoons ClCH_2CONCO + C_6H_5COOH$

a 5.42 τ b 5.79 τ c −2.24 τ

(NCO), and 1705—1760 cm^{-1} (C=O)) and benzoic acid (1700 cm^{-1} (C=O)). In C_6H_6, the spectra showed only those of dissociation components. The dissociation percentage of IVa—IVd were estimated by means of their NMR absorption. For illustration the spectra of IVb are given in Figs. 1 and 2. From the results shown in Table 3, it is concluded that the compounds IVa—IVd are partly dissociated into their components in solution, the degree of dissociation depending on the structure of the anhydrides and nature of the solvents. In the IR spectra of II and III, a very weak absorption of NCO appeared in $CHCl_3$ or C_6H_6 solution. The amount of dissociated species seemes to be negligible.

X=S III
X=O IV

Experimental

Materials. Commercial phenyl isocyanate, methyl isocyanate, thioacetic acid and thiobenzoic acid employed were used. *p*-Nitrothiobenzoic, *p*-chlorothiobenzoic and *p*-thiotoluic acids were prepared according to the method given in literature.[5] *m*-Nitrophenyl isocyanate was prepared from *m*-nitroaniline and phosgene.[6] Acyl isocyanates were prepared from the corresponding amides and oxalyl chloride.[7,8]

Acylcarbamoyl Sulfides (IIa)—(IIf). To a solution of 4.76 g (0.04 mol) of phenyl isocyanate in 50 ml of *n*-hexane was added a solution of 5.52 g (0.04 mol) of thiobenzoic acid in 10 ml *n*-hexane at room temperature with vigorous stirring. The yellow color of thiobenzoic acid disappeared and white precipitates formed. Recrystallization of the product from *n*-hexane yielded 8.2 g (86%) of IIa melting at 95—97 °C with decomposition. The other compounds (IIb)—(IIf) were prepared in a similar way. The results are shown in Table 1.

Acyl Acylcarbamoyl Sulfides (IIIa)—(IIIi), Chloroacetylcarbamoyl Benzoic Anhydride (IVb) and Dichloroacetylcarbamoyl Benzoic Anhydride (IVc). To a solution of 7.36 g (0.05 mol) of benzoyl isocyanate in 80 ml of ether was added a solution of 6.91 g (0.05 mol) of thiobenzoic acid in 50 ml of ether at 0 to −5 °C with stirring. The yellow color of thiobenzoic acid soon disappeared. Colorless needles were formed immediately. Recrystallization of the product from ligroin yielded 13.3 g (93%) of IIIa melting at 75—76 °C with decomposition. The other compounds (IIIb)—(IIIi), (IVb) and (IVc) were prepared in a similar way. The results are shown in Tables 2 and 3.

Benzoylcarbamoyl Benzoic Anhydride (IVa) and Trichloroacetylcarbamoyl Benzoic Anhydride (IVd). To a solution of 7.36 g (0.05 mol) of benzoyl isocyanate in 50 ml of ether was added a solution of 6.10 g (0.05 mol) of benzoic acid in 50 ml of ether at room temperature with stirring. After the addition of benzoic acid, the solvent was immediately evaporated under reduced pressure. White solid thus obtained was washed with ether and dried to yield 11.2 g (82%) of VIa melting at 62—65 °C with decomposition. As the compound was difficult to be recrystallized, it was analyzed without further purification. IVd was prepared in a similar way. The results are shown in Table 3.

The Induced Optical Rotatory Dispersion of Mercury Orange-Phosphoenolpyruvate Carboxylase*

Masataka MIYAMURA and Shuichi SUZUKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received August 16, 1973)

Synopsis. On reacting with a SH group, the mercury orange enzyme formed, showed a positive Cotton effect near 500 nm, and the optical activity of which was remarkably induced by adding ADP or PEP. It seemed that ADP or PEP might move to the vicinity of the active amino acid residues.

It has been reported that phosphoenolpyruvate carboxylase (EC4.1.1.a), which is activated by the manganous ion, has a sulfhydryl group in the active center, judging from the fact that the activity of this enzyme is inhibited by the addition of *p*-chloromercury benzoate.[1-3] A kinetic study of this enzyme has been carried out by us.[4] It is, however, necessary to accumulate more data for a better understanding of the active center of this enzyme.

It is known that 1-(4-chloromercuriphenylazo)naphthol-2 (mercury organge) reacts with enzyme to form mercury–sulfur bondings.[5,6] It has been found that phosphoenolpyruvate carboxylase reacts with mercury orange and that the product shows an absorption maximum near 492 nm because of the azochromophore of mercury orange. This chromophoric group at the active center of the enzyme has been found to be environmentally sensitive to the optical activity.

This paper will show how the environment of the active center of phosphoenolpyruvate carboxylase can be studied using mercury orange by means of the optical rotatory dispersion spectrophotometric method.

Experimental

The phosphoenolpyruvate carboxylase was prepared from Baker's yeast in the way described in a previous paper.[4] The optical rotatory dispersion (ORD) and the visible spectra were measured by means of the JASCO ORD/UV/CD-5 spectrometer. The enzyme and the substrates were dissolved into a 0.25 mol/l phosphate buffer solution (pH 6.0), and the ORD spectra were measured at 18 °C.

Results and Discussion

Mercury orange exhibits an absorption maximum at 500 nm and shoulders near 450 nm and near 550 nm on a visible spectrum, as is shown in Fig. 1. The shoulder near 450 nm and λ_{max} at 500 nm might be assigned to the *cis* and *trans* isomers respectively, for it is known that a diazo-containing compound gives *cis* and *trans* configurations upon transformation, and because the absorption maximum of the *cis* isomer generally appears at a shorter wavelength than that of the *trans* isomer.[7] The mercury orange-binding enzyme (MO–enzyme) shows an absorption spectrum similar to that of mercury orange. The absorbance near 500 nm decreases and the absorbance near 450 nm increases upon the addition of adenosine-5'-diphosphate (ADP) or phosphoenolpyruvate (PEP) into the MO-enzyme (Fig. 1). It could be said that ADP or PEP are located near the mercury orange group in the MO-enzyme and affect the transformation of a

diazo group of mercury orange.

The MO–enzyme showed a positive Cotton effect near 500 nm (Fig. 2). Neither mercury orange nor the enzyme exhibits an optical activity in the same region. The ORD spectrum of the MO–enzyme is not influenced by the addition of manganous ion (Fig. 2), which means that there is no interaction between the manganous ion and the active center of the enzyme. This is to be expected if mercury orange might be located in the active center, thus forming mercury-sulfur binding, and if the manganous ion should bind with the sulfhydryl group in the active center, thus activating the enzyme. In this connection, the bicarbonate ion was found not to interact with the MO–enzyme. The optical activity of the MO–enzyme is remarkably induced by adding ADP or PEP. It can be deduced from the visible absorption and the ORD spectra that the diazo group in the MO–enzyme has the *trans* configuration mainly, and that this configuration can be influenced by the interaction between the mercury orange goup and ADP or PEP. It seemed that ADP or PEP might move to the vicinity of the active site of the enzyme.

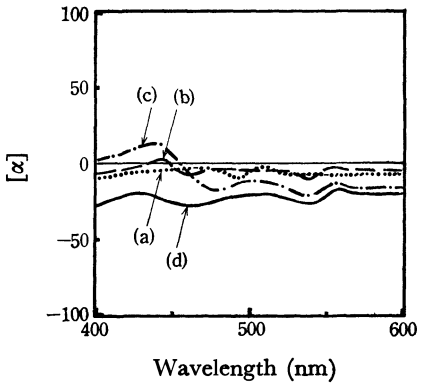

Fig. 3. ORD spectra of mercury orange–phosphoenolpyruvate carboxylase–adenine derivatives complex.
a): MO–enzyme (1.0 mmol/l)
b): a)+adenine (1.0 mmol/l)
c): a)+adenosine (1.0 mmol/l)
d): a)+ADP (1.0 mmol/l)

The optical activity of the MO–enzyme was induced by the addition of adenine, adenosine, or adenosine-5′-triphosphate (ATP) instead of ADP, as is shown in Fig. 3. The ORD spectrum of ATP seems almost the same as ADP, and those of adenine and adenosine exhibit a tendency similar to that of ADP. In every case, another Cotton effect appears around 400 nm. It seems that the adenine or adenine group of adenosine, ADP or ATP, may be located at the binding site of the active center, thus transform in the diazo group from the *trans* to the *cis* configuration as follows:

A Study on Phosphorylation by Means of 8-Quinolyl Phosphates

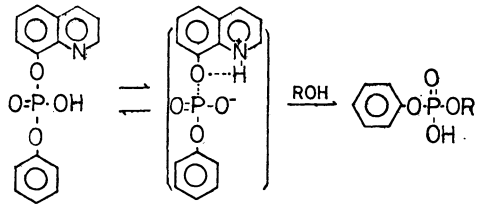
Hiroshi TAKAKU, Yoshifusa SHIMADA, and Kenichi ARAI

Department of Chemistry, Chiba Institute of Technology, Narashino, Chiba 275

(Received August 31, 1973)

Synopsis. Phosphorylation of phosphates and nucleosides forming unsymmetrical pyrophosphates and nucleotides by the use of 8-quinolyl phosphates has been investigated. According to this method, various pyrophosphates and nucleotides were obtained in high yields.

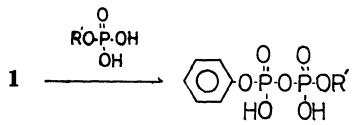
Recently, we reported[1] that mixed diesters of phosphoric acid (**2**) were prepared in a high yield by treating an active ester, phenyl 8-quinolyl phosphate (**1**), with alcohols as shown in the following scheme.



1 **1′** **2**

This paper deals with the reaction of 8-quinolyl phosphates[2] such as **1** or tris-(8-quinolyl) phosphate (**5**), with phosphates and nucleosides which give unsymmetrical pyrophosphates and nucleotides that are expected from the above reaction.

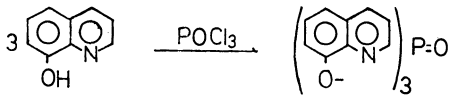
First, an attempt was made to synthesize unsymmetrical pyrophosphate (**3**) by the reaction of **1** with phosphates. When a mixture of one equiv. of **1** and 1.5 equiv. of *p*-chlorophenyl phosphate in dry pyridine was allowed to stand at 50 °C for 5 hr, the corresponding P^1-*p*-chlorophenyl P^2-phenyl pyrophosphate (**3a**) was obtained in 78% yield. However, when a small quantity of triethylamine was added to the pyridine solvent, the yield of **3a** decreased markedly.[3]



3

In a similar manner, various unsymmetrical pyrophosphates (**3**) were obtained in a high yield as shown in Table 1. When adenosine 5′-phosphate was used in the above experiments, P^1-adenosine-5′ P^2-phenyl pyrophosphate (**3d**) was obtained in 54% yield. Thus it can be said that phenyl 8-quinolyl phosphate (**1**) is effective for the synthesis of pyrophosphates.

Next, the synthesis of nucleoside 5′-phosphate was tried by the use of a phosphorylating reagent, tris-(8-quinolyl) phosphate (**5**). The reagent (**5**) was prepared in 75% yield by treating six equiv. of 8-quinolinol (**4**) with one equiv. of phosphoryl chloride.



4 **5**

When a mixture of one equiv. of 2′,3′-*O*-isopropylideneadenosine and two equiv. of **5** in dry pyridine was heated at 80 °C for 8 hr, 2′,3′-*O*-isopropylideneadenosine 5′-bis-(8-quinolyl) phosphate (**6a**) was formed. The phosphate (**6a**) without isolation, was further treated with aqueous solution of cupric chloride and 2′,3′-*O*-isopropylideneadenosine 5′-phosphate was obtained. After removal of the protecting group, adenosine 5′-phosphate (**7a**) was obtained in 70% yield, which was determined by UV absorption after separation by paper chromatography. Nucleoside 5′-phosphates were characterized by comparison of ultraviolet absorption properties with those of authentic samples,[4] R_f values in paper chromatography, and paper electrophoresis.

a) Paper chromatography was carried out by the descending technique using Toyo Roshi No. 51 paper. Solvent systems used were: 2-propyl alcohol–saturated ammonium sulfate–water (2:79:19 v/v) (Solvent C) and *n*-propyl alcohol–concentrated ammonia–water (20:20:3 v/v) (Solvent D).

tained in a high yield as shown in Table 2.

Experimental

Paper chromatography was carried out the descending technique using Toyo Roshi No. 51 paper. The solvents used were isopropyl alcohol–concentrated ammonia–water (8:1:1 v/v) (Solvent A), or (7:1:2 v/v) (Solvent B), 2-propyl alcohol–saturated ammonium sulfate–water (2:79:19 v/v) (Solvent C), and *n*-propyl alcohol–concentrated ammonia–water (20:20:3 v/v) (Solvent D). Paper electrophoresis was carried out on Toyo Roshi No. 51A paper at 80 V/cm in system E (0.05 M potassium phosphate (pH 7.5)). Nucleotides were confirmed by Hanes and Isherwood spray,[5] followed by ultraviolet irradiation.

Phenyl 8-quinolyl phosphate (**1**) was prepared from the phosphorylation of 8-quinolinol (**4**) with phenyl phosphorodichloridate according to the previous paper.[1]

P^1-p-*Chlorophenyl* P^2-*Phenyl Pyrophosphate (3a).* A mixture of 602 mg (2 mmol) of phenyl 8-quinolyl phosphate (**1**) and 624 mg (3 mmol) of *p*-chlorophenyl phosphate in dry pyridine (10 ml) was allowed to stand at 50 °C for 5 hr. To the reaction mixture, 991 mg (10 ml) of cyclohexylamine and water (10 ml) was added, and the mixture was kept overnight in a refrigerator. The precipitate was collected by filtration and washed with water and acetone. The precipitate was recrystallized from a mixture of ethanol and water (1:1 v/v). Bis-cyclohexylammonium salt of *P*^{1}-*p*-chlorophenyl *P*^{2}-phenyl pyrophosphate (**3a**) (876 mg, 78%) was obtained as white prisms; mp 262—264 °C; R_f 0.60 (Solvent A).

Found: C, 50.97; H, 6.74; N, 5.01%. Calcd for $C_{24}H_{37}ClN_2O_7P_2$: C, 51.25; H, 6.58; N, 4.98%.

P^1-*Adenosine-5′* P^2-*Phenyl Pyrophosphate (3d).*[6] A solution of 452 mg (1.5 mmol) of phenyl 8-quinolyl phosphate (**1**) and 347 mg (1 mmol) of adenosine 5′-phosphate in dry pyridine (10 ml) was allowed to stand at 50 °C for 8 hr. The pyridine solution was evaporated *in vacuo* and the residue mixed with water (10 ml). The solution was adjusted to pH 8 and passed through a column of Amberlite IR-120 (H^+) (50—100 mesh) ion-exchange resin. The eluate was neutralized with 6 M ammonium hydroxide and evaporated to dryness. The residue was dissolved in methanol (10 ml). Bis-ammonium salt of *P*^{1}-adenosine-5′ *P*^{2}-phenyl pyrophosphate (**3d**) (339 mg, 54%) was separated by the addition of ether; R_f 0.40 (Solvent B).

Found: C, 30.17; H, 5.41; N, 15.49%. Calcd for $C_{16}H_{25}N_7O_{10}P_2 \cdot 5H_2O$: C, 30.60; H, 5.62; N, 15.56%.

Tris-(8-Quinolyl) Phosphate (5). To a solution of 8.70 g (60 mmol) of 8-quinolinol (**4**) in dry pyridine (20 ml) was added dropwise a solution of 1.53 g (10 mmol) of phosphoryl chloride in dry pyridine (10 ml) with stirring at 0 °C. The mixture was stirred for 2 hr and further at room temperature for 3 days. After removal of pyridinium chloride, the filtrate was concentrated *in vacuo*. Tris-(8-quinolyl) phosphate (**5**) was separated and collected 3.59 g (75%). It was recrystallized from dimethylformamide; mp 202—203 °C; R_f 0.90 (Solvent B). IR ν_{max}^{KBr} cm^{-1}: 1620—1570. (C=C and C=N) and 1253 (P=O).

Found: C, 67.39; H, 3.75; N, 8.97%. Calcd for $C_{27}H_{18}N_3O_4P$: C, 67.64; H, 3.75; N, 8.76%.

Adenosine 5′-Phosphate (7a). A mixture of 286 mg (0.60 mmol) of tris-(8-quinolyl) phosphate (**5**) and 92 mg (0.30 mmol) of 2′,3′-*O*-isopropylideneadenosine in dry pyridine (3 ml) was heated at 80 °C for 8 hr. The mixture was treated 0.48 ml of 43% aqueous cupric chloride at 100 °C for 1.5 hr and concentrated. The residue was treated with 80% acetic acid at 70 °C for 1.5 hr. Adenosine 5′-phosphate (**7a**) was obtained in an over-all yield of 70%, as determined by means of the ultraviolet absorption after separation with paper chromatography. This sample is identical with an authentic specimen of adenosine 5′-phosphate[4] by paper chromatography and paper electophoresis. The R_f values are summarized in Table 2; ultraviolet absorption was $\lambda_{max}^{H_2O}$ 257 mμ.

Similarly, guanosine and uridine 5′-phosphate were obtained in high yields as shown in Table 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47 (3), 781—782 (1974)

Direct Syntheses of Methyl 2-Deoxy-2-alkoxycarbonylamino-D-glucopyranoside from 2-Amino-2-deoxy-D-glucose

Sinichi OTANI

Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received November 20, 1973)

Synopsis. Methyl 2-deoxy-2-methoxycarbonylamino- and methyl 2-deoxy-2-ethoxycarbonylamino-D-glucopyranosides were synthesized by the reaction of 2-amino-2-deoxy-D-glucose with alkyl chlorocarbonate and sodium carbonate in methanol by a one-step process.

This note deals with the direct syntheses of methyl 2-deoxy-2-methoxycarbonylamino-α- (MI-α), methyl 2-deoxy-2-methoxycarbonylamino-β- (MI-β), methyl 2-deoxy-2-ethoxycarbonylamino-α- (MII-α) and methyl 2-deoxy-2-ethoxycarbonylamino-β-D-glucopyranoside (MII-β) starting from 2-amino-2-deoxy-D-glucose hydrochloride.

MI-β and MII-β were synthesized in two steps with 15—28% yield,[1,2] the first step being the formation of 2-deoxy-2-methoxycarbonylamino- (I) and 2-deoxy-2-ethoxycarbonylamino-D-glucose (II) by the reaction of 2-amino-2-deoxy-D-glucose with a half equivalent of methyl and ethyl chlorocarbonate respectively in methanol, and the second step the glycosidation with methanolic hydrogen chloride. Recently, MI-α has been synthesized in 78% yield[3] by the reaction of 2-amino-2-deoxy-D-glucose with an equivalent of methyl chlorocarbonate and sodium carbonate in aqueous acetone, followed by evaporation to dryness and the glycosidation with methanolic hydrogen chloride without isolation of I. The author has found that 2-amino-2-deoxy-D-glucose reacts with excess methyl or ethyl chlorocarbonate in methanol to give the main product MI-α, MI-β, MII-α, or MII-β in a good yield. The reaction might be utilized as a convenient procedure for the syntheses.

2-Amino-2-deoxy-D-glucose hydrochloride was dissolved in methanol containing an equivalent of sodium. After the addition of finely powdered anhydrous sodium carbonate, excess methyl or ethyl chlorocarbonate was added under stirring. The components of the reaction products were detected by thin-layer chromatography with silica gel and *n*-propanol–concd ammonia water–water (6: 2: 1). It was confirmed that, after the formation of I or II, β-glycoside appeared, gradually changing into α-glycoside. Separation of the components was carried out by column chromatography using silicic acid and ethyl acetate–methanol (9: 1). Evaporation of the elution and crystallization gave the pure products. At refluxing temperature overnight, the thermodynamically stable α-glycoside was the major product in 83% yield accompanied by a small amount of the kinetically favorable β-glycoside in 9—10% yield. After being stirred at room temperature for three days, the β-glycoside was found to be the main product in 65—66% yield, in addition to a considerable amount of the α-glycoside as a by-product in 29% yield.

The α- and β-glycoside were identified by elementary analysis and the physical constant measurements.[1,2] The melting point of MI-α differed from that of the reference,[3] MII-α being an unknown compound. In the NMR spectrum of MI-α in deuterium oxide the protons OCH_3 (singlet, τ 6.60), $NHCOOCH_3$ (singlet, τ 6.32) and H-2,3,4,5,6,6′ (multiplet, τ 6.1—6.6) were identical with those of the reference.[3] However, the proton of H-1, reported[3] to appear at τ 5.18 (doublet, J=2 Hz), could not be detected because of the overlapping with HOD signal (τ 5.15—5.4). The data are in good agreement with the NMR spectrum of MI-β except the protons OCH_3 and H-1. In the NMR spectrum of MII-α in deuterium oxide, protons $NHCOOCH_2CH_3$ (triplet, τ 8.78), $NHCOOCH_2CH_3$ (quartet, τ 5.91) and H-2,3,4,5,6,6′ (multiplet, τ 6.1—6.6) were essentially identical with those of MII-β, and protons OCH_3 (singlet, τ 6.62) were in good agreement with those of MI-α, differing from those of MI-β (τ 6.50) and MII-β (τ 6.52). As in the case of MI-α the proton of H-1 of MII-α could not be detected at τ 5.2. Therefore, by measuring the NMR spectra in acetic acid-d_4, protons of H-1 of MI-α and MII-α were detected at τ 5.26 (doublet, J=1.8 Hz) and at τ 5.27 (doublet, J=1.7 Hz), respectively. These NMR data were compatible with those of the α-glycoside.

The reaction mechanism is considered to consist of the formation of I or II and the subsequent methyl glycosidation catalyzed with hydrogen chloride liberated by the decomposition of alkoxy chlorocarbonate.

Experimental

All melting points were taken in capillaries with a Yamato melting point apparatus model MP-21. NMR spectra were measured with a JEOL PS-100 spectrometer. Sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for the solution of deuterium oxide) and tetramethyl silane (for the solution of acetic acid-d_4) were used as an internal standard. Thin-layer chromatography (tlc) was carried out on precoated plates of silica gel G (E. Merck) with the solvent (*n*-propanol–concd ammonia water–water (6: 2: 1)), and the spots were visualized with iodine vapor. Column chromatography was carried out with silicic acid (AR 100 mesh, Mallincrodt).

Reaction at Refluxing Temperature in Methanolic Solution. 2-Amino-2-deoxy-D-glucose hydrochloride (2 g) was dissolved in methanol (50 ml) containing sodium (0.23 g). After the addition of finely powdered anhydrous sodium carbonate (1 g), methyl chlorocarbonate (6 ml) was added dropwise to the mixture under stirring. When the mixture was refluxed overnight, tlc showed two spots corresponding to MI-α (R_f

0.65, major spot) and MI-β (R_f 0.57, minor spot). The mixture was neutralized with lead carbonate and filtered. The clear solution was evaporated to a crystalline residue, which was chromatographed on a column of silicic acid (65×4.5 cm) with ethyl acetate–methanol (9: 1). The two components were obtained as needles after evaporation of the elution. MI-α was recrystallized from methanol–ether; 1.85 g (83%), mp 150—151 °C, $[\alpha]_D^{22}$ +137° (*c* 2, methanol); (lit,[3] mp 126—128 °C, $[\alpha]_D^{22}$ +135° (*c* 2, methanol)).

Found: C, 42.75; H, 7.00; N, 5.49%. Calcd for $C_9H_{17}NO_7$: C, 43.02; H, 6.82; N, 5.58%.

NMR (in D_2O): τ 6.61 (3H, s, OCH_3), 6.32 (3H, s, $NHCOOCH_3$), 6.1—6.6 (6H, m, H-2,3,4,5,6,6′). (in CD_3COOD): 6.63 (3H, s, OCH_3), 6.33 (3H, s, $NHCOOCH_3$), 6.0—6.5 (6H, m, H-2,3,4,5,6,6′), 5.26 (1H, d, J=1.8 Hz, H-1).

MI-β was recrystallized from methanol: 0.21 g (9%), mp 197—198 °C, $[\alpha]_D^{22}$ −35° (*c* 1, water); (lit,[1] mp 196—197 °C, $[\alpha]_D^{18}$ −33.8° (water)). (Found: C, 42.86; H, 6.82; N, 5.53%).

NMR (in D_2O): τ 6.50 (3H, s, OCH_3), 6.32 (3H, s, $NHCOOCH_3$), 6.1—6.7 (6H, m, H-2,3,4,5,6,6′), 5.58 (1H, d, J=8 Hz, H-1).

When ethyl chlorocarbonate (6 ml) was used, the reaction gave MII-α (R_f 0.70, major product) and MII-β (R_f 0.61, minor product) on tlc. MII-α was recrystallized from methanol–ether; 2.05 g (83%); mp 113—115 °C, $[\alpha]_D^{21}$ +114° (*c* 1, water), +127° (*c* 1, methanol).

Found: C, 45.46; H, 7.26; N, 5.37%. Calcd for $C_{10}H_{19}NO_7$: C, 45.27; H, 7.22; N, 5.28%.

NMR (in D_2O): τ 8.78 (3H, t, $NHCOOCH_2\underline{CH_3}$), 6.62 (3H, s, OCH_3), 6.1—6.6 (6H, m, H-2,3,4,5,6,6′), 5.89 (2H, q, $NHCOOC\underline{H_2}CH_3$). (in CD_3COOD): 8.78 (3H, t, $NHCOOCH_2\underline{CH_3}$), 6.64 (3H, s, OCH_3), 6.05—6.5 (6H m, H-2,3,4,5,6,6′), 5.91 (2H, q, $NHCOOC\underline{H_2}CH_3$), 5.27 (1H, d, J=1.7 Hz, H-1).

MII-β was recrystallized from methanol; 0.24 g (10%), mp 188—189 °C, $[\alpha]_D^{22}$ −30° (*c* 1, water); (lit,[2] mp 188—189 °C, $[\alpha]_D^{15}$ −31° (*c* 3.2, water). (Found: C, 45.05; H, 7.24; N, 5.30%).

NMR (in D_2O): τ 8.78 (3H, t, $NHCOOCH_2\underline{CH_3}$), 6.52 (3H, s, OCH_3), 6.1—6.8 (6H, m, H-2,3,4,5,6,6′), 5.91 (2H, q, $NHCOOC\underline{H_2}CH_3$), 5.62 (1H, d, J=8 Hz, H-1).

Reaction at Room Temperature. 2-Amino-2-deoxy-D-glucose hydrochloride (2 g) was dissolved in methanol (50 ml) containing sodium (0.23 g). After addition of finely powdered anhydrous sodium carbonate (1 g) methyl chlorocarbonate (4 ml) was added dropwise to the mixture under stirring. When the mixture was stirred for 3 days at room temperature, tlc showed MI-β (major product) and MI-α (minor product). The same treatment gave the two components which yielded on crystallization; 1.53 g (66%) of MI-β and 0.68 g (29%) of MI-α.

When ethyl chlorocarbonate (4 ml) was used, the reaction gave MII-β yielding 1.60 g (65%) and MII-α yielding 0.72 g (29%).

The author is grateful to Dr. Jyun'ichi Hayami for his helpful discussions and for the NMR spectra measurements.

(Received September 10, 1973)

Synopsis. Five polyether-amides were prepared from the title reaction. The physical properties ([η], T_m, T_g, and decomp. temp.) and the effects of the reaction conditions were examined. These polymers were superior in some physical properties to the polymers obtained from the melt polycondensation.

We have previously reported[1] on polyether-amides obtained from the condensation of ω-(*p*-carboxyphenoxy)alkanoic acids (CPAA) with aliphatic diamines, in which three types of polymers were included in the variety of diamines; ethylenediamine, hexamethylenediamine, and piperazine. The polymers prepared from CPAA and hexamethylenediamine, Hm, showed higher intrinsic viscosities and moderate melting points (200—240 °C), but the polymer prepared from *p*-carboxyphenoxyacetic acid (CPAC) and hexamethylenediamine, Hl, showed a low intrinsic viscosity (0.38). Similarly, other polymers prepared from CPAC and ethylenediamine, El, or piperazine, Pl, also showed low intrinsic viscosities. In the second polymer, El, it was concluded that the small difference between the decomposition temperature (293 °C) and the melting point (294 °C) may cause a low intrinsic viscosity because the polymerization was carried out in a molten state. However, in the first polymer, Hl, we found that the polymer set to gel or was partially insoluble in *m*-cresol when it was heated at an elevated temperature (higher than 250 °C). This may be caused by the active methylene group placed between the oxygen atom and the carboxyl group of CPAC. A similar reason may be deduced as one of the causes of the intrinsic viscosity of El being low.

Therefore, we investigated the interfacial polymerization of CPAC dichloride and aliphatic diamines.

Results and Discussion

White polyether-amides were prepared by the interfacial polymerization of CPAC dichloride and such diamines as ethylenediamine, propylenediamine, 1,3-diaminopropane, hexamethylenediamine, or piperazine, whose polymers will be abbrebiated here as Ed, P-2, P-3, Hm, and Pz (the Ed, Hm, and Pz are essentially equal to El, Hl, and Pl respectively, but the latter were obtained by the melt polycondensation). The melting point (T_m), the glass transition temperature (T_g) and the intrinsic viscosity ([η]) of five polyether-amides are summarized in Table 1. These polymers were superior in some physical properties to the polyether-amides obtained by the melt polycondensation. For example, the intrinsic viscosity of Ed was 0.68; this value is 0.56 higher than that of the intrinsic viscosity of El. Ed did not melt on a hot plate below 325 °C. The thermal analysis of Ed showed that the weight loss of Ed began at about 300 °C; no endothermic peak was detected below that temperature. The *T*m of Pz was determined only by observing the temperature at which melting was complete, because Pz showed no endothermic peak in the DTA analysis.

The reaction conditions (the effects of the volume of tetrachloroethylene and of the molar ratio of diamine to CPAC dichloride) were also examined; the results are summarized in Table 2. The relationship between the diamine partition coefficient and the intrinsic

viscosity is shown in Table 3.

Morgan and Kwolek[2] said that the polyamidation takes place near the interface in the organic phase. The results listed in Tables 2 and 3 can best be explained on the basis of their idea. When the polymer terminates at the chlorocarbonyl group, it reacts with the diamine or it is hydrolyzed by water; the latter case leads to the termination of the polymerization. Therefore, the amino group is desirable as the polymer-end; that is, a higher diamine/CPAC dichloride ratio may be favorable so long as the transfer rate of the diamine from the aqueous layer to the organic layer is not as fast as the reaction rate of diamine and CPAC dichloride. The low concentration of CPAC dichloride is also favorable.

The following results were obtained by Morgan and Kwolek;[2,3] In the unstirred polymerization, a solvent which extracts diamine strongly, such as chloroform, gives a polymer with a higher intrinsic viscosity, and the optimum reactant diamine/dichloride ratio at which the highest polymer is obtained shifts to a lower value. On the contrary, in the stirred polymerization, the intrinsic viscosities in the optimum reactant ratio are nearly equal when the solvent is changed. In this paper, the polymerization was carried out in four solvents, with the ratio of diamine/dichloride kept at a constant value (1.11). As a result, the intrinsic viscosity increased with an increase in the diamine partition coefficient.

CPAA, unlike CPAC, was not chlorinated by a similar method, so other polyether-amides with a repeating unit of were not obtained.

Experimental

p-Carboxyphenoxyacetic Acid Dichloride. A mixture of 58.9 g (0.3 mol) of *p*-carboxyphenoxyacetic acid (CPAC) and 107 g of (0.9 mol) thionyl chloride was refluxed for 5 hr. After an excess amount of thionyl chloride had been distilled off, the CPAC dichloride was distilled under a vacuum. Distillation was then repeated two times. bp 164—165 °C /0.9 mmHg (lit,[4] bp 107—108 °C/0.08 mmHg) Yield, 95.0%.

Interfacial Polycondensation. A typical example will be shown as follows. A mixture of 0.02 mol of diamine, 0.04 mol of sodium hydroxide, and 60 g of ice was diluted with water to 300 ml. The aqueous solution was placed in a home-mixer (Matsushita Electric, type MX-83). While the solution was being stirred vigorously, a solution of 0.02 mol of CPAC dichloride in 150 ml of tetrachloroethylene was prepared and then poured rapidly into the aqueous solution. After 10 min, the resulting polymer was collected on a glass filter, washed with a sufficient amount of hot water, and dried in a vacuum.

Intrinsic Viscosity. The specific viscosity was measured in *m*-cresol at 25 °C with an Ubbelohde viscometer, plotted *versus* the concentration, and extrapolated to zero.

Melting Point. The melting point was determined by observing the temperature at which the sample on a hot plate reached a completely molten state (T_m) or by DTA (T_{m2}).

Glass Transition Temperature (T_g). The T_g was measured by means of a dilatometer.

Decomposition Temperature (T_d). The T_d was measured by TGA (Cho Keiryoki, TRDA$_1$-L; heating rate, 2.8 °C/min in N_2).

Diamine Partition Coefficient. Conditions: hexamethylenediamine, 0.002 mol; sodium hydroxide, 0.004 mol; water, 60 ml; organic solvent, 30 ml; temperature, 25 °C.

The Preparation of 2,2-Bis(trifluoromethyl)-1,3-heterocycles from 2,2,4,4-Tetrakis(trifluoromethyl)-1,3-dithietane

Tomoya KITAZUME and Nobuo ISHIKAWA

Tokyo Institute of Technology, Department of Chemical Engineering, Ookayama, Meguro-ku, Tokyo 152

(Received October 16, 1973)

Synopsis. 2,2-Bis(trifluoromethyl)-1,3-heterocyclic compounds, **3**, **4**, **6**, **7**, and **8**, were prepared by the reaction of 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (**1**) with bifunctional compounds such as amino alcohols, *o*-aminophenol, *o*-aminothiophenol and *o*-phenylenediamine.

In earlier communications we reported on several nucleophilic reactions of 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (**1**), which can be obtained from hexafluoropropene and sulfur. Alkyl- and arylamines reacted with **1** to give *N*-substituted hexafluoroisopropylideneimines,[1] while neither alcohol nor thiol reacted without the catalytic fluoride ion.[2] In this paper, we wish to report on the reactions of aminoalcohols, *o*-aminophenol, *o*-aminothiophenol, or *o*-phenylenediamine with **1**. In these cases, we found that both functional groups in a molecule, an amino and a hydroxyl for example, reacted with the positive carbon atom of **1** to afford 2,2-bis(trifluoromethyl)-1,3-heterocyclic compounds.

2-Aminoethanol and **1** reacted at room temperature in methylene chloride with a liberation of sulfur, which is usual in the reactions between amines and **1**.[1] The structure of the reaction product, 2,2-bis(trifluoromethyl)oxazolidine (**3**), was elucidated by means of its IR and NMR spectra.

In the IR spectrum, the presence of N–H and C–O–C was shown by the bands at 3370 and 1265 cm^{-1} respectively, but no O–H band was observed. In the ^{19}F NMR spectrum, only one singlet signal, at −2.1 ppm from external CF_3CO_2H in CCl_4, appeared. This is in contrast to the spectra of the hexafluoroisopropylidene imines, which have two ^{19}F signals corresponding to *syn* and *anti* CF_3. 3-Amino-1-propanol gave a similar compound, **4**.

Anilines with a functional group in the *ortho*-position reacted with **1** in dimethylformamide. *o*-Aminophenol, *o*-aminothiophenol, and *o*-phenylenediamine gave 2,2-bis(trifluoromethyl)benzoxazolidine (**6**), -benzothiazolidine (**7**), and -benzimidazolidine (**8**) respectively. The structures of these compounds were also elucidated by the IR, NMR, and mass spectra. The presence of the N–H group was proved by the band at 3200—3300 cm^{-1} in their IR spectra. In the ^{19}F NMR spectra, there was only one singlet signal each at about −3 ppm from external CF_3CO_2H in CCl_4. In the mass spectrum of **8**, for example, the strong molecular ion (M^+ 256) was observed, together with the appropriate fragment peaks,[3] such as *m/e* 187 ($C_8H_6F_3N_2$), 167 ($C_8H_5F_2N_2$), 117 ($C_7H_5N_2$), 90 (C_6H_4N), and 69 (CF_3). When **6** was treated with methyl iodide, the *N*-methyl compound was obtained as expected.

Since alkyl- or arylamines are known to give hexafluoroisopropylideneimines by reacting with **1**,[1] the ring formations mentioned above were estimated to proceed by the addition reaction of ZH across the neighboring >C=N double bond of **2** or **5**.

a) Given δ in ppm from ext. CF_3CO_2H in CCl_4.

Experimental

2,2-Bis(trifluoromethyl)oxazolidine (3). To a stirred mixture of 2-aminoethanol (5.0 g, 0.08 mol) and methylene chloride (30 ml), **1** (18.2 g, 0.05 mol) was added, drop by drop, at room temperature. The stirring was continued for 1 hr at that temperature, and then the liberated sulfur was removed by filtration. The filtrate was distilled to give **3** (n=2) (3.8 g); bp 48—51 °C.

2,2-Bis(trifluoromethyl)tetrahydro-1,3-oxazine (4). This compound was prepared by using 3-amino-1-propanol (6.0 g) instead of the 2-aminoethanol used in the preceding reaction.

2,2-Bis(trifluoromethyl)benzoxazolidine (6). A mixture of **1** (7.30 g, 0.02 mol), 2-aminophenol (2.18 g, 0.02 mol). and dimethylformamide (30 ml) was stirred for 4 hr at room temperature, and then filtered. The filtrate was poured into water, and the oily material thus separated was extracted with ethyl ether. The extract was dried over magnesium sulfate, and the solvent was removed. A fraction with a bp of 91—93 °C/21 mmHg was collected to give **6** (3.15 g, 61%).

5-Methyl-substituted **6** was prepared in a similar manner, using 4-methyl-2-aminophenol.

N-*Methyl Derivative of* **6**. Into a mixture of **6** (2.57 g, 0.01 mol), potassium hydroxide (0.56 g, 0.01 mol) and ethyl alcohol (15 ml), methyl iodide (1.44 g, 0.01 mol) was added, drop by drop, after which the whole was stirred for 10 hr at room temperature. The reaction mixture was poured into water, and the oily material was extracted with ethyl ether. The extract was then dried over magnesium sulfate, and the solvent was removed. The vaccum distillation of the residue gave an *N*-methyl derivative (bp 109—110 °C/29 mmHg), in a yield of 63%. Found: F, 42.5%. Calcd for $C_{10}H_7F_6NO$: F, 42.1%.

2,2-Bis(trifluoromethyl)benzothiazolidine (7). A mixture of **1** (14.6 g, 0.04 mol), 2-aminothiophenol (6.00 g, 0.04 mol), and dimethylformamide (30 ml) was stirred for 4 hr at room temperature. The usual work-up process gave a product (**7**) (6.5 g).

2,2-Bis(trifluoromethyl)benzimidazolidine (8). *o*-Phenylenediamine (4.32 g, 0.04 mol), **1** (14.6 g, 0.04 mol), and dimethylformamide (30 ml) were used as in the preceding reaction, and then worked up similarly. Subsequent distillation gave **8** (4.3 g). 5-Fluoro-**8** was prepared similarly by using 4-fluoro-*o*-phenylenediamine.

Die Kinetische Racemat-Spaltung des 1-Phenyläthanols und 1-Phenyläthylamins durch die aktivierten *N*-Tosyl-L-prolin-ester

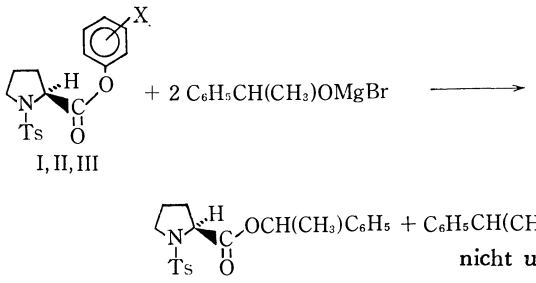
Takeo SAKAN, Yutaka MORI, Tomio YAMAZAKI, Tetsushi YAMASHITA, und Nobuo NAKAMURA

Chemische Abteilung, Naturwissenschaftliche Fakultät, Städliche Universität Osaka, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Eingegangen den Dezember 18, 1973)

Synopsis. Die optische Ausbeute von 10—50% wird erzielt. Einander entgegengesetztes Reaktionsverhalten zeigen die Magnesiumbromide des 1-Phenyläthanols und des 1-Phenyläthylamins bei der Umsetzung mit den Reagenzien.

Bisher wurden zur kinetischen Racemat-Spaltung der Alkohole optisch aktive Carbonsäureanhydride[1] oder Aminosäuren[2] verwendet, und die Horeausche Regel war in zahlreichen Fällen zur Konfigurationsbestimmung dieser Alkohole anwendbar. Wir haben die Reaktionsverhalten der aktivierten *N*-Tosyl-L-prolin-ester, d. h. Chinolyl-(8)-, (I),[3] *p*-Nitrophenyl-, (II),[4] und Naphthyl-(1)-ester, (III),[5] bei der Umsetzung mit Alkoxymagnesiumbromid des racem. 1-Phenyläthanols untersucht. Die Racemat-Spaltung durch die *S*-konfigurierten Reagenzien (I), (II), und (III), die aus *N*-Tosyl-L-prolylchlorid und dem betreffenden Phenol hergestellt wurden, läßt sich wie folgt durchführen:



Die Versuche wurden gleichartig durchgeführt. Als Beispiel sei ein Versuch durch das Reagenz (I) beschrieben: Bei Raumtemperatur fügte man unter Rühren zu 16.4 mMol Alkoxymagnesiumbromid des 1-Phenyläthanols in 15 ccm Äther und 18 ccm Benzol 8.2 mMol von I in 30 ccm Benzol zu und rührte 4 Stdn. bei dieser Temperatur. Anschliessend versetzte man das Gemisch mit 10 ccm Wasser und filtrierte den abgetrennten Niederschlag. Die organische Phase wurde mit 2M HCl und Wasser gewaschen. Nach Trocknen und Verdampfen des Lösungsmittels erhielt man ölige Rohprodukte und destillierte den nicht umgesetzten Alkohol vorsichtig im Vakuum ab. Zur Hydrolyse des dabei zurückbleibenden Esters kochte man 2 Stdn. mit 5% iger wäßriger Natronlauge unter Rückfluß und ätherte mehrfach aus. Der umgesetzte Alkohol wurde durch Destillation gereinigt.

Unter den selben Bedingungen versuchten wir auch die Racemat-Spaltung des 1-Phenyläthylamins, um seine Konfigurationspriorität mit der des 1-Phenyläthanols zu vergleichen. Dabei wurde das Amin als Aminomagnesiumbromid oder als freies Amin eingesetzt.

In Tabelle 1 sind die Ergebnisse der kinetischen Racemat-Spaltung des 1-Phenyläthanols und 1-Phenyläthylamins zusammengestellt.

Die Magnesiumbromide des 1-Phenyläthanols und des 1-Phenyläthylamins zeigen einander entgegengesetztes Reaktionsverhalten bei der Umsetzung mit den Reagenzien (I) (II), und (III) (Versuch Nr.

Role of Germanate Catalyst in the Transformation of Germanium Dioxide

Michiko YONEMURA and Yoshihide KOTERA

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received July 4, 1973)

The role of alkali germanates as catalysts in the polymorphic transformation of germanium dioxide was investigated by high-temperature X-ray diffraction method. Lithium germanate and sodium germanate catalyze the transformation in a solid state, the activation energies being larger than 80 kcal/mol. Potassium germanate catalyst plays its role in a liquid state, the activation energy being smaller than that of other catalysts.

It was found[1] that pure germanium dioxide does not undergo transformation on being heated up to 1000 °C, but it is transformed into tetragonal modification from hexagonal modification in the presence of lithium carbonate or potassium chloride. It was confirmed by means of DTA and high-temperature X-ray diffraction that a solid state reaction first occurs between the alkali salt and germanium dioxide to form germanate compounds which, in a crystalline or glassy state, catalyze the transformation.[2] Since it is expected that the occurence of such a reaction may disturb the determination of the transformation rate, it is necessary to investigate the transformation with an alkali germanate salt which is prepared by separate procedure. The phase diagrams of alkali oxide and germanium dioxide having been studied by Murthy *et al.*,[3-5] it was possible to elucidate the role of alkali germanate salts during the course of transformation.

We have studied the role of the alkali germanate salt during the course of phase transformation in detail under standardized conditions. It was found that lithium germanate and sodium germanate catalyze the transformation in solid state, while potassium germanate does so in liquid state, the activation energy being smaller than that of other salts.

Experimental

The starting materials were much the same as previously reported. Alkali germanate was prepared by a solid state reaction between Li_2CO_3, K_2CO_3 or Na_2CO_3 and GeO_2, as follows.

1) Lithium germanate: Li_2CO_3 and GeO_2 were mixed in a 1 : 7 mole ratio and ignited at 750 °C for 5 hr or at 1020 °C for 40 min. The end point of formation of $Li_2O \cdot 7GeO_2$ was confirmed by comparing the X-ray diffraction patterns of the product with the data given by Murthy and Ip.[3] The catalyst ignited at high temperature is of a larger crystal size than that at low temperature.

2) Potassium germanates: In order to prepare $3K_2O \cdot 11GeO_2$, K_2CO_3 and GeO_2 were mixed in a 3 : 11 mole ratio and ignited at 800 °C for 4 hr or at 1020 °C for 30 min, while K_2CO_3 and GeO_2 were mixed in a 1 : 7 mole ratio and ignited at 940 °C for 30 min, the product being $K_2O \cdot 7GeO_2$.[4] The end point of formation of these salts was confirmed by the same procedure as described above. In the case of $K_2O \cdot 7GeO_2$, the sintering was observed to occur, and the salt was used as catalyst after being finely ground.

3) Sodium germanate: $2Na_2O \cdot 9GeO_2$ was prepared by igniting a mixture of Na_2CO_3 and GeO_2 in a 2 : 9 mole ratio at 1050 °C for 40 min and the X-ray diffraction patterns of the product were compared with that reported by Murthy and Aguayo.[5]

High-temperature X-ray diffraction and measurements of transformation rate were carried out as reported.[2] All the experiments were carried out in dry nitrogen atmosphere.

Results

Some typical plots of logarithm of a hexagonal fraction, α, against time are shown in Figs. 1 and 2, where α was calculated by $H/H+T$, H or T being the peak height of hexagonal or tetragonal modification. The catalyst and its amount in weight percentage are given in the figures.

Activation energies were calculated from the Arrhenius plots (Figs. 3 and 4), where k was determined from the slope of straight lines. The results are given in Tables 1 and 2.

Discussion

From the study on the role of catalyst during the phase transformation of germanium dioxide[2] it was found that lithium and potassium salts added react with germanium dioxide to form germanate compounds. It was clarified for lithium salt that the formation of lithium germanate, $LiO_2 \cdot 7GeO_2$, occurs at a lower temperature than that of the transformation. Lithium germanate thus formed seems to catalyze the transformation in solid state. Potassium germanate, in contrast, seems to act as a catalyst in liquid state. It is expected that the kinetics of the transformation differ for the two cases. Murthy *et al.*[4] reported that there are many stable or metastable states in the K_2O-GeO_2 system, but since the added amount of potassium salt is rather small, it is desirable to select stable compounds rich in GeO_2. $3K_2O \cdot 11GeO_2$ and $K_2O \cdot 7GeO_2$ were prepared and used as catalysts, and it was found that the difference exists between them.

The phase transformation proceeds with alkali germanate salts. The plots of $\log \alpha$ against time (Figs. 1 and 2) consist of two straight lines, which can be explained by the assumption that the transformation proceeds in two stages, probably nucleation and propagation. However, activation energies calculated for two stages (Figs. 3 and 4) do not differ as much for lithium and sodium germanate as in the case of potassium germanate. This might be accounted for by the difference of solid and liquid catalyst. It could be concluded that lithium and sodium germanate remain in solid state even during the course of transformation, while potassium germanate turns to liquid.

a' : final stage of transformation (Fig. 2-A)
b : initial stage of transformation (Fig. 2-C)
b' : final stage of transformation (Fig. 2-C)

This is also supported by the fact that the temperature where the phase transformation occurs is lower in the case of liquid than in solid catalyst.

In the case of $K_2O \cdot 7GeO_2$ the results seem to be caused by the change of its state, as shown in Fig. 2 (B). The mean value of activation energy obtained from the Arrehnius plot is 50±5 kcal/mol between 850 °C and 900 °C (Table 1). Such a phenomenon was not observed with germanates other than $K_2O \cdot 7GeO_2$.

Table 2. Effect of amount of catalyst upon activation energy (in N_2)

Catalyst	$Li_2O \cdot 7GeO_2$	$3K_2O \cdot 11GeO_2$
1 wt%	110—100	70—98
5 wt%	83— 91	92—
10 wt%	109— 83	—

In the case of $3K_2O \cdot 11GeO_2$ it is probable that the interaction between the salt and germanium dioxide would occur during the course of the transformation and $K_2O \cdot 7GeO_2$ is formed.[4] However, this change was not detected by high-temperature X-ray diffraction, probably because of an insufficient amount of the catalyst for detection. The small values of the activation energy obtained for $3K_2O \cdot 11GeO_2$ may be the result of such an interaction. The catalyst, whose melting point is known to be 1055 °C, would be solid during the transformation so far as no interaction took place.

In the case of sodium germanate the results shown in Figs. 2(C) and 4 are much the same as in the case of lithium germanate. The activation energy obtained is 157 and 149 kcal/mol for first and final stages, respectively. The large values of activation energy would be explained by the fact that sodium germanate is stable and would catalyze the transformation in solid state.

The effect of the preparative method of catalysts on the transformation was observed for lithium germanate as an example for the solid catalyst (Table 1). The rate constant, k, was larger for the catalyst prepared at low temperature than prepared at high temperature, the activation energies differing a great deal from each other. No such effects were observed when potassium germanate was used. It would be concluded that the transformation carried out with solid catalysts is affected by characteristics such as particle size and morphology of the catalyst.

The amount of catalysts used in the transformation has in general no influence upon the activation energy of the transformation (Table 2). In the case of $LiO_2 \cdot 7GeO_2$, the transformation rate increased with 1—5 wt% increase in amount and it becomes saturated at 5—10 wt%. In the case of $3K_2O \cdot 11GeO_2$, the increase in amount causes the sintering of germanium dioxide. This would be accelerated by the presence of the catalyst in liquid state. As a result the calculation of activation energy could not

be carried out in the case of large amounts of $3K_2O \cdot 11GeO_2$.

The role of lithium salt in this transformation was recently reported.[6] The intermediate phase found by the same method as that applied in the transforma- of silicon dioxide[7] increased during the course of the transformation of germanium dioxide.

Effect of Surrounding Atmosphere in the Transformation of Germanium Dioxide

Michiko YONEMURA and Yoshihide KOTERA

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received July 4, 1973)

The effect of surrounding atmosphere on the phase transformation of germanium dioxide with alkali germanate catalysts was investigated by high temperature X-ray diffraction method. The catalysts were $Li_2O \cdot 7GeO_2$, $3K_2O \cdot 11GeO_2$, $K_2O \cdot 7GeO_2$ and $2Na_2O \cdot 9GeO_2$. The ambient atmospheres were dry or wet nitrogen and oxygen. The effect of atmosphere was found to be not so large as that of the catalyst. Water vapor has prominent effects upon the transformation as in other solid state reactions.

The role of the catalyst during the phase transformation of germanium dioxide was elucidated in a previous paper.[1] It is known that the surrounding atmosphere affects the rate and activation energy of the transformation singnificantly. It is thought that the atmosphere has a different effect on the transformation depending upon the catalyst used. In the present study the role of the surrounding atmosphere during the transformation was studied in detail under standardized conditions.

Experimental

The starting materials and the procedure of high-temperature X-ray diffraction were similar to those reported.[1] A high-temperature X-ray cell was filled with gas, dry or wet nitrogen and oxygen being used for the ambient atmospheres. Nitrogen and oxygen were dried by passing through concd. sulfuric acid and anhydrous calcium chloride; or wetted by allowing the gas to flow through water at 0 or 51±1 °C (water vapor pressure 5 or 100 mmHg, respec-

tively). The flow rate of gas was held constant by a tube flowmeter.

Results

Typical plots of logarithm of hexagonal fraction against time are shown in Fig. 1. Rate constant, k, was calculated in the same way as that described in the previous paper for the initial and final stages. The catalyst and atmosphere used are given in the Figures.

Activation energies were calculated from Arrhenius plots (Fig. 2). The experimental data with the atmosphere of dry nitrogen were reported.[1] The values of activation energy and pre-exponential factor are given in Tables 1 and 2.

Discussion

It was found that lithium or potassium salt added reacts with germanium oxide to form a germanate compound,[1,2] and that the surrounding atmosphere affects the rate and activation energy of the transformation significantly.[3] In these cases a different effect depending on the kind of germanate was expected, especially between one acting in solid state and one in liquid state.

From the values of activation energy it was confirmed that the effect of the surrounding atmosphere upon the phase transformation is smaller than that of the catalyst. While the values of activation energy do not change so much, the pre-exponential factor of transformation was dependent upon the surrounding atmosphere (Table 1).

A comparison of the relative positions of initial and final stages in the Arrhenius plot (Fig. 2), shows that they do not intersect in the temperature range studied in the cases of $Li_2O \cdot 7GeO_2$, ((A) a and a', b and b'), $2Na_2O \cdot 9GeO_2$ ((A) c and c') and $K_2O \cdot 7GeO_2$ ((C) a and a', b and b') catalysts. Their positions are in contrast to those of the two former catalysts acting in a solid state and the latter in a liquid one. This indicates that the rate k is higher in the final stage than in the initial stage for solid catalysts and lower for liquid ones. In the case of $3K_2O \cdot 11GeO_2$ ((B) a and a', b and b') the lines cross, the points of intersection lying between 870 and 890 °C. These temperatures lie near the eutectic point between $K_2O \cdot 7GeO_2$ and GeO_2 in the phase diagram reported by Murthy *et al.*[4] This salt would be formed by the reaction of $3K_2O \cdot 11GeO_2$ and GeO_2.

The effect of oxygen atmosphere is shown in Table 1, where oxygen makes the activation energy in the final stage small for $Li_2O \cdot 7GeO_2$ and $2Na_2O \cdot 9GeO_2$ which act in a solid state. However the difference between nitrogen and oxygen is not so large for liquid $K_2O \cdot 7GeO_2$ as in the two former catalysts. The effect of oxygen could be explained by the formation of germanium monoxide, which is assumed to be stable at high temperature. The effect of germanium monoxide seems to be more prominent on the transformation with a solid catalyst than with a liquid one.

The effects of the preparing conditions of solid catalysts upon the activation energy of the phase transformation, recognized in the nitrogen atmosphere,[1] were not observed in the present experiment in which oxygen atmosphere was used. They were not observed for liquid catalysts independent of the atmosphere during the transformation. The effect upon the rate of transformation is independent of the atmosphere and a high rate was found for catalysts prepared at lower temperature. It seems that the effect of the surrounding atmosphere upon the transformation is larger than that of the preparing conditions of the catalyst.

The effect of water vapor was observed only for the initial stage for low pressure. It was found also for the final stage when its pressure is as high as 100 mmHg. We see that water vapor influences the pre-exponential factor (Table 2), such phenomena being often found in the solid state reaction. When the vapor pressure was as high as 500 mmHg, the transformation rate was found to be high especially in the final stage, but the lowering of X-ray intensity made accurate determination of the rate impossible.

The effect of oxygen or water vapor upon the transformation rate is observed to be similar by independent

Table 2. Values of pre-exponential factor

Atmosphere			log A (A : pre-exponential factor) Catalyst			
			$Li_2O \cdot 7GeO_2$ 5 wt%	$3K_2O \cdot 11GeO_2$ 1 wt%	$K_2O \cdot 7GeO_2$ 2 wt%	$2Na_2O \cdot 9GeO_2$ 5 wt%
N_2	Dry		13.4 15.3	11.3 16.9		27.2 26.0
			(21.6 22.1)	(11.7 19.9)

		100 mmHg	15.1 12.6			
O_2	Dry		15.9 13.2	6.9 23.1	5.5	24.5 17.8
			(15.9 14.3)	(7.8 22.3)		
	Wet	5 mmHg	13.4 15.1	6.8 19.9	19.9 20.3	17.8 13.5
		100 mmHg	13.1 12.1	15.6 23.7	9.5 10.2	

Note: See Table 1.

of the catalyst; k is larger for oxygen than for nitrogen and for wet atmosphere than for dry one. However, the log α–t plot (Fig. 1) scatters more in the wet atmosphere than in the oxygen atmosphere.

The co-operative effect of oxygen and water vapor is so complicated that it is difficult to give an explanation. They might compensate each other when the catalyst is $Li_2O \cdot 7GeO_2$ and the vapor pressure of water as low as 5 mmHg. For the catalyst $3K_2O \cdot 11GeO_2$, the co-operative effect is very clear.

The so-called "compensation effect" was observed (Tables 1 and 2) and the linearity between activation energy and common logarithm of pre-exponential factor was established. This might be the first time for it to be found in the solid state reaction.

Vibrational Spectrum of Trisdimethylaminocyclopropenium Perchlorate

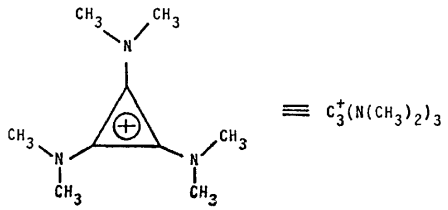
Zen-ichi YOSHIDA, Yoshiyuki TAWARA, Shizue HIROTA, and Hisanobu OGOSHI
Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received July 6, 1973)

Infrared spectrum in the region 4000—100 cm^{-1} and Raman spectrum of trisdimethylaminocyclopropenium perchlorate (1) have been measured. Band assignments have been made on the basis of normal coordinate analysis and deuteration of the methyl groups. Remarkable stabilization of cyclopropenium ion due to the peripheral amino groups is attributed to a marked delocalization of the positive charge of the ring on the amino groups through conjugation. Peculiar electronic structure of trisaminocyclopropenium ion is explained in terms of its vibrational spectrum.

Cyclopropenium cations have received much attention in both the field of organic chemistry and molecular spectroscopies, mainly because of the fact that the smallest non-benzenoid aromatic cation (2π electron system) possesses high strain energy. The infrared spectrum of this system is usually discussed on the characteristic bands assigned to the skeletal vibrations of the three membered ring (C_3^+ core). The normal coordinate analysis of parent,[11] trimethyl-[11] and trichloro-cyclopropenium cations[1,11] was carried out using the Urey-Bradley force field. The calculation by the GVFF method was also reported for trichloro- and triphenyl-cyclopropenium cations in the simplified model.[2] However, no vibrational spectra of the cyclopropenium ion substituted with the strongly electron donating group (X) have been found so far. Such a tri-X-substituted cyclopropenium ion is considered to offer a good model for the investigation of physical and chemical properties of the strongly perturbed cyclopropenium ion.

Recently we have succeeded in the synthesis of triaminocyclopropenium ion[3] which is very stable (even in hot water) in contrast to the cyclopropenium ions reported so far. Thus the unusual physico-chemical properties of triaminocyclopropenium ion are expected to reflect on its vibrational spectrum. The present paper deals with the vibrational spectra of tris(dimethylamino)cyclopropenium ion(1) and its deutero analog in order to elucidate its structural feature at the ground state.



(1)

Experimental

1,2,3-Trisdimethylaminocyclopropenium perchlorate (1) was obtained by the treatment of tetrachlorocyclopropene with dimethylamine in methylene chloride.[3] Deuteration was performed with dimethylamine hydrochloride-d_6 (99%, E. Merck Co.) as a starting material.

The infrared spectra between 4000 and 300 cm^{-1} were recorded on a Perkin-Elmer Model 521 spectrophotometer and the far-infrared spectra on a Perkin-Elmer-Hitachi FIS-3 far-infrared photometer. The KBr-pellet technique was used for the former and the Nujol mull technique with a polyethylene window for the latter. Raman spectrum in the solid state was recorded on a JASCO R-1100 spectrophotometer with He-Ne laser (6328 Å).

Normal Coordinate Analysis

Figure 1 illustrates the molecular model and the internal coordinates used for normal coordinate analysis. According to a recent crystallographic study[4] of (1), the molecular symmetry can be approximated to D_{3h}. Out-of-plane deviations of six methyl groups are found to be very small. In order to simplify the calculation, each of the six methyl groups is treated as a single atom having a mass of 15.035. The G-matrix elements were evaluated by using the structure parameters listed in Table 1. These values were slightly changed from those of the original X-ray study in order to adjust the molecular dimension to D_{3h} symmetry.[6] Thus in this model, thirty normal vibrations, 30 ($12\times3-6$), are grouped into $4A_1'+3A_2'+$

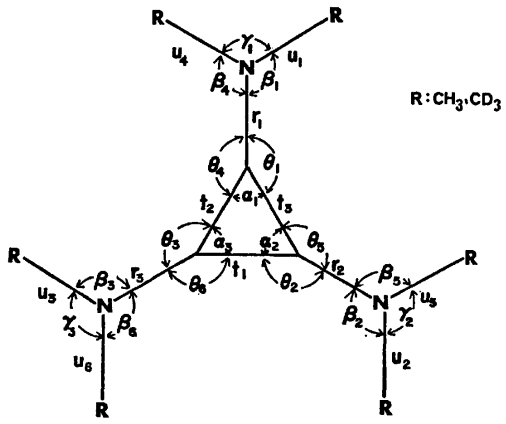


Fig. 1. Internal coordinates for the in-plane vibrations of trisdimethylaminocyclopropenium ion.

TABLE 1. MOLECULAR DIMENSIONS

Bond length (Å)	Bond angle
d(N-R)=1.457 (1.457)	∠C-N-R=120° (119.5°)
d(C-N)=1.332 (1.333)	∠R-N-R=120° (119.0°)
d(C-C)=1.362 (1.363)	∠N-C-C=150° (150.0°)
	∠C-C-C=60° (60.0°)

Values in brackets indicate the average value from X-ray analysis.[4]

	$S_{12}=(\Delta\beta_2-\Delta\beta_5-\Delta\beta_3+\Delta\beta_6)/2$	δ(C-C-N)

a) Symbols ν and δ denote stretching and in-plane bending vibrations, respectively.

$7E'+1A_2''+3E'')$. There are sixteen infrared active modes; 7E′ (in-plane) and $2A_2''$ (out-of-plane), and twenty four Raman active modes; 7E′ (in-plane), $4A_1'$ (in-plane) and 3E″ (out-of-plane). We have calculated eleven in-plane vibrations (7E′ and $4A_1'$) by means of Wilson's GF matrix method. The twelve symmetry coordinates used in the calculation are given in Table 2.

The F-matrix elements are expressed by the simple Urey-Bradley force field. In the first calculation, the stretching force constants K(C–C), K(C–N), and K-(N–CH_3) were estimated from those of trichlorocyclopropenium ion,[1] guanidium salt,[7] and alkyl urea,[8] respectively. The bending and repulsive forec constants were transferred from those of the amide compounds.[9]

The computational procedures were carried out by using the FACOM in Kyoto University. The final set of force constants were obtained by referring to the Jacobian matrix elements followed by further refinement using the least squares method (Table 3). Calculated frequencies are compared with those observed for (1) and (1)-d_{18} (Table 4). We see that agreement is quite satisfactory in spite of a single mass approximation for the methyl group. For the band assignments, the potential energy distribution was calculated for each normal vibration in terms of the symmetry coordinates are shown in the last column of Table 4.

Results

Band Assignments. The infrared spectra of (1) and (1)-d_{18} from 4000 to 400 cm^{-1} and from 400 to 100 cm^{-1} are shown respectively in Figs. 2 and 3. The Raman spectrum of (1) in the solid state is shown in Fig. 4. In normal coordinate analyses, we have approximated the methyl group as a single atom having masses of 15.035 and 18.035 for (1) and (1)-d_{18}, respectively. Thus the absorptions due to the methyl group were confirmed by comparing the spectrum of (1) with that of (1)-d_{18}. The four bands at 2970, 2935, 2892, and 2842 cm^{-1} are assigned to the C–H stretching vibrations, which disappear upon deuteration of the methyl groups. The deutero analog (1)-d_{18} shows three bands at 2370, 2235 and 2079 cm^{-1} assigned to the C–D stretching vibrations. The broad and strong absorption at 1553 cm^{-1} is mainly due to the C_3^+–N< stretching vibration and the C–C ring stretching vibration according to the potential energy distribution. However, the calculation indicates a slight shift of ν_5 upon deuteration. The observed value shows a

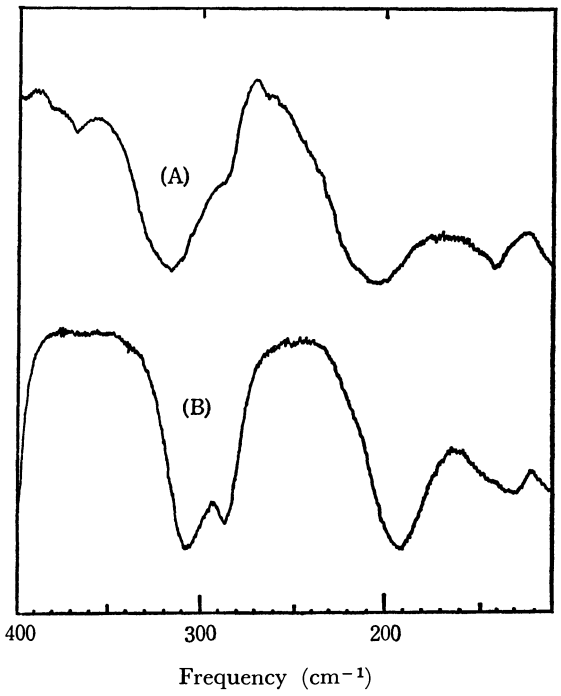

Fig. 3. Far-infrared spectrum of trisdimethylaminocyclopropenium perchlorate (A) and its deutero analog (B).

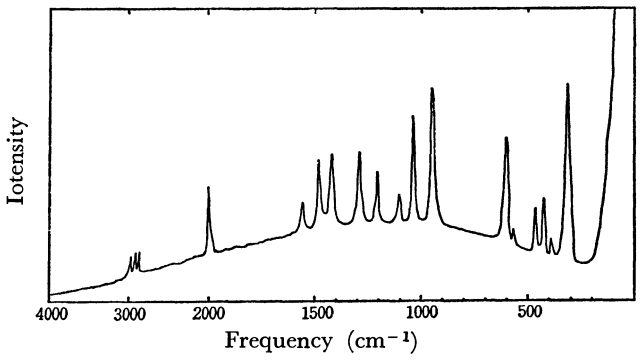

Fig. 4. Raman spectrum of trisdimethylaminocyclopropenium perchlorate.

lower frequency-shift of about 20 cm^{-1} upon deuteration. The discrepancy is attributed to the one mass approximation of the CH_3 and CD_3 groups. Breslow *et al.* reported that the degenerate ring deformation of the $C_3H_3^+$ mode appears at 1276 cm^{-1}.[10] We have assigned the corresponding absorption of the $C_3(CH_3)_3^+ \cdot SbCl_6^-$ to 1490 cm^{-1} referring to the spectra of the $C_3(CD_3)_3^+ \cdot SbCl_6^-$.[11]

The Raman line at 1135 cm^{-1} is assigned to the symmetric C_3^+–N< stretching (ν_2) coupled with the N–CH_3 symmetric stretching (ν_3). The band at 1238 cm^{-1} is assigned to the C_3^+–N< stretching vibration. The Raman line at 1985 cm^{-1} of medium intensity is assigned to the totally symmetric C–C stretching vibration S_1(C_3^+ core breathing) coupled with the C_3^+–N stretching mode (S_2). The C_3^+ core stretching (S_1) shows the largest contribution to ν_1. The calculation indicates that the coupling of the C_3^+ ring stretching vibration with the C–N< stretching mode in E′ species is stronger than that in A_1' species.

The bands at 1455 and 1405 cm^{-1} of (1) are interpreted to be the CH_3 asymmetric and symmetric deformation modes. No CH_3 deformation band appears for (1)-d_{18} in this region. The two bands of (1)-d_{18} appear at 1180 and 1120 cm^{-1} as shoulder bands of the strong absorption (1100 cm^{-1}) of the ClO_4^-. A lower frequency band of the CH_3 rocking of (1) appears at 1225 cm^{-1} and 1134 cm^{-1}. The deutero compound (1)-d_{18} shows two absorptions due to the CD_3 rocking modes at 904 and 835 cm^{-1}.

The sharp band at 1060 cm^{-1} of (1)-d_{18} is explained to be the C–C stretching of the C_3^+ ring and the N–CD_3 stretching vibration. The corresponding absorption of (1) seems to shift to a slightly higher frequency region resulting in the overlapping with the strong absorption of the ClO_4^- ion. The band at 790 cm^{-1} of (1) can be assigned to the N–CH_3 stretching mode, which is confirmed by deuteration of the methyl group. The N–CD_3 stretching appears at 732 cm^{-1} in accordance with the calculation. The Raman line at 614 cm^{-1} is assigned to the symmetric N–CH_3 stretching vibration. The bands at 455, 316, and 130 cm^{-1} of (1) are assigned to the CH_3–N–CH_3 bending, the C_3^+–N–CH_3 bending and the $C_3^+N(CH_3)_2$ bending modes, respectively. The bands shift to a slightly lower frequency region upon deuteration. A weak band at 290 cm^{-1} and a band at 206 cm^{-1} are presumably due to the out-of-plane deformations of the N–$(CH_3)_2$ groups. The presence of perchlorate ion is confirmed by the bands at 1100 and 680 cm^{-1} assigned to the Cl–O stretching and bending modes of ClO_4^- ion.

Discussion

It is noted that extremely stable triaminocyclopropenium ion (1) shows the highest frequency of the totally symmetric C–C stretching vibration of the C_3^+ core among the various cyclopropenium ions reported so far (Table 5). For example, the ions $C_3(CH_3)_3^+$, $C_3(C_6H_5)_3^+$ and $C_3Cl_3^+$ exhibit the C–C stretching mode (A_1') at 1880, 1845 and 1791 cm^{-1} in their Raman spectra respectively. It is noteworthy that there is

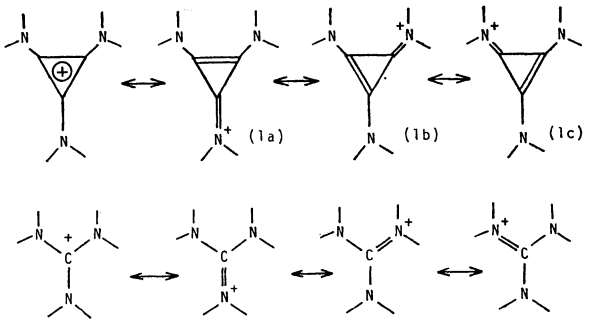
an empirical linear relationship between the stability (pK_{R^+}) of C_3^+ core and the frequencies of the C_3^+ core vibrations (A_1' and E′).[12] The two frequencies shift towards a higher frequency region with the increase of the relative stability of the cyclopropenium ion. Although pK_{R^+} of (1) could not be determined by the usual potentiometric titration because of its alkaline hydrolysis,[5] we could estimate this value to be 13 from the relationship between pK_{R^+} values of cyclopropenium ions and their degenerate ring deformation (Table 5). Such a remarkable stabilization of cyclopropenium ion by amino-substitution has also been observed in the case of aminodiphenylcyclopropenium ion[14] ($pK_{R^+}=10$). The INDO calculation of triaminocyclopropenium ion suggests that its high stability is due to the large electron-donating π conjugative effect of amino group on the C_3^+ ring.[15] Since the frequency of ring deformation vibration is sensitive to the peripheral substituent, the vibrational spectrum of highly strained cyclopropenium ion may provide an accessible and convenient method to estimate its relative stability.

Of the force constants obtained for trisdimethylaminocyclopropenium ion (Table 3), the force constant (6.62) of the C–C stretching vibration of (1) is larger than the force constants (6.22 and 6.31) of trichloro- and trimethyl-cyclopropenium ions.[11] The values ($Cl< CH_3<N(CH_3)_2$) seem to be strange, since electron-donating π conjugative effect of the amino group (+0.190) is larger than that of Cl- and CH_3- (+0.005) groups.[15] Since the C–C π bond order ($CH_3> N(CH_3)_2$) of the C_3^+ ring decreases with increase in electron-donating nature of substituent, the observed increase of the ring stretching force constant ($CH_3< N(CH_3)_2$) might be responsible for the marked increase of the C–C σ-bond order in (1). This is a peculiar property of the cyclopropenium ring. The X-ray crystallographic study[6] of (1) indicates that the C–C bond length of (1) is about 0.01 Å shorter than that of triphenylcyclopropenium ion.[13] The result seems to support the larger C–C stretching force constant of (1). It is possible to explain the increase in the K(C–C) on the basis of the decrease in the replusion between the carbon nuclei of the three membered ring due to the strong electron donating amino groups. It is of particular interest to compare the C–N stretching vibration of (1) with that of the guanidine hydrochloride, for which Yamaguchi[7] assigned the infrared



absorption at 1640 cm^{-1} and Raman line at 1015 cm^{-1} to the degenerate C–N stretching vibration and symmetric C–N stretching vibration, respectively. The large contribution of the C_3^+–N< stretching mode to this band indicates a strong π-conjugative interaction between the amino group and the C_3^+ core. The canonical structures of (1) can be shown as above in analogy with guanidium salt. The INDO type calculation shows a considerable migration of the positive charge from the C_3^+ ring to the peripheral amino groups,[15] suggesting a large contribution of the charge-delocalized structures (Ia, Ib, and Ic).

It is interesting to note that the C_3^+–N stretching force constant is very large and comparable to that of guanidium salt.[7] This can be interpreted in terms of the large delocalition of the positive charge to the peripheral amino groups. The C–N bond lengths of (1) and guadinium salt obtained by X-ray analysis are 1.333 Å and 1.34 Å, respectively, which are markedly smaller than the length of the ordinary C–N single bond (*ca.* 1.47 Å). The small negative bending force constant of the C_3^+ core is derived from the transformation of the internal coordinates to the symmetry involving the redundant condition of the ring C_3^+ system.[11]

Characteristic Studies on Dealumination of Faujasite-type Zeolite

Kazuo TSUTSUMI, Hisao KAJIWARA, and Hiroshi TAKAHASHI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received July 11, 1973)

Aluminium ion was extracted stoichiometrically from the framework of the faujasite-type zeolite by EDTA treatment. Dealuminated zeolites with various silica/alumina ratios (from 4.80 to 10.29) were obtained. A dealuminated zeolite does not necessarily show the molecular-sieve-type adsorption isotherm of nitrogen. The lattice constant of zeolite decreases with the silica/alumina ratio. The zeolite with an increased silica/alumina ratio has a higher catalytic activity for a cumene-cracking reaction than the parent H-$Y_{4.80}$ zeolite. It is suggested, on the basis of infrared spectroscopic and calorimetric measurements, that the total number of acid sites decreases with dealumination, while the number of strong acid sites increases. These strong aicd sites seem to contribute to the catalytic activity of dealuminated zeolite.

The catalytic properties of zeolite depend mostly on the type of zeolite, the kind and degree of the exchanged cation, and the silica/alumina ratio. The first three factors have been reported on by many authors, but the effect of the silica/alumina ratio has scarcely been investigated at all. Ward showed that the Brönsted acidity of Ca- or Mg- exchanged faujasite-type zeolite and the catalytic activity for the isomerization of *o*-xylene increased[1] with the silica/alumina ratio.

We have investigated the acidity,[2] and catalytic activity for cumene cracking[3] and the electrostatic-field strength[4] of faujasite-type zeolite as functions of the silica/alumina ratio. In the case of Ca-exchanged zeolite, the electrostatic-field becomes stronger with the increase in the silica/alumina ratio. The cumene-cracking activity of Ca-form zeolite follows in magnitude the change in the electrostatic-field strength. The number of acid sites and the catalytic activity of decationated zeolite increase with the increase in the silica/alumina ratio.

It has been established that the aluminium ion can be readily extracted from the framework of clinoptilolite[5] or erionite[6] by a mineral-acid treatment. The removal of aluminium from mordenite frameworks can also be performed by hydrochloric-acid treatment without distroying the crystal structure as far as the X-ray diffraction patterns are concerned. The catalytic activity and other physicochemical properties of Al-deficient mordenite have been examined by several authors in order to make clear the effect of the dealumination on the diffusion behavior of reactants.[7,8]

It was recently reported that aluminium could also be removed from faujasite-type zeolite frameworks by ethylenediamine-tetraacetic acid (H_4EDTA) treatment.[9] Topchieva and T'huoang reported that the highest activity was exhibited by a specimen in which half of the aluminium atoms had been removed from the faujasite frameworks.[10] Beaumont and Barthomeuf[11–13] and Beaumont *et al.*[14] measured the acidity of the dealuminated zeolite by means of *n*-butylamine titration and infrared spectroscopy.

This paper reports on studies of the effect of the silica/alumina ratio in correlation with the structure, adsorption, acidity, acid strength and catalytic activity, by using the EDTA-treated faujasite-type zeolites.

Experimental

Synthetic sodium faujasite (Linde SK-40) was used as the starting material. The ion exchange for the ammonium ion was performed in an aqueous solution of ammonium chloride by the conventional method. Twenty grams of NH_4^+-exchanged zeolite was treated with an EDTA aqueous solution of an appropriate concentration by means of a Soxhlet extractor. The samples obtained were washed, dried and then equilibrated with saturated vapor of water and the compositions were determined by chemical analysis.

The X-ray powder diagrams were recorded with an X-ray diffractometer (Rigaku Denki Co., Ltd., D-9C Type) using Cu$K\alpha$ radiation, the scanning speed being 1° or 1/8° 2θ/min, the time constant 4 s, receiving slit 0.15 mm, and angular aperture 1°. Silicon was used as an internal standard for the measurement of the lattice constant. The (642) diffraction line of zeolite was used for the measurement.

Mid-infrared spectroscopy has been applied to changes in the zeolite structure with dealumination. The spectra were obtained using the KBr wafer technique. The wafer concentrations were adjusted to obtain the desired absorbance. The spectra were recorded with a Hitachi Model EPI-G3 spectrophotometer.

The nitrogen adsorption isotherms were obtained with a conventional volumetric adsorption apparatus. The pore distribution was calculated by the Inkley method.

The catalytic activity for the cumene-cracking reaction was measured by means of a pulse reactor. The apparatus has been described in detail.[3]

The second infrared spectroscopic technique was used to measure the spectra in the OH stretching region and those of the adsorbed pyridine. The zeolite samples were pressed into a wafer with a thickness of about 10 mg/cm^2. The sample was set in a quartz cell fitted with NaCl windows and heated to 450 °C under 10^{-5} mmHg. The cell was then cooled to room temperature under vacuum; the spectrum was thus obtained. The spectrum of the pyridine adsorbed was also observed. Excess pyridine was adsorbed on the sample and allowed to equilibrate for 3 hr. The spectrum of the adsorbate was obtained after the sample-adsorbate had been evacuated at 250 °C in order to remove the physically adsorbed pyridine.

The differential heats of the adsorption of ammonia were measured in order to estimate the acid strength of zeolite. About one gram of zeolite was placed in the stainless-steel cell, and evacuated at 400 °C under 10^{-5} mmHg over a period of several hours. The cell was set in a twin con-

duction-type calorimeter until thermal equilibrium was reached at 25 °C. Gaseous ammonia was then introduced into the cell. The heat liberated was recorded and calibrated by a known amount of heat.

Results and Discussion

Chemical Compositions. The compositions of the samples obtained are shown in Table 1. Zeolite becomes cation-deficient with dealumination. The silica/alumina ratios are plotted against the moles of EDTA used in Fig. 1. The broken line indicates the relation calculated by Eq. (1).

$$x\mathrm{H_4EDTA} + \mathrm{NH_4AlO_2(SiO_2)_{2.40}} \longrightarrow x\mathrm{NH_4AlEDTA} + (\mathrm{NH_4AlO_2})_{1-x}(\mathrm{H_2O})_{2x}(\mathrm{SiO_2})_{2.40} \quad (1)$$

The close fit of the points shows that the dealumination reaction proceeds stoichiometrically as Kerr suggested.[9]

Table 1. Zeolite compositions

Sample	Composition
H-$Y_{4.80}$	$0.78(NH_4)_2O\cdot 0.15Na_2O\cdot Al_2O_3\cdot 4.80SiO_2$
H-$Y_{5.97}$	$0.71(NH_4)_2O\cdot 0.17Na_2O\cdot Al_2O_3\cdot 5.97SiO_2$
H-$Y_{6.54}$	$0.70(NH_4)_2O\cdot 0.18Na_2O\cdot Al_2O_3\cdot 6.54SiO_2$
H-$Y_{7.38}$	$0.68(NH_4)_2O\cdot 0.19Na_2O\cdot Al_2O_3\cdot 7.38SiO_2$
H-$Y_{10.29}$	$0.67(NH_4)_2O\cdot 0.16Na_2O\cdot Al_2O_3\cdot 10.29SiO_2$

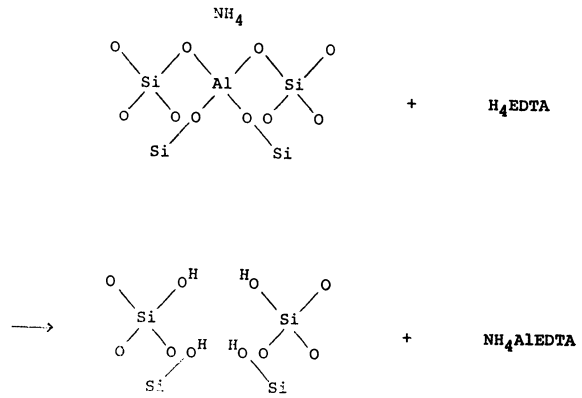

Fig. 2. Two-dimentional representation of the dealuminated zeolite.

The resulting model of zeolite when aluminium ion was removed from the framework according to Eq. (1) is illustrated two-dimensionally in Fig. 2.

Structural Characters. The X-ray diffraction diagrams are illustrated in Fig. 3. It can be seen that the structure of zeolite is not essentially destroyed by the treatment with EDTA. However, on the basis of the changes in the half-value of the breadth and integral intensity, amorphous species were partially produced as EDTA treatment became severe.

The correlation between the lattice constant and the silica/alumina ratio is plotted in Fig. 4. The lattice is contracted as the silica/alumina ratio becomes higher, which seems to be due to the removal of the constitutional aluminium of the zeolite lattice. It is well-known that the lattice constant decreases with the increase in the silica/alumina ratio in X- and Y-type zeolites.[15–17] The results obtained are of interest in the light of this fact.

The mid-infrared spectra of H-$Y_{4.80}$, H-$Y_{7.38}$ and H-$Y_{10.29}$ are shown in Fig. 5. The absorption bands were assigned in detail by Flanigen and Khatami.[18]

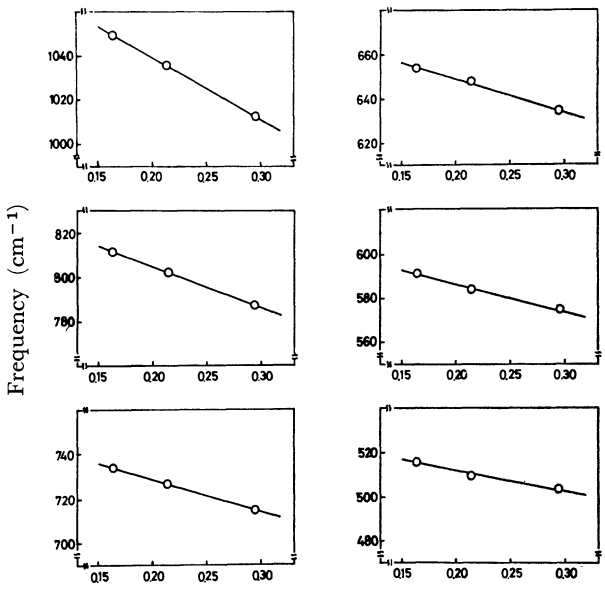

Fig. 6. Correlations between silica/alumina ratio and frequency of various adsorption bands.

Except for the band at about 460 cm^{-1}, the bands are shifted to higher frequency with an increase in the silica/alumina ratio.[19,20] The most intense absorption band, caused by the T–O (T represents Si or Al) asymmetric stretching vibration in the 1010—1050 cm^{-1} region, is very sensitive to the silica/alumina ratio. The absorption wave numbers change linearly with the Al fraction in the zeolite frameworks as is shown in Fig. 6. Since the masses of Al and Si are similar, the increase in frequency with the decrease in Al content is due to the difference in bond length and bond order. The fact that the bond length of Al–O is longer and Al is more electronegative seems to cause a decrease in the force constant of the T–O bond.

Nitrogen Adsorption Behaviors. N_2 adsorption isotherms at the temperature of liquid nitrogen are shown in Fig. 7. H-$Y_{4.80}$ shows a typical molecular-sieve adsorption isotherm; H-$Y_{7.38}$ and H-$Y_{10.29}$ samples with

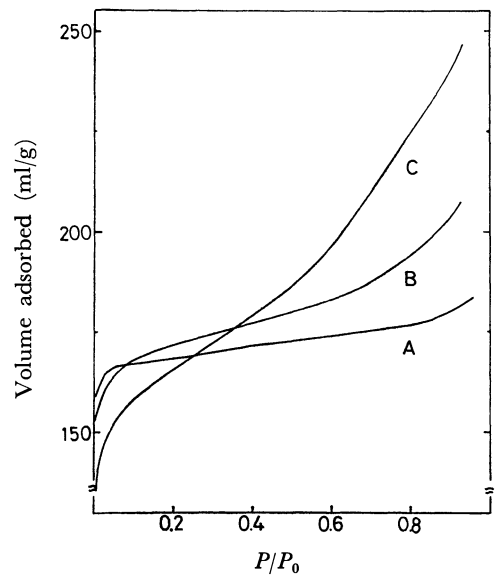

Fig. 7. Nitrogen adsorption isotherms.
A: H-$Y_{4.80}$, B: H-$Y_{7.38}$, C: H-$Y_{10.29}$

higher silica/alumina ratios adsorb increased amounts of nitrogen at higher relative pressures. This is probably due to the presence of amorphous parts. The cumulative pore volume distributions calculated from the adsorption isotherm show that, as the silica/alumina ratio increases, the pore size becomes widely distributed and the typical regular pore structure of zeolite must be partially destroyed.

Catalytic and Acid Properties. Figure 8 shows the cracking activity *vs.* silica/alumina ratio. With the rise in silica/alumina ratio the activity increases reaching a maximum and then decreases. Since Brönsted acid sites are effective for a cumene-cracking reaction, the increased activity seems to be due to the change in the surface-acid properties.

The infrared spectra and the heat of adsorption were studied in order to estimate the acidity and the acid strength.

Hydroxyl bands were detected on H-$Y_{4.80}$ zeolite near 3640 and 3550 cm^{-1} after evacuation at 450 °C.[21] Both hydroxyl groups are known to be acidic. An additional band was observed at 3750 cm^{-1} in the case of Al-deficient zeolite. The band agrees with that of the isolated silanol on the silica surface.[22]

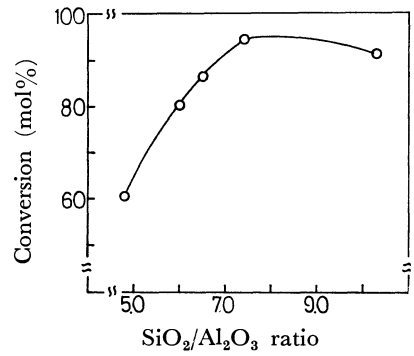

Fig. 8. Correlation between silica/alumina ratio and cumene-cracking activity.
Pretreatment, 550 °C; Reaction, 300 °C

Since four Si–OH bonds are expected to be newly formed by treatment with EDTA, it is probable that the additional band appears at 3750 cm^{-1} (Fig. 2).

Under pyridine adsorption, all the hydroxyl bands were eliminated and new bands were detected at 1400—1700 cm^{-1}. The integrated adsorptivities were measured for the 1540 cm^{-1} band, which was assigned to the pyridinium ion bonded to the Brönsted acid site.[21] From the adsorptivities, the Brönsted acid site was calculated using the apparent integrated molar adsorption intensity of 2.5 cm/μmol.[23] The results are shown in Table 2 for H-$Y_{4.80}$, H-$Y_{7.38}$, and H.$Y_{10.29}$ zeolite. The order of the number of acid sites is H-$Y_{7.38}$>H-$Y_{4.80}$>H-$Y_{10.29}$. Since the protonic acid site is combined with a zeolite negative site, that is $(AlO_2)^-$ ion, Brönsted acid sites are considered to decrease in proportion to dealumination. However, H-$Y_{7.38}$ zeolite showed an increased acidity. This can be explained as follows. The proton becomes mobile as the negative shield of the structural aluminium ion is decreased. As a result, an increased number of sites become effective for the acid. The ratio of Brönsted sites to Lewis sites was also calculated from the integrated absorptivities of the 1490 cm^{-1} band. The ratio of $\varepsilon^{B}_{1490}/\varepsilon^{L}_{1490}$ is assumed to be 5.2.[24] The ratio increases with the silica/alumina ratio. This results from the fact that the distance between Brönsted acid sites becomes longer as Al is removed, and the conversion of the Brönsted sites into Lewis sites on dehydroxylation becomes unfavorable. The H-$Y_{10.29}$ zeolite shows a higher cracking activity than would be expected from its acidity, suggesting the contribution of acid strength to be significant.

Table 2. Brönsted and Lewis acid site concentrations measured by the infrared spectra of adsorbed pyridine

Sample	$\log [T_0/T]d\nu$[a] (cm^{-1})	B acid[b] (mmol/g)	B/L
H-$Y_{4.80}$	8.9	0.44	0.9
H-$Y_{7.38}$	10.8	0.66	5.8
H-$Y_{10.29}$	3.3	0.18	10.2

a) 1540 cm^{-1} band of adsorbed pyridine. b) Apparent integrated molar adsorption intensity taken as 2.5 cm/μmol.

The effects of dealumination on the strength and distribution of acid sites were investigated by measuring the differential heats of adsorption of ammonia. The differential heats of adsorption are plotted against the ammonia molecules adsorbed in Fig. 9. The region of initial adsorption seems to be important in interpreting the relation between the energy distribution and the activity. The initial heats on the samples used are all over 25 kcal/mol at the adsorbed amount of 3×10^{-2} mmol/g. If we assume that one ammonia molecule is adsorbed on each acid site, the number of acid sites with a heat of adsorption of ammonia of over 23 kcal/mol is larger in H-$Y_{10.29}$ than in others. As the amount adsorbed increases to about 1.75 mmol/g, heats of adsorption on H-$Y_{10.29}$ and H-$Y_{7.38}$ fall off steeply to about 14 kcal/mol; on the other hand, the

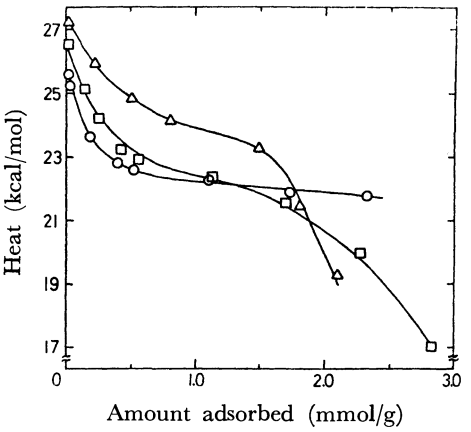

Fig. 9. Differential heats of adsorption of ammonia at 25 °C.
—○—: H-$Y_{4.80}$, —□—: H-$Y_{7.38}$, —△—: H-$Y_{10.29}$

heats of adsorption on H-$Y_{4.80}$ decrease gradually. As a result, the total number of acid sites with heats of adsorption of over 20 kcal/mol of H-$Y_{4.80}$ is larger than that of H-$Y_{10.29}$ and H-$Y_{7.38}$. This would not contradict the infrared spectroscopic data, since the heat of adsorption of ammonia would depend on both Brönsted and Lewis acids and the conversion of the former into the latter could easily occur on H-$Y_{4.80}$.

It is thus evident that the ratio of strong acid sites to all sites increases with dealumination. Beaumont *et al.* showed by means of infrared spectroscopy that the concentration of weak acid sites was lower in aluminium-deficient zeolite than in Y zeolite, while the concentration of strong acid sites was higher.[14] The results agree with ours. The strong acid sites thus formed seem to produce the higher cracking activity of H-$Y_{10.29}$, though the pyridinium-ion concentration of H-$Y_{10.29}$ is lower than that of H-$Y_{4.80}$.

It can be concluded that the change in acid properties with dealumination predominantly influences catalytic activity for the cumene-cracking reaction. However, the appearance of amorphous parts might play a role in the catalytic activity, especially in the case of H-$Y_{10.29}$. The effect of the pore volume on catalytic activity seems to be significant in the structure-sensitive reaction.

Normalization of Potentials in Propylene Carbonate, Ethylene Carbonate, *N,N'*-Dimethylformamide, and Dimethyl Sulfoxide to the Water Scale Studied by Polarographic Method

Niro MATSUURA, Kisaburo UMEMOTO, Masako WAKI, Zen'ichi TAKEUCHI, and Mariko OMOTO

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received July 28, 1973)

The polarographic behavior of alkali metal ions were studied in propylene carbonate(PC), ethylene carbonate(EC), water, *N,N'*-dimethylformamide(DMF), and dimethyl sulfoxide(DMSO). The polarographic half-wave potentials measured in these solvents against an aqueous saturated calomel electrode(SCE) were normalized to the potential of SCE in aqueous system by making corrections of potential required for transfer of rubidium ion from water to these solvents. The free energies of transfer of rubidium ion from water to other solvents were calculated by the application of the modified Born equation. The potential series on the normalized potential scale were given in the order DMSO<DMF<water<PC<EC, indicating that the metal ion-solvent interaction increases with increasing the electron donor property of the solvent. The solvent shifts in potential calculated by the application of the modified Born equation disagreed with the experimental results. In order to fit well the calculated solvent shifts in potential with the experimental results, following values of liquid junction potential must be assumed for these solvents; +0.090 V for DMSO, +0.085 V for DMF, +0.004 V for PC, and −0.064 V for EC against the aqueous phase.

One of the most urgent problems in non-aqueous electrochemistry is to find a way of intercorrelating the potential series measured in different solvents. A direct comparison of electrode potentials measured in various solvents is impossible in the thermodynamic sense. The main difficulty is that the unknown liquid junction potential is inevitably introduced when one attempts to calibrate the potential of a reference electrode in a given solvent against a universal common reference point *viz.* hydrogen electrode or SCE in the aqueous medium. Some efforts have been devoted to estimate the magnitude of the shift in potential for the transfer of a reference redox system from one solvent to another by the application of extrathermodynamic methods.[1,2] In one of these approaches, the standard potentials of redox systems of rubidium,[3,4] ferrocene,[5] cobaltocene,[5] or iron(II–III) complexes of phenanthroline and of its derivatives[6] have been assumed to be respectively constant in various solvents. The ion, constructing each redox system, has been considered to exert a similar type of a weak electrostatic interaction with various solvents, since the ion is symmetrical in shape and slightly polarizable and has large radius but small charge. Accordingly, there should be practically no difference in solvation energies by transfer of these preferred redox systems from one solvent to another. In an alternative way of approach the change in the solvation energy in the process of transferring the ion from one solvent to another was estimated on the assumption of "modified Born equation." The application of the Born equation[7] is in principle seriously limited owing to the ignorance of specific solvation or dielectric saturation effect of solvent towards solute ions. Nevertheless, a consistent value of free energy of solvation has been plausibly obtained, provided a correction term for crystal radius of an ion is introduced in Born equation as effective ionic radius which fits with the radius of a cavity present in the dielectric medium.[8] A similar approximation has been also proposed for Born equation by taking into account the dielectric properties of solvent in the nearest neighborhood of ions.[9] The classical method of Latimer's effective radii of hydrated ions has been recently revalued since there is no other reliable data on the variation of dielectric constant of solvent in the vicinity of solute ions.[10] In this connection, Koepp *et al.*[11] have estimated the solvation energies for rubidium ion in non-aqueous solvents by measuring the solubility products of alkali metal halides in various solvents. Still more, Coetzee *et al.*[12,13] calculated the free energy of transfer for rubidium ion in various nitriles by measuring the polarographic half-wave potentials.

Takaoka[14] proposed an experimental method to refer the polarographic half-wave potentials in DMF to an aqueous SCE. As a reference electrode, he used an aqueous SCE equipped with a non-aqueous salt bridge. He estimated the liquid junction potential at the interphase between the aqueous and the non-aqueous media negligibly small. However, his argument for estimating the liquid junction potential was based on only the transference phenomena of solute ions and the solvent shift in the activity coefficients of ions was not taken into account. Accordingly, his conclusion should be open to further examination.

In this work, polarographic behaviors of alkali metal ions in several selected organic solvents were studied for examining the reversibility of the electrode process. The free energy changes in transfer of rubidium ion from water to other solvents were evaluated from the reversible polarographic half-wave potentials by using the modified Born equation. The liquid junction potentials of the interphase between water and non-aqueous solvent were estimated by comparing the calculated solvent shift in potentials with the experimental results.

Experimental

Solvent. DMF was dehydrated over oven-dried potassium carbonate and DMSO was freed from impurities with activated alumina prior to distillation. PC and EC were

treated with *p*-toluenesulfonic acid for the removal of basic contaminants.[15] All these solvents were distilled twice in a current of dry nitrogen gas at a reduced pressure of about 20 Torr. The water content of the middle fraction of the distillates was always less than 0.01%, as determined by the Karl-Fischer titration. Triply distilled water was used throughout the runs for the measurement in aqueous medium.

Electrolyte. Tetraethylammonium perchlorate(TEAP) was prepared by the double decomposition of tetraethylammonium iodide with sodium perchlorate.[16] The starting material, tetraethylammonium iodide, was synthesized by heating an equimolar mixture of triethylamine and ethyliodide at 80 °C for two hours in nitrobenzene.[17] Tetrabutylammonium perchlorate(TBAP) was prepared in a similar way as TEAP from tetrabutylammonium bromide which was synthesized by refluxing an equimolar mixture of tributylamine and butyl bromide in acetonitrile for 36 hours.[18] TEAP was recrystallized from hot water for five times. TBAP was purified by dissolving it in hot ethyl alcohol followed by precipitation with the addition of water, and this treatment was repeated for five times. Conversions into perchlorate of potassium, rubidium, caesium and thallium were made by the double decomposition of their chlorides or nitrates with perchloric acid. Zinc perchlorate was prepared by heating zinc metal to dryness with an excess of perchloric acid. Lithium and sodium perchlorates were obtained commercially. All these perchlorates were recrystallized from water for several times. The G. R. grade barium and silver perchlorates, and cadmium nitrate were used without further purification. All these electrolytes were kept over phosphorus pentoxide, and before use TEAP and TBAP were dried at 70 °C and other perchlorates at 100 °C in vacuum-oven.

Polarography. The polarographic measurement was made by using an H-type cell with compartments A and B separated by a sintered glass diaphragm. The dropping mercury electrode(DME) was inserted into compartment A and an agar salt bridge into compartment B. The salt bridge was prepared as follows: the lower half portion of a glass tubing sealed with a fine porosity sintered glass at one end was filled with agar solution composed of 70% DMF-30% water mixture containing 0.5 M TEAP, and then the upper half portion with aqueous agar solution containing 1.0 M sodium chloride. The potential drift caused by the salt bridge amounts to several tens of milli-volts immediately after the preparation of the salt bridge, while it fell to minimum after several tens of days of aging by immersing it in DMF. The potential of the SCE with the salt bridge was calibrated against an auxiliary aqueous SCE of common type. As the SCE of the former special type being kept in compartment B of the H-type cell, the DME in compartment A was replaced with another SCE of common type. Potential measurement between these two SCE was performed by allowing the KCl solution to flow out slightly from the latter aqueous SCE through a sintered glass.[14] Polarogram was recorded after the passage of nitrogen gas for 20 min. The potential was supplied manually with an accuracy of ± 0.1 mV and iR drop was corrected. During the runs the temperature was kept at 40 °C for EC and at 25 °C for all other solvents. The DME has following characteristics; $m=0.620$ mg/s and $t=4.0$ s for water, $m=0.764$ mg/s and $t=3.9$ s in DMSO and $m=0.727$ mg/s and $t=4.0$ s in PC.

Results and Discussion

Reversibility. The DC and AC polarograms of alkali metal perchlorated indicated that the electrode process is one electron reduction process not only in aqueous medium but also in the non-aqueous solvents. The DC polarographic waves were diffusion-controlled as evidenced by the limiting currents proportional to the square root of the height of mercury head. The peak current of the AC polarogram was independent of the height of mercury head. A trace of water left unremoved in the non-aqueous media, if it is less than 0.1%, did not affect the half wave potential $E_{1/2}$ and the peak potential E_p. The reversibility of the electrode reaction was examined from the slope of $\log(i_d-i)/i$ *vs.* E plots, the half-width of E_p peak ($\delta E_{p/2}$) and the reversibility factor defined by the current ratio $i_p/i_d\tau^{1/2}$.[19] All these data are represented together with the potential values in Table 1. The observed waves were all reversible or quasi-reversible except for a few example, particularly for lithium ion.

Potentials in Aqueous Medium. In Table 1(a) the half wave potentials and the peak potentials of alkali metal ions at a fixed concentration of 1×10^{-3} M in 0.1 M TEAP aqueous solution are represented. The values of half-wave potential for alkali metal ions are in good agreement with those given in literatures.[4,20] The reversibilities were shown excellent as examined from the slope of log-plots, $\delta E_{p/2}$, $i_p/i_d\tau^{1/2}$ ratio and $(E_p-E_{1/2})$ by comparing them with the referred values of thallium(I) ion whose reversibility in perchlorate solution is well accepted.[21] By varing the concentration of supporting electrolyte in the range between 0.025 and 0.25 M, the $E_{1/2}$ values differed less than several milli-volts. Consequently, it is possible to assume that there is no association between the alkali metal cations and the perchlorate anion, at least in a TEAP concentration range cited above.[22-24]

Potentials in PC and EC. The results in Tables 1(b) and (c) for the potentials of alkali metal ions in PC and EC can be regarded as potential values of reversible process except for caesium in EC and lithium in both PC and EC. Despite of reversibility, an unusual form of polarogram was obtained in PC, showing an appreciable deviation of slope of log-plots, depending on whether a maximum or an average current is taken for DC ploarogram. The values in parentheses in Table 1(b) for the slope of log-plot made with the average current showed deviation from values of reversible wave. A correct analysis of DC polarogram in solvent of high viscosity,[13] PC, must be made with the maximum current polarogram.

Potentials in DMF and DMSO. The results in Tables 1(d) and (e) show that all the alkali metal ions except for lithium ion gave reversible wave in DMF and DMSO containing 0.1 M TEAP. The irreversibility of the polarographic wave of lithium ion was improved by using TBAP in place of TEAP as supporting electrolyte. However, in this time, there appeared a polarographic maximum, which made the accurate determination of the half-wave potential difficult. Since there was found no effective suppressor for the maximum in these solvents, the obtained potentials were less accurate for lithium. For this reason, with the exception for lithium, all the potential measurements were made by the use of TEAP. The half-

1) Values obtained from maximum current polarogram.
2) Values obtained from mean current polarogram.

a) $E_{1/2}$ and E_p are half-wave and peak potentials directly measured against aq. SCE. I_d is polargraphic diffusion current constant; $i_d/Cm^{2/3}t^{1/6}$. $\delta E_{p/2}$ is the half width of AC current peak. $i_p/i_d\tau^{1/2}$ is the reversibility factor, τ is the drop time at AC peak, in s. b) The half-wave potentials of lithium ion in DMF and DMSO are 2.308 and 2.461, respectively when TBAP was used as supporting electrolyte.

wave potentials of alkali metal ions showed a good internal consistency with those given in literatures.[25,26)]

The shifts in half-wave potentials with increasing the concentration of TEAP are shown in Fig. 1. The shift in the half wave potential of lithium ion was found to be abnormally large to an extent of exceeding the usual effect of increasing ionic strength. The unusual behavior of lithium ion has not been clearly explained. As the reversibility was found to be recovered for lithium ion by the use of TBAP, the ion-pair formation of lithium ion with perchlorate anion in TEAP solution is not the primary reason for the unusually large negative shift of the half-wave potential. It is worthy to note the similar observation made by Izutsu *et al.*, *i. e.* an unexpectedly large negative values of the half-wave potential of alkali metal ions of small radius with TEAP or TMAP(tetramethylammonium perchlorate) in hexamethylphosphoramide, but a small shift with TPAP(tetrapropylammonium perchlorate) or TBAP.[27)]

Significance of Half-Wave Potential. A systematic survey on the reversible polarograhpic half-wave potentials for a group of cations provides data for evaluating the free energy of solvation of the cations. An approach for obtaining a common potential scale in various solvents is undertaken by evaluating the free energy of transfer of cation from one solvent to another. The evaluation of transfer free energy is based on the assumption that the standard potential of metal-ion system can be obtained by Born-Haber cycle, involving the free energies of sublimation $\Delta G°$(sub), ionization $\Delta G°$(ion), photoelectric work function $\Delta G°$(w). The thermodynamic expression for standard potential $E°$ in absolute scale is given by Eq. (1).

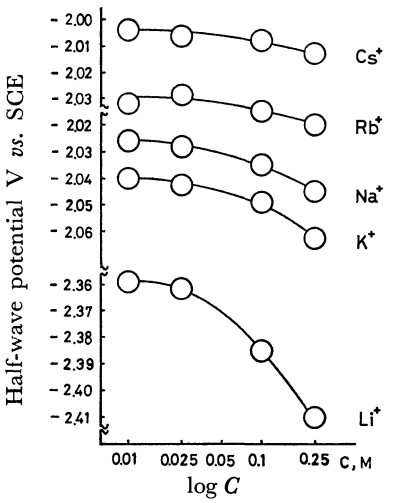

Fig. 1. Half-wave potentials of alkali metal ions in DMF at various concentration of TEAP (A similar result was obtained for DMSO).

$$nE^{\circ}F = \Delta G^{\circ}(\text{sub}) - \Delta G^{\circ}(\text{ion}) - \Delta G^{\circ}(\text{w}) + \Delta G^{\circ}(\text{solv}) \quad (1)$$

The reversible polarographic half-wave potentials are related to the standard potential of amalgam electrode by Eq. (2),

$$E_{1/2} = E^{\circ}_{\text{amalgam}} - \frac{RT}{nF}\ln\frac{f'}{f} - \frac{RT}{nF}\ln\frac{\sqrt{D}}{\sqrt{D'}} \quad (2)$$

where f and f' are activity coefficients, and D and D' are diffusion coefficients respectively, the values being concerned with metallic ion in solution and metal in amalgam. The second and third terms of Eq. (2) make a very small contribution to $E_{1/2}$, since the ratio f'/f and D/D' deviate not largely from unity. The reversible polarographic half-wave potential is regarded as a good approximation of standard amalgam potential.[29] The difference between the standard electrode potential and the standard amalgam electrode potential is given by the free energy of amalgamation. In as much as the calculation of the transfer free energy of ions between solvents is concerned, the free energy of amalgamation can be out of consideration, because of the cancellation of this free energy term by computing the potential difference of identical amalgam electrode in two different solvents.

The ambiguity involved in the evaluation of transfer free energy of ions from the observed polarographic half wave potential data is due to the undetermined activity coefficients and diffusion coefficients in Eq. (2). However, these ambiguous terms can be excluded from consideration by taking the potential difference between a pair of cations i_+ and j_+, $\underset{i_+-j_+}{\Delta} E_{1/2}$, for each solvent and then by taking the difference of this difference in two solvents k and l, $\underset{k-l}{\Delta}\underset{i_+-j_+}{\Delta} E_{1/2}$. The ratio of the activity coefficients as well as the ratio of the diffusion coefficients for a pair of ions, appearing in the double comparison cited above, are nearly constant irrespective of the kind of solvent, as being evidenced from Eq. (2) by calculating the activity coefficient with the Debye-Hückel equation and by replacing the diffusion coefficient with the polarographic diffusion current constant given in Table 1. Accordingly, by taking the solvation energy difference between a pair of ions $\Delta\Delta G^{\circ}$(solv) from Eq. (1), the expression for the transfer free energy is written as

$$nF\underset{k-l}{\Delta}\underset{i_+-j_+}{\Delta} E_{1/2} = (\Delta\Delta G^{\circ}_{i_+,j_+}(\text{solv}))_k - (\Delta\Delta G^{\circ}_{i_+,j_+}(\text{solv}))_l \quad (3)$$

Effective Radii of Solvated Ions by the Application of Born Equation. The free energy change in electrostatic work for transfering a pair of gaseous ions, with diameters r_+ and r_- and charges z^+ and z^-, to a medium of dielectric constant ε is given by the modified Born equation.

$$\Delta G_{\pm}^{\circ}(\text{solv}) = -(Ne^2/2)\left(1-\frac{1}{\varepsilon}\right) \times \{z_+^2/(r_+ + R_+') + z_-^2/(r_- + R_-')\} \quad (4)$$

In Eq. (4) R_+' and R_-' are empirical correction terms for solvated cations and anions, respectively, and N denotes Avogadro's number. There are two most basic assumptions in Eq. (4); first, the interaction of alkali metal ions with solvent is predominantly electrostatic in nature, and second, the contribution of the neutral part of solvation energy is to the same extent for all the solvents according to the zero energy assumption.[9]

In this work the perchlorate salts were employed as common anion and the specific interaction between alkali metal cations and perchlorate anion is unimportant even at 0.1 M of TEAP concentration as evidenced by the concentration dependence of half-wave potentials on TEAP (Fig. 1). Consequently, the contribution of anionic species to the solvation energy can be discounted because of its invariant values for any couple of the ion pairs. On this ground the double comparison procedure in Eq. (3) is a reasonable way of calculation for relative values of cationic solvation energy by eliminating the contribution from the anionic part.

The expression for $\Delta\Delta G^{\circ}_{i_+,j_+}$ (solv) is, then, given by Eq. (5), showing the solvation energy difference between a couple of cations i_+ and j_+ in each solvent. For simplification, $\Delta\Delta G^{\circ}_{i_+,j_+}$ (solv) is denoted by $\Delta\Delta G^{\circ}_{i_+,j_+}$ in the following discussion.

$$\Delta\Delta G^{\circ}_{i_+,j_+} = -(Ne/2)(1-1/\varepsilon)\{1/(r_{i_+}+R_+') - 1/(r_{j_+}+R_+')\} \quad (5)$$

The expression for calculating the transference free energy between non-aqueous solvent S and aqueous solution is given by Eq. (6).

$$(\Delta\Delta G^{\circ}_{i_+,j_+})_{\text{aq}} - (\Delta\Delta G^{\circ}_{i_+,j_+})_{\text{S}} = -(Ne^2/2)[(1-1/78.5) \times \{1/(r_{i_+}+R'_{+\text{aq}}) - 1/(r_{j_+}+R'_{+\text{aq}})\} - (1-1/\varepsilon_{\text{S}})\{1/(r_{i_+}+R'_{+\text{S}}) - 1/(r_{j_+}+R'_{+\text{S}})\}] \quad (6)$$

The value for dielectric constant for aqueous solution ε_{aq} is taken as 78.5 esu at 25 °C and for radius correction term the value of 0.72 Å was tentatively assigned to $R'_{+\text{aq}}$ in Eq. (6). All values except for $R'_{+\text{S}}$ have been found; r_+ from crystal data, ε_{S} from dielectric data and $\Delta\Delta G^{\circ}$ from our potential data. The values of radius correction term $R'_{+\text{S}}$ were obtained from Eq. (6) and the results are shown in Table 2. A comparison was made in Table 2 with the published data for the solvents other than our's. In the solvent system so far investigated, there exists a

close relation with the donor number rather than the dielectric constant of the solvent for the radius correction term. The value R_+' decreases with increasing value of the donor number. This means that a solvent of large donor number shows a strong interaction with the solute cation. The theoretical values of $\Delta\Delta E_{1/2}$ were calculated by the use of R_+' given in Table 2. A comparison was made for $\Delta\Delta E_{1/2}$ between experimental and the theoretical values in Table 3. The agreement is reasonablly good except for lithium ion, indicating that the radius correction term is a convenient and very useful parameter for computing the solvation energy of free ions in these solvents.

Transfer Energy of Rubidium Ion. The estimation of the potential shift caused by changing the solvent for rubidium ion was made by use of the R_+' values in Table 2. The results are given in Table 4, along with the experimental potential shifts. If the liquid junction potentials were properly calibrated the calculated values of solvent shift in potential should coincide with the experimental values. The data represented in Table 4 show poor agreements between the theoretically expected values and the experimentally obtained ones. The deviations shown in fourth row of Table 4 are far greater than a limit of 10 mV expected inevitably for the difference in salt activity coefficient and diffusion coefficient in Eq. (2). This discrepancy can mainly be attributed to the liquid junction potential appeared in the interface between the aqueous SCE and applied organic solvent containing 0.1 M of TEAP. The liquid junction potentials shown in the fifth row of Table 4 are the average values for the difference of half-wave potentials of alkali metal ions between the theoretically computed and experimentally obtained data. These liquid junction potentials must be reduced from the experimentally obtained half-wave potentials for the purpose to intercorrelate the potentials in different solvents on the common potential scale (Corrected Rubidium Scale). The half-wave potential series of cations on the common potential scale are alined in the order DMSO<DMF<water<PC<EC, the more negative value indicating the stronger solvation, showing a good agreement with the cationic solvation property of these solvents.[30,31]

Comment to the Ferrocene Scale and the Rubidium Scale. Half-wave potentials of cations referred to those of ferrocene and rubidium are given in Table 5. A con-

tradictory behavior is noticed between the rubidium and the ferrocene scale for the transfer of potassium ion from water to acetonitrile(ACN). On the ferrocene scale, the shift in the half-wave potential of potassium for the transfer of potassium ion from water to ACN, $\Delta_{\text{A-W}}\Delta_{\text{K}^+\text{-Fe}}E_{1/2}$, is given as −0.06 V, whereas on the rubidium scale, $\Delta_{\text{A-W}}\Delta_{\text{K}^+\text{-Rb}^+}E_{1/2}$ is given as +0.03 V; opposite signs of $\Delta\Delta E_{1/2}$ were obtained whether the half-wave potential of potassium was referred to the ferrocene scale or to the rubidium scale. Suzuki *et al.*[32)] have reported a similar observation; the half-wave potentials of thallium and cadmium referred to the ferrocene scale shifted to more negative with increasing content of ACN in ACN–water mixture, while half-wave potentials referred to the rubidium scale shifted to less negative.

ACN is a poor solvent for inorganic electrolyte and yields a smaller solvation energy for inorganic ions. Accordingly, the free energy in transfer of ions from water to ACN is positive, resulting in a positive value of $\Delta\Delta E_{1/2}$. The observed contradiction in $\Delta\Delta E_{1/2}$ is probably due to the inaccuracy of the ferrocene scale. The solubility of ferrocene in ACN is greater than in water by a factor of 10^4.[6,12)] A large increase of the ferrocene solubility in ACN results in a large shift of the redox potential of ferrocene-ferricinium couple to less negative side by the change of solvent from water to ACN. Accordingly, it is quite probable that such a potential shift to the negative direction is expected by the transfer of ions from water to a solvent of high ferrocene solubility, when ferrocene is chosen as reference. In fact, it can be seen from the potential data in Table 5 that the ferrocene scale gives about 0.1 V more negative shift of potential in transfer of cations from water to ACN than the rubidium scale does.

Furthermore, it would be worthy to give a comment to the method employed by Strehlow and his coworkers to correct the ferrocene scale. They calculated the electrostatic free energy change in transfer of ferricinium ion from water to ACN by the modified Born equation with a radius correction term R_+' which was obtained for alkali metal cations. It should be noticed that the radius correction term is very sensitive to the specific interaction between solute ion and solvent molecules, and accordingly, a value of R_+' obtained for a series of alkali metal ions, whose interaction with solvent is similar among them, should not be applied for ferricinium ion whose interaction with solvent is quite different from that of alkali metal ions.

Standard Potentials of Alkali Metals, Silver, and Thallium Metal/Ion Couples in *N,N'*-Dimethylformamide, Dimethyl Sulfoxide, and Propylene Carbonate

Niro MATSUURA, Kisaburo UMEMOTO, and Zen'ichi TAKEUCHI

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received August 7, 1973)

The relative standard potentials of alkali metals, silver, and thallium metal/ion couples in *N,N'*-dimethylformamide(DMF), dimethyl sulfoxide(DMSO), and propylene carbonate(PC) were measured against an aqueous saturated calomel electrode(SCE). These standard potentials of lithium, sodium, potassium, rubidium, caesium, thallium, and silver are −3.237, −2.898, −3.116, −3.079, −3.079, −0.643, and +0.372 V *vs.* SCE respectively in DMSO, and −3.163, −2.830, −3.067, −3.040, −3.048, −0.559, and +0.538 V *vs.* SCE respectively in DMF, and −2.906, −2.691, −3.002, −2.980, −2.986, −0.402, and +0.813 V *vs.* SCE respectively in PC. The thallium electrode was found to be stable enough to be used as a reference electrode in these solvents. For the purpose of examining the Debye-Hückel equation for estimating the activity coefficient, the formal potentials of the thallium electrode were measured at various ionic strengths. The Debye-Hückel equation was confirmed to be applicable in these solvents, provided a proper value was chosen for the ionic radius parameter, *a*, for each solvent—3.6 for DMSO, 5.0 for DMF and 0.0 for PC.

The measurements of the standard potentials of metal/ion couples in non-aqueous media have been made for only a few media, such as alcohols, acetonitrile, and liquid ammonia.[1] In this connection, we have attempted to determine the standard potentials of alkali metals, silver, and thallium metal/ion couples in DMF, DMSO, and PC. The method employed by Lewis and his co-workers[2–4] for the determination of the potentials of alkali metal electrodes in aqueous solutions is applicable for a variety of non-aqueous solvents. According to a modification of Lewis *et al.*'s method, we determined the potential of a dilute metal amalgam electrode against aqueous SCE equipped with a specially-constructed non-aqueous salt bridge. After correcting the difference in potential between the metal amalgam and the pure metal electrode, a relative potential series was determined for each solvent. The purpose of determining the potential of an electrode in a non-aqueous solvent is to find a stable electrode which can be used as a reference electrode in the solvent. For this purpose we studied the stability of alkali metal, silver, and thallium electrodes and found the potential of the thallium electrode to be very stable in these solvents. It is also important to confirm the applicability of the Debye-Hückel equation for calculating the activity coefficient in these solvents. In order to examine the applicability of the Debye-Hückel equation, the shifts of the formal potentials of the thallium amalgam electrodes were determined at various ionic strengths.

Experimental

Solvents and Electrolytes. The purification of DMF, DMSO, and PC, as well as the preparation and purification of tetraethylammonium perchlorate (TEAP) and perchlorates of alkali metals and thallium, have been described elsewhere.[5] The silver perchlorate was obtained commercially. The electrolytes were dried in a vacuum oven for several tens of hours at 70—100 °C.

Preparation of Metal Amalgams. The alkali metal amalgams were prepared by electrolysis; the aqueous solution of alkali metal chloride or nitrate was electrolyzed with a mercury cathode and a plutinum anode. The thallium amalgam was prepared by adding pure thallium metal to distilled mercury, heating them with an infrared lamp under a nitrogen atmosphere. The metal contents in the amalgams were determined by acidimetric titration;[6] the amalgams were decomposed in a 0.01 M H_2SO_4 solution, and then the excess acid was titrated with a standard NaOH solution. A pure silver rod was used as the silver electrode. The silver rod was polished well with fine emery paper and then with filter paper until a stable potential was obtained. The silver electrode was kept immersed in the solvent for several hours before use.

Measurement of the Potential with an Amalgam Electrode. The apparatus for storing the amalgam and measuring the potential was a modification of Lewis *et al.*'s cell. The cell equipment is given in Fig. 1. The reservoir (B) was evacuated first. The amalgam was introduced into the com-

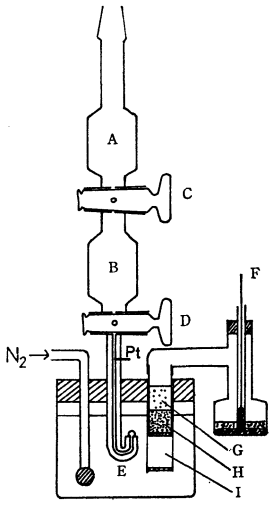

Fig. 1. Cell equipment for measurement of the potential of amalgam electrode.
A, B: amalgam reservoir. C, D: stopcock. E: capillary electrode. F: aqueous SCE. G: agar salt bridge composed of DMF-water mixture containing 0.05 M TEAP. H: agar salt bridge composed of aqueous solution containing 0.1 M NaCl. I: non-aqueous salt bridge containing 0.01 M TEAP.

partment (A) and then evacuated in order to remove the trace of water and oxygen, after which the amalgam was filtered into the reservoir (B) through the stopcock (C) by opening the stopcock (C) slightly with great caution. The prospect of the amalgam in the reservoir was the same as with pure mercury. Before measurement, the reservoir (B) was filled with pure nitrogen gas at a pressure of about 1.5 atm. Nitrogen gas was bubbled through the solution for 30 min, and an atmosphere of nitrogen was maintained during the measurement. The amalgam was admitted to the capillary electrode (E) from the reservoir (B) through the stopcock (D). The potential of the amalgam electrode was measured against an aqueous SCE equipped with a non-aqueous salt bridge.[7] The potential of the electrode was measured at various concentrations of electroactive species, ranging from 1×10^{-4} to 2×10^{-3} M, under a constant ionic strength kept by TEAP. During the measurements, the cell was thermostated at 25.0±0.05 °C. The potential measurement was made with Yokogawa Hewlett-Paccard Model 2727 potentiometer.

Results and Discussion

The cell arrangement is as follows:

$$\text{SCE} \;\Big|\; \underset{\text{(I)}}{\text{TEAP 0.01 M}} \;\Big|\; \underset{\text{(II)}}{\begin{matrix}\text{TEAP 0.01 M}\\ \text{MClO}_4\ C\ \text{M}\end{matrix}} \;\Big|\; \text{M(Hg)} \qquad (1)$$

Phase (I) is a salt bridge consisting of the same solvent as Phase (II). The electromotive force (e.m.f.) of this combination changed slowly on standing. A little more amalgam was admitted into the capillary electrode (E), thus effecting a removal of the electrode surface. When the surface was removed, the e.m.f. almost always returned to a given constant value, although occasionally it deviated from this value by several milli-volts. This was the case for alkali metal amalgams, especially when the concentration of the electroactive species was lower than 5×10^{-4} M. The potential was continuously monitered for a few hours. The total potential drift during this time was typically of the order of a few milli-volts for alkali metal amalgams and of several milli-volts for the silver electrode. The potential drift of the thallium amalgam was of the order of one to two milli-volts. The thallium amalgam electrode was very stable, especially when the concentration of Tl^+ in the solution was greater than 1×10^{-3} M, the potential drift did not exceed one milli-volt.

The overall potential of Cell (1) is given by;

$$E_{\text{cell}} = E_{\text{M}^+/\text{M(Hg)}} - E_{\text{SCE}} - E_{\text{LJ1}} - E_{\text{LJ2}} \qquad (2)$$

where E_{LJ1} and E_{LJ2} represent the liquid junction potentials of the left- and the right-hand junctions of the salt bridge respectively. By defining E'_{SCE} as $E'_{\text{SCE}}=E_{\text{SCE}}+E_{\text{LJ1}}$, and by assuming initially that the liquid junction potential, E_{LJ2}, is negligible and that the Debye-Hückel equation applies, the following relations can be written:

$$E'_{\text{cell}} = E_{\text{cell}} - 0.0591\ \log C \qquad (3)$$

$$E'_{\text{cell}} = E^{\circ\prime}_{\text{M}^+/\text{M(Hg)}} - E'_{\text{SCE}} - (0.0591)\frac{A\sqrt{\mu}}{1+Ba\sqrt{\mu}} \qquad (4)$$

$$E^{\circ\prime}_{\text{M}^+/\text{M(Hg)}} = E^{\circ}_{\text{M}^+/\text{M}} + E_{\text{A}} \qquad (5)$$

where E'_{cell} is the formal potential of Cell (1) and where $E^{\circ\prime}_{\text{M}^+/\text{M(Hg)}}$ is the potential of the amalgam electrode when the activity of the metal ion in the solution is unity; $E^{\circ}_{\text{M}^+/\text{M}}$ is the standard potential of the metal/ion couple, and E_{A}, the e.m.f. of the following cell:

$$\text{M}\,|\,\text{M}^+\,|\,\text{M(Hg)} \qquad (6)$$

viz. the difference between the potentials of the metal and the amalgam electrode. The other terms have their usual meanings.

The E_{A} values of our amalgam electrodes were calculated from the literature values of the potential of Cell (6), in which the concentration of metal in the amalgam is different from ours. The concentrations of metal in our amalgams are given in Table 1, along with those in the amalgams used for the direct measurement of the potential of Cell (6) in the literature. The concentration of metal in the amalgams used in this work does not greatly differ from that used in the literature. Accordingly, the activity coefficients of metal in the two amalgams can reasonably be assumed to be equal. The potential of our amalgam electrode against the metal electrode can, therefore, be calculated from the following equation:

$$E_{\text{A2}} = E_{\text{A1}} - 0.0591\ \log\frac{x_2}{x_1} \qquad (7)$$

where E_{A1} and E_{A2} indicate the e.m.f. of Cell (6), consisting of amalgam electrode used in the literature and in this work respectively, and where x_1 and x_2 are, respectively, the mole fraction of metal in each amalgam. The values of E_{A2} thus calculated are given in Table 1, along with the values of E_{A1}. The potential of the

a) Ref. 3b. b) Ref. 2. c) Ref. 3a. d) Ref. 4. e) H. E. Bent, G. S. Forbes, and A. F. Forziati, *J. Amer. Chem. Soc.*, **61**, 709 (1939).

thallium amalgam electrode against the metallic thallium electrode was calculated by using Lewis and Randlall's results, which give the relation among the concentration of thallium in the amalgam, the activity coefficient of thallium, and the potential of the amalgam electrode against the matallic thallium electrode.[8] The potential of the thallium electrode thus estimated is also given in Table 1.

The equilibrium potential of Cell (1) was measured at various concentrations of electroactive species by maintaining the concentration of TEAP at 0.01 M. The values of the cell potential, E_{cell}, and the formal potential, E'_{cell}, are given in Tables 2—4. As the concentrations of electroactive species approach zero, the contents of bothphases, (I) and (II), in Cell (1) approach an identical solution of TEAP. Upon extrapolation to zero concentration of electroactive species, a potential, E'_{cell}, is obtained at a fixed ionic strength from which the liquid junction potential, E_{LJ2}, has been eliminated. For this purpose, the data were analyzed by the method of least squares; the results are also given in Tables 2, 3, and 4.

From the values of E'_{cell} at a fixed ionic strength, $E^{\circ\prime}_{M^+/M(Hg)}-E'_{SCE}$ can be calculated from Eq. (4) if we know the radius parameter, a, in the Debye-Hückel equation. The radius parameter, a, was determined as follows.

From Eq. (4) a plot of the formal potential of the cell against the $\sqrt{\mu}/(1+Ba\sqrt{\mu})$ term should be a straight line with the slope of $-0.0591\,A$. In DMSO, DMF, and PC at 25 °C, A and B are calculated to be 1.18 and 0.435 for DMSO, 1.73 and 0.493 for DMF, 0.717 and 0.363 for PC, respectively. The a term can be varied to give the best fit.

For the purpose of examining this relation, the formal potentials of the thallium amalgam electrode were measured at various concentrations of TEAP in the right-hand-half cell of Cell (1) by maintaining the concentration of TEAP in the Phase (I) at 0.01 M. This time, the measured formal potentials include the liquid junction potential, E_{LJ2}. In this case, the liquid interphase between Phases (I) and (II) is composed of the same solvent; only the concentrations of the same electrolyte TEAP differ from each other. For such a simple liquid interphase, Henderson equation for estimating the liquid junction potential can be used with sufficient accuracy. E_{LJ2} was calculated by the following Henderson equation:

$$E_{LJ2} = 0.0591\frac{u_+-u_-}{u_++u_-}\log\frac{a_{II}}{a_I} \qquad (8)$$

where a_I and a_{II} are the mean activities of ions in the Phases (I) and (II) respectively, and where u_+ and u_- are the ionic mobilities of the tetraethylammonium cation and the perchlorate anion respectively, which were obtained from conductance measeurments as 16.8 and 24.6 ohm^{-1} cm^2 in DMSO, as 36.9 and 50.6 ohm^{-1} cm^2 in DMF, and as 13.8 and 18.3 ohm^{-1} cm^2 in PC, respectively.[9] The contribution of the small amount of thallium perchlorate in the right-hand-half cell was neglected in this calculation. Plot of E'_{cell} against $\sqrt{\mu}/(1+Ba\sqrt{\mu})$ should, then, give a straight line with a slope of $-0.0591A\{1-(u_+-u_-)/(u_++u_-)\}$, again, a was used as a fitting parameter to obtain the best fit to the straight line. By means of this method we have determined the values of a for the solvents to be 3.6, 5.0, and 0.0 for DMSO, DMF, and PC respectively. The results, the plots of E'_{cell} corrected for the liquid junction potentials E_{LJ2} from Eq. (8) by the use of estimated a values, are shown in Fig. 2.

A satisfactory best fit was obtained for each solvent; these best fits indicate that the slopes of the straight lines are −0.073, −0.10, and −0.060 for DMSO, DMF, and PC respectively. For DMSO and DMF the experimentally-determined slopes are nearly equal to the theoretical values, −0.070 for DMSO and −0.102 for DMF, but for PC the experimental value

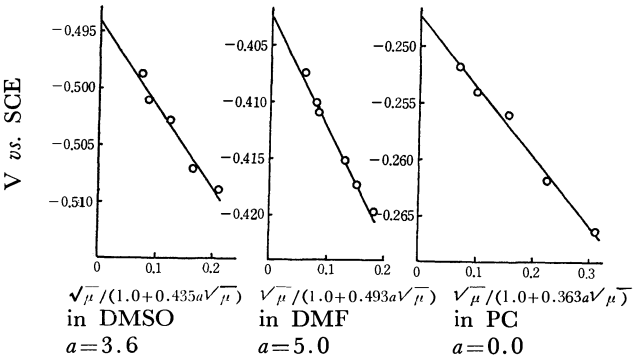

Fig. 2. Formal potential of thallium amalgam electrode as a function of ionic strength.

is slightly different from the theoretical value, −0.042. In order to obtain the theoretical slope for PC, a value of −2.0 must be estimated for a. However, in this case the best fit to the straight line is not obtained; moreover, the negative value of a is not understandable. Accordingly, we tentatively estimate the value of a for PC to be 0.0. With the use of these values of a, small corrections in the potential due to the activity coefficient were calculated, and the values of $E^{\circ\prime}_{M^+/M(Hg)}-E'_{SCE}$ were obtained from Eq. (4). Then, the standard potentials, relative to the aqueous SCE, were calculated from Eq. (5); they are given in Table 5.

These standard potentials include the liquid junction potential between the aqueous and non-aqueous interphase, E_{LJ1}. The estimation of the liquid junction potential is made by comparing the experimentally-determined potential scale with the common potential scale established in a previous work.[5] The solvent shifts in the potential of rubidium by the transfer of the rubidium ion from water to these solvents have been estimated as −0.034 V for DMSO, +0.005 V for DMF, and +0.149 V for PC. Accordingly, the standard potentials of rubidium should be −3.200, −3.161, and −3.017 V *vs.* SCE in DMSO, DMF, and PC respectively, since the standard potential of rubidium in an aqueous solution has been given as −3.166 V *vs.* SCE.[10] By comparing these potentials of rubidium with the experimental values, the liquid junction potentials of aqueous and non-aqueous interphases were estimated as +0.121 V for DMSO, +0.121 V for DMF, and +0.037 V for PC against the aqueous phase. By correcting these liquid junction potentials, the standard potentials on the common potential scale—Corrected Rubidium Scale—were obtained; these values are shown in Table 5.

The liquid junction potentials estimated in this work are different from the values previously estimated from the polarographic half-wave potentials by +0.031 V for DMSO, by +0.036 V for DMF, and by +0.033 V for PC. These differences may be attributed partly to the different concentration of electrolyte in the non-aqueous phase in the two experiments: in present work the non-aqueous phase includes 0.01 M TEAP, while in the previous polarographic study it included 0.1 M TEAP. Moreover, these differences

a) Standard potential measured directly against aqueous SCE. b) Standard potential on the corrected rubidium scale. Solvent shift in rubidium standard potential is −0.034 V for DMSO, +0.005 V for DMF and +0.149 V for PC by transfer of rubidium ion from water to these solvents as determined in Ref. 5. c) Estimated liquid junction potential against aqueous phase. d) Ref. 10.

may also be due to the solvent shift in the polarographic half-wave potentials caused by the variation in the diffusion constants and the salt activity coefficients of ions for changing the solvent.

At first, the present authors intended to estimate the solvent shift in the potential of rubidium by the application of the modified Born equation by the use of the standard potential series determined in this work. However, this attempt was unsuccessful, because the accuracy of the determined standard potentials was not good enough to be used for this purpose. The authors found that the potentials of an amalgam measured with different capillary electrodes showed a deviation of several milli-volts among them, although the potential of each electrode was stable by itself. The potential of the amalgam electrode must be affected by the structure of the capillary electrode. In this connection, for the purpose of obtaining more accurate and reproducible potentials, it would be worth-while to examine the utility of the dropping amalgam electrode used by Ulich and Spiegel.[11]

The authors wish to express their thanks to Miss Mariko Omoto, Mr. Toshio Shingyouchi, and Mr. Mikio Ochi for their cooperation in the experimental work.

Infrared Absorption Spectra and Normal Coordinate Analysis of Metal-DL-Tyrosine Chelates

Yoshie INOMATA, Tadaaki INOMATA, and Takao MORIWAKI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received August 8, 1973)

The infrared absorption spectra of DL-tyrosine and six metal DL-tyrosine chelates have been investigated from 4000 to 300 cm^{-1}. A detailed normal coordinate analysis was performed for the metal chelates as a 39-body problem and an approximate description of the vibrational modes has been assigned to the observed frequencies. DL-Tyrosine chelates are found to be coordinated with the metal through nitrogen and oxygen and to have a *trans* configuration; the same is true for other aliphatic amino acid chelates. The bond-stretching force constants for the metal-nitrogen bonds have been found to decrease in the order Pd(II)>Cu(II)>Zn(II)>Cd(II)>Ni(II)>Co(II). The calculated frequencies, which were obtained using the same force constants as in other aliphatic amino acid chelates, were in good agreement with the observed frequencies.

The infrared absorption spectra and the normal coordinate analysis for aliphatic α-amino acid chelates have already been studied.[1-4] However, amino acids having a substituent in the β-position and their metal-chelates have not yet been studied in detail. Recently, the authors have investigated the infrared spectra and the normal coordinate analysis for DL-α-serine[5] having a hydroxy group and DL-phenylalanine[6] having a benzene ring in the β-position.

Laurie[7] has synthesized three isomers of bis(DL-tyrosino)-copper(II) and reported that two isomers have a *trans* configuration, and the third is 4-coordinated with either a *trans* or *cis* configuration. He used both diffuse reflectance spectra and infrared absorption spectra for this configuration assignment.

In the present investigation, detailed assignments for the infrared absorption bands of DL-tyrosine and its six metal chelates have been made by a comparison with the results of the normal coordinate analysis. In addition, we discuss how the phenolic group in the β-position influences the order of the metal-ligand bond strength which has already been found in aliphatic α-amino acid chelates.[8]

Experimental

Preparation of Compounds. *Bis(DL-tyrosino)-palladium(II)* was prepared by adding 0.81 g (0.0025 mol) of K_2PdCl_4 to hot water in which 0.91 g (0.005 mol) of DL-tyrosine was thoroughly dissolved, and stirring for half an hour. The yellow crystals which precipitated were washed with hot water and dried at room temperature *in vacuo* for several hours.

Found: C, 45.75; H, 4.22; N, 5.98% Calcd for Pd-$[C_6H_4OHCH_2CHNH_2CO_2]_2$: C, 46.31; H, 4.33; N, 6.00%

Bis(DL-tyrosino)-copper(II) was prepared by the method of Laurie,[7] which yielded the blue, prismatic form of bis(DL-tyrosino)-copper(II).

Found: C, 45.95; H, 5.47; N, 5.90% Calcd for $Cu[C_6H_4OHCH_2CHNH_2CO_2]_2\cdot 2\frac{1}{2}H_2O$: C, 46.09; H, 5.38; N, 5.97%.

Bis(DL-tyrosino)-nickel(II) was prepared by adding 1.2 g (0.005 mol) of $NiCl_2\cdot 6H_2O$ to a hot solution of 1.81 g (0.01 mol) of DL-tyrosine and 0.56 g (0.01 mol) of KOH and stirring. After filtering while hot, the filtrate was allowed to stand overnight. The sky blue precipitate separated was recrystallized from hot water and dried at room temperature *in vacuo* for several hours.

Found: C, 45.91; H, 5.41; N, 5.93% Calcd for $Ni[C_6H_4OHCH_2CHNH_2CO_2]_2\cdot 2\frac{1}{2}H_2O$: C, 46.57; H, 5.44; N, 6.04%.

Bis(DL-tyrosino)-cobalt(II)

Found: C, 48.99; H, 5.10; N, 6.35% Calcd for $Co(C_6H_4OHCH_2CHNH_2CO_2]_2\cdot 1\frac{1}{3}H_2O$: C, 48.43; H, 5.20; N, 6.28%.

Bis(DL-tyrosino)-cadmium(II)

Found: C, 44.90; H, 4.20; N, 5.74% Calcd for $Cd[C_6H_4OHCH_2CHNH_2CO_2]_2$: C, 45.72; H, 4.27; N, 5.93%.

Bis(DL-tyrosino)-zinc(II)

Found: C, 45.61; H, 5.08; N, 5.86% Calcd for $Zn[C_6H_4OHCH_2CHNH_2CO_2]_2\cdot 2\frac{1}{2}H_2O$: C, 45.92; H, 5.36; N, 5.95%.

These three chelates were prepared by employing essentially the same procedure as for the nickel(II) chelate. For cobalt(II) chelate, after filtering the solution while it was hot, the pink filtrate was allowed to stand for several days at room temperature. The precipitates of cobalt(II), cadmium(II), and zinc(II) chelates were washed twice in hot water and dried at room temperature *in vacuo*.

Deuteration of Compounds. The deuterated DL-tyrosine and copper(II) chelate were prepared by dissolving DL-tyrosine and copper(II) chelate, which had been dried thoroughly, in 99.75% deuterium oxide at 80 °C and drying them *in vacuo*. The NH and OH groups were deuterated by this method. The perfect deuteration of the other chelates was difficult, since they were insoluble in water.

Thermal Analysis of Chelates. Thermal analysis was carried out with a Rigaku Denki TG–DTA from room temperature 250 °C in air; the decrease in weight was measured when an endothermic reaction occurred. It was found that the nickel(II), the copper(II), and the zinc(II) chelates had $2\frac{1}{3}$ molecules of water and cobalt(II) had $1\frac{1}{2}$ molecules. The cadmium(II) and the palladium(II) chelates had no water.

Absorption Measurement. Infrared absorption spectra from 4000 cm^{-1} to 300 cm^{-1} were obtained with Hitachi EPI-G2 and EPI-L spectrophotometers, which were calibrated with polystyrene and atmospheric water vapor. Samples were prepared as potassium bromide discs and nujol mulls. The observed absorption frequencies and assignments for DL-tyrosine and the metal chelates are listed in Table 1.

Discussion

The assignments for DL-tyrosine and its metal chelates have been based on a comparison of the observed spectra with those of aliphatic α-amino acids,[1-5] DL-phenylalanine,[6] and those metal chelates which had

Abbreviations: RH=DL-tyrosine, s=strong, m=medium, w=weak, sh=shoulder, b=broad

been thoroughly studied.

The spectra of DL-tyrosine chelates are similar to the spectra of those which have a *trans* configuration. Laurie[7] reported that the blue prismatic DL-tyrosine copper(II) chelate had a *trans* configuration. Therefore, in spite of the lack of X-ray data for the metal chelates, it seems reasonable that they have a *trans* configuration.

Assignment of Observed Frequencies. *DL-Tyrosine*: The sharp band at 3212 cm^{-1} is assigned to the OH stretching vibration, because of its disappearance on deuteration and the absence of bands in this region for DL-phenylalanine.[6] The broad bands from 3100 to 2800 cm^{-1} are due to NH_3^+ and CH stretching vibrations of the benzene ring. The CH stretching vibration bands are assigned easily, since they do not shift on deuteration. The CH stretching vibrations of an aliphatic group are observed in a lower frequency region than those of a benzene ring.

The bands at 1627, 1528, 1199, and 1098 cm^{-1} which shift on deuteration are due to NH_3^+ deformation vibrations, since no corresponding bands appear in the metal chelates.

It is very difficult to assign C–O stretching and OH

deformation vibrations in the phenolic group. Jakobsen[9] has reported about the group frequencies of *para*-substituted phenols in detail. He shows that *p*-cresol has bands at 1253, 1215, 1170, and 555 cm^{-1}, which have been assigned to C–O and C–CH_3 stretching and OH deformation vibrations. The frequencies of DL-tyrosine, however, may be different from those of *p*-cresol on account of the intermolecular hydrogen bonding. Therefore it is reasonable to assign the bands at 1249 and 1216 cm^{-1} to the C–O stretching and the OH in plane deformation vibrations, and the band at 644 cm^{-1} to the OH out of plane deformation vibration by a comparison with the *N*-deuterated compound and with phenylalanine.[6]

CN and CC stretching and skeletal deformation vibrations are assigned by a comparison with the spectra of the metal chelates.

If the phenolic group (C_6H_4OH) is treated as possessing C_{2v} symmetry, it has thirty normal vibrations which are divided into symmetry classes as follows: $(11A_1+10B_1)$planar and $(3A_2+6B_2)$ non planar. The A_2 symmetry class is infrared inactive. The eight vibrations $(4A_1+3B_1+B_2)$ of these normal vibrations have already been mentioned above. The remaining 19 vibrations are assigned by referring to the assignments in *p*-cresol and phenylalanine.[6]

Metal-Chelates: As the bands above 3500 cm^{-1} of the nickel(II) and the zinc(II) chelates disappear in the spectra are obtained after DTA analyses, these bands are assigned to the OH stretching vibrations in the water of crystallization.

Although the bands from 3400 to 3100 cm^{-1} are due to NH_2 symmetric and antisymmetric and OH stretching vibrations, it is difficult to assign them separately, since all bands shift on deuteration. The CH stretching vibrations are observed at the same region as in the ligand.

In the region 1700 to 500 cm^{-1} the assignment of the observed bands is accomplished by a comparison of the spectrum of each chelate with that of the ligand.

For the metal chelates, the NH_2 deformation vibrations appear instead of NH_3^+ deformation vibrations of the ligand. The COO^- antisymmetric stretching vibrations for all chelates are intense and overlap with the C=C stretching vibrations of the benzene ring and the NH_2 scissors vibrations to some extent. The COO^- antisymmetric stretching vibrations are observed at higher frequencies and symmetric stretching vibrations are at lower frequencies than those of the ligand. The OH in plane and out of plane deformation vibrations shift to higher frequencies. The vibrations of the phenolic group and the skeletal deformation vibrations occur at the same regions as in the ligand.

From 500 to 300 cm^{-1}, absorption bands which cannot be observed in the ligand appear at 407 cm^{-1} for palladium(II) chelate, 393 cm^{-1} for copper(II) chelate, 359 cm^{-1} for zinc(II) chelate, 317 cm^{-1} for nickel(II) chelate, 316 cm^{-1} for cadmium(II) chelate and 315 cm^{-1} for cobalt(II) chelate. They are assigned to the metal-nitrogen stretching vibration by comparison of chelate spectra with the ligand spectrum and by referring to the metal chelates of DL-phenylalanine,[6] DL-serine[5] and other amino acids.[1-4]

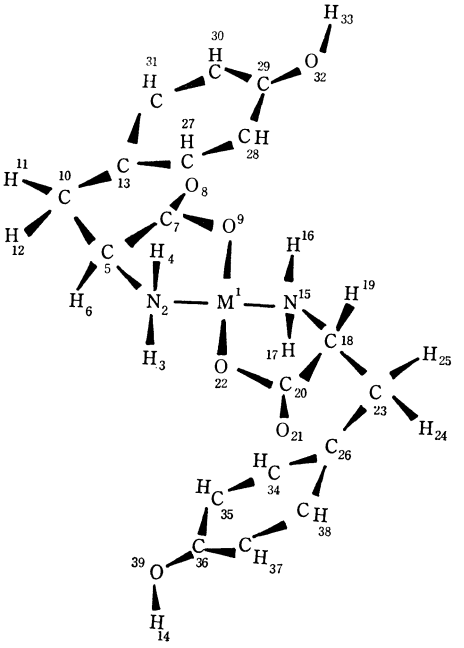

Fig. 1. Structure of DL-tyrosine chelates.

Normal Coordinate Analysis. The normal coordinate analysis for a metal chelate was performed as a 39-body problem using the model illustrated in Fig. 1. Major calculations were carried out on HITAC 5020E and 8700/8800 computers.[10]

The model adopted has M_1 as a center of symmetry. The atoms M, N(2,15), C(5,18), C(7,20), O(9,22) form planar five-membered chelate rings and O(8,21) is in the same plane. The atoms C(5,18), C(10,25), C(13, 26), C(29,36), and O(32,39) are in the same plane, which is perpendicular to these chelate rings. The atoms C(10,23) and phenolic groups are in the same plane, which makes half of a tetrahedral angle with

	θ : 109°28′		

All other angles are assumed to be 109° 28′. The same bond lengths and bond angles are used for second chelate ring.

a) Calculated to insure ring closure.

these chelate rings.

The CH groups in the phenolic groups are considered as one unit. (Mass=13.007825)

In the absence of X-ray data, the bond lengths and bond angles listed in Table 2 were used for all DL-tyrosine metal chelates in the calculation.

The frequencies for the infrared active vibrations were calculated using the same symmetry coordinates as those of Ref. 4 except for the phenolic group vibrations.

Wilson's GF matrix method was used and all results were obtained using FORTRAN program designed by Shimanouchi.[15] The potential field employed was the modified Uray-Bradley type, similar to that used for the chelates of DL-α-serine.[5]

Most of the force constants in Table 3 were transferred from the corresponding values determined for the DL-α-serine[5] and other amino acids chelates. The remaining force constants were evaluated so as to obtain the best fit between the calculated and observed frequencies. Adjustment of the force constant values was accomplished by a trial and error method guided by the values of a Jacobian matrix.

Calculated frequencies for the palladium(II)chelate are shown in Table 4. An approximate description of the vibrational mode is given for each observed frequency, which is based on the potential energy distribution to the symmetry coordinates and force constants. In this model, the CH groups in the phenolic groups were considered as a single unit. Therefore, the frequencies corresponding to the stretching and deformation vibrations of those groups will not appear in the calculations.

A similar calculation was accomplished for the cadmium(II), copper(II), zinc(II), nickel(II) and cobalt(II) chelates and good agreement was obtained between the observed and calculated frequencies for these chelates.

Metal-ligand Bonds. The important frequencies and the force constants related to the metal-ligand bonds are summarized for each chelates in Table 5 and 6.

As shown in Table 5, the frequency separation of the COO^- antisymmetric and symmetric stretching vibrations of chelates which have the same number of molecules of water increases in the order Ni(II)< Zn(II)<Cu(II). This trend is the same as that in many aliphatic α-amino acid chelates.[1-4,8]

In Table 6, the F_{dia} terms represent the diagonal elements of the symmetrized F matrix: *i. e.*, the

strengths of the forces opposing the corresponding vibrational modes.

The values for the M–N bond-stretching force constants and the values of F_{dia} (M–N str.) vary in the order Pd(II)>Cu(II)>Zn(II)>Cd(II)>Ni(II)>Co(II), which demonstrates a corresponding order in the strengths of the metal-nitrogen bonds.

Similar trends are found for the M–N stretching, the NH_2 wagging, and the NH_2 rocking frequencies.

The frequencies of NH_2 scissors vibrations show a different trend. This may be due to an overlap with the COO^- stretching and C=C stretching vibrations to some extent.

These facts show that the phenolic group in the β-position of DL-tyrosine has no influence on the order of metal ligand bond strengths which has already been found in aliphatic α-amino acid chelates.

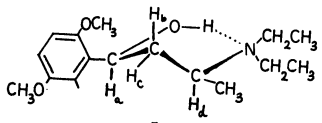
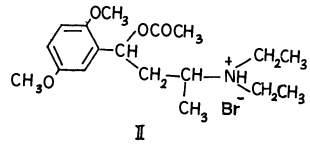
(Received September 21, 1973)

In order to determine the stereospecificity and absolute configuration of 1′-(2,5-dimethoxyphenyl)-3′-diethylamino-*n*-butanol, X-ray structure analysis of its acetate hydrobromide has been carried out. The crystal of the derivative belongs to the monoclinic space group C2, with lattice constants $a=14.21_8$, $b=8.29_0$, $c=18.18_7$Å, $\beta=108.1°$, containing four formula units of $C_{18}H_{29}O_4N\cdot HBr$ in a unit cell. The structure was solved by the heavy atom method and refined by the block-matrix least squares method to an R value of 0.06. The absolute configuration was determined by the use of the anomalous dispersion method, the configuration at the two asymmetric carbon atoms being found to be *S*.

In the course of a study on antitussives, it was found that 1′-(2,5-dimethoxyphenyl)-3′-diethylamino-*n*-butanol (I) strongly potentiates the antitussive activity of codein.[2] However, this compound has four stereoisomers and it seemed to be of importance to compare their pharmacological activities. One of us (H. H.) attempted to synthesize each isomer stereoselectively and obtained two diastereomers I_a and I_b.[3] The diastereomer, I_a, was then acetylated, being resolved by using *d*-camphorsulfonic acid. Their infrared spectra showed that the hydroxyl group forms an intramolecular hydrogen bonding to the diethylamino nitrogen. The nuclear magnetic resonance spectrum of I_a, on the other hand, showed a nuclear Overhauser effect between the protons H_a and H_d. Thus the relative configuration of I_b was presumed to be *erythro* type and that of I_b *threo* type.



Ia



II

An X-ray analysis was undertaken to establish the absolute configuration of I_a. The crystal of its levorotatory acetate hydrobromide(II) was used for the analysis.

Experimental

(−)-*erythro*-1′-(2,5-Dimethoxyphenyl)-3′-diethylamino-*n*-butyl acetate hydrobromide (II) was prepared as follows. To a solution of I_a-acetate (100 mg) in absolute ether (10 ml) was added dropwise a 2% solution of HBr in absolute ether (10 ml) at −60°. Ether was evaporated *in vacuo* to obtain a crystal (110 mg). The cyrstal was recrystallized from absolute ether–methanol mixture under exclusion of moisture. Colorless thin plates parallel to (001); mp 147—148 °C, IR (KBr) 1745, 1505, 1230, 1210, 1045 cm^{-1}. $[\alpha]_D^{20}$ −82.5° (*c* 0.627, EtOH). ORD (*c* 4.8×10^{-4}, MeOH) $[\phi]_{400}$ −116°, $[\phi]_{350}$ −168°, $[\phi]_{300}$ −402°, $[\phi]_{250}$ −2940°, $[\phi]_{233}$ −8800° (trough). Found: C, 53.16; H, 7.38; N, 3.34%. Calcd for $C_{18}H_{30}O_4NBr$: C, 53.46; H, 7.48; N, 3.46%.

The Laue symmetry and systematic extinction on the precession photographs taken with Zr-filtered Mo radiation indicated that the space group is C2 or Cm or C2/m. The density of the crystal (1.32 g cm^{-3}) measured by the flotation method is in good agreement with the calculated value of 1.317 g cm^{-3} assuming four formula units in a unit cell. The space group was taken to be C2 considering the asymmetry of the molecule.

Crystal Data. (−)-*erythro*-1′-(2,5-Dimethoxyphenyl)-3′-diethylaminobutyl acetate hydrobromide, $C_{18}H_{29}O_4N\cdot HBr$, mol wt 404.35. Monoclinic, $a=14.218\pm0.008$, $b=8.290\pm0.005$, $c=18.187\pm0.010$ Å, $\beta=108.1\pm0.1°$, $Z=4$, $D_m=1.32$ g cm^{-3}, $D_x=1.317$ g cm^3, Space group: C2.

The lattice constants and intensity data were obtained by using a four-circle X-ray differentometer with Zr-filtered Mo$K\alpha$ radiation. Intensities were measured by the θ–2θ scanning method with a scan speed of $2\theta=4°$/min. The backgrounds were counted on both sides of each diffraction peak for 10 sec. Out of about 3310 possible hkl and $\bar{h}kl$ reflections having a 2θ value less than 60°, 1647 structure factors were evaluated as being observed since they have net intensities greater than three times their estimated standard deviations.

Determination and Refinement of the Structure

The crystal structure was determined by the heavy atom method. The two methoxy groups attached to the benzene ring have large temperature factors and it was hard to find their exact positions on the Fourier map. One of the terminal methyl groups, C(14) of the methoxy group at C(9), could not be found and the atom was excluded from the present analysis. Refinement of the atomic parameters was carried out by the block-matrix least-squares method using the HBLS program.[4] Several cycles of calculations with anisotropic temperature factors for non-hydrogen atoms reduced the R value to 0.063 for 1647 observed structure factors. The weighting scheme used was:

$$w = 1 \text{ when } F_o > 2.5$$

$$w = 0 \text{ when } F_o \leq 2.5 \ .$$

The final atomic parameters are listed in Table 1 with their estimated standard deviations. A comparison of the observed and calculated structure factors is given in Table 2†. The final difference Fourier map showed only a trace of the peak which might be as-

† Table 2 has been deposited at the office of the Chemical Society of Japan (Document No. 7406).

Table 1. Atomic parameters and their estimated standard deviations

Temperature factors are of the form: $T=\exp\{-(\beta_{11}h^2+\beta_{22}k^2+\beta_{33}l^2+2\beta_{12}hk+2\beta_{13}hl+2\beta_{23}kl)\}$. To represent the absolute configuration, x, y and z should be referred to the left-handed coordinate system.

sociated with C(14), but it was almost impossible to locate the atom.

Determination of the Absolute Configuration

The absolute configuration was determined by use of the anomalous dispersion method. The dispersion corrections for the atomic scattering factors of bromine for Mo$K\alpha$ radiation were taken to be $\Delta f'=-0.3$, $\Delta f''=2.5$.[5] The calculated values of intensity ratio between the Friedel pair of reflections agreed with those observed on the $hk0$, $hk1$ and $0kl$ precession photographs if one takes the left-handed coordinate system. A comparison of observed and calculated intensity ratios is given in Table 3. The Figures in this paper are drawn with the correct absolute configuration.

C(5)	−0.02		
O(2)	0.01		
C(6)	0.01		

a) Not included in the least-squares calculation.

Table 5. Internal rotation angles

A-B-C-D	τ
O(1)-C(1)-C(2)-C(3)	−70°
C(1)-C(2)-C(3)-C(4)	−74
C(1)-C(2)-C(3)-N	−164
C(2)-C(3)-N-C(15)	53
C(2)-C(3)-N-C(17)	−74
O(1)-C(1)-C(7)-C(8)	−36
C(11)-C(12)-O(3)-C(13)	13

The torsion angle τ of the bonded group A-B-C-D is defined as the angle between planes A-B-C and B-C-D. It is positive if clockwise and negative if anticlockwise from the near atom A to the further D.

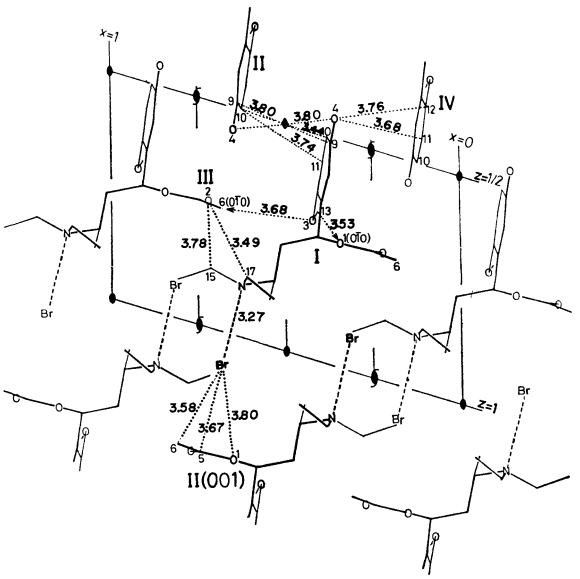

Fig. 4. Projection of crystal structure along the b axis. Intermolecular short contacts of atoms less than 3.8 Å are shown by dotted lines. The positions of the molecules are: I at x, y, z; II at $1-x$, y, $1-z$; III at $1/2+x$, $1/2+y$, z; IV at $1/2-x$, $1/2+y$, $1-z$, where x, y and z are given in Table 1. Translations are shown in parentheses, thus, II (001) be at $1-x$, y, $2-z$.

that the absolute configurations at C(1) and C(3) are both *S* configuration. The bond lengths and angles are shown in Figs. 2 and 3, respectively. The standard deviations of the values for light atoms are about 0.01—0.02 Å and 1°, respectively, except for those involving C(9), C(13), O(3) and O(4) atoms for which they are about 0.04 Å and 2°. The large values for these atoms are due to the extremely large anisotropic thermal vibrations. No abnormal lengths and angles are found in the structure. The diethylamino nitrogen is protonated and takes a tetrahedral configuration. The bromide anion is 3.27 Å apart from the nitrogen atom and a hydrogen bond is formed between them. The planarities of the benzene ring and acetyl group are shown in Table 4.

The skeleton of the butyl acetate group, C(6), C(5), O(1), C(1), C(2), C(3), and C(4), is strongly folded at C(2) and C(3). The C(6), C(5), O(1) and C(1) atoms are extended in a *trans* planar form while the C(4) atom is folded back and closer to C(1) at 3.12 Å, the internal rotation angles about the C(1)–C(2), C(2)–C(3) bonds being −70° and −74°, respectively. The reason for the *gauche* conformation about the C(2)–C(3) bond is to make the nitrogen atom *trans* with respect to C(1) and to locate the charged diethylamino group far from the acetyl group. As for the rotation about the C(1)–C(2) bond, it is easy to see that if it were a *trans* conformation, either the methyl group $C(4)H_3$ or the diethylamino group would be too close to the phenyl group. Some internal rotation angles to be noted are listed in Table 5.

The projection of the crystal structure along the b axis is shown in Fig. 4, together with short intermolecular distances less then 3.8 Å. The diethylamino nitrogen atom is protonated and forms a hydrogen bond to the bromide ion. There are many van der Waals contacts among molecules I, III and their translation equivalents along the a and b axes. The bromide ion also interacts with the acetyl group of the neighboring molecule mainly through van der Waals forces. The methoxyphenyl groups are stacked in **a** direction and several close contacts are found between them.

The authors would like to express their sincere thanks to Mr. W. Tanaka, Manager of the Research Laboratory, Nippon Kayaku Co., Ltd., for permission to publish the present work, and also to Professors Y. Kasuya and S. Okuda of the University of Tokyo for their valuable discussions.

(Received October 4, 1973)

Novel polymeric radical salts prepared by inserting alkali-metals into semi-conductive polymers derived from poly(tetrahalophenylene sulfides) were found to be effective hydrogenation catalyst for α-olefins; their activity trends as to the sort of alkali-metal and halogen of the matrix polymer were Cs>K>Na and F>Cl>Br respectively. The catalyst also showed an activity for the *cis-trans* isomerization of hex-2-ene which was proportional to that for the hydrogenation. The activities of the catalyst were discussed in terms of its steric confinement.

The enhanced *para-ortho* hydrogen conversion catalysis[1] found for polymeric radical salts prepared by alkali-metal insertion into poly(tetrahalophenylene sulfides) and the semi-conductive polymers derived therefrom[2] prompted us to examine their catalytic activity for the hydrogenation of unsaturated compounds. Along these lines, we investigated the hydrogenation activity of these novel polymeric radical salts for some olefins referring to their *para-ortho* hydrogen conversion activity. We will report here that the present radical salts, despite a lack of metal with a d-electron shell, are effective hydrogenation catalysts for α-olefins.

Experimental

Hydrogenation was carried out at 140 °C for 3 hr in an autoclave (volume, 100 ml) containing 4 ml of olefin, 0.5 g of the radical salt, and hydrogen pressurized up to 35 kg/cm² unless otherwise noted. The reaction products were identified with authentic samples and were quantitatively determined by using gas-liquid partition chromatography (DMS 30 wt%, 6 m).

Commercial reagents, hex-1-ene, hex-2-ene, 4-methylpent-1-ene, 4-methylpent-2-ene, and cyclohexene were purified by distillation over metallic sodium. Propylene, but-1-ene, and *cis*-but-2-ene in commercial cylinders were simply dried over calcium hydride. All the olefins were confirmed before use to contain no appreciable amount of any impurity detected by the glc.

The radical-salt complexes were prepared by bringing poly(tetrahalophenyl sulfides) or semi-conductive polymers (*vide infra*) into contact with alkali-metal vapor in a vacuum at the evaporation temperature of alkali-metals up to their saturated insertion into the polymers. The amounts of the inserted alkalimetals were determined by means of atomic-absorption spectroscopy.

We utilized poly(tetrahalophenylene sulfides) prepared by careful polycondensation of sodium pentahalothiophenoxide, and semi-conductive polymers prepared by a dehalogenation condensation of poly(tetrahalophenylene sulfides), as described previously.[2] In this investigation we also used new semi-conductive polymers which were obtained by treating the radical salt complexes with water in a Soxhlet extractor for an extended period until no trace of alkali-metal was detected in the extract. Some characteristics of those modified semi-conductive polymers are given in Table 1, together with those of the poly(tetrahalophenylene sulfides) and semi-conductive polymers previously prepared.

TABLE 1. CHARACTERISTICS OF ACCEPTOR POLYMERS

Acceptor polymers[a)]	Elemental Analysis, %					Free spins per g
	C	H	N	X	S	
PTF	40.2	0	0	—	19.0	nil
PTCl	29.3	0	0	57.4	12.8	nil

mSMCl	76.0	2.9	9.0	1.9	2.7	8.1×10^{18}
mSMBr	62.5	2.8	7.7	2.9	10.5	4.0×10^{18}

a) PTX (X : F, Cl, Br), SMX (X : F, Cl, Br) and mSMX (X : F, Cl, Br) are abbreviations for the poly(tetrahalophenylene sulfides), the semi-conductive polymers, and the modified semi-conductive polymers, respectively, mentioned in the text. mSMX(X : F, Cl, Br) were prepared from SMX-Cs(X : F, Cl, Br) radical salts (see Table 3)

The free spin concentrations of the acceptor polymers and the radical-salt complexes were determined by means of their ESR spectra measured at 9000 MHz in 100 kHz modulation, in comparison with the DPPH spectra obtained under the same operating conditions as with the polymers and the complexes.

Results and Discussion

Table 2 shows the results of the hydrogenation of some olefins in the presence of the semi-conductive polymer alkali-metal complexes as catalyst. It can be seen that the present catalyst hydrogenates α-olefins fairly well, but not inner olefins and cyclic olefins. This may be interpreted as a consequence of the severe steric requirements of the present catalyst, which controls an effective interaction with olefins on the surface of the catalyst.

Thus, the study was focused on the hydrogenation activity of the polymeric radical salt for α-olefin, *i.e.*, hex-1-ene. The results of the hydrogenation of hex-1-ene in the presence of the poly(tetrahalophenylene sulfide)–Cs complex and the semi-conductive polymer–Cs complex are given in Table 3. The hydrogenation

TABLE 2. HYDROGENATION OF OLEFINS WITH THE RADICAL SALT POLYMERS

Olefins	Radical salts	Conversion, %	Selectivity, %
Propylene[a)]	SMBr-K	90	100
But-1-ene[a)]	SMBr-K	99	60
cis-But-2-ene[a)]	SMF-K	—	0
Hex-1-ene	SMCl-Cs	50	24
Hex-2-ene	SMCl-Cs	—	0
4-Methylpent-1-ene	SMCl-Cs	31	40
4-Methylpent-2-ene	SMCl-Cs	—	0
Cyclohexene	SMCl-Cs	0	0

a) Olefin 200 mmHg and H_2 300 mmHg were introduced into a 300 ml volume reactor containing SMX (X : F, Br) 0.2 g and distilled potassium 0.3 g, the hydrogenation being carried out at 100°C for 2.5 hr.

selectivity was low because of the concurrent isomerization of hex-1-ene to hex-2-ene; however, the activity of the present catalyst can be fully appreciated when one considers that no hydrogenation of hex-1-ene occurred in the presence of alkali-metal alone under the same reaction conditions. Further, the present catalysts incorporating the halogen were more effective on the hex-1-ene conversion, and hence on the hexane yield, than the poly(phenylene sulfide)–Cs complex (abbreviated as PPS–Cs), which contained no halogen, although the *para-ortho* hydrogen conversion activity of the PPS–Cs, as is shown in Table 3, was not inferior to that of the present catalysts. Here, it should be noted that the *cis/trans* isomer ratios of the hex-2-ene isomerized from hex-1-ene were larger than the thermodynamic equilibrium ratio about 0.43.† This suggests a correlation between the hydrogenation and the *cis-trans* isomerization activity of the catalyst, as will be discussed below in conjunction with a later experiment.

In spite of the characteristics detailed above, the rather poor activity of the hydrogenation, together with the obscure activity trend as to the sort of halogen, forced us to prepare the catalyst more elaborately. The poor activity was considered to be due to a partial destruction of the radical-salt structure of the catalyst, followed by the formation of alkali-metal halide. The catalysts were, therefore, treated with water (see Experimental) to remove the alkali-metal halide, thus giving newly modified semi-conductive polymers from which we could again prepare radical salts of alkali-metals.

The results of the hydrogenation of hex-1-ene in the presence of these modified radical salt polymers are given in Table 4. It can be seen that there is a clear trend for the activities of the catalysts as to sort of halogen and also as to sort of alkali-metal, together with enhanced hydrogenation activity as was collated by their extraordinarily high *para-ortho* hydrogen conversion rate constant.

This activity trend, increasing towards the catalyst with less electronegative alkali-metals, has frequently been observed in radical salts previously studied.[4,5] It should be interpreted on the basis of the nature of alkali-metals, *viz.*, the ionization potential, the electron affinity, the ion radius, and finally the structure of the catalysts in which alkali-metals are located.

The activity trend for this sort of halogen—*viz.*, the larger the electronegativity of halogen, the stronger the hydrogenation activity—is the first experimental evidence, as far as we are aware, as to radical salts containing halogen; however, the extremely low halogen content of the catalyst (see Table 1) compels us to postpone a discussion of the role of the halogen until a structural elucidation of the catalyst has been made.

TABLE 3. HYDROGENATION OF HEX-1-ENE WITH THE RADICAL SALT POLYMER

Radical salts	Cs inserted wt%	Conversion, %	Selectivity, %	Hex-2-ene isomer ratio, *cis/trans*	*Para-ortho* conversion rate const. at 20 °C min^{-1}
PTF-Cs	57.2	73.2	14.4	0.56	1.9×10^{-1}

† This value was obtained in the glc analysis of commercial hex-2-ene.

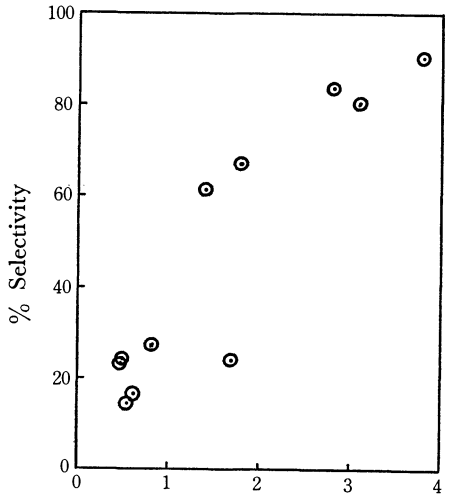

Fig. 1. A correlation between the selectivity in the hydrogenation of hex-1-ene and the *cis/trans* isomer ratio of hex-2-ene.

Also notable was a prominent elevation of the *cis/trans* isomer ratio of the hex-2-ene isomerized from hex-1-ene, as may also be seen from Table 4. The relation between the hydrogenation selectivity of hex-1-ene and the *cis/trans* isomer ratio of hex-2-ene, by using the values in Tables 3 and 4 is shown in Fig. 1. In the present catalyst the hydrogenation activity for hex-1-ene is nearly proportional to the *cis-trans* isomerization activity for hex-2-ene. This result confirms the correlation between the hydrogenation and the *cis-trans* isomerization activity of the catalyst. The linear relation and the high *cis-trans* isomer ratio at high selectivity imply that the active site for the hydrogenation is also active for the *cis-trans* isomerization. The steric requirement of olefins for the hydrogenation and the activity for the *cis-trans* isomerization process lead us to suspect that the active site of the catalyst consists of a sterically-confined structure.

Thus, attention should again be directed to the structural characteristics of the catalysts, especially those of the acceptor polymers prepared through the extraction; however, because of the scarcity of appropriate analytical methods, only their element compositions and free spin concentrations have been collected (Table 1). As was noted in a previous paper,[2] the semi-conductive polymers tightly bind the pyridine used in the preparation. Although the bound pyridine remained, giving rise to its enriched presence in the extracted polymers (Table 1), it could not execute a dramatic enhancement in the hydrogenation activity since no activity difference was observed between the radical salts from poly(tetrahalophenylene sulfides) and those from the semiconductive polymers. One rather troublesome thing for the enhancement might be the role of oxygen, which mainly filled†† the residual composition, amounting to about 10%, of the extracted polymers, besides the role of the halogens, as has already been noted. In addition, it may be useful to note that the extracted polymers have no hydrogen bound by any such reaction as an ion exchange of alkali-metals in the radical salt polymer with the water, since the binding of alkali-metals in the radical salt was considered to be a loose one which lead to such reaction as hydrogen evolution.

In any case, however, the increase in the free-spin concentrations of the extracted polymers from that of the original polymer might lead to some inferences, such as that the extracted polymers came to have largely developed conjugated networks favorable for the accommodation of large amounts of free spins, thus increasing the sterically-confined active sites for the hydrogenation.

Eventually, the low content of halogen and the large amount of free spins in the extracted polymer may be a consequence of the acceptor polymer acquiring a structure functionable for the present catalysis at high densities.

The Crystal Structure of 2,4,6-Triphenylpyrylium-1,1,3,3-tetracyanopropenide, $[(C_{23}H_{17}O)^+ \cdot (C_7HN_4)^-]$[1]

Toshiaki TAMAMURA, Takashi YAMANE*,[2], Noritake YASUOKA and Nobutami KASAI[3]

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

**Institute for Protein Research, Osaka University, Yamadakami, Suita, Osaka 565*

(Received October 4, 1973)

The crystal structure of an organic charge transfer salt 2,4,6-triphenylpyrylium-1,1,3,3-tetracyanopropenide has been determined by means of X-ray diffraction. The crystals are monoclinic in the space group $P2_1/a$. The unit cell dimensions are: $a=13.024$, $b=21.357$, $c=8.324$ Å, $\beta=94.56°$. The cation and the anion are nearly planar and form an "ion-pair." The crystal is built up from infinite columns stacked by these ion-pairs along the c axis. Between two adjacent anions in the neighboring columns, a weak hydrogen bond (C–H···N 3.265 (5), H···N 2.185(4) Å) is present. The charge transfer interaction between the anion and the cation seems to have less influence on the crystal structure than the electrostatic force or the hydrogen bonding.

The charge transfer interaction has been observed spectroscopically in a number of ionic compounds composed of an electron-donating anion and an electron-accepting cation.[4] However, few systematic studies have been made on the physical properties and the crystal structure of these organic charge transfer salts. The effect of interionic charge transfer force on the crystal structure is almost unknown, because of the presence of the strong electrostatic force in addition to the charge transfer and van der Waals interaction between the anion and the cation.

In this paper we describe the crystal structure of an organic charge transfer salt 2,4,6-triphenylpyrylium (TPP)-1,1,3,3-tetracyanopropenide (TCP). A series of structural studies have been made on organic charge transfer salts,[5] as well as on the interionic charge transfer interaction in organic charge transfer salts consisting of a polycyanoacid anion and a heteroaromatic cation.[1,6] The charge transfer absorption of TPP-TCP is observed in non-polar solvents and also in solid state.[7] The study was also promoted by the interesting relationship between the crystal structure and the charge transfer dichroism.

Experimental

Crystal Data. $[(C_{23}H_{17}O)^+ \cdot (C_7NH_4)^-]$, F.W.=450.5, monoclinic, $a=13.024$, $b=21.357$, $c=8.324$ Å, $\beta=94.56°$, $Z=4$, $D_m=1.38$ g·cm^{-3}(CCl_4–C_6H_6), $D_x=1.32$ g·cm^{-3}, space group; $P2_1/a$, absent spectra; $h0l$: $h\neq 2n$, $0k0$: $k\neq 2n$.

Dark red needles of TPP-TCP were recrystallized from a methanol solution.

Oscillation and Weissenberg photographs showed that the crystals belong to the monoclinic system, the space group being $P2_1/a$. Both the determination of cell constants and the collection of intensity data were carried out on a Rigaku four-cycle diffractometer.

The crystal used for the intensity measurement had the dimension $0.32\times0.45\times0.15$ mm. The crystal was mounted on a goniometer-head along the c axis. Nickel-filtered Cu$K\alpha$ radiation was used. The ω-2θ scan technique was applied. The scan range, $\Delta(2\theta)$, of each reflection, was computed by the equation: $\Delta(2\theta)=(2.0°+0.3°\tan\theta_c)$. The starting angle of the scan is $(2\theta_c-1.0)°$, where θ_c is the calculated value of the Bragg angle for λ(Cu$K\alpha_1$) (=1.5405 Å), the scanning speed being 4° min^{-1}. The background was measured at both ends of each scan range. A total of 3394 independent reflections was obtained. No absorption correction was made ($\mu=8.2$ cm^{-1} for Cu$K\alpha_1$).

Structure Determination and Refinement

The phases of the reflections were determined by means of the symbolic addition procedure.[8] SIGMA program was used to compute the normalized structure factor magnitude $|E|$, and to list the Σ_2 relationships for each reflection. Three reflections, 0 3 2, 1 10 6, 11 5 5, were chosen in order to specify the origin, and two other reflections were assigned as phases A and B in order to facilitate the symbolic addition procedure (Table 1). The signs of 108 reflections out of 143 reflections ($|E|\geq2.0$) were determined by hand calculations. TANGENT FORMULA program was then used to calculate the phases of 628

Table 1(a). Distribution of normalized structure factors and statistical averages

	Distribution of $\|E\|$	
	Experimental (%)	Theoretical (centrosymmetric) (%)
$\|E\|\geqq3.0$	0.8	0.5
$\|E\|\geqq2.0$	4.2	5.0
$\|E\|\geqq1.8$	29.0	32.0
$\langle\|E\|\rangle$	0.752	0.798
$\langle\|E\|^2\rangle$	0.996	1.000
$\langle\|E\|^2-1\rangle$	1.027	0.968

Table 1(b). Starting set of application of Σ_2 formula

h	k	l	$\|E\|$	Phase

1	10	6	4.91	+
11	5	5	3.59	+
0	4	2	5.55	A
9	13	$\bar{2}$	4.83	B

Table 1(c). Process of the symbolic addition procedure

Run number	Number of reflections	$\|E\|$	Number of phases determined
0	5		Starting set
1	143	$\geqq2.0$	108 (hand calculations)
2	628	$\geqq1.3$	579

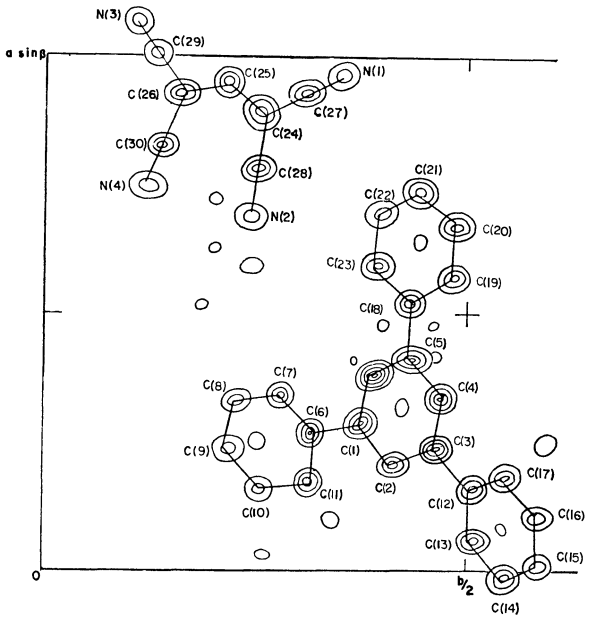

Fig. 1. *E* map viewed along the c axis.

reflections with $|E| \geq 1.3$. From the interaction list the signs of phases A and B were both assigned to be negative.

The positions of all non-hydrogen atoms were found from *E* map (Fig. 1). The oxygen atom in the pyrylium ring was identified by the Fourier synthesis based on these atomic coordinates assuming that all the atoms in the ring are carbon ($B=3.5$ Å^2). This was confirmed by the block-diagonal least-squares refinement using the FBLS program. Four cycles of isotropic refinement reduced the *R* value to 0.150. Three cycles of anisotropic refinement using 2867 reflections ($\sin\theta/\lambda \leq 0.53$) reduced the *R* value to 0.084. The positions of hydrogen atoms were found from the difference Fourier synthesis computed at this stage. Further refinement including hydrogen atoms gave the final *R* value as 0.053 for non-zero reflections (0.058 for all reflections). In the refinement the function minimized was $\sum w(F_o - k|F_c|)^2$, where $w=1.00$ for all reflections. The atomic scattering factors were taken from the values determined by Hanson and his co-workers.[9]

The final positional and anisotropic thermal parameters of non-hydrogen atoms are listed in Tables 2 and 3, respectively, the coordinates and isotropic temperature factors of hydrogen atoms in Table 4, and the observed and calculated structure factors in Table 5.[10]

Results and Discussion

Structure of TPP Cation. The bond lengths and bond angles in the TPP cation are given in Fig. 2(a). The dimensions of the pyrylium ring, which contains 6π electrons as well as benzene and pyridinium rings, have so far not been reported. The pyrylium ring is almost planar with a maximum deviation of 0.015 Å from the best plane (Table 6). The bond angle of oxygen is 122.5(3)° and the two C–O bond lengths

are both 1.355(4)Å, which are slightly shorter than that for conjugated *O*-heterocyclic, furan (1.371(5) Å).[11] The bond lengths of C(1)–C(2) and C(4)–C(5) are significantly shorter, however, those of C(2)–C(3) and C(3)–C(4) are slightly longer than the value accepted for the benzene ring (1.397 Å).[12]

The three C–C bond lengths connecting the benzene rings with the pyrylium ring (1.456(5), 1.471(5) and 1.461(5)Å) gave value for a single bond between two sp^2 hybridized carbon atoms. The considerably small angles of O–C(1)–C(6) and O–C(5)–C(18), 113.6 (3) and 113.3(3)° might be due to the absence of a hydrogen atom bonded with the oxygen atom. The three benzene rings are planar within experimental error, but tilt from the plane of the pyrylium ring at angles of 10.4, 18.0 and 2.3° for A, B and C rings, respectively. No unusual bond lengths and bond angles were found.

Structure of TCP Anion. The bond lengths and bond angles in the anion are given in Fig. 2(b). The

TCP anion is also approximately planar, the maximum deviations from the least-squares plane being 0.053 Å (above) for N(2) and −0.051 Å (below) for N(4). However, two C–C(CN)$_2$ groups are planar within 0.0017 Å, and both tilt at an angle of 1.3° from the best plane of the anion. The large bond angle of C(24)–C(25)–C(26), 129.6°, presumably indicates a steric repulsion between the C(CN)$_2$ groups. The conjugated C–C bonds between two sp^2 carbon atoms, C(24)–C(25)=1.388(5) and C(25)–C(26)=1.379(5)Å, are significantly shorter than the C–C bond associated with the CN group, the average value being 1.41 Å. Molecular orbital calculation shows that the bond order is 0.61 for the former and 0.49 for the latter. The result is consistent with the observed bond lengths. The average C≡N bond length, 1.145 Å, is in agreement with that observed in other polycyanoacid anions.[5c,13]

Crystal Structure. The packings of cations and anions in the unit cell viewed along the c and a axes are respectively shown in Figs. 3 and 4. Interionic atomic contacts less than 3.6 Å are given in Table 7.

The crystal structure consists of parallel columns

of infinite length along the c axis in which the cations and anions stack alternately (Fig. 4). The least-squares planes of the cation and the anion are almost parallel to the a axis, the former inclining to the c axis at 53.0° and the latter at 53.7°, and the dihedral angle

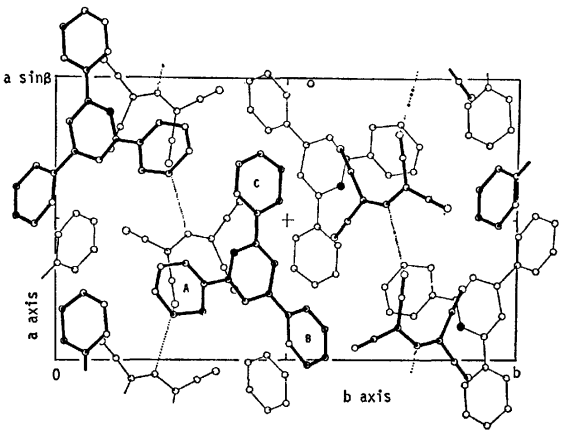

Fig. 3. The crystal structure viewed along the c axis. The dotted lines show the presence of the hydrogen bonding.

between them being 3.2°. In the column, although the TCP anion is sandwiched by TPP cations and *vice versa*, the TCP anion has a larger overlap and closer contact with one of the cations than the other. Thus, the TCP anion and TPP cation can be considered to form an "ion-pair" in the crystal as a stacking unit.

The relative arrangement between the cation and the anion in the column is shown in Fig. 5. In the ion-pair the anion overlaps mainly with the pyrylium ring of the cation. The average interplanar spacing between the best planes of the anion and the pyrylium ring is 3.31 Å, and the closest atomic contact is N(4)–C(3), 3.267(5)Å. They are slightly shorter than the corresponding van der Waals distances. In addition to the alternate arrangement and close contact of the

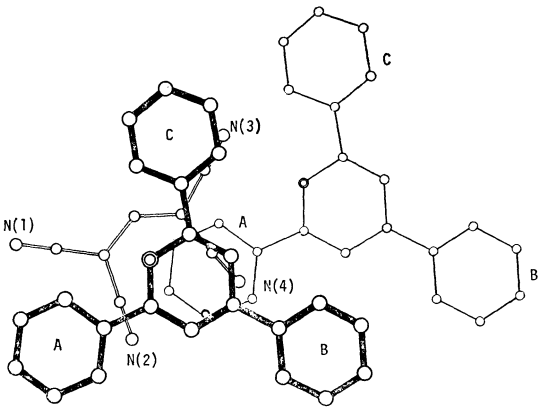

Fig. 5. The relative arrangement of the cation and the anion in the column projected on the best plane of the anion.

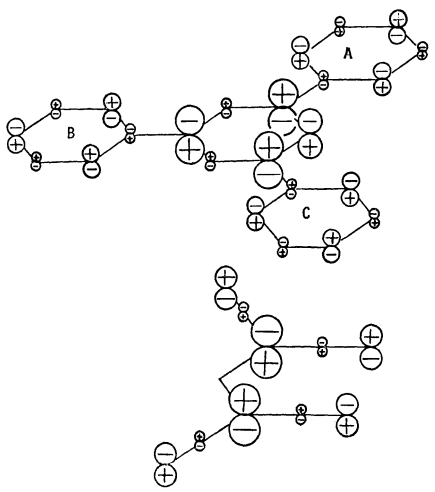

Fig. 6(a). The shapes of the lowest vacant molecular orbital of the cation and the highest occupied molecular orbital of the anion calculated by Hückel MO method using ω-technique.
The parameters were assumed as follows; the resonance integrals are $1.0\beta_0$ for all C-C bonds, $0.9\beta_0$ for two C-O bonds, and $1.2\beta_0$ for C-N bonds, and the Coulombic integrals are α_0 for all C atoms, $\alpha_0+2.5\beta_0$ for O atom, and $\alpha_0+1.0\beta_0$ for four N atoms, and the parameters $\omega=1.4$.

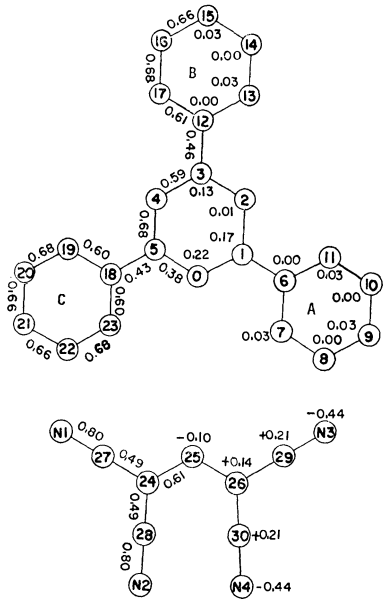

Fig. 6(b). The charge distributions (shown in the right half of the molecule) and the bond orders (shown in the left half of the molecule) calculated by Hückel MO method using ω-technique. The negative values of the charge density indicate the excess of negative charge.

two components characteristic of organic charge transfer complexes, the overlap between the highest occupied molecular orbital of the anion and the lowest vacant molecular orbital of the cation can be considered as a measure of the charge transfer interaction. The shapes of these orbitals, charge distributions and bond orders, shown in Figs. 6(a) and 6(b), were calculated by the Hückel MO method using the ω-technique.[14] However, they cannot explain the observed overlapping between the cation and the anion in terms of the interionic charge transfer interaction. Only slight coincident overlaps between the atoms are observed in Fig. 5. This does not indicate an appreciable contribution of charge transfer force on the relative arrangement of the cation and the anion.

Figure 6(b) shows that the negative charge in the anion is significantly distributed on four nitrogen atoms, whereas the positive charge in the cation is localized at the oxygen and neighboring carbon atoms in the pyrylium ring. The observed overlap of the cation with the anion in which the oxygen atom of the cation is located approximately above the center of the anion, can thus be explained mainly by the electrostatic interaction.

A short atomic contact between the C(25) atom of the TCP anion and the N(2) atom of the adjacent TCP anion along the a axis (dotted line in Fig. 3) indicates the existence of a strong interaction like hydrogen bond between anions in the neighboring columns. The C(25)···N(2)^{iv} and H(25)···N(2)^{iv} distances are 3.265(5) and 2.185(5) Å, respectively, and the C(25)–H(25)···N(2)^{iv} angle is 170°. Although the C–H···N hydrogen bond was scarcely observed, in the present case this type of hydrogen bond is present, which is probably caused by the activation of H(25) atom by four electron-withdrawing cyano groups. The relative

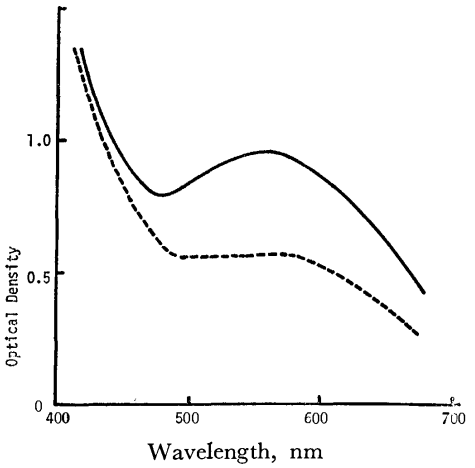

Fig. 7. Polarized absorption spectrum of TPP-TCP single crystal.
—— // c axis, ---- ⊥ c axis.

arrangement of the anion also seems to be affected by this interaction.

The tilt angles of the three benzene rings from the pyrylium ring may be affected by the degree of the overlap with the TCP anion. The C-ring, with the least tilt angle, overlaps the anion in the ion-pair where the interplanar spacing is fairly short. However, the contact between the A-ring and the anion is in the van der Waals distance, which may slightly restrict free rotation of the benzene ring (Fig. 5). On the other hand, the slight overlap observed between the B-ring and the anion allows rotation of the B-ring.

The polarized absorption spectrum of a single crystal of this salt is given in Fig. 7. The optical density of the absorption band at 535 nm, usually assigned to interionic charge transfer band, is about 1.65 times higher in the c-polarization spectrum than the other. Assuming that the direction of the transition moment is perpendicular to the planes of the anion and the cation, which is inclined to the c axis by *ca.* 37°, the ratio of two components of the dipole moment parallel and perpendicular to the c axis is given by cos 37°/cos 53° (=1.32). The dichroism ratio, therefore, is $(\cos 37°/\cos 53°)^2$, 1.74. This agrees approximately with the observed dichroism ratio. Thus the polarized absorption spectrum can be explained in terms of the crystal structure.

All the programs used for the structure analysis were written by Professor T. Ashida. The program of ω-technique used for the molecular orbital calculations was written by one of us (T. T.). Most of the calculations were carried out at Kyoto university on a FACOM 230-60 computer.

The authors wish to express their deep thanks to Prof. Masao Kakudo, and Prof. Tamaichi Ashida for their valuable suggestions and encouragement in the X-ray structure analysis, and also to Prof. Hiroshi Mikawa and Prof. Shigekazu Kusabayashi for their helpful discussions.

The Relative Determination of the Soret Coefficients of Electrolytes. IV

Toshio IKEDA and Yasuki YAMAMOTO

Department of Chemistry, Shizouka University, Shizouka 420

(Received October 29, 1973)

The relative values of the Soret coefficients of 0.01 M aqueous solutions of symmetric tetraalkylammonium chlorides (R_4NCl, R=Me, Et, *n*-Pr, *n*-Bu, and *n*-Am) were determined by measuring the initial thermoelectric power of "combined thermocells" made up of AgCl electrode systems, taking LiCl as a reference. The results obtained were found to be rather high, higher by about 20% than those previously found on the combined thermocells made up of calomel-electrode systems.

In a previous paper,[1] the Soret coefficients of a series of symmetric tetraalkylammonium chlorides were determined by using a "combined thermocell" made up of calomel-electrode systems. The merit of using a combined thermocell for the determination of the Soret coefficients is that thereby the nature of the electrode system used in the cell is completely canceled out. On the other hand, the electrode potentials of calomel-electrodes have rather high temperature coefficients as much as 950 μV/deg at 0.01 M; accordingly, a considerable error may be caused in the thermoelectric power by an occasional slight shift in the temperature of an electrode system, thereby losing the merit of using combined thermocells. For this reason, in the present work, silver chloride electrodes with a relatively low temperature coefficient of about 600 μV/deg were used in place of the calomel-electrodes.

A combined thermocell of the following system was constructed:

$$\underset{T}{\text{Ag-AgCl}},\ \text{LiCl}(m),\ \underset{T+\Delta T}{\text{AgCl-Ag-AgCl}},\ \text{R}_4\text{NCl}(m),\ \underset{T}{\text{AgCl-Ag}} \qquad (1)$$

where R_4NCl represents a symmetric tetraalkylammonium chloride of the same concentration, m, as that of lithium chloride. Lithium chloride was chosen here as a reference substance because it shows a very slight Soret effect. From the measured initial thermoelectric power, $(dE/dT)_0$, of the cell (1), the Soret coefficient, σ, of R_4NCl can be calculated by means of the following equation:[2]

$$\sigma^{\text{QCl}} = \frac{t_{\text{Li}^+}^{\text{LiCl}} B^{\text{LiCl}}}{t_{\text{Q}^+}^{\text{QCl}} B^{\text{QCl}}}\sigma^{\text{LiCl}} - \frac{F(dE/dT)_0}{2RTt_{\text{Q}^+}^{\text{QCl}} B^{\text{QCl}}} - \frac{\bar{\bar{S}}_{\text{Cl}^-}^{\text{QCl}} - \bar{\bar{S}}_{\text{Cl}^-}^{\text{LiCl}}}{2RTt_{\text{Q}^+}^{\text{QCl}} B^{\text{QCl}}} \qquad (2)$$

where Q stands for R_4N, where σ's are the Soret coefficients, where t's are the ionic transport numbers for the ions indicated by the subscripts corresponding to the solution phases indicated by the superscripts, where F is the Faraday constant, where T is the absolute temperature, and where the B's are defined by:

$$B^{\text{LiCl}} = (1 + d\ \ln\gamma_{\pm}^{\text{LiCl}}/d\ \ln m)_{T,P}$$

$$B^{\text{QCl}} = (1 + d\ \ln\gamma_{\pm}^{\text{QCl}}/d\ \ln m)_{T,P}$$

where the $\gamma_{\pm}$'s are the mean activity coefficients on the molality scale in an m molal solution and where the $\bar{\bar{S}}_{\text{Cl}^-}$'s represent the transported entropies of the chloride ions in the solution phases indicated by the superscripts. In the present work, the third term on the right-hand side of Eq. (2) was omitted in the practical calculation because this contribution is negligible in the present experimental accuracy.

Experimental

Materials. The symmetrical tetraalkylammonium chlorides, R_4NCl (R: Me=CH_3, Et=C_2H_5, *n*-Pr=*n*-C_3H_7, *n*-Bu=*n*-C_4H_9, and *n*-Am=*n*-C_5H_{11}), were of the C. P. grade, while the lithium chloride was of a Guaranteed Reagent grade obtained from Wako Pure Chemical Industry, Ltd. All the solutions were prepared to a concentration of 0.01 M± 0.3% using conductivity water.

Silver Chloride Electrodes. Two ways of preparation were tried: (a) the chlorination of the silver electrode by electrolysis and (b) a modification of Haase's process of thermal decomposition.[3] These two processes were found to give practically the same electrochemical stability, and so both were used conveniently. The practice of these processes was as follows: (a) the silver-plated surface of a silver electrode (10×10 mm² in area) was converted into silver chloride by anodic electrolysis in 1 N hydrochloric acid under a current of 15—20 mA for about 5 min, washed with water, and dried in the open air. After it had been heated in an electric furnace at about 500 °C for 15 min, it was left overnight in the furnace to allow for natural cooling for annealing. (b) A silver electrode, 10×10 mm² in area, the surface of which was coated with a muddy paste of a 4 : 1 mixture of silver oxide and silver chloride in weight, was heated in an electric furnace at about 500 °C for about 15 min and then cooled for a few minutes in the open air. This process of coating the surface with paste and heating was repeated several times, and then finally the electrode was subjected overnight to natural cooling from 600 °C to room temperature for annealing.

Cells and Measurements. An H-type cell was used to make single thermocells of LiCl and R_4NCl. The outside of the H-cell was painted black to keep the silver chloride electrode from the light. The temperature of the cell was controlled by thermostated water in a Dewar vessel as has been described previously;[2] however, it was changed in a descending way from room temperature (about 25°) down to about 15° in order to minimize the vertical thermal convection of electrolytes in the legs of the H-cell. The temperature near the silver chloride electrode was measured directly by the aid of a mercury thermometer of 0.1 degree divisions which was inserted near the electrode in a leg of the H-cell. The electromotive force of the combined thermocell was measured with a Yokogawa D. C. potentiometer, Type P-7B, using a sensitive Yokogawa electronic galvanometer, Type 2700, as a zero indicator accurately to 0.1 μV.

Results and Discussion

Some typical results are represented in Fig. 1. The initial thermoelectric powers, $(dE/dT)_0$, of the combined thermocells were determined by the method of the least squares; they are listed in Table 1. Despite the lower temperature coefficient of the electrode potential of the silver chloride electrode used here, fairly large fluctuations were unexpectedly found in the observed values of $(dE/dT)_0$. This may possibiy be caused by a thermal convection occasionally occurring in the electrolyte solutions in the cell. The Soret coefficient of lithium chloride, which was used as a reference in the present work, was assigned to be -0.01×10^{-3} deg^{-1}, a value obtained by adjusting Snowdon and Turner's value[4] of -0.02×10^{-3} deg^{-1} at 0.01 M and at 25.3 °C to the value at 25 °C. Using this value and our data on $(dE/dT)_0$, the relative values of the Soret coefficients, σ^{QCl}, at 25 °C and at 0.01 M were determined by the aid of Eq. (2) taking $\bar{\bar{S}}^{QCl}_{Cl^-}=\bar{\bar{S}}^{LiCl}_{Cl^-}$; the results are listed in Table 1. Here, the σ-values determined in the present work are found to be rather higher (by about 20%) than our previous results[1] and the value of tetraalkylammonium chloride found by the use of the direct method by Snowdon and Turner.[4] Though the mean temperature is not 25° but 20° in the present work, such a large difference in the σ-values cannot be explained by the difference in mean temperature, because, in many cases, the influence of the mean temperature upon the σ-values of univalent electrolytes at 0.01 M is known to be of an order of magnitude of 0.1×10^{-3} deg^{-2}.[5] For the present, it is difficult to judge which of them is proper; however, the results of the present work may be nicely compared with the σ-values of symmetrical tetraalkylammonium bromides, R_4NBr: σ in 10^{-3} deg^{-1} are -5.78 for R=Me, -9.65 for R=Et, -13.4 for R=*n*-Pr, -16.3 for R=*n*-Bu, and -18.5 for R=*n*-Am, all of which were previously estimated by one of the present authors[6] from the initial thermoelectric powers[7] of single thermocells of the $HgBr/R_4NBr$(0.01 M) system at 25 °C. Further, Agar and Turner[5] reported a value of -9.20×10^{-3} deg^{-1} for Et_4NCl at 0.01 M and at 25 °C. Upon taking into consideration the fact that the σ-values of the bromides should, accodring to Snowdon and Turner,[4] be higher by only about 0.06×10^{-3} deg^{-1} in absolute value than those of the chlorides at 25° in 0.01 M aqueous solutions of univalent salts, the σ-values found for the symmetrical tetraalkylammonium chlorides in the present work seem likely to be more reasonable.

Thermal Decomposition Reaction of Halogenoammineruthenium(III) Halide Complexes[1)]

Akira OHYOSHI, Shunichi HIRAKI, and Hideo KAWASAKI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received April 17, 1973)

The thermal decomposition of halogenopentaammine- and *cis*-dihalogenotetraammineruthenium(III) complexes was studied by the techniques of thermogravimetry(TG), differential thermal analysis(DTA), and evolved gas analysis(EGA). The stoichiometry of the decomposition reaction was determined by the analysis of the reaction intermediates and products. The order of decreasing thermal stability, as well as order of temperature of mass-loss initiation, seems to be: $[RuCl(NH_3)_5]Cl_2 > [RuBr(NH_3)_5]Br_2 > [RuI(NH_3)_5]I_2$ for monohalogeno complexes, and *cis*-$[RuCl_2(NH_3)_4]Cl$ > *cis*-$[RuBr_2(NH_3)_4]Br$ > *cis*-$[RuI_2(NH_3)_4]I$ for dihalogeno complexes. Trihalogeno-triammine complexes were observed as intermediates for the cases of dichloro and bromo complexes. a simple decomposition reaction was found for the iodo complexes, and then the activation energy for the following reaction was determined: $[RuI(NH_3)_5]I_2 \rightarrow RuI_3 + 5NH_3$, $E_a = 41.9$ kcal/mol and *cis*-$[RuI_2(NH_3)_4]I \rightarrow RuI_3 + 4NH_3$, $E_a = 27.8$ kcal/mol. The reaction mechanisms may be summarized as follows: (a) an electron-transfer mechanism, in which the ruthenium(III) was reduced by the ammonia molecule or the halide ion, (b) the thermal splitting of the ruthenium-ammine bond, and (c) the bond formation between the ruthenium(III) and the halide ion after the ion migration from the outersphere to the innersphere of the complex. The predominant factors which control these mechanisms may be the coordinate bond strength of the ruthenium(III) and various ligand species, the relative potential of electron transfer from the ligand to the ruthenium(III), and the ease of halide-ion migration from the outersphere to the innersphere of the complex.

The thermal decomposition of a number of cobalt(III)[2-9)] and chromium(III)[10-15)] ammine complexes has been previously reported. Recently, the thermal decomposition of hexaammineruthenium(III) chloride only has been studied by Trehoux *et al.*[16)] It is thus the object of this investigation to study the thermal decomposition of complexes of the $[RuX(NH_3)_5]X_2$ and $[RuX_2(NH_3)_4]X$ type, where X is Cl^-, Br^-, and I^-, by the techniques of thermogravimetry(TG), differential thermal analysis(DTA), and evolved gas analysis(EGA). The reaction intermediates and products were analyzed by spectrophotometry.

Experimental

Preparation of Ruthenium Complexes. $[RuCl(NH_3)_5]Cl_2$, $[RuBr(NH_3)_5]Br_2$, and $[RuI(NH_3)_5]I_2$ were prepared from ruthenium trichloride, hydrazine hydrate, and the respective hydrohalogenic acid by the method of Allen and Senoff.[17)] The $[RuX_2(NH_3)_4]X$, (X=Cl^-, Br^- and I^-) were prepared by the method of Gleu and Breuel.[18)] The compounds thus prepared were analyzed by the usual elemental analysis and confirmed by studying their electronic spectra.

Apparatus and Procedure. A Shimadzu D. T. 20B micro-differential thermal analyzer connected with an EGD 20 evolved gas detector was used for a series of thermal-decomposition reactions. Another series of experiments formed the thermogravimetry of a complex by using a Shimadzu T.G.C. 20-type microthermobalance. A Shimadzu UV 200 recording spectrophotometer was used for the measurement of the absorption spectra of the initial complexes, reaction intermediates, and products.

Samples of about 5—8 mg were pyrolyzed in a dynamic helium atmosphere in a furnace at a heating rate of 5 °C per min. The electric responses corresponding to the variation in the temperature, the gas evolution, and the sample massloss were recorded as functions of the furnace temperature on a potentiometric recorder with a sensitivity of ±50 μV.

The reaction products were analyzed as follows. The sample of about 30—40 mg was pyrolyzed in dynamic helium by using a differential thermal analyzer connected with a gas evolution detector. The liberated ammonia gas was absorbed in a series of traps containing 0.02 M sulfuric acid. For all the aliquots of the trap solution, the concentration of ammonia was determined by potentiometric titration with a 0.02 M sodium hydroxide standard solution. An aliquot of the solution was also used for the colorimetric determination of ammonia with the Nessler reagent.

The liberated halogen gas was dissolved in a dilute potassium iodide solution and titrated with a standard sodium thiosulfate solution.

The reaction products, which were condensed on the wall of apparatus, were collected and identified by the tests for ammonium ion and halide ions. The final reaction product was analyzed by direct weighing and found to be ruthenium oxide after heating in the air. To analyze the halide content, titration with the potassium thiocyanate standard solution was carried out after dissolving the product in water and adding an excess of a standard silver nitrate solution.

The UV and visible spectra were measured in order to identify some decomposition intermediates and products.

Results and Discussion

Differential Thermal Analysis-Gas Evolution Studies. The DTA and GE curves of the monohalogenopentaammineruthenium(III) and *cis*-dihalogenotetraammineruthenium(III) halogenides are given in Figs. 1 and 2. All of the DTA curves of the monohalogenopentaammineruthenium(III) halogenides are characterized by an endothermic peak: at 313 °C (chloro complex), 319 °C (bromo complex), and 258 °C (iodo complex) respectively. A small peak was also observed at 388 °C for the last complex. Each endothermic peak corresponds well to the respective peak on the GE curves. This fact shows that the main decomposition reaction, probably taking place during the first endothermic reaction, is accompanied by the evolution of such gases as ammonia, free halogen and/or ammonium halide. The DTA curves of the *cis*-dihalogenotetra-

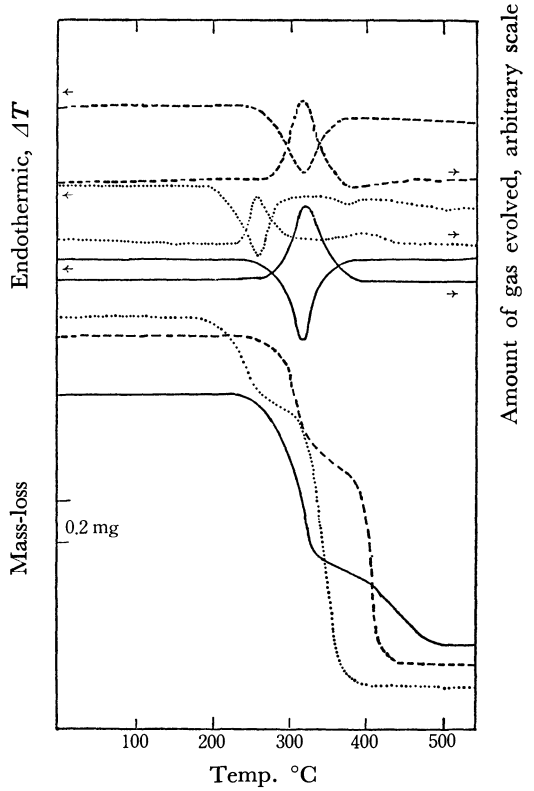

Fig. 1. DTA, GE and TG curves of $[RuX(NH_3)_5]X_2$, in a helium atmosphere. —— X=Cl, ---- X=Br, ····· X=I.

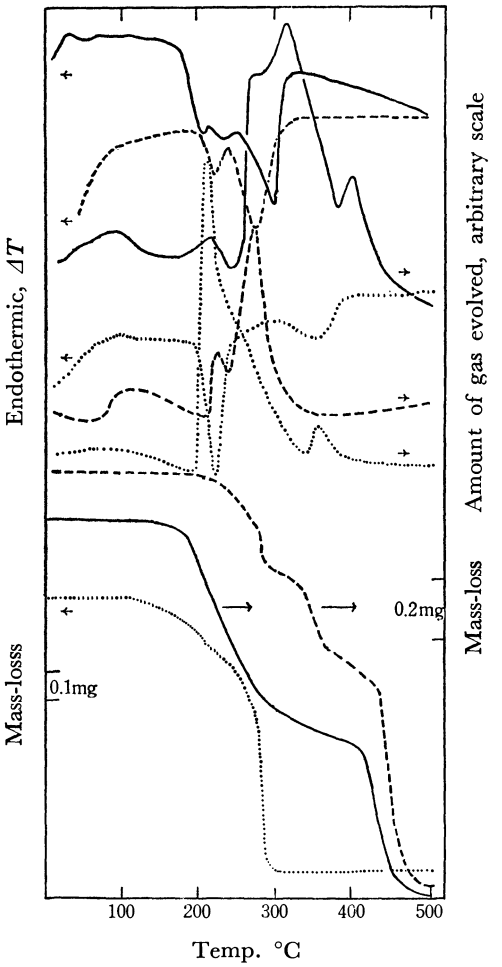

Fig. 2. DTA, GE and TG curves of $[RuX_2(NH_3)_4]X$, in a helium atmosphere. —— X=Cl, ---- X=Br, ····· X=I.

ammineruthenium(III) halogenides (Fig. 2) are different from each other and also from those of the monohalogeno complexes. In particular, that of the dichloro complex shows an endothermic peak at 246 °C between the first (220 °C) and the third (310 °C) peaks. For both the dibromo and the diiodo complex, the DTA curves show two endothermic peaks; however, the relative intensities of the first to the second peak is different. For the dichloro and dibromo complexes, the last peak is the largest, while for the diiodo complex, first peak at 220 °C is sharper and larger than the last one (353 °C). The temperature at each peak on the GE curves in Fig. 2 corresponds to that at the respective endothermic peak on the DTA curves. From this fact, it may be concluded that all the decomposition reactions are endothermic and gas-evolving.

Thermogravimetric Analysis. The curves obtained by the thermogravimetry(TG) are given in Figs. 1 and 2. The thermal decomposition is initiated at 246 °C (chloro complex), 244 °C (bromo complex), 174 °C (iodo complex), 200 °C (dichloro complex), 210 °C (dibromo complex), and 114 °C (diiodo complex). The initial decomposition temperature of each dihalogeno complex is generally lower than that of the corresponding monohalogeno complex, while the final temperature for the mass-loss is higher than that of the monohalogeno complex, except in the case of the iodo complex.

The orders of the decrease in thermal stability, along with the temperature of mass-loss initiation, seem to be: $[RuCl(NH_3)_5]Cl_2 > [RuBr(NH_3)_5]Br_2 > [RuI(NH_3)_5]I_2$ for the monohalogeno complexes and *cis*-$[RuCl_2(NH_3)_4]Cl > cis$-$[RuBr_2(NH_3)_4]Br > cis$-$[RuI_2(NH_3)_4]I$ for the dihalogeno complexes. The complexes containing iodide were certainly least stable. Similar relations have been reported in the thermal decomposition studies of halogenoammine complexes of cobalt(III)[3,5,7] and chromium(III).[13]

Table 1 shows the numerical data of mass-loss studies along with those of evolved gas analysis. The calculated mass-loss values for chloro complexes could not be determined because of their continuous thermal decompositions. From these results, the intermediate products were estimated to be as follows: $RuBr_2$ at 398 °C for the monobromo complex and at 431 °C for the dibromo complex; RuI_3 at 268 °C for the monoiodo complex and at 222 °C for the diiodo complex.

Product-analysis Studies. Table 2 shows the results of the evolved-ammonia-gas analyses, the mass of the final reaction products, and the molar ratios of ammonia to ruthenium metal. The mass of the final product is nearly in agreement with that of the ruthenium metal in each complex. The molar ratios (NH_3/Ru) are different from each other, however all the ammine ligands in the iodo complexes are liberated as ammonia molecules, while only three molecules for bromo complexes and only one or two for chloro complexes are liberated. These facts suggest that the

contribution of the halide ion to the weakening of the strength of the ruthenium–ammine coordinate bond is variable.

The absorption spectra of the initial complexes and the decomposition intermediates are shown in Figs. 3—8. The temperature for the sampling of the intermediates was selected by reference to the variation points on the DTA and TG curves. The initial spectrum of the monochloro complex shows an absorption peak at 30.5 kK which decreases with the progress of

the thermal decomposition, and a new peak appears at 34.7 kK. The formation of trichlorotriammine complex was apparently confirmed by the appearance of a peak at 30.2 kK in the spectra of the intermediates obtained at 215 and 235 °C only in the case of the dichloro complex, as is shown in Fig. 6, while it was difficult to identify this complex in the case of the monochloro complex. A similar complex has been assumed to be the same as an intermediate in the thermal decomposition of the hexaammineruthenium(III) trichloride by Trehoux *et al.*[16] The absorption peak at 34.7 kK in the spectra of the final products in Figs. 3 and 6 has not yet been assigned definitely. The chemical formula of this product was estimated to be Ru_2Cl_2-NH_3 from the results of elemental analysis. These facts suggest that the ruthenium(III) has already been reduced to the low valence state when the temperature is elevated to 297 °C.

As is shown in Fig. 4, the absorption peak at 25.1 kK ascribed to the monobromo complex decreases with a slight shift toward the side of higher wave numbers. A new peak at 33.1 kK begins to appear in the spectrum of the intermediate obtained at 300 °C (Fig. 4). In the spectrum of the intermediate obtained at 320 °C, the 25.1 kK peak has entirely disappeared, and the spectrum is found to consist of 33.1 kK peak and a continuous absorption in the region of ultraviolet wavelengths (Fig. 4). This 33.1 kK peak has not yet been assigned. The variations in the absorption spectra in the course of thermal decomposition for *cis*-dibromotetraammine appear to be somewhat complex. The character of the spectrum of the initial complex has entirely vanished in that of the intermediate obtained at 215 °C (Fig. 7). At this temperature, the deammonation has already started, as is shown by the endothermic peak at 226 °C and the mass-loss curve starting at 210 °C in Fig. 2. The absorption peak at 24.9 kK in the spectrum of the intermediate obtained at 215 °C may be attributable to the tribromotriammine complex because the spectral change is similar to that corresponding to the transformation from *cis*-dichlorotetraammine to the trichlorotriammineruthenium(III) complex.

The absorption spectra of intermediates produced in both the thermal decompositions of iodopentaammine and *cis*-diiodotetraammineruthenium(III) iodides show the continuous variation, as is shown in Figs. 5 and 8. Such a variation in the spectrum suggests that only deammonation is continuously proceeding because of the difficulty of the substitution reaction by the iodide ions in the outerspheres of complexes.

Stoichiometry of the Thermal-decomposition Reaction. In view of the results obtained from the DTA, EGA, and TG and the product analysis, the following thermal decomposition reactions are presumably established. For the chloroammineruthenium(IIII) complexes:

$$[RuCl(NH_3)_5]Cl_2 \rightarrow [RuCl_3(NH_3)_3] + 2NH_3 \quad (1)$$

$$\rightarrow Ru + 2NH_3 + 2NH_4Cl + HCl + 1/2\,N_2 \quad (2)$$

$$[RuCl_2(NH_3)_4]Cl \rightarrow [RuCl_3(NH_3)_3] + NH_3 \quad (3)$$

$$\rightarrow Ru + NH_3 + 2NH_4Cl + HCl + 1/2\,N_2 \quad (4)$$

For the bromoammineruthenium(III) complexes:

$$2[RuBr(NH_3)_5]Br_2 \rightarrow 2[RuBr_3(NH_3)_3] + 4NH_3 \quad (5)$$

$$\rightarrow 2RuBr_2 + 7NH_3 + 2NH_4Br + 1/2\,N_2 + 1/2\,H_2 \quad (6)$$

$$\rightarrow 2Ru + 2Br_2 + 7NH_3 + 2NH_4Br + 1/2\,N_2 + 1/2\,H_2 \quad (7)$$

$$2[RuBr_2(NH_3)_4]Br \rightarrow 2[RuBr_3(NH_3)_3] + 2NH_3 \quad (8)$$

$$\rightarrow 2RuBr_2 + 5NH_3 + 2NH_4Br + 1/2\,N_2 + 1/2\,H_2 \quad (9)$$

$$\rightarrow 2Ru + 2Br_2 + 5NH_3 + 2NH_4Br + 1/2\,N_2 + 1/2\,H_2 \quad (10)$$

For the iodoammineruthenium(III) complexes:

$$[RuI(NH_3)_5]I_2 \rightarrow RuI_3 + 5\,NH_3 \quad (11)$$

$$\rightarrow Ru + 3/2\,I_2 + 5\,NH_3 \quad (12)$$

$$[RuI_2(NH_3)_4]I \rightarrow RuI_3 + 4\,NH_3 \quad (13)$$

$$\rightarrow Ru + 3/2\,I_2 + 4\,NH_3 \quad (14)$$

The intermediates of the above reactions, the trichlorotriammineruthenium(III), $[RuCl_3(NH_3)_3]$, and the ruthenium dibromide, $RuBr_2$, were confirmed by the elemental analysis.

Found: H, 3.60; N, 16.52%. Calcd for $[RuCl_3(NH_3)_3]$: H, 3.48, N, 16.24%.

Found: Br, 61.6%. Calcd for $RuBr_2$: Br, 62.2%.

From the above reaction scheme, we have noted that the complexes are dissociated by two different mechanisms, that is, that in which the ruthenium(III) is reduced by the halide ion and that in which the ruthenium(III) is reduced by the ammonia molecule. Of course, the displacement of ligand species by the halide ions in the outersphere of the complex was also observed.

One of the probable factors controlling the two different mechanisms may be the relative reducing power of the ligands, which is presumed, from the order of their reduction potentials, to be $I^- > Br^- > NH_3 > Cl^-$. By this assumption, it can be interpreted that the ruthenium(III) is reduced by the ammonia molecule in the thermal-decomposition reactions of chloro- and bromopentaammine complexes, while the ruthenium(III) is reduced by iodide in the iodopentaammine complex.

The monohalogenopentaammine complexes are thermochemically more stable than the corresponding dihalogeno complexes, while the iodo complexes are the least stable of the series of complexes. This means that the bond nature of the ruthenium(III)-ammine ligand may be reflected by the bond strength of the ruthenium(III)-halogen ligand.

The order of the thermal stability, chloro complexes > bromo complex > iodo complex, is also in agreement with that of the strength of the ruthenium(III)-ammine bond as estimated from the vibrational frequencies of the complexe, *i. e.*, the ν(Ru–N) values are 485, 463 and 451 cm^{-1} for chloropentaammines > 479, 459 and 448 cm^{-1} for bromopentaammine > 468, 450, 442 and 424 cm^{-1} for iodopentaammine, as has been re-

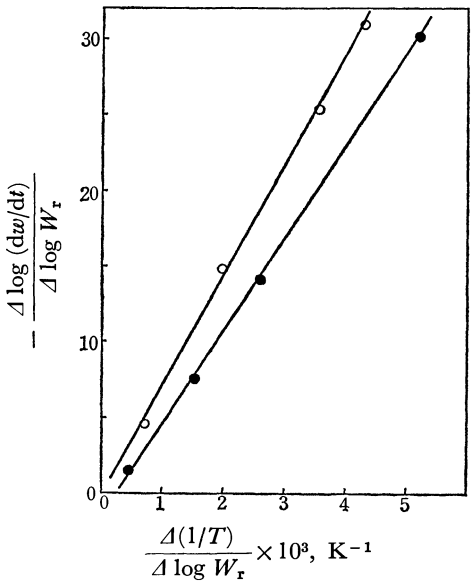

Fig. 9. The plots of Freeman-Carroll equation for the reaction, $[RuI_n(NH_3)_{6-n}]I_{3-n} \rightarrow (6-n)NH_3 + 3/2\ I_2$, $n=1$ and 2. $W_r = w_0 - w$, w_0 = weight loss at completion of reaction, w = total weight loss up to time t. ○ diiodo complex, ● monoiodo complex

ported by Allen and Senoff.[17]

The Thermal-reaction Kinetics. Since the decompositions of iodo complexes were definitely observed to consist of ammonia-gas and free-iodine liberations, the kinetic treatment of the ammonia-gas evolution reaction for two iodo complexes was made using the method of Freeman and Carroll.[19] These kinetic plots are shown in Fig. 9; the activation energies were calculated as follows:

$[RuI(NH_3)_5]I_2 \rightarrow 5NH_3 + RuI_3$, 41.7 ± 0.7 kcal/mol

$[RuI_2(NH_3)_4]I \rightarrow 4NH_3 + RuI_3$, 27.8 ± 0.2 kcal/mol

Wendlandt and Smith[4] reported the activation energy for the deammonia reaction of halogenopentaamminecobalt(III) to be 28 kcal/mol for chloropentaammine and 21 kcal/mol for bromopentaammine. Though the species of the halide ligands are different, these values are smaller than that of iodopentaammineruthenium(III). This fact may suggest that the metal-ammine bond is stronger in the ruthenium(III) complex than in the cabalt(III) complex, because the metal-halide bond strength is rather the reverse.

The authors wish to thank the Ministry of Education for the financial support granted to this research.

The Synthesis and Spectroscopic Study of Some Bis(tertiary-phosphine)bis(*N,N*-dialkylselenocarbamate) Complexes of Palladium(II) and Platinum(II)

Koji TANAKA and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received July 20, 1973)

Ten *N,N*-dialkylselenocarbamate complexes of palladium(II) and platinum(II), $[(C_6H_5)_3P]_2Pd[SeC(O)NR_2]_2$ (**1**), $[(C_6H_5)_3P]_2Pt[SeC(O)NR_2]_2$ (**2**) (R=CH_3, C_2H_5, *n*-C_3H_7, and *n*-C_4H_9), $[CH_3(C_6H_5)_2P]_2Pd[SeC(O)N(CH_3)_2]_2$ (**3**), and $[CH_3(C_6H_5)_2P]_2Pt[SeC(O)N(CH_3)_2]_2$ (**4**), have been prepared. The infrared spectra and molecular-weight determinations indicate that the selenocarbamate ligand is bonded to the palladium(II) or platinum(II) through the selenium atom, with a free carbonyl group in the solid state, while in **1** and **2** two and one triphenylphosphine dissociate in a dilute solution to exist as compounds with bidentate selenocarbamate, $Pd[SeC(O)NR_2]_2$ and $[(C_6H_5)_3P]Pt[SeC(O)NR_2]_2$, respectively. The ^1H- and ^{31}P-NMR spectra of **3** and **4** reveal that they have a *trans*-configuration. The same configuration is suggested for the *N,N*-dibutyl derivative of **2** on the basis of the spin-spin coupling constant between the ^{31}P and ^{195}Pt nuclei.

Although *N,N*-dialkyldithiocarbamate- and -diselenocarbamate-metal complexes have widely been investigated, there have not been many studies of metal complexes of carbamate with hetero ligand atoms.[1-5] They have been limited only to the *N,N*-dialkylthiocarbamate and *N,N*-dialkylthioselenocarbamate complexes, and a little attention has been paid to the difference in coordination ability to metal between oxygen and sulfur[6] or between sulfur and selenium.[7]

The present work was undertaken in an attempt to prepare a series of *N,N*-dialkylselenocarbamate complexes of palladium and platinum, $[(C_6H_5)_3P]_2M[SeC(O)NR_2]_2$ and $[CH_3(C_6H_5)_2P]_2M[SeC(O)N(CH_3)_2]_2$ (M=Pd(II) and Pt(II); R=CH_3, C_2H_5, and *n*-C_3H_7), in order to elucidate their configurations by the infrared, ^1H-, and ^{31}P-NMR techniques.

Experimental

Physical Measurements. The molecular-weight determinations were carried out by means of a Hitachi-Perkin-Elmer 115 vapor pressure osmometer in chloroform at 30.5 °C. The infrared spectra were recorded on a Hitachi-Perkin-Elmer 225 spectrophotometer in Nujol mulls, and the electronic spectra were measured on a Hitachi 124 spectrophotometer in a dichloromethane solution, using a 1-cm quartz cell. The proton and P-31 NMR spectra were recorded on a Japan Electron Optics PS-100 spectrometer at 100 and 40.5 MHz respectively. The chemical shifts were measured against tetramethylsilane as the internal standard and 85% H_3PO_4 as the external standard, and were calibrated by the audio-frequency side-band technique.

Preparation. *N,N*-Dialkylammonium *N,N*-dialkylselenocarbamates were prepared by the reaction of the appropriate dialkylamine with selenium powder and carbon monoxide in tetrahydrofuran, as has been described elsewhere;[8] they were used as the solutions to prepare metal complexes without isolating them.

The method of preparing the complexes, $[(C_6H_5)_3P]_2M[SeC(O)NR_2]_2$ (M=Pd(II) and Pt(II); R=CH_3, C_2H_5, and *n*-C_3H_7), was basically the same as that for the *N,N*-dibutyl derivatives described in a previous paper;[5] the yields were almost quantitative. A suspension of $[(C_6H_5)_3P]_2MCl_2$ (M=Pd(II) and Pt(II)) (0.5 mmol) in dry benzene (20 ml) was stirred, drop by drop, into a tetrahydrofuran solution (10 ml) of dialkylammonium *N,N*-dialkylselenocarbamate (1.0 mmol) at room temperature, and then the mixture was further stirred for 4 hr. With the *N,N*-dimethyl and *N,N*-diethyl derivatives, the precipitates which appeared were filtered and washed with methanol several times to remove the dialkylammonium chloride. The products were then reprecipitated from a large amount of a chloroform–ether mixture.

$[(C_6H_5)_3P]_2Pd[SeC(O)N(CH_3)_2]_2$ (**1a**), mp 207 °C(decomp).

Found: C, 53.30; H, 4.51; N, 3.01%. Calcd for $C_{42}H_{42}N_2O_2P_2Se_2Pd$: C, 54.06; H, 4.53; N, 3.02%.

$[(C_6H_5)_3P]_2Pd[SeC(O)N(C_2H_5)_2]_2$ (**1b**), mp 202—203 °C (decomp).

Found: C, 56.05; H, 5.23; N, 2.72%. Calcd for $C_{46}H_{50}N_2O_2P_2Se_2Pd$: C, 55.86; H, 5.01; N, 2.83%.

$[(C_6H_5)_3P]_2Pt[SeC(O)N(CH_3)_2]_2$ (**2a**), mp 203—204 °C.

Found: C, 48.68; H, 4.24; N, 2.52%. Calcd for $C_{42}H_{42}N_2O_2P_2Se_2Pt$: C, 49.37; H, 4.14; N, 2.74%.

$[(C_6H_5)_3P]_2Pt[SeC(O)N(C_2H_5)_2]_2$ (**2b**), mp 217—220 °C.

Found: C, 50.79; H, 4.52%. Calcd for $C_{46}H_{50}N_2O_2P_2Se_2Pt$: C, 51.26; H, 4.68%.

In the case of the *N,N*-di-*n*-propyl derivatives, the ammonium chloride appearing in the reaction was filtered off, and the filtrate was evaporated to dryness under reduced pressure at room temperature. The resulting product was washed with a small amount of methanol and was recrystallized from benzene.

$[(C_6H_5)_3P]_2Pd[SeC(O)N(n\text{-}C_3H_7)_2]_2$ (**1c**), mp 185 °C.

Found: C, 57.45; H, 5.59; N, 2.68%; mol wt, 624 (6.83×10^{-3} M), 465 (4.12×10^{-3} M). Calcd for $C_{50}H_{58}N_2O_2P_2Se_2Pd$: C, 57.46; H, 5.59; N, 2.86%; mol wt, 1045.

$[(C_6H_5)_3P]_2Pt[SeC(O)N(n\text{-}C_3H_7)_2]_2$ (**2c**), mp 225 °C.

Found: C, 52.78; H, 5.27; N, 2.52%; mol wt, 832 (5.76×10^{-3} M), 764 (4.61×10^{-3} M). Calcd for $C_{50}H_{58}N_2O_2P_2Se_2Pt$: C, 52.96; H, 5.16; N, 2.47%; mol wt, 1134.

The characterization of the di-*n*-butyl derivatives, $[(C_6H_5)_3P]_2M[SeC(O)N(n\text{-}C_4H_9)_2]_2$ (M=Pd(**1d**) and Pt(**2d**)), was previously reported.[5]

Into $[(CH_3)_2NH_2][SeC(O)N(CH_3)_2]$ (1.0 mmol) in tetrahydrofuran (10 ml), we stirred a suspension of $[CH_3(C_6H_5)_2P]_2PdCl_2$ (0.5 mmol) in benzene (20 ml) over a 3 hr period at room temperature. The resulting dark red solution was filtered to remove the dimethylammonium chloride precipitated, and the solution was evaporated under reduced pressure to yield a red solid. Recrystallization from toluene gave orange crystals of $[CH_3(C_6H_5)_2P]_2Pd[SeC(O)N(CH_3)_2]_2$ (**3**) (0.47 mmol), mp 186—188 °C.

Found: C, 47.61; H, 4.92; N, 3.68%; mol wt, 701 (4.98×10^{-3} M), 745 (1.42×10^{-2} M). Calcd for $C_{32}H_{38}N_2O_2P_2$-

Se_2Pd: C, 47.51; H, 4.74; N, 3.46%; mol wt, 809.

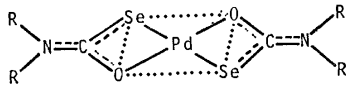
The $[CH_3(C_6H_5)_2P]_2Pt[SeC(O)N(CH_3)_2]_2$ (**4**) was similarly prepared by the reaction of $[CH_3(C_6H_5)_2P]_2PtCl_2$ (0.5 mmol) with the *N*,*N*-dimethylselenocarbamate salt (1.0 mmol); it was recrystallized from toluene to give light yellow crystals (0.45 mmol), mp 182—184 °C.

Found: C, 43.26; H, 4.45; N, 3.18%; mol wt, 800 (3.99×10^{-3} M), 841 (1.33×10^{-2} M). Calcd for $C_{32}H_{38}N_2O_2P_2Se_2Pt$: C, 42.82; H, 4.27; N, 3.12%; mol wt, 898.

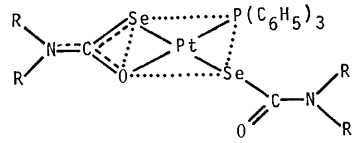
Results and Discussion

Properties. The palladium(II) and platinum(II) complexes obtained are stable in air; their solubilities are dependent on the nature of the *N*-alkyl group as well as on the phosphine coordinated. Among the triphenylphosphine complexes, **1d** and **2d** are fairly soluble in non-polar solvents, but less soluble in polar ones, such as acetone, alcohol, and water. **1c** and **2c** are somewhat soluble only in non-polar solvents, but **1a**, **1b**, **2a**, and **2b** are not sufficiently soluble to undergo spectroscopic study. On the other hand, both **3** and **4** are fairly soluble in common organic solvents.

In a previous communication,[5] the molecular-weight determination and the infrared spectra of **1d** and **2d** at various concentrations in solution have been reported to establish that: (i) the selenocarbamate ligand acts as a monodentate through the selenium atom in the solid state, (ii) in solution, partial dissociations of triphenylphosphine result in the ligand acting in a bidentate manner, and (iii) in a dilute solution, the palladium(II) and platinum(II) complexes dissociate into three and two species, and mainly exist as the following species, A and B respectively. Al-



A



B

though the molecular-weights of **1c** and **2c** could not be determined at high concentrations due to their limited solubility, they exhibit a concentration dependence of the molecular weight similar to the cases of **1d** and **2d**, as is shown in Fig. 1.

The infrared spectra of **1c** and **2c** in the solid state show a strong band due to the ν(C=O) at about 1600 cm^{-1}, while in dichloromethane solution an additional weak band appears around 1540 cm^{-1}, as is listed in Table 1. The band in the 1540 cm^{-1} region is intensified by a decrease in the concentration of the solution, and at the same time the 1600 cm^{-1} band is weakened; these bands may be assigned to the carbonyl groups coordinated and uncoordinated to the metal atom. This infrared behavior is coincident with that of **1d** and **2d**.[5] Thus, conclusions (i)—(iii) for **1d** and **2d**

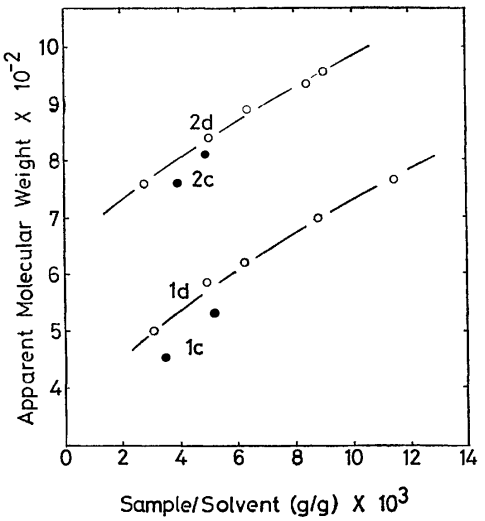


Fig. 1. Apparent molecular weights of $[(C_6H_5)_3P]_2Pd[SeC(O)N(n\text{-}C_3H_7)_2]_2$ (**1c**), $[(C_6H_5)_3P]_2Pt[SeC(O)N(n\text{-}C_3H_7)_2]_2$ (**2c**), $[(C_6H_5)_3P]_2Pd[SeC(O)N(n\text{-}C_4H_9)_2]_2$ (**1d**), and $[(C_6H_5)_3P]_2Pt[SeC(O)N(n\text{-}C_4H_9)_2]_2$ (**2d**) at various concentrations in chloroform.

a) dmsc: $SeC(O)N(CH_3)_2$, desc: $SeC(O)N(C_2H_5)_2$, dpsc: $SeC(O)N(n\text{-}C_3H_7)_2$, and dbsc: $SeC(O)N(n\text{-}C_4H_9)_2$. b) s, strong; m, medium; sh, shoulder; vw; very weak. The wave number in parentheses are those in dichloromethane solution (1.0 mm cell, 0.8 wt%).

presented above are reasonable for **1c** and **2c** also.

On the other hand, the molecular-weight determination indicates that both **3** and **4** are less dissociated than the triphenylphosphine complexes in solution. In accordance with this, the infrared spectra of these complexes show little change between the solid state and in solution, even in a very dilute solution.

NMR Spectra. As is shown in Table 2, the complexes of **3** and **4** in dichloromethane exhibit two N–CH_3 proton signals resulting from the restricted rotation around the carbamate C—N bond at low temperatures, although at room temperature broad singlets due to the N–CH_3 are observed. The approximate coalescence temperature was about −5 °C for both complexes. This temperature is considerably lower than that of $(CH_3)_2Sn[SeC(O)N(CH_3)_2]_2$ (50 °C) in nitrobenzene, which has a bidentate selenocarbamate, though the coordination of the carbonyl oxygen to the tin atom is weak.[4] This result suggests that the

Table 2. ^{1}H- and ^{31}P-NMR parameters of the complexes in chloroform solution; concd. 5.0 and 12 wt%, respectively

Complex		δ(N-CH_3) ppm	δ(P-CH_3) ppm	$\Delta(^{31}P)$[a] ppm

$[(C_6H_5)_3P]_2Pt(dbsc)_2$	(**2d**)			−25.6
$[CH_3(C_6H_5)_2P]_2Pt(dmsc)_2$	(**4**)	2.57 2.56[b] 2.49	2.43	−31.2

a) $\Delta=\delta(^{31}P)_{complexed}-\delta(^{31}P)_{free}$; $\delta(^{31}P)_{(C_6H_5)_3P}=5.6$ and $\delta(^{31}P)_{CH_3(C_6H_5)_2P}=28.1$ ppm from 85% H_3PO_4. b) Measured at −15°C.

double-bond character of the carbamate C–N bond of **3** and **4** is small, resulting from the fact that only the selenium atom attaches to the palladium(II) or platinum(II).

The P–CH_3 signal of **3** and **4** appears as a triplet, and the latter compound exhibits an additional triplet of the satellite in the higher magnetic field (this triplet results from spin interaction between the ^{195}Pt and (P-)CH_3 protons), whereas the lower satellite is obscured by the N-CH_3 signal, as is depicted in Fig. 2. This kind of "virtual coupling" phenomenon[9] establishes a *trans* disposition of the phosphine in the square-planar complexes of **3** and **4**.

Fig. 3 shows the ^{31}P-NMR spectra of the complexes, together with those of the free phosphines. **1d** shows a broad signal of the ^{31}P nucleus, which may be due to a dissociative exchange of $(C_6H_5)_3P$ in solution. On the other hand, a sharp signal of the ^{31}P is observed in the remaining complexes. In addition, the Pt(II) complexes exhibit the satellite due to a spin-spin interaction with the ^{195}Pt nucleus, while no coupling between the ^{31}P and ^{77}Se nuclei has been observed. Moreover, no appreciable change in the ^{31}P chemical shift occurred, even when a large excess of the phosphines was added to the solution, in contrast to the the case of **1d**. That the $J(^{195}Pt-^{31}P)$ value of **2d** is comparable to those of **4** and some *trans*-bis(tertphosphine)platinum(II) dichlorides (J=2385—2531Hz)[10,11] leads us to the conclusion that **2d** is also of a *trans* configuration.

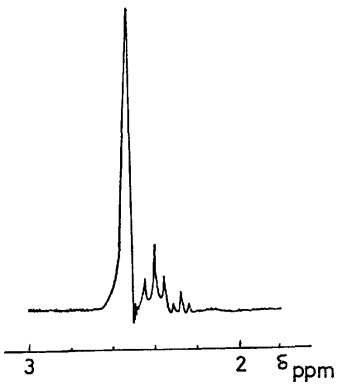

Fig. 2. PMR spectrum of $[CH_3(C_6H_5)_2P]_2Pt(dmsc)_2$ (**4**); 5wt% in $CHCl_3$.

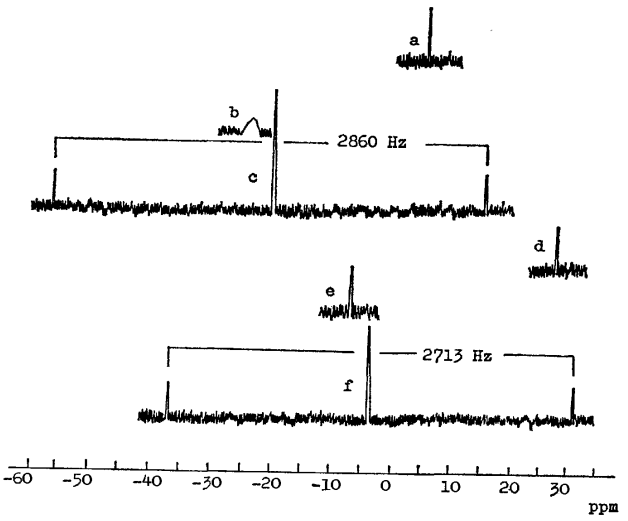

Fig. 3. ^{31}P-NMR spectra of $(C_6H_5)_3P$ (a), $[(C_6H_5)_3P]_2M(dbsc)_2$ (M=Pd (b), Pt (c)), $CH_3(C_6H_5)_2P$ (d), and $[CH_3(C_6H_5)_2P]_2M(dmsc)_2$ (M=Pd (e), Pt (f)) in $CHCl_3$; conc. 12 wt%.

Table 2 also lists the coordination chemical shifts, which are defined as the ^{31}P chemical shifts (relative to 85% H_3PO_4) of the complexes minus that of the free phosphine.[12] It may be noted that the coordination chemical shifts of the methyldiphenylphosphine complexes are larger than those of the triphenylphosphine complexes, while the reverse is true for the $J(^{195}Pt—^{31}P)$ value. A similar finding with regard to the ^{31}P-NMR spectra has been reported on *cis*-bis-(triphenylphosphine)-[13] and bis(methyldiphenylphosphine)-platinum-(II) dichloride,[10] in which the phosphines acting as good σ donors produce a large down-field shift upon coordination, whereas the π bonding with the platinum-(II) causes an up-field shift. Thus, the difference in coupling constants between **2d** and **4** may be ascribed to an increase in the π bonding character of the Pt–P bond in the former complex.

Electronic Spectra. The electronic spectra of some complexes are summarized in Table 3. The apparent spectrum of **1d** changes gradually with an increase in the amounts of triphenylphosphine added to the solution, possibly because of a considerable dissociation of triphenylphosphine of **1d** in the measured concentration. Thus, the data for **1d** are those measured in the presence of a large excess of triphenylphosphine.

TABLE 3. ELECTRONIC SPECTRA OF SOME COMPLEXES IN DICHLOROMETHANE; BAND MAXIMA IN nm AND log ε IN PARENTHESES

		CT band	d-d band	
$[(C_6H_5)_3P]_2Pd(dbsc)_2$	(**1d**)	340 (4.12)	494 (2.52)	410 (3.47)
$[CH_3(C_6H_5)_2P]_2Pd(dmsc)_2$	(**3**)	325 (4.20)	474 (2.52)	390 (3.40)
$[(C_6H_5)_3P]_2Pt(dbsc)_2$	(**2d**)	280 (4.23)	398 (2.50)	336 (3.46)
$[CH_3(C_6H_5)_2P]_2Pt(dmsc)_2$	(**4**)	273 (4.35)	383 (2.68)	322 (3.45)

On the contrary, there was no appreciable change in the spectra of the remaining complexes when an excess amount of the phosphines was added to the solution. As may be seen in Table 3, the d-d bands of **3** and **4** appear at wavelength shorter by about 20 nm than those of **1d** and **2d**, indicating a stronger ligand field for methyldiphenylphosphine than for triphenylphosphine.

Kinetic Studies of the Electron Transfer Reaction in Iron(II) and Iron(III) Systems. VI. Reaction in *N,N*-Dimethylformamide[1]

Goro WADA, Yoshiko SAHIRA, Kyoko OHSAKI, and Fusako SHINODA

Department of Chemistry, Nara Women's University, Nara 630

(Received August 2, 1973)

The electron transfer reaction between Fe(II) and Fe(III) in *N,N*-dimethylformamide (DMF) was found to be influenced by the presence of perchloric acid, chloride ion, and water in the reaction system. This suggests that the reaction involves chemical species such as partially hydrated iron, its deprotonated iron, and $FeCl^{2+}$ and $FeCl_2^+$. The individual rate constants in DMF, containing a small amount of water, are $k_0=33.6\ M^{-1}s^{-1}$ for Fe^{2+}–Fe^{3+}, $k_1=1.2\times10^2\ M^{-1}s^{-1}$ for Fe^{2+}–$FeCl^{2+}$, and $k_2=\sim10^3\ M^{-1}s^{-1}$ for Fe^{2+}–$FeCl_2^+$ at $\mu=0.20$ M and 25 °C. The formation constant for $FeCl^{2+}$ was determined to be $K_1=(2.0\pm0.3)\times10^4\ M^{-1}$ at $\mu=0.20$ M and 25 °C. In the mixed solvents of DMF and water, the apparent rate constant exhibited a minimum at a certain water concentration. The activation parameters for the reactions Fe^{2+}–Fe^{3+} and Fe^{2+}–$FeCl^{2+}$ are $\Delta H_0^{\neq}=8.3$ kcal/mol, $\Delta S_0^{\neq}=-24$ cal/deg·mol, $\Delta H_1^{\neq}=4.5$ kcal/mol, and $\Delta S_1^{\neq}=-34$ cal/deg·mol, respectively. The results are compared with those in H_2O, D_2O, and DMSO.

The electron transfer reaction between iron(II) and iron(III) has been investigated in various solvents. In protic solvents such as water[2,3] and mixed solvents of water with some alcohols,[1,4,5] the predominant reaction path in the absence of catalytical bridging ligand was deduced to be one *via* a hydrogen-atom-transfer mechanism, first proposed by Reynolds and Lumry.[6] On the other hand, in dimethyl sulfoxide (DMSO)[7] as an aprotic solvent, the reaction was found to proceed faster than in water, although the hydrogen-atom-transfer mechanism does not seem to occur in aprotic solvents. In such a medium, therefore, an inner-sphere mechanism should be more favorable.

In this study, *N,N*-dimethylformamide(DMF), another aprotic solvent, of a little larger basicity than DMSO,[8,9] was adopted in order to see how its properties reflect on the reaction mechanism. Dependence upon the concentrations of acid, chloride ion, and water was investigated.

Experimental

Materials. Commercial DMF of E. P. grade (Nakarai Chemicals, Ltd.) was dried over potassium carbonate and sodium sulfate, and distilled twice under reduced pressure of nitrogen at about 40 °C. DMF solution of perchloric acid, prepared by mixing 70% perchloric acid of reagent grade and pure DMF, was used soon after preparation. The water content introduced by this method was about twice in molarity of the acid concentration in DMF. The concentration of water was kept constant at 0.3 M, unless otherwise stated.

An extremely anhydrous acid solution could be made up either by dissolving an anhydrous solid acid such as crystal of toluenesulfonic acid in DMF, or by passing a DMF solution of ammonium perchlorate through a column of cation-exchange resin of H-form. However, the former method was not free from the anion effect upon the reaction and the latter was accompanied by a small degree of decomposition of DMF during the treatment, deteriorating the reproducibility of the rate measurements considerably. Thus neither method was employed in the present preparation.

Other materials used were prepared by the procedure described elsewhere.[7,10] The ionic strength of the solution was controlled with sodium perchlorate at $\mu=0.20$ M. Radioactive iron-59 was used as a tracer.

Apparatus and Procedure. The methods for determining the formation constants and the rate constants were similar to those described previously.[7,10,11]

Results and Discussion

Reaction Order with Respect to Iron Concentrations. The reaction rate R of the electron transfer reaction, Fe(II)+*Fe(III)→Fe(III)+*Fe(II), is expressed by the following McKay's relation,[12]

$$R=\frac{0.693[\mathrm{Fe(II)}][\mathrm{Fe(III)}]}{\{[\mathrm{Fe(II)}]+[\mathrm{Fe(III)}]\}t_{1/2}} \quad (1)$$

where [Fe(II)] and [Fe(III)] represent the total concentrations of iron(II) and iron(III) species, respectively, and $t_{1/2}$ the half-life period of the reaction. If the reaction is of the first order with respect to each of [Fe(II)] and [Fe(III)], the apparent second-order rate constant k_{app} of the reaction can be obtained by the following equation, which should give a constant value at different iron concentrations under a fixed condition, this being proved in Table 1.

$$k_{app}=\frac{0.693}{\{[\mathrm{Fe(II)}]+[\mathrm{Fe(III)}]\}t_{1/2}} \quad (2)$$

Acid Dependence. The reaction rate was influenced by the concentration of perchloric acid in the concentration range 0.03—0.15 M; the higher the acid concentration the slower the reaction. When k_{app} was plotted against the reciprocal acid concentra-

Table 1. Constancy of second-order rate constants at fixed acid and water concentrations at $\mu=0.20$ M and 25 °C

$[HClO_4]$ M	$[H_2O]$ M	[Fe(II)] 10^{-4} M	[Fe(III)] 10^{-4} M	$t_{1/2}$ s	k_{app} $M^{-1}s^{-1}$
0.15	0.3	1.55	0.10	112	37.5
		1.26	0.34	120	36.9
		0.972	0.12	172	36.9
0.05	1.80	1.61	0.12	155	25.9
		1.22	0.20	161	30.6
		0.73	0.23	272	26.5
		0.59	0.21	305	28.7

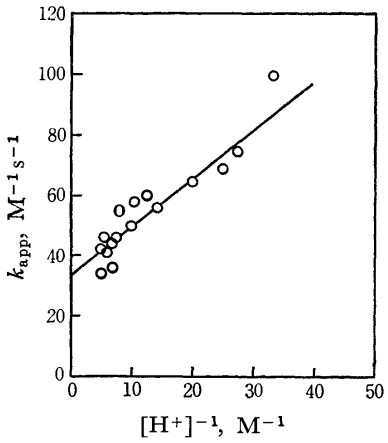

Fig. 1. Dependence of k_{app} upon $[H^+]^{-1}$ at $[H_2O]=0.3$ M, $\mu=0.20$ M, and 25 °C in DMF.

tion, a straight line was obtained with an intercept 33.6 $M^{-1}s^{-1}$ and a slope 1.71 s^{-1} at 25 °C, as is shown in Fig. 1. This implies that the reaction involves a path with a deprotonated species of the reactant. Thus, the acid-dependent reaction scheme in the presence of water in DMF is deduced as follows:

$$Fe^{2+} + {}^*Fe^{3+} \rightarrow Fe^{3+} + {}^*Fe^{2+} \quad (k_o) \qquad (3)$$

$$Fe^{2+} + {}^*Fe(-H)^{2+} \rightarrow Fe(-H)^{2+} + {}^*Fe^{2+} \quad (k_H) \qquad (4)$$

where $Fe(-H)^{2+}$ stands for an iron(III) species, of which one coordinated solvent molecule is deprotonated, keeping an equilibrium with acid concentration in the medium, and Fe^{2+} and Fe^{3+} stand for normally solvated ones.

Since DMF is more basic than DMSO,[8,9] it is not likely that the solvating DMF dissociates to lose a proton as an acid. The deprotonated species $Fe(-H)^{2+}$ might be one attributed to a coordinating water molecule which is present in the solvent. Thus, k_{app} can be expressed by the following equation, in which K_H is defined as the dissociation constant of the equilibrium $Fe^{3+} \rightleftarrows Fe(-H)^{2+} + H^+$.

$$k_{app} = \frac{k_o + k_H K_H/[H^+]}{1 + K_H/[H^+]} \qquad (5)$$

Accordingly, $k_{app}(1+K_H/[H^+])$ should have a linear relationship with $[H^+]^{-1}$. The value of K_H is not known here but since $K_H/[H^+]$ seems to be negligibly small as compared with unity, k_{app} would also exhibit an approximate linearity with $[H^+]^{-1}$, as is evident from Fig. 1. Thus, k_0 and $k_H K_H$ are found to be $k_0=33.6$ $M^{-1}s^{-1}$ and $k_H K_H=1.71$ s^{-1}, respectively.

The value of k_0 is very close to that of the corresponding reaction in DMSO, 34.4 $M^{-1}s^{-1}$.[10] On the other hand, the value of $k_H K_H$ is difficult to be quantitatively analyzed. However, when *N*-methylacetamide or *N*,*N*-dimethylacetamide partially coordinates with iron(III) in aqueous solution, the electron transfer reaction is known still to occur *via* path 4.[13] It is not absurd to consider that the reaction can occur in a similar way in water-containing DMF.

Formation Constants of Fe(III)-Cl⁻ Complex. When sodium chloride is added to iron(III) perchlorate solution at $[Cl]=3.53\times10^{-4}$ M, $[Fe(III)]=4.92\times10^{-5}$ M, $[H^+]=0.15$ M in DMF, the optical absorbance in

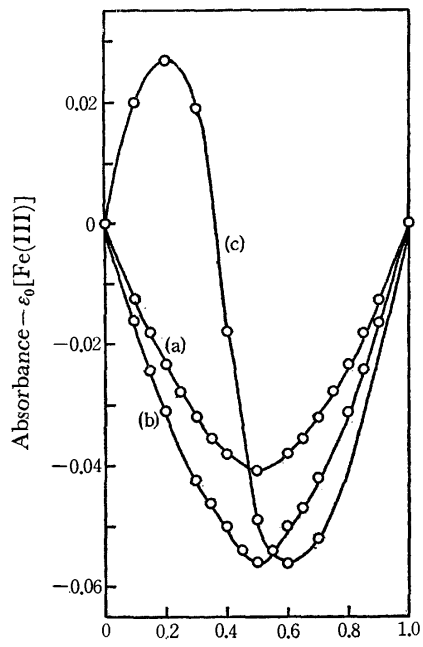

Fig. 2. Job's continuous variation curves for Fe(III) and Cl^- at $[H^+]=0.15$ M, $[H_2O]=0.3$ M, $\mu=0.20$ M, and 25 °C in DMF.
(a) $[Fe(III)]+[Cl]=1.4\times10^{-4}$ M at 290 nm
(b) $[Fe(III)]+[Cl]=1.8\times10^{-4}$ M at 290 nm
(c) $[Fe(III)]+[Cl]=2.0\times10^{-3}$ M at 440 nm

the wavelength range 280—400 nm diminishes as a whole with a peak at *ca.* 340 nm and a minimum at *ca.* 290 nm. In Fig. 2, Job's curves are given at different total concentrations of iron(III) and chloride ion at $[H_2O]=0.3$ M, $\mu=0.2$ M, and $[H^+]=0.15$ M, where the acid concentration is so high that the influence of the deprotonation of iron(III) species is removed. Curves (a) and (b) indicate that a 1 : 1 complex is formed between iron(III) and chloride ion at lower total concentrations and curve (c) that, at a higher concentration, a higher complex, probably of a composition of $FeCl_2^+$, is formed. The formaiton constant, $K_1=[FeCl^{2+}]/[Fe^{3+}][Cl^-]$, and the molar absorptivity ε_1^{290} for $FeCl^{2+}$ are calculated[11] from the curves (a) and (b) at 25 °C and 16 °C as follows.

$$\left.\begin{aligned} K_1 &= (2.0\pm0.3)\times10^4\ M^{-1} \\ \varepsilon_1^{290} &= (5.35\pm0.06)\times10^3\ M^{-1}cm^{-1} \end{aligned}\right\} \ 25\ °C$$

$$\left.\begin{aligned} K_1 &= (1.9\pm0.4)\times10^4\ M^{-1} \\ \varepsilon_1^{290} &= (5.20\pm0.05)\times10^3\ M^{-1}cm^{-1} \end{aligned}\right\} \ 16\ °C$$

Both K_1 and ε_1^{290} seem to be independent of temperature. The K_1 value at 25 °C is about five times greater than that in DMSO, $K_1=3.7\times10^3$ M^{-1}.[11]

Catalysis by Chloride Ion. The electron transfer reaction is accelerated by the presence of chloride ion; its apparent rate constant grows higher as the concentration of chloride ion increases at a constant acid concentration, $[H^+]=0.15$ M. If chloroiron(III) complexes such as $FeCl^{2+}$ and $FeCl_2^+$ are involved in the reaction, the following two paths may occur in addition to 3 and 4:

$$Fe^{2+} + {}^*FeCl^{2+} \rightarrow FeCl^{2+} + {}^*Fe^{2+} \quad (k_1) \qquad (6)$$

$$Fe^{2+} + {}^*FeCl_2^+ \rightarrow FeCl_2^+ + {}^*Fe^{2+} \quad (k_2) \qquad (7)$$

The apparent rate constant k_{app} is expressed by

$$k_{app} = \frac{k_0 + k_H K_H/[H^+] + k_1 K_1 [Cl^-] + k_2 K_1 K_2 [Cl^-]^2}{1 + K_H/[H^+] + K_1[Cl^-] + K_1 K_2 [Cl^-]^2} \qquad (8)$$

where K_2 represents the second stepwise formation constant of $FeCl_2^+$, which is roughly estimated to be about $10^3\ M^{-1}$ from a simple comparison with that of DMSO. According to Eq. 8, the following linearity between Y and $[Cl^-]$ should be established, where D is the denominator in Eq. 8.

$$Y = \frac{k_{app} \cdot D - (k_0 + k_H K_H/[H^+])}{[Cl^-]}$$

$$= k_1 K_1 + k_2 K_1 K_2 [Cl^-] \qquad (9)$$

The linearity is proved in Fig. 3. The intercept and slope of the straight line give the values $k_1K_1 = 2.37 \times 10^6 M^{-2} s^{-1}$ and $k_2K_1K_2 = 4.64 \times 10^{10} M^{-3} s^{-1}$, respectively. By using the values of K_1 and K_2, the individual rate constants are obtained as follows.

$$k_1 = 1.2 \times 10^2\ M^{-1} s^{-1}$$

$$k_2 = \sim 10^3\ M^{-1} s^{-1}$$

Dependence upon Water Concentrations. Since the DMF we used inevitably contained a small amount of water, it was necessary to examine the influence of water upon the rate constants. When the water concentration was changed in DMF as mixed solvents, the value of k_{app} decreases with the increase in water concentration and reaches a broad minimum, beyond which it increases at a constant acid concentration. The minimum points of k_{app} appear at about 2 and 4 M of water concentration when the fixed acid concentrations are 0.01 M and 0.05 M, respectively. Such behaviors of water are reproduced in Fig. 4. The value of k_{app} is always smaller at higher acid concentrations within the water concentration range studied.

In aqueous DMF, the partially-hydrated iron species such as $Fe(III)(H_2O)_x(DMF)_{6-x}$ should be considered

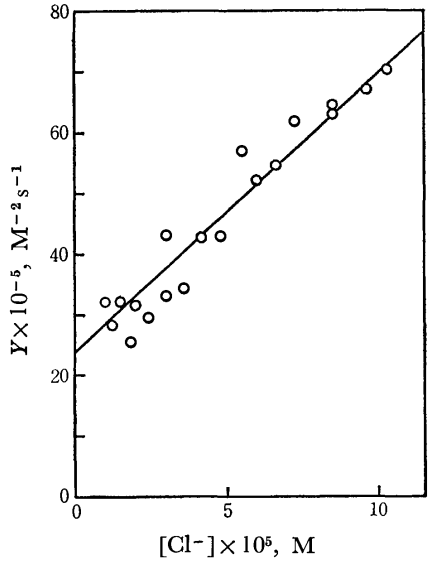

Fig. 3. Linear relationship between Y and $[Cl^-]$ at $[H^+] = 0.15$ M, $[H_2O] = 0.3$ M, $\mu = 0.20$ M, and 25 °C in DMF.

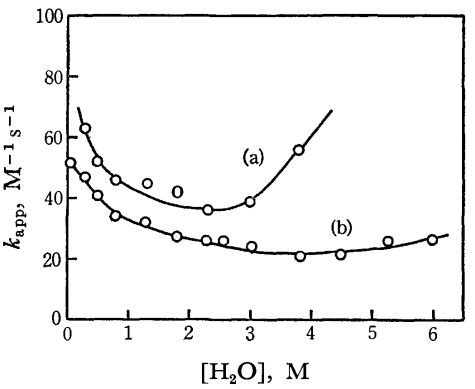

Fig. 4. Dependence of k_{app} upon $[H_2O]$ at $\mu = 0.20$ M and 25 °C in DMF.
(a) $[H^+] = 0.01$ M, (b) $[H^+] = 0.05$ M

to be involved in the electron transfer reaction. Judging from the fact that k_{app} is dependent upon the acid concentration, the deprotonated species of the hydrated iron, $Fe(III)(OH^-)(H_2O)_{x-1}(DMF)_{6-x}$, seems also to take part in the reaction with a larger rate constant than that due to the unhydrolyzed one. Since the formation constants and hydrolysis constants for the iron species hydrated to various extents are not known, the individual rate constants cannot be estimated.

The phenomenon that k_{app} exhibits a minimum at a certain water concentration when the acid concentration is constant, has been also observed in the cases of mixed solvents of DMSO and water.[7] As the water content varies from zero to 100%, the predominant mechanism of the reaction may also turn from an inner-sphere type to a hydrogen-atom-transfer one in DMF as in DMSO.

The DMSO used for the first investigation on the electron transfer reaction between iron(II) and iron(III) contained water at as high as $[H_2O] = 0.015$ M.[7] The water concentration was much higher than those of reactants 10^{-5}—10^{-4} M. However, since DMSO is very hydrophilic[14] and water is likely to be preferentially excluded from the coordination sphere of metal ions in DMSO-rich mixed solvents of DMSO and water,[15] the occurrence of partially hydrated iron species was not so great as expected. This might be the case with DMF, although the water concentration is larger.

An important difference between DMSO and DMF is as follows. In the former, the acid dependence of k_{app} tends to disappear[7] or become smaller at least[10] as the water concentration is lowered. In the latter, it tends to remain according to the extrapolation of water concentration to zero. The reason for this is not clear at present.

Activation Parameters and General Discussion. Kinetic measurements were carried out at 10 °C—35 °C at intervals of five degrees. The activation parameters, $\Delta H_0^{\neq}$, $\Delta S_0^{\neq}$, $\Delta H_1^{\neq}$, and $\Delta S_1^{\neq}$ were calculated from the linearity between $\log(k_0/T)$ and $\log(k_1/T)$ *vs.* T^{-1}, respectively. The results are listed in Table 2, along with various related data in other solvents in literature. The data related to DMF may be approximately regarded as those in pure DMF.

TABLE 2. SUMMARY OF RATE CONSTANTS AND ACTIVATION PARAMETERS IN VARIOUS SOLVENTS

Solvent	Dielectric constants	Condition μ, temp. °C	k_0 $M^{-1}s^{-1}$	k_1 $M^{-1}s^{-1}$	k_2 $M^{-1}s^{-1}$	$\Delta H_0^{\neq}$ kcal/mol	$\Delta S_0^{\neq}$ cal/deg·mol	$\Delta H_1^{\neq}$ kcal/mol	$\Delta S_1^{\neq}$ cal/deg·mol	$\log K_1$ (M^{-1})
H_2O[3,16]	80	0.5, 25°	4.0	22.8(20°)	53(20°)	10.5	−20.6	11.0	−15	1.48
D_2O[3,16]	79	0.5, 25°	1.0	9.1(20°)	—	—	—	13.2	−10	—
DMSO[7,10,17]	46.7	0.2, 20°	34.4(25°)	1.3×10^2 (μ=0.1)	1.02×10^3 (μ=0.1)	9.7	−19	5.2	−27	3.62
DMF	36.1	0.2, 25°	33.6	1.2×10^2	$\sim10^3$	8.3	−24	4.5	−34	4.30

The rate constants and activation parameters for DMSO and DMF are very close. This suggests that the solvent effects on the reaction are similar to each other, and accordingly the reaction scheme is the same. DMF, as well as DMSO, is a unique aportic solvent in which the value of k_0 is larger than that in water.

A DMF molecule coordinates with an iron ion on the oxygen atom,[18] and has a tendency to be hydrolyzed to give formate ion and dimethylamine in the presence of hydroxide ion in DMF–water mixture.[19] Thus, it is probable that hydroxide ion reacts with DMF intramolecularly in the coordination sphere of an $Fe(OH^-)(DMF)$-type complex in the case of DMF–water mixed solvents, making the electron transfer reaction somewhat more complicated.

The value of the formation constant of $FeCl^{2+}$, $\log K_1$ in Table 2, varies in the sequence H_2O <DMSO <DMF, being in line with what is expected from the dielectric constants of the solvents.

Association Involving Optically Active Ions. III. Pfeiffer Effect in Tris(phenanthroline)-zinc(II) or -nickel(II) -Alkaloid Systems

Kazuko OGINO* and Tokue KUMAGAI**

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received October 11, 1973)

Pfeiffer effect was studied in aqueous solutions containing tris(phenanthroline)metal(II) (metal=zinc or nickel) complexes and various alkaloids. The results were interpreted quantitatively from the viewpoint of stereoselective association and the resulting equilibrium shift. The contribution of π-π interaction between the complex and the alkaloid conjugate systems to the stereoselective association is suggested. NMR data were found to be consistent with the π-π interaction. Relation between the sign of the Pfeiffer rotation and the absolute configuration of the complex is presumed.

The induction of new optical activity by the addition of some resolvable complexes to a solution containing optically active substances is known as Pfeiffer effect.[1] It has been interpreted from the viewpoint of equilibrium shift,[1-6] configurational activity,[3] differential association,[2] hydrophobic bonding,[6] *etc.* However, few quantitative analyses based on the mechanisms listed above have been reported. In this paper, Pfeiffer rotation was measured in solutions containing various alkaloids, and a quantitative analysis of Pfeiffer rotation from the viewpoint of differential association and the resulting equilibrium shift was attempted.

Experimental

Optical rotatory dispersion curves were obtained with a Jasco UV/ORD 5 spectrophotometer equipped with a constant temperature cell compartment. Nuclear magnetic resonance spectra were recorded on a Varian A-60 spectrometer. The complexes $[Zn(phen)_3]Cl_2 \cdot 6H_2O$ and $[Ni(phen)_3]Cl_2 \cdot 6H_2O$ were obtained by mixing the corresponding metal chloride with stoichiometric amount of phenanthroline and recrystallized from water. Alkaloid hydrochlorides were obtained by neutralizing the free base with an equivalent amount of hydrochloric acid. All other chemicals were of guaranteed reagent grade.

Results and Discussion

Optical rotatory dispersion curves were recorded from 350 to 650 nm in aqueous solutions containing phenanthroline complexes, alkaloid monohydrochloride and some electrolyte in a 1 cm cell. Fig. 1 shows the curves in a solution containing 0.02 M $[Ni(phen)_3]^{2+}$, 0.02 M cinchonine hydrochloride and 0.5 M NaCl. An instantaneous change in rotation takes place after mixing the solution. Rotation at this stage is denoted by α_i. A further change in rotation proceeds gradually and after *ca.* 70 hours a final value, α_∞ is reached. This slow change is considered to be due to the inversion of configuration of the complex. The rotatory dispersion curve of cinchonine hydrochloride (denoted by α_X) is also given in Fig. 1. In the case of zinc complex, the inversion of configuration is so rapid

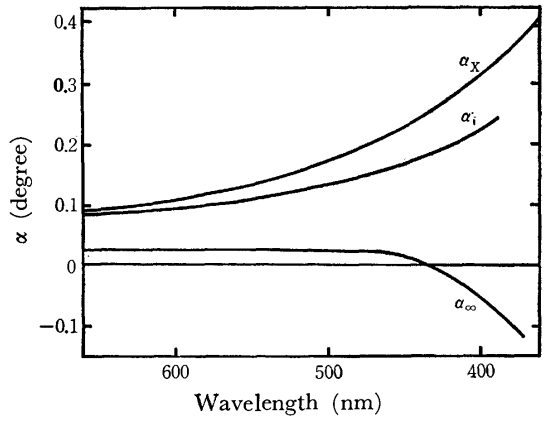

Fig. 1. Optical rotatory dispersion curves of 0.02 M cinchonine hydrochloride (α_X) and a solution containing 0.02 M cinchonine hydrochloride, 0.02 M $[Ni(phen)_3]Cl_2$ and 0.5 M NaCl(α_i and α_∞). The α_i curve was measured immediately after mixing and the α_∞ curve at equilibrium. Cell lengh, 1 cm; temperature, 30 °C.

that only the α_∞ value is measured. The overall rotational change is defined as the Pfeiffer rotation in this paper:

$$\alpha_P = \alpha_\infty - \alpha_X$$

Nature of Alkaloids. The Pfeiffer rotations with various alkaloids are tabulated in Table 1. The α_P values were obtained most accurately at 400 nm, and data at this wavelength are given. The magnitude of Pfeiffer rotation decreases in the order, cinchonine and cinchonidine>strychinine and brucine≳quinine and quinidine for both zinc(II) and nickel(II) complexes. The same order was obsreved at other wave-

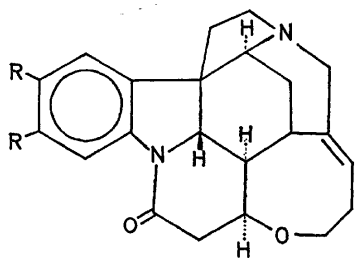
a) The chemical shift is for the proton on the carbon atom adjacent to the quinolyl nitrogen atom. b) The assignment is after J. D. Miller and R. M. Prince, *J. Chem. Soc*, **1965**, 3185.

lengths in 350~700 nm region. Cinchonidine is a stereoisomer of cinchonine(I)[7] with reversed configurations of the two carbon atoms C^a and C^b. The magnitude of Pfeiffer rotation caused by these alkaloids are similar to each other except the sign. Quinine and quinidine(II) are methoxyl derivatives of cinchonidine and cinchonine respectively. The magnitudes of Pfeiffer rotations by these alkaloids are much smaller than those by cinchonine and cinchonidine. These differences should be related to the presence of a methoxyl group on the quinolyl part in quinine or quinidine. This fact suggests that there is π-π interaction between the conjugate system of phenanthroline rings of the complex and the quinolyl group of cinchonine or cinchonidine, and that stereoselectivity in such an interaction is responsible for Pfeiffer rotation. The presence of methoxyl group at the quinolyl part of quinine or quinidine would make π-π interaction less favorable sterically than in cinchonine or cinchonidine. As will be mentioned later, such stereoselectivity is related more directly to $(\alpha_\infty-\alpha_i)$ values than to α_P values (see Eq. 11). It is seen in Table 1 that $\alpha_\infty-\alpha_i$ values for cinchonine or cinchonidine are much larger than those for quinine or quinidine for nickel(II) complexes. The π-π interaction mentioned above has hydrophobic nature. Brasted *et al.*[6] reported that the effects of solvent and urea on the Pfeiffer effect in $[Zn(phen)_3]^{2+}$–alkaloid(cinchonine hydrochloride or strychinine hydrosulfate) systems and in other systems indicate hydrophobic bonding between the complex and the optically active substance.

The magnitudes of the Pfeiffer rotations of strychinine(III)[8] hydrochloride and brucine(IV) hydrochloride are of the same order to each other and much smaller than those of cinchonine or cinchonidine hydrochloride. This fact shows that the methoxyl groups in brucine do not exert significant influence on Pfeiffer effect. The π-π interaction between the phenanthroline rings of the complex and the phenyl group of strychinine may be smaller than that between the complex and the quinolyl group of cinchonine or contribution of other interactions may be larger.



III. R=H; strychinine
IV. R=OCH_3: brucine

NMR Data. Table 2 gives NMR data of cinchonine hydrochloride and $[Zn(phen)_3]^{2+}$. Chemical shifts were given in cps from sodium trimethylsilyl sulfonate(TMS*) used as external standard.[9] The data in the table indicate that the quinolyl protons of cinchonine are shifted toward higher field by 8 or 9 cps by the addition of 0.01 M $[Zn(phen_3)]^{2+}$. Other protons in cinchonine are shifted by only 5 to 6 cps. The phenanthroline protons of the complex are also affected by the addition of cinchonine hydrochloride: 2, 9 and 3, 8 protons are shifted by 2 or 3 cps and 4, 7 and 5, 6 protons by *ca.* 4 cps toward higher field. These shifts can be due to the effect of the ring current of the phenanthroline or the quinolyl group. These results are not inconsistent with the π-π interaction mentioned above.

Influence of Indifferent Electrolyte. Both the complex ion and the monoprotonated alkaloid ion are positively charged. Association between these cations by hydrophobic bonding or π-π interaction should overwhelm the electrostatic repulsion between them.

Table 3. Effect of electrolyte on Pfeiffer rotation at 400 nm in $[Zn(phen)_3]^{2+}$- cinchonidine hydrochloride system

0.01	0.02	0.03 M $CaCl_2$	0.248°
0.01	0.02	0.5 M NaCl	0.294°

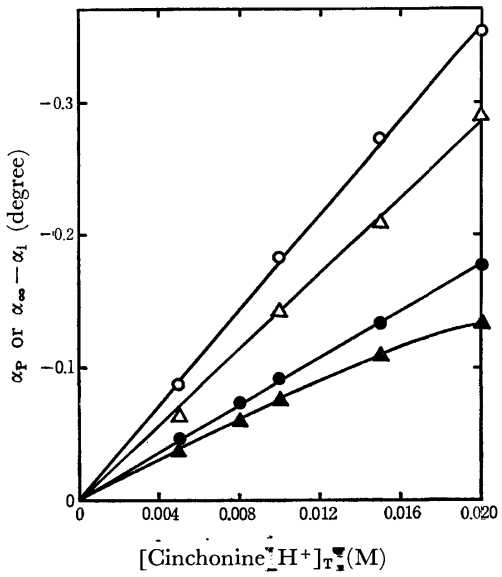

Fig. 2. Dependence of α_P (○, ●) and $\alpha_\infty - \alpha_i$ (△, ▲) values on cinchonine hydrochloride concentration in solutions with (○, △) and without (●, ▲) 0.5 M NaCl. Cell length, 1 cm; temperature, 30 °C; $[Ni(phen)_3]Cl_2$, 0.02 M.

Addition of electrolyte would diminish such a repulsion. Table 3 and Fig. 2 give Pfeiffer rotations in the presence and in the absence of electrolytes. It is seen that both sodium chloride and calcium chloride have considerable enhancing effect on Pfeiffer rotation. The enhancing effect seems to be more than that to be understood from simple electrostatic consideration.

Concentrations of Alkaloids and the Complex. The dependencies of Pfeiffer rotation on concentrations of the complexes and alkaloids were studied (Figs. 2 to 4). In these solutions 0.5 M NaCl was added in order to maintain ionic strength of the solution constant. The concentration ranges of the complexes and alkaloids were restricted because of the limited solubility. In the following, concentration dependence is analyzed quantitatively in terms of stereoselective association between the complex and the alkaloid cations. As is mentioned later, 1 : 1 association seems to be predominant under the experimental condition and only 1 : 1 association was taken into consideration in the following treatment. The association of the optically active alkaloid with one enantiomer of the complex

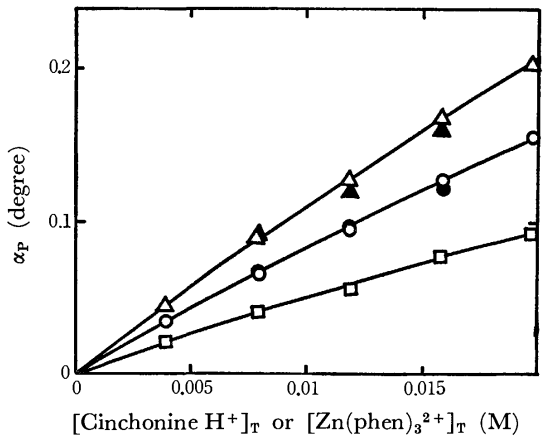

Fig. 3. Dependence of Pfeiffer rotation on cinchonine hydrochloride concentration in solutions containing 0.0049 M $[Zn(phen)_3]Cl_2$ and 0.5 M NaCl at 380 (△), 400 (○) and 450 (□) nm. Dependence on $[Zn(phen)_3]^{2+}$ concentration in solutions containing 0.0049 M cinchonine hydrochloride and 0.5 M NaCl at 380 (▲) and 400 (●) nm is also shown. Cell length, 1 cm; temperature, 30 °C.

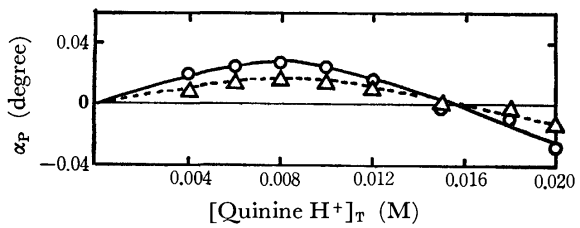

Fig. 4. Pfeiffer rotation at 400 (○) and 450 (△) nm in solutions containing 0.01 M $[Zn(phen)_3]Cl_2$, 0.5 M NaCl and various amount of quinine hydrochloride. Cell length, 1 cm; temperature, 30 °C.

can be different from that with the other enantiomer:

$$d\text{-M} + d\text{-X} \rightleftharpoons d\text{-M}\cdot d\text{-X},$$

$$K_{dd} = [d\text{-M}\cdot d\text{-X}]/([d\text{-M}][d\text{-M}][d\text{-X}]) \quad (1)$$

$$l\text{-M} + d\text{-X} \rightleftharpoons l\text{-M}\cdot d\text{-X},$$

$$K_{ld} = [l\text{-M}\cdot d\text{-X}]/([l\text{-M}][d\text{-X}]) \quad (2)$$

where *d*-M and *d*-X denote one enantiomer of the complex and the optically active substance(*e. g.* alkaloid cation), respectively and *l*-M and *l*-X their antipodes. A stereoselective association has been reported between some tervalent complex ions and tartrate ions.[10,11]

The optical rotation of the solution containing a racemic salt of the complex and alkaloid in a cell of unit cell length is given by

$$\alpha = \theta_X[d\text{-X}] + \theta_d([d\text{-M}] - [l\text{-M}]) + \theta_{dd}[d\text{-M}\cdot d\text{-X}] + \theta_{ld}[l\text{-X}\cdot d\text{-X}] \quad (3)$$

where θ_X, θ_d, θ_{dd} and θ_{ld} denote molecular rotations of *d*-X, *d*-M, *d*-M·*d*-X and *l*-M·*d*-X, respectively. Until inversion of the complex takes place, the concentrations of the two enantiomers of the complex should be equal:

$$[d\text{-M}]_i + [d\text{-M}\cdot d\text{-X}]_i = [l\text{-M}]_i + [l\text{-M}\cdot d\text{-X}]_i = [M]_T/2 \quad (4)$$

where the suffix i denotes the time immediately after

mixing before any inversion takes place. It follows from Eqs. (1) to (4) that a new optical activity is induced even when no inversion occurs unless $K_{dd}=K_{ld}$ and $\theta_{dd}=-\theta_{ld}$. It was shown previously that θ_{dd} is considerably different from θ_{ld} in some Co(III) complex-tartrate systems.[11] In the case of the nickel complex, the rate of inversion is slow and the α_i values in Table 1 are considered to correspond to the optical rotations given by Eqs. (3) and (4).

When K_{dd} is not equal to K_{ld}, assoications represented by Eqs. (1) and (2) cause differences in concentrations of free *d*-M and *l*-M, and inversion of the complex will take place to make them equal:

$$[d\text{-M}]_\infty=[l\text{-M}]_\infty \tag{5}$$

where the parenthesis with suffix ∞ denotes the concentration at equilibrium. The optical rotation of the equilibrated solution, α_∞, is given by

$$\alpha=\theta_X[d\text{-X}]_\infty+(\theta_{dd}K_{dd}+\theta_{ld}K_{ld})[d\text{-M}]_\infty[d\text{-X}]_\infty \tag{6}$$

If the extent of association is small, the equation

$$[d\text{-X}]_T\simeq[d\text{-X}]_\infty \tag{7}$$

holds, where $[d\text{-X}]_T$ is the total concentration of the alkaloid salt, and the Pfeiffer rotation is expressed as

$$\alpha_P=a[d\text{-M}]_\infty[d\text{-X}]_\infty \tag{8}$$

where

$$\alpha=\theta_{dd}K_{dd}+\theta_{ld}K_{ld} \tag{9}$$

Eq. (8) is transformed to

$$[\text{d-X}]_\infty/\alpha_P=2(1+K_{app}[d\text{-X}]_\infty)/(a[M]_T) \tag{9}$$

where

$$K_{app}=(K_{dd}+K_{ld})/2 \tag{10}$$

The plot of the left-hand side of Eq. (9) *vs.* $[d\text{-X}]_\infty$ should be a straight line, and the ratio of slope to intercept is equal to K_{app}.

This procedure was applied to the data in Fig. 3. A correction was made for Eq. (7) by stepwise approximation. The values of K_{app} thus obtained are listed in Table 4. Values obtained from data at different wavelengths are in agreement with one another. It is in accord with the assumption of the absence of the higher order association.[11] Theoretical curves calculated by use of Eq. (8) and K_{app} values in Table 4 are given in Fig. 3 by solid lines. They are in agreement with experimental plots. From the temperature dependence of Pfeiffer rotation and that of K_{app} value, the ΔH° for the association between $[Zn(phen)_3]^{2+}$ and cinchonine hydrochloride was calculated to be -3 kcal/mol. This value is comparable with those reported for some systems where hydrophobic bonding is concerned.[12]

Table 4. Association constants between $[Zn(phen)_3]^{2+}$ and monoprotonated alkaloid cations in solutions containing 0.5 M NaCl obtained by use of Eq. (9)

Alkaloid	Temp.	K_{app}[a]
Cinchonine	30°	8.3 (380 nm) 8.3 (400 nm) 8.4 (450 nm)
	35°	7.7 (400 nm)
	25°	8.9 (400 nm)
Cinchonidine	30°	7.3 (400 nm) 7.0 (420 nm) 9.5 (450 nm)

a) Because of the uncertainty in the measurement in optical rotation the precision of K_{app} values is ±1.5. The values in parentheses are wavelengths at which measurement was made.

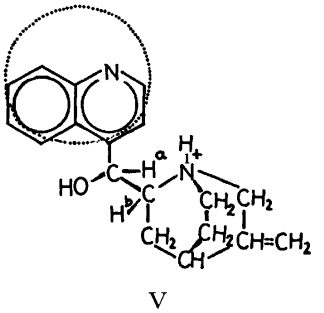
Figure 4 shows concentration dependence of Pfeiffer rotation in $[Zn(phen)_3]^{2+}$–quinine hydrochloride system. The magnitude is much smaller than those observed in cinchonine or cinchonidine hydrochloride systems, and the sign of α_P changes with change in quinine concentration, positive for $[X]<0.015$ M and negative for $[X]>0.015$ M at 400 nm. It may be because of the presence of higher order association to a considerable extent.

As is seen in Fig. 2, α_P is proportional to the alkaloid concentration within experimental error in $[Ni(phen)_3]^{2+}$–cinchonine hydrochloride system. Though K_{app} value could not be obtained in this system, an upper limit is given: $K_{app}\lesssim8$. From a comparison of Eqs. (3) and (6), it follows that the value $\alpha_\infty-\alpha_i$ can be approximated as

$$\alpha_\infty-\alpha_i\simeq\theta_d([d\text{-M}]_i-[l\text{-M}]_i)\simeq\theta_d([l\text{-M}]_{T,\infty}-[d\text{-M}]_{T,\infty}) \tag{11}$$

within $\pm10\%$ if $K_{app}\lesssim8$, $0.5<K_{dd}/K_{ld}<2$ and $0.5<|\theta_{dd}/\theta_{ld}|<2$. From data in Fig. 2 and optical rotation of pure $(-)_D$-$[Ni(phen)_3](ClO_4)_2$, it is calculated that when a solution containing 0.02 M $[Ni(phen)_3]Cl_2$, 0.02 M cinchonine hydrochloride and 0.5 M NaCl is equilibrated, the total amount of *l*-rotatory complex is more than that of the *d*-rotatory complex by about 3 %. Taking $K_{app}<8$ for this system into account, it follows that K_{ld} is considerably larger than K_{dd} for the association between $[Ni(phen)_3]^{2+}$ and cinchonine hydrochloride.

Sign of Pfeiffer Rotation and Absolute Configuration. The more favorable conformation of cinchonine is presumed to be one in which the two hydrogen atoms on the two carbon atoms adjacent to quinolyl group, H^a and H^b, are *trans* to each other as depicted in V. If π-π interaction between the phenanthroline rings of the complex and the quinolyl group of cinchonine is contributing to the association (see V), cinchonine seems to associate more favorably with tris(phenanthroline)complex of Λ configuration than with that of Λ configuration. The absolute configuration of $(+)_D$-$[Ni(phen)_3]^{2+}$ was determined to be Λ by X ray



V

The dotted circle denotes interaction between the quinolyl group and the phenanthroline rings of the complex.

analysis.[13] Hence the sign of the Pfeiffer rotation in $[Ni(phen)_3]^{2+}$–cinchonine system should be minus. This is in accord with the experimental results. It is concluded that the absolute configuration of phenanthroline complexes can be deduced from the sign of Pfeiffer rotation with certain types of alkaloid. The sign of Pfeiffer rotation in $[Zn(phen)_3]^{2+}$–cinchonine system is minus. It follows from above argument that the absolute configuration of $(+)_D$-$[Zn(phen)_3]^{2+}$ is *Λ*.

The prediction of the absolute configuration of Pfeiffer active complexes has also been proposed by Kirschner and Pollock[14] using optically active dibasic acids.

The authors wish to thank Professors Kazuo Saito and Junnosuke Fujita for their helpful discussions.

Bromine Addition Reaction to Olefins with Magnesium Bromide and Aroyl Peroxides

Masao Ōkubo, Hisahiro Kusakabe, Tsunenori Hiwatashi, and Kazuo Kishida
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honshō-chō, Saga 840
(Received June 11, 1973)

When $MgBr_2$ prepared in anhydrous tetrahydrofuran was added to a mixture of olefin and benzoyl peroxide, the peroxide decomposed at a moderate rate at room temperature. Olefin dibromide and magnesium benzoate were obtained in nearly quantitative yields. The effects of *p*- and *m*-substituents of peroxide and of the structure of olefin were studied. A complex consisting of $MgBr_2$ and peroxide was formed. Abstraction of brominium cation from the complex by the olefinic double bond was proposed.

The addition of bromine to cyclohexene in an orange-colored solution of a complex prepared from PhCOOMgBr and benzoyl peroxide(BPO) in tetrahydrofuran(THF) has been reported.[1] The results and the fact that $MgBr_2$ is considered to be a component of Grignard reagents[2] prompted us to examine the reaction of BPO and $MgBr_2$ in anhydrous THF. When equimolar BPO was added to a solution of $MgBr_2$, an orange color appeared. The colored solution has the ability to add bromine to cyclohexene giving *trans*-1,2-dibromocyclohexane in a good yield. Results of studies of this reaction are given in this paper.

Results and Discussion

The same reaction was reported by Yang and Lawesson,[3] who obtained *trans*-1,2-dibromocyclohexane almost quantitatively. They suggested the reaction to be a simple addition of molecular bromine produced in the reaction of BPO and $MgBr_2$ (Reaction 1), but gave no precise mechanism. Whereas they used ethyl ether

$$(PhCOO)_2 + MgBr_2 \rightarrow (PhCOO)_2Mg + Br_2 \qquad (1)$$

as solvent, we used THF. It should be noted that ethyl ether cannot maintain the reaction components in solution and forms a heavy precipitate easily. In contrast, the reaction mixture is homogeneous in THF when the concentration is about 40 mmol/l.

When equimolar BPO was added to a clear solution of $MgBr_2$ in anhydrous THF[4] at 15 °C, the mixture turned yellow, deepening to orange in the course of 45 to 60 min. No more deepening took place after the solution has been left to stand for several hours under nitrogen atmosphere. The color is similar to that of "Complex II"[5] prepared from PhCOOMgBr and a half equimolar BPO. The coloration is not due to molecular bromine, since Br_2 attacks the THF molecule easily even at 0 °C giving hydrogen bromide. Neither molecular bromine nor hydrogen bromide was detected in the distillate of the orange colored solution. The color did not fade and the peroxide-content(determined by iodometry) did not decrease when the solution was left to stand overnight. Turbidity appeared when ethyl ether was added to the concentrated solution at 0 °C. Orange-red crystals were obtained after the mixture was left to stand in a refrigerator for about two weeks. Thus, it was confirmed that $MgBr_2$ and BPO from a complex(Reaction 2), hereafter called Complex III.[5] Reaction

$$(PhCOO)_2 + MgBr_2 \rightleftharpoons [\text{Complex III}] \qquad (2)$$

2 will be expressed as an equilibrium process.

When equimolar cyclohexene was added to the solution of Complex III, the peroxide-content decreased and became nearly 10% after about two hours(Fig. 1, case A) accompanied by fading of the color.[6] From the reaction mixture, magnesium benzoate and *trans*-1,2-dibromocyclohexane were obtained almost quantitatively. When anhydrous THF solution of $MgBr_2$ was added to the mixture of BPO and cyclohexene dissolved in THF(Fig. 1, case B),

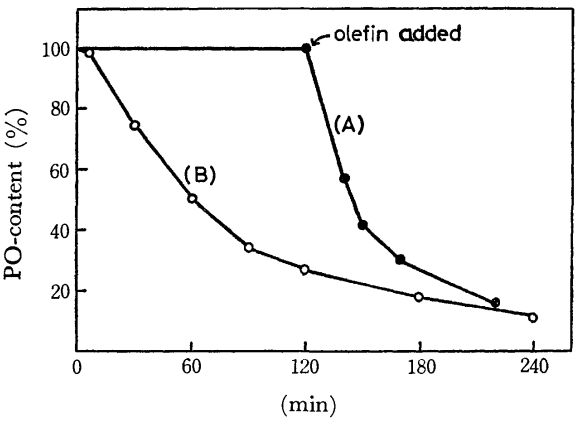

Fig. 1. Consumption of BPO-content at 20 °C.
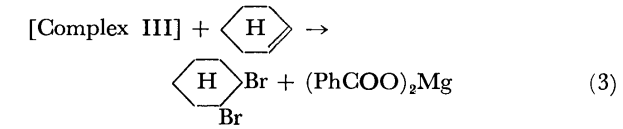
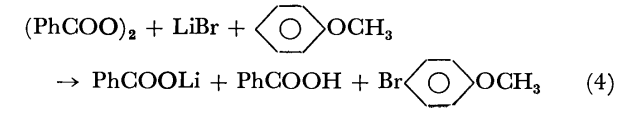
Concn: 0.0042 mol in 100 ml THF.
Curve A: After 2 hr, olefin is added to Complex III.
Curve B: $MgBr_2$ is added to the mixt. of BPO and olefin.

the peroxide-content decreased immediately. The reaction was slow and a longer time was needed for it to be completed, the products being the same as those in case A. The two curves in Fig. 1 show that Complex III liberates the first bromine atom on access of olefin molecule (Reaction 3).



(3)

Kochi and his co-workers reported the formation of *p*-bromoanisole in the reaction of lithium bromide with BPO in a mixture of acetic acid and anisole[7] (Reaction 4).



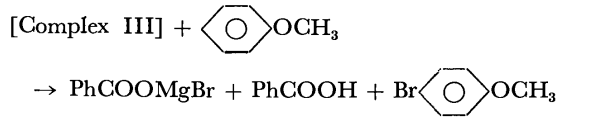
(4)

Table 1. Reaction of case B at 20 °C
Concentration: 0.0042 mol in 100 ml THF.

Time (s)	P. O.-content consumed (%)	Rate consts. calcd. on 1st-order eq.[a] (s^{-1}) $\times 10^4$	2nd-order eq. ($l \cdot mol^{-1} \cdot s^{-1}$) $\times 10^3$	3rd-order eq. ($l^2 \cdot mol^{-2} \cdot s^{-1}$) $\times 10^1$
480	3.2	0.68	1.63	0.39
1740	22.5	1.46	3.95	1.07
3420	46.4	1.82	6.00	2.04
4320	58.0	2.01	7.58	3.03
5520	66.6	1.99	8.56	4.05
7020	72.5	1.84	8.90	4.89

a) The latter four numbers were used to calculate the mean value of the apparent-first-order rate constant.

An equimolar mixture of Complex III and anisole in THF at 25 °C slowly gave *p*-bromoanisole(Reaction 5).



$$[\text{Complex III}] + \text{C}_6\text{H}_5\text{OCH}_3 \rightarrow \text{PhCOOMgBr} + \text{PhCOOH} + \text{Br-C}_6\text{H}_4\text{-OCH}_3 \quad (5)$$

This suggests that anisole as well as cyclohexene abstract brominium cation from Complex III in reactions 5 and 3, respectively.

The possibility that Complex III consists of benzoyl hypobromite and benzoyloxymagnesium bromide(Reaction 6), could be excluded since no Hunsdiecker-Prévost-type product such as 2-bromocyclohexyl benzoate[8] was detected in cases A and B.

$$(PhCOO)_2 + MgBr_2 \rightarrow [PhCOOBr][PhCOOMgBr] \quad (6)$$

Since Complex III no longer has characteristic infrared absorption bands of BPO itself,[9] it cannot be pictured as a simple mixture of $MgBr_2$ and BPO. If the structure of Complex III were to be depicted, the Mg-Br bond and O–O bond might be said to have excited characters. Bromine atom may have a positive charge as the result of coordination of electron-seeking peroxide molecules to the Mg-atom. This is justified by the formation of *p*-bromoanisole. Complex III liberates bromine when it is treated with water.[5]

Since a straight line was obtained when the olefin had not yet been added(Fig. 1, case A) and no appreciable fluctuation which we came across in the lithium bromide–BPO system[7] was not observed(Fig. 1, case B), the features of decomposition of Complex III could be followed by iodometry. Typical results of measurements in case B are listed in Table 1. The first-order rate constants show a smaller fluctuation as compared with the other two series of values. The apparent-first-order rate constants remained virtually unchanged when two molar equivalents of cyclohexene were used. $MgBr_2$ in slight excess, however, greatly accelerates the reaction as shown in Fig. 2. In case A, no satisfactory rate constant was obtained by using any of the first-, second- and third-order rate equations. This might be due to the change of degree of association(or dissociation) of Complex III(Reaction 2) caused by the change in

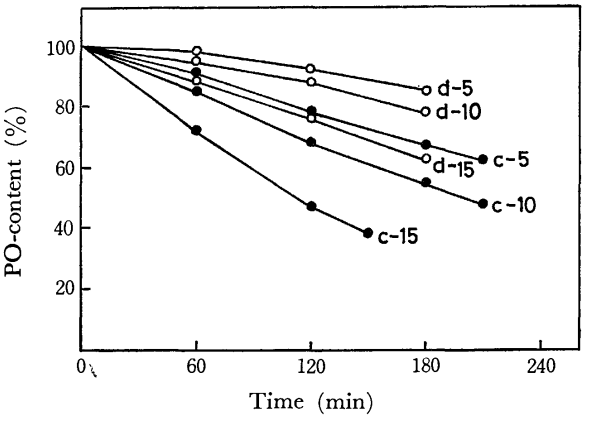


Fig. 2. Consumption of BPO-content (case B). Effect of temperature and $MgBr_2$-concentration.
i) Concn. of BPO and cyclohexene are fixed to 0.00238 mol in 45 ml THF. ii) Numbers (5, 10 and 15) denote the temperature (°C). iii) "c" and "d" denote the concn. of $MgBr_2$-soln (15 ml). c: 0.173 M, d: 0.159 M.

concentration. Addition of olefin-THF solution at the initial stage of case A alters the concentration at that time, affecting the rate of decomposition of Complex III. The overall path of reaction should thus consist mainly of i) equilibrium(2), and ii) abstraction of brominium cation from Complex III to form 2-bromocyclohexyl carbonium ion, which may combine rapidly with the bromide ion in the subsequent step.

Effects of the substituent of BPO and the structure of olefin were examined mainly for case B. *p,p'*-Dinitrobenzoyl peroxide greatly accelerates the reaction which completed within 20 min. at 20 °C (Table 2, and Fig. 3-a, b). Since the species abstracted by the π-electron system of cyclohexene should be brominium cation, the facilitation of this step by the electron-attracting substituent is reasonable.[10] We see from Fig. 3-b and 3-c that the difference between the rate of BPO and that of *m,m'*-dimethoxy derivative decreases with the lowering in temperature. Weakly electron-attracting *m*-methoxy group should be less favorable to complex-formation(Reaction 2). The tendency might become greater at a higher temperature; thus, the overall rate of *m,m'*-dimethoxy derivative becomes relatively lower(Fig. 3-b). Both equilibrium(2) and the rate of abstraction of bromi-

nium cation by the olefinic system should change with temperature and substituent. Lower temperature and an electron-donating substituent favor the association of Complex III; higher temperature and an electron-attracting substituent favor the abstraction of brominium cation. At 10 °C, *m,m'*-dinitro-derivative decomposed at a rate somewhat higher than that for *p,p'*-derivative(Fig. 3-c). In case A at 5 °C, however, the *p,p'*-derivative decomposed much faster than the *m,m'*-derivative(Fig. 3-d). Thus the *m*-nitro group should be more favorable to the association of Complex III than the *p*-nitro group; the *p*-nitro group accelerates the abstraction of brominium cation to a greater extent than the *m*-nitro group.

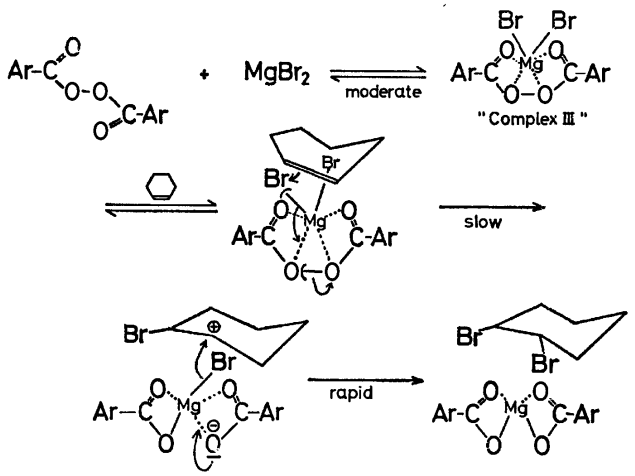
Apparent-first-order rate constants(case B) for several olefins were obtained when unsubstituted BPO was used (Table 3). The rate decreases in the following order:

cyclohexene > 1-octene > styrene > *t*-butylethylene > *cis*-stilbene > *trans*-stilbene.

The rate of *trans*-stilbene at room temperature is so low that the peroxide-content was consumed after about 30 days. The rate of *cis*-isomer was as high as twice that of *trans*-isomer. π-Electron density of the ethylene groups of stilbenes and styrene is lower than that of alkyl-substituted ethylenes owing to delocalization of electrons on the whole of molecule, and might be unfavorable to the abstraction of brominium cation. Bulkiness of the phenyl and *t*-butyl groups may also be

another retarding factor. The fact that cyclohexene reacts very fast and that *cis*-stilbene reacts faster than *trans*-isomer shows that the olefins having *cis*-type configuration favor the reaction.

The course of the reaction in the case of cyclohexene could be formulated as follows:



Experimental

Materials. A clear solution of $MgBr_2$(about 0.2 M) in anhydrous THF was prepared from Mg-turnings and ethylene dibromide.[4] Its concentration was determined by the magnesium-oxinate method.[11] When necessary benzoyl peroxide was purified by reprecipitation with methanol from its chloroform solution. *p,p'*-Difluoro-, *p,p'*-dimethoxy-, *m,m'*-dimethoxy-, *p,p'*-dinitro- and *m,m'*-dinitro-benzoyl peroxides were prepared from the corresponding acyl chlorides and peroxide.[12] *p*-Nitro-*p'*-methoxybenzoyl peroxide was prepared by the condensation of *p*-nitroperoxybenzoic acid and *p*-anisic acid with dicyclohexylcarbodiimide.[13] Cyclohexene and styrene were purified by distillation before use. *trans*- and *cis*-Stilbene were prepared from *trans*- and *cis*-α-phenylcinnamic acids, respectively.[14] *t*-Butylethylene was prepared from pinacolone by reduction and dehydration by means of the methylxanthate method.[15]

Rate Measurements. A typical procedure for case B is described in the following. Anhydrous THF(60 ml) was introduced into the N_2-purged reaction flask at 20 °C and 1.0113 g (0.0042 mol) of BPO was added. Cyclohexene (0.346 g, 0.0042 mol) dissolved in 10 ml THF was added to the solution. Twenty milliliters of $MgBr_2$ solution (0.211 M) and 10 ml THF were successively introduced into the reservoir,[16] and the apparatus was set up under a slow stream of nitrogen. The mixture in the reaction flask was vigorously stirred and the $MgBr_2$ solution was added at once by turning the reservoir upside-down. After mixing, the total volume of the reaction mixture was 100 ml. One milliliter portions of the reaction mixture were pipetted out at definite intervals, introduced into a CO_2-purged flask containing acetic acid and potassium iodide, and titrated.[17]

For case A, BPO and $MgBr_2$ were mixed in THF under N_2-atmosphere. The reaction flask was kept in a water bath controlled at a definite temperature for over 8 hr, when the solution turned orange. Cyclohexene dissolved in 10 ml THF was added at once, and the peroxide-content was followed by iodometry.

Analysis of Products. After the peroxide-content became zero, the reaction mixture was concentrated under reduced pressure to a small volume, decomposed by saturated ammonium chloride solution, extracted with ether and worked up as usual. Benzoic acid was obtained quantitatively. From the neutral part, *trans*-1,2-dibromocyclohexane was obtained in 82—90% yields. 2-Bromocyclohexyl benzoate was prepared[8] and used for comparison with the products of this reaction on tlc. The yield of dibromide was determined on vpc using hexachloroethane as an internal reference. The conformation of the dibromide was identified by comparing its retention time on vpc with that of the dibromide prepared by adding bromine to cyclohexene in CCl_4.[18]

p-Nitro-*p'*-methoxybenzoyl peroxide is known to decompose with ionic mechanism *via* carboxy-inversion.[19] However, in our reaction no *p*-methoxyphenol was detected.

Electrophilic Bromination. A solution of Complex III was prepared from 0.726 g (0.003 mol) of BPO and equimolar $MgBr_2$ solution (total volume: 60 ml). Anisole(0.324 g) dissolved in 10 ml THF was added. After the mixture was stirred at 25 °C for 6 hr, the peroxide-content fell to 69%. The yield of *p*-bromoanisole was determined to be 13% on vpc.

The authors are grateful to Professor Kazuhiro Maruyama, Kyoto University, for his stimulating discussions.

Photoreactions of *N*-Vinylcarbazole Induced by Metal Salts. VI. Cyclodimerization Catalyzed by Copper(II) Perchlorate in Aprotic Solvents

Michihiko ASAI,* Hiroshi MATSUI, and Shigeo TAZUKE**

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received June 15, 1973)

Photocyclodimerization of *N*-vinylcarbazole(VCZ) catalyzed by $Cu(ClO_4)_2 \cdot 6H_2O$(Cu(II)) in tetrahydrofuran was investigated under irradiation at 365 nm. At $[Cu(II)]_0 = 10^{-2}$ M in air, when $[VCZ]_0$ was less than 0.4 M, only 1,2-*trans*-dicarbazylcyclobutane(D) was formed, but when $[VCZ]_0$ was higher than 0.5 M, rapid cationic polymerization commenced after about 0.3 M of VCZ had been converted to D. Any consumption of Cu(II) could not be detected in the course of reaction. The change of reaction course from dimerization into polymerization in the midway of reaction was presumably brought about by the consumption of oxygen. Kinetic expression for dimerization rate(R_d) was obtained as follows:

$$R_d \propto I_0^{1.0}[VCZ]_0^{1.0}[Cu(II)]_0^0$$

The quantum yield for D production was much larger than 1, indicating production of D *via* chain mechanism.

A number of metal salts have been found to be effective catalyst for the photosensitized polymerization and cyclodimerization of *N*-vinylcarbazole (VCZ) in organic solution. Sensitizing effect of the group Ib metal salts such as gold(III), silver(I) and copper(II) salts in various aprotic solvents upon these reactions have been preliminarily reported.[1] Due to the subtle changes in the reaction modes, polymerization or cyclodimerization, from system to system and remarkable effects of atmosphere and ligand in some cases, the mechanisms of sensitization by these metal salts seem to be very intricate and to vary with cases. Breitenbach[2] has reported also the photoinduced cyclodimerization in the presence of mercury(II) cyanide, lead(II) thiocyanate or cadmium(II) nitrate in acetonitrile. Ledwith[3] and Wang[4] have investigated the thermal cyclodimerization of VCZ with iron(III) and cerium(IV) in methanolic media to propose two different chain mechanisms involving initiation with the cation radical of VCZ.

The photoreaction of organic substrate in the presence of metal salt can be classified roughly into three categories in terms of the effective light absorption species:

$$\left.\begin{array}{ll} \text{Type I;} & M \xrightarrow{h\nu} M^* \xrightarrow{L} \\ \text{Type II;} & L \xrightarrow{h\nu} L^* \xrightarrow{M} \\ \text{Type III;} & M + L \rightleftharpoons ML \xrightarrow{h\nu} \end{array}\right\} \text{reaction products}$$

where M and L denote metal salts and organic substrate, respectively. As described previously,[1] the photodimerization of VCZ catalyzed by copper(II) perchlorate belongs to the Type II analogous to the photopolymerization of VCZ with silver(I) salts.[5] Type II, the reaction of an excited organic molecule with a metal salt, is very unique and has been unequivocally confirmed in a few limited systems.[6] On the other hand, quenching of fluorescence and phosphorescence from excited molecules by metal ions has been studied with emphasis of physical viewpoint.[7] As to photoreactions catalyzed by copper(II) salts, such as cyclodehydrogenation and oxidative fission of stilbene derivatives by copper chloride,[8] methanolysis of styrene by copper(II) perchlorate[9] and chlorination of simple organic substrate by copper(II) chloride[10] examined qualitatively.

In the present article, kinetic and mechanistic studies on the photosensitized cyclodimerization catalyzed by copper(II) perchlorate were undertaken under irradiation of 365 nm light in tetrahydrofuran at 20 °C in air. While effect of solvent, ligand or anion, and atmosphere were examined, cationic polymerization was observed under specific conditions. Furthermore, interaction of the excited VCZ with copper(II) perchlorate as well as with oxygen were investigated quantitatively.

Experimental

N-Vinylcarbazole (Koch-Light Lab. Ltd.) was recrystallized twice from hot *n*-hexane and dried *in vacuo*. $Cu(ClO_4)_2 \cdot 6H_2O$ and $Cu(NO_3)_2 \cdot 3H_2O$ were used after drying *in vacuo* at room temperature. Anhydrous $CuCl_2$ was prepared by drying commercial $CuCl_2 \cdot 2H_2O$ at 110 °C *in vacuo*. $Cu(ClO_4)_2 \cdot 2H_2O$, acetylacetonatocopper(II) and $Cu(ClO_4)_2(pyridine)_4 \cdot 2H_2O$ were prepared.[11] Tetrahydrofuran(THF), ethyl methyl ketone(EMK), ethyl acetate(EA), benzonitrile (BN), acetophenone(AP), and dimethyl sulfoxide (DMSO) were purified by the conventional methods. Purification of all other materials and apparatus for photoreaction were described previously.

Monochromatic light of 365 nm was selected by filtering the emission from a 300 W high pressure Hg lamp with combination of UV-DlA and UV-35 (Toshiba Electric Co. Ltd.) The incident intensity of light was 4×10^{-8} Einstein/min. cm^2 as determined by the Hatchard-Parker actinometry[12] and controlled with wire meshes. The reaction rate was determined by dilatometry, using a cylindrical quartz cell with parallel flat windows (optical length 10 mm, diameter 44 mm) connected to a capillary with glass joint. No special care was taken to remove dissolved air and trace amount of moisture from the reaction mixture, unless otherwise stated. Pure oxygen or nitrogen was bubbled into the reaction mixtures at least ten minutes prior to reaction if required. To identify 1,2-*trans*-dicarbazylcyclobutane after the comple-

tion of reaction as confirmed by volume contraction, the reaction mixture was poured into an excess of methanol to precipitate polymer which might be produced simultaneously. After filtration, the filtrate was evaporated to dryness. The residue was confirmed as the cyclodimer from its melting point(195 °C) and its NMR spectra.[13]

The molecular weight of polymer was determined by viscosity measurement according to the equation, $[\eta]=3.35\times 10^{-4}M^{0.58}$, at 20 °C in benzene.[14]

Absorption and emission spectra were measured by Shimadzu spectrophotometer MPS-50 and Hitachi fluorescence photometer MPF-3, respectively.

Results

Exploratory experiments were carried out using various kinds of copper(II) species in THF, EMK and DMSO. As shown in Table 1, photo and thermal reactions were dramatically affected by combinations of anion, ligand and solvent. Both hexa- and dihydrate of copper perchlorate gave the same initial rate of photodimerization in THF. Anhydrous copper(II) chloride induced photosensitized cationic polymerization in THF, which was confirmed by additive effects of cationic inhibitors, to produce polyVCZ with molecular weight of about 30000. Meanwhile, acetylacetonato complex and nitrate salt were completely inert in THF. The perchlorate salt seems to be the best catalyst because of its unique reactivity for cyclodimerization indifferent of the kinds of solvent. The reaction modes and the time-conversion curves of the copper perchlorate catalyzed as well as the non-catalyzed photoreactions in a number of solvents under

various reaction conditions are depicted in Figs. 1 and 2, respectively, and summarized in Table 2. The behaviors of non-catalyzed photoreaction agreed with the results reported by Mikawa.[15] Remarkable change in the reaction mode from the non-catalyzed photosensitized radical polymerization to the catalyzed photodimerization in THF and DMSO is particularly interesting. The VCZ–$Cu(ClO_4)_2\cdot 6H_2O$–THF system was chosen for detailed investigation.

Photoreactions Induced by Copper(II) Perchlorate in THF. Under the standard conditions ($[VCZ]_0=0.25$ M, $[Cu^{II}]_0=10^{-2}$ M, 20 °C, $\lambda=365$ nm, in air), the thermal

and non-catalyzed* photoreactions along with photodimerization were negligibly slow.

Light Absorbing Species. Absorption spectra of relevant compounds under the present reaction conditions are shown in Fig. 3. Absorption bands of copper perchlorate appeared in the near ultraviolet region and near infrared region which are assigned to the charge transfer band and the d-d band, respectively. On the other hand, the absorption band of VCZ in the ultraviolet region was scarcely affected by the addition of Cu(II), except negligibly weak 1 : 1 interaction between VCZ and Cu(II). Consequently, the photoenergy at 365 nm was absorbed almost exclusively by VCZ molecule. Meanwhile, it was confirmed that the prolonged irradiation at the d-d band of Cu(II) in longer wavelength region by means of a 500 W incandescent lamp with a cut-off glass filter (λ_{max}= 550 nm) induced no photoreaction of VCZ. These facts indicate that the effective absorbing species leading to photoreactions is VCZ itself.

Effect of Additives. The photodimerization in the presence of dissolved air was not affected at all by the addition of methanol(10^{-2} M). Addition of a trace amount(10^{-2} M) of water did not affect the initial rate, whereas large amounts of water exceeding 5×10^{-2} M reduced the stationary rate(R_d) as expressed by the following relation.

$$R_d \propto 1/[H_2O]_0$$

Under standard conditions the dimerization proceeded up to the complete conversion after a short acceleration period, while the bubbling of oxygen into reaction mixture prior to irradiation retarded the rate at the early stage of reaction as shown in Fig. 4. When the atmosphere was replaced with nitrogen, remarkably different features of reaction were observed that the rate was accelerated in the midway and polymerization proceeded simultaneously with dimerization. In this case, the fraction of polymer was about 70 percent. This polymerization was of cationic nature as judged by the inhibitory effect of methanol.

$[VCZ]_0=0.25$ M, $[Cu^{II}]_0=10^{-2}$ M, 25 °C.
-○-: in air. -□-: in oxygen. -●-: in nitrogen.

Effect of Monomer Concentration. At $[Cu^{II}]_0=10^{-2}$ M in air, when $[VCZ]_0$ was less than approximately 0.4 M, cyclodimer was formed. When $[VCZ]_0$ was higher approximately 0.5 M, the authors have found an unusual phenomenon that rapid polymerization commenced after the conversion of 0.25—0.3 M of VCZ to the cyclodimer, as demonstrated in Fig. 5. This polymerization was inhibited by methanol(5×10^{-2} M) but not by DPPH (2×10^{-4} M), indicating cationic polymerization. On the other hand, when the reaction system was saturated with oxygen

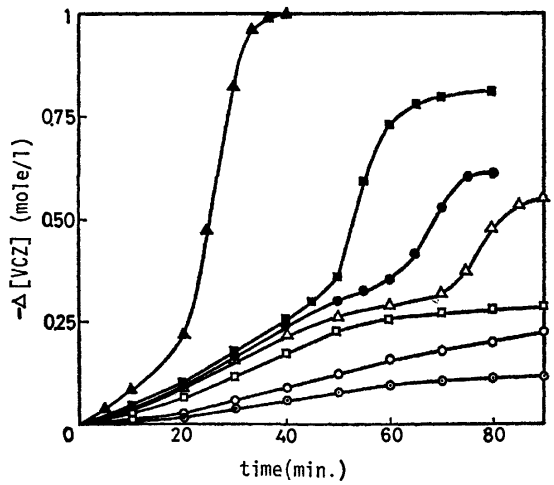

Fig. 5. Effect of the initial concentration of VCZ on the photoreaction.

$[VCZ]_0$(M): -⊙-: 0.125. -○-: 0.25. -□-: 0.40. -△-: 0.50. -●-: 0.60. -■-: 0.75. -▲-: 1.0.

* This photopolymerization was completely inhibited by 1,1-diphenyl-2-picrylhydrazyl(10^{-4} M) but not affected by methanol (10^{-2} M), indicating radical propagation. Since the rate of polymerization(R_p) *in vacuo* was less than a half of that in the presence of dissolved air, oxygen seems to participate more or less in the initiation processes. The R_p was expressed as follows:

$$R_p \propto I_0^{0.45}[VCZ]_0^{1.4}$$

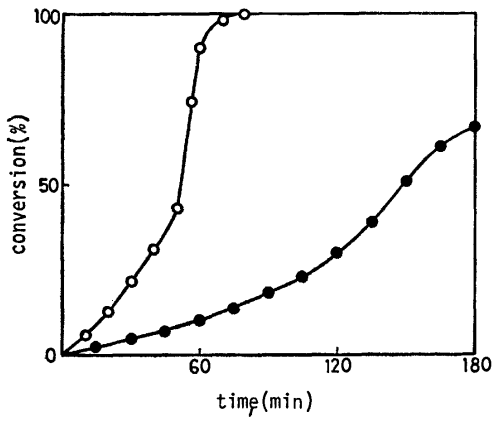

Fig. 6. Effect of an excess of oxygen.
$[VCZ]_0=0.75$ M, $[Cu^{II}]_0=10^{-2}$ M, 20 °C.
-○-: in air. -●-: in saturated oxygen.

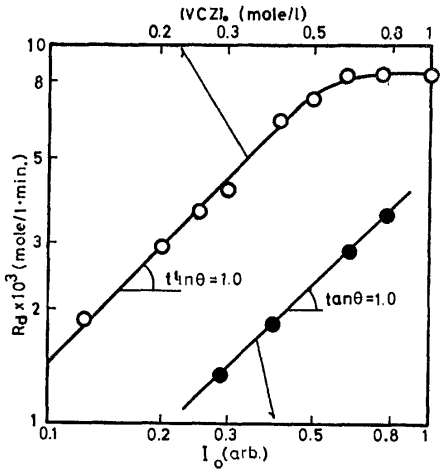

Fig. 7. Dependence of R_d on $[VCZ]_0$ and I_0.
$[Cu^{II}]_0=10^{-2}$ M, 20 °C, in air.

-●-: $[VCZ]_0=0.25$ M, I_0=variable.

before photoirradiation, the cationic polymerization in the later stage was suppressed, and the cyclodimer alone was obtained all through the reaction with a slower rate, as shown in Fig. 6. This fact suggests that oxygen plays some major roles in either the production of the cyclodimer or the inhibition of the polymer formation, and that the subsequent polymerization starts after the consumption of oxygen.

Dependence of the stationary rate (R_d) after the short acceleration period on the initial concentration of VCZ is shown in Fig. 7. Although R_d saturated at higher concentration, R_d was proportional to $[VCZ]_0$ up to 0.5 M VCZ.

Effects of Copper(II) Perchlorate Concentration. In the concentration range of 10^{-3}—10^{-1} M of copper perchlorate the initial R_d is nearly constant. The saturation of time conversion curve was observed at lower conversion with increasing $[Cu^{II}]_0$. This saturation effect seems to be attributed to the different concentration of water involved in these Cu(II) salts, since the same effect was observed when water was added into the reaction mixture. Another finding in support of this assumption is the fact that the dimerization by dihydrate copper(II) perchlorate proceeded up to nearly the complete conversion without saturation.

Changes of $[Cu^{II}]$ during the reaction were measured spectroscopically by following the d-d absorption band of Cu(II). Any consumption of Cu(II) could not be detected in the course of both dimerization ($[VCZ]_0=0.25$ M) and polymerization($[VCZ]_0=0.75$ M) subsequent to dimerization, indicating the role of Cu(II) to be purely catalytic.

Quantum Yield for Dimer Production. Linear dependence of R_d on the incident intensity of light(I_0) was depicted in Fig. 7. Upon interrupting irradiation, the dimerization stopped completely after a short after-effect, as shown in Fig. 8, indicating the production of relatively short lived species. The apparent quantum yield for dimer production including the after-effect was calculated from Fig. 8 to be about 15. This value of more than unity suggests that the cyclodimer is formed *via* some type of chain mechanism.

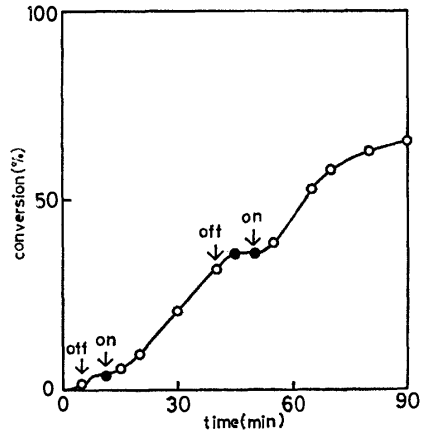

Fig. 8. On-off test.
$[VCZ]_0=0.25$ M, $[Cu^{II}]_0=10^{-2}$ M, 20 °C, in air.

Interaction of the Excited Singlet State of VCZ with Copper(II) Perchlorate or Oxygen. As shown in Table 3, under excitation at 345 nm VCZ emitted monomer and excimer fluorescence at 365—370 nm and at 460 nm, respectively. The mirror image relation of absorption and monomer emission spectra was held very well. Excimer fluorescence was observed only at high concentration of VCZ. Both fluorescences were quenched by Cu(II), where the Stern-Volmer plots fall on a straight line as typically depicted in Fig. 9. The quenching constants $K_{q,Cu}(=k_{q,Cu}\cdot\tau_0)$ for monomer and excimer emission were exactly identical as shown in the first row in Table 3. On the other hand, oxygen also quenched both emissions to nearly an equal extent(the second row). Therefore, $K_{q,Cu}$ must depend on the concentration of oxygen. Assuming the concentration of dissolved oxygen as 10^{-3} M and conformity to the Stern-Volmer equation as well, K_{q,O_2} was calculated from measurements of emission in air, nitrogen and oxygen in the presence of an appropriate concentration of Cu(II). Dependence of atmosphere on $K_{q,Cu}$ was also tabulated in Table 3 (the third row). The value of K_{q,O_2} (the forth row) thus

Discussion

Photoreactions of VCZ in the presence of copper(II) salts exhibited very intricate features depending on various factors such as anion or ligand of the salt, solvent, atmosphere, water or concentration of VCZ. The fact that copper perchlorate induces the photocyclodimerization alone indifferent of solvent under the condition of $[VCZ]_0=0.25$ M and in the presence of air is the characteristic nature of this metal salt in contrast to gold(III) complexes or silver(I) salts.[1] The authors classified[1] the photoreactions of VCZ with these metal salts into three categories in terms of the effective light absorbing species: Type I; metal salt, Type II; VCZ and Type III; VCZ/metal salt complex. The copper perchlorate-THF-365 nm system belongs to the Type II similar to the photoreaction with silver(I) salts. In the latter system, however, cyclodimerization and/or cationic polymerization took place depending upon solvents.

The sequences of the rate of photocyclodimerization in both Cu(II) catalyzed and non-catalyzed systems seem to depend upon the donor-number of solvent (DN) proposed by Gutmann,[16] which is an indication of donating power of solvent to cation, as follows:

$Cu(ClO_4)_2\cdot6H_2O$ system:

R_d; BN>EMK~AP>EA>THF>DMSO

DN; 12< <17< 20 < 30

Non-catalyzed system: R_d; BN≫EMK≧AP>EA

The parallelism between the Cu(II) catalyzed and non-catalyzed photoreactions with respect to the solvent effect on R_d suggests that the major solvent effect is not to influence the activity of Cu(II). The cyclodimerization in DMSO in the presence of Cu(II) should be noted since such reaction has not been reported in the cases of photo- or γ-ray induced reactions both in the presence and absence of organic acceptors.

Effect of atmosphere on the reaction mode is of interest. When $[VCZ]_0$ is higher than 0.5 M, the rapid cationic polymerization commences after about 0.3 M of VCZ has been converted to the cyclodimer and in the presence of an excess of oxygen this polymerization is completely suppressed and cyclodimerizaiton alone proceeds. These findings suggest that oxygen is indispensable to the formation of cylcodimer or for the inhibition of cationic polymerization, and that oxygen is consumed in the course of the cyclodimerization. This oxygen effect is also supported by the fact that cationic polymerization predominates in nitrogen atmosphere.

Kinetic relation, $R_d\propto I_0[VCZ]_0\,[Cu^{II}]_0^0$, is identical with that of the photodimerization by $Hg(CN)_2$ in acetonitrile briefly described by Breitenbach.[2] Apparent quantum yield for the production of cyclodimer is observed to be about 15, suggesting the chain mechanism as proposed by Ledwith in the photocyclodimerization sensitized by organic dyes.[3]

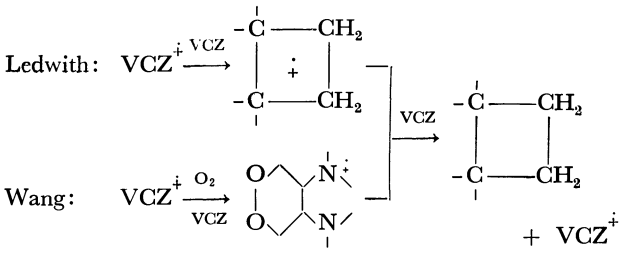
Fluorescence of VCZ was quenched by both Cu(II) and oxygen. Provided that the actions of Cu(II) and oxygen on fluorescence are mutually independent, the following equations are derived, respectively.

$$K_{q,O_2}=\frac{K^\circ_{q,O_2}}{1+K^\circ_{q,Cu}[Cu^{II}]},\quad K_{q,Cu}=\frac{K^\circ_{q,Cu}}{1+K^\circ_{p,O_2}[O_2]}$$

where, K°_{q,O_2} and $K^\circ_{q,Cu}$ denote the intrinsic quenching constants of oxygen and Cu(II) in the absence of the other, respectively. These hyperbolic relations agree with the experimental results qualitatively. Fluorescence of VCZ is supposed to be quenched dynamically by Cu(II), since interaction between VCZ and Cu(II) in the ground state is negligible. Meanwhile, dynamic quenching by oxygen may not be characterized unequivocally because of possible formation of the ground state charge-transfer complex. The equal quenching constants for monomer and excimer emissions indicate that apparent quenching of excimer emission was attributed to a result of quenching of monomer fluoresence. Quantitative studies on the quenching of or-

ganic fluorescence by metal ion have been scarcely reported.[7] On the other hand, the quenching effect of inorganic ion on phosphorescence has been investigated systematically by several authors to some extent.[7] Although in the present study no phosphorescence was observed under reaction conditions, at room temperature and in air, interactions of the excited triplet state of VCZ with Cu(II) ion seem to be also very likely, as inferred from quenching action of Cu(II) to the triplet state of aromatic molecules.[7] Quenching mechanisms may be roughly classified into three categories: i) energy-transfer ii) electron-transfer iii) enhancement of intersystem crossing S*→T*. Similar quenching action of oxygen to the excited aromatic molecule has been reported in details.[17]

As to the mechanism of cyclodimerization of VCZ, the following different two types of mechanisms have been proposed by Ledwith[3] and by Wang,[4] respectively.

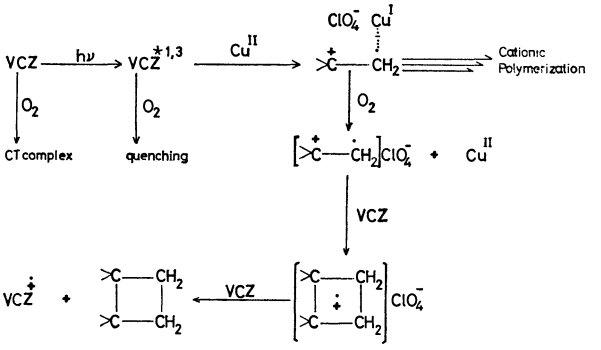


Both mechanisms are common in the sense of assuming chain reaction *via* radical-cation intermediate ($M^{\dot{+}}$). The former assumed the cyclodimer radical cation intermediate ($D^{\dot{+}}$) whereas the latter considered the six-membered ring peroxide intermediate. However, the problem of oxygen consumption has never been investigated by them. Recently, the direct evidence for the following equilibrium

$$M^{\dot{+}} + VCZ \rightleftharpoons D^{\dot{+}}$$

was obtained by means of the pulse radiolysis technique by Imamura.[18] They have proposed that $D^{\dot{+}}$ is a common precursor for both cyclodimerization and cationic polymerization of VCZ.

The following reaction scheme is proposed. Either excited singlet or triplet state ($VCZ^{*1,3}$) would collide with Cu(II), while one electron transfer from $VCZ^{*1,3}$ to Cu(II) produces $VCZ^{\dot{+}}$ and Cu^{I}. Simultaneously, Cu^{I} would interact with radical part of the $VCZ^{\dot{+}}$ in either the formation of organometallic bond or radical complex[19] to stabilize the free spin and consequently, cationic polymerization is initiated from the carbonium ion. The role of oxygen is to oxidize Cu^{I} to Cu^{II} accompanied by the production of radical-anion of oxygen ($O_2^{\dot{-}}$) and the free $VCZ^{\dot{+}}$ which reacts with VCZ to produce the cyclodimer cation-radical (D^{+}). Subsequent processes would be almost similar to the Ledwith's chain mechanism with the exception of the role of $O_2^{\dot{-}}$ and termination reaction. In this mechanism, propagation proceeds *via* $D^{\dot{+}}$ with a counter-ion $O_2^{\dot{-}}$ and termination takes place by electron-transfer between them resulting none of consumption of molecular oxygen. In the present study, however, it is suggested that oxygen is consumed through the main route of the reaction but not as side reactions, since about 0.3 M VCZ was always converted into the cyclodimer indifferent of the initial concentration of VCZ if it is over 0.4 M, as shown in Fig. 5, under the standard conditions. Therefore, $O_2^{\dot{-}}$ might be consumed by some types of bimolecular reaction as reported in the pulse radiolysis studies[20] or the cerium(IV) salt catalyzed reaction of hydroperoxide.[21]



Scheme

Termination is assumed as monomer termination, for example, the Friedel-Crafts type reaction of carbonium ion with the carbazyl ring as proposed previously.[22] By applying the assumption of stationary concentration $M^{\dot{+}}$, $D^{\dot{+}}$ and $\overset{+}{C}—\dot{C}\cdots\cdots Cu^{I}$, the following rate expression is derived.

$$R_d \propto I_{abs}^{M}[Cu^{II}]_0^0 = I_0\{1-\exp(-\varepsilon_M[VCZ]_0)\}\ [Cu^{II}]_0^0$$

This kinetic relation explains the experimental results very well. Another role of oxygen in this mechanism is the interaction with either ground state or excited state of VCZ to quench the emission of VCZ, which may result the retardation of the rate in the presence of an excess of oxygen in the reaction system. Further detailed investigations on the vacuum system and the direct measurement of oxygen consumption as well as the effects of water would be future problems.

The authors are indebted to professors Seizo Okamura and Toshinobu Higashimura for their encouragement and helpful discussion and express their thanks to Mr. I. Umehara for his help in measuring molecular weight of polymer.

A Study of the Interaction of Diethylcadmium with Lewis Bases as Solvents

Osami NAKASUGI, Michihiro ISHIMORI, and Teiji TSURUTA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 21, 1973)

The infrared spectra of diethylcadmium($CdEt_2$) in a variety of different solvents were measured. The affinity of $CdEt_2$ toward oxygen and sulfur bases was studied by infrared frequency shifts of $CdEt_2$. Linear relationships were observed for the plots of the two frequency shifts $\Delta\nu_a$(C–Cd–C) of $CdEt_2$ *vs.* $\Delta\nu_a$(C–Zn–C) of $ZnEt_2$ and $\Delta\nu_a$(C–Cd–C) *vs.* $\Delta\nu$(O–D) of CH_3OD. The deviation of the plots for the systems of $CdEt_2$ with cyclic sulfides from the linear behavior was interpreted in terms of dative back-bonding from $CdEt_2$ to sulfides. The enhanced reactivity of the Cd–S compound toward propylene oxide compared to that of the Cd–O compound was considered to result from a harder acid character of the Cd atom in the Cd–S compound caused by its back-bonding nature.

Several studies of organozinc compounds as catalysts for propylene oxide polymerization have been reported.[1-3] The polymerization proceeds by a coordinate anionic mechanism, in which the coordination of the monomer molecule to the zinc atom is considered to be important in the activation of the monomer and of the catalyst, and also for the high stereoregulation observed in this polymerization.

The binary system of diethylzinc with water[2,4] or alcohol[1,5] has an excellent activity for propylene oxide polymerization. In contrast, the corresponding binary system of diethylcadmium with water or alcohol has little or no activity for the ring-opening reaction of propylene oxide.[6] It was recently found, however, that systems of $CdEt_2$ with thiocarboxylic acid[6] and of $CdEt_2$ with mercaptan[7] have favorable catalyst activities for the ring-opening reactions of propylene oxide; especially, $CdEt_2$–RCOSH systems gave high-molecular-weight polymers in satisfactory yield. A marked difference in catalyst activity between Cd-S and Cd-O compounds has been noted.

In order to elucidate the factors influencing the catalytic activities of Group IIb organometallic compounds, the mode of the interaction of $CdEt_2$ with an oxygen base and a sulfur base was studied in terms of the magnitude of the infrared frequency shifts of $CdEt_2$ and was compared with those of $ZnEt_2$ and methanol-*d*. It was previously reported that cadmium metal ions are classified into "soft"[8] or "class b"[9] acids, whereas zinc ions are "borderline" acids. The bonding natures of Group IIb organometallic compounds with oxygen (hard) and sulfur (soft) bases are of considerable interest.

Results and Discussion

Infrared Spectrum of Diethylcadmium. The infrared spectrum of $CdEt_2$ in the region of 4000 to 200 cm^{-1} was measured. The spectrum in the range of 4000 to 650 cm^{-1} is approximately identical to the data reported by Kaesz and Stone.[10] However, the bands[10] at 1186 (assigned to the CH_2 rocking vibration), 670, and 663 cm^{-1} ($C–CH_3$ rocking) were not observed in our spectrum. These bands may be due to the contamination of diethylmercury (*cf.* the spectrum in Ref. 10), which could itself be formed by the reaction of $CdEt_2$ with mercury metal.[11]

Three bands for $CdEt_2$ at 614, 494, and 441 cm^{-1} were observed in the region of 700 to 200 cm^{-1}. To obtain a reasonable assignment for the infrared frequencies, it is necessary to consider its plausible symmetry form. It was previously reported that methyl derivatives of Group IIb metals, $Cd(CH_3)_2$, $Zn(CH_3)_2$, and $Hg(CH_3)_2$, have linear C–M–C chains (M=Cd, Zn and Hg).[12] We interpreted the bands of $CdEt_2$ on the basis of the reasonable assumption that the C–Cd–C skeleton is linear in a similar way to $ZnEt_2$.[1] From the general similarity of the spectra between $CdEt_2$ and $ZnEt_2$ shown in Table 1, the bands at 614, 494, and 441 cm^{-1} were assigned to the CH_2 rocking $\gamma_r(CH_2–(Cd))$, C–Cd–C antisymmetric ν_a(C–Cd–C), and C–Cd–C symmetric ν_s(C–Cd–C) vibrations, respectively. Although the C–Cd–C skeleton is considered to be linear, a very weak band of ν_s(C–Cd–C) was observed similarly to the ν_s(C–Zn–C) of $ZnEt_2$;[3] this indicates some deviation of the above C–Cd–C symmetric vibration from the ideal one, probably due to the interaction of $CdEt_2$ with another $CdEt_2$ or solvent molecule and/or the free internal rotation of the ethyl groups of the $CdEt_2$ molecule itself. The deformation frequency of the C–Cd–C chain is expected to lie beyond the range of our measurement.

Table 1. INFRARED FREQUENCIES OF DIETHYLCADMIUM IN KBr REGION[a]

$CdEt_2$	Ref. $ZnEt_2$[3]	Assignment
614(s)	617(s)	$\gamma_r(CH_2–(M))$
494(s)	561(s)	ν_a(C–M–C)
441(w)	479(w)	ν_s(C–M–C)

a) Measured without solvent. cm^{-1}. (s): strong; (w): weak

The reliability of the above assignment for $CdEt_2$ was roughly checked for the spectra of reaction products between $CdEt_2$ and CH_3OH. The frequencies of $EtCdOCH_3$ and $Cd(OCH_3)_2$ in the region of 700 to 200 cm^{-1} are shown in Table 2. Tentative assignments for the frequencies of $EtCdOCH_3$ and $Cd(OCH_3)_2$ were made on the assumption of bending structures of the C–Cd–O and O–Cd–O chains, with reference to the corresponding zinc systems.[1,3] The bands of $CdEt_2$ at 494 and 441 cm^{-1} ascribed respectively to the ν_a(C–Cd–C) and ν_s(C–Cd–C) vibration disappeared completely in the spectra of $EtCdOCH_3$ and $Cd(OCH_3)_2$. The CH_2 rocking vibration of $EtCdOCH_3$ was observed at 608 cm^{-1}, a frequency somewhat lower than that of $CdEt_2$; no sign of the corresponding band was observed in the spectrum of

a) An instrument of EPI-G3 was used. See "Experimental" section. (—): not observed due to the bands of solvents. b) ν_a(C-Zn-C) of $ZnEt_2$[3] and ν(O-D) of CH_3OD[15] for the solvents (No. 1—9) were previously reported. Differences between the values in this paper and those in the previous ones were ± 1 cm^{-1}.

$Cd(OCH_3)_2$. The two strong bands at 461 and 345 cm^{-1} in the spectrum of $EtCdOCH_3$ were assigned to the pseudoantisymmetric and pseudosymmetric ν(C-Cd-O) vibrations, respectively. The bands at 550(m) and 245(s) cm^{-1} in $Cd(OCH_3)_2$ could be assigned to the skeletal vibrations of the O-Cd-O chain, ν(O-Cd-O), from the spectral similarity between $Cd(OCH_3)_2$ and $Zn(OCH_3)_2$.[1]

In the light of these spectral changes, the above-mentioned assignments for the frequencies of $CdEt_2$ are considered to be reasonable.

Interaction between $CdEt_2$ and Lewis Bases. The infrared spectra of $CdEt_2$ in a variety of different solvents were measured in the KBr region. The frequencies of $CdEt_2$, $\gamma_r(CH_2)$, ν_a(C-Cd-C), and ν_s(C-Cd-C) in a series of Lewis base solvents are summarized in Table 3, together with three frequency shifts, $\Delta\nu_a$(C-Cd-C) of $CdEt_2$, $\Delta\nu_a$(C-Zn-C) of $ZnEt_2$, and ν(O-D) of CH_3OD. The frequency shifts of $CdEt_2$ and $ZnEt_2$ were calculated by reference to each frequency in *n*-heptane solvents. The shifts of methanol-d were calculated on the basis of the value in carbon tetrachloride.

Since the frequency shifts in donor solvents are due to the formation of donor-acceptor complexes between Lewis acids and bases, the magnitudes of the frequency shifts are considered to reflect the strength of the bondings of these complexes. For instance, some enthalpy data for hydrogen bondings have been reported to generate linear relationships with the infrared OH frequency shifts.[13]

The $\Delta\nu_a$(C-Cd-C) shifts of $CdEt_2$ are plotted against the corresponding shifts, $\Delta\nu_a$(C-Zn-C), of $ZnEt_2$, in Fig. 1. The $\Delta\nu_a$(C-Zn-C) *vs.* $\Delta\nu_a$(C-Cd-C) plots lie on a straight line for most of the Lewis base solvents examined.

In tetrahydrofuran solution, the ν_a(C-Zn-C) of $ZnEt_2$ showed a doublet band at 543 and 532 cm^{-1}; it was assigned to the vibrations of the $ZnEt_2$·THF and $ZnEt_2$·2THF complexes, respectively.[3] On the other hand, the spectrum of $CdEt_2$ in the same solvent showed a singlet band of ν_a(C-Cd-C). The plot for $CdEt_2$ in tetrahydrofuran (No. 9) against the one-to-one complex of $ZnEt_2$·THF lies on the straight line of $\Delta\nu_a$-(C-Zn-C) *vs.* $\Delta\nu_a$(C-Cd-C) in Fig. 1, indicating the presence of $CdEt_2$·THF as the sole complex in the tetrahydrofuran solution of $CdEt_2$. The difference in affinity with tetrahydrofuran between $CdEt_2$ and $ZnEt_2$ indicates the difference between their Lewis acidities toward ether-oxygen. The weaker Lewis acidity of $CdEt_2$ than that of $ZnEt_2$ is also suggested by the slope of the plots in Fig. 1, which is much smaller than unity. It was previously reported by Bellamy, Hallam and Williams (BHW)[14] that a linear relationship held between the relative frequency shifts of the common characteristic bands of two different solutes in a variety of different solvents; the $\Delta\nu/\nu$ (O-D) of CH_3OD, for example, has a linear relationship with the $\Delta\nu/\nu$ (N-H) of $C_6H_5NH_2$ or the $\Delta\nu/\nu$ (S-H) of H_2S. It has been suggested that the slopes of the plots for solutes against a standard acid are a measure of their Lewis acidities. The BHW plots between $\Delta\nu/\nu$(C-Cd-C) and $\Delta\nu/\nu$(C-Zn-C) gave a linear relationship, the slope of

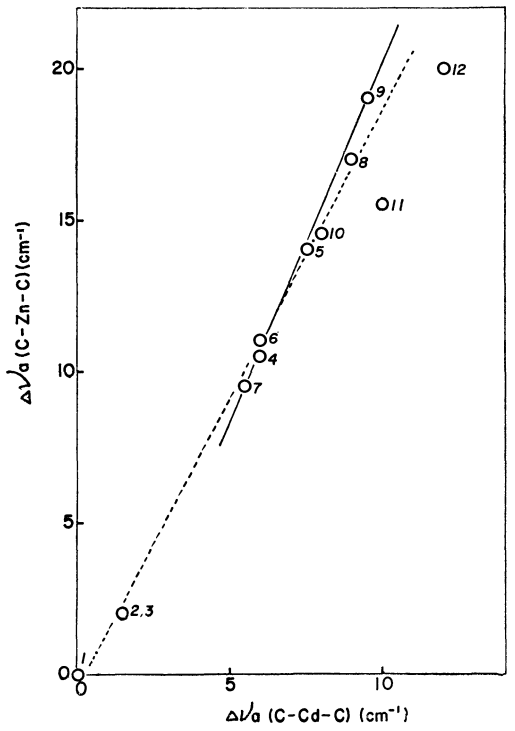

Fig. 1. Frequency shifts of $\Delta\nu_a$(C-Zn-C) of $ZnEt_2$ *vs.* frequency shifts of $\Delta\nu_a$(C-Cd-C) for a series of Lewis base solvents.
1: *n*-heptane, 2: benzene, 3: toluene, 4: diethyl ether, 5: propylene oxide, 6: styrene oxide, 7: epichlorohydrin, 8: dioxane, 9: tetrahydrofuran, 10: diethyl sulfide, 11: propylene sulfide, 12: tetrahydrothiophene.

Table 4. Frequency shifts of ν(C-O) of dioxane

Organometal. compd.	ν(C-O)(cm^{-1})	$\Delta\nu$(cm^{-1})
None	873	0
$CdEt_2$	832	41
$ZnEt_2$	830	43
$InEt_3$	831	42
$AlEt_3$	823	50

which again suggested a weaker acidity for $CdEt_2$. Then the relative Lewis acidity of $CdEt_2$ toward ether-oxygen was precisely examined by measuring the magnitude of the infrared band shift of ν(C-O) of dioxane[2] at 873 cm^{-1} due to the coordination of oxygen to metal. The results are shown in Table 4, toegther with those for $AlEt_3$ and $InEt_3$ as references. The Lewis acidity toward ether-oxygen increases in the order: $CdEt_2 < InEt_3 < ZnEt_2 < AlEt_3$.

The most remarkable point about the $\Delta\nu_a$(C-Zn-C) *vs.* $\Delta\nu_a$(C-Cd-C) relationship in Fig. 1 is the anomaly of the plots for propylene sulfide and tetrahydrothiophene (No. 11 and 12) from the linear behavior. Namely, the relative affinity of $CdEt_2$ with the sulfur base compared with that with oxygen bases is different from that of $ZnEt_2$. The greater affinity of $CdEt_2$ toward soft bases of sulfide than that of $ZnEt_2$ is coincident with the "softer"[8] nature of the cadmium ion.

The rocking vibration of the CH_2 group of $CdEt_2$ in π-bases of benzene and toluene (No. 2 and 3) was observed at higher frequencies than that for *n*-heptane, similarly to the case of $ZnEt_2$.[3] Another type of interaction, *i. e.*, that of the π-complex of $CdEt_2$ with benzene rings, is suggested by the deviation of the plots for benzene, toluene, and styrene oxide (No. 6) from the linear relationship of $\Delta\gamma_r CH_2$ (calculated from the value in *n*-heptane) *vs.* $\Delta\nu_a$(C-Cd-C), as is shown in Fig. 2.

In order to examine in detail the above difference

Diethyl ether	6.0	12	10.5	19	96

a) The frequencies ν of $\Delta\nu/\nu$ for $CdEt_2$ and $ZnEt_2$ are each value in *n*-heptane solvents.

between $CdEt_2$ and $ZnEt_2$, the frequency shifts of $CdEt_2$ and $ZnEt_2$ for a series of Lewis base solvents are plotted against the $\Delta\nu$(O–D) of methanol-*d* in Fig. 3. The steric requirement of a hard acid of CH_3CD is small, and its frequency shift, $\Delta\nu$(O–D), is known as a scale of the basicity in the usual sense.[15]

The plots of $\Delta\nu_a$(C–Cd–C) *vs.* $\Delta\nu$(O–D) in Fig. 3(a) indicate again a special interaction of $CdEt_2$ with such cyclic sulfides as propylene sulfide and tetrahydrothiophene. In contrast, such a special interaction is considerably weak in the systems of $ZnEt_2$ with cyclic sulfur bases, as is shown by the $\Delta\nu_a$(C–Zn–C) *vs.* $\Delta\nu$(O–D) plots in Fig. 3(b). This phenomenon is more clearly shown by the relative frequency shifts of $CdEt_2$, $ZnEt_2$, and CH_3OD with cyclic sulfides and ethers, as are listed in Table 5. The shifts of $CdEt_2$ with cyclic sulfides are much greater than those with the corresponding ethers. Namely, the "soft" characters of the above Lewis acids are in this order: $CdEt_2 > ZnEt_2 \gtrsim CH_3OD$.

However, the plot for $CdEt_2$ with diethyl sulfide (No. 10) falls onto a straight line in Fig. 3. The apparent lack of any special interaction for this system is considered to be caused by the steric hindrance between ethyl groups of $CdEt_2$ and those of diethylsulfide. The marked deviation of the plots for diethyl ether with $CdEt_2$ and $ZnEt_2$ from the linear behavior in the direction of the methanol-*d* side (No. 4 in Fig. 3) can also be explained in terms of the above steric hindrance.

The special interaction of $CdEt_2$ with sulfide can be interpreted in terms of dative back bonding[9,16] from the occupied 4d orbital of the cadmium atom of $CdEt_2$ to the 3d vacant orbital of the sulfur atom of sulfide.

It was described in the "Introduction" section that Cd–S compounds are much more reactive toward propylene oxide than the Cd–O compounds. This fact can be interpreted as follows; Cd atoms in Cd–S compounds are "harder" than those of Cd–O compounds because of their back-bonding nature which increases the positive charge of Cd atoms by a process of electron transfer from Cd to S; accordingly, they are much more reactive toward a hard oxygen base of propylene oxide.

Experimental

All the experiments concerned with organometallic compounds were carried out under purified nitrogen atmosphere.

Reagents. Diethylcadmium[17] and triethylindium[18] were prepared by the methods which involve the reactions of metal halides with Grignard reagents. Organometallic compounds ($CdEt_2$, $ZnEt_2$, $AlEt_3$ and $InEt_3$) were purified by fractional distillation under reduced pressure. Methanol-*d* was used after distillation.

Propylene sulfide was prepared by the reaction between propylene oxide and potassium thiocyanate.[19] Solvents (hydrocarbons, ethers, and sulfides) were purified by the standard methods[20] and were fractionally distilled.

Infrared Measurements. A Hitachi EPI-G3 and a JASCO DS-402G grating infrared spectrometers were used to collect the infrared data. The spectrum of diethylcadmium was measured as a liquid film. The spectra of diethylcadmium, diethylzinc, and methanol-*d* in solvents were measured using liquid cells with KBr windows at the concentration of 1.0 mol/l. Ethylcadmium methoxide and cadmium dimethoxide were measured as mulls in dry liquid paraffin. Expanded frequency scales were used to obtain accurate values of the shifts, $\Delta\nu$. The frequencies in the KBr region were corrected by reference to the band of CO_2 at 667 cm^{-1}. The data in Tables 1 and 2 were recorded with a DS-402G instrument, while the data in Tables 3, 4 and 5 were recorded with an EPI-G3 instrument. A slight difference in frequency for any sample, but especially for γ_r (CH_2), was observed when it was measured with the above two instruments, however, the magnitude of the frequency shifts ($\Delta\gamma_r$) was approximately the same (± 1 cm^{-1}).

Products Obtained by the Reaction of Trichlorotrimethylbenzenes with Fuming Nitric Acid. Side-chain Nitrooxylation *versus* Oxidation to Unsaturated Cyclic Ketones[1)]

Hitomi SUZUKI, Shigeru MARUYAMA, and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

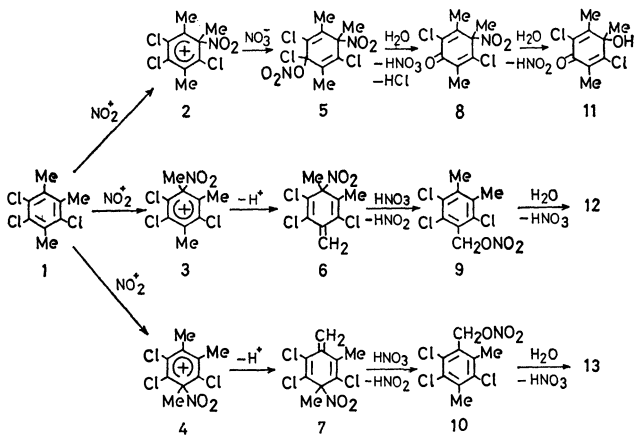
(Received August 23, 1973)

The reaction of trichlorotrimethylbenzenes with fuming nitric acid has been investigated. Trichloropseudocumene underwent both side-chain nitrooxylation and nuclear oxidation to give 2,5,6-trichloro-3,4-dimethylbenzyl nitrate, 3,5,6-trichloro-2,4-dimethylbenzyl nitrate, and 3,6-dichloro-4-nitro-2,4,5-trimethylcyclohexa-2,5-dienone. Trichloromesitylene yielded a mixture of several carbonyl compounds, from which 3,5-dichloro-4-hydroxy-2,4,6-trimethylcyclohexa-2,5-dienone and two nitro-ketones, tentatively formulated as 2,4,6-trichloro-5-hydroxy-6-nitro-2,3,5-trimethylcyclohex-3-enone and 3,5-dichloro-2-hydroxy-6,6-dinitro-2,4,5-trimethylcyclohex-3-enone, were obtained as crystalline products by chromatography and fractional extraction. Trichlorohemimellitene behaved similarly towards the nitrating agent to give 2,6-dichloro-4-hydroxy-3,4,5-trimethylcyclohexa-2,5-dienone as the major product. The competitive modes of side-chain nitrooxylation and formation of cyclic ketones have been described.

In recent years attention has been paid to several new aspects of aromatic nitration, including various substitutions on alkyl side-chain of polyalkylbenzenes,[2)] acyloxylation,[3)] nitrative coupling,[4)] and oxidation to cyclic ketones.[5)] Although these reactions have so far been regarded as discrete and anomalous, they could be classified as branched-off processes of ordinary nitration. Nitronium ion attacks a polyalkylbenzene to form a nitrobenzenium ion, which could undergo four different types of reactions; loss of proton or some cationic species from the ring to give a nitrobenzene derivative (path *a*), proton release from the alkyl side-chain to yield a nitromethylenecyclohexadiene which could be transformed into benzylic compound (path *b*), capture of nucleophile to give an addition product which will collapse to form unsaturated cyclic ketone or acyloxylated product (path *c*), and attack on another aromatic ring to give a coupling product such as nitrobiaryl (path *d*). When the normal course *a* is suppressed, an unusual path *b*, *c*, or *d* will emerge. With highly alkylated benzene derivatives, the major nitrative processes are the side-chain nitrooxylation (path *b*) and the formation of unsaturated cyclic ketones (path *c*), the competitive modes of which are best illustrated by the behaviors of three isomeric trichlorotrimethylbenzenes towards fuming nitric acid.

Trichloropseudocumene (1): A solution of **1** and excess of fuming nitric acid (d=1.5) in dichloromethane was left standing at room temperature overnight. Quenching with water, followed by removal of the solvent *in vacuo* gave a syrupy substance, which was passed over alumina to give two trichlorodimethylbenzyl alcohols, mp 197—198 °C and 204—206 °C, and a carbonyl compound, mp 146—147 °C. Benzyl alcohols were identified as 2,5,6-trichloro-3,4-dimethylbenzyl alcohol (**12**) and 3,5,6-trichloro-2,4-dimethylbenzyl alcohol (**13**), respectively, by a comparison of their melting points, infrared spectra and ^{1}H NMR spectra with those of the authentic specimens prepared from xylidines according to the sequences shown in Scheme 4. There was no indication of isomeric 3,4,6-trichloro-2,5-dimethylbenzyl alcohol (**14**) in the product.

A carbonyl compound with the molecular formula



Scheme 1

$C_9H_{10}O_2Cl_2$ showed mass peaks at *m/e* 220 (M^+), 205 (M^+-CH_3), and 185 (M^+-Cl). Its infrared spectrum showed carbonyl absorption at 1666 cm^{-1}, carbon-carbon double bond absorption at 1621 cm^{-1}, and hydroxyl absorption at 3240—3400 cm^{-1}, suggesting a cross-conjugated hydroxy-ketone. Its ultraviolet spectrum exhibited absorption maxima at 246—247 (log ε=4.08) and 286—287 nm (log ε=3.34) characteristic of a 2,5-cyclohexadienone structure.[6)] Proton NMR spectrum showed three peaks due to methyls at 8.40, 7.96, and 7.73 τ, and a broad peak due to hydroxyl at *ca.* 7.3 τ. The dienone was thus presumed to be either 3,6-dichloro-4-hydroxy-2,4,5-trimethylcyclohexa-2,5-dienone (**11**) or 5,6-dichloro-4-hydroxy-2,3,4-trimethylcyclohexa-2,5-dienone, the former being favored upon an examination of the chemical shifts given in Table 1. Since the crude product mixture prior to chromatographic treatment showed intense infrared bands due to nitro and nitrooxy groups, products **11**, **12** and **13** no doubt were formed by the hydrolysis of the nitro-ketone **8** and benzyl nitrates **9** and **10**, respectively, during the elution.

Nitronium ion attacks **1** to form a mixture of benzenium ions, in which **2**—**4** would be important, since the electron-donating methyl group is bonded direct to the reaction site (Scheme 1). Proton release form

a) In carbon tetrachloride solution. b) With a KBr disc.

the most activated methyl groups of **3** and **4** would lead to the formation of nitromethylenecyclohexadienes **6** and **7**, which will pass over a benzylic intermediate—nitrite ion pair to give the corresponding benzyl nitrates **9** and **10**. Capture of the nitrate ion by **2** will give an unstable chloro-nitrate **5**, from which nitryl chloride is eliminated to yield ketone **8**. No change in the pseudocumene skeleton was observed in the products.

*Trichloromesitylene (**15**)*: A similar treatment of **15** with fuming nitric acid gave a mixture of several carbonyl compounds as a yellow pasty solid, which on chromatography over alumina gave a new carbonyl compound, mp 96—98 °C, from ether eluates. It had the molecular formula $C_9H_{10}O_2Cl_2$ and showed mass peaks at *m/e* 220 (M^+), 205 (M^+–CH_3), and 185 (M^+–Cl). Proton NMR spectrum showed peaks at 8.31, 7.99, and *ca.* 7.3 τ with an intensity ratio of 6 : 3 : 1. The infrared and ultraviolet data given in Table 1 are consistent with a cyclohexa-2,5-dienone structure. A lower shift of C=O frequency indicated the absence of chlorine atoms on both sides of the carbonyl group. These spectral evidences readily led to the formulation of 3,5-dichloro-4-hydroxy-2,4,6-trimethylcyclohexa-2,5-dienone (**19**) for the carbonyl compound.

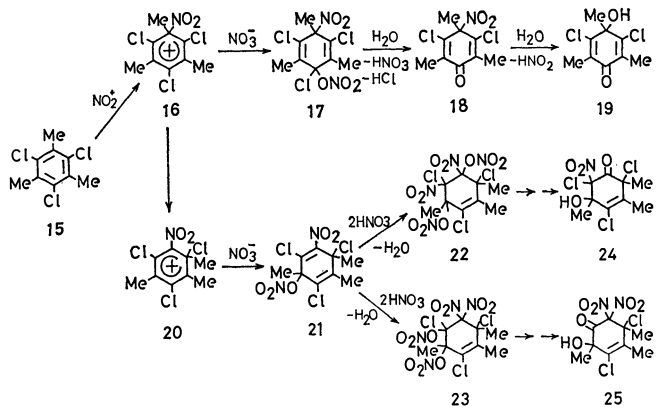
When the product was subjected to fractional extractions with a mixture of light petroleum and dichloromethane, another ketone was obtained with the composition $C_9H_{10}NO_4Cl_3$, mp 153—154 °C with decomposition. Its mass spectrum showed fragment ion peaks derived from non-detectable molecular ion at *m/e* 220 (M^+–NO_2–Cl), 185 (M^+–NO_2–2Cl), 177 (M^+–NO_2–Cl–CO–CH_3), and 142 (M^+–NO_2–2Cl–CO–CH_3). The lower mass spectrum consisted of the prominent peak clusters centered at *m/e* 107 ($C_7H_6OH^+$), 91 ($C_7H_7^+$), and 77 ($C_6H_5^+$) in accord with a structure related to the benzenoid compound. Its ultraviolet spectrum showed no maximum above 220 nm, suggesting a cyclohex-3-enone structure. Proton NMR spectrum contained three methyl singlets at 8.21, 7.76, and 7.73 τ and one hydroxyl peak at *ca.* 5.5 τ (broad, exchangeable with D_2O). Its infrared spectrum showed absorption due to an aliphatic nitro group at 1572, 1560, 1359, and 1342 cm^{-1}; a carbonyl group at 1715 cm^{-1}; a carbon-carbon double bond at 1650 cm^{-1}; and a hydroxy group at 3440 cm^{-1}. The asymmetric vibration bands of nitro group are shifted towards a high-frequency region, while the symmetric frequency is lowered. This may reflect the presence of a geminal chloro-nitro grouping,[7] which can be attached to C-2, C-5, or C-6 of the cyclohex-3-enone skeleton. Chlorine atoms do not undergo intramolecular migration under the nitrating conditions. The nitro group on the activated allylic carbon atom usually undergoes a facile solvolytic replacement during aqueous work-up. This makes it possible for three chlorine atoms to be placed on C-2, C-4, and C-6, respectively, and favors the chloro-nitro grouping to be placed on the less

activated C–6. Thus the hydroxy group must be located on C–5, and three methyl groups on the remaining C–2, C–3, and C–5. The product may be represented by the formula 2,4,6-trichloro-5-hydroxy-6-nitro-2,3,5-trimethylcyclohex-3-enone (**24**).

When the reaction mixture was flash-evaporated *in vacuo* and the resulting pasty substance was immediately chromatographed over silica gel, a third carbonyl compound melting at 131—135 °C under the liberation of a brown fume was eluted from benzene. It had the formula $C_9H_{10}N_2O_6Cl_2$ and showed mass peaks at *m/e* 249 (M^+–NO_2–OH), 220 (M^+–$2NO_2$), 185 (M^+–$2NO_2$–Cl), 177 (M^+–$2NO_2$–CO–CH_3), and 142 (M^+–$2NO_2$–Cl–CO–CH_3). Prominent peak clusters centered at *m/e* 107, 91, and 77 are typical of a structure closely related to the benzenoid compound. The absence of ultraviolet maximum above 220 nm suggests a cyclohex-3-enone structure. Its proton NMR spectrum displayed three methyl peaks at 8.39, 7.88, and 7.76 τ and one hydroxyl absorption at *ca.* 7.7 τ (broad, exchangeable with D_2O). Its infrared spectrum indicates the presence of geminal nitro groups (1582, 1572, 1333, and 850 cm^{-1}), a carbonyl group (1750 cm^{-1}), a carbon-carbon double bond (1628 cm^{-1}), and a hydroxy group (3495 cm^{-1}). It is unlikely that chlorine atoms underwent the intramolecular migration or replacement by nitro group during the course of reaction.[8] Two chlorine atoms could reasonably be assigned to C–3 and C–5 of the cyclohex-3-enone. The unusually higher shift of the C=O stretching vibration at 1750 cm^{-1} is attributed to the presence of a *gem*-dinitro grouping adjacent to the carbonyl group. We lean toward the location of this grouping at the non-allylic C–6 position because of its stability toward solvolytic replacement. Placing the hydroxy group on C-2 and three methyl groups on C-2, C-4, and C-5, respectively, we can formulate the product as 3,5-dichloro-2-hydroxy-6,6-dinitro-2,4,5-trimethylcyclohex-3-enone (**25**).

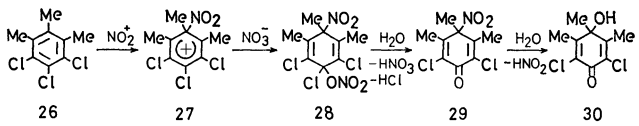
The infrared and proton NMR spectra of the crude product from **15** indicated the presence of some additional carbonyl compounds which, however, could not be isolated as crystalline solid. Formation of the side-chain substitution products could not be observed.

Scheme 2 outlines one possible pathway from **15** to these carbonyl compounds. Nitrobenzenium ion **16**[9] derived from **15** has neither a good leaving group nor a methyl group favorably situated for proton release. Thus it will take up the nitrate ion to give **18** *via* **17**, or undergo isomerization to **20** followed by the anion capture to give **21**, from which **24** and **25** could be derived through an addition-elimination sequence and subsequent hydrolysis.



Scheme 2

*Trichlorohemimellitene (**26**)*: A similar treatment of **26** with fuming nitric acid followed by ordinary work-up gave a carbonyl compound, mp 204—205 °C, as the major product. Its formula, as established by mass spectrometric molecular weight determination and elemental analysis, was $C_9H_{10}O_2Cl_2$. On the basis of the spectroscopic data (Table 1), it was readily identified as 2,6-dichloro-4-hydroxy-3,4,5-trimethylcyclohexa-2,5-dienone (**30**). Formation of **30** from **26** can be rationalized by Scheme 3; preferential attack of nitronium ion will occur at C-2 of **26** to give ion **27**. Capture of the nitrate ion by **27** followed by elimination of nitryl chloride from unstable chloro-nitrate **28** would give a nitro-ketone **29**, which undergoes a facile hydrolysis during aqueous work-up to yield **30** as the final product.

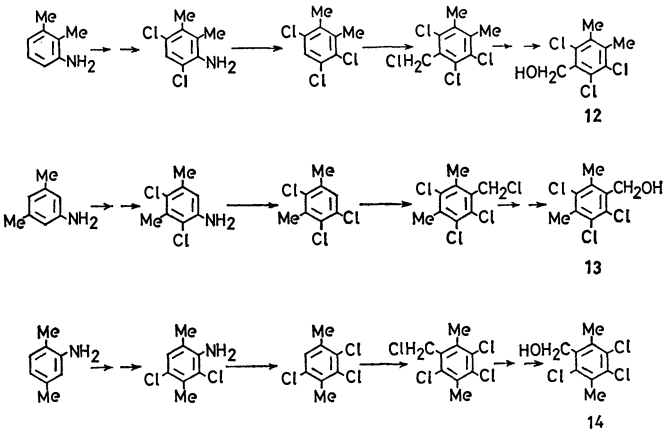


Scheme 3

The presence of a pair of methyl groups in position *para* to each other seems critical for the facile formation of benzyl nitrates. A pair of *para* methyl groups at C-1 and C-4 in **1** undergo side-chain nitrooxylation to form two benzyl nitrates **9** and **10**, whereas the unpaired methyl group at C-2 remains intact during the course of reaction. In contrast to **1**, **15** and **26** both bearing no paired methyl groups in *para* positions undergo only addition-elimination sequences to give unsaturated cyclic carbonyl compounds **19**, **24**, **25**. and **30**. No side-chain substitution was observed with these compounds.

The process of the side-chain nitrooxylation could be explained by the intermediacy of 1-methyl-1-nitro-4-methylenecyclohexa-2,5-dienes **6** and **7**, which would undergo the heterolytic scission of the carbon-nitrogen bond to give a benzyl cationic species—nitrite ion pair; recombination at benzyl carbon atom followed by oxidation affords side-chain nitrooxylation products **9** and **10**. The required disposition of methyl groups in position *para* one another might be taken to indicate that the transition state of the conversion of nitromethylenecyclohexadiene to benzyl nitrite is closer to the benzylic structure and stabilized more effectively by the electron-donating methyl group at *para* position. **1** bearing a pair of methyl groups reacts with the nitrating agent more readily than **15** and **26** which lack such structural advantage, indicating the high propensity of the nitrobenzenium ions **3** and **4** to form nitromethylenecyclohexadienes **6** and **7** rather than to take up anion or undergo isomerization. Oxidation to unsaturated cyclic ketone (path *c*) could effectively compete with side-chain nitrooxylation (path *b*) only under the conditions in which the formation of 1-nitro-4-methyl-

enecyclohexa-2,5-diene intermediate is structurally disfavored. Thus, on dissolution in excess fuming nitric acid (d=1.5) at room temperature, tetrachloro-*p*-xylene gave 2,3,5,6-tetrachloro-4-methylbenzyl nitrate (mp 80—82 °C) in 88% yield,[10] while a similar treatment of tetrachloro-*o*-xylene and tetrachloro-*m*-xylene led to the formation of a mixture of carbonyl compounds. Addition of sulfuric acid to the reaction system was found to facilitate the proton removal from the side-chain in favor of path *b* over path *c*. This is best exemplified by the nitration of 5,6-dinitroprehnitene; treatment with fuming nitric acid afforded 4,5-dinitro-2,3,6,6-tetramethylcyclohexa-2,4-dienone and 2,3,4,5-tetranitro-2,3,6,6-tetramethylcyclohex-3-enone, whereas the action of the mixed acid gave 5,6-dinitro-2,3,4-trimethylbenzyl nitrate as the major product.[11]



Scheme 4

Experimental

Melting points are uncorrected. IR spectra were determined in mulls on a Jasco 402G spectrophotometer. Proton NMR spectra were obtained in deuteriochloroform on a Hitachi Perkin-Elmer spectrometer using TMS as internal standard. Ultraviolet spectra were measured in methanol with a Shimadzu QV-50 spectrophotometer. Mass spectra were recorded on a Hitachi RMU-6E instrument.

Trichloropseudocumene, trichloromesitylene, and trichlorohemimellitene were prepared by the chlorination of the corresponding hydrocarbons and purified through chromatography on alumina. 2,5,6-Trichloro-3,4-dimethylbenzyl alcohol, 3,5,6-trichloro-2,4-dimethylbenzyl alcohol, and 3,4,6-trichloro-2,5-dimethylbenzyl alcohol were obtained from the corresponding chlorides *via* hydrolysis of acetates, which in turn were prepared from 3-*o*-xylidine, 5-*m*-xylidine, and *p*-xylidine, respectively, following the sequences shown in Scheme 4. Physical properties of trichlorodimethylbenzyl compounds obtained in context with the present work are summarized in Table 2. All new compounds gave satisfactory analytical results.

Nitration of Trichlorotrimethylbenzenes: The general procedure is illustrated below, taking an example from the reaction of trichloropseudocumene **1**.

To a stirred solution of **1** (7.5 g; 0.034 mol) in dichloromethane (38 ml) maintained at 0—5 °C, fuming nitric acid (d=1.5; 17.4 g; 0.375 mole) was added dropwise over a period of 30 min. After standing at room temperature overnight, the reaction mixture was poured into a large excess of

Effect of Pressure on the Rate of Solvolysis. Volume Parameters and Solvolysis Mechanism[1)]

Chisako YAMAGAMI, Akira SERA, and Kazuhiro MARUYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 10, 1973)

The effect of pressure on the solvolysis rates of representative primary, secondary, and tertiary tosylates was investigated in three representative solvents—formic acid, aqueous acetone, and methanol. The calculated activation volumes for these reactions were found to depend on the substrate structure and on the nature of solvent in a systematic manner. The activation volumes for k_c-like reactions were less negative than those for k_s-like reactions. In the case of the nearly k_s-like reactions, the activation volume was found to be governed by the partial molal volume of the initial state.

In previous papers concerning the pressure dependence of the solvolytic rates of secondary tosylates,[2)] we have discussed some correlations between the activation volumes, $\Delta V^{\neq}$, and the reaction mechanisms. It was suggested that the activation volume for the reactions of a series of substrates in a given solvent became less negative with an increase in the k_c-character of the substrate. It was also found that a reaction in formic acid resulted in a less negative value of activation volume than the corresponding reaction in methanol. If these observations are common to various types of substrates and solvents, this activation parameter could be expected to provide an additional criterion for examining the detailed reaction mechanisms. However, much of the published data on the activation volume is of limited usefulness for this purpose; there has been no systematic investigation of the activation volume upon changes in the type of substrate and the nature of solvent.

From this point of view, in this report we wish to extend our solvolytic studies under pressure to primary, secondary, and tertiary substrates in three different types of solvent—formic acid, 85% aqueous acetone (v/v), and methanol. It is generally accepted that primary substrates are solvolyzed by a solvent assisted pathway (k_s), and tertiary substrates by a solvent unassisted pathway (k_c). It may, then, be anticipated from our previous assumption[2)] that the activation volume for a tertiary system is less negative than for a primary system. Methyl, isopropyl, and adamantyl tosylates were chosen as model compounds for primary, secondary, and tertiary systems respectively. Methyl tosylate, possessing the lowest m-value[3)] of 0.30, has often been used as a reference standard for k_s-type behavior.[4)] On the other hand, adamantyl system has been well established to exhibit limiting behavior (k_c).[5)] Formic acid was chosen as a polar solvent which facilitates the k_c-process, whereas methanol was employed as a solvent of high nucleophilicity promoting the k_s-process. An aqueous organic solvent was expected to be intermediate in character between the above two solvents. The composition of the aqueous binary solvent (85%, v/v) was adopted so as to give appropriate rate constants at the temperatures employed in this investigation.

Results and Discussion

The solvolysis rate constants of typical primary, secondary, and tertiary alkyl tosylates were measured at various pressures (Table 1), and the activation volumes, $\Delta V^{\neq}$, were estimated by means of the following equations;

$$\Delta V^{\neq} = -RT(\partial \ln k/\partial P)_T \quad (1)$$

$$\ln k = a + bP \quad (2)$$

The parameter b in Eq. (2) was determined by the least-squares method in the range from 1 to 700 kg/cm^2.

The activation volumes obtained at atmospheric pressure, $\Delta V_0^{\neq}$, are summarized in Table 2 and are also illustrated in Fig. 1. As the wide range of reactivities of the substrates prevented rate measurements at a common temperature, two temperatures were employed for each solvent (25 °C and 45 °C for formolysis, and 25 °C and 40 °C for methanolysis and hydrolysis). The check of the temperature dependence of $\Delta V_0^{\neq}$ was performed in the case of isopropyl tosylate. The results indicate that an increase in the temperature results in a slight decrease in $\Delta V_0^{\neq}$ (Table 2).[6)] However, these differences are considered to be small enough to advance our argument without any corrections. In the case of formolysis, 2-adamantyl tosylate was used in the place of 1-adamantyl tosylate because all tertiary tosylates are too reactive to be measured at 25 °C. This replacement is reasonable since secondary 2-adamantyl tosylate is well known to behave like tertiary substrates.[5)]

TABLE 3. PARTIAL MOLAL VOLUMES AND MOLAR VOLUMES OF METHYL AND ISOPROPYL TOSYLATES AT 25.0±0.001 °C

ROTs R=	Solvent	$\bar{V}_g$[a]	V_m[b]	$\bar{V}_g - V_m$[c]
Methyl	HCOOH	154.4	151.8	2.6
	MeOH	142.9		−8.9
Isopropyl	HCOOH	194.5	188.2	6.3
	MeOH	181.6		−6.6

a) Partial molal volume of the initial state, cm³/mol. The average deviation from the mean of several trials is ±0.5 cm³/mol. b) Molar volume of substrate, cm³/mol. c) cm³/mol.

The partial molal volumes ($\bar{V}_g$) of methyl and isopropyl tosylates were measured at 25.0±0.001 °C by the dilatometric method.[7] The results are presented in Table 3, together with the molar volumes of the substrates (V_m).

Dependence of Activation Volume on the Nature of Solvent. All the activation volumes listed in Table 2 are negative. The invariable observation of negative activation volumes in solvolyses of neutral substrates is consistent with the view that the volume contraction by the electrostriction of the solvent predominates over the volume expansion due to bond extension during the activation process.[8] Accordingly, the activation volume which reflects the degree of solvation should, of course, be sensitive to the solvent change. In fact, Fig. 1 clearly shows the solvent dependence of $\Delta V_0^{\neq}$. The magnitude of $\Delta V_0^{\neq}$ for a given substrate is seen to decrease in the order; formic acid, aqueous acetone, and methanol. Such behavior is compatible with the previous observation in the Menschutkin reactions that the change in solvent from a non-polar to a polar one causes a remarkable increase in $\Delta V_0^{\neq}$.[9] The explanation was given that a polar solvent should be less constricted by the partly ionic transition state because of its low compressibility. Our results may also be considered to conform to this generalization.

In the case of limiting adamantyl systems, in which the volume contraction due to the partial bond formation is negligible, it may be said that the change in $\Delta V_0^{\neq}$ with solvent directly reflects the difference in the degree of the electrostrictive volume contraction of the solvent. Accordingly, the magnitude of the difference in $\Delta V_0^{\neq}$ between any two solvents could be regarded as a measure of the relative solvating ability of the solvent.

It is also interesting to note that a more favorable solvent for the k_c-process gives a less negative activation volume. Two solvent parameters, Y-[3] and N_{BS}-[4] values, are useful for describing the solvent character under discussion. The comparison of the Y-values (Y=2.05, −1.27,[10] and −1.09 for formic acid, aqueous acetone, and methanol respectively) indicates that formic acid is the most favorable for the k_c-process, whereas the N_{BS}- values, recently established solvent nucleophilicity parameters (N_{BS}=−2.05, −0.4,[10] and 0.01 for formic acid, aqueous acetone, and methanol respectively), indicate that methanol is the most favorable for the k_s-process.

The above-mentioned behavior will become more obvious if we examine the volumes of the initial state ($\bar{V}_g$) presented in Table 3.[11] The most important point to be noted is that $\bar{V}_g$ in formic acid is greater than V_m for a given substrate, while the reverse trend

is observed in methanol. The observed increase in the volume of the solution in the case of formic acid, when one mole of a solute was dissolved in the solvent, is most likely attributable to the inherent structuredness of the solvent. On dissolving the solute, the polar formic acid, already highly oriented itself, should be compelled to expand in order to make a "hole" to accept the solute. On the other hand, in methanol, a less structured medium, the process of the reorientation of solvent molecules around the dissolved solute becomes more important than the hole-making process; hence, the total contraction of the solvent system may result. As the activation volume is represented by the following equation;

$$\Delta V^{\neq} = \overline{V}_t - \overline{V}_g \quad (3)$$

the partial molal volume of the transition state species, $\overline{V}_t$, can be calculated from the values of $\overline{V}_g$ and $\Delta V_0^{\neq}$. Calculations were made for $\overline{V}_t$ of isopropyl tosylate to give rise to values of 162.7 cm^3/mol in methanol and 179.8 cm^3/mol in formic acid. The difference in $\overline{V}_t$ for isopropyl tosylate in these two solvents amounts to 17 cm^3/mol. This large difference in $\overline{V}_t$ is understandable in terms of the general concept in organic chemistry that methanol has a powerful solvating ability, while formic acid is a solvent of low nucleophilicity.

Dependence of Activation Volume on the Structure of Substrate. An inspection of Fig. 1 indicates that the variation in $\Delta V_0^{\neq}$ with the substrate structure reveals a similar behavior in all solvents. In each case, the $\Delta V_0^{\neq}$ for adamantyl tosylate is less negative by about 8 cm^3/mol than that for isopropyl tosylate. This finding is compatible with our assumption that the more k_c-like process results in a less negative activation volume.[2] However, a conflicting tendency was observed in the case of the primary system; a change in structure from isopropyl to methyl is accompanied by an increase in $\Delta V_0^{\neq}$ by 2—3 cm^3/mol, in spite of the fact that the latter is inevitably a more k_s-like substrate than the former. This observed discrepancy can be explained by assuming a larger contribution of the initial state volume to $\Delta V_0^{\neq}$ in the case of methyl tosylate than in that of isopropyl tosylate. In our previous discussion we have considered the activation volume to reflect chiefly the degree of solvation in the transition state. Such a view is quite reasonable as long as the systematic change of the substrate structure can govern the systematic alteration of solvation, in situation and degree, in the transition state. However, once the intensely solvated transition state is attained, that is, when the reaction is thought to be classifiable as a nearly pure k_s-process, the transition state volume ($\overline{V}_t$) can no longer be expected to be modified by a further change in the substrate structure. In this case, the contribution of the initial state volume becomes important, and the activation volume, $\Delta V_0^{\neq}$, must be controlled by $\overline{V}_g$ rather than by $\overline{V}_t$. This may be the case for methyl tosylate. In order to get information about the initial state contribution,[7] it would be useful to examine the quantity of $\overline{V}_g - V_m$. It may be seen from Table 3 that the value of $\overline{V}_g - V_m$ for methyl tosylate is smaller than that for isopropyl tosylate in each solvent. Although $\Delta V_0^{\neq}$ and $\overline{V}_g$ were not measured at the same temperature, the observed decreases in $\overline{V}_g - V_m$ with the substrate change from isopropyl to methyl tosylate (about 4 cm^3/mol for formic acid and about 2 cm^3/mol for methanol at 25 °C) seem to correspond approximately to the increases in $\Delta V_0^{\neq}$ in the same structural change (2—3 cm^3/mol for both of the solvents at either 40 or 45 °C). This suggests that $\overline{V}_g$ is more sensitive to the change in the substrate structure from the secondary to primary system than is $\overline{V}_t$. That is, the transition state of isopropyl tosylate constricts the surrounding solvent to nearly the same extent as that of methyl tosylate. The importance of the k_s-character of isopropyl tosylate has already been described in the case of methanolysis.[2] It is worthwhile to note again that the behavior of isopropyl tosylate is far from limiting solvolysis, even in formic acid. The same conclusion has been reported by Schleyer and his-coworkers[5] on the basis of a scrutiny of the relative rates of the corresponding substrates.

It can be seen from our results that the change in mechanism from a k_s- to a k_c-process causes a considerable variation in $\Delta V_0^{\neq}$ (about 8 cm^3/mol). As has been reported,[2a] this mechanistic change in the case of formolysis was achieved by means of the successive introduction of alkyl groups into the parent substrate, isopropyl tosylate. A good linear regression of the activation volume with the characteristics of the substrate was actually observed; the more k_c-like substrate was characterized by the less negative activation volume. The most k_c-like substrate, 2-adamantyl tosylate, gave the least negative-value (−6.9 cm^3/mol), while the most k_s-like substrate, isopropyl tosylate, gave the most negative value (−14.7 cm^3/mol). The others exhibited values between these two. However, the leveling effect on the activation volume[2a] in the case of the pure k_s-substrate, methyl tosylate, embosses the importance of the initial state partial molal volume. These observations lead us to conclude that the activation volume is a quite useful parameter or criterion for the study of solvolytic reaction mechanisms, especially for a series of reactions in which the degree of the k_s-contribution to the whole kinetic process varies.

Experimental

Materials. Methyl tosylate was a commercial material. Isopropyl and 2-adamantyl tosylates were prepared from the corresponding alcohols by the usual method. 1-Adamantyl tosylate was prepared from 1-adamantyl iodide and silver *p*-toluenesulfonate according to the procedure in the literature.[12] All the tosylates were found by NMR analysis to be satisfactorily pure.

Formic acid and methanol were purified as has previously been described.[2a] Acetone was dried over Drierite and distilled. The distilled water used was stored out of contact with air.

Rate Measurements. The high-pressure apparatus has previously been described.[6c] Temperature was controlled within 0.03 °C for all the kinetic runs. The reaction rate was measured using the conductance technique.[2a] The concen-

trations of the kinetic solutions were 0.019, 0.005, and 0.003 M for formolysis, hydrolysis, and methanolysis respectively. The rate constants for all the reactions of adamantyl tosylates and for the formolysis of isopropyl tosylate were determined by the Guggenheim method.[13] Pre-cooling of the medium in the high-pressure vessel was required to establish the thermal equilibrium rapidly.[2a] For the other slow reactions, we employed the procedure previously described for the methanolysis of secondary alkyl tosylates.[2a]

Partial Molal Volume Measurements. The technique used here was the dilatometric method recommended by Hyne and his co-workers.[7] 30 μl of tosylate was injected into a dilatometer consisting of a 190 cm^3 bulb containing a magnetic spin bar and fitted with precision bore capillary, 25 cm in length. The bath temperature during the measurement was kept within 0.002 °C. The density of the substrate used in calculating the molar volume was determined by the usual picnometer technique.

The present work has been supported by a Grant-in-aid for Scientific Research from the Ministry of Education.

The Structure of Ternstroemiaxanthin, a New Aldehydic C_{40}-Carotenoid*

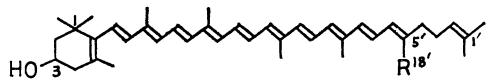
Kiyoshi KIKUCHI** and Masaru YAMAGUCHI

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received September 10, 1973)

A new carotenoid, ternstroemiaxanthin, was isolated as a main constituent from the red seeds of "*Ternstroemia japonica*," and the structure of the pigment was determined to be 3-hydroxy-β,ψ-caroten-18′-al (I) by spectral and chemical methods.

The deep red coloration of the seeds of "*Ternstroemia japonica*" (Mokkoku) is mainly due to the presence of a new phytocarotenoid, which is named ternstroemiaxanthin. In this paper we will describe its isolation and the structural studies which led to the conclusion that the pigment has the formula (3-hydroxy-β,ψ-caroten-18′-al)[1] represented by I. This is the first example of the presence of aldehydic C_{40}-carotenoid in higher plants.



I R=CHO
II R=CH_2OH

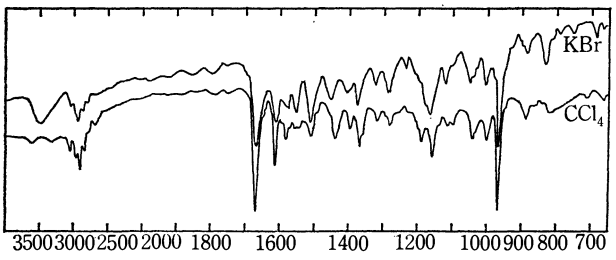


Fig. 1. Infrared spectra of ternstroemiaxanthin (I).

Results and Discussion

Ternstroemiaxanthin has the molecular formula of $C_{40}H_{54}O_2$ (elementary analysis and mass spectra). The presence of a hydroxyl group is indicated by the solubilities, the partition ratio,[2] the IR spectrum (3500, 1050—1040 cm^{-1}),[3] the mass spectrum (ions associated with m/e 18), and the formation of acetate or trimethylsilyl ether. The possibility of a tertiary nature of the group is eliminated by the absence of the characteristic 1150—1130 and 905 cm^{-1} IR absorptions.[4] The possibility of the allylic hydroxyl group can also be excluded by the negative result in the oxidation with chloranil[5] or by the difficulty in an attempted dehydration of the pigment with an acid–chloroform reagent.[6a,b] From the 1042 cm^{-1} position of ν_{C-O} (in carbon tetrachloride), the hydroxyl group seems likely to be secondary and to be on an alicyclic system.[7]

The presence of a formyl group is indicated by the IR [2720 cm^{-1} (in carbon tetrachloride); 1667 (conjugated) and 1160 cm^{-1}] and NMR spectra [δ 9.30]. The conjugated nature of the group can also be seen in the large red shift (10 nm) and the disappearance of fine structures in the UV spectrum taken in a polar solvent.[8]

In *cis,trans*-isomerization with iodine under light,[9] no particular evidence has been obtained to contradict the assumption that the compound has a normal all-*trans* configuration, at least in the central part of the polyene chain. This means that complications due to the presence of thermostable poly-*cis*-,[9] hindered *cis*-,[10] or *cis*-structures with a cross-conjugated aldehyde group[11] can be eliminated in the estimation of the length or the type of chromophore of the pigment from the UV data. A central *cis* or retro-type structure of the chromophore may also be excluded on the basis of the appearance of the δ_{CH} absorption at 965 cm^{-1} (sharp singlet).[12] The pigment absorbs thirteen moles of hydrogen, presumably twelve for double bonds and one for a carbonyl group; it appears, therefore, to be monocyclic. From the λ_{max} of ternstroemiaxanthin (486 nm, petroleum benzin) and its moderately-developed fine structures, it can be inferred that one of the double bonds is out of conjugation and that a part of the chromophore is in a substituted cyclic structure, such as a β-ionone ring, where the effective conjugation of that part with the main chromophore is hindered.[6b] If a partial chromophore involving the terminal carbonyl group is in the cyclic system, however, the fine structures should almost disappear and the λ_{max} should further shift toward blue to a considerable extent, as can be seen in compounds with a 4-keto-β,ψ-carotene chromophore (λ_{max} 462 nm).[13] Therefore, the chromophore given by I, for example, seems appropriate for the pigment. The similarity in the UV spectra of the pigment and of 4′-apo-β,ψ-caroten-4′-al[14] supports this conclusion. The above arguments are also supported by the fact that dihydroternstroemiaxanthin (II) or its diacetate exhibits absorption maxima almost identical with those of β,ψ-carotene,[15] β,ψ-caroten-3-ol[16] or 4′-apo-β,ψ-caroten-4′-ol.[14]

The ions [m/e 413(M–153) and 373(M–193)] in the mass spectrum are considered to give strong evidence for the presence of a hydroxylated β-ionone ring;[17] this is further confirmed by the mass spectra of the trimethylsilyl ether[18] of the pigment and the bistrimethylsilyl ether of the dihydro derivative (II).

The 4-position of the hydroxyl group can be eliminated because of its non-allylic nature. The NMR signal (δ 3.95) of the methine proton adjacent to the hydroxyl group is quite similar to that (δ 4.00) of β,β-carotene-3,3′-diol[19] and different from that (δ 3.55) of β,β-caroten-2-ol.[20] The hydroxyl group can, therefore,

** Present address: Kowa Chemical Industries Co., Ltd., Kitakojiya, Ota-ku, Tokyo 144.

be assigned to the 3-position on the β-ionone ring.

The ions associated with *m/e* 69 clearly indicate the presence of a isopentenyl group which is common in ψ-type carotenoids.[17] The NMR spectrum, however, shows only nine methyl groups and shows the absence of the δ 1.81 signal which is characteristic of the 5'-methyl group in β,ψ-type carotenoids.[19] This indicates that the formyl group is at the 5'-position in the pigment.

Further confirmations of the structure have been made by chemical means. The lithium aluminium hydride or sodium borohydride reduction of the pigment gave a dihydro compound (II), which gave diacetate or bistrimethylsilyl ether. An attempt to oxidize the aldehyde group into carboxylic acid with silver oxide failed completely. A similar observation regarding the resistance of polyene aldehyde toward oxidation has been previously reported.[21]

Experimental

Anhydrous sodium sulfate was used for drying the solutions. The calcium carbonate or calcium hydroxide used for chromatography was activated by heating it at 150 °C for 3 hr just before use. The instruments used for the measurements of the spectra were as follows: UV spectra, Hitachi, Model EPS-3T. IR spectra, Hitachi, Model 215. NMR spectra, JEOL, Model TS 100. Mass spectra, Hitachi, Model TMS-4, and JEOL, Model JMS-01SG.

Isolation and Properties of Ternstroemiaxanthin (I). The seeds were repeatedly extracted with acetone, the pigment was transferred into petroleum benzin (bp 60—70 °C) by the addition of water, and the solution was concentrated to a deep red oil. The oil was diluted with petroleum benzin and chromatographed on alumina (Merck, neutral; grade II). The ternstroemiaxanthin ester formed a wide violet zone in the middle of the column, besides several minor zones above and below it. A colorless vegetable oil was removed as thoroughly as possible by prolonged washing. The main zone was eluted (petroleum benzin containing a little methanol), and the evaporation residue of the elute was saponified with 10% methanolic potassium hydroxide in petroleum benzin at room temperature for 20 hr. The solution was washed with water, dried, and concentrated to give a reddish-black resinous residue, which was then chromatographed on calcium carbonate from a petroleum benzin solution. A wide, purplish-red main zone (the fourth from the top) was eluted (10% methanolic benzene) and concentrated under reduced pressure. The residue, redissolved in a small amount of methylene chloride, crystallized on the drop-by-drop addition of methanol. Several recrystallizations from the same mixture gave pure ternstroemiaxanthin as blackish-violet needles (8 mg from 1 Kg seeds); mp 160.5 °C (uncorr.). Found: C, 84.32; H, 10.00%. Calcd for $C_{40}H_{54}O_2$: C, 84.75; H, 9.60%. UV spectra: 518(ε 98000), 486(ε 127000), 460_{sh} nm(hexane); 496 nm(ε 115000) (ethanol); 536, 504, 472_{sh} nm(benzene). IR spectra: Fig. 1. NMR spectrum: δ ($CDCl_3$) 1.08(6H, s; 1,1-dimethyl); 1.58 and 1.64(each 3H, s; 1',1'-dimethyl); 1.73(3H, s, 5-methyl); 1.97(12H, s; 9,13,9',13'-tetramethyl); 4.00(1H, m, 3-proton); 5.15(1H, m, 2'-proton); 5.98—6.95 (15H, m, polyene chain protons); 9.30(1H, s, aldehyde). Mass spectrum: 566.4132(M, calcd for $C_{40}H_{54}O_2$, 566.4124), 548 (M−18, 2.6%), 497(M−69, 1.1), 487(M−79, 0.8), 479 (M−69−18, 0.6), 474(M−92, 2.5), 460(M−106, 4.5), 456 (M−92−18, 0.7), 442(M−106−18, 1.1), 413(M−153, 1.3), 408(M−158, 1.8), 405 (M−92−69, 1.0), 391 (M−106 −69, 1.7), 373(M−193, 1.0), 368(M−106−92, 1.6), 106(32), 91(63), 69(17), 28(100), 18(53).

cis,trans-*Isomerization.* After equilibration in benzene in the presence of iodine and light, the 504-nm maximum of the pigment shifted to 500 nm, accompanied with a decrease in the extinction coefficient, and a *cis*-peak was newly formed at 381 nm, with a shoulder at 361 nm.

Catalytic Hydrogenation:[22] 13.28 mol of hydrogen were absorbed (PtO_2, acetic acid; reference substance, β,β-carotene-3,3'-diol).

The partitioning ratio[2] between petroleum ether (bp 50—60 °C) and 90% methanol was 42 : 58.

The pigment (0.1 mg) dissolved in chloroform (0.2 ml) was treated with three drops of an acid-chloroform reagent[6a] for fifteen minutes. Most of the pigment was recovered unchanged, and no dehydrated product was observed on working up, including a chromatographic examination. The pigment (0.1 mg) was also treated with chloranil (0.09 mg) in a mixture of benzene (0.6 ml) and ethanol (0.07 ml) at room temperature for 20 hr. No product exhibiting wavelength maxima longer than those of the starting pigment was observed in the chromatographic analysis of the mixture.

Acetate. Acetate was prepared by the usual procedure from the pigment and acetic anhydride in pyridine and was purified by chromatography on calcium carbonate. A reddish-black precipitate. Partition ratio: 95.5:4.5 (petroleum benzin and 90% methanol). λ_{max} 518, 486, 457_{sh} nm(petroleum benzin). IR; 2960, 2880, 1738 (CH_3COO), 1670, 1242, 962 cm^{-1}.

Trimethylsilyl Ether. This was prepared from the pigment, hexamethyldisilazane, and trimethylchlorosilane in pyridine,[18] and was purified by chromatography (calcium carbonate, petroleum benzin). Some characteristic peaks in the mass spectrum were as follows: *m/e* 638 [M, for $C_{40}H_{53}O_2Si(CH_3)_3$], 569(M−69), 566(M−72), 548(M−90), 546(M−92), 532(M−106), 480(M−158), 477(M−69−92), 463(M−69−106), 413(M−72−153), 373(M−72−193), 41 (base peak).

Dihydroternstroemiaxanthin (II). Ternstroemiaxanthin (2 mg) dissolved in ethanol (15 ml) was treated with sodium borohydride (50 mg) for thirty minutes. The mixture was then treated as usual, and after chromatographic purification (calcium carbonate, petroleum benzin), a dihydro derivative was obtained as red needles (1.1 mg); mp 174 °C (from benzene-petroleum benzin). Lithium aluminium hydride gave a poorer yield. λ_{max}: 490(ε 107000), 459(ε 122000), 434_{sh} nm(petroleum benzin); 508, 476, 447_{sh} nm(benzene).

Diacetate; λ_{max} 492, 461, 434 nm(petroleum benzin).

Bistrimethylsilyl ether, prepared by the usual procedure,[18] gave the following characteristic peaks: *m/e* 712(M for $C_{46}H_{72}O_2Si_2$), 643(M−69), 622(M−90), 620(M−92), 606 (M−106), 532(M−90−90), 487(M−72−153), 447(M−72−193), 73(base peak).

The authors wish to thank Dr. Michio Nakanishi of the Yoshitomi Pharmaceutical Co. Ltd., for the help he gave them in the measurement of the NMR and mass spectra, and the members of the authors' laboratory for their help in the collection of materials.

Kinetic Studies on the Hydrolysis of Ethyl Benzenesulfinates[1]

Michio KOBAYASHI, Ritsuko NISHI, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received September 22, 1973)

The rates of hydrolysis of ethyl *p*-substituted benzenesulfinates were determined in acidic and alkaline media; the rates were greater in the former with the sulfinates containing electron-releasing substituents, $\rho = -0.54$ (20 °C); and in the latter with the sulfinates containing electron-withdrawing substituents, $\rho = 1.60$. The mechanisms of the hydrolysis are discussed.

By use of oxygen-18, Bunton and Hendy established that hydrolysis of methyl *p*-toluenesulfinate proceeds with S(O)–O bond fission under both alkaline and acidic conditions.[2] The alcoholysis of alkyl *p*-toluenesulfinates catalyzed by potassium acetate was found to proceed also with S(O)–O bond fission and inversion on the sulfur atom.[3] The hydrolysis of benzhydryl arenesulfinates, however, was found to proceed with S(O)–O bond fission and inversion on the sulfur atom.[3] The hydrolysis of benzhydryl arenesulfinates, however, was found to proceed with O–C bond fission; part of the sulfinate anion-benzhydryl cation ion pair formed recombined, forming a sulfone.[4,5]

The only kinetic study on the hydrolysis of sulfinates carried out by Bunton and Hendy[2] described the hydrolysis of methyl *p*-toluenesulfinate under acidic conditions, and no substituent effects were investigated. Concerning the alkaline hydrolysis, they stated that the reaction proceeds too rapidly to determine the rates, and gave only one approximate value.

We have determined the rates of hydrolysis of ethyl *p*-substituted benzenesulfinates in aqueous ethanol under acidic and alkaline conditions, and calculated the activation parameters. The results are given in this paper together with their implication.

Results and Discussion

Ethyl arenesulfinates (I) show a strong absorption near 250 nm due to n→pdπ transition, whereas arenesulfinate anions show a weak one.[6] Thus, the rates of hydrolysis of I in alkaline media can be determined by observing the decrease of the absorption near 250 nm.

Arenesulfinic acids are fairly strong acids (p*K*a< 2),[7] and dissociate almost completely in dilute aqueous solutions, their UV spectra showing the absorption of the sulfinate anions alone.[4] Thus, the rates of hydrolysis of I in acidic media also can be determined by observing the decrease of the absorption near 250 nm.

Rates of Hydrolysis in Alkaline Media. An ester was dissolved in a 2/3 (v/v) mixture of ethanol and a dilute NaOH solution (the concentration of the ester, $\sim 10^{-3}$ M). Aliquots were withdrawn at suitable intervals, cooled with ice, diluted with a 0.1 N H_2SO_4 aqueous solution (20 times), and the UV absorption of the mixture was determined. An example of such a spectrum, exhibiting an isosbestic point, is shown in Fig. 1. The rates of hydrolysis were calculated from the decrease of the absorbance near 240—250 nm, and were of first order both in [ester] and in [OH^-]. Since the rate of hydrolysis of ethyl *p*-nitrobenzenesulfinate in alkaline media near room temperature was very large, the reaction was carried out in a UV cell, and its absorption was repeatedly determined at suitable intervals without acidifying the reaction mixture.

Rates of Hydrolysis in Acetic Media. An ester was dissolved in a 2/3 (v/v) mixture of ethanol and a dilute

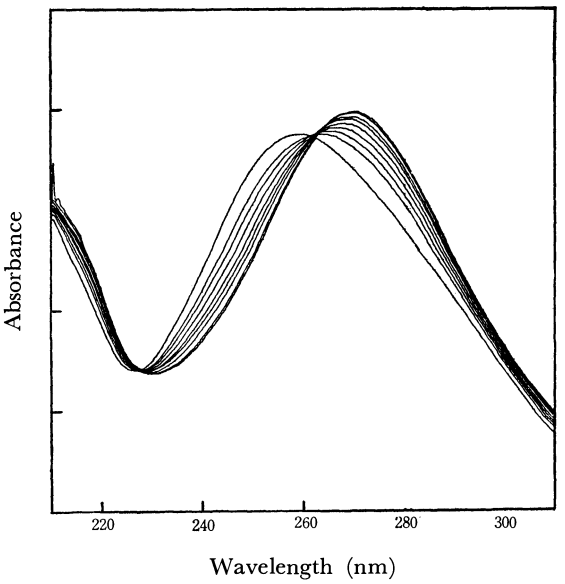

Fig. 1. Changes of the UV absorption of ethyl *p*-nitrobenzenesulfinate in alkaline hydrolysis.

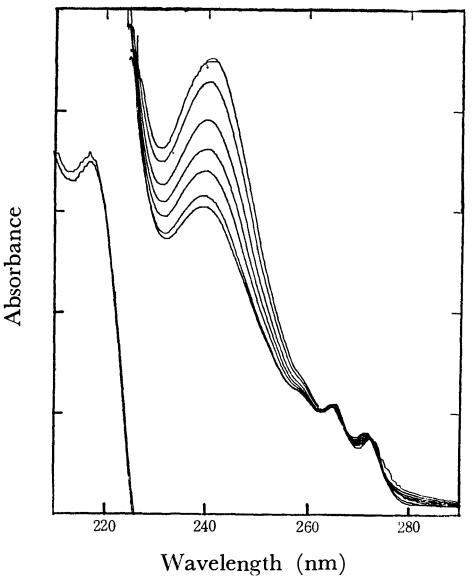

Fig. 2. Changes of the UV absorption of ethyl benzenesulfinate in acidic hydrolysis.

H_2SO_4 solution (the concentration of the ester was about 10^{-3} M and that of H_2SO_4 was 2~5 N). Aliquots were withdrawn at suitable intervals, cooled with ice, diluted with distilled water (20 times), and the UV absorption of the mixture was determined. A group of spectra obtained possessed an isosbestic point (Fig. 2).

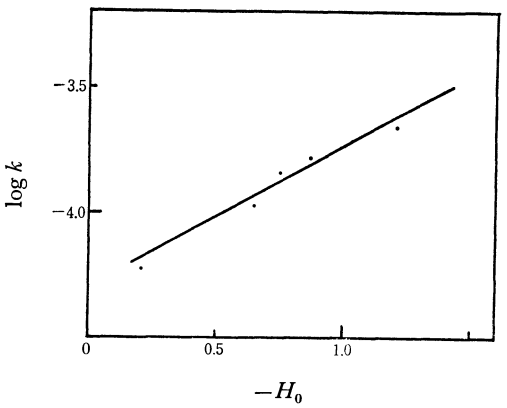

Fig. 3. The relationship between $\log k$ and acidity function H_0 in the hydrolyses of ethyl *p*-bromobenzenesulfinate.

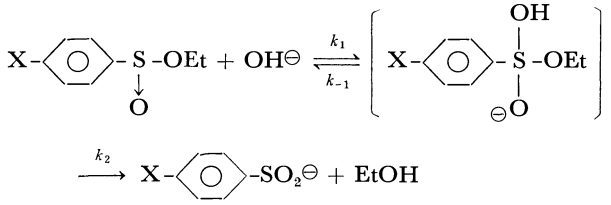
In strongly acidic media, benzenesulfinic acids undergo disproportionation, forming a 1 : 1 mixture of thiolsulfonate and sulfonic acid, the disproportionation being much slower than the hydrolysis of sulfinates. The UV absorption of a disproportionated mixture near 240—260 nm was weak, its molar absorbance differing from that of a hydrolyzed mixture (sulfinate anion). Thus, the rates of hydrolysis of I were calibrated by determining the rates of disproportionation of sulfuric acids under the same conditions.

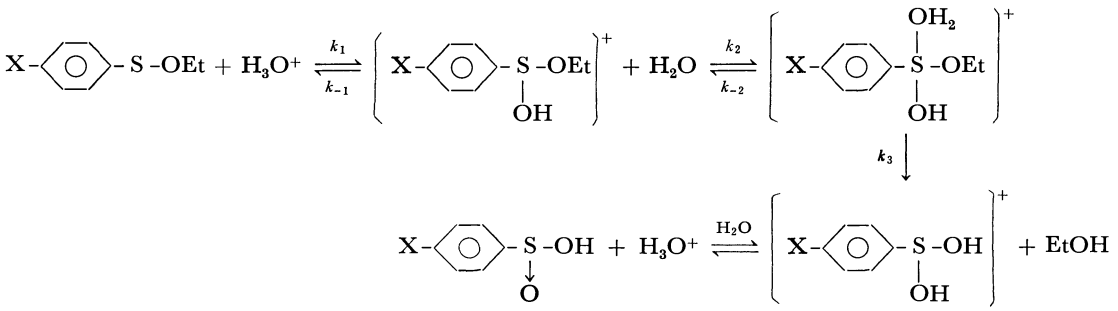
The rates of hydrolysis of I in acidic media were of first order in I, and were nearly proportional to acid concentration. The rate constants were calculated by assuming a second-order rate equation, (Tables 1 and 2). The values of $\log k$ were found to show a linear relationship with acidity function H_0 (Fig. 3).[8] In the case of the hydrolysis of methyl *p*-toluenesulfinate catalyzed by perchloric acid in aqueous dioxane, Bunton and Hendy reported a similar linear relationship between $\log k$ and H_0.

Hammett Relationship. For the hydrolysis in alkaline media, good linear relationship was found between the rate constants and Hammett σ-values (the ρ value was 1.60 at 0, 10, and 20 °C; the correlation coefficient, γ was 0.99 in every case). For the hydrolysis in acidic media, fair linear relationship was found ($\rho=-0.54$ at 21 °C ($\gamma=0.96$); $\rho=-0.85$ at 30 °C ($\gamma=0.93$); $\rho=-0.95$ at 40 °C ($\gamma=0.95$)).

Reaction Mechanism. For the hydrolysis in alkaline media, the following mechanism is proposed on the basis of the findings that the Hammett ρ value was positive (+1.60), the value of the activation entropy is a large negative value (~−30 e.u.), and the reaction involves S(O)–O fission.[3]



The positive ρ value suggests that the first step (*i.e.*, the addition of OH^- to I) is rate-determining. When the hydrolysis of ethyl *p*-toluenesulfinate in ^{18}O-enriched



water was stopped before completion and the unchanged ester was recovered, no incorporation of ^{18}O in the ester was found.[10] Therefore, k_2 should be far greater than k_{-1}. Thus, the life time of the tetracoordinated intermediate should be very short, and the addition-elimination mechanism described above is kinetically indistinguishable from that which involves a one-step S_N2-type displacement of OEt of I with OH^-. However, nucleophilic attack on an atom containing a double bond (for example, C=O, C=N) is usually not a one-step S_N2-type displacement (for example, the hydrolysis of carboxylate esters proceed by an addition-elimination mechanism similar to that presented for I), and the S–O bonds in sulfinate esters and sulfoxides are considered to have semipolar double bond character. Hence, we prefer the addition-elimination mechanism, but we admit that there is no concrete evidence for the choice between the two mechanisms.

For the hydrolysis in acidic media, the mechanism shown above is proposed on the basis of the following findings; the ρ value is negative and relatively small, $\log k$ is proportional to H_0, the entropy of activation is fairly large negative value characteristic of an A2 type reaction, and the reaction involves S(O)–O fission.

The ρ value of the first step is expected to be negative, that of the second step positive, and that of the third step negative. If the rate-determining step is the second or third step, the ρ value of the overall reaction will be small. The ρ value experimentally obtained was a small and negative value. The linear relationship between $\log k$ and H_0 is consistent with the hypothesis that the first step is the protonation of I and the rate-determining step is the second step (*i. e.*, the addition of water to the conjugate acid of I) or a later step.

The hydrolysis in acidic media proceeds *via* several steps, and the effect of substituents varies in each step. Therefore, it is reasonable that the linearity of the Hammett relationship between $\log k$ of the overall reaction and the σ values was not too good and that of the Arrhenius plots ($\log k$ vs $1/T$) was poorer than that observed in alkaline hydrolysis.

When ethyl *p*-toluenesulfinate was partially hydrolyzed in ^{18}O-enriched water and the unchanged ester was recovered, no increase in its ^{18}O content was found.[10] Hence, k_3 must be far greater than k_{-2}.

Experimental

Materials. Ethyl arenesulfinates were prepared by adding dicyclohexylcarbodiimide (0.90—0.95 mol per mol of sulfinic acids) to an anhydrous ethanol solution of a sulfinic acid at 0 °C, and by allowing the mixture to stand overnight;[11] the ester was purified by vacuum distillation or recrystallization (in the case of ethyl *p*-nitrobenzenesulfinate).

Kinetics. Acid Hydrolyses. Stock solutions were prepared by dissolving a weighed amount of I in ethanol. The stock solution (2~5 ml) was diluted with an EtOH–dil.H_2SO_4 mixture (v/v, 2/3) to 100 ml, and the reaction mixture was placed in a constant temperature bath. At suitable intervals, a 5 ml sample was withdrawn, diluted to 100 ml with distilled water, and its UV spectrum was determined.

Alkaline Hydrolysis. Two to five ml of a stock solution of I was diluted with an EtOH–NaOH aq mixture (v/v, 2/3) to 100 ml, and the reaction mixture was placed in a constant temperature bath. At suitable intervals, a 5-ml sample was withdrawn, diluted to 100 ml with a 0.1 N H_2SO_4, and its spectrum was determined. In a 0.1 N H_2SO_4, arenesulfinic acids ($\sim 10^{-4}$ M) are almost completely dissociated.[4]

When the rates were very large, the hydrolysis was carried out in a UV cell. A stock solution was diluted with an EtOH–NaOH aqueous mixture, and the UV spectrum of the ester solution ([I]=about 10^{-5} M) was repeatedly determined.

The rate was determined several times for each case. The average values are given in Tables 1 and 2.

Hydrogen Exchange Reactions of Sulfilimines and Sulfoximines[1)]

Michio KOBAYASHI, Akira MORI, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

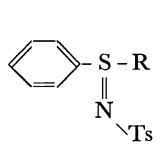
(Received September 22, 1973)

Alkyl phenyl sulfilimines, benzyl phenyl sulfilimine and the corresponding sulfoximines were found to exchange their α-hydrogens with deuteriums in heavy water when the medium was alkaline. No exchange was observed when the medium was acidic or neutral. The rates of exchange in a sulfilimine were greater than those of the corresponding sulfoximine. The kinetics of these H-D exchange reactions were investigated by use of pyridine as a catalyst, and the reaction mechanism was discussed.

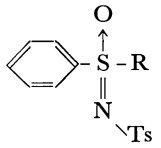
The α-hydrogens of sulfoxides and sulfones are known to undergo H-D exchange, and the stereochemistry has been studied.[2)] However, H-D exchange in sulfilimines(I) and sulfoximines(II) has not been studied. In order to determine whether or not they also undergo H-D exchange and, if so, whether or not the exchange is stereospecific, an investigation was carried out.

Results and Discussion

When benzyl phenyl sulfilimine(Ia) or benzyl phenyl sulfoximine(IIa) was heated in a dioxane–D_2O mixture at 95 °C, no decrease in their NMR benzyl signals was observed. Addition of acetic acid or dilute HCl did not cause exchange either.



Ia: R=$PhCH_2$
Ib: R=CH_3
Ic: R=C_2H_5



IIa: R=$PhCH_2$
IIb: R=CH_3
IIc: R=C_2H_5

However, when a small amount (2～5 mol%) of sodium hydroxide was added as a catalyst, the benzyl hydrogens of Ia undergo complete exchange on being heated at 95 °C for 10 min. The two benzyl hydrogens of Ia show an AB quartet in the NMR spectrum owing to chirality on the sulfur atom. However, the rates of exchange of these two hydrogens did not appear to differ, and no stereospecificity was observed. This finding differs from what was observed with benzyl sulfoxides.[3)]

The α-hydrogens of Ib, Ic, IIa and IIb also undergo exchange readily in D_2O in the presence of sodium hydroxide. The rates of H-D exchange in a 95% dioxane–5% D_2O mixture were determined by means of NMR with the tosyl methyl signal as a built-in standard, since the tosyl methyl hydrogens do not undergo exchange at all. In alkaline media, I is slowly hydrolyzed, but its rate is far smaller than that of H-D exchange and can be neglected.

The rates of H-D exchange of Ia～Ic were determined with [NaOH]=0.013 M at 10 °C. The exchange was of first order in I, and the pseudo first-order rate constants per one exchangeable hydrogen atom are as follows.

Ia: $k_{obs}=6.35\times10^{-5}\ s^{-1}$
Ib: $k_{obs}=2.10\times10^{-6}$
Ic: $k_{obs}=1.39\times10^{-6}$

The ratio of reactivities per one α-hydrogen is Ia : Ib : Ic=30 : 1 : 0.66. The presence of an adjacent phenyl group promotes the H-D exchange, whereas the presence of an adjacent methyl group retards the exchange.

These results show that the S=N bond of I is strongly polarized and α-carbanions are readily formed. However, in order to compare the effect of the S=N group with those of >C=O, $>SO_2$ and >S=O groups, accurate determination of the H-D exchange rate constants is necessary. For this, sodium hydroxide is unsuitable since the reaction proceeds too rapidly. When a very small amount of sodium hydroxide was used in the later stages of the reaction, part of the catalyst was neutralized with the *p*-toluenesulfonamide formed by hydrolysis of I. Pyridine was, therefore, chosen as catalyst, and the H-D exchange in pyridine–D_2O was studied.

Sulfilimines (Ia or Ib) or sulfoximines (IIa or IIb) (1～2 mmol) were dissolved in pyridine (5 ml), and D_2O (0.5～2.0 g, 24～102 mmol) was added. The mixture was allowed to react in ampoules at a constant temperature. At suitable intervals, ampoules were cooled in ice, and their NMR absorptions were determined. The rates of exchange were calculated from the decrease of integrated intensity of α-methyl or α-methylene absorptions. Since D_2O is present in far excess of I or II, the backward reaction (D-H exchange) can be neglected. The apparent rate constants were calculated by using the following equation, as in the case of the NaOH-catalyzed reaction. The tosyl

$$k_{obs}=\frac{2.303}{t}\log\frac{(M/R)_\infty-(M/R)_0}{(M/R)_\infty-(M/R)_t}$$

R: Integrated intensity of the tosyl methyl signal.
M: Integrated intensity of the α-methyl or α-methylene signal.
$(M/R)_\infty$: Value calculated for $t=\infty$.
$(M/R)_0$: Value calculated for $t=0$; it is 1 for Ib or IIb, and 2/3 for Ia or IIa.

methyl group was used as a built-in standard. This method is similar to that of Hine *et al.*, who determined base-catalyzed H-D exchange rates of $CH_3OCH_2CO_2$-CH_3 by using the methoxy methyl NMR signal as a built-in standard.[4)]

For the calculation of rate constants, the first-order rate equation described above was used with assumption that the H-D exchange is not stereospecific and rates of exchange of three α-methyl or two α-methylene hydrogens are equal. This might be reasonable since the rates of exchange of two benzyl hydrogens of Ia were equal.

TABLE 1. RELATIONSHIP BETWEEN k_{obs} AND D_2O CONCENTRATION

Substrate	$[D_2O]$ (mol/l)	Temperature (°C)	k_{obs}[a] (s^{-1})
Ia	4.31	60.0	1.57×10^{-5}
	8.60	60.0	3.26×10^{-5}
	4.48	70.0	3.91×10^{-5}
	8.60	70.0	8.15×10^{-5}
Ib	4.69	70.0	1.94×10^{-5}
	8.14	70.0	2.78×10^{-5}

a) k_{obs} was calculated for one α-hydrogen atom.

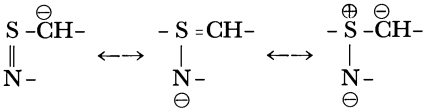
Since pyridine was the catalyst and the solvent, the catalyst concentration was constant. When the relationship between k_{obs} and $[D_2O]$ was examined at 60 °C and 70 °C, k_{obs} was approximately proportional to $[D_2O]$ as shown in Table 1. Thus, the rate constant k was calculated by dividing k_{obs} with $[D_2O]$.

$$v = k_{obs}[Ia]$$
$$= k[D_2O][Ia]$$
$$= k'[Py][D_2O][Ia]$$

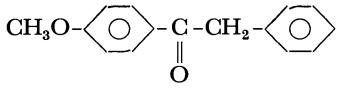
The values of k_{obs}, k ($=k_{obs}/[D_2O]$) and the activation parameters are shown in Table 2. No exchange was observed with Ic and IIc under these conditions.

The data in Table 2 show that the H-D exchange in benzyl sulfilimine and benzyl sulfoximine is faster than that in the corresponding methyl analog. This is probably due to the stabilization of the carbanion by resonance with the adjacent phenyl group.

The H-D exchange in sulfoximines (IIa and IIb) is much slower than that in sulfilimines(Ia and Ib). If the effect of the >S=N′ or >S(=O)=N′ group is only inductive effect alone, the >S(=O)=N′ group containing an additional oxygen atom should facilitate the abstraction of α-hydrogens to a greater extent. However, the experimental findings are to the contrary; the H-D exchange in I is 10 times that in II and its activation energy is about 1 kcal/mol smaller than that of II. These results are surprising, and the only possible explanation seems to be the more extensive stabilization of the carbanion by the resonance with the >S=N′ group than with the >S(=O)=N′ group, but at present no other data supporting such difference are available.

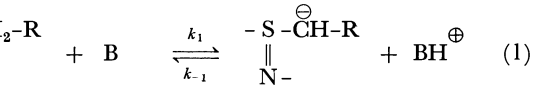


In order to compare the ability of >S=N′ and >S(=O)=N′ for stabilizing carbanions with that of >C=O, the H-D exchange of benzyl *p*-methoxyphenyl ketone(III) was measured in pyridine–D_2O by using its methoxy hydrogens as a built-in standard. The reaction was of first-order in III, and at 70 °C k_{obs} was 2.68×10^{-4} s^{-1} and k ($=k_{obs}/[D_2O]$) was 5.85×10^{-5} $M^{-1}s^{-1}$ (both k_{obs} and k were calculated for one methylene hydrogen). These values are about 7 times that of Ia and 60 times that of IIa. Thus the ability of >S=N′ or >S(=O)=N′ for stabilizing carbanions is much less than that of >C=O.



(III)

The base-catalyzed H-D exchange of sulfilimines is considered to proceed *via* the following steps (similar steps can be formulated for the H-D exchange of sulfoximines).



(1)

TABLE 2. H-D EXCHANGE RATES AND ACTIVATION PARAMETER[a]

Substrate	Temperature (°C)	$[D_2O]$ (mol/l)	$10^6\times k_{obs}$ (s^{-1})	$10^6\times k$ ($s^{-1}M^{-1}$)	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$ (e. u.)
Ia	49.5	4.48	5.00	1.12		
	54.0	4.48	7.75	1.73		
	60.0	4.31	15.7	3.63		
	65.0	4.48	22.9	5.10		
	70.0	4.48	39.1	8.70	21.4	−19.6
Ib	60.0	4.69	3.70	0.79		
	65.0	4.69	10.7	2.28		
	70.0	4.69	19.4	4.13		
	75.0	4.44	26.4	5.93		
	80.0	4.44	68.0	14.8	31.4	+8.6
IIa	60.0	4.75	1.67	0.352		
	75.0	4.32	7.85	1.82		
	80.0	4.32	11.6	2.68		
	85.0	4.32	16.2	3.73	22.2	−21.5
IIb	60.0	5.08	0.0453	0.00893		

a) Both k_{obs} and k were calculated for one α-hydrogen atom, error ranges being ±20%.

$$-S(=N-)-\overset{\ominus}{C}H-R + D_2O \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} -S(=N-)-CHD-R + OD^{\ominus} \quad (2)$$

$$-S(=N-)-CHD-R + B \underset{k'_{-1}}{\overset{k'_1}{\rightleftharpoons}} -S(=N-)-\overset{\ominus}{C}D-R + BH^{\oplus} \quad (3)$$

$$-S(=N-)-\overset{\ominus}{C}D-R + D_2O \underset{k'_{-2}}{\overset{k_2'}{\rightleftharpoons}} -S(=N-)-CD_2-R + OD^{\ominus} \quad (4)$$

For the sake of simplicity, only steps (1) and (2) are considered, since (3) and (4) are repetitions of (1) and (2), and $k_1'=k_1$, $k'_{-1}=k_{-1}$, $k_2'=k_2$ and $k'_{-2}=k_{-2}$. Since I and II are very weak acids, the concentration of carbanions must be very small. On the basis of the usual steady-state assumption, the following equation is derived.

$$v = \frac{k_1k_2}{k_{-1}[BH^+]+k_2[D_2O]}[I][B][D_2O]$$

If $k_{-1}[BH^+] \gg k_2[D_2O]$,

$$v = \frac{k_1}{k_{-1}[BH^+]}k_2[I][B][D_2O]$$

and

$$k_{obs} = \frac{k_1}{k_{-1}[BH^+]}k_2[B][D_2O]$$

If $k_{-1}[BH^+] \ll k_2[D_2O]$,

$$v=k_1[I][B] \quad \text{and} \quad k_{obs}=k_1[B]$$

In this case, a large kinetic isotope effect is expected, and changes in $[D_2O]$ should not alter the rate.

In fact, two types of H-D exchange in labile hydrogens have been reported. In the case of the exchange of α-hydrogens of toluene in cyclohexylamine in the presence of lithium cyclohexylimide, the isotopc effect (k_H/k_D) was greater than 10, indicating that the first step (the abstraction of proton) is rate-determining.[5] In the case of the exchange of α-hydrogens of toluene in DMSO in the presence of potassium *t*-butoxide, k_H/k_D was 0.6, indicating that the second step is rate-determining.[6]

When the D-H exchange of α,α-dideuteriobenzyl phenyl sulfilimine (Ia-d_2) was measured in pyridine–H_2O at 70 °C, the following values were obtained.

$$k_{obs} = 2.07\times10^{-5}\,s^{-1}$$
$$k_D^{70°} = k_{obs}/[H_2O] = 4.84\times10^{-6}\,s^{-1}\,M^{-1}$$
$$(k_H/k_D)_{70°C} = 1.80$$

For α,α,α-trideuteriomethyl phenyl sulfilimine (Ib-d_3), the following values were obtained.

$$k_{obs} = 8.40\times10^{-6}\,s^{-1}$$
$$k_D = k_{obs}/[H_2O] = 1.89\times10^{-6}\,M^{-1}\,s^{-1}$$
$$(k_H/k_D) = 2.19$$

Ph-S(=N-Ts)-CD_2Ph (Ia-d_2) Ph-S(=N-Ts)-CD_3 (Ib-d_3)

Thus, kinetic isotope effect was observable, and the abstraction of the α-hydrogens must be involved in the rate-determining steps. However, the k_H/k_D values were not so great, and k_{obs} was proportional to the concentration of water. Thus, $k_{-1}[BH^+]$ might be slightly greater than $k_2[D_2O]$.

Experimental

Materials. *N-p*-Toluenesulfonylsulfilimines (Ia, Ib and Ic) were prepared from the reaction between the corresponding sulfides and chloramine-T in methanol.[7]

N-p-Toluenesulfonylsulfoximines (IIa, IIb and IIc) were prepared by the oxidation of the corresponding sulfilimines with perbenzoic acid in chloroform,[8] and recrystallized from methanol.

α,α,α-Trideuteriomethyl phenyl *N-p*-toluenesulfonylsulfilimine(Ib-d_3). An anhydrous dioxane solution (60 g) of Ib (2.88 g) was mixed with an NaOH (20 mg) solution in D_2O (99.75%, 4.0 g). After the mixture was heated at 80 °C for several hours, it was concentrated under reduced pressure and cooled. Colorless crystals obtained were washed with D_2O and recrystallized from methanol.

α,α-Dideuteriobenzyl phenyl *N-p*-toluenesulfonylsulfilimine(Ia-d_2). A mixture of Ia (4.0 g), dioxane (40 g), D_2O (4.0 g) and NaOH (16 mg) was heated at 70 °C for 1 hr. After the solvents were removed under reduced pressure, the residue was washed with D_2O and recrystallized from methanol.

Kinetics. Exchange in Ia in the presence of NaOH. A mixture of Ia (1.200 g), D_2O (99.75 atom%, 5.0 ml, containing 2.23×10^{-2} mol/l NaOH) and spectroscopic-grade dioxane (100 ml) was allowed to stand at 10 °C. At suitable intervals, 10-ml samples were withdrawn, acidified with acetic acid and evaporated under reduced pressure. The residue was washed with D_2O, dried in vacuum and its NMR spectrum was determined in $CDCl_3$. The rate of exchange was calculated from the decrease in the methylene signal in comparison with the tosyl methyl signal.

Exchange in Ib in pyridine. A mixture of Ib (1.708 g) and pyridine (15.56 ml, containing 5.175 mol/l D_2O) was divided into ampoules (0.5 ml each), which were placed in a constant-temperature bath. Ampoules were withdrawn at suitable interval and cooled with ice. The rate of exchange was calculated from the decrease in the *S*-methyl signal in comparison with the tosyl methyl signal.

Cationic Arylation. VII. Cationic Phenylation and Benzoyloxylation of Aromatic Compounds with Benzoyl Peroxide in Trifluoroacetic Acid

Nobumasa KAMIGATA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received October 9, 1973)

Benzoyl peroxide (BPO) was decomposed in benzene in the presence of trifluoroacetic acid. The thermal reaction is first order in BPO, and the activation energy and activation entropy are 18.7 kcal/mol and −26.3 e. u., respectively. The isomer distributions in the phenylation and benzoyloxylation of substituted benzenes determined indicate that the phenylation and benzoyloxylation are electrophilic substitution reactions. The reaction mechanisms are discussed.

Studies on the decomposition of the arylazo and aryldiazonium compounds revealed that both phenyl radical and phenyl cation can be generated by selecting the suitable reaction conditions from an arylazo or aryldiazo compound.

Benzenediazonium salts spontaneously decompose in aprotic polar solvents, yielding phenyl cation;[1,2] but they form phenyl radical when nitrite ion,[3] hydroxide ion[4] or pyridine[5] is added to the reaction medium. Phenylazo *p*-tolyl sulfone decomposes homolytically basic agents such as pyridine, quinoline, and magnesium oxide are present,[6] while ionic decomposition yielding phenyl cation takes place in the presence of a large excess of trifluoroacetic acid.[7] Phenylazotriphenylmethane (PAT), regarded as a dependable source for the phenyl radical,[8] decomposes heterolytically, yielding phenyl cation when trifluoroacetic acid is added.[9]

Decomposition of benzoyl peroxide (BPO) has been extensively investigated,[10] but the generation of phenyl cation from BPO has not been reported.

In order to determine whether or not phenyl cation could be generated, BPO was decomposed in aromatic solvents in the presence of excess trifluoroacetic acid, and the isomer distributions in the phenylation and benzoyloxylation of substituted benzenes were determined.

In this paper, the results of this investigation are described and the mechanism of the reaction discussed.

Results and Discussion

BPO was thermally decomposed in a mixture of benzene and trifluoroacetic acid, and the reaction was followed by iodometry. The results are summarized in Table 1. The decomposition was found to be of first order in BPO. The rate constant at 70 °C in benzene–trifluoroacetic acid mixture is larger than that in pure benzene at the same temperature (by about 24%), but the extent of acceleration is much less than those in the cases of azosulfone[7] or PAT.[9] The data in Table 1 satisfied the Arrhenius equation, and the activation parameters calculated (E_a=18.7 kcal/mol, $\Delta S^{\neq}$=−26.3 e.u.) are quite different from those reported for the decomposition of BPO in pure benzene (E_a=33.6 kcal/mol, $\Delta S^{\neq}$=13.8 e.u.);[11] the activation energy is much smaller and the activation entropy has a large negative value. The results suggest that the mechanism of the decomposition of BPO in trifluoroacetic acid differs from that in neutral solvents. The products of decomposition of BPO in benzene–trifluoroacetic acid were benzoic acid (95.9%), biphenyl (6.1%), phenyl benzoate (20.2%), a trace of phenol, and some resinous materials. When BPO was decomposed in a mixture of an arene and trifluoroacetic acid, both phenyl benzoate and aryl benzoate were formed. The results indicate that the part of phenyl benzoate observed in the reaction in benzene–trifluoroacetic acid is formed by intermolecular benzoyloxylation, while other parts could be attributed to the intramolecular rearrangement.[12,13]

chlorobenzene, or nitrobenzene by BPO in the presence of trifluoroacetic acid.

The isomer distributions in the phenylation (Table 2) are similar to those observed for the phenylation with phenyl cation (benzenediazonium trifluoroacetate[2]), but differ from those with phenyl radical (*N*-nitrosoacetanilide[14]). The difference is conspicuous in the phenylation of nitrobenzene, in which the nitro group behaves as a *meta* director towards phenyl cation but behaves as an *ortho-para* director fowards phenyl radical.

The partial rate factors in the phenylation of chlorobenzene shown in Table 4 are also similar to those for the phenylation with phenyl cation generated from benzenediazonium tetrafluoroborate,[1] benzenediazonium trifluoroacetate,[2] or phenylazotriphenylmethane in the presence of trifluoroacetic acid,[9] but differ from those for the phenylation with phenyl radical generated from *N*-nitrosoacetanilide[14] or BPO.[15] Isomer distributions and partial rate factors for the phenylation of substituted benzenes suggest that the decomposition of BPO in trifluoroacetic acid is heterolytic and phenyl cation is formed as a reactive intermediate.

Edward, Chang, and Samad reported that phenyl cation was not formed in the decomposition of BPO in the presence of aluminum chloride, since they could not detect chlorobenzene by gas-chromatographic analysis of the reaction mixture.[16] The discrepancy might be ascribed to the difference in the reaction conditions; their reaction medium is heterogeneous while ours is homogeneous.

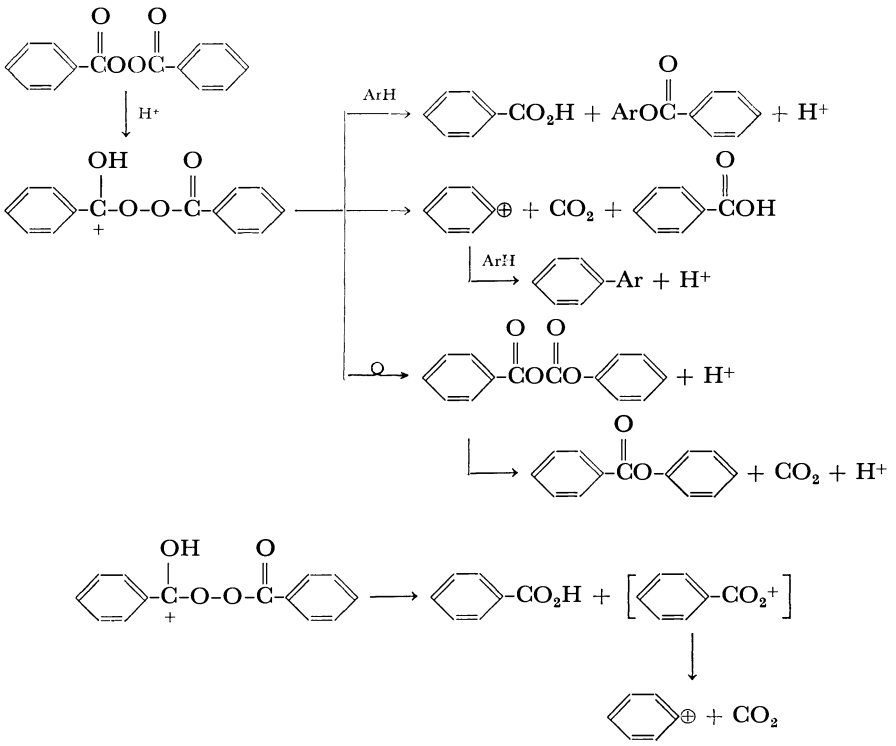
It was reported that benzoyloxylation of aromatic compounds with BPO does not occur unless oxidizing agent such as cupric chloride,[17] oxygen,[18] or iodine[19] is present in the reaction system. However, in our reaction system (when trifluoroacetic acid is present) benzoyloxylation occurred. It is of interest that benzoyloxylation takes place in the absence of oxidizing agents.

The figures of isomer distribution for anisole (Table 3) are similar to those reported for the benzoyloxylation with BPO in the presence of oxygen which has been considered to involve benzoyloxy radical. However, the isomer distributions for anisole with benzoyloxy radical reported vary with the kind of oxidizing agent. The isomer distribution for toluene is similar to that for the benzoyloxylation with BPO–iodine but differs from that with BPO–oxygen. As for the benzoyloxylation of chlorobenzene with benzoyloxy radical, there has been only one report,[20] the isomer distribution differing a great deal from the present. Hitherto, the benzoyloxylation of nitrobenzene was considered to be improbable. The present result (Table 3) is the first case of the benzoyloxylation of nitrobenzene. The fact that it took place mainly at the *meta* position suggests that the benzoyloxylation with BPO in the presence of trifluoroacetic acid is electrophilic.

Table 5 shows the ratio of the total yield of aryl benzoates to that of arylbenzenes, and the yield of phenyl benzoate formed from BPO itself (probably by carboxy-inversion followed by decarboxylation). The ratio of the yield of aryl benzoates to that of arylbenzenes decreases in the order X=MeO, Me, Cl, NO_2. The results indicate that the arenes containing electron-releasing substituents react rapidly with the protonated BPO before decarboxylation or carboxy-inversion takes place. The absence of phenyl benzoate in the reaction product in the benzoyloxylation of anisole suggests that anisole is readily benzoyloxylated before carboxy inversion takes place.

Table 5. Ratio of the yield of $PhCO_2C_6H_4X$ to that of PhC_6H_4X in the decomposition of BPO in C_6H_5X in the presence of CF_3CO_2H

X	OCH_3	CH_3	Cl	NO_2
$\frac{PhCO_2C_6H_4X}{PhC_6H_4X}$	14.3	4.5	1.0	0.2
Yield of $PhCO_2Ph$	0	20	35	14



The following mechanism seems plausible for the decomposition of BPO in the presence of trifluoroacetic acid. The first step is the protonation of BPO, and then the protonated BPO reacts with arenes or undergoes carboxy-inversion.

It is possible that the protonated BPO spontaneously decomposes to benzoic acid and benzoyloxy cation. The benzoyloxy cation reacts with arenes or decomposes to carbon dioxide and phenyl cation, which reacts with arenes yielding arylbenzenes.

The mechanism of the formation of phenyl benzoate from BPO in the presence of trifluoroacetic acid is probably similar to that proposed by Leffler,[12] and Denney, Valega and Denney[13] for the decomposition of BPO in the presence of a Lewis acid.

Experimental

Materials. BPO of Wako Pure Chemical Industries LTD. was purified by recrystallization from chloroform-methanol. Trifluoroacetic acid of Wako Pure Chemical Industries LTD. was used without further purification. Purification of benzene and arenes, and preparation of authentic samples of arylbenzenes were described previously.[1b]

Kinetic Measurement of the Decomposition of BPO in the Presence of Trifluoroacetic Acid. BPO (2.422 g, 10 mmol) was dissolved in 25.0 ml of trifluoroacetic acid, and the solution was diluted to 50.0 ml with benzene ([BPO]=0.2 M). The solution was placed in a constant-temperature bath (regulated within ±0.1 °C). At suitable intervals aliquots (5.0 ml) were withdrawn and subjected to the iodometric analysis of Wagner, Smith, and Peters,[21] using a 0.1 N sodium thiosulfate solution.

Products of Decomposition of BPO in the Presence of Trifluoroacetic Acid. BPO (2.319 g, 9.57 mmol) was dissolved in 25.0 ml of trifluoroacetic acid, and the mixture was diluted to 50.0 ml with benzene. The decomposition was carried out at 60±0.1 °C for 70 hr. The dark gray solution obtained was washed with water and then with a 10% sodium hydrogen carbonate solution. The sodium hydrogen carbonate extracts were acidified by hydrochloric acid, and the benzoic acid liberated was extracted with ether, and determined gravimetrically. The benzene layer was dried over anhydrous magnesium sulfate, and the products were separated by elution chromatography after removal of benzene (Wakogel Q-22 200 mesh; eluant, n-hexane-benzene).

Determination of Isomer Ratios and Partial Rate Factors for the Phenylation and Benzoyloxylation of Arenes with BPO in the Presence of Trifluoroacetic Acid. BPO (2.00 g, 8.26 mmol) dissolved in an arene (200 mmol) and trifluoroacetic acid (40.0 g) was decomposed at 40±0.1 °C for 18 days. The reaction mixture was diluted with ether, washed with water and a 10% of aqueous sodium carbonate solution, and then dried over anhydrous magnesium sulfate. After removal of the ether and about 70% of the unchanged arene, the biphenyl isomers and aryl benzoates in the residue were determined by glc. Details of the glc analysis were described previously.[1b,20]

The Action of Alkali on Inosine. The Formation of 5-Amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide and 9-β-D-Ribopyranosyl Hypoxanthine

Yoshihisa SUZUKI

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received October 8, 1973)

On treating inosine with aqueous dilute alkali hydroxide (pH 10) over 100 °C, three types of reactions have been found to occur in competition with one another: (1) the hydrolysis of the glycosidic bond to give hypoxanthine and D-ribose, (2) the opening of the pyrimidine ring at C-2 to give 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide, and (3) the isomerization of the ribose moiety to give mainly 9-β-D-ribopyranosyl hypoxanthine. The last two are newly-found reactions, and the products were isolated through column chromatography using Dowex 50W. The products are obtainable in yields of 30 and 10% respectively under optimum conditions. Hypoxanthine was cleaved in an alkaline solution to give 5-amino-4-imidazolecarboxamide, and 5′-inosinic acid was supposed to give 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide-5′-monophosphate. The ring-opening reaction at C-2 was not observed for adenosine or guanosine.

In the course of an investigation of the stability of inosine to acid and alkali, 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide (AICA-riboside) and 9-β-D-ribopyranosyl hypoxanthine were obtained when inosine was heated over 100 °C for several hours with aqueous dilute alkali hydroxide (pH 10). The reactions are considered to be useful for preparing those compounds conveniently from inosine.

It is well known that the acid treatment of inosine causes a hydrolysis at the *N*-glycosyl bond to give hypoxanthine and D-ribose. Such a hydrolysis is regarded as an acid-base catalyzed reaction; therefore, the same reaction was expected to take place when inosine was treated with alkali. This expectation was right. However, under alkaline conditions, especially in a dilute alkaline solution (pH 10), two other interesting reactions have been found to take place besides hydrolysis.
