The Crystal Structure of Acridinium Bis(7,7,8,8-Tetracyanoquinodimethanide), $ARD^+(TCNQ)_2^-$ and Some Remarks on the Possibility of a Peierls Distortion of a Linear Chain of TCNQ

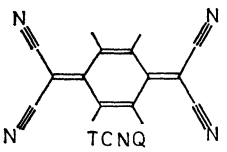
Hayao KOBAYASHI

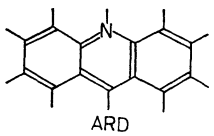
Department of Chemistry, Faculty of Science, Toho University, Narashino, Chiba 275

(Received December 10, 1973)

Crystals of acridinium-TCNQ(ARD(TCNQ)$_2$) are triclinic, space group $P\bar{1}$ with $a=3.841(2)$, $b=13.018(6)$, $c=18.370(12)$ Å, $\alpha=114.32(5)$, $\beta=119.31(4)$, $\gamma=90.57(7)°$ and $Z=1$. ARD and TCNQ are separately stacked to form columns along the a axis. Each ARD column is surrounded by six TCNQ columns. The orientation of ARD is disordered. Intermolecular distance between adjacent TCNQs is 3.246 Å and that between adjacent ARDs is 3.418 Å. The possibility of a Peierls distortion of TCNQ columns was discussed on the basis of the model of one-dimensional distorted lattice. Calculations of free energy show that alternation of intermolecular spacing disappears at Peierls transition temperature, T_p of about 200 K. For $T>T_p$, the one-dimensional band is not split (metallic), while it is split below T_p(semiconductive). The specific heat curve shows a peak at about 180 K and the heat of transition is calculated to be about 130 cal/mol.

The recent reports on the extraordinarily high conductivity of TTF–TCNQ[1] ($\sigma>10^4(\Omega\ cm)^{-1}$(60 K)) shed light on the physical basis of the conduction mechanism of TCNQ salts. Besides TTF–TCNQ, three TCNQ salts have been known, whose temperature dependence of the electrical conductivities shows their metallic nature. They are *N*-methylphenazinium-TCNQ (NMP–TCNQ)[2], quinolinium–$TCNQ_2$ (Q(TCNQ)$_2$) and acridinium–$TCNQ_2$(ARD(TCNQ)$_2$)[3,4].





Crystals of ARD(TCNQ)$_2$ were subjected to X-ray crystal structure analysis to obtain structural information. A simple calculation was made to examine the possibility of a Peierls distortion of TCNQ columns.

Experimental

The crystals of ARD(TCNQ)$_2$ were prepared by a diffusion method, an acetonitrile solution of acridinium hydrochloride and an aqueous solution of Li-TCNQ and LiI being used. The black needles were obtained after a month. The crystals are triclinic. The crystal data are: $(C_{13}H_{10}N)^+(C_{12}H_4N_4)_2^-$, F. W. 588.6; $a=3.841(2)$, $b=13.018(6)$, $c=18.370$ (12) Å, $\alpha=114.32(5)$, $\beta=119.31(4)$, $\gamma=90.57(7)$, Space group, $P1$ or $P\bar{1}$; $U=703.5$ Å^3; $D_m=1.389$ g/cm^3, $D_x=1.389$ g/cm^3; $Z=1$

The intensity data were collected on an automated Rigaku four-circle diffractometer with Mo$K\alpha$ radiation monochromated by a graphite crystal. The $\omega-2\theta$ scan technique was employed. Among the 3149 accessible reflections ($2\theta\leqq55°$), 900 non-zero reflections were observed.

Structure Determination

The trial atomic coordinates were easily deduced from the three-dimensional Patterson synthesis and were refined isotropically by the block-diagonal least-squares method. The space group $P\bar{1}$ was assumed. The nine hydrogen atoms were found on the difference synthesis. Further refinements were carried out in anisotropic mode, however, the thermal parameters of the hydrogen atoms were assumed to be isotropic. The R-value converged to 0.087. The shifts of the parameters were about one fifth of their standard deviations. The weighting scheme adopted was: $w=1$ for $|F_o|\geq5.5$ and $w=0.32$ for $|F_o|<5.5$. The atomic scattering factors were taken from International Tables for X-ray Crystallography.[5] Because the orientation of ARD is disordered, the atomic scattering factor of CN(Table 1) was assumed to be $(f_C+f_N)/2$.

The final positional and thermal parameters are listed in Table 1. The calculated structure amplitudes are compared with the observed values in Table 2.*

Description of the Structure and Discussion

An ARD cation lie at (0,1/2,0) whose site symmetry is $\bar{1}$. Therefore, the orientation of ARD must be disordered because ARD is not centrosymmetric. Similar orientational disorder of cations has been frequently observed in the crystals of highly conducting salts(NMP–TCNQ[6] and Q(TCNQ)$_2$[7]). Fig. 1 shows that TCNQ and ARD are stacked along the a axis to form infinite columns. Each column of cations is surrounded by six columns of TCNQ as found in the crystals of Q(TCNQ)$_2$, which is a so-called complex salt (TCNQ/cation=2). The intermolecular distances of TCNQ and ARD are 3.246 and 3.418 Å, respectively. The least-squares planes and the displacement of the atoms from them are listed in Table 3. The mode of overlap of TCNQ is ring-external bond type as illustrated in Fig. 2. The similar type of overlapping of TCNQ is also found in NMP–TCNQ, Q(TCNQ)$_2$, Rb–TCNQ II,[8] ditoluenechromium (TCNQ)$_2$[9] and TTF–TCNQ[10]. All of them contain columns of monadic units of TCNQ, which indicates that this type of overlapping is common to the salts with monadic units of TCNQ. Short intermolecular contacts are listed in Table 4. A close approach distance of 3.15 Å occurs between the nitrogen atom of

the cyano group of TCNQ and the CN atom(Table 1) of ARD cation. This indicates the possibility of the existence of the hydrogen bond of N–H···N type. Similar contact has been observed in the crystals of $Q(TCNQ)_2$ (3.13 Å).

TCNQ is almost planar but the cyano groups are rotated by about 2.4° around C=C bond from the molecular plane. Interplanar distance of ARD is approximately equal to the normal van der Waals distance.

The bond lengths and angles are shown in Fig. 3. The molecular geometry of TCNQ is that of $TCNQ^{-1/2}$ because only one TCNQ is crystallographycally independent. However, it dose not seem to be practicable to compare the bond lengths with those of $TCNQ^0$ and $TCNQ^-$ because of their large standard deviations.[11] Some rigid-body parameters are given in

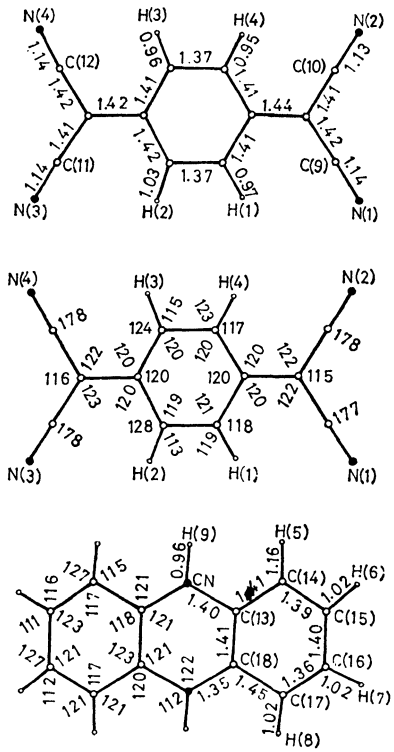

Fig. 3. Bond lengths (Å) and angles (°).
Estimated standard deviations for C–C(N) and C(N)–H bonds are about 0.018 and 0.10 Å, respectively. Those for C–C(N)–C(N) and C–C(N)–H angles are 1.1° and 5°, respectively.

Classification of Columnar Structures of TCNQ. The magnetic susceptibility of alkali metal–TCNQ can be understood on the basis of the one-dimensional band model.[12] The extraordinarily large conductivity of TTF–TCNQ seems to suggest that the band gap produced by the deformation of a linear chain of TCNQ is important for the electrical properties of this salt. Thus it may be useful to make an attempt to interpret the physical properties of TCNQ salts on the basis of one-dimensional band picture. Table 7 shows the relationship between the columnar structures and the electrical conductivities of some TCNQ salts of known crystal structure. The columns composed of monadic, diadic, triadic and tetradic units of TCNQ have been reported. The salts with triadic and diadic units are

a) Anisotropy of R(Ωcm at R.T.) is neglected. E_a is activation energy.[1-3,13,20] b) Rb-TCNQ I and RbTCNQ II are monoclinic and triclinic modification, respectively. c) Activation energy is that of low temperature region. d) The columnar structure of Rb-TCNQ II is similar to that of the salts of group (iii) but Rb-TCNQ I was not classified into group (iii) for convenience, because of its high resistivity. However, attention should be called to the fact that the conductivity of this modification is 10^3 times larger than that of the monoclinic modification.

low conductive(Cs_2TCNQ_3,[14] morpholinium$_2$TCNQ$_3$,[15] Rb-TCNQ I[16]). The salts with tetradic units are intermediately conductive(TEA(TCNQ)$_2$,[17] methyl triphenylphosphonium(TCNQ)$_2$, methyltriphenylarsonium(TCNQ)$_2$,[18] *N*-(*n*-propyl)quinolinium-(TCNQ)$_2$[19]). These facts indicate that the salts which contain two excess electrons in a repeating unit of TCNQ(2e/3TCNQ(Cs_2TCNQ_3), 2e/4TCNQ(TEA-(TCNQ)$_2$) are not highly conductive. Among these salts, those with tetradic units are more conductive. The high conductive salts are constructed from monadic units of TCNQ. The activation energy of the electrical conductivity of semiconductive region is less than 0.04 eV.[1-3,20] This small value suggests that the electrical conduction is not due to hopping process of excess electrons accompanying the deformation of TCNQ skeletons because such a process needs the activation energy more than 0.05 eV ($TCNQ_1^0 + TCNQ_2^- \rightarrow TCNQ_1^- + TCNQ_2^0, E > 0.05$ eV[17]) (a simple consideration is presented in Appendix). This seems to be one example showing the validity of the band picture. According to the band picture, the salts of groups (i) and (ii) (Table 7) are not metallic because they have filled bands (Fig. 4). Whereas, the salts of group (iii) with unfilled bands seem to be metallic and large electrical conductivity can be expected, which is consistent with the large conductivities of these salts. Thus, it may be useful to classify the columnar structure by the band picture.

Some Remarks on the Possibility of a Peierls Distortion of a Linear Chain of TCNQ. Although the columnar structures of the high conducting TCNQ salts indicate that these salts are metallic, they are semiconductive at low temperature. It may be of interest to see why they are not metallic at low temperature. The main reasons seem to be as follows:

(1) Owing to the Coulombic repulsion between two electrons on the same TCNQ site the antiferromagnetic state is considered to be more stable than the paramagnetic state, so that a simple band picture does not seem to be appropriate.[21] The metal-insulator transition of NMP–TCNQ has been analyzed in detail from this point of view.

(2) At low temperature, one-dimensional metallic lattice is unstable and the lattice seems to be distorted periodically with the wave vector of $2k_F$ (Peierls instability of one-dimensional lattice). Therefore, the metallic state may not be realized.[22]

A simple calculation was made in order to examine the possibility of a Peierls distortion of TCNQ columns.

If Peierls transition is realized at T_p, the following situations may result:

(1) At low temperature($T < T_p$), the electronic energy is lowered by the lattice distortion which produces the band gap at $k = k_F$.

(2) As temperature increases($T > T_p$), the free energy of the metallic state(columns with monadic units of TCNQ) becomes lower than that of semiconductive state(distorted columns) because the entropy of the metallic state increases. Accordingly the stabilization energy due to the lattice deformation will not be important.

Figure 5 shows a model of one-dimensional lattice

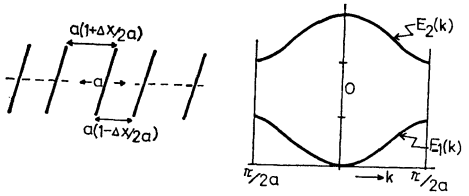

Fig. 5. A model of one-dimensional lattice of TCNQ and its split-band. a is assumed to be 3.25 Å.

of TCNQ. The two interplanar spacings $a(1+\Delta x/2a)$ and $a(1-\Delta x/2a)$ appear alternately. Each TCNQ is assumed to have one excess electron as in the case of NMP–TCNQ, which is usually called as a simple salt. Similar analysis may be applied to complex salts but the mode of alternation of lattice spacing will be more complicated. Δx is a parameter indicating the magnitude of the distortion of the lattice. Of course, real lattices are not one-dimensional, so that Δx may be regarded as a parameter representing a longitudinal modulation of a three-dimensional lattice. The tight-binding model of the band structure was adopted. The band structure is given by[12]

$$E_1(k) = -E_c(g^2 + \cos^2 ak)$$
$$E_2(k) = -E_1(k) \qquad (1)$$

where $E_c = 2(h_1h_2)^{1/2}$ and $g = E_g/E_c$ ($E_g = |h_1| - |h_2|$, h_1 and h_2 are transfer integrals ($|h_1| > |h_2|$)). The transfer integral is estimated from Eq. (2).

$$h = h_0 \exp(-p\Delta x) \qquad (2)$$

where $\Delta x = R - 3.16$ and $h_0 (= 1878$ K) and $p (= 3.91)$ are evaluated using the values employed by Vegter *et al.*[12] ($h(3.48$ Å$) = 538$ K, $h(3.16$ Å$) = 1878$ K). If $\Delta x \neq 0$, band gap is produced by lattice distortion at $k = k_F (= \pi/2a)$. The energy of lattice deformation is $\beta(\Delta x/2)^2/2$ per TCNQ(β=force const.). Free energy is written as

$$F = N\mu - k_B T \sum_\tau \log(1 + \exp(-(\varepsilon_\tau - \mu)/k_B T) + N\beta(\Delta x/2)^2/2 \qquad (3)$$

where $\varepsilon_\tau = E_1(k)$ or $E_2(k)$ and chemical potential μ is determined by,

$$N = \sum_\tau (\exp((\varepsilon_\tau - \mu)/k_B T) + 1)^{-1} \qquad (4)$$

By employing this simple model, Δx which minimizes free energy was obtained numerically at various temperatures. When $\beta = 1.2 \times 10^5$ dyn/cm, the transition indicating Peierls instability was obtained at about 200 K(T_p). Considering the stiffness of the columns of TCNQ, this value does not seem to be unreasonable. The temperature dependence of Δx is shown in Fig. 6a. Δx decreases to zero as temperature increases up to T_p and it is zero when $T > T_p$. Figure 6b shows the specific heat of the electrons which is calculated by use of the values of Δx shown in Fig. 6a. A peak accompanied by Peierls instability is obtained around the temperature about 20 K below T_p. The heat of the transition is about 130 cal/mol. The magnetic susceptibility (Fig. 6c) is temperature independent above T_p($\chi = 9.0 \times 10^{-5}$ emu), indicating the Pauli spin susceptibility.

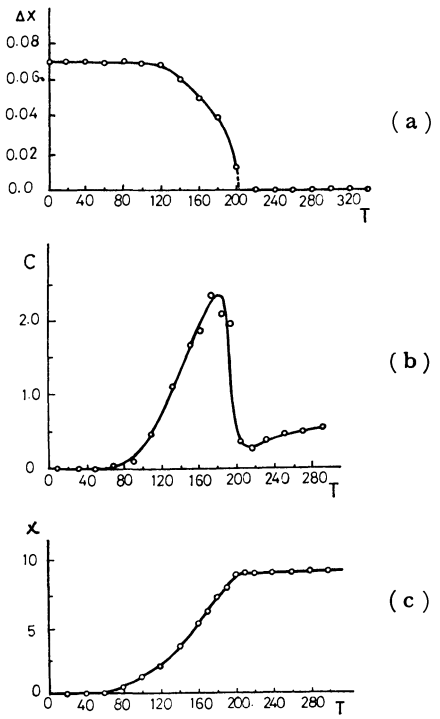

Fig. 6. (a) The temperature dependence of Δx(Å). (b) Specific heat. C is in $0.05k_B$ unit. (c) Magnetic susceptibility ($\chi \times 10^5$).

Thermal expansion of the intermolecular spacing was neglected in this model. Although this model seems to be oversim lified, it may be reasonable to consider that it shows the possibility of a Peierls distortion of high conducting TCNQ salts. Recently, Rice and Strässler have presented an interesting theory of Peierls distortion and Peierls soft mode of a quasi-one-dimensional band-conductor. Starting from a Fröhlich electron-phonon Hamiltonian, they show "how the giant Kohn anomaly in a higher-temperature metallic state can be the precusor of a second-order phase transition to a lower-temperature insulating phase (Peierls insulator)".[23] Zeller *et al.* showed that the evidence of Peierls instability or Kohn anomaly in one-dimensional conductors of type $K_2Pt(CN)_4Br_{0.30}\cdot xH_2O$.[24] The coherence length of the modulated chains is found to be larger than 400 Å. Anomaly in the longitudinal acoustic phonon branch of $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$ was observed by inelastic neutron scattering.[25]

The calculations were performed on the HITAC 8700/8800 computer at the Computer Centre of Tokyo University.

The author would like to express his thanks to Professor Yoshihiko Saito for his keen interest and for his kind permission to use the four-circle diffractometer. He also thanks to Dr. Ichimin Shirotani for valuable discussions.

Appendix

The molecular geometry of TCNQ°(neutral molecule) is different from that of TCNQ$^-$.[11,26] The magnitude of the change in bond lengths corresponds to the change in their bond orders. It is the purpose of this Appendix to see a role of molecular deformation on a hopping motion of an excess electron TCNQ columns.

Table 8. Bond lengths and force constants

	TCNQ°	TCNQ$^-$	$\lvert\Delta r\rvert$	k[30]	m
1	1.344 Å	1.356 Å	0.012 Å	5.7 mdyn/Å	4
2	1.446	1.425	0.021	3.6	8
3	1.371	1.401	0.030	4.8	4
4	1.434	1.417	0.017	4.9	8
5	1.140	1.155	0.015	16.7	8

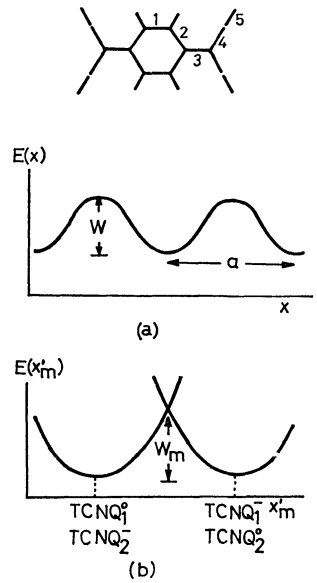

Fig. 7. (a) Potential energy-configuration diagram. (b) The deformation energy of TCNQs for one-electron transfer.

Because the frequency of hopping motion of an excess electron ($\nu_0 \simeq 10^{12}$ s^{-1})[27] is considered to be less than that of molecular vibrations ($\nu_m \simeq 10^{13}$ s^{-1}), the hopping motion of the excess electron may be accompanied by the molecular deformation. Consider an excess electron moving on an adiabatic potential surface $E(x)$ (see § 4 in Ref. 28). $E(x)$ is a periodic potential with a period of a Å. By a simple consideration, following equation can be obtained.[28,29]

$$\sigma = \nu_0 e^{-W/kT} Nne^2a^2/kT \qquad \text{(A1)}$$

where σ is the electrical conductivity, N is the number of chains of TCNQ per unit cross sectional area and n is the electron density on the chain. If $W=0$, Eq. (A1) is identical to that derived by Bloch *et al.* (Einstein equation).[27] σ is maximum when $T=W/k$ (Eq. (A1) is not accurate when $kT \geqq W$ but it may be useful for qualitative discussion). The activation energy may be written as

$$W = W_l + W_m, \qquad \text{(A2)}$$

where W_l and W_m are deformation energies due to lattice and molecular distortions, induced by the excess electron respectively. In most cases, W_m may be approximately equal to the energy of deformation of TCNQ and can be estimated using molecular geometries obtained by X-ray crystal structure analyses (Table 8 and Fig. 7)

$$W_m = \sum_i m_i k_i (\Delta r_i/2)^2/2 \qquad \text{(A3)}$$

where k_i is the force constant of the i-th bond, Δr_i is the change of bond length and m_i is the multiplicity of the i-th bond per

two TCNQs.

W_m is calculated to be 0.059 eV. Therefore, $W(=W_1+W_m)>W_m\simeq 0.06$ eV. Considering that W is larger than kT (=0.025 eV at R. T.), the molecular distortion seems to play important role when an excess electron moves between strongly localized states. Of course, the situation is more complicated in real crystals. Electron-electron interaction may be important. However, concerning the interaction between molecular vibrations and excess electrons, the situation would be similar to that of this simple model to some extent. From this point of view, it may be unlikely that the electric conduction of the highly conductive TCNQ salts is due to the simple hopping mechanism because the activation energies are less than 0.04 eV.[1-3,20]

Some Environmental Effects on the shf Lines in the ESR Spectra of Vanadyl Tetraphenylporphin

Mitsuo SATO and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received October 8, 1973)

The ESR spectra of vanadyl tetraphenylporphin (VOTPP) have been studied in a number of organic matrices, with special attention paid to the resolution of the nitrogen shf lines. The matrices were classified into three groups according to their effects on the resolutions of the vanadium hf lines and of the nitrogen shf lines. In the A-group matrices, the spectra of VOTPP displayed well-resolved hf lines, accompanied by shf splittings; in the B-group matrices, the spectra gave rise to well-resolved hf lines, but without shf splittings, and in the C-group matrices, the hf lines were resolved only poorly. It is suggested that a high dispersion of VOTPP molecules is required for the higher resolution of spectra.

The ESR spectra of vanadyl porphyrin complexes have been studied by many workers,[1-4] but superhyperfine (shf) splittings due to the ligand nitrogen nuclei($I=1$) have been only poorly characterized.

For example, it was shown by O'Reilly[1] and Roberts *et al.*[2] that each of the vanadyl complexes of etioporphyrin, I and II, the mesoporphyrin IX dimethylester, and the deuteroporphyrin IX dimethylester gave the hyperfine (hf) structure due to the vanadium nucleus ($I=7/2$), but none had any observable shf splittings. Kivelson *et al.*,[3] however, found that nitrogen shf lines could be resolved when vanadyl tetraphenylporphin (VOTPP) was diluted in the frozen matrices of $CHCl_3$ and CS_2 although the spectra of VOTPP in other matrices failed to yield any evidence of shf splittings. On the contrary, Assour[4] shortly afterward reported that VOTPP did not display the shf splittings even in the $CHCl_3$ and CS_2 matrices.

More recently, the present authors,[5] studying the spectra of vanadyl phthalocyanine (VOPc) diluted in the matrices of conc. H_2SO_4, α-chloronaphthalene, quinoline, metal-free phthalocyanine, and zinc phthalocyanine,[6] found that the spectra of VOPc can give rise to nitrogen shf splittings in all the matrices investigated. This result was in contrast with those of previous studies of vanadyl porphyrin complex, and stimulated us to reinvestigate the spectra of VOTPP diluted in many kinds of organic matrices, with special attention being paid to the effects of matrix states on the resolution of the shf lines. As a result, we found, contrary to the previous authors,[3,4] that shf lines could be easily detected in almost all the matrices and that their resolution is associated with the homogeneity of the matrix environment of VOTPP. The present paper will report the results of such investigations.

Experimental

Materials. *Vanadyl Tetraphenylporphin (VOTPP)*: Tetraphenylporphin (H_2TPP) and its vanadyl complex (VOTPP) were prepared according to the procedure in the literature[7] and were purified by recrystallization from benzene. The thin-layer chromatograph[8] showed few impurities to be present.

Organic Matrices: The various organic solvents and crystals used as diluents for VOTPP are listed in Table 1. These were all commercial samples either of a reagent grade or of an extra pure grade; all of them except α- and β-methylnapthalene, *o*-dichlorobenzene, triphenylphosphate, and triphenylmethane were further purified, either by distillation or by recrystallization.

Preparation of Diluted VOTPP Samples. *VOTPP in Frozen Organic Solvents*: The VOTPP was dissolved in various organic solvents in a concentration of $1-5\times10^{-3}$ mol/l at room temperature. Each solution was then subjected to rapid cooling with liquid nitrogen to form either a polycrystalline or glassy matrix. In the present paper, the expression "polycrystalline state" will arbitrarily be used to signify the matrix state accompanied by polycrystals which scatter light strongly, while the term "glassy state" indicates the transparent matrix state. The two states were easily distinguishable from one another with the naked eye. The matrix states for the respective frozen solutions are shown in Table 1 in terms of "p" (polycrystalline state) and "g" (glassy state) respectively.

VOTPP in Organic Crystals: The VOTPP samples diluted in organic crystals were prepared in the following way otherwise stated. After the VOTPP had been dissolved in 100—500 times their weight of melts of organic crystals which had been kept at a temperature 50—60 °C above their melting points, the melts were suddenly cooled to 77 K with liquid nitrogen. Although most of the samples formed excellent glasses at this stage, they were later warmed to room temperature. This procedure generally gave finely polycrystalline matrices.

VOTPP in H_2TPP: A chloroform solution containing VOTPP and H_2TPP in a weight ratio of 1 : 200 was poured into a large amount of methanol, causing finely-dispersed precipitates to separate out. The precipitates thus obtained were washed with methanol and dried. The powder was then heat-treated in a vacuum at 300 °C.

Measurements of the ESR Spectra. The ESR spectra were recorded with a JEOL spectrometer, Model JES P-10 (X-band), using 100 KHz field modulation. The magnetic field was calibrated with an ESR marker, MgO: Mn^{2+} powder, supplied by JEOL. The *g*-values were determined using powdered DPPH, with $g=2.0036$ as the standard.

The VOTPP samples diluted in frozen organic solvents were measured at 77 K, while those in organic crystals were measured mainly at room temperature. Degassing was not carried out for all the samples, since the effect of oxygen on the linewidths was preliminarily found to be negligible for VOTPP in the $CHCl_3$, toluene, H_2TPP, and triphenylphosphine matrices.

Results and Discussion

As is summarized in Table 1, the organic solvents and crystals employed as the diluents of VOTPP were

Table 1. Resolution of hf and shf lines in ESR spectra of VOTPP diluted in various organic matrices

	Matrices		Vanadium hf lines	Nitrogen shf lines	Diluted states of VOTPP
	Frozen organic solvent[a]	Organic crystals			
A-Group	Toluene(g) *o*-Xylene(p) *m*-Xylene(p) Xylene(g)[b] α-Methylnaphthalene(g) $CHCl_3$(p) CH_2Cl_2(p) Quinoline(g) α-Chloronaphthalene(p) *o*-Dichlorobenzene(p) *o*-Fluorotoluene(p)	H_2TPP Triphenylmethane *sym*-Triphenylbenzene Triphenylphosphine Triphenylphosphate[d]	well resolved	resolved	well dispersed (homogeneous environment)
B-Group	*p*-Xylene(p) CS_2(p)[c] Tetrahydrofuran(p) α-Methyltetrahydrofuran(g) Pyridine(p) Isoquinoline(p)		well resolved	unresolved	well dispersed (inhomogeneous environment)
C-Group	Benzene(p) CCl_4(p)	Naphthalene β-Methylnaphthalene	poorly resolved	unresolved	aggregated

a) (g): "glassy state", (p): "polycrystalline state". b) A commercial mixture of three isomeric xylenes. c) Many attempts to obtain an evidence of shf splittings in the CS_2 matrix were unsuccessful. This agreed with the result by Assour[4] rather than that by Kivelson *et al.*[3] d) See text.

classified conventionally into three groups according to their effects on the resolutions of the vanadium hf lines and the nitrogen shf lines. In the "A group" matrices, the spectra of VOTPP gave rise to well-resolved vanadium hf lines, accompanied by nitrogen shf splittings; in the "B-group" matrices, the spectra gave rise to well-resolved hf lines, but without any evidence of shf splittings, and finally, in the "C-group" matrices, only poorly-resolved hf lines were observed.

Vanadium hf Lines. As has been reported in the literature,[3,4] the spectra of VOTPP showed, in general, eight hf lines due to the vanadium nuclei ($I=7/2$) in the matrices employed. The present work also showed such a characteristic. However, the apparent linewidth of hf lines was found to depend upon the kind of matrix species, hence causing the degree of hf resolution to differ from one matrix to the other. The linewidths observed in the A-group and B-group matrices were much smaller than those observed in the C-group matrices. Some representative spectra are illustrated in Figs. 1 and 2.

The interpretation of these spectra follows closely the method developed by Sands[9] and Bleaney.[10] The spin Hamiltonian used in the one reflecting the axial symmetry:

$$\mathcal{H} = \beta[g_{//}H_zS_z + g_\perp(H_xS_x+H_yS_y)] + A_{//}I_zS_z + A_\perp(I_xS_x+I_yS_y) \quad (1)$$
$$S = 1/2, \quad I = 7/2$$

where $A_{//}$ and $A_\perp$ are the vanadium hf coupling constants and where the other symbols have their usual meanings. The spectrum shown in Fig. 1 is composed of two distinct set of hf lines that correspond to $g_{//}$ and $g_\perp$; the two weak peaks at the low-field peaks

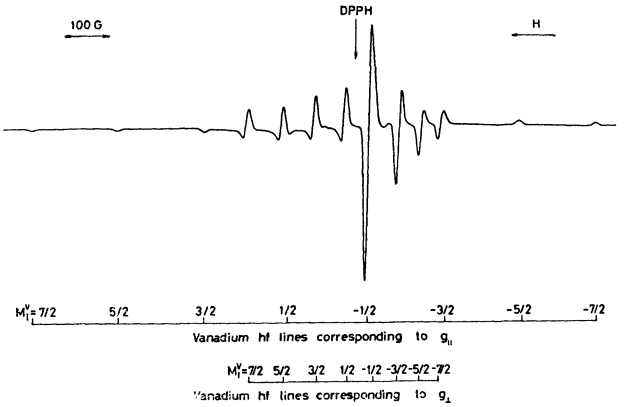

Fig. 1. ESR spectrum typical for VOTPP diluted in the A-group and B-group matrices.
Matrix: Toluene, Concentration of VOTPP: [VOTPP]$=2.9\times10^{-3}$ M, Temperature: $T=77$ K.
(Two sets of vanadium hf lines that correspond to $g_{||}$ and $g_\perp$ are indicated at the bottom of the figure. M_I^V refers to the nuclear-spin quantum number of the vanadium atom and is assigned on the basis of the negative values of hf constants.)

and the three high-field peaks correspond to $g_{//}$, while the strong central peaks are associated with $g_\perp$. However, such a spectral feature is rather obscure in the spectrum shown in Fig. 2 because of its larger linewidth. The spin Hamiltonian parameters obtained from some of the A-group and B-group matrices are summarized in Table 2.

Since a smaller linewidth is usually taken to imply smaller magnetic interaction between the neighboring VOTPP molecules, it may be suggested that VOTPP

TABLE 2. ELECTRON SPIN RESONANCE DATA OF VOTPP DILUTED IN ORGANIC MATRICES

Matrices	$g_{//}$	$g_{\perp}$	$A_{//}$ ($\times 10^{-4}$ cm^{-1})	$A_{\perp}$ ($\times 10^{-4}$ cm^{-1})	Average separation of shf multiplets (G)
Toluene	1.960	1.985	160	56	~2.8

molecules are highly dispersed in the A-group and B-group matrices, without any intermolecular interactions such as association and aggregation. It is interesting to note that the apparent hf linewidth observed in the A-group matrices did not differ much from that observed in the B-group matrices, irrespective of their different effects on the shf resolutions. This aspect will be discussed below.

On the other hand, the spectra observed in the C-group matrices displayed an extraordinarily large linewidth, indicating that strong magnetic interactions between neighboring VOTPP molecules exist in these matrices. Moreover, the spectral line shape was quite similar to that observed for the polycrystalline VOTPP sample, as is shown in Fig. 2. It can, therefore, be presumed that VOTPP molecules are present in either a crystalline or an aggregated form in the C-group matrices. Probably, the aggregation of the VOTPP molecules proceeded during the course of cooling with liquid nitrogen. Actually, microcrystals of VOTPP were observed in the frozen matrix of benzene. Moreover, some finely-dispersed precipitates of VOTPP were perceptible when the frozen CCl_4, naphthalene, and β-methylnaphthalene solutions were thawed.

Nitrogen shf Lines. When ESR spectra were recorded with a small amplitude of the field modulation such as 0.5 G, some of the vanadium hf lines were further split into shf lines due to the magnetic interaction between the V^{4+} electron and the pyrrole nitrogens. Typical examples are illustrated in Figs. 3 and 4. The matrices which gave rise to shf splittings are listed in Table 1, where it is apparent that the great majority belong to the A-group. This result might be compared with the previous results[3,4] which showed that the spectra of VOTPP seldom gave rise to shf splittings.

Judging from the spectral features of the vanadium hf lines in various matrices, it seems very likely that a high dispersion of VOTPP molecules through the matrices is essential for the resolution of shf lines, although the state of dispersion alone would not be sufficient to meet the requirements.

In the A-group matrices, the best resolution of shf lines was recorded from the $CHCl_3$ matrix. It can be seen from Fig. 3 that each of the hf lines is further split into shf multiplets, which are apparently composed of nine equally-spaced lines of varying intensities. Their average separations were 2.9 and 2.7 gauss for the parallel and perpendicular hf components respectively, indicating that the nitrogen shf interaction is nearly isotropic.

The shf Hamiltonian ($\mathscr{H}_{shf}$) describing the system of this sort can generally be expressed as.[11]

$$\mathscr{H}_{shf} = \boldsymbol{S}\cdot\sum_{n}\boldsymbol{A}_n\cdot\boldsymbol{I}_n \qquad (2)$$

where $\boldsymbol{A}_n$ and $\boldsymbol{I}_n$ refer to the shf tensor and the nuclear

spin operator for the ligating nitrogen atom, n, respectively. Since the shf tensors, $\boldsymbol{A}_n$, have different functional forms for different nitrogen atoms in terms of the molecular coordinates (x,y,z), it is a rather complicated problem to derive the resonance field from Eq. (2). However, if one assumes that the shf tensors are isotropic and that the four nitrogen ligands are magnetically equivalent, Eq. (2) can simply be rewritten as:

$$\mathscr{H}_{\text{shf}} = a^{\text{N}}(S_z I_z^{\text{N}} + S_x I_x^{\text{N}} + S_y I_y^{\text{N}}) \quad (3)$$

where a^{N} represents the isotropic shf constant and where I_z^{N}, I_x^{N}, and I_y^{N} are the sums of the nitrogen nuclear-spin components in the z, x, and y directions respectively.

One can, then readily obtain the predicted spectrum in which each of the vanadium hf lines is split into 9 shf components, with an equal separation of a^{N} and with the intensity ratio of 1 : 4 : 10 : 16 : 19 : 16 : 10 : 4 : 1. The shf multiplets observed on the hf components other than that corresponding to $M_{\text{I}}^{\text{V}}=-1/2$ are, in fact, consistent with this expectation, with the isotropic shf constant being approximated as $a^{\text{N}}=2.8$ G. The observation of at least 13 shf components on the $M_{\text{I}}^{\text{V}}=-1/2$ hf line is not in conflict with the above prediction either, since the $M_{\text{I}}^{\text{V}}=-1/2$ hf line exhibits a "polycrystalline anomalous line" which has previously been discussed.[12]

It was noted that the resolution of the shf multiplets is rather poor except for the $CHCl_3$ matrix in the A-group matrices. In these matrices, the M_{I}^{V} values of the hf components with resolved shf multiplets were also found to differ from those observed in the $CHCl_3$ matrix. As can be seen from Fig. 4, the shf multiplets have a tendency to be resolved not on the parallel hf components but the perpendicular hf components.

Although the accurate determination of the shf constant was difficult due to its poor resolution, the average separation of the shf lines was estimated to range from 2.6 to 3.0 G in the matrices of toluene, xylene, H_2TPP, CH_2Cl_2, and triphenylphosphine. If Eq. (3) is valid in these cases, the above values of 2.6—3.0 G can be regarded as a^{N}, in agreement with the the shf constant, $a^{\text{N}}=2.8$ G, obtained for the $CHCl_3$ matrix.

It follows from the above arguments that the matrices have little effect on the magnitude of the shf constant, while they play a significant role in the resolution of shf multiplets.

Environmental Effect on the Resolution of shf Lines.

While the solution of $CHCl_3$ or CH_2Cl_2 was polycrystalline by itself at 77 K, the mixed solution of $CHCl_3$–CH_2Cl_2 (1 : 1 volume ratio) exhibited an excellent glassy state when it was subjected to rapid cooling with liquid nitrogen. The shf lines observed in these different matrix states are compared in Fig. 5. It can clearly be seen from Fig. 5 that the mixed $CHCl_3$–CH_2Cl_2 solution gives no appreciable shf splittings, while both solutions show well-resolved shf lines.

It might be considered, therefore, that VOTPP molecules in the $CHCl_3$–CH_2Cl_2 glass have slightly different g-values and hf coupling constants, hence causing the apparent absence of shf splittings in the observed spectrum.

Triphenylphosphine formed an excellent glass at 77 K when the molten sample was subjected to sudden

cooling with liquid nitrogen; the resulting glassy matrix was, however, converted into a polycrystalline one on warming to room temperature. Such a polycrystalline matrix was also formed upon cooling the molten triphenylphosphine slowly to room temperature. The ESR spectra obtained in these glassy and polycrystalline matrices are illustrated in Fig. 6, from which it can also be seen that the shf lines are resolved in the polycrystalline matrix rather than in the glassy one.

On the other hand, a commercial mixture of three isomeric xylenes was frozen in a glassy state at 77 K, each of the *o*-, *m*-, and *p*-xylenes was polycrystalline at 77 K. The order of the increasing resolution of the shf lines in these matrices was; xylene (mixture of the three isomers) > *o*-xylene $\simeq$ *m*-xylene > *p*-xylene. This is in marked contrast with the $CHCl_3$-CH_2Cl_2 systems.

For triphenylphosphate, both the glassy and polycrystalline samples were prepared in the same manner as triphenylphosphine. In this case, however, the resolution of the shf lines in the polycrystalline matrices was found to depend upon the method of sample preparation. When the polycrystalline matrix was prepared by cooling the molten triphenylphosphate to room temperature, the spectrum of VOTPP exhibited poorly-resolved hf lines without any shf splittings like that shown in Fig. 2. This indicates that the aggregation of VOTPP molecules takes place in the course of slow cooling. On the other hand, in the polycrystalline matrix obtained by warming the frozen glassy sample to room temperature, the shf lines were clearly detected. However, this spectrum changed from a well-resolved type into a poorly-resolved one with the lapse of time, suggesting that VOTPP molecules can diffuse through the polycrystalline triphenylphosphate matrix to form an aggregated state.

To summarize briefly, there is much evidence to show the importance of environments in the ESR spectra of VOTPP. A homogeneous dispersion of VOTPP molecules in a given matrix usually yields a highly-resolved spectrum. However, the method of obtaining such a dispersed state sensitively depends on the kind of matrix species and the mode of sample preparation.

Studies of the ESR Spectra of Semiquinone Anions of Xanthene Dyes. Variation in the Linewidth of the Phloxine Semiquinone Anion with the Temperature and the Viscosity in Protic Solvents

Kazuie KIMURA and Masashi IMAMURA

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received October 13, 1973)

The ESR linewidths of semiquinone anions of xanthene dyes in alkaline protic solvents were studied as functions of the temperature and the viscosity. It was found that the linewidths of phloxine semiquinone, the ESR spectra of which show three hyperfine lines due to two equivalent protons, decrease with a decrease in the temperature or an increase in the viscosity of the solvents, and vary unimolecularly. Such a variation can not be explained either by a usual "chemical exchange" process between different states or by intramolecular motion. We propose that the linewidths may be due to the modulation of the hyperfine coupling constants of H atoms; the modulation results from the dissociation and/or distortion of the hydrogen bonds.

We previously reported the formation of stable semiquinone anions of xanthene dyes by the γ-irradiation of degassed alkaline alcoholic solutions, and the photo-dehalogenation reaction of the halogenated ones.[1]

In the course of ESR studies of these semiquinone anions, we have found that the linewidths of the ESR spectra of some of them, *e. g.*, phloxine semiquinone (X=Br and Y=Cl, in Fig. 1), decrease without any further splitting of their three lines with a decrease in the temperature or an increase in the viscosity of solutions, and that the process of sharpening is pseudo-unimolecular.

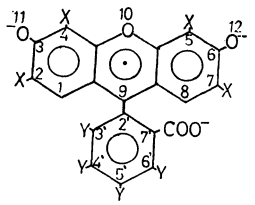

Fig. 1. Structure of xanthene-dye semiquinone anion.

The linewidth variation can not be explained in terms of a "chemical exchange" process between different states or the relaxation matrix theory developed by Freed *et al.*[2]

The present results seem to suggest that hydrogen bonding between semiquinone anions and solvent molecules plays an important role in the variation of linewidths. This paper will describe the results obtained with phloxine semiquinone and the discussion leading to the conclusion put forward above.

Experimental

Materials. The xanthene dyes were recrystallized three times from slightly alkaline methanolic solutions. The alcohols and water were purified by distillation as has been described previously.[1] The glycerol was distilled *in vacuo*. Extra pure lithium, sodium, and potassium hydroxides were used without further purification.

Preparation of Semiquinone Solutions. Xanthene semiquinones (S) were prepared by the ^{60}Co γ-irradiation of degassed alkaline solutions of xanthene dyes (D) in alcohols or in water containing small amounts of methanol at room temperature. The reduction of D proceeds by these reactions:

$$RCH_2OH \xleftarrow{r\text{-}\wedge\!\vee\!\wedge} e^-_{sol}, \dot{H}, \dot{R}CHOH$$

$$D + e^-_{sol} \longrightarrow S$$

$$D + \dot{H} \xrightarrow{OH^-} S + H_2O$$

$$D + \dot{R}CHOH \xrightarrow{OH^-} S + RCHO + H_2O$$

This method gives S in a higher yield and with fewer by-products than other methods, such as chemical or photochemical reduction. The concentration of S produced was adjustable by controlling the initial concentration of the dye and the γ-ray dose, and was determined spectrophotometrically. The semiquinone solutions were so stable in the dark that no detectable change in the concentration was found during ESR measurements.

The ESR spectra were recorded by using a JEOL JES-X spectrometer at various temperatures between -100 and 60 °C with an accuracy of $\pm$0.5 °C. The temperature of the cavity was carefully kept constant by circulating thermostated water through a pipe around the cavity. The magnetic field was calibrated by means of proton resonance.

Results

The Lineshape and Temperature Dependence of the Linewidth. Phloxine semiquinone gives three well-resolved hyperfine lines with an intensity ratio of 1 : 2 : 1 in the temperature range of -80—$+60$ °C. They have the Lorentzian shape and equal linewidths, independent of the total nuclear spin quantum number, M_1, in the temperature range of -50—$+5$ °C. Below -60 °C, the lines were broadened heterogeneously and were dependent on M_1, indicating "anisotropic broadening."

On the other hand, as is shown in Fig. 2, the linewidth of 1.02$\pm$0.02 gauss at 23 °C in methanolic solutions (T/η=510 K/cp) decreases with a decrease in the temperature to attain a minimum of 0.4$\pm$0.02 gauss at -58 °C (T/η=80 K/cp). No such a variation in the linewidth has been previously reported, and so detailed experiments were focused on this point.

Effects of Solutes. If alkali metal ions play an important role in some such a manner as ion-pair formation or any "chemical exchanges," the concentration and the kind of metal ion should affect the linewidth variation with the temperature. However, no

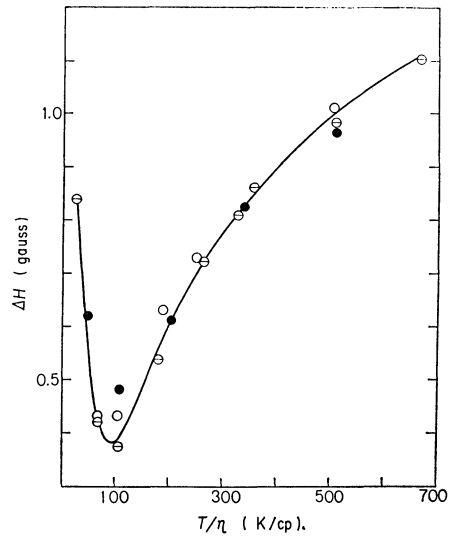

Fig. 2. Temperature dependence of the linewidth of phloxine semiquinone anion in alkaline methanolic solutions: Concentrations of the semiquinone and unreduced phloxine are: ⊖ [2.9×10^{-4}, 6.4×10^{-5} M; ○ 4.2×10^{-5}, 1.4×10^{-5} M; ● 1.3×10^{-3}, 5×10^{-3} M. [KOH], 0.1 M.

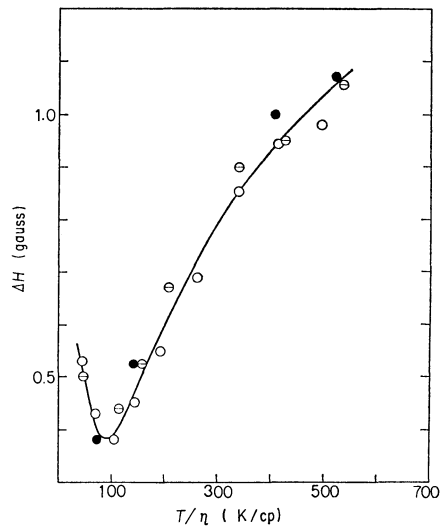

Fig. 3. Variation of linewidth with T/η at various concentrations of KOH in methanol: ○ 0.2 M, ⊖ 0.04 M, ● 0.005 M. Concentration of the semiquinone is about 1.5×10^{-4} M.

essential change in the curve was observed over a range of KOH concentrations (Fig. 3). The variation in the linewidth with T/η was compared for LiOH, KOH, and NaOH solutions, but no detectable differences were observed among these systems, as is shown in Fig. 4. Therefore, it may be concluded that the effect of the metal ions on the linewidth is negligible in the present case; any effect on the linewidths by protons is also ruled out.

Neither the dependence of the semiquinone concentration on the linewidth up to 1.3×10^{-3} M, nor the effects of unreduced parent phloxide $D(5\times10^{-5}$—5×10^{-3} M) on the linewidth of the semiquinone (10^{-4} M), were observed between 35 and −75 °C. (Fig. 2).

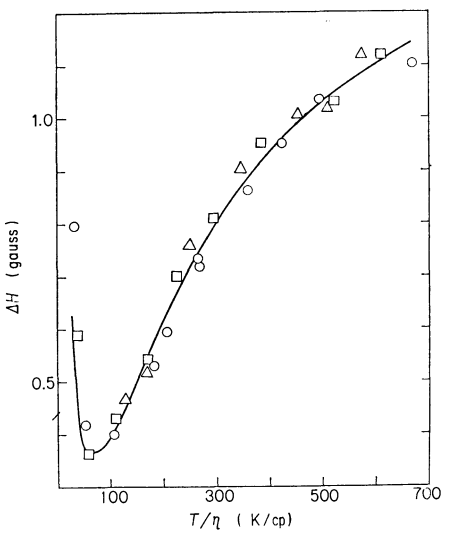

Fig. 4. Variation of linewidth with T/η in the 0.05 M solutions of KOH (○), NaOH (□), and LiOH (△).

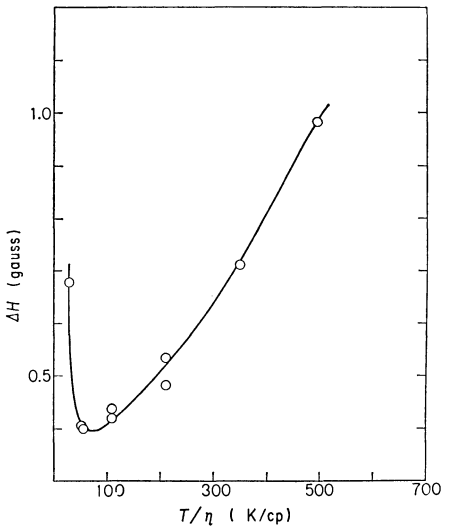

Fig. 5. Dependence of linewidth on solvent viscosity at 22°C. The viscosity was varied by changing the concentration of glycerol (10, 20, 30, 40, and 50 vol%) in methanolic solutions.

It is apparent, therefore, that the variation in the linewidth proceeds unimolecularly.

Dependence of the Linewidth on the Viscosity of a Solvent. Since the viscosity of the solution varies with the temperature, measurements were made of the net viscosity effect on the linewidth, using solutions of various compositions of glycerol in methanol at room temperature. The linewidths at 22 °C are shown in Fig. 5 as a function of T/η for mixtures containing 10, 20, 30, 40, and 50 vol% glycerol in methanol, where the concentration of the semiquinone was kept constant in the range of 7.2×10^{-5}—1.42×10^{-4} M. Figure 5 shows that the increase in viscosity caused a decrease in the linewidth of about 0.6 G, which is the same amount of variation as when the temperature was lowered; it also shows that the linewidth has a minimum value of

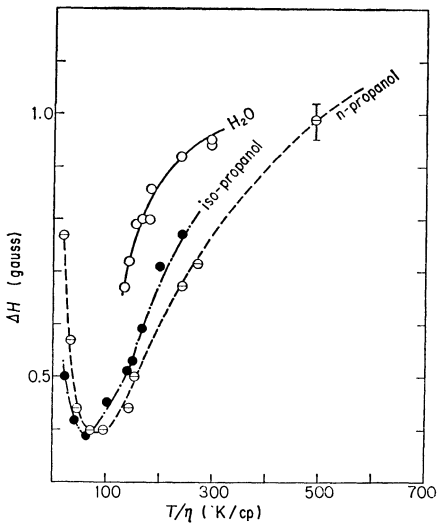

Fig. 6. Variation of linewidth with T/η in 1-propanol (⊖), 2-propanol (●), and aqueous solutions. (○).

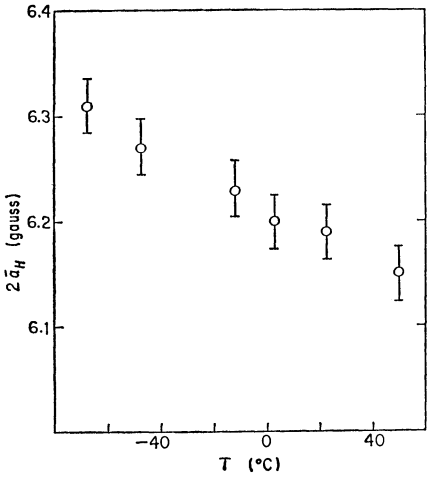

Fig. 7. Temperature dependence of hyperfine coupling constants of protons. The $2a_H$ means the sum of the coupling constants of two equivalent protons.

about 0.4 Gauss at T/η=80 K/cp. These results indicate that the linewidth is strongly dependent on the viscosity of the solvent, or that the linewidth variation is due to the motion of the solvent molecules. The temperature dependence of the linewidth mentioned above may also be explained as being due to the motion of solvent molecules rather than to an intramolecular motion of the semiquinone.

Effect of Solvents. The ESR spectra of the phloxine semiquinone were also taken in other protic solvents: 1-propanol, 2-propanol, and water. The linewidths in three solvents were 0.46, 0.51, and 0.96 Gauss respectively at room temperature. However, the plots of the linewidth against T/η are similar to that in the methanolic solution except for slight differences in curvatures, as is shown in Fig. 6. Since semiquinones were found to be very unstable in aprotic solvents or even in alcoholic solutions containing only a few tens vol% of aprotic solvents, no experiment has been carried out.

Dependence on the Temperature of Hyperfine Coupling Constants of Two Protons in Xanthyl Ring. In Fig. 7 is shown the temperature dependence of a sum of the hyperfine coupling constants of two protons (2a in Fig. 7) in a methanolic solution. For the other solvents mentioned above, a similar dependence was also obtained within the range of experimental errors.

Measurements at the Q-band were also carried out at room temperature, but no difference from the above results at X-band was observed in either the linewidth or the line-shape. Therefore, it may be concluded that the linewidth is not dependent on the static magnetic field, H_0.

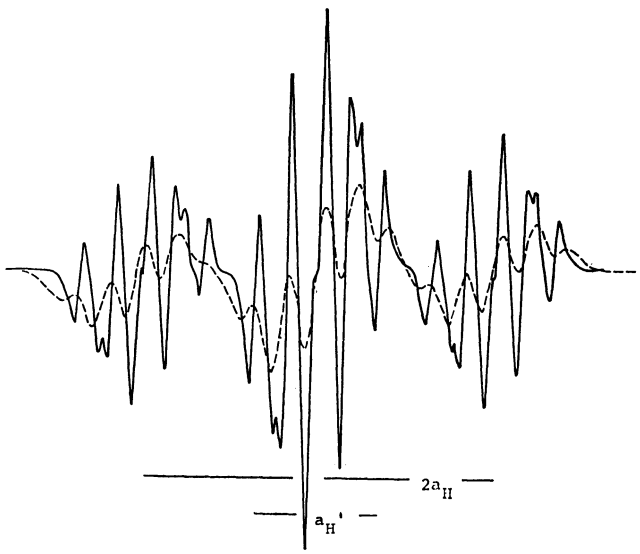

Fig. 8. ESR spectra of eosine semiquinone anion: ——, 24 °C; ----, −54 °C.

ESR Spectra of Eosine Semiquinone. The linewidths of eosine semiquinone (X=Br and Y=H) increase with a decrease in the temperature, while the total hyperfine coupling constants of the four hydrogen atoms on the 9-phenyl ring increase slightly (Fig. 8 and Table 1). From the spectral simulation, it was found that large three groups with an intensity ratio of 1 : 2 : 1 are ascribed to two equivalent protons at the 1- and 8-positions on the xanthyl ring. Each group is further split into lines with an intensity ratio of 1 : 1 : 3 : 3 : 3 : 3 : 1 : 1 by three nearly-equivalent protons with hyperfine coupling constants of 0.3 and by one proton

TABLE 1. TEMPERATURE DEPENDENCE OF HYPERFINE COUPLING CONSTANTS OF EOSINE SEMIQUINONE

Temp. (°C)	24.0	4.0	−17.0	−31.0	−43.3	−54.4
a_H' (G)	2.3_0	2.3_0	2.3_4	2.3_7	2.4_0	2.4_9
$2a_H$ (G)	6.4_4	6.4_4	6.5_2	6.6_0	6.4_7	6.5_2

of 0.2 G on the 9-phenyl ring.[1]

However, the MO calculation shows that the spin densities at the 3′- and 5′-positions on the 9-phenyl ring are much larger than those at the 4′- and 6′-positions, and that the latter two are nearly equivalent. These discrepancies must be due to the calculation being made for a fixed molecular structure. Therefore, the observed coupling constants are thought to be the averaged ones under the hindered rotation of the 9-phenyl ring.

Discussion

The experimental results on the linewidths of phloxine semiquinone may be summarized as follows. The linewidth decreases with a decrease in the temperature or an increase in the solvent viscosity, while no further splitting of the lines is observed and their Lorentzian shapes are kept. The variation in the linewidth is unimolecular, strongly dependent on the motion of the solvent molecules and independent of the H_0.

The linewidth variation has mostly been explained by a usual "chemical exchange" process. However, this process can not be applied to the present results as will be described below. According to the simple exchange process between two different states, A and B, when the exchanging rate is high, the lines of a Lorentzian shape should appear between each pair of A and B. As the rate is slowed down, however, the lines are broadened, deviate from Lorentzian, and finally separate into Lorentzian lines intrinsic to A and B, the linewidths of which decrease. Similar behavior may be expected when there are three or four different states.[3]

Other processes which are worth further consideration may be (1) Orbach effects,[4] (2) the spin-rotational coupling,[5] (3) the collapsing of hyperfine lines of Cl atoms, and (4) the modulation of the hyperfine coupling constants of H atoms by interaction with the solvent molecules.

For the (1) process to be appreciable, the phloxine semiquinone should have energy levels adjacent to and above the ground Zeeman levels. However, its electronic absorption band at 415 nm is sharp, indicating that the (1) process does not apply.

The (2) process does not apply either, because the linewidth calculated by Kivelson's equations[5] is only about 5×10^{-6} gauss.[6]

According to the (3) process, the linewidth should be dependent on the spin density on the 9-phenyl ring. It may be plausible that, with an increase in the temperature, the xanthyl and the 9-phenyl rings of phloxine semiquinone may approach a coplanar structure and that, therefore, the spin density on the latter ring may increase. This might not be inconsistent with the linewidth variation in the present results. However, the roughly estimated linewidth of the collapsed hyperfine lines of four Cl atoms is about 0.18 gauss at room temperature,[7] six times smaller than the observed value, indicating that the (3) process is not appropriate for explaining the results. It is also noted that the linewidth caused by the quadrupole effects of Cl atoms is generally smaller in a liquid state, and that the effects of the temperature and the viscosity are opposite to the present results.[9]

Now, therefore, we should like tentatively to propose the (4) process as the most plausible explanation for the present results. The semiquinone anion of xanthene dye must form hydrogen bonds at the anionic oxygen atoms ($-O^-$) of the 11- and 12-positions. This induces the variation in the spin densities, especially at the 1- and 8-positions, which has been demonstrated experimentally[10] and from the MO calculation.[11] Therefore, in view of the fact that the linewidth is strongly dependent on the motion of the solvent molecules, it seems plausible that the modulation of hydrogen bonds is a source of the linewidth.

As the temperature increases, the frequency of (a) the dissociation and/or (b) the ligand exchange of hydrogen bonds will increase. Suppose that, in the case of (a), the hyperfine coupling constants of the hydrogen-bonded form are modulated by its dissociation that the dissociated (anionic) form has no sufficient lifetime to be observable in ESR. Then the transverse relaxation time, $T_{2,\mathrm{obs}}$, may be given as below, intuitively by analogy with the lifetime broadening or by solving the modified Bloch equations by assuming that the dissociated form has a short lifetime:

$$T_{2,\mathrm{obs}}^{-1} = T_2^{-1} + \tau^{-1} \tag{1}$$

where τ is the lifetime of the hydrogen-bonded semiquinone and where T_2 is the transverse relaxation time when no dissociation of hydrogen bonds occurs. If, on the other hand, the lifetime of the dissociated form is long, the process may be regarded as a usual "chemical exchange" process, which has already been ruled out.

In the case of (b), a simple exchange of solvent molecules in the ligand causes neither line broadening nor sharpening, since no difference in the spin state is expected before and after the exchange. Therefore, we assume that, in the ligand exchange of the hydrogen-bonded form, there is an exchange intermediate which coordinates with excess solvent molecules. Such an intermediate may have a very short transverse relaxation time, since it is easily and frequently distorted by the collisions of solvent molecules. Therefore, the relaxation time in the hydrogen-bonded form is given by the same equation as has been given above from the modified Bloch equations. This equation is based on a similar one reported by McConnell[12] and Johnson, Jr.[13] for the linewidth of the broad-line NMR of diamagnetic ions undergoing electron-exchange reactions with their paramagnetic ions.

The temperature effect of the linewidth being sharpened with a decrease in the temperature without any further splitting can be explained by Eq. (1).

The decrease in the linewidths with a decrease in the temperature, which does not affect the Lorentzian shape and which proceeds unimolecularly, implies that the relaxation time can be represented by this equation:

$$\Delta H = \hbar(\sqrt{3}g\beta T_2)^{-1} \propto \tau^{-1}$$

The τ^{-1} may be given by $\tau^{-1}=A\exp(\Delta E/RT)$; therefore, as is obvious from Eq. (1), $T_{2,\mathrm{obs}}^{-1}$ may also be given by a similar equation when T_2 can be neglected. In fact, the plots of $\ln T_{2,\mathrm{obs}}^{-1}$ *vs.* $1/T$ are linear, from which

activation energies of 2.1, 3.1, and 2.4 kcal/mol were obtained for methanol, 2-propanol, and aqueous solutions. Each of these values is very close to the activation energy of the self-diffusion of each solvent, suggesting a strong dependence of the linewidth upon the viscosity of the solvent.

The lack of nuclear-spin dependence of the linewidth may be explained on the basis of the fact that the formation of hydrogen bonds at the two $-O^-$ sites should be at random, so the spin densities on the 1- and 8-positions are occasionally in "uncorrelated conditions".[2] (*Cf.* Ref. 11)

On the other hand, it is noted that, in the eosine semiquinone, the 9-phenyl ring undergoes a hindered rotation, and the resulting modulation of the hyperfine coupling constants of the H atoms on the 9-phenyl ring is perhaps a principal source of the linewidth, for the modulation must be much larger than in the cases of (a) and (b).

The authors are grateful to Professor Keiji Kuwata, Professor Shunichi Ohnishi, Dr. Masamoto Iwaizumi, and Dr. Tadamasa Shida for many helpful discussions and suggestions. They also wish to express their thanks to Dr. Suehiro Iwata for the use of his computer programs for the MO calculations.

Anomalous Light Scattering by Poly(2-vinylpyridine) in Methanol

Noriyuki SAKAMOTO, Masafumi YOSHIDA*, and Shizuo ARICHI*

Department of Chemistry, Faculty of Literature and Science, Shimane University, Nishikawatsu-cho, Matsue 690

**Chemical Laboratory, Department of General Education, Kumamoto University, Kurokami-2-chome, Kumamoto 860*

(Received October 15, 1973)

The light scattering of a poly(2-vinylpyridine) solution was measured under various conditions. In solvents such as methanol, ethanol, 2-propanol, 2-butanone, and pyridine, anomalous Zimm plots with an upward inflection at lower angles were observed. This anomaly was especially striking in methanol, in which the dissymmetry coefficient was frequently less than unity. Systematic investigations carried out with methanol as a solvent revealed that; (1) the anomaly does not depend appreciably on the concentration or tacticity of the polymer, the temperature, or the wavelength of the incident light; (2) the anomaly diminishes with an increase in the molecular weight of the polymer; (3) the anomaly disappears upon the addition of dry ammonia of 10^{-2} mol/l or more in methanol, and (4) similar perturbed Zimm plots are realized by the addition of a trace amount of hydrochloric acid or sulfuric acid in a methanol solution of a higher-molecular-weight fraction which showed a normal Zimm plot in pure methanol. The anomaly can not be explained in terms of the effects of the optical anisotropy of the polymer segment, but the external interference arising from the non-random arrangement of the polymer in solution may contribute to it.

Recently several reports on the anomalous light-scattering behavior of solutions of vinylpyridine polymers have been published. Miura *et al.*[1] reported an anomaly with poly(2-methyl-5-vinylpyridine) in methanol; Cashin,[2] with poly(2-vinylpyridine) in nitromethane, and Fuoss *et al.*[3] suggested the existence of some trouble in the measurement of the light scattering of poly(4-vinylpyridine) in absolute ethanol. In the course of studies of the poly(2-vinylpyridine) solution one of the present authors[4] showed in brief the existence of the anomaly in several solvents. More recently, Seely[5] reported on the anomaly with poly(4-vinylpyridine) in nitromethane. However, no reasonable explanation of the origin of the anomaly of the light scattering of the poly(vinylpyridine) solution has yet been given. On the other hand, the similar anomaly of the light-scattering behavior of several other polymers has been clarified by some theoretical considerations.[6–10] In this paper we will present the results of our experimental investigation of the light-scattering behavior of the poly(2-vinylpyridine) solution, especially when the measurement is carried out in methanol. The results will be discussed in terms of the theories proposed for the other polymers.

Experimental

Atactic Poly(2-vinylpyridine). The polymerization, fractionation, and characterization of atactic poly(2-vinylpyridine), our sample number A-2 ($M_w=3.4\times10^4$), E-2 (1.20×10^5), G-2 (2.19×10^5) and I-2 (3.11×10^5), were described in a previous paper.[4] Three other higher-molecular-weight fractions, P-4 (1.1×10^6), P-3 (1.6×10^6), and P-2 (4.0×10^6), were obtained by redox polymerization using potassium persulfate and sodium bisulfite in an acidic aqueous solution of the monomer[11] and by subsequent fractionation.[12] The $2U_0$ sample (3.30×10^5) was obtained by thermal polymerization in an ampoule without any initiator or diluents, and was then purified by repeated precipitation.

Isotactic Poly(2-vinylpyridine). The polymerization and purification of isotactic poly(2-vinylpyridine) were carried out in the same way as in a previous paper.[13] The polymres were fractionated by the precipitation method, using the benzene-ligroin system. The tacticity was checked by the methods of X-ray diffraction, IR spectrum, melting point, and insolubility in hot acetone.[13] The fourth fraction, S4F-4 (3.25×10^5), was mainly used in this study.

Solvent. All the solvents used in this study were dried by the standard methods[14] and were fractionally distilled before use. The middle fractions of each solvent were retained for use in the experiment described below.

Light-scattering and Viscosity. All the apparatus and procedure for the measurements of the light scattering and viscosity were approximately the same as those previously described by one of the present authors.[4] Measurements were made of the intensity of scattered light in eleven different directions, ranging from 30° to 150° with unpolarized or polarized blue light (436 mμ) or green light (546 mμ) of Hg. The correction for the backward reflection was applied throughout the measurements.[15] The solutions were ordinarily optically purified by filtering the solution by means of double membranes of "mittel" or "fein" supplied by the Sartorius Co., Göttingen, West Germany.

Results and Discussion

The fundamental equation of the light scattering of the polymer solution is expressed,[16] as is well known, by:

$$Kc/R(\theta) = 1/[M_wP(\theta)] + 2A_2c$$
$$= 1/M_w + (16\pi^2/3\lambda^2M_w)\langle s^2\rangle\sin^2(\theta/2) + 2A_2c$$

where K is the optical constant; c the concentration expressed by g/ml; $R(\theta)$, the reduced intensity of scattering at the angle θ; M_w, the molecular weight of the polymer; $P(\theta)$, the factor arising from the internal interference of scattered light in the polymer molecule; A_2, the second virial coefficient; λ, the wavelength of the incident light, and $\langle s^2\rangle$, the mean square of the radius of gyration of the polymer chain.

For random coils of linear polymers, straight lines are obtained to a good approximation if $Kc/R(\theta)$ is plotted against $\sin^2(\theta/2)$; therefore, in the so-called Zimm plots (plots of $Kc/R(\theta)$ *vs.* $\sin^2(\theta/2)+kc$, where k is the arbitrary constant) the initial slope of the extrapolated straight line at $c=0$ corresponds to the radius

In addition, the Zimm plots of the light scattering of the standard polystyrene, MS–I,[17] in benzene was a normal one, from which no inflection of lines for $Kc/R(\theta)$ *vs.* $\sin^2(\theta/2)$ is observed; the molecular weight as estimated from the plots is 2.20×10^5, which is in accord with the average value of 2.53×10^5 reported in the literature.[17] Furthermore, the results of our measurements of the absolute scattering intensity of a polystyrene solution of the identical sample showed no particular defect in our apparatus or procedure.[18]

Concerning the optical purification of the solution, similar results were obtained even if the solution of the G-2 sample in methanol was ultra-centrifugated at 2×10^4 *G* for 2 hr. The effect of fluorescence from the polymer was checked and found to have no considerable effect in methanol.

Recently theoretical investigations of similar anomalies in light scattering have been reported for other polymer-solvent systems as well. According to those results, the anomaly can be explained in some cases by the effects of the optical anisotropy of segments,[7-9] while in the other cases it can be explained by the effects of intermolecular interference arising from a non-random arrangement of the solute molecules in solution.[6,10] Some qualitative examinations of our results with regard to these theories were carried out as follows.

The Effect of the Optical Anisotropy of the Polymer. Uchiyama and Kurata[7,8] have shown that the unusual Zimm plots obtained by Ehrlich and Doty[19] for aqueous solutions close to the isoionic point of a copolymer consisting of approximately equal amounts of methacrylic acid and 2-dimethylaminoethylmethacrylate, and also obtained by Uchiyama and Kurata themselves for the monochlorobenzene solution of isotactic polystyrene can be explained by the effects of the large optical anisotropy of the polymer. In such cases they proposed primarily to use polarized incident light and to correct the effects of anisotropy by subtracting four-

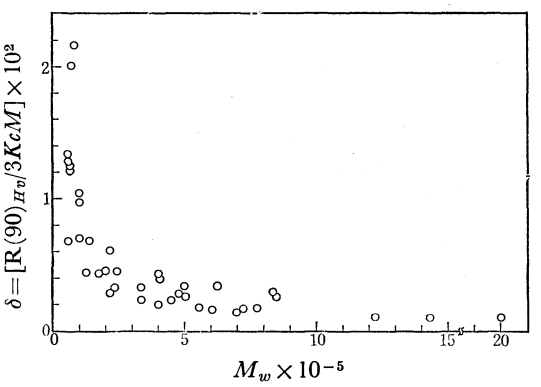

Fig. 5. Dependence of the values of optical anisotropy parameter, $\delta=R(90)_{Hv}/3K_cM$, of isotactic poly(2-vinylpyridine) in methanol at 25 °C on molecular weight of the polymers.

thirds of the amount of the *Vh* or *Hv* component of the scattered light from that of the *Vv* component at each scattering angle. Schurz *et al.*[20] found that the anomaly they observed with solutions of vinyon N (copolymer of 40% acrylonitrile and 60% vinylchloride) in dimethylformamide disappeared when they used verticallypolarized light.

The results of the measurements of all the components of scattered light with vertically-polarized incident light are given in Fig. 4 for the fraction of isotactic poly(2-vinylpyridine) S4F-4 in methanol. As is illustrated by the figure, the intensity of the *Hv* component and, consequently, the effects of depolarization for this polymer in methanol are, in general, comparatively small, and the anomaly can not be corrected by subtracting $(4/3)R_{Hv}$ from R_{Vv}. This situation was further confirmed by additional experiments carried out with a series of fractions whose molecular weights covered a wide range. In Fig. 5 the values of the optical anisotropy parameter, δ, defined[7] by:

$$\delta = R_{Hv}/3KcM$$

for a series of isotactic poly(2-vinylpyridine) in methanol are plotted as a function of the molecular weight of the polymers. The amounts of depolarization are not very large, and the values of δ are, in general, in the order of 10^{-3} except for very-low-molecular-weight fractions.

Secondly, when the measurements were carried out with unpolarized incident light in methanol, the values of the dissymmetry coefficient were often smaller than unity; consequently, the application of the data to the equations proposed by Uchiyama and Kurata for the correction of the effect of optical anisotropy was impossible. Even in the solvents other than methanol, where the application of the data to the equations is possible, the effects of the correction were not appreciable. In conclusion, the anomaly in Zimm plots can not be explained by the effect of the optical anisotropy of polymer segments.

The Effect of Order in Solution. It was first reported by Doty and Steiner[6] in the case of bovine serum albumin, and later by Oth and Doty[21] in the case of polyelectrolytes in the absence of added electrolytes,

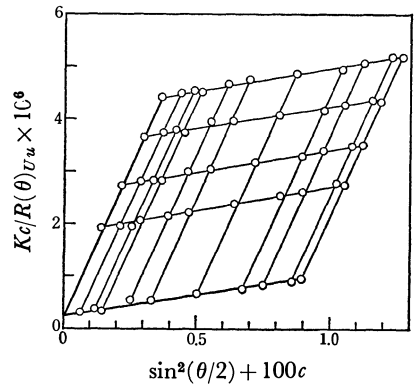

Fig. 6-1. Effects of the concentration, c, of added hydrogen chloride in methanol at 25 °C on the inflection in Zimm plots for atactic poly-(2-vinylpyridine), P-2 ($M_w=4.0\times10^6$). $\lambda=436$ mμ, unpolarized light. $c=0$ mol/l.

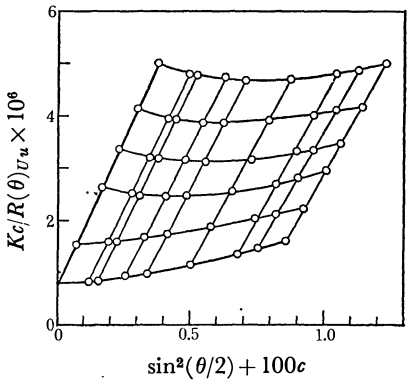

Fig. 6-2. $c=10^{-8}$ mol/l.

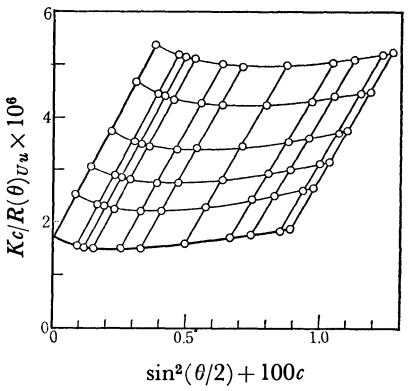

Fig. 6-3. $c=10^{-6}$ mol/l.

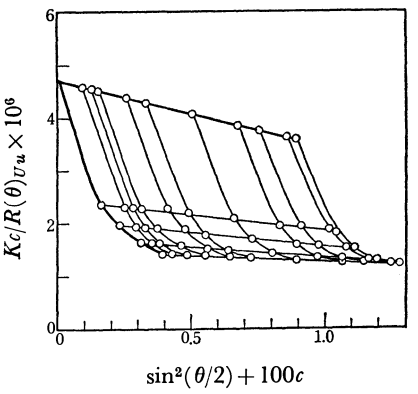

Fig. 6-4. $c=10^{-4}$ mol/l.

that unusual light scattering was caused by the external interference arising from non-random rearrangements of the polymer, the so-called "order" in solution. More recently, Burchard[10] has explained an anomalous light-sattering behavior like ours for poly(vinylcarbanilate) in diethyl ketone in terms of the influence of order arising from a certain strong solvation due to hydrogen bonding in solution.

According to Burchard, the ordering rearrangements of polymer coils in solution are perhaps caused by the effects of; (1) electrostatic repulsion force, (2) the formation of an intramolecular-bond-forming wire netting, and (3) a certain strong solvation.

First, we tried to check for the possible ionization of our polymer at nitrogen atoms in solution. Figures 6-1—6-4 demonstrate several Zimm plots observed for a fraction of atactic poly(2-vinylpyridine), P-2, in methanol, to which were added increasing amounts of hydrochloric acid. The light-scattering behavior for this fraction in pure methanol is normal, as is shown in Fig. 6-1. A similar perturbation as observed for lower-molecular-weight fractions in pure methanol appeared when the fraction was partially ionized by the addition of hydrochloric acid to methanol until the concentration reaches 10^{-8}—10^{-6} mol/l; the degree of anomaly increased with the concentration of hydrochloric acid, as is shown in Figs. 6-2 and 6-3. The pattern of the Zimm diagram at the concentration of 10^{-4} mol/l shows some similarities to the one reported for a polyampholite based on methacrylate by Ehrlich and Doty.[19]

The results of viscometric measurements for the same fraction in the solvents used above are shown in Fig. 7. The curves for these systems are typical for polyelectrolytes in a medium with a low ionic strength.

Similar results of light-scattering measurements were obtained when a trace amount of sulfuric acid was added to methanol used as a solvent until the con-

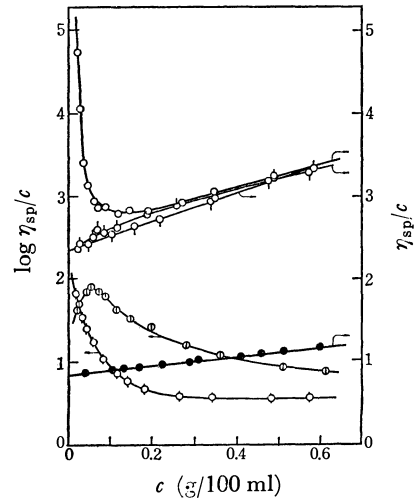

Fig. 7. Effects of the concentration, c, of added hydrogen chloride in methanol at 25 °C on the reduced viscosity number for fractions of atactic poly-(2-vinylpyridine) P-2 [○ ($c=0$ mol/l), ○ (10^{-8}), ○ (10^{-6}), ○ (10^{-4}), ⊙ (10^{-3})] and G-2 [● (0)].

centration reaches 10^{-8}—10^{-4} mol/l. From these results, it may be concluded that the anomaly in these cases depends on the effects of electrostatic interaction between ionized groups of the polymer.

We then considered whether the anomaly was affected by the same origin in the case of lower-molecular-weight-fractions. We have repeatedly measured the reduced viscosity numbers of many fractions of poly(2-vinylpyridine) in pure methanol and have always obtained normal viscosity curves typical of non-electrolytic polymers, as is shown in Fig. 7 for the G-2 fraction as an example.

On the other hand, the results of light scattering and viscosity in pure methanol for the $2U_0$ sample, which had been prepared with particular care taken to diminish any possibility of contamination by electrolytes, were the same as those of other fractions. Judging from these results, the explanation of the anomaly in terms of ionization in methanol may not be possible.

Secondly, the occurrence of strong solvation by means of hydrogen bonding between poly(vinylpyridine) homologues and alcohols has been ascertained by the large value of the Flory constant,[22,23] defined by:

$$K = 6^{3/2}\Phi_0(\langle s^2\rangle_0/M)^{3/2}$$

where Φ_0 is the universal constant and $\langle s^2\rangle_0$ the unperturbed radius of the gyration of the polymer chain, and by the large negative values of the parameters of excess enthalpy and entropy for dilution, as evaluated by measurements of the temperature coefficient of the intrinsic viscosity and the osmotic second virial coefficient.[24] The results of the direct calorimetric determination of the heat of solution equally support the possibility of hydrogen-bonding formation in these systems.[25]

Judging from these facts, it may be supposed that the anomalous light-scattering behavior with poly(2-vinylpyridine) in methanol was caused by strong fixation due to hydrogen bonds between the nitrogen atoms in the pyridine residue and the –OH groups of the methanol, as in the case of poly(vinylcarbanilate) in diethyl ketone.[10] Such a coil may have a weakly elastic repulsive potential and might resist the overlapping of the segment clouds.

The molecular-weight dependence of the degree of inflection of the light-scattering curves shown in Fig. 2 may be explained by the masking of the external interference by the internal one for larger particules, as was pointed out by Doty and Steiner.[6]

It may be supposed that the influence of added ammonia on the anomalous light scattering for methanol solutions is due to the diminution of solvation rather than some possible dissociation of the polymer. This may be supposed on the basis of the facts that the values of the intrinsic viscosity number and those of the Flory constant decrease considerably with an increase in the amount of added ammonia in methanol and ethanol, as has previously been shown by one of the present authours.[22]

In conclusion, it seems probable that anomalous behavior of light scattering such as is reported here is caused by the effect of order in solution, arising from a strong solvation.

Gel Filtration of Starch–Iodine System

Makoto KODAMA* and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Tokyo 158

(Received November 8, 1973)

The well-known starch-iodine reaction was taken up to study the applicability of gel filtration to the problem of physical chemistry. Gel filtration by the frontal analysis was carried out, the following results being obtained. (1) Soluble starch- and amylose-iodine systems give elution volumes of iodine containing constituents (V_{si} and V_{ai}, respectively) distinctly smaller than that of iodine, which decrease with increasing concentration of iodine, C, and starch, approaching the elution volume of starch. This is a direct experimental evidence of starch-iodine complex formation. (2) An equation derived for V_{si} *vs.* C and V_{ai} *vs.* C relations holds satisfactorily. The concentration of free iodine in equilibrium with the complex is calculated by the equation. (3) Presence of iodide ion facilitates the complex formation, but its decomposition is instantaneous when it is isolated from free iodine. (4) Some iodide ions are found to be incorporated in the complex. (5) Amylopectin also forms a complex with iodine, but the amount of iodide incorporated is not large. (6) Potentiometric titration of starch with iodine exhibits a similar behavior to the gel filtration measurement.

A number of studies have been made on starch–iodine complex formation by various methods such as potentiometry,[1] spectrophotometry,[2] electrophoresis[3] and X-ray diffraction,[4] but there do not seem to be many on the direct experimental confirmation of the binding between starch and iodine. The gel filtration method is suitable for such a measurement, since it enables us not only to identify the independent solute species as in the usual analytical procedure but also to study the solutes mutually in a rapid equilibrium such as

$$mA \rightleftharpoons A_m \text{ (a) or } A + B \rightleftharpoons AB \text{ (b)}$$

Case (a) has been reported for the system of aqueous solution of sodium dodecyl sulfate[5] and case (b) for polyvinylacetate–sodium dodecyl sulfate system.[6] The starch–iodine system belongs to the latter case, for which the gel filtration method is expected to give direct information on the formation of a starch–iodine complex.

Experimental

Material. Starch used included soluble starch, amylose and amylopectin. Commercial soluble starch (Wako Pure Chemicals Industries, Co., Ltd.) was used without further purification. Amylose and amylopectin were prepared from potato starch by selective precipitation with *n*-amyl and methyl alcohols.[7] Amylose and amylopectin solutions were prepared by dissolving purified sample in aqueous potassium hydroxide solution (0.5 M), neutralizing with dilute hydrochloric acid and desalting by gel filtration. Iodine was purified by repeated sublimation. Other reagents were of the commercial purest grade and were used without further purification. The gel used was Sephadex G-50 fine.

Apparatus. The apparatus used for gel filtration was similar to that described in a preceding report,[5] except for the flow cell for measuring the absorbance of blue starch-iodine mixture in place of the conductance cell. Absorbance was conventionally measured using a light source of an ordinary 40 W lamp without filter, the intensity being recorded as an electrical output of a photocell. The gel column used was Sephadex column K 15/30 (colorless) or brown glass column. The former, 1.5 cm in diameter, 30 cm long, and containing gel 11.4 cm in height, was used for the soluble starch-iodine system, and the latter, 1.1 cm in diameter, 30 cm long, and containing gel 20.0 cm in height, was used used for the amylose-iodine and amylopectin-iodine systems. The latter column was equipped with a water jacket thermostated at 30.0±0.05 °C. Soluble starch-iodine system was studied at room temperature (*ca.* 18 °C).

Method. The gel column was previously equilibrated with distilled water or 0.004 mol/l potassium iodide solution. A starch–iodine mixture of varying concentrations of starch and iodine as listed in each figure, and a constant iodide concentration of 0.004 or 0.025 mol/l was charged on top of the gel column. In order to carry out elution, the sample solution was charged in sufficient amount to ensure a wide plateau in the elution curve. The elution volume of starch, V_s, is determined by a slight depression appearing in the elution curve of soluble starch–iodine system shown in Fig. 2. The slight depression observed is further confirmed to be V_s since the outer volume of the gel as determined by blue dextran is in agreement with V_s obtained above, which would be expected from the gel used. This serves for the determination of the elution volume of amylose where the slight depression is lacking in the elution curve. The elution volume of free iodine, V_i, is determined by detecting yellow iodine eluted by the photocell. All experiments were carried out in a dark room to protect a light sensitive iodine–iodide solution.

Theoretical

When a sufficient amount of starch–iodine solution is subjected to gel filtration using an appropriate gel, a starch and starch–iodine complex, if any, moves faster than free iodine in the gel column. However, a part of starch–iodine complexes eluted in advance of free iodine decomposes and liberates starch and iodine at the front. Equilibrium is established between these substance and the remaining complexes, provided that decomposition is sufficienly rapid. As a result, starch is eluted first, followed by starch-iodine complexes and iodine. The behavior is shown schematically in Fig. 1. An imaginary elution front of starch–iodine complexes moves from left to right without decomposition (Fig. 1(A)). In this figure, □ACDH and □HDEG respectively represent the outer (or void) and inner

spaces of the gel column, AG and CE the upper and lower ends of the gel, AH and GH the cross sections of outer and inner gel spaces, CE and FB the imaginary elution fronts of starch-iodine complexes (⊙) and iodine (•). The actual front where the decomposition of the complexes takes place is shown in Fig. 1(B). The line CE indicates the front of starch (○) and PQ that of starch-iodine and iodine. The starch-iodine complexes in □SPCD decompose to liberate iodine of a constant equilibrium concentration to fill the space □FBPQ.

Such a decomposition is similar in nature to the case of the elution of sodium dodecyl sulfate above the critical micelle concentration, where the decomposition of micelles occur at the elution front.[5] Thus we obtain the equation

$$\frac{1}{V_{si}-V_s} = -\frac{1-\alpha}{(V_i-V_s)a} + \frac{C}{(V_i-V_s)a\alpha} \qquad (1)$$

from Eq. (8) for the micelle decomposition[5] by substituting $1/V_s$, $1/V_i$ and $1/V_{si}$ for R_f^m, R_f^s and R_f respectively. V_{si}, corresponding to the line PQ, represents the elution volumes of starch-iodine, V_s corresponding to EC the elution volume of starch, V_i corresponding to FB the elution volume of iodine, a the concentration of free iodine in equilibrium with starch-iodine complexes and α the rate parameter of the decomposition of starch-iodine complexes. $\alpha=1$ indicates that the decomposition of the isolated complexes is faster than the rate of elution and $\alpha=0$ no decomposition.[5] According to Eq. (1), V_{si} approaches V_s when C becomes large and C *vs.* $1/(V_{si}-V_s)$ plots are linear provided that a is constant. If the linear part of the plot when extrapolated passes the origin, we have $\alpha=1$ and decomposition of the complexes is rapid.

Results and Discussion

(1) Soluble starch. Elution volumes were determined by the sharp rise (V_{si}) and slight depression (V_s) of the elution curve shown in Fig. 2. In Fig. 3,

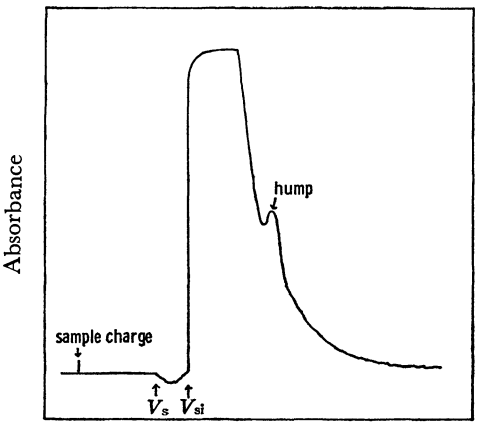

Fig. 2. The elution pattern of soluble-starch-iodine system.

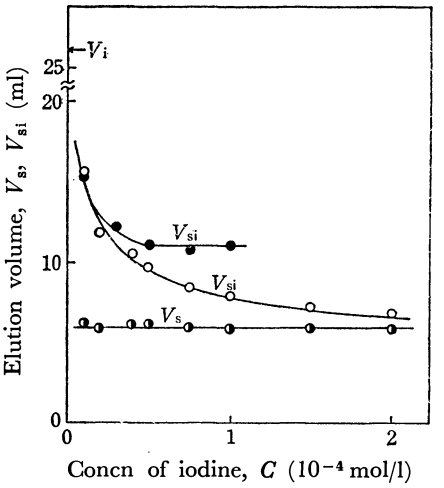

Fig. 3. V_s *vs.* C and V_{si} *vs.* C plots for soluble starch-iodine systems.
Sample solution: Concn of KI 0.025 mol/l
Concn of soluble starch ○ 0.5%, ● 0.05%
Gel column: Concn of KI 0 mol/l

V_{si} and V_s obtained are plotted against iodine concentration C. Here, the value V_s is constant (5.91 ml) as might be expected. The value V_{si}, being smaller than V_i (26.16 ml), decreases with C and approaches a constant for sufficiently large value of C. The constant is still a function of the concentration of soluble starch and approaches V_s for sufficiently high concentration as shown in Fig. 3.

The appearance of blue iodine front, V_{si}, moving faster than free iodine front is direct indication of the formation of large solute particles containing iodine, namely starch-iodine complexes. The tendency of V_{si} to approach a constant value distinctly larger than V_s for smaller starch concentration and larger iodine concentration as shown in the upper V_{si} *vs.* C curve of Fig. 3 indicates the saturation or a limit of binding capacity of iodine for starch.

The applicability of Eq. (1) was tested by plotting C against $1/(V_{si}-V_s)$. Figure 4 shows the results for soluble starch-iodine system. A straight line passing through the origin with a deviation in dilute and

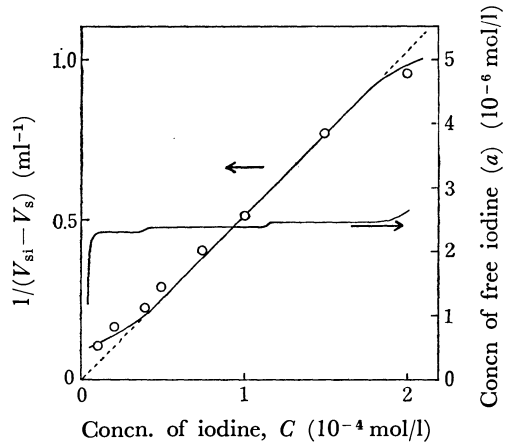

Fig. 4. $1/(V_{si}-V_s)$ *vs.* C plots and the potentiometric titration curve for soluble starch-iodine systems.
Gel filtration: Concn of KI 0.025 mol/l, V_s and V_{si} same as in Fig. 3
Potentiometry: Concn of KI 0.025 mol/l

concentrated iodine regions was obtained. The linear part shows the constancy of the concentration of free iodine in equilibrium with the complexes (a) and $\alpha=1$ obtained proves a rapid decomposition of the complexes at the elution front. From the inclination of the linear part of the plot and the values of V_s and V_i, a was calculated to be 9.6×10^{-6} mol/l.

The potentiometric titration of soluble starch (0.5%) with iodine in 0.025 mol/l KI solution was carried out for comparison. The results are shown in Fig. 4. Since soluble starch contains several hydrolysis products, the plateau part of the titration curve consists of several flat steps. The presence of hydrolysis products is also indicated in the elution curve as a hump in Fig. 2.

It is evident from Fig. 4 that the linear part of the gel filtration curve corresponding as a whole to the plateau part of the titration curve shows a constant value of a while the initial and final deviations from the linearity of the gel filtration curve indicate a smaller and larger concentration, respectively, of free iodine than a. The latter deviation also corresponds to the saturation of iodine in starch. A detailed potentiometric titration confirmed the value a to be *ca.* 2.5×10^{-6} mol/l. The smaller value as compared with the value obtained from gel filtration may be due to the absence of KI in the gel column in the former system as mentioned later.

(2) Amylose. The iodide concentration was kept constant to 0.004 mol/l, which was the largest possible concentration without the formation of amylose–iodine precipitate at high iodine concentration (2.0×10^{-4} mol/l). The gel column is equilibrated with distilled water as in the case of soluble starch. Elution curves obtained (not shown) lack the hump due to hydrolysis product shown in Fig. 2. Plots of the elution volume of blue amylose–iodine solution, V_{ai} and $1/(V_{ai}-V_a)$ against C shown in Figs. 5 and 6 respectively (called system II) resemble those of soluble starch. The observed V_a value of 4.50 ml was used. It is seen from Fig. 6 that $1/(V_{ai}-V_a)$ *vs.* C plots for different amylose concentration fall on a common straight line passing through the origin with similar deviations to

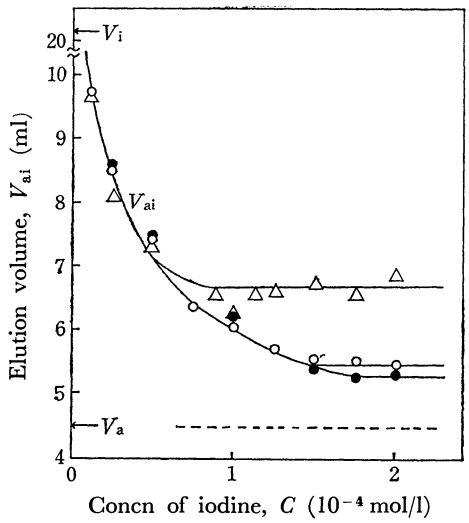

Fig. 5. V_{ai} *vs.* C plots for amylose-iodine systems.
Sample solution: Concn of KI 0.004 mol/l
Conc. of amylose 0.08%, 0.12%, 0.02%
Gel column: Concn of KI 0 mol/l

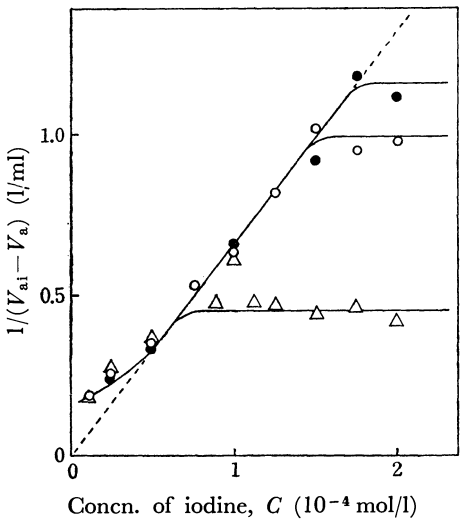

Fig. 6. $1/(V_{ai}-V_a)$ *vs.* C plots for amylose-iodine systems.
Sample solution: same as in Fig. 5
Gel column: same as in Fig. 5

those in Fig. 3.

From Fig. 5 it is clear that the constant V_{ai} for large C depends on the concentration of amylose. Such a tendency and similar behavior appearing in the potentiometric titration curve (not shown) also indicate the saturation of iodine in amylose as in the case of soluble starch. The value a calculated from Eq. (1) using the values $V_s(=V_a=4.50$ ml) and $V_i(21.17$ ml) is 9.1×10^{-6} mol/l.

While the binding of iodine with soluble starch or amylose is well accepted, the state of iodide ion in the solution has been precisely studied only in a few reports.[1,2] Although the blue amylose–iodine complexes are believed to form in the presence of iodide ions in the solution,[8] amylose–iodine complexes can be prepared without the addition of potassium iodide, *viz.*, as a solution almost free from iodide ions. Using

Table 1. Effects of iodide ion in amylose-iodine complex

System	Iodine species in solution	Gel matrix	a (mol/l)	V_{ai} at $C=1.0\times10^{-4}$ mol/l (ml)	Mol I_2 bound per g amylose at $C=1.0\times10^{-4}$ mol/l
I	I_2	—	19×10^{-6}	8.8	1.0×10^{-4}
II	I_2, I^-	—	9.1×10^{-6}	6.0	1.1×10^{-4}
III	I_2, I^-	I^-	1.1×10^{-6}	4.7	1.2×10^{-4}

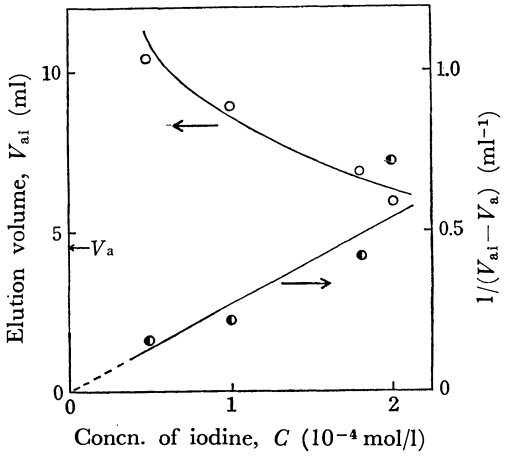

Fig. 7. V_{ai} and $1/(V_{ai}-V_a)$ *vs.* C plots for amylose-iodine systems.
Sample solution: Concn of KI 0 mol/l
Concn of amylose 0.08%
Gel column: Concn of KI 0 mol/l

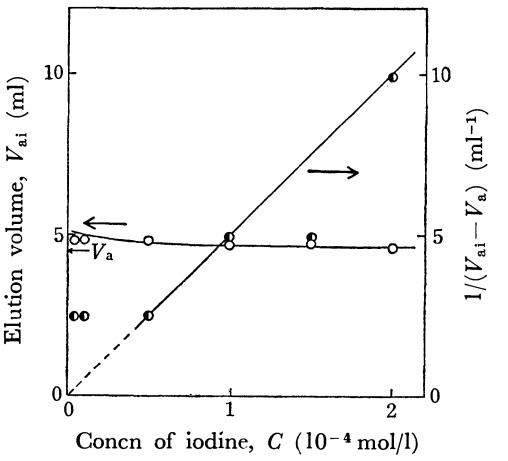

Fig. 8. V_{ai} and $1/(V_{ai}-V_a)$ *vs.* C plots for amylose-iodine systems.
Sample solution: Concn of KI 0.004 mol/l
Concn. of amylose 0.08%
Gel column: Concn of KI 0.004 mol/l

such an iodide free solution, gel filtration of 0.08% amylose was carried out under the same conditions as in system II. The result is shown in Fig. 7 (system I). The value a was calculated to be 19×10^{-6} mol/l. We further made the gel filtration of 0.08% amylose which is similar to system II except that the gel column was filled with aqueous potassium iodide solution of the same concentration as that for system II. The results are shown in Fig. 8 (system III). The value a was also calculated from the $1/(V_{ai}-V_a)$ *vs.* C plots to be 1.1×10^{-6} mol/l. As seen in Figs. 7 and 8, the plots scatter about a straight line and the value a calculated are not accurate. However, it might be certain from V_{ai} of system II that the value a of system III is smaller than that of system II.

Potentiometric determination of a was also carried out for system III, giving 1.6×10^{-6} mol/l which is in agreement with the result of gel filtration. This may be expected since the titration system resembles the gel filtration system for system III more closely than the other two systems as regards the addition of iodide ions. The results obtained from Figs. 5, 7 and 8 are summarized in Table 1. The effect of iodide ions in the solution and in the gel matrix on gel filtration of the amylose-iodide system is compared. It is seen that the values a and V_{ai} decrease as the iodide ions added becomes distributed over the solution and gel matrix. In the region of constant a, mol of iodine bound per g of amylose at a given concentration C is equal to $(C-a)/0.8$ for $C=1.0\times10^{-4}$ mol/l. We see from Table 1 that in order to obtain a nearly equal amount of iodine bound to amylose, 19×10^{-6} mol/l free iodine is

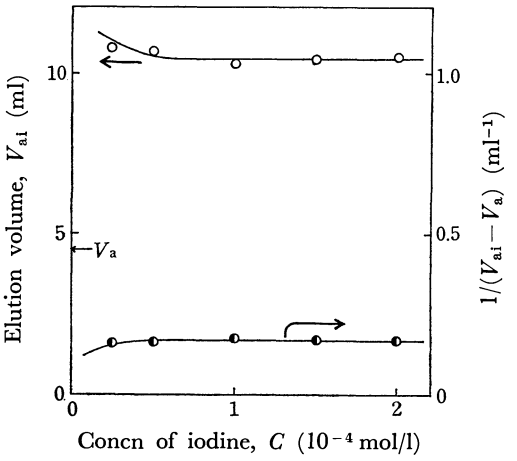

Fig. 9. V_{ai} and $1/(V_{ai}-V_a)$ *vs.* C plots for amylopectin-iodine systems
Sample solution: Concn of KI 0.004 mol/l
Concn. of amylopectin 0.08%
Gel column: Concn of KI 0 mol/l

necessary for system I and 9.1×10^{-6} mol/l for system II, but only 1.1×10^{-6} mol/l is sufficient for system III. Thus, iodide ions seem to favor the complex formation.

Iodide ions are bound to amylose in addition to iodine molecules. If amylose-iodine complexes of system II (Table 1) do not bind iodide ions, its elution front, which is in advance of the free iodide ions and is therefore exposed to the iodide free medium, is in the same condition as that elution front of the system I, and the value a should be equal to that of system I.

This, however, is not the case. Incorporation of iodide ions into amylose molecule increases iodide ions at the front and gives a lower a value compared with that of system I. Thus, iodide ions can be explained as bound to to amylose molecule.

(3) Amylopectin. Amylopectin, another component of starch, was further used for gel filtration. The result is shown in Fig. 9. For a wide range of iodine concentration, elution volume of amylopectin–iodine complexes, V_{ai} is nearly constant and is very large compared with the elution volume of amylopectin, V_a and amylose–iodine complexes V_{ai} for the same concentration of iodine. Plots $1/(V_{ai}-V_a)$ *vs.* C show a straight line. However, the nearly zero inclination of this straight line as well as the large V_{ai} value might give a large a value, and this in turn indicates the instability of amylopectin–iodine binding. The potentiometric titration curve (not shown), showing no plateau, is also in accordance with this. All these facts are in agreement with the general view that amylopectin–iodine binding is not so strong as soluble starch- and amylose–iodine binding.[6]

Mass Spectrometric Study of the Primary Processes in Photochemical Reactions. II. Mass Spectra of Methyl and Ethyl Radicals

Shigeru YAMASHITA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received December 12, 1973)

The mass spectra of methyl and ethyl radicals have been determined by the photolyses of methyl and ethyl iodide using a high intensity light beam and a collision-free photochemical reactor incorporated in the ion-source of a mass spectrometer. The parent ion peak was the most intense in the mass spectra of methyl and of ethyl radicals. Fair agreement was found between the present work and the result obtained by previous workers for pyrolytically produced methyl radicals.

In a previous work, the primary processes in 1,1′-azopropane photolysis were studied with a collision-free reactor incorporated in the ion source of a mass spectrometer.[1] The photofragments produced were ionized by electron impact without their undergoing secondary processes and estimation of the primary processes was thus facilitated as compared with the conventional procedure of analysis of final reaction-products.

The primary step of the photolysis of 1,1′-azopropane was found to be composed of three competitive processes:

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \longrightarrow CH_3CH_2CH_2N_2CH_2 + CH_2CH_3 \quad (1)$$

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \longrightarrow CH_3CH_2CH_2N_2 + CH_2CH_2CH_3 \quad (2)$$

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \longrightarrow 2CH_3CH_2CH_2N \quad (3)$$

As many as five kinds of photofragment radicals were formed in the primary step, and their assignments had to be made from the recorded mass spectrum of the photolyte mixture without any information on their cracking patterns. It is known that a large number of photochemical reactions consist of several competitive primary processes as in the case of 1,1′-azopropane. For analysis of the recorded mass spectrum of the photolyte mixture of photofragment radicals, it is desirable that the cracking patterns of the expected radicals are known before the experiment.

The mass spectra of free radicals have been measured only in a few cases.[2] Only the parent-ion peaks of a number of free radicals were observed with the use of several kinds of reactors connected to the ion sources of mass spectrometers in the studies of free radicals produced by pyrolyses[3-6] and of photochemical reactions.[7-9]. It was thought to be worthwhile and of theoretical interest to measure the mass spectra of some frequently-appearing free radicals such as simple alkyl radicals, since several theoretical treatment have been reported for explaining the cracking pattern of the stable molecules.[10,11] The theory could be extended to free radicals provided that suitable parameters are chosen for calculation.

In the present work, alkyl iodides were used for producing the corresponding alkyl radicals by photolyses. Since the C–I bond dissociation energies of alkyl iodides are much smaller than those of the C–C and C–H bonds,[12] only the C–I bond rupture is expected in the primary step of the alkyl iodide photolysis.

Experimental

Methyl iodide and ethyl iodide(guaranteed-reagent grade, Tokyo Kasei Kogyo Co.) were purified by vacuum distillation.

The apparatus and method of operation were reported previously.[1] The molecular flow of the reactant gas was supplied from a 5-l reservoir kept in the dark into the reactor zone of the ion source through an orifice and a Pyrex glass gas-lead. The light source was a USH-500D 500W high-pressure mercury lamp(Ushio Electric Co.) and the light output was collimated in a housing fitted with a condensing lens system and a spherical mirror to obtain maximum intensity. The light flux was focused on the molecular flow of the reactant in the reactor through a quartz window fixed on a side-hole of the ion source of a Hitachi RMU-5 mass spectrometer. Considering the absorption spectra of methyl iodide and ethyl iodide in gas phase[13] and the transmission of the Pyrex glass of the apparatus, the effective wavelength for the photolyses was estimated to be in the range 290—320 nm of the mercury-lamp output.

The mass spectrum obtained at 50 eV for each run was a superposition of the cracking patterns of the photofragments and that of unreacted alkyl iodide. The mass spectrum of the photofragment mixture was obtained after subtracting the contribution from unreacted alkyl iodide.

Results and Discussion

Mass spectrum of a photofragment mixture from the recorded mass spectrum is given in Table 1. By subtracting the contribution from unreacted methyl iodide from the recorded peak height, the residue Δ was obtained as the sum of the mass spectrum of each photofragment. Subtraction was done by normalizing at the mass number 142, the parent-ion peak of methyl iodide. Since all peaks can be attributed to CH_3 and I, it would be evident that only one primary process

Table 1. Mass spectrum of the photolyte flow of methyl iodide at 50 eV (in arbitrary units)

m/e	Peak height	Methyl iodide contribution	Δ	Assignment
12	1.1	0.8	0.3	CH_3
13	2.1	1.5	0.6	
14	5.3	3.6	1.7	
15	55.0	48.5	6.5	
127	60.5	55.2	5.3	I
142	150.5	150.5	—	methyl iodide

(4) is possible under the present conditions.

$$CH_3I + h\nu \longrightarrow CH_3 + I \quad (4)$$

The mass spectrum of methyl radical obtained by averaging the results of nineteen runs is given in Table 2. The results of the present work are compared with those of Osberghaus and Taubert.[2] In both cases, the parent-ion peak was found to be the most intense and a fair agreement is obtained in relative abundance of the peaks at each mass number except for *m/e* 14. The discrepancy at *m/e* 14 might be caused by the difference between the procedure for methyl radical formation in the present work and that of Osberghaus and Taubert. In the latter, methyl radicals were produced by the pyrolysis of tetramethyl lead at 900 °C.

TABLE 2. MASS SPECTRUM OF METHYL RADICAL

m/e		12	13	14	15
Relative abundance	This work	5±2	11±6	25±8	100
	Osberghaus and Taubert	3	10	54	100

TABLE 3. MASS SPECTRUM OF THE PHOTOLYTE FLOW OF ETHYL IODIDE AT 50 eV (in arbitrary units)

m/e	Peak height	Ethyl iodide contribution	*Δ*	Assignment
15	0.6	0.6	—	C_2H_5
25	0.5	0.4	0.1	
26	5.5	5.0	0.5	
27	30.0	24.9	5.1	
28	12.0	10.1	1.9	
29	39.0	33.7	5.3	
127	13.9	12.2	1.7	I
156	41.0	41.0	—	ethyl iodide

The mass spectrum of the photolyte flow of ethyl iodide is shown in Table 3. It can be seen that the procedure for obtaining it is the same as in the case of methyl iodide. Since the peak height at *m/e* 128 was found negligible in the residue *Δ* of each run, the process

$$C_2H_5I + h\nu \longrightarrow C_2H_4 + HI$$

could be neglected. Thus, only the following process is possible under the present experimental conditions.

$$C_2H_5I + h\nu \longrightarrow C_2H_5 + I \quad (5)$$

The mass spectrum of ethyl radical obtained by averaging the results of twelve runs is shown in Table 4. In the mass spectrometric study of argon-ion bombardment on the ethylated surface of germanium,[14] occurrence of the fragment-ion from the liberated ethyl radicals by electron impact was suggested although the relative abundance of fragment-ion peak in the mass spectrum of ethyl radical was not determined because of the coexistence of other species emitted from the surface.

The peaks at *m/e* 12~15 were not detected, indicating a negligible contribution of C–C bond rupture by electron impact of ethyl radical (Table 4).

Thus the results of the present work suggest that all the significant fragment-ions are produced solely by C–H bond rupture resulting from the electron bombardment at 50 eV both in the case of methyl and ethyl radicals. It is seen that the relative abundance of the fragment-ion is larger in the mass spectrum of C_2H_5 than in that of CH_3. The difference might be caused by the difference of excess energy partition in C_2H_5 and CH_3.

TABLE 4. MASS SPECTRUM OF ETHYL RADICAL

m/e	25	26	27	28	29
Relative abundance	1±1	13±3	82±12	44±10	100

The excess energy E_{exc} is expressed by the following equation:

$$\begin{aligned} E_{exc} &= h\nu + E^{P}_{int} - D(\text{C–I}) \\ &= E_{tr} + E_{int} \\ &= (E^{R}_{tr} + E^{I}_{tr}) + (E^{R}_{int} + E^{I}_{int}) \end{aligned} \quad (6)$$

where, $h\nu$ is the photon energy, E^{P}_{int} the initial parent molecule internal energy which is small, and D(C–I) the dissociation energy of the C–I bond. The excess energy is distributed in the total translational energy E_{tr} of alkyl radical R and iodine atom I and in the total internal energy E_{int} of both fragments.

In their photofragment spectroscopic study of the photodissociation of alkyl iodides, Riley and Wilson[15] pointed out that the ratio of E^{R}_{int} appearing as the energy for alkyl-fragment internal excitation to the total energy E^{R}_{tot} (translational and internal) given to alkyl fragment was found to be three times larger in C_2H_5 than in CH_3. It is plausible that the higher fraction of internal excitation can be one cause for the larger relative abundance of fragment-ion in the mass spectrum of ethyl radical as compared with methyl radical.

The author is grateful to Professor Teruo Hayakawa for encouragement and discussion. The work was supported in part by a grant of the Ministry of Education.

Solution Properties of Phycocyanin. I. Studies of Dissociation-Association by Sedimentation Measurement*

Takahide SAITO, Naomichi ISO, and Haruo MIZUNO

Department of Food Science and Technology, Tokyo University of Fisheries, Konan, Minato-ku, Tokyo 108

(Received December 28, 1973)

The dissociation-association properties of phycocyanin, isolated from the red algae, "*Porphyra tenera*," have been investigated by sedimentation velocity measurements at pH 6.8 and 5.4 and at the ionic strengths of 0.1 and 0.2. The sedimentation coefficient data indicated that the predominant component in the phycocyanin solution was a trimer at pH 6.8 and a hexamer at pH 5.4. The concentration dependence of the sedimentation coefficient for various hypothetic systems of the dissociation-association equilibrium of phycocyanin was simulated by a computer model. It was reasonable to consider, from the simulation, that the dissociation-association system of phycocyanin was trimer$\rightleftarrows$monomer at pH 6.8 and hexamer$\rightleftarrows$monomer at pH 5.4. The dissociation constant was calculated for each system. The value of the dissociation constant was 0.15×10^{-4} (g/dl)^2 at pH 6.8 and an ionic strength of 0.1; 0.13×10^{-4} (g/dl)^2 at pH 6.8 and an ionic strength of 0.2; 0.5×10^{-13} (g/dl)^5 at pH 5.4 and an ionic strength of 0.1 and 0.1×10^{-13} (g/dl)^5 at pH 5.4 and an ionic strength of 0.2. The dissociation constants decrease with an increase in the ionic strength in solution.

Phycocyanin is an accessory photosynthetic chromoprotein obtained from red- and blue-green algae. The properties of phycocyanin have been studied by many investigators. Svedberg and Katsurai[1] and Svedberg and Eriksson[2] measured the molecular weight of the protein under various pH conditions by the sedimentation equilibrium method; they found that the molecular weight of phycocyanin changed reversibly according to the pH change of the solution. Recently, Hattori and Fujita[3] and Berns *et al.*[4] confirmed this phenomenon by ultracentrifugation and spectrometry. It was showen that the reversible aggregation of this protein depended upon the ionic strength and the temperature of the solution.[5-7] It has also been reported by Berns *et al.*[8] that phycocyanin decomposed into many smaller units in the presence of urea or sodium dodecyl sulfate, and that the minimum molecular weight of phycocyanin was 30000. Scott and Berns.[7] claimed that the molecular weight of the phycocyanin aggregates were 90000, 180000, or 360000. From these observations, it has been presumed that the aggregates of phycocyanin are a trimer, a hexamer and a dodecamer, and also that the dissociation-association equilibrium was attained between these higher aggregates and lower aggregates or a monomer in the solution.

Hattori *et al.*[6] obtained the equilibrium constant from their measurements of the concentration dependence of the extinction coefficient of the phycocyanin solution. Scott and Berns[7] observed two or more peaks in the schlieren patterns obtained by the sedimentation velocity measurement of phycocyanin from *Plectonema calothricoides*, and calculated the equilibrium constant using the relative areas under these peaks.

Adams *et al.*[9-12] have published a theory of the association-dissociation of molecules in an ultracentrifugal field and have derived a method for evaluating the equilibrium constant from the sedimentation equilibrium experiment. They applied this theory to the study of the self-association of β-lactoglobulin B in an acid solution[13] and showed that the experimental results could easily be explained by this theory.

In order to investigate the molecular shape and size of phycocyanin, which undergoes the dissociation-association reaction according to the environmental changes in the solution, it is necessary to estimate the dissociation-association constant of this protein. Adams' method is not always a convenient one for obtaining such preliminary knowledge as described above. If it is possible to estimate the equilibrium constant for the dissociation-association of phycocyanin by using the sedimentation transport method, such an experiment would, however, be quite useful.

In this paper we will attempt to estimate the equilibrium constant by using the sedimentation velocity method, and also to presume the state of the equilibrium of phycocyanin in solution. Moreover, we wish to contribute to the knowledge about the solution properties of the phycocyanin.

Experimental

Preparation. The phycocyanin used in this study was obtained from dried *Porphyra tenera* by repeating the precipitation with ammonium sulfate. The details of this preparation were reported by Fujiwara.[14] The outline of this procedure is presented in Fig. 1. The purity of phycocyanin was ascertained by measurements of its electrophoretic behavior, while the absorption spectra of this protein solution were measured at pH 6.8 and at an ionic strength of 0.1. As is shown in Fig. 2, the ratio of extinction at 620 nm and 280 nm was greater than 4.0. This value agreed with that obtained by earlier investigators[3,15,16] for pure phycocyanin. The purified phycocyanin was stored at 5 °C under 40% saturated ammonium sulfate. The sample of phycocyanin was dissolved in water and dialyzed against a phosphate or acetate buffer at 5 °C. Dialysis was continued for at least 48 hr, with an occasional change of the external solution.

Determination of Concentration. The protein concentrations were determined by weighing the substances after they had been dried at 105 °C for 24 hr; they were also determined by the semi-micro-Kjeldahl method. The value of the concentrations obtained by the different methods

* Some of the experimental results in this paper were presented at the 27th Annual Meeting of The Chemical Society of Japan, Nagoya, October 12, 1972, and at the 22nd Annual Meeting of The Society of Polymer Science, Japan, Kyoto, May 30, 1973.

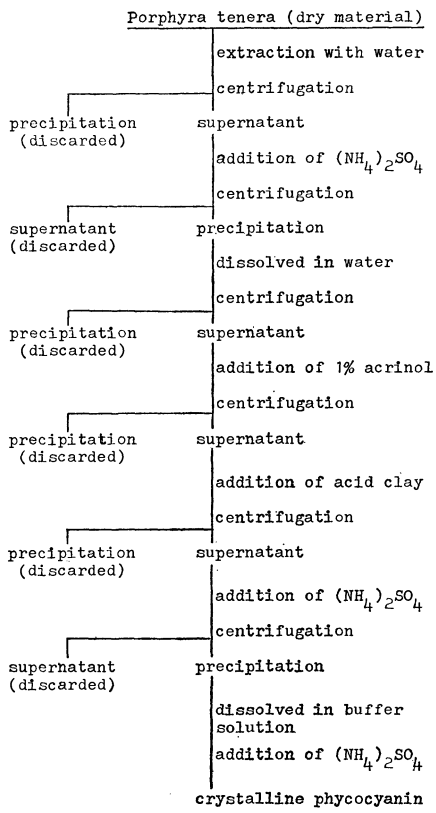

Fig. 1. Flow-sheet of preparation of phycocyanin.

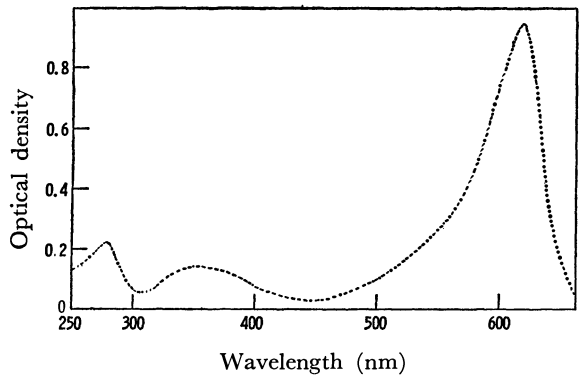

Fig. 2. Absorption spectrum of aqueous solution of phycocyanin.

agreed with each other within the limits of experimental error.

Ultracentrifugation. The sedimentation velocity experiments were performed with a Hitachi Model UCA-1 ultracentrifuge with a schlieren optical system; double sectorial cells were used. In all runs the rotor speed was set at 47,300 rpm, and the temperature was maintained at 25 °C.

The sedimentation coefficient, s, is represented by the following equation:

$$s = \frac{\ln(r_p/r_m)}{\omega^2(t-t_0)},$$

where r_p is the boundary position measured from the second moment of the refractive index gradient; r_m, the position of the meniscus; ω, the angular velocity; t, the time, and t_0, the initial time correction. In general, if the shape of the schlieren pattern is of a Gaussian type, $r_p=r_h$, where r_h is the position of the maximum of the refractive index gradient. In our experiment, the schlieren patterns were satisfactorily considered to be Gaussian, as is shown in Fig. 3; the position of the maximum of the refractive index gradient dose not differ significantly from the boundary position obtained. For example, the calculated values of r_p and r_h were 6.362 cm and 6.363 cm respectively 30 min after reaching a constant speed of 47300 rpm, in the sedimentation velocity measurement of phycocyanin at pH 6.8 and at I (ionic strength) of 0.1. The position of the maximum of the refractive index gradient was, then, used in place of the boundary position for the evaluation of the sedimentation coefficient throughout this study. The position of maximum of the refractive index was measured using a Sinko-VF-12 projector.

Estimation of the Equilibrium Constant for Dissociation-Association Reactions. The sedimentation coefficient for a system containing many species is represented by the following equation:

$$s = \frac{\sum s_i c_i}{\sum c_i}. \quad (1)$$

where c_i and s_i are the weight concentration(g/dl) and the sedimentation constant for the i-th species respectively. The equilibrium constant for the i-mer$\rightleftarrows$monomer($M_i \rightleftarrows iM_1$) system, K_i, is defined by using the mass-action equation:

$$K_i = \frac{{c_1}^i}{c_i}. \quad (2)$$

The total concentration, c, is given by the following equation:

$$c = \sum c_i. \quad (3)$$

Thus, Equation (1) is rewritten in the form:

$$s = \frac{\sum ({c_1}^i/K_i)s_i}{c}. \quad (4)$$

The concentration dependence of the sedimentation coefficient is usually shown as follows:

$$s_i^* = s_i^0(1-\alpha_i), \quad (5)$$

$$s^* = \frac{\sum ({c_1}^i/K_i)s_i^0(1-\alpha_i)}{c}, \quad (6)$$

where s^* is an apparent sedimentation coefficient and s^0, the sedimentation coefficient at an infinite dilution. Moreover α_i is $k_{s_i}c_i$, where k_{s_i} is the concentration-dependence coefficient of the i-th species. Now, by assuming that α_i is constant for all species, the following equation is obtained from Eq. (6):

$$s^* = \left[\frac{\sum ({c_1}^i/K_i)s_i^0}{c}\right](1-k_s c). \quad (7)$$

Thus the equilibrium constant, K_i, can be evaluated if the values of s_i^0, c_1, s^*, and k_s are known.

The sedimentation coefficient of the phycocyanin aggregates, s_i^0, was determined by extrapolating the linear plot over a limited region at higher concentrations to an infinite dilution, while the concentration-dependence coefficient, k_s, was determined from the slope according to Eq. (5). The sedimentation coefficient of the monomer, s_i^0, was assumed to be 3.2 S, a value reported by Hattori *et al.*[6] Then K_i can be computed by assuming the value of c_1. In practice, the value of the right-hand side of Eq. (7) are calculated by assuming both the values of c_1 and K_i, and then compared with the s^* obtained experimentally. The values of c_1 and K_i were systematically changed, and the most probable value of K_i was decided according to where the standard deviation of the difference between the calculated s^* and the observed s^k reaches its minimum. The TOSBAC-3400 computer was used for the calculations.

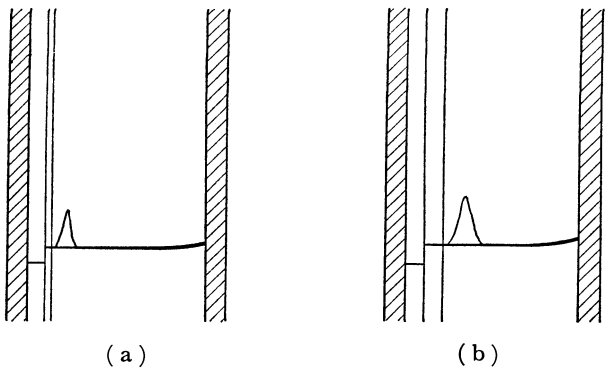
Results and Discussion

Some investigators[6,7,15-17] have observed two or more peaks in the sedimentation patterns of a phycocyanin solution under various values of pH and the ionic sterngth. However, all of our sedimentation patterns showed a single peaks, as is shown in Fig. 3. This discrepancy seems to be caused by the sources of phycocyanin being different from one another.

Scott and Berns[7] estimated the equilibrium constant using the relative areas under the peaks of the schlieren patterns, but in our experiments this procedure is inapplicable to the estimation of the equilibrium constant. Therefore, the following treatment was necessary for the estimation of the equilibrium constant.

Figures 4—7 show the sedimentation coefficients of phycocyanin as a function of the protein concentration at pH 6.8 and 5.4 and at I values of 0.1 and 0.2. In these figures, the calculatted lines for the dissociation-association equilibria are given. The variation of s^* with the concentration shows a tendency to increase with a decrease in the concentration in the higher-concentration region, while it tends to decrease near a zero concentration. These results show that the protein molecules associate in the higher-concentration region. This behavior is similar to that of β-lactoglobulin or γ-G-globulin.[18]

Figure 4 shows the results at pH 6.8 and at $I=0.1$. From the plots in Fig. 4, the s_i^0 of 6.3 S and the k_s of 0.30 were obtained. Since the s_i^0 value agreed with the value reported for the trimer,[6,17] we assumed that this dissociation-association equilibrium was the trimer$\rightleftarrows$monomer ($M_3\rightleftarrows 3M_1$) system. The calculated line A is that for the $M_3\rightleftarrows 3M_1$ system. In order to know whether or not the hexamer species exist in the solution, the (hexamer+trimer)$\rightleftarrows$monomer($M_6+M_3\rightleftarrows 9M_1$) system was calculated as a trial. Line B is that calculated for the system. As is shown in Fig. 4, the experimental results can be well represented by the calculated line A. The hexamer could not be considered to exist in the solution. The equilibrium constant for the $M_3\rightleftarrows 3M_1$ system, K_3, was decided to be 0.15×10^{-4} (g/dl)^2.



(a) (b)

Fig. 3. Sedimentation patterns of phycocyanin.
(a): at pH 6.8, ionic strength 0.1; phosphate buffer, 26 min after reaching constant speed, (b): at pH 5.4, ionic strength 0.1; acetate buffer, 28 min after reaching constant speed.

The results at pH 5.4 and $I=0.1$ are shown in Fig. 5; values of 10.8 S for s_i^0 and 0.30 for k_s were obtained from the results. The s_i^0 value agreed with the value which was reported for the hexamer.[6,7,15,16] This result shows clearly that the state of the dissociation-association equilibrium of the protein is closely related to the pH change in the solution. It was assumed that this dissociation-association equilibrium was the hexamer$\rightleftarrows$monomer($M_6\rightleftarrows 6M_1$), hexamer$\rightleftarrows$trimer($M_6\rightleftarrows 2M_3$), or $M_6+M_3\rightleftarrows 9M_1$ system. The calculated line C is that for the $M_6\rightleftarrows 6M_1$ system; line D, that for the $M_6+M_3\rightleftarrows 9M_1$ system, and line E, that for the $M_6\rightleftarrows 2M_3$ system. It is shown in this figure that the calculated line C for the $M_6\rightleftarrows 6M_1$ system almost coincides with the experimental points, while the other two lines show a larger deviation from the results obtained experimentally. The value of 0.5×10^{-13} (g/dl)^5

for the $M_6 \rightleftarrows 6M_1$ dissociation constant, K_6, was obtained.

In order to determine the effect of the ionic strength on the dissociation-association, sedimentation-velocity experiments were also carried out at $I=0.2$ under the same pH condition as before. Some investigations with regard to the effect of the ionic strength on the dissociation-association of phycocyanin have been reported by several authors,[6,7] and it has been found that the quantity of aggregates increased with an increase in the ionic strength of the solution. However, these studies have been done in the lower ionic strength region.

Figure 6 shows the results at pH 6.8 and at $I=0.2$. From the results, the s_i^0 of 6.5S and k_s of 0.16 were obtained. This s_i^0 value agreed with that obtained $I=0.1$ and pH 6.8 in this work. It seemed reasonable to assume that the dissociation-association equilibrium was the $M_3 \rightleftarrows 3M_1$ or the $M_6+M_3 \rightleftarrows 9M_1$ system. This assumption was clearly the same as that at pH 6.8 and at $I=0.1$. The calculated line F is that for the $M_3 \rightleftarrows 3M_1$ system, while line G is that for the $M_6+M_3 \rightleftarrows 9M_1$ system. As is shown in Fig. 6, it was clear that the hexamer did not exist in the solution. The equilibrium constant for the $M_3 \rightleftarrows 3M_1$ system, K_3, was decided to be 0.13×10^{-4} (g/dl)^2. At the same pH, K_3 of 0.4×10^{-4} (g/dl)^2, which acts for the dissociation of phycocyanin in the 0.01 M phosphate buffer solution ($I=0.04$), and K_3 of 1.0×10^{-4} (g/dl)^2 in the 0.001 M phosphate buffer solution(I 0.004) were reported by Hattori *et al.*[6], using an absorption method. As has been described above, K_3 of 0.15×10^{-4} (g/dl)^2 for the phycocyanin solution was obtained in this work at the same pH and at $I=0.1$. These four values for K_3 under the different conditions of ionic strength show a tendency for the equilibrium constant to decrease with an increase in the ionic strength.

Figure 7 shows the results at pH 5.4 and at I=0.2; the s_i^0 of 11.3 S and the k_s of 0.24 were obtained. The s_i^0 value agrees with s_i^0 of 10.8 S which was obtained at $I=0.1$ and at pH 5.4 in this work. As before, this dissociation-association equilibrium was assumed to be $M_6 \rightleftarrows 6M_1$, $M_6+M_3 \rightleftarrows 9M_1$, or $M_6 \rightleftarrows 2M_3$ system. The calculated line H is that for the $M_6 \rightleftarrows 6M_1$ system, line I, that for the $M_6+M_3 \rightleftarrows 9M_1$ system, and line J, that for the $M_6 \rightleftarrows 2M_3$ system. Figure 7 shows that both the H and I calculated lines seem to be in satisfactory agreement with the experimental points. However, the concentration of the trimer, which was calculated in the process of the computation of K_i on the assumption of the $M_6+M_3 \rightleftarrows 9M_1$ system, was negligibly small. Therefore, it seems reasonable to say that the $M_6 \rightleftarrows 6M_1$ equilibrium was attained in the solution at pH 5.4 and at $I=0.2$. The equilibrium constant for the $M_6 \rightleftarrows 6M_1$ system, K_6, was decided to be 0.1×10^{-13} (g/dl)^5. The value is smaller than that obtained in this work at pH 5.4 and at I=0.1. It is found that the increase in the ionic strength relates to the decrease in the equilibrium constant; this result is identical with that obtained at pH 6.8. Hattori *et al.*[6] have explained that an increase in ionic strength results in a reduction of the electrostatic repulsive force of phycocyanin particles, and that this leads to the association of the monomer. The experimental results obtained in this study support their conclusion.

The association-dissociation equilibrium system of phycocyanin was suggested to be either the $6M_1 \rightleftarrows 2M_3 \rightleftarrows M_6$ system or two parallel reactions, that is, the $3M_1 \rightleftarrows M_3$ and the $6M_1 \rightleftarrows M_6$ system.[6,7] Berns *et al.*[19] proposed that the equilibrium system involved three parallel reactions, that is, the $3M_1 \rightleftarrows M_3$, the $6M_1 \rightleftarrows M_6$, and the $2M_3 \rightleftarrows M_6$ systems. In our experiments, the value of the equilibrium constant was small under the pH conditions of 6.8 and 5.4. Thus, it seems reasonable to assume that the dissociation-association equilibrium of phycocyanin under the conditions in this study inclines toward an one-side extreme (aggregate).

The concentration-dependence coefficients, k_s, of these solutions were found to be 0.30 (pH 6.8, $I=0.1$),

0.30 (pH 5.4, I=0.1), 0.16 (pH 6.8, I=0.2), and 0.24 (pH 5.4, I=0.2). As with the k_s values of many other proteins, these values were small. Weirich *et al.*[20] have published a basic theory of the sedimentation coefficient of self-association species and described a method of estimating the sedimentation coefficient using the equilibrium constant, K_i, and the monomer concentration, c_1, obtained from sedimentation-equilibrium, light-scattering, or osmotic-pressure experiments on the same self-associating solute. Our study was aimed at estimating the equilibrium constant of the dissociation-association equilibrium system from the results of the sedimentation-velocity experiment. Since a sedimentation coefficient is not an equilibrium quantity, the equilibrium constant derived in this study should be considered to be only approximate values. Nonetheless, the dissociation constants obtained in this work are in fair agreement with those constants previously reported.[6] In view of the fact that the sedimentation-velocity measuement requires only a short time, it can be said that the procedure in this paper is a convenient method for the study of the dissociation-association system of a protein.

Three Methods to Look at Walsh-type Diagrams Including Nuclear Repulsions*+

Yuuzi TAKAHATA† and Robert G. PARR

Department of Chemistry, The Johns Hopkins University, Baltimore, Maryland 21218, U.S.A.

(Received October 21, 1973)

Energy correlation diagrams for molecules of type AH_2 are examined by three different methods: (1) the quantum-mechanical virial theorem, (2) the method of median partition, (3) the integral Hellmann-Feynman theorem. Nuclear-nuclear repulsions are included. The formula for the first method takes the form $W=-\sum t_i$, where t_i is an orbital kinetic energy. The theory is applied to H_2O, CH_2, and BeH_2. Negative-kinetic-energies-*versus*-angle diagrams for these molecules are presented. The pattern of the diagrams is quite different from the usual Walsh diagram. With this resolution non-bonding electrons play a significant role in determining bond angles. In the second method the resolution of the total energy takes the form $W=\sum_i[e_i+V_n(i)]$, where e_i is a median electronic energy and $V_n(i)$ is a resolved nuclear repulsion energy calculated from an expression derived from ideas of population analysis. The energies-*versus*-angle diagram thus obtained for H_2O is similar to the one obtained by the first method. For the third method, the integral Hellmann-Feynman formula for the electronic energy change on bending is written in terms of corresponding orbital contributions, $\Delta E_l=\sum_i \Delta E_l(i)$, and nuclear-nuclear repulsion is added in a resolved form. For H_2O the ΔE_l resemble Walsh diagrams closely, both with and without the nuclear-nuclear repulsion increments. Wave functions used throughout are LCAO-SCF functions built from medium-size Gaussian basis sets.

Much effort has been dedicated to elucidate numerical rules governing molecular shapes, since Walsh first pointed out the existence of such rules for large number of simple polyatomic molecules.[1] There are two schools of thought in explaining the rules, valence bond theory and molecular orbital theory. It has been shown that the valence-shell electron pair repulsion theory (VSEPR) can explain Walsh's rules.[2] More recently it has been argued that closed shells on terminal atoms play an important role in the bending process, and a model has been given which predicts Walsh's magic numbers.[3,4] Connections between the model and the crystal field theory were noted.

Most quantum mechanical explanations of Walsh's rules have followed the lines laid by Mulliken[5] and Walsh.[1] Molecular orbital theory has been extensively applied giving "Walsh Diagrams."[6] United-atom approaches have also been applied producing Walsh-type diagrams.[7] It has remained a matter of argument, however, whether one should use the LCAO-MO-SCF orbital energies or some other one-electron MO energy quantities which genuinely add to give the total electronic energy in order to identify the Walsh ordinate.[8] There is another difficulty in the MO approach; Nuclear-nuclear repulsion has almost always been left out of consideration in calculating a Walsh diagram or at most added at the end.

In the present paper we explore the possibilities of obtaining method which enable one to partition the *total* molecular orbital energy of a molecule into one-electron energy quantities which are genuinely additive. Three schemes are employed for this purpose. They are the quantum-mechanical virial theorem, the method of median partition, and the integral Hellmann-Feynman theorem. The first method has already been applied by us to the H_2O molecule.[9] The energy correlation diagram obtained differed very much from the Walsh diagram. In Section II numerical results of further calculations on H_2O are presented, and the theorem is also applied to CH_2 and BeH_2. The second method follows closely the work of Coulson and Neilson[10] except that nuclear-nuclear repulsion energy is divided and included in the individual orbital components. The third method is of interest since it parallels the analysis of the same problem with the Hellmann-Feynman theorem, by Coulson and Deb.[8]

I. Wave Functions

Throughout this work we use single-determinantal linear combinations of Gaussian-type orbitals (LCGTO) SCF wave functions. A medium-size Gaussian basis set $(53/3)^{11a)}$ is employed for H_2O, while basis sets $(73/3)^{11b)}$ and $(53/3)^{11c)}$ are used for CH_2 and BeH_2 respectively. Gaussian exponents are tabulated in Table 1. LCGTO-SCF calculations are carried out at various bond angles and bond distances. The calculated equilibrium geometry H_2O has bond length 1.85 a.u. and bond angle of 112°, the corresponding experimental values being 1.8103 a.u. and 105°.

In the calculations reported in Section II below, the variation of bond distances with bond angle are considered, as described there. In the diagrams in Sections III and IV, on the other hand, the bond distances are held constant with change in bond angle.

II. Correlation Diagrams from the Quantum-mechanical Virial Theorem

It has already been pointed out that the polyatomic virial theorem in the form given by Nelander[12] gives theoretically rigorous correlation diagrams.[9] The central result of the Nelander theorem is that the relation $W=-T$ holds between the total energy W

and the total kinetic energy T not only at the equilibrium geometry of a polyatomic molecule, but also for bond angles distorted from equilibrium, if the bond distances are optimum for each set of angles. Since kinetic energy is a one-electron quantity in the Hartree-Fock scheme, the total energy may be expressed as a sum of negative orbital kinetic energies:

$$W = \sum_i(-t_i). \quad (1)$$

This seems to be the only known theory which makes it possible to partition the total energy (including nuclear-nuclear repulsion) into genuinely additive one-electron componets. No nuclear-nuclear repulsion or electron-electron terms appear in the expression.

For approximate wave functions, the virial theorem as just stated does not hold unless the wave functions are scaled. The scaling procedure for polyatomic molecules may be patterned after Löwdin's treatment for diatomic molecules.[13]

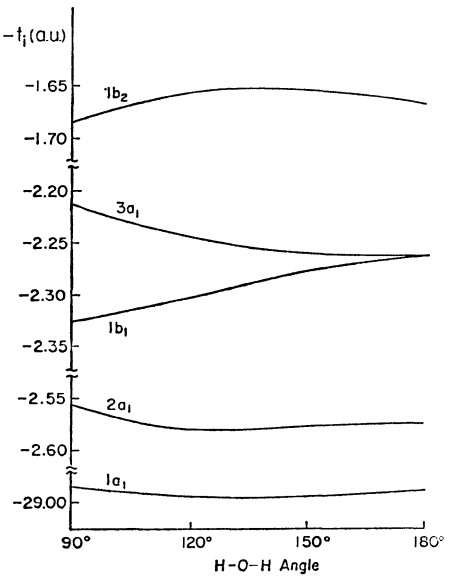

Fig. 1. Negative kinetic energies of the molecular orbitals of H_2O, as a function of H-O-H angle. See text.

In Table 2 are shown scaling factors (η), equilibrium bond lengths (R_e), kinetic (T), potential ($V=V_{ne}+V_{ee}$), nuclear repulsion (V_{nn}), and total (W) energies at various bond angles for H_2O. Note that the total energies are indeed equal to negative kinetic energies. The kinetic energies partitioned into one-electron components are listed in Table 3. These are plotted in Fig. 1 as a function of HOH angle.[9]

Figure 1 differs from a conventional Walsh diagram in two respects; (1) The order of the top three orbitals: $(1b_2)>(3a_1)>(1b_1)$, *versus* $(1b_1)>(3a_1)>(1b_2)$ in the conventional Walsh diagram, (2) The trends in changes of orbital energies differ. The $3a_1$ orbital energy component, for example, decreases with increasing apex angle in our diagram, whereas it increases in Walsh's.[1] The $1b_1$ orbital energy increases in Fig. 1, it remains constant in the Walsh diagram; *etc.*

We may note that the kinetic-energy-*versus*-angle diagram in Fig. 1 appears almost identical qualitatively with that of Coulson and Neilson,[10] who obtained their diagram by an entirely different method; see Section III below.

Earlier we argued,[9] by considering the diagram corresponding to Fig. 1 which is obtained by a certain unitary transformation of the orbitals, that lone-pair kinetic energies dominate the determination of geometry. The previously given evidence was basis-set dependent, but the conclusion may survive with accurate molecular orbitals if one makes an appropriate definition of the localization process—we do not know.

We next consider the molecule CH_2, in its $^1A_1$ state. This species has six valence electrons, and according to the Walsh rules it should be bent. In Fig. 2 are plotted the negative kinetic energies of CH_2 as functions of the HCH angle. If the figure is compared with the corresponding diagram for H_2O, Fig. 1, it can be seen that the same order of orbital (negative) kinetic energies prevails: $1b_2>3a_1>2a_1>1a_1$. However,

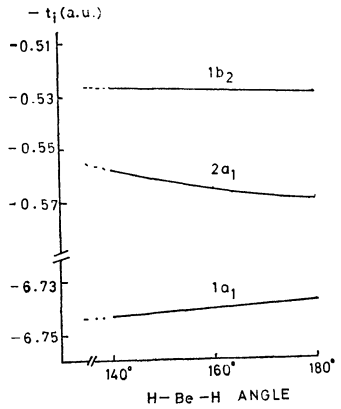

Fig. 3. Negative kinetic energies of the molecular orbitals of BeH_2.

energy changes with angle of individual orbitals are not the same in the two cases.

In Fig. 3 are plotted the corresponding orbital kinetic energies for BeH_2. The two top curves show minima at 180°, which may be regarded as showing how the four valence electrons drive the molecule linear.. This could be considered to be an explanation of one of the Walsh rules, which states that AH_2 molecules containing four valence electrons are linear. In the Figure it is seen that, indeed, the two bonding orbitals, $1b_2$ and $2a_1$, favor a linear conformation. This kinetic energy correlation diagram accounts for the shape of BeH_2. The orbital which contributes most in determining the molecular shape is $2a_1$.

Comparisons among the kinetic energy diagrams of H_2O, CH_2, and BeH_2 reveal that the kinetic diagram varies from one molecule to another—there seems to be no universal kinetic energy diagram. However, the kinetic diagrams do contain information about the roles played by the various orbitals, and they certainly do correspond to a rigorous resolution of the energy into components.

III. Correlation Diagrams from the Method of Median Partition

A true energy-angle correlation diagram must take into account all effects which occur on changing bond-angles, including nuclear-nuclear repulsion changes. The application of the virial theorem is an *indirect* method to include the nuclear repulsion energy; in this section we search for a possibility of including nuclear-nuclear repulsion directly. The question is how the total energy W can be resolved into additive parts $w(i)$ such that $W=\sum_i w(i)$. With $W=E+V_{nn}$, the problem is to find methods which partition both E and V_{nn} into additive parts.

First we consider the partition of the electronic energy E. In the Hartree-Fock approximation the additive resolution of E was discussed as early as 1951 in connection with semi-empirical calculations with the LACO-MO method; namely,

$$E = \sum_{\text{occupied MO's}}(\varepsilon_i + I_i) = 2\sum_i m_i \tag{2}$$

where I_i is the core integral $\int \phi_i^* H_{\text{core}} \phi_i d\tau'$ of the molecular orbital ϕ_i, and

$$m_i = 1/2(\varepsilon_i + I_i) = 1/2e_i. \tag{3}$$

The quantity m_i has been called the *median one-electron energy* or simply median energy.[14]

In 1963 Coulson and Neilson suggested the use of the median energies m_i in obtaining Walsh diagrams.[10] They rejected the use of the Hartree-Fock orbital energies ε_i for that purpose on the basis that ε_i are not truly additive. The Walsh diagram of median energies for the water molecule H_2O reported by Coulson and Neilson differs significantly from the diagram of orbital energies. Since then the use of the median energies m_i for a Walsh diagram has been a matter of controversy. Yet Eq. (2) is a resolution, which is truly additive of the total electronic energy, and we will use this in this section.

The task left is how to partition V_{nn} into additive parts. Coulson and Neilson did not address this problem.

Consider a diatomic molecule AB with nuclear charges Z_A and Z_B. Let N_A and N_B be gross atomic populations according to Mulliken's definition,[15] on atoms A and B, respectively. $N(i, A)$ and $N(i, B)$ are subtotal populations in molecular orbital ϕ_i on A and B, and related to N_A and N_B by $N_A = \sum_i N(i,A)$, and $N_B = \sum_i N(i, B)$. The nuclear-nuclear repulsion energy V_{nn} of AB is exactly $V_{nn} = Z_A Z_B/R$, where R is the bond length of the molecule. V_{nn} is related to N_A and N_B by the formula

$$\begin{aligned} V_{nn} &= \frac{1}{R}[(Z_A - N_A)(Z_B - N_B) + (Z_A N_B + Z_B N_A) - N_A N_B] \\ &= \frac{1}{R}[(Z_B - 1/2N_B)N_A + (Z_A - 1/2N_A)N_B] \\ &\quad + \frac{1}{R}(Z_A - N_A)(Z_B - N_B). \end{aligned} \tag{4}$$

Let us assume that the second term of Eq. (4) is much smaller than the first term, call it Δ. Then V_{nn} is given by,

$$\begin{aligned} V_{nn} &= \frac{1}{R}[(Z_B - 1/2N_B)N_A + (Z_A - 1/2N_A)N_B] + \Delta \\ &= \sum_i \frac{1}{R}[(Z_B - 1/2N_B)N(i,A) + (Z_A - 1/2N_A)N(i,B)] + \Delta \\ &= \sum_i \left[V_n'(i) + \frac{V_n'(i)}{\sum_i V_n'(i)}\Delta \right] = \sum_i V_n(i) \end{aligned} \tag{5}$$

where

$$V_n'(i) = \frac{1}{R}[(Z_B - 1/2N_B)N(i,A) + (Z_A - 1/2N_A)N(i,B)]. \tag{6}$$

The quantity Δ vanishes when $Z_A = N_A$ or $Z_B = N_B$. This happens whenever $Z_A = Z_B$. The quantity in the bracket of Eq. (5),

$$V_n(i) = V_n'(i) + \frac{V_n'(i)}{\sum_i V_n'(i)}\Delta, \tag{7}$$

defines the i-th component of the partitioned V_{nn}.

For polyatomic molecules, the foregoing partitioning method may be applied to each contribution to the nuclear repulsion energy. For instance the nuclear repulsion energy of a molecule AH_2 is the sum of two terms as follows,

$$\begin{aligned} V_{nn} &= 2\frac{Z_A Z_H}{R_{AH}} + \frac{Z_H^2}{R_H} \\ &= 2\sum_i \frac{1}{R_{AH}}[(Z_H - 1/2N_H)N(i,A) + (Z_A - 1/2N_A)N(i,H)] \\ &\quad + \sum_i \frac{1}{R_H}[(Z_H - 1/2N_H)N(i,H) \\ &\quad + (Z_H - 1/2N_H)N(i,H)] + \Delta \\ &= \sum_i [2V_{AH}'(i) + V_{HH}'(i)] + \Delta \\ &= \sum_i \left[V_n'(i) + \frac{V_n'(i)}{\sum V_n'(i)}\Delta \right] = \sum_i V_n(i), \end{aligned} \tag{8}$$

where

$$V_{AH}'(i) = \frac{1}{R_{AH}}[(Z_H - 1/2N_H)N(i,A) + (Z_A - 1/2N_A)N(i,H)], \tag{9}$$

$$V_{HH}'(i) = \frac{2}{R_H}(Z_H - 1/2N_H)N(i,H), \tag{10}$$

and

$$V_n(i) = 2V_{AH}'(i) + V_{HH}'(i) + \frac{V_n'(i)}{\sum V_n'(i)}\Delta. \tag{11}$$

For the total energy, from Eq. (2) and Eq. (8) we have a rigorous partitioning,

$$W = E + V_{nn} = \sum_{\text{occupied MO's}} [\varepsilon_i + I_i + V_n(i)] = \sum_i w(i) \tag{12}$$

where

$$w(i) \doteq \varepsilon_i + I_i + V_n(i). \tag{13}$$

The partitioned nuclear energies in H_2O are tabulated in Table 4. In Table 5 are presented the quantities $w(i)$. The sum $\sum w(i)$ in Table 5 does not necessarily agree with W in Table 3, since the bond distances are fixed to 1.8103 in Table 5 whereas in Table 2 they are varied to satisfy Eq. (1).

In Fig. 4 is given the correlation diagram obtained

by plotting $w(i)$ *versus* bond angle. If Fig. 4 is compared with Fig. 1, it is noticed that the order and the patterns of the curves are similar in the two figures. The coincidences prevailing among the figures are remarkable because they are obtained by entirely different methods of partition.

It is interesting to see how the "lone pair" energies $[w(3a_1)+w(1b_1)]$ change with θ. In Fig. 5 are plotted the relative lone pair energies and the total energy with the reference angle $\theta=90°$. The "lone pair" energies are seen to monitor the total energy W. We previously found a similar result when the quantum-mechanical virial theorem was applied for partitioning W.[9] The implication again is that lone pair electrons may control the equilibrium bond angle in H_2O. Further investigation along this line is required.

The partitioned nuclear-nuclear repulsion components are relatively small in comparison with the electronic energy components, as seen in Tables 4 and 5. This implies that inclusion of the partitioned nuclear repulsion energies does not alter general appearance of correlation diagrams obtained without including nuclear repulsion.

It would be interesting to extend the present method of partitioning W to various diatomic molecules as well as to other polyatomic molecules, and to compare the correlation energy diagrams so obtained—energy-*versus*-bond length for diatomic molecules, energy-*versus*-bond angle for polyatomic molecules—with the traditional ones.

IV. Correlation Diagrams from Integral Hellmann-Feynman Theorem

An energy difference ΔW_i between two isoelectronic states X and Y may be obtained from the integral Helmann-Feynman Theorem (IHF):[16]

$$\Delta W_i = \int \Psi_X H' \Psi_Y d\tau \Big/ \int \Psi_X \Psi_Y d\tau \qquad (14)$$

where H' is the difference of the two Hamiltonian operators of states X and Y. If one defines the transition density between the two states X and Y by

$$\rho_{XY}(1) = \frac{N}{S} \int \Psi_X(12\cdots N)\ \Psi_Y(12\cdots N)\ d\tau(23\cdots N) \qquad (15)$$

then Eq. (14) becomes

$$\Delta W_i = \int \rho_{xy}(1) h(1) d\tau(1) + \Delta V_{nn}, \qquad (16)$$

where $h(1)$ is the change in the nuclear-electron attraction operator. This equation shows that the electronic energy difference is directly related to the transition density. Hence the IHF theorem admits a classical interpretation of an energy change.

If approximate wavefunctions Ψ_X and $\tilde{\Psi}_Y$ for states X and Y are specified as single Slater determinants built from one-electron orbitals ϕ_X and ϕ_Y, it is always

possible to find $\tilde{\Psi}'_X$ and $\tilde{\Psi}'_Y$ which diagonalize the transition density matrix by unitary transformations of $\tilde{\Psi}_X$ and $\tilde{\Psi}_Y$. It can be shown that Eq. (16) may be written[17)]

$$\Delta W_l = 2\sum_{k}^{N/2} \frac{\langle \hat{\phi}_k^X | h(1) | \hat{\phi}_k^Y \rangle}{\langle \hat{\phi}_k^X | \hat{\phi}_k^Y \rangle} + \Delta V_{nn} \qquad (17)$$

where $\hat{\phi}_k$'s are molecular orbitals from which Ψ''s are built. They are called corresponding orbitals. Equation (17) shows that the change of the total electronic energy ΔE_l can be expressed as a sum of the partitioned quantities $\Delta E(i) \equiv 2\langle \hat{\phi}_i^X | h(1) | \hat{\phi}_i^Y \rangle / \langle \hat{\phi}_i^X | \hat{\phi}_i^Y \rangle$. This is an equation which we may make use of to obtain energy-angle correlation diagrams for polyatomic molecules by plotting $\Delta E(i)$ as a function of bond angle.

Integral Hellmann-Ferynman calculations were carried out for the molecule H_2O to compute energy changes with changes of bond angles. In Table 6 are presented the results, for the symmetric bent in which two hydrogen atoms are moved symmetrically. They are plotted in Fig. 6 as functions of HOH angles. This is a *relative correlation* diagram because only relative electronic energies to that of HOH angle 90° are plotted.

From Fig. 6 we can see which orbital components favor linear conformations and which favor bent conformations, and so on. For instance $[3a_1]$ strongly favors the bent conformation for H_2O, whereas both $[1b_2]$ and $[2a_1]$ favor the linear conformation. The rest, $[1a_1]$ and $[1b_1]$, have little effect in determining the shape of the molecule. Thus the bent shape of H_2O may be attributed to the specific character of $[3a_1]$. This is in accord with Walsh's statement of the role played by the $3a_1$ orbital from the point of view of binding energy.[1)] If Fig. 6 is compared with the energy diagram of Walsh, an interesting feature is noticed: The *trends* of energy changes of individual orbital components coincide completely. In both diagrams $1a_1$ and $1b_1$ remain constant, $3a_1$ increases, $2a_1$

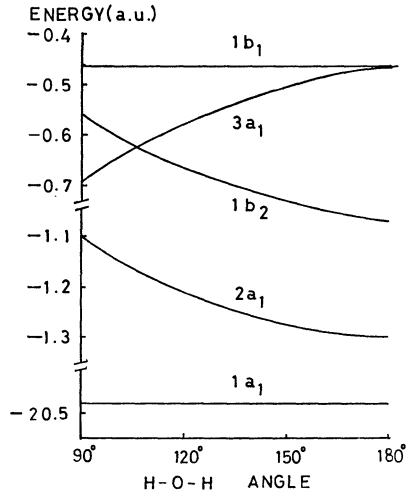

Fig. 7. Energy correlation diagram for H_2O including nuclear repulsion energies.

and $1b_2$ decrease as the bond angle increases from 90° to 180°.

Instead of using the IHF theorem, Coulson and Deb used the ordinary Hellmann-Feynman theorem, giving a new interpretation of the ordinate in the Walsh diagram.[8] Their force diagram looks similar to our IHF diagram except that $2a_1$ contribution rises in force diagram while it goes down in our diagram, as the bond angle increases.

So far the nuclear repulsion energies ΔV_{nn} have been left out, although clearly they should be taken into account in dealing with the problem of total energy change with conformational change. Resolution of ΔV_{nn} may be achieved in an analogous manner to the way V_{nn} was resolved in orbital components in Section III using corresponding orbitals and the method of population analysis of Mulliken with modifications. Because of close analogy between the two, detailed descriptions will not be given here. The resolved nuclear repulsion energies $\Delta V(i)$ are presented in Table 7.

The $\Delta V(i)$ may be divided into two classes: One is $\{[1a_1], [2a_1]$, and $[1b_1]\}$, the other is $\{[3a_1]$ and $[1b_2]\}$. The first class remains nearly constant with variations of bond angles, whereas the second changes very much more. The resolved nuclear energies $\Delta V(i)$ were added to the corresponding part of the electronic energies ΔE (i) to give total energy changes; these are listed in Table 8.

A *relative* correlation diagram such as Fig. 6 is useful when relative energy changes are concerned. However, it is desirable to have absolute correlation diagrams that show which orbital is higher in energy, and one comes next, and so on in treating Walsh's rules. If we assume a one to one correspondence between a Hartree-Fock molecular orbital and a corresponding orbital CMO in the IHF theory, $(1a_1)_{MO}$ *vs.* $[1a_1]_{CMO}$, $(2a_1)_{MO}$ *vs.* $[2a_1]_{CMO}$, $(3a_1)_{MO}$ *vs.* $[3a_1]_{CMO}$ *etc.*, and, assume that they have the same orbital energies at H–O–H angle 180°, an aboslute correlation diagram may be obtained, as in Fig. 7. If the correlation diagram in Fig. 7 is compared with the Walsh original diagram, a parallelism between the two figures is seen. Walsh's rules can be explained exactly as by Walsh if Fig. 7 is used.

The general trends of changes of one electron component stay more or less the same before and after inclusions of ΔV_{nn} terms, as seen in Figs. 6 and 7. This is another implication that *qualitative* Walsh-diagram may be obtained without taking ΔV_{nn} into consideration.

(Received November 19, 1973)

The gas-phase radiolysis of a mixture of toluene or ethylbenzene and dimethylamine has been studied at room temperature as a function of the dimethylamine pressure in order to investigate the structure and reactivity of the $C_7H_7^+$ ion. The structure of the $C_7H_7^+$ ion which takes part in the subsequent ion-molecule reaction was suggested to be the benzyl type on the basis of the reaction products. The radiolyses of toluene-α-d_3 and ethylbenzene-α-d_2 in the presence and in the absence of dimethylamine have been investigated, and the following information has been obtained: (i) the $C_7H_7^+$ ion formed from toluene and ethylbenzene mainly consists of the benzyl ion, retaining its original structure; (ii) two types of scrambling processes may be involved in the $C_7H_7^+$ ion formation, one of which, especially important in the case of toluene, includes the ring expansion of the original molecular ion, while the other consists of repeated rapid isomerization between the benzyl ion and the tropylium ion. These results were compared with those of mass spectrometric studies, which indicate that an almost complete isotope scrambling occurs, hence supporting the symmetrical tropylium structure for the $C_7H_7^+$ ion.

The structure of the $C_7H_7^+$ ion formed by the electron impact of toluene and higher alkylbenzenes has been the subject of numerous mass spectrometric investigations.[1] Extensive labeling experiments indicate the $C_7H_7^+$ ion, which further decomposes to the $C_5H_5^+$ ion, is a symetrical tropylium ion rather than a benzyl ion.[2] For example, the isotope retentions in the $C_7H_7^+$ ions from deuterated toluenes indicate that the eight hydrogen atoms are almost completely scrambled in the molecular ion. On the basis of this evidence and energetic considerations, Meyerson concluded that the toluene molecular ion rearranges to a cycloheptatriene-like structure of an even higher symmetry.[3] Harrison proposed instead an irreversible isomerization of the molecular ion to the cycloheptatriene isomer involving a transfer of an α-hydrogen to the adjacent ring carbon atom, followed by the insertion of the methylene group at random between any two ring carbon atoms.[4] This random insertion, leading to carbon scrambling, has been supported by studies using di-^{13}C-labeled toluene.[5,6]

Furthermore, Harrison's postulation has been supported by Howe and McLafferty.[7] They have also reported that the degree of scrambling decreases with an increase in the internal energy; hence, in the case of toluene some part of the $C_7H_7^+$ ion is formed by the direct dissociation of α-hydrogen before the scrambling of the hydrogen atoms occurs. For ethylbenzene, the tropylium structure has been again assigned to the $C_7H_7^+$ ion, although the formation process has not been clarified.[2]

More recently, Dunbar[8] has investigated the photoexcitation of toluene parent ions by ion-cyclotron resonance and shown that the photodissociation occurs with a complete hydrogen scrambling and a strong isotope effect. The energy dependence agrees with that determined for dissociative electron-impact ionization by Howe and McLafferty.[7] However, it has been also shown that non-dissociating $C_7H_8^+$ ions from toluene and cycloheptatriene are non-interconverting and that there is no important degree of interconversion among the toluene, cycloheptatriene, and norbornadiene molecular ions or conversion to a common structure, as determined on the basis of different photodissociation curves of these compounds.[9] This behavior is also in accord with the conclusion drawn from the ion-molecule reaction of $C_7H_8^+$ ions with nitrate by Hoffman and Bursey.[10]

On the other hand, during the course of our investigations of the gas-phase radiolysis it has been found that the $C_7H_7^+$ ions from toluene, ethylbenzene, xylenes, and cycloheptatriene react with aromatics to produce benzylated compounds; the reaction has been regarded as an electrophilic substitution reaction, which is well-known in solution chemistry.[11,12] Such a reactivity of the $C_7H_7^+$ ion with aromatics, as well as the structures of the products, seemed to suggest that the $C_7H_7^+$ formed in the gas-phase radiolysis of these compounds is a benzyl ion with a positive-charged center rather than a tropylium ion in which the positive charge is distributed equally among the seven carbon atoms. However, the question has been raised whether a tropylium ion is produced, since such a less electrophilic ion can hardly react with aromatics even if formed.

In connection with these problems, we have investigated the gas-phase radiolysis of alkylbenzene–dimethylamine (DMA) mixture. DMA has a higher basicity than aromatics and, therefore, would be expected to react with the tropylium ion.[13] Moreover, we have also investigated the gas-phase radiolysis of toluene-α-d_3 and ethylbenzene-α-d_2 in order to obtain information about the formation process of the $C_7H_7^+$ ion. The present paper will describe the structure and formation process of the ion from toluene and ethylbenzene on the basis of more evidence than in the preceding communications.[14]

Experimental

Materials. Toluene and ethylbenzene obtained from the Wako Pure Chemicals Industries Co. were fractionated through a spinning-band column after the usual purification. The purity, as determined gas-chromatographically, was more than 99.9%. The xylene isomers were purified in the same way; the purities were more than 99.1%. Cycloheptatriene prepared by the pyrolysis of 7,7-dichloronorcarane was purified by preparative gas chromatography. Norbornadiene obtained from the Aldrich Chemical Company, Inc. was purified by preparative gas chromatography. The DMA was

evolved by heating an aqueous dimethylamine solution obtained from the Wako Pure Chemicals Industries Co., dried by being passed through a KOH column twice, and stored in a storage bulb. Oxygen obtained from the Awao Industrial Co. was dried by means of a P_2O_5 column and was then used without further purification.

The toluene-α-d_3 was prepared by the method given in the literature,[15] and the deuterium content of the methyl group was determined to be more than 93.5% by NMR analysis. Ethylbenzene-α-d_2 was prepared by means of the following paths:

$$C_6H_5COCH_3 \xrightarrow{LiAlD_4} C_6H_5CD(OH)CH_3 \xrightarrow{SOCl_2}$$

$$C_6H_5CDClCH_3 \xrightarrow{LiAlD_4} C_6H_5CD_2CH_3$$

The isotopic purity was found by NMR analysis to be better than 99%. *N,N*-Dimethylbenzylamine-α-d_2, a standard authentic sample for analytical purposes, was prepared by the reduction of *N,N*-dimethylbenzamide with $LiAlD_4$ under THF reflux conditions. The isotopic purity was found to be better than 99% by NMR analysis.

Procedures. The experimental procedures were almost the same as those reported previously[11b] With the exception of the labeled experiments, all the irradiations were carried out in Pyrex cylinders approximately 110 ml in volume with γ-rays from a 5000 Ci ^{60}Co source at room temperature. The dosimetry was based on $G(C_2H_4 \rightarrow H_2) = 1.28$,[16] assuming that the energy distribution was proportional to the electron density of the sample. The dose rates in the present experiments were 3.0×10^{15} eV/hr·μmol for toluene, cycloheptatriene, and norbornadiene, and 3.47×10^{15} eV/hr·μmol for ethylbenzene and xylenes. The *G*-values in the runs were calculated on the basis of the energy absorbed by alkylbenzene, cycloheptatriene, or norbornadiene alone. The identification of the products was carried out by gas-chromatographic comparison with authentic samples using several columns (Apieson L—KOH, 6 m at 80 °C or 140 °C and Amine 3 m at 80 °C).[17] The yields of the products were determined by a comparison of the peak areas with those of known amounts of benzene, which were submitted to gas chromatography before each analysis. The calibration of the sensitivity for a flame-ionization detector was also carried out.

For the labeled experiments, spherical cells approximately 5 l in volume were used. Irradiation was carried out with a 3000 or 7000-Ci ^{60}Co source. The irradiated samples were collected in a glass tube by trap distillation. The reaction products, *N,N*-dimethylbenzylamine or diphenylmethanes, were isolated by preparative gas chromatography (Apiezon L-KOH, 3 m at 105 °C and Thermol 2 m at 190 °C respectively). The product isolated in a trap was dissolved with CCl_4 for NMR measurements and then submitted to NMR spectrometry (Hitachi Perkin-Elmer R-20 spectrometer), using CAT and a gas chromatography-mass spectrometry combination (Hitachi RMS-4).

Results and Discussion

The Reaction of the $C_7H_7^+$ Ion with DMA. Toluene-DMA mixtures were irradiated with ^{60}Co γ-rays to a dose of 8.4×10^{18} eV at 10 mmHg of toluene at room temperature. The formation of *N,N*-dimethylbenzylamine (DMBA) and a trace amount of an unknown product were observed, along with such products as benzene, ethylbenzene, xylenes, bibenzyl, and methyldiphenylmethanes(MDPM), which are known as radiolysis products of toluene. Figure 1 shows the correlation between the yields of DMBA and MDPM from toluene irradiated in the presence of varying amounts of DMA. The yields of these products were not affected by oxygen added as a radical scavenger. Quite similar relationships between DMBA and ethyldiphenylmethanes (EDPM) were also observed in the radiolysis of ethylbenzene–DMA mixtures, as is shown in Fig. 2. In this case, the formation of a small amount of *N,N*-dimethyl-α-phenethylamine was observed in addition to that of DMBA. Furthermore, in the radiolysis of xylenes, cycloheptatriene, and norbornadiene in the presence of DMA, the formation of DMBA was observed and the yields were not affected by the addition of oxygen (Table 1). These hydrocarbons are known to produce a similar $C_7H_7^+$ ion by electron impact.[18,19] Thus, the results suggest the formation of a common $C_7H_7^+$ ion as a precursor of both alkyldiphenylmethanes and DMBA, as is shown in Eqs. (1)—(3).

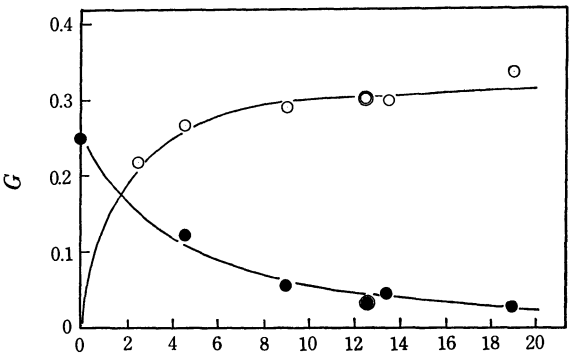

Fig. 1. Variations of the yields of methyldiphenylmethanes (MDPM, ●) and *N,N*-dimethylbenzylamine (DMBA, ○) as a function of the dimethylamine pressure in the radiolysis of toluene vapor (10 mm); ◉, ◎, when 10 mol% of oxygen was added.

From the data shown in Figs. 1 and 2, the relative reactivities of the $C_7H_7^+$ ion with DMA, ethylbenzene, and toluene were calculated to be 5.7, 2.1, and 1.0 respectively.

However, *N*,*N*-dimethyltropylamine, which is expected to be formed by the reaction of a tropylium ion with DMA, was not detected among the products under these experimental conditions except for the case of the cycloheptatriene–DMA mixture.[20]

$C_7H_7^+$ Ion from Ethylbenzene. Although a tropylium ion was not captured in the gas-phase radiolysis of alkylbenzenes, the possibility still remains that a tropylium ion is formed as an intermediate and that it reacts with the substrate after being rearranged to a benzyl ion. Since the deuterium-labeling study would be expected to present instructive information in this respect, ethylbenzene-α-d_2 and toluene-α-d_3 were irradiated in the presence and in the absence of DMA, and the NMR and mass spectra of the DMBA, EDPM, and MDPM thus produced were measured. The results obtained from these measurements are shown in Table 2 and Fig. 3.

The mass spectra of the DMBA formed in the gas-phase radiolysis of an ethylbenzene-α-d_2–DMA mixture agreed very closely with that of authentic *N*,*N*-dimethylbenzylamine-α-d_2, suggesting that the precursor

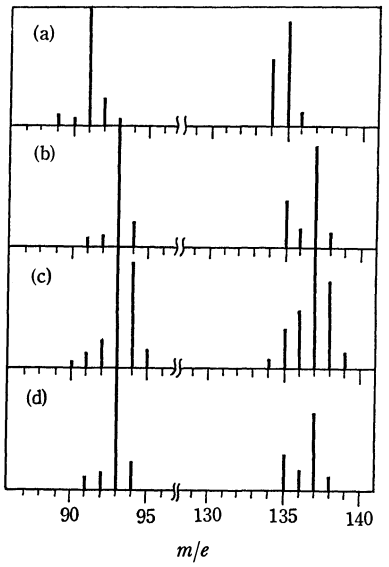

Fig. 3. Partial mass spectra of (a) authentic DMBA-d_0, (b) authentic DMBA-α-d_2, (c) DMBA formed in the gas-phase radiolysis of a toluene-α-d_3–dimethylamine mixture, and (d) DMBA formed in the gas-phase radiolysis of an ethylbenzene-α-d_2–dimethylamine mixture.

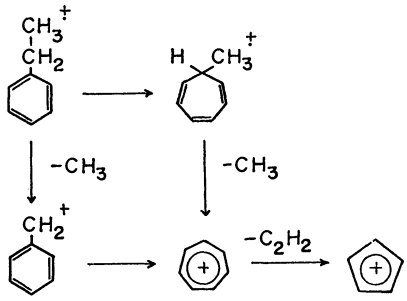
ion for this product is the $C_7H_5D_2^+$ ion formed by the loss of β-methyl from the original molecular ion without involving any isotopic mixing between β-methyl and benzyl groups (Fig. 3). Although the mass spectra of the EDPM formed in the gas-phase radiolysis of

pure ethylbenzene-α-d_2 were not analyzed because of its complexity resulting from the scrambling of this compound in the mass spectrometer, it seems reasonable to conclude on the basis of Eqs. (1)—(3) that the precursor ion for this product is also the $C_7H_5D_2^+$ ion.

The NMR data provide an important clue to the information on the isotopic distribution in these products. The ratios of the methylene protium atoms to the total phenyl protium atoms in DMBA and EDPM were determined and converted into the ratio of the methylene protium atoms to phenyl protium atoms of the benzyl group originating from the $C_7H_5D_2^+$ ion. If the $C_7H_5D_2^+$ ion took a symmetrical structure, that of a tropylium ion or another possible ion, the protium and deuterium atoms of the benzyl group of both products would be statistically distributed between the methylene and phenyl units and the H_{CH_2}/H_{Ph} ratio would be 0.40. On the other hand, if the $C_7H_5D_2^+$ ion were the benzyl ion retaining the original structure, no protium atoms would be introduced to the methylene group of either product. Since the observed H_{CH_2}/H_{Ph} ratios are between these two values except for one case (ethylbenzene-α-d_2 2.2 mmHg, DMA 3.8 mmHg), it may be suggested that a partial hydrogen scrambling occurs in the $C_7H_5D_2^+$ ion. The degree of scrambling calculated is also shown in Table 2.

On the other hand, in the mass spectrometric studies of ethylbenzene it has been proposed that the $C_7H_7^+$ ion, which undergoes further decomposition, is a tropylium ion, though the timing when ring expansion occurs is obscure, as is shown in Scheme 1.[21]



Scheme 1.

On the basis of the present observation, however, it seems reasonable to conclude that the $C_7H_7^+$ ion is formed as a benzyl ion by a loss of β-methyl from the ethylbenzene molecular ion before the ring expansion of the molecular ion. The benzyl ion thus formed reacts rapidly with DMA to produce DMBA without involving hydrogen scrambling when DMA is present at a higher pressure. When, in the absence of DMA, the $C_7H_7^+$ ion reacts with ethylbenzene, which has a lower reactivity to the ion, a hydrogen scrambling of the $C_7H_7^+$ ion may come to compete with the product formation. Such a hydrogen scrambling may occur *via* a tropylium ion, as has been suggested by the mass-spectrometric studies. For each experiment, the extent of scrambling was determined and plotted against the pressure of ethylbenzene, as is shown in Fig. 4. The extent of scrambling depends on the reaction

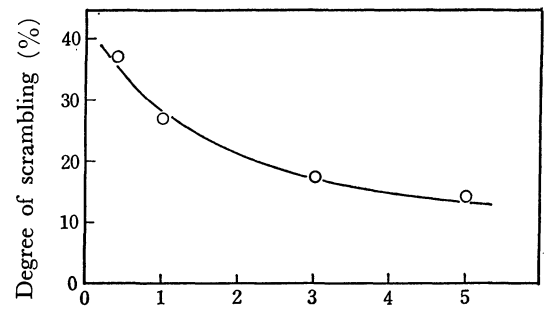


Fig. 4. Pressure effect on scrambling of EDPM formed in the gas-phase radiolysis of ethylbenzene-α-d_2.

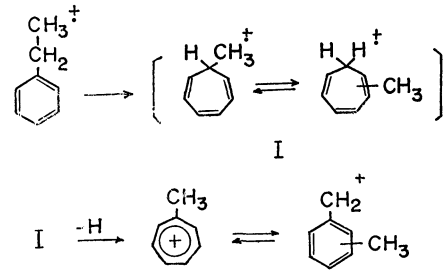
system; the scrambling becomes more remarkable as the pressure of ethylbenzene decreases, while the scrambling is completely depressed in the presence of enough DMA (3.8 mm) in the reaction system.

It is likely that the mechanism described above is also supported by the formation of a product derived from the $C_8H_9^+$ ion from ethylbenzene. It has been suggested in the mass-spectrometric investigations[22] that the $C_8H_9^+$ ion from ethylbenzene undergoes an extensive scrambling of the ring and α-hydrogen atoms, and that this scrambling is caused by a ring expansion from the ethylbenzene ion to the methylcycloheptatriene ion, followed by hydrogen shift, before the loss of the hydrogen (Scheme 2).

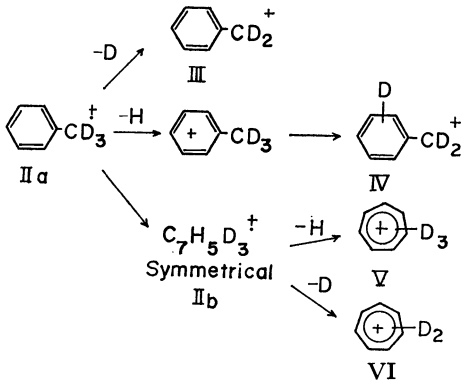


Scheme 2.

If the methyltropylium ion were formed in this manner in the gas-phase radiolysis of ethylbenzene, this ion would be expected to rearrange to the xylyl ion,[23] which would react with DMA to produce *N,N*-dimethylxylylamines. However, no *N,N*-dimethylxylylamines were detected among the reaction products; *N,N*-dimethyl-α-phenetylamine was observed instead. The precursor ion for *N,N*-dimethyl-α-phenetylamine is presumably the α-phenetyl ion, which is formed either by a hydrogen loss from the ethylbenzene ion or by a hydride transfer from ethylbenzene to any primary ion, and which does not rearrange to the methyltropylium ion nor to xylyl ions. Therefore, it may be concluded that the rearrangement from the ethylbenzene ion to the methylcycloheptatriene ion does not occur, at least not under the present radiolytic conditions.

$C_7H_7^+$ Ion from Toluene. As is shown in Fig. 3, the mass spectra of the DMBA formed in the gas-phase radiolysis of a toluene-α-d_3–DMA mixture is different

from that of authentic *N,N*-dimethylbenzylamine-α-d_2, indicating that both DMBA-d_2 and DMBA-d_3 are formed. The ratio of DMBA-d_2 to DMBA-d_3 was calculated to be 1.2 from relative intensities of the ions in the molecular ion region and the region corresponding to the $C_7H_7^+$ ion. This ratio also indicates that of $C_7H_5D_2^+$ to $C_7H_4D_3^+$. From the NMR spectrum, the ratio of the methylene protium atoms to the phenyl protium atoms was determined to be 0.14. The observed value suggests that a partial isotope scrambling occurs in the precursor ions of DMBA. The results can be explained by assuming the following scheme:



Scheme 3.

The benzyl ions, III and IV, are formed by the direct dissociations of D and H respectively from the molecular ion, IIa; the second dissociation is followed by a rapid intramolecular D^- transfer from the methyl to the phenyl group. These ions rapidly react with DMA to produce DMBA before the isomerization to tropylium ions occurs, since the concentration of DMA is high enough (12 mmHg). On the other hand, the tropylium ions, V and VI, are formed by the loss of H and D respectively *via* the symmetrical intermediate, IIb, as has previously been proposed by Meyerson. These tropylium ions also produce the DMBA, in which the deuterium atoms are statistically distributed in the benzyl groups *via* the isomerization to the benzyl ions. The benzyl ions, III and IV, produce DMBA containing five and four H_{Ph} respectively and no H_{CH_2} in the benzyl group. When i represents the isotope effect (k_H/k_D) on the hydrogen loss from the symmetrical intermediate, IIb, the ratio of V to VI is $3/5i$; the numbers of H_{Ph} and H_{CH_2} in the benzyl group of the DMBA originating from these ions are given by $5[(5\times 3)+(4\times 5i)]/7(5i+3)$ and $2[(5\times 3)+(4\times 5i)]/7(5i+3)$ respectively. On the other hand, the experimental values for H_{Ph} and H_{CH_2} in the benzyl group of the DMBA formed in the gas-phase radiolysis of a toluene-α-d_3-DMA mixture were calculated to be 4.0 and 0.56 respectively on the basis of the NMR and mass spectra. On the assumption of the wide range of i, 1~4, the relative contributions of III, IV, and V and VI to the DMBA formation were calculated to be 28~33, 33~31, and 39~36% respectively by correcting for the isotopic impurity in toluene-α-d_3.

The results for the MDPM formed in the gas-phase radiolysis of toluene-α-d_3 in the absence of DMA were treated in a similar manner; the relative contributions of III, IV, and V and VI to the MDPM formation were thus calculated to be 30~37, 39~29, and 33~31% respectively.

Aspects of the Mechanism. In the radiolysis of toluene, the degree of scrambling estimated from the DMBA formation agreed approximately with that from MDPM as described above; about one-third of the $C_7H_7^+$ ion leading to the product formation is a scrambled ion. This coincidence might be attributed to the fact that scrambling occurs only by a ring expansion from the toluene molecular ion to a symmetrical cycloheptatriene-like intermediate, not by isomerization from the benzyl ion to the tropylium ion. The reason for this is that, in the radiolysis of ethylbenzene-α-d_2, the benzyl ion formed by direct dissociation was trapped without involving as much isomerization in the presence of DMA as in the radiolysis of the toluene system. If the isomerization of the benzyl ion to a tropylium ion occurs, some differences in the degree of scrambling should be observed between the DMBA and MDPM formation, since this scrambling process competes with product formation, in which the reactivities of the $C_7H_7^+$ ion to DMA and toluene are different, as has been shown previously.

However, the scrambling is, generally, not so significant in the gas-phase radiolysis of toluene and ethylbenzene as in the mass spectrometry. As reasons why such a disagreement is observed, two factors may be considered; (i) the difference in the magnitude of the internal energy of the molecular ion, and (ii) the difference in such conditions as the pressure; these factors are both concerned with the lifetime of the ion. As for (i), in the fields of mass spectrometry Howe and McLafferty[7] have repoted that the degree of scrambling decreases with an increase in the internal energy; thus, in the case of toluene the direct dissociation of α-hydrogen becomes significant compared with the scrambling process. Assuming that the molecular ion fromed in the gas-phase radiolysis posseses greater internal energy, the question seems to be answered in a satisfying manner. Furthermore, with regard to (ii), the benzyl ion formed by such a direct dissociation comes to isomerize to a tropylium ion when the pressure of the substrate is low (Fig. 4) or when the rate of the product formation is slow (trapping by aromatics). These possibilities may become large under the conditions in a mass spectrometer.

Finally, a distinction between toluene and ethylbenzene in the $C_7H_7^+$-ion-formation process may be considered; the ethylbenzene ion does not rearrange to a symmetrical molecular ion, while a part of the toluene ion does. This difference can be explained in terms of the lifetimes of molecular ions. Since the ethylbenzene ion, in which the β C–C bond fission occurs with greater facility,[24] is probably more short-lived than the toluene ion, the scrambling path cannot compete with the direct dissociation. The benzyl ion thus formed is rapidly trapped by the successive ion-molecule reaction with ethylbenzene or DMA, without involving any significant unimolecular isomerization when enough of these trapping agents are present in the reaction system.

We wish to thank Dr. Seung Geon Kim for his advice on the preparation of toluene-α-d_3 and ethylbenzene-α-d_2. Thanks are also due to Mr. Yoshio Takai and Mr. Norio Kimura for their measurements of the NMR and mass spectra respectively, and Mr. Tomikazu Sawai and Mr. Tamotsu Yamamoto for the γ irradiations.

23) This rearrangement is analogous to that from tropylium ion to benzyl ion, and it was also observed in the radiolysis of xylene–DMA mixtures.
24) This correlation is compatible with the relative intensities of M^+ to $C_7H_7^+$ in the mass spectra of both compounds; the ratio in ethylbenzene (0.32) is smaller than that in toluene (0.74), indicating that the ethylbenzene ion decomposes more rapidly to $C_7H_7^+$ ion than toluene ion does.

Molecular Structure of Tungsten Oxide Tetrachloride by Gas Electron Diffraction

Kinya IIJIMA and Shuzo SHIBATA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 420

(Received October 13, 1973)

The molecular structure of tungsten oxide tetrachloride was determined by the sector-microphotometer method of gas electron diffraction. The molecule was found to have a square-pyramidal structure, and the following molecular parameters were obtained by a least-squares method; r_g(W–Cl)=2.281±0.003 Å, r_g(W–O)=1.686±0.011 Å, and r_g(Cl···Cl(s))=3.151±0.015 Å. The OWCl angle, 102.4±1.3°, is much larger than the corresponding angles found in other square-pyramidal molecules such as $XeOF_4$ and IF_5.

The geometrical structures of five-coordinated molecules can be divided into trigonal bipyramid and square pyramid. The former type was reported, for example, for PCl_5[1] and SOF_4,[2,3] though SOF_4 was found to be slightly distorted from a regular trigonal bipyramid. The latter type was reported for ClF_5,[4] BrF_5,[4] IF_5,[4] and $XeOF_4$.[4,5] The possibility of these structures can be explained in terms of the valence-shell electron-pair repulsion theory of Gillespie.[6] The electron configurations in the outermost shell of neutral tungsten and sulfur atoms are $(5d)^4(6s)^2$ and $(3s)^2(3p)^4$, respectively, and hence, the numbers of valence electrons in $WOCl_4$ and SOF_4 are equal to each other. Therefore, the structure of $WOCl_4$ should essentially be the same as that reported for SOF_4. From spectroscopic studies of $WOCl_4$ in the gas phase,[7,8] where the molecule is monomeric, however, the molecular structure is predicted to be square pyramidal. It is therefore interesting to determine the gas-phase structure of $WOCl_4$ by means of electron diffraction.* On the other hand, an X-ray diffraction study[9] has shown that the $WOCl_4$ molecule has C_{4v} symmetry in the crystal state by formation of –O–W–O– linkages.

Experimental and Analysis

The sample was prepared by the method described in Ref. 10 and was purified by repeated sublimations *in vacuo*. Since the sample was very reactive with moisture, it was loaded in a high-temperature nozzle in a dry box. The sample was vaporized at 65 °C, and electron-diffraction photographs were taken with an r^3-sector at a camera length of 144.08 mm. The accelerating voltage was about 40 kV, the exposure times were 30~40 sec, and the electron-beam current was 0.6 μA. Diffraction patterns of gold, the lattice constant of which was calibrated by means of X-ray diffraction, were used in order to measure the electron wavelength. Photographs were recorded on Fuji process hard plates, and the photographic densities of two plates were measured with a digital microphotometer at intervals of 0.4 mm. Intensities in a range of q=17~102 Å^{-1} were obtained and leveled by a theoretical background, which was calculated by using the elastic scattering factors of Kimura *et al.*[11] and the inelastic scattering factors of Tavard[12] for chlorine and oxygen and that of Bewilogua[13] for tungsten.

The radial distribution function was calculated by the use of the method of Bartell[14] because of the large differences in the atomic numbers. The corresponding correction terms for the radial distribution function are

$$\Delta M(q) = R\sum_{i\neq l}\sum C_{ij}(N_{ij}-\mu_{ij})\cos(\Delta\eta_{ij}) \times \sin[(\pi q/10)\{r_{a_{ij}}-\kappa(\pi q/10)^2\}] \times \exp\{-l_{ij}^2(\pi q/10)^2/2\}/(\pi q/10)r_{a_{ij}},$$

where R is the index of resolution, and

$$C_{ij} = Z_{ij}/\sum_k (Z_k^2+Z_k),$$

$$\mu_{ij} = |\dot{F}_i||F_j|/C_{ij}\sum_k (|F_k|^2+S_k),$$

$$N_{ij} = a_{ij} + b_{ij}\exp(-c_{ij}q^2),$$

$$|F_k| = h^2(\pi q/10)^2|f_k|/8\pi^2 me^2.$$

Other notations follow Refs. 14 and 15. N_{ij} was determined as follows so as to fit μ_{ij} in the whole range of the scattering angle:

$$N_{W\text{-}Cl} = 1.200$$

$$N_{W\text{-}O} = 1.205 + 0.289\exp(-0.00040\,q^2)$$

$$N_{Cl\cdots Cl} = 1.695 + 0.531\exp(-0.00029\,q^2)$$

$$N_{Cl\cdots O} = 1.762 + 1.049\exp(-0.00046\,q^2)$$

The parameters μ_{ij} and N_{ij} and the radial distribution curve are shown in Figs. 1 and 2, respectively. By inspection of the radial distribution curve and by comparison of the observed molecular intensities with those calculated on the assumption of C_{2v}, C_{3v}, and C_{4v} models, it was concluded that the molecular structure of $WOCl_4$ is a square pyramid, C_{4v}.

In order to refine the structure parameters, least-squares analyses based on the smooth-background method[16] by use of a polynomial of 7th degree were carried out. When the molecule was assumed to be a trigonal bipyramid like SOF_4, several parameters did not converge even after the 10th cycle of refinement. All the parameters carried large standard deviations, and the equatorial and polar W–Cl distances converged to the same value within the limit of error. The C_{3v} model was not tested in the least-squares calculation. On the other hand, when the molecule was assumed to be a square pyramid, all the parameters converged after several iterations. Thus the above-mentioned conclusion was confirmed by the least-squares analysis.

The index of resolution, r(W···Cl), r(W···O), r(Cl···Cl(s)), and five root-mean-square amplitudes l(W···Cl), l(W···O), l(Cl···Cl(s)), l(Cl···Cl(1)), and l(Cl···O) were determined by the least-squares analysis. The asymmetry parameters for bonded distances were estimated by a diatomic-molecule

* Preliminary results were reported in *Chem. Lett.*, **1972**, 1033. Spiridonov *et al.* have also reported the molecular structure of gaseous $WOCl_4$ by electron diffraction (V. P. Spiridonov, E. Z. Zasorin, I. M. Zharskii, and G. I. Novikov, *Zh. Strukt. Khim.*, **13**, 511 (1972)). The configuration reported by them is the same as that determined in the present study, but their bond lengths are much larger than those determined in the present study. The origin of the discrepancies, which exceed the limits of error, is unknown.

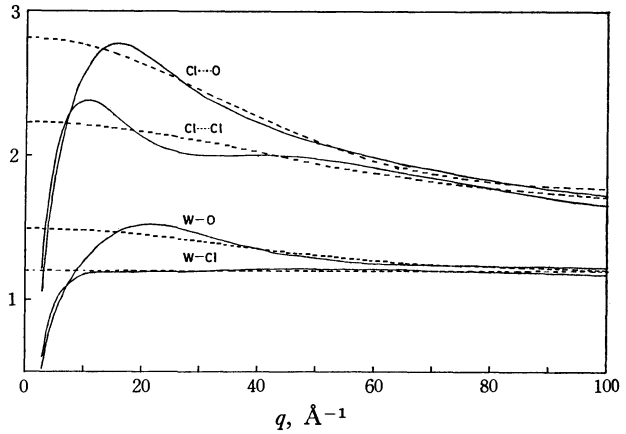

Fig. 1. μ_{ij} (solid lines) and N_{ij} (dashed lines) for $WOCl_4$.

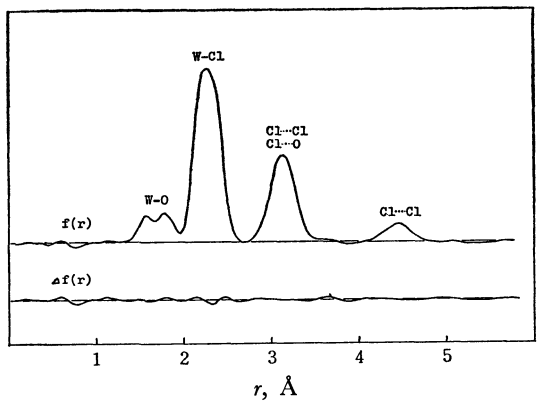

Fig. 2. Radial distribution for $WOCl_4$, $f(r)$, and the difference between observed and theoretical ones, $\Delta f(r)$.

approximation.[17] The parameter in the Morse function, a, was assumed to be 2.0 $Å^{-1}$, and the frequencies of ν_{W-O} and ν_{W-Cl} were taken to be 1027 and 402 cm^{-1}, respectively.[8] The assymmetry parameters thus obtained were 0.5×10^{-6} $Å^3$ for W–O and 4.0×10^{-6} $Å^3$ for W–Cl, and those for non-bonded distances were assumed to be zero. These asymmetry parameters were fixed throughout the least-squares analysis.

In the first stage, it was discovered that the correlation between the Cl···Cl(s) and Cl···O amplitudes was very large. This is probably because of the small difference between the distances, as observed by Jacob *et al.* in the analysis of $XeOF_4$.[5] In the analyses, where no constraint was set on the l(Cl···Cl(s)) and l(Cl···O), the difference between them was estimated to be about 0.03 Å, as listed in Table 1.

Since the results obtained from two independent intensity data are in good agreement with each other, as shown in Table 1, random errors were estimated as 2.5 σ_1 from the standard errors in least-squares calculations.[18] Systematic errors were estimated as follows. The error associated with the calibration of the lattice constant of gold was 0.06%, and the errors in the measurements of the diffraction patterns of the gold foil and the camera length were 0.08 and 0.04%, respectively. Then the total error of the wavelength was estimated to be 0.11% from the square root of the squared sum of the individual errors. The error in the q values was estimated from those in the electron wavelength and the camera length. The total errors in the bond distances were evaluated from the systematic errors (0.12%) and the random errors. The uncertainties in the atomic scatterign factor, f, and the phase angle, η, of tungsten were estimated** to have negligible effect on the systematic error in the atomic distances, but the systematic errors from this origin were found to be about 0.01 Å for l(Cl···Cl(s)) and l(Cl···O).

Table 1. Results of the least-squares analysis (in Å units)

	Plate 1	Plate 2	Average	σ_1
r_a(W–Cl)	2.2793	2.2800	2.2797	0.0007
r_a(W–O)	1.6847	1.6841	1.6844	0.0043
r_a(Cl···Cl(s))	3.1427	3.1493	3.1460	0.0057
l(W–Cl)	0.0523	0.0520	0.0522	0.0015
l(W–O)	0.0456	0.0439	0.0448	0.0043
l(Cl···Cl(s))	0.1220	0.1214	0.1217	0.0102
l(Cl···Cl(l))	0.1160	0.1202	0.1181	0.0078
l(Cl···O)	0.1002	0.0903	0.0953	0.0148
R	0.9232	0.9226	0.9229	0.0071

Table 2. Distances and mean amplitudes

r_g(W–Cl)	2.281±0.003 Å
r_g(W–O)	1.686±0.011
r_g(Cl···Cl(s))	3.151±0.015
r_g(Cl···Cl(l))	4.452±0.021
r_g(Cl···O)	3.120±0.026
l(W–Cl)	0.052±0.004
l(W–O)	0.045±0.011
l(Cl···Cl(s))	0.122±0.028
l(Cl···Cl(l))	0.118±0.020
l(Cl···O)	0.095±0.038
∠OWCl	102.4±1.3°
∠ClWCl	87.3±0.5°

The final results of the analysis are given in Table 2, where r_g parameters were calculated from r_a parameters by $r_g = r_a + l^2/r_a$. The correlation matrix[19] is given in Table 3, and the best-fit theoretical intensity curve is shown in Fig. 3.*** The least-squares computations were carried out by the use of a FACOM 230—60 at Nagoya University Computing Center.

Discussion

The square-pyramidal structure of $WOCl_4$ in the gas phase is in accord with that derived from infrared and Raman spectroscopy.[7,8] Although the structure of $WOCl_4$ in the gas phase is essentially the same as those of IF_5, ICl_5, IBr_5, and $XeOF_4$, the XMY angle in an MXY_4 molecule of C_{4v} symmetry is found to be remarkably different. The OWCl angle is 102.4± 1.3°, whereas the corresponding angles in IF_5, ICl_5, IBr_5, and $XeOF_4$ are about 90° or less. Moreover,

** A least-squares calculation, where the f and η values for platinum were used in place of those for tungsten, was carried out, and the changes in the parameter values were used for the estimation of their errors. The choice of platinum was inferred from a comparison of the observed cut-off point with the calculated ones.

*** Numerical experimental data of the leveled total intensity and the background have been deposited with the Chemical Society of Japan (Document No. 7411).

Fig, 3. Calculated molecular intensities, M_c, and the difference between observed and calculated ones, ΔM. The arrows 1 and 2 indicate the theoretical cut-off points due to the atomic pairs of W-O and W-Cl, respectively.

the OWCl angle in $WOCl_4$ is nearly equal to the OTiCl angle in $TiOCl_4^{2-}$ (102°) in crystalline $[N(C_2H_5)_4]_2$-$TiOCl_4$.[20] $TiOCl_4^{2-}$ has approximate C_{4v} symmetry in the crystalline state, and the Ti–O distance is 1.79 Å and the Ti–Cl distances are 2.32 and 2.34 Å. The shortening of the W–Cl distances of $WOCl_4$ in comparison with the Ti–Cl distance of $TiOCl_4^{2-}$ is consistent with the fact that the ionic radius of W^{6+} is about 0.06 Å shorter than that of Ti^{4+}.

The W–Cl distance found in the gaseous $WOCl_4$ molecule is equal to that in the crystal (2.28 Å), whereas the W–O distance in the vapor is considerably shorter than those in the crystal (1.8 and 2.2 Å).[9] The lengthening of the W–O distance in the crystal is apparently due to the decrease in the double bond character by the formation of –O–W–O– linkage.

Available data of infrared and Raman spectra are not sufficient to calculate the mean amplitudes of vibration of the atomic pairs in $WOCl_4$. However, if fundamental frequencies, ν_{W-O} and ν_{W-Cl}, are estimated to be 1027 and 402 cm^{-1}, respectively,[8] l(W–O) and l(W–Cl) can be estimated by a diatomic-molecule approximation to be 0.034 and 0.049 Å, respectively, in essential agreement with the results from the electron diffraction analysis.

We are pleased to acknowledge a grant from the Ministry of Education.

On the EPR Emission Spectrum of Transient Naphthosemiquinone Radical

Hiroshi YOSHIDA, Junkichi SOHMA, and Tetsuo WARASHINA*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

**Research Reactor Institute, Kyoto University, Kumatori-cho, Osaka 590-04*

(Received November 5, 1973)

EPR spectrum in emission mode at the low-field hyperfine lines was observed for 1,4-naphthosemiquinone radical formed by the steady-state photolysis of solution of corresponding quinone in ethanol flowing through the cavity. Observed behavior of this spectrum was analyzed by a phenomenological way. The results support the view that the anomalous electron spin polarization is generated in the radical formation process. The conclusion was compared with the results of intermittent photolysis.

Since the first observation of EPR emission spectrum (more precisely emission-absorption combined spectrum) for H radical during the radiolysis of alkanes,[1] chemically induced dynamic electron spin polarization (CIDEP) in short-lived free radicals has been reported[2] and also generated theoretical interests.[3] Among several theoretical attempts to interpret the anomalous spin polarization, the most promising mechanism at present seems to be a formation of radical pair, in which nonequilibrium populations of the spin levels arises from the combined effects of an exchange interaction between a radical pair and differences in the Larmor frequencies between the two radicals in the pair. This mechanism leads to the spin polarization which produces the EPR spectra composed of hyperfine lines both in emission and in enhanced absorption at such high field as 3000G. Fessenden applied this radical pair mechanism to interpret the anomalous spectra of H radical[1c] and others[4] and attained the conclusion that the nonequilibrium population was generated during the decay of the radicals by mutual recombination. This was the reason why the emission-absorption spectrum could be observed during the steady-state radiolysis, though the spin-lattice relaxation time should be much shorter than the chemical lifetime.

However, the radical pair mechanism does not seem to be a general and exclusive one for all CIDEP phenomena, because some photochemically generated transient free radicals were found to give EPR spectra entirely in emission. Among them, Wong and Wan studied the inversion from emission to absorption for 1,4-naphthosemiquinone radical formed in a solution of naphthoquinone in 2-propanol by intermittent photolysis, and found the time constant of about 300 μs for this inversion process.[5] They mentioned also that all hyperfine lines of the radical exhibited the same behavior. They proposed, to interpret this observation, a mechanism where the spin polarization occurs in photoexcited naphthoquinone during the course of intersystem crossing from singlet to triplet state and it is retained when the triplet-excited naphthoquinone abstracts a hydrogen atom from solute.[2e]

During the course of EPR study of short-lived free radicals under the steady-state photolysis of the solutions of quinones in ethanol, the present authors (H.Y. and T.W.) found an anomalous behavior of the spectrum due to 1,4-naphthosemiquinone radical which was recorded as a combination of emission and absorption.[6] This appeared different from the results obtained by Wong and Wan under the intermittent photolysis. Therefore, the study is extended to elucidate the behavior of the spectrum under the steady-state photolysis and the difference between two different photolysis conditions and to understand fully the spin polarization mechanism in this particular free radical.

Experimental

The apparatus used has been described in detail elsewhere.[7] EPR measurements were carried out with a conventional X-band spectrometer (Varian, E-3) during photolysis of flowing solution of 1,4-naphthoquinone (3.8 mM) in ethanol with unfiltered light from a super-high pressure mercury arc (Philips, SP 500). The effective volume of a quartz flat cell was $7\times0.2\times32$ mm). Ethanol and naphthoquinone were of analytical grade and were used without further purification. The solution was purged with helium gas before use to remove dissolved oxygen.

Results

Typical examples of the observed spectra are shown in Fig. 1. Although the photochemical reactions involved and the observed hyperfine structures were reported previously,[6] they are summarized here briefly. In a neutral solution, naphthosemiquinone anions and naphthosemiquinone radicals are formed simultaneously as shown in Fig. 1a. Their hyperfine structures are illustrated by the stick-spectra. The coupling constants for the anions are 3.25, 0.64 and 0.51 G (two equivalent protons for all three values), which agree with those reported by Wenkataraman *et al.*[8] The radical spectrum is identified by referring to the spectrum observed

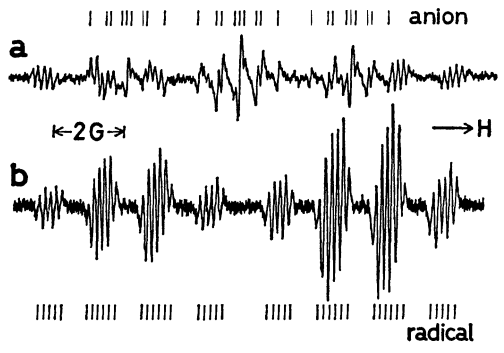

Fig. 1. EPR spectra observed during photolysis of 1,4-naphthoquinone (3.8 mM) (a) in ethanol at the residence time of the solution in the cell 0.07 s and (b) in ethanol with acetic acid (30 mM) at the residence time of 1.2 s.

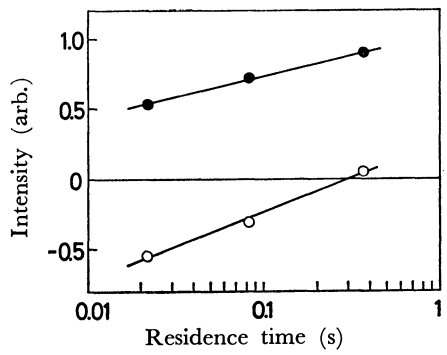

Fig. 2. Dependence of spectral line intensity of the naphthosemiquinone radical formed during the photolysis of naphthoquinone (3.8 mM) solution in ethanol on the residence time of the flowing solution in the cell at 20 °±3 °C, (○) average intensity of the second and fourth hyperfine lines from the low-field extreme and (●) that of the second and fourth lines from the high-field extreme.

when the solution is acidified with acetic acid (Fig. 1b). Its hyperfine coupling constants are temperature dependent and determined to be 6.80, 1.63 (2 protons), 1.50, 0.37 and 0.17 G (2 protons) at 34 °C.

The remarkable feature of the radical spectrum is that the intensity ratio of hyperfine lines depends very much on the flow rate of the solution. At the highest flow rate examined, a half of the spectrum at the low field is recorded as emission lines, whereas the high field half is in absorption (see Fig. 1a). The central part is too weak to be observed clearly. When the flow rate decreases, the emission lines gradually revert to normal absorption. The reversion of the spectrum is illustrated in Fig. 2 by the observed intensity of the second and fourth hyperfine lines from the low field end and those from the high field end as a function of the residence time of the solution in the cell (flow rate/cell volume) with other experimental conditions unchanged. It is surprising that the emission lines are observed not only under the intermittent photolysis condition[5] but also the steady-state photolysis condition. However, the spectrum is not entirely in emission in the latter case.

The chemical lifetime of the radical was estimated by means of a boxcar integrator and a rotating sector (11 cps) at the residence time of 1 s. The free radicals are thought to disappear by following a second-order kinetics, so that the lifetime may depend on the average concentration. However, the observed curve of radical formation and decay gives a rough estimate of the lifetime, 10 ms in the present photolysis condition.

Discussion

Normal steady-state photolysis is not a pertinent method to study the CIDEP phenomena in detail, because the observed spectra provide the information of spin populations in Zeeman sublevels averaged over the chemical lifetime of the free radical in question. However the steady-state photolysis method has some advantages, because the stability and sensitivity of the measurements are generally better than the time-resolved EPR measurement with flash (or intermittent) photolysis. Therefore, the anomalous behavior of the EPR spectra observed by this method indicates unequivocally, though qualitatively, something about CIDEP. In this discussion, we shall not go into the mechanism of spin polarization in detail but try to interpret phenomenologically the present observations.

Emission-absorption spectra are observed by the steady-state photolysis at high flow rates, but the chemical lifetime of free radicals as well as the residence time of the solution is very much longer than the spin-lattice relaxation time of the free radicals. This seems to indicate that the anomalous spin population is not generated in the radical formation process but by a continuous "pumping" during the decay of the radicals. For simplicity, let us consider a model radical with single proton. According to Fessenden's treatment based on the radical pair theory,[4] the spin populations are well approximated by the following differential equations:

$$\mathrm{d}(n_2-n_1)/\mathrm{d}t = -\{[(n_2-n_1)-\beta(n/4)]/T_1\} - f_{\mathrm{R}}k''(n/4)^2 \quad (1)$$

$$\mathrm{d}(n_4-n_3)/\mathrm{d}t = -\{[(n_4-n_3)-\beta(n/4)]/T_1\} + f_{\mathrm{R}}k''(n/4)^2 \quad (2)$$

where the subscripts 1,2,3 and 4 indicate the Zeeman sublevels (α_e, α_N), (β_e, α_N), (α_e, β_N) and (β_e, β_N), β the Boltzmann factor given by $h\nu/kT$, f_{R} the fractional degree of polarization induced by the recombination reaction, and k'' the second-order decay constant. For the steady-state photolysis of flowing solution, the number of total spin n changes as the following function of photolysis time, t,

$$n = (c/2k'')^{1/2}\tanh\{(2k''c)^{1/2}t\} \quad (3)$$

when the free radicals in question disappear by a second-order reaction, which should be additionally taken into account. c is the rate of radical formation. The observed intensity of the low-field hyperfine line is proportional to $\tau^{-1}\int_0^{\tau}(n_2-n_1)\mathrm{d}t$, where τ represents the residence time of solution in the cell.[9] Although the integration cannot be given analytically, Eqs. (1) and (2) indicate the qualitative nature of the low-field emission line. For the emission line to be observed, (n_2-n_1) should be negative, which turns out that $\mathrm{d}(n_2-n_1)/\mathrm{d}t$ should be negative in an appropriate range of time. Under proper conditions (strictly speaking, when $\beta<k''f_{\mathrm{R}}T_1(n''_s/4)$), the emission line develops in $\tau\approx 1/k''n''_s$ and its intensity reaches $\beta(n''_s/4)\{1-f_{\mathrm{R}}k''T_1(n''_s/4)/\beta\}$ at $\tau=\infty$ where n''_s is the steady-state value of $n(=\sqrt{c/2k''})$. The observation that the emission lines are recorded only for big flow rate, or short residence time τ (see Fig. 2) is just contrary to what is theoretically expected on the basis of the phenomenological analysis and excludes the possibility of generation of the anomalous spin population during the decay of radicals.

An alternative approach is that the CIDEP phenomena observed in steady-state photolysis and intermittent photolysis experiments are from the same origin, that is, the anomalous spin polarization generated at

the moment of radical formation when, no matter what the operative mechanism is, both (α_e, α_N) and (α_e, β_N) sublevels are overpopulated. Then Eqs. (1) and (2) are modified as follows,

$$d(n_2-n_1)/dt = -\{[(n_2-n_1)-\beta(n/4)]/T_1\} - f_F(c/2) \quad (4)$$

$$d(n_4-n_3)/dt = -\{[(n_3-n_4)-\beta(n/4)]/T_1\} - f_F(c/2) \quad (5)$$

under the assumption that the radical lifetime is much longer than T_1, where f_F represents the fractional degree of polarization induced in the radical formation process. The steady-state treatment can be applied to Eq. (4) except for the small time interval $t \lesssim T_1$, and the approximate relation

$$n_2 - n_1 = \beta(n/4) - f_F(c/2)T_1 \quad (6)$$

is obtained.

For simplicity, let us assume at first that the radical disappears in the following first-order decay:

$$n = (c/k')\{1-\exp(-k't)\}, \quad (7)$$

where k' represents the first-order decay rate constant. From (6) and (7), the line intensity is derived as

$$\frac{1}{\tau}\int_0^\tau (n_2-n_1)dt = \beta(n'_s/4)\{[1-(2f_Fk'T_1/\beta)] - (1/k'\tau)[1-\exp(-k'\tau)]\}, \quad (8)$$

where n'_s represents the steady-state value of n, c/k'. If $2f_Fk'T_1>\beta$, the emission line is observed regardless of the residence time τ. Even if $2f_Fk'T_1$ is smaller than β but not very much, the line can be in emission at such a low flow rate as $\tau\sim 1/k'$, as shown in Fig. 3. In this case, the line reverts from emission to absorption with increasing τ. If one takes values 1.48×10^{-3} for Boltzmann factor β for 9300 MHz at room temperature, 10^2 s^{-1} for k' and, arbitrarily 10^{-5} s for T_1, $f_F=0.7$ well develops the emission line. This f_F value turns out that the enhancement factor $f_F/2\beta$ of 250, which is compared with the value of 313 estimated by Wong *et al.* for naphthosemiquinone radical based on the intersystem crossing mechanism.[3e]

For the second-order decay, the line intensity is

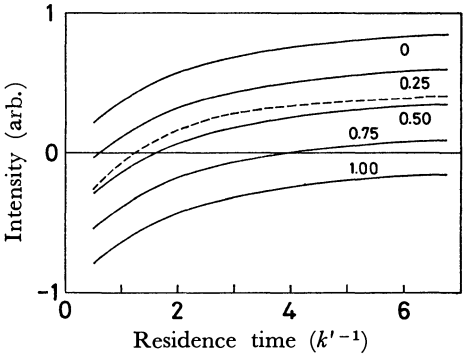

Fig. 3. Dependence of line intensity on the residence time of flowing solution expected from Eq. (8) for the first-order decay of radical. The value of parameter $2f_Fk'T_1/\beta$ for each curve is shown in the figure. The dependence for the second-order decay based on Eq. (9) is shown only for $2f_F\sqrt{2k''c}\cdot T_1=0.5$ by a dashed line. The intensity 1.0 corresponds to the Boltzmann distribution and negative intensities represent spectral lines in emission.

derived from equations (3) and (6) and expressed by a somewhat complex form as

$$\frac{1}{\tau}\int_0^\tau (n_2-n_1)dt = \beta(n_s''/4)\{(\sqrt{2k''c}\cdot\tau)^{-1} \times \ln[\cosh(\sqrt{2k''c}\cdot\tau)] - 2f_F\sqrt{2k''c}\cdot T_1/\beta\} \quad (9)$$

The intensity increases from negative to positive value and approaches to the limiting value of $\beta(n''s/4)\{1-2f_F\cdot\sqrt{2k''c}\cdot T_1/\beta\}$ in similar manner as that for the first-order decay. The difference in the dependence of the intensity upon τ is not significant between the second-order decay and the first-order one, as shown in Fig. 3 representatively for $2f_F\sqrt{2k''c}\cdot T_1/\beta=0.5$. Therefore, behavior of the spectrum is not seriously affected by the mode of radical decay except for unrealistically small values of τ.

It is most crucial to test whether the totally emissive spectrum immediately after the photolysis with pulsed light can be recorded as the emission-absorption spectrum under the steady-state photolysis. Really it can if f_F and/or T_1 are dependent on the nuclear spin state (in the simplified single proton model radical, dependent on the state α_N or β_N) as shown in Fig. 3. Assuming that the value of $2f_F\sqrt{2k''c}\cdot T_1$ is slightly smaller for the high field lines in naphthosemiquinone radical spectrum, they revert to absorption, as a function of τ, much quicker than the low field lines do.

Paramagnetic relaxation times were tried to be measured from the cw saturation and the line width. They were estimated as $T_1\sim T_2\sim10^{-6}$ s and their dependence on hyperfine lines could not be observed. However, the relaxation times based on the cw saturation may not be reliable enough to be involved in the present discussion of CIDEP. In addition, it was claimed by Atkins *et al.*[10] that a simple T_1 determination using the saturation properties of an emission is invalid.

In conclusion, the latter approach is reasonable to interpret the emission-absorption spectrum of naphthosemiquinone radical observed during steady-state photolysis of the flowing solution of naphthoquinone in ethanol. Although the flow rate is very slow compared with T_1, the anomalous spin polarization observed is generated at the radical formation rather than at the radical recombination. It was shown that the emission-absorption spectrum in the present study can be consistent, by choosing proper parameters, with the totally emissive spectrum previously observed by the intermittent photolysis. However, to attain the rigid conclusion, it is essentially desirable to examine the behavior of the emission lines of this particular radical by a time-resolved EPR measurements for a long time duration after a photolysis pulse, even though it may be difficult experimentally because of weak signal intensities.

Finally, it should be noted that the hyperfine lines at the high field of the naphthosemiquinone radical spectrum are in reduced absorption, as the population difference between electronic Zeeman sublevels is smaller than that in Boltzmann distribution as illustrated in Fig. 3. This feature is in contrast to the enhanced absorption observed for the high-field line of the H

radical spectrum in which the radical pair mechanism is operative at the radical disappearance. The present investigation suggests that the reduced absorption may sometimes occur for the electron paramagnetic resonance of short-lived free radicals which are known to give asymmetric EPR spectra very often.

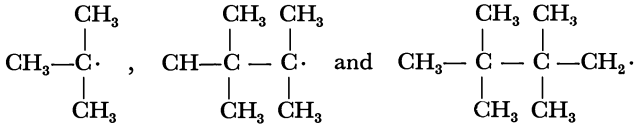
ESR Study on Transient Radicals in Plastic Crystals under Electron Irradiation

Hirotsugu SHIRAISHI, Hajime KADOI, Kenichi HASEGAWA, Yoneho TABATA, and Keichi OSHIMA

Department of Nuclear Engineering, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received December 21, 1973)

An apparatus was constructed for ESR measurements during electron irradiation, and the behavior of transient radicals in the plastic crystals of cyclohexane (CyH) and 2,2,3,3-tetramethylbutane (TMB) was investigated. It was found from the experiment that cyclohexyl radical produced by irradiation of CyH decays with a rate constant of 2×10^{-8} exp $(-7.9$ kcal$/RT)$ cm^3/s. The rate constant is in good agreement with the results reported by Buben *et al.* On the other hand, radicals formed in irradiated TMB were assigned to be



from the present results. It was shown from the results that the assignment made by Marx *et al.* before should be corrected to some extent. In the plastic crystals of CyH and TMB, it was suggested that the decay reactions of the observed radicals are controlled by the diffusional migration of the radicals. The analysis of radiolytic products of TMB was also made, and the results were compared with the results of ESR observation.

In order to study early stages of radiation chemical processes, it is very important to follow the dynamical behavior of transient species. The method of pulse radiolysis has been used with great success in the optical measurement of various kinds of transient species. ESR methods have been employed to give useful information about radicals produced by irradiation, but most studies were made by trapping of radicals in solids at low temperatures.

The ESR measurement of short-lived radicals under electron irradiation was first reported by Molin and his coworkers,[1] and an extensive study has been made by Fessenden and Schuler.[2] Recently a pulsed irradiation method in ESR spectroscopy has been developed by Smaller and his co-workers.[3] In the present paper, we report on apparatus for ESR measurements during electron irradiation and on some recent experimental results. Since there is much to be learned about the transient behavior of radicals in solids, the experiments using the apparatus are primarily aimed at such transient species. As the first step we have tried to measure transient radicals in cyclohexane (CyH) and in 2,2,3,3-tetramethylbutane (TMB), which are known to be typical of plastic crystals. It is known that radicals produced in a plastic crystal exhibit a well-resolved ESR spectrum due to motional narrowing and that they disappear rapidly far below the melting point of the crystal. Radicals formed in irradiated cyclohexane in its plastic crystal phase have been studied by previous investigators.[4-6]

The products formed in the radiolysis of TMB in its plastic crystal phase were analyzed chromatographically, and the results were correlated with radicals observed by ESR spectroscopy.

Experimental

Figure 1 illustrates the schematic diagram of the irradiation system. A Dynamitron accelerator was used as the irradiation source, and it was usually operated at 1.2 MeV with the beam current of 10—200 μA for ESR measurements. The focusing of an electron beam was at first difficult because of the long distance from the accelerator to the ESR cavity; the latter was located at the end of beam duct which penetrated through one of the pole pieces of ESR magnet. Several focusing magnets and a coil for the compensation of terrestrial magnetism were located along the beam duct to get a stable electron beam. When a sample of 3 mm in diameter and 7 mm in length was irradiated with an electron beam of 0.05 μA, the dose rate was about 1.5×10^8 R/hr. The dose rate was determined by the method developed by Tamura *et al.*,[7] that is, by measuring peroxy radicals formed in irradiated

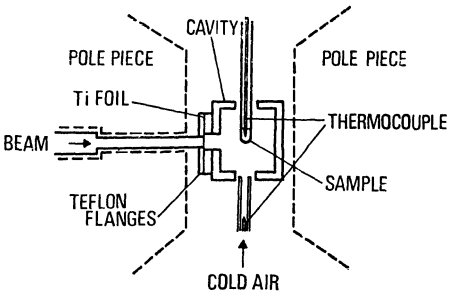

Fig. 2. ESR magnet and cavity.

polytetrafluoroethylene.

The ESR spectrometer used is a conventional X-band system with 100 kHz field modulation, and with cylindrical TE-011 mode cavity. The cavity has a 5 mm-diam. circular aperture on the wall to let an electron beam pass through it. Figure 2 is a sketch around the ESR magnet.

Dry air cooled by liquid nitrogen is used to control the temperature of the samples. Oxygen in air rapidly captures free electrons produced in the cavity and reduces their steady state concentration during irradiation. Oxygen, therefore, serves to suppress fluctuations of the resonant frequency of the cavity which would occur due to the presence of conduction electrons in the irradiated cavity if pure nitrogen was used as the coolant.

Commercial grade CyH and TMB (both above 99.9% purity) were used without further purification. Samples were degassed by a usual freeze-pump-thaw method, and were sealed off in thin-walled tubes of Spectrosil quartz.

The analysis of radiolytic products of TMB was made by a conventional gas-phase chromatograph with a flame ionization detector. Columns of squalane and of Apiezone L were used.

Results and Discussion

CyH exists in a plastic crystal phase between the transition point of −87.1 °C and the melting point of 6.3 °C. ESR studies on radicals formed in the plastic crystal of CyH under electron irradiation were already carried out by Buben *et al.*[4] and by Fessenden *et al.*,[5] and the radicals were assigned to cyclohexyl radicals. This decay was also studied by Buben *et al.*[6]

The decay characteristic of cyclohexyl radicals after the cessation of irradiation was studied more precisely in the plastic crystal phase by using our apparatus. The plots of reciprocal of radical concentration *versus* time obtained from the decay curves at different temperatures are shown in Fig. 3, where for convenience the reciprocal of each initial concentration is subtracted for each series of plots. All curves represent good fit to linear plots at the early stage of the decay. This implies that the decay is dominated by the second-order reaction, as was indicated by Buben *et al.* From the analysis of Fig. 3, the rate constant is estimated to be 2×10^{-8} exp(−7.9 kcal/RT) cm³/s, which is a little smaller than the value of 3×10^{-8} exp(−8 kcal/RT) cm³/s obtained by Buben *et al.*

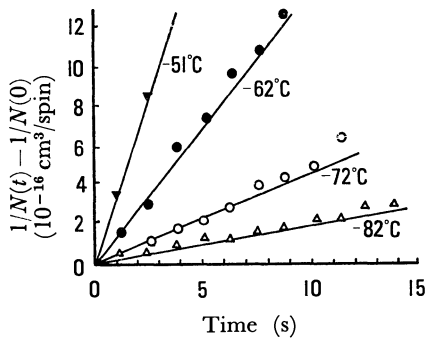

Fig. 3. Second-order plots of the decay of cyclohexyl radicals.
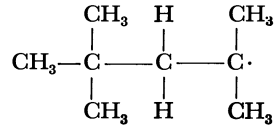
$1/N(t)$, $1/N(0)$: Reciprocal radical concentration at time t and zero, respectively.

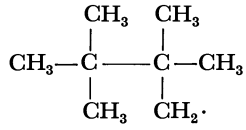
As pointed out in their previous study, both the abrupt change in the rate of the decay at the transition point of −87 °C and the coincidence of the activation energy with that of self-diffusion in the plastic crystal phase, 8 kcal/mol,[8] seem to support the view that the decay reaction is controlled by the diffusional migration of the radicals. But the rate constant obtained, though smaller than the value of Buben *et al.*, seems too large compared with the one expected from Smoluchowsky equation of diffusion-controlled reaction, 2.5×10^{-9} exp(−8 kcal/RT) cm³/s, assuming a diffusion constant of 2×10^{-3} exp(−8 kcal/RT) cm²/s[9] and a reaction radius of 5 Å. Since it is not probable that the radicals observed are distributed homogeneously, the above-mentioned fact may indicate that the radicals are able to diffuse more easily than ordinary molecules in the crystalline matrix.

TMB (2,2,3,3-tetramethylbutane) is in the plastic crystal phase between the transition point of −120.6 °C and the melting point of 100.6 °C. The ESR spectrum of γ-irradiated TMB was recently reported by Marx *et al.*,[10] but the present study led us to different assignments of the radicals. Figure 4a is the ESR spectrum of TMB at −113 °C, which was taken after electron irradiation, since the decay is very slow at this temperature. Marx *et al.* obtained a similar spectrum, but they seem to have been unaware of two outermost lines, which are small due to the corresponding binominal coefficient. They analyzed the spectrum as having 15 lines, and attributed the spectrum to radical A of 15 lines and B of three lines, where radical A was considered to be formed by isomerization of

[R_A]

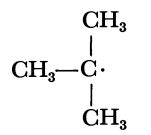


[R_B]

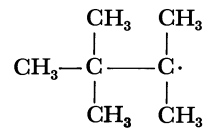


radical B. But in fact there are 17 lines, and it is plausible that the spectrum consists of sets of ten and of seven equally spaced lines, both exhibiting the same hyperfine splitting of 23.4±0.2 G and about the same g-factor; 2.0026±0.0002 for the 10 lines, and 2.0025±0.0002 for the seven lines. The line width is about 2.5 G at this temperature. The observed ratio of the relative intensities of the ten lines is 1 : 10 : 65 : 201 : 377 : 361 : 194 : 62 : 9.5 : 1 in the order of increasing magnetic field. The 10 lines are attributable to the *tert*-butyl radical R_I, though a considerable contribution from other radicals may be inferred from the observed ratio, which should be 1 : 9 : 36 : 84 : 126 : 126 : 84 : 36 : 9 : 1 in case of the *tert*-butyl radical alone. The fact that the ratio of the

[R_I]



[R_{II}]



$$[R_{III}] \quad CH_3-\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}-\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}-CH_2\cdot$$

line next to the outermost is close to 9 : 1 indicates radical R_A contributes little to the spectrum. Moreover, it is improbable that the rate of the decay of R_A is greater than that of R_B, which must be assumed to explain the spectrum at the higher temperature. The discrepancy between the observed central part of the ratio and that expected for R_I cannot be ascribed to a definite primary radical. Part of this discrepancy may be explained by the isobutyl radical which must be formed by an addition of a hydrogen atom to R_I. The presence of this secondary addition process is also presumed from the results of the analysis of the radiolytic products, as described later. The ratio of the relative intensities of the 7 lines is 1 : 6.5 : 21 : 41 : 23 : 6.5 : 1 in the order of increasing magnetic field, and the 7 lines are attributable to the overlapping of R_{II} of seven lines and R_{III} of three lines that have about the same hyperfine coupling constant; the ratio of the concentration of the former to the latter is about 2.3 : 1.

Figure 4b is the spectrum obtained at −40 °C under electron irradiation, and it shows that the intensity of *tert*-butyl radical became smaller relative to radicals of R_{II} and R_{III}. Correspondingly the measured decay rate of the former was larger than that of the latter at the higher temperature. This seems to imply that in this case also the reaction is diffusion-controlled and that the activation energy of the diffusion of *tert*-butyl radical is smaller.

Isobutene	0.30	0.17
Neopentane	0.02	0.02
2-methylbutane	0.01	0.02
2,3,3-trimethyl-1-butene	0.07	0.06
2,2,3-trimethylbutane	0.16	0.23
2,2,4-trimethylpentane	0.25	0.30
2,2,3-trimethylpentane	0.03	0.03
2,3,3-trimethylpentane	0.03	0.02

a) The dose rate was about 2 Mrad/min and samples were irradiated to about 60 Mrad. b) The absolute *G*-values may have errors of ±20% due mainly to possible errors in the dose rate measurements, but the relative *G*-values in each series are accurate with errors of ±5%.

Quantitative analysis of the decay curve was not made because of the complication brought about by the coexistence of three kinds of radicals and by the presence of secondary reactions during irradiation; these are discussed in the next section.

Table 1 shows analysis of products in the range C_4 to C_8[11] formed in samples irradiated at −50 and −10 °C. The irradiation was carried out under the same conditions as the ESR experiments.

The major products of the radiolysis are isobutane, isobutene, 2,2,3-trimethylbutane and 2,3,3-trimethyl-1-butene. These products are considered to be formed by the disproportionation reactions of R_I and R_{II}, respectively. But the ratios of the unsaturated to the saturated products are less than unity for both C_4 and C_8 products. This indicates that secondary addition reaction must have occurred during irradiation. This interpretation is consistent with the fact that the lower the temperature of irradiation, the closer the ratio approaches unity.

It must be noted that the ratio of C_4 to C_8 products is far larger than expected from the ratio of the *G*-values of R_I to R_{II}, which were estimated to be about 0.5 from the ESR measurements. This implies that a considerable fraction of C_4 products is formed by processes other than the radical mechanism.

A large *G*-value of 2,2,4-trimethylpentane is not expected directly from the assigned radicals but its presence is reasonably explained by the recombination of R_I with isobutyl radical that is thought to be formed by the addition of a hydrogen atom to isobutene. The isobutyl radical is not clearly recognized in the ESR spectrum, although the presence of such a radical is inferred from the consideration of relative intensities of the lines, as mentioned earlier.

As for products larger than C_8, two were found to have *G*-values of about 0.1∼0.2. These products are presumably related to the assigned R_{III} radical, but their exact identification is difficult.

The authors wish to thank Mr. M. Onoue and Mr. T. Kawanishi for their help in the experimental setup and for operating the accelerator.

The Crystal Structure of *dl*-1,2,3,4,5,6-Hexahydro-6,11,12,12-tetramethyl-2,6-methano-3,11-propano-3-benzazocine Hydrochloride Monohydrate

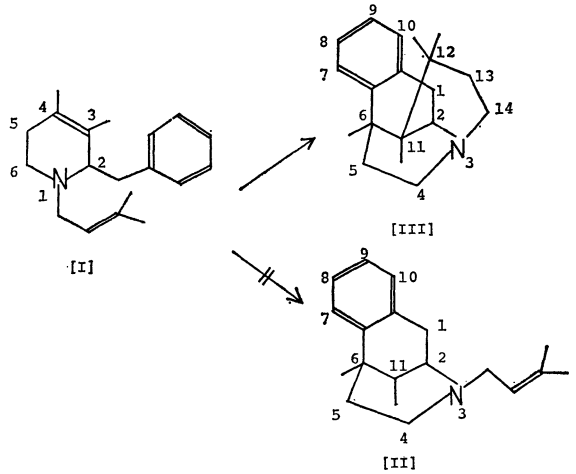
Michio KIMURA, Takesi NAKAJIMA, Shigeho INABA, and Hisao YAMAMOTO

Takarazuka Research Laboratories, Sumitomo Chemical Co., Ltd., Takatsukasa, Takarazuka, Hyogo 665

(Received December 26, 1973)

The structure of the title crystal ($C_{19}H_{27}N \cdot HCl \cdot H_2O$) has been determined by X-ray diffraction method. The racemate crystallizes in monoclinic, space group $P2_1/c$ with $a=14.30$, $b=15.74$, $c=7.79$ Å, $\beta=98°58'$ and $Z=4$. The reflection intensities were measured visually from equi-inclination integrating Weissenberg photographs taken with Cu$K\alpha$ radiation. The structure was solved by the direct method of phase determination. The final R factor was 0.113. The molecules are linked in endless chains along c-axis by $N^+ \cdots Cl^-$ and $Cl^- \cdots H_2O \cdots Cl^-$ hydrogen bonds. Two piperidine rings in the molecule have the chair conformation. This product which shows analgesic activity has a new molecular structure having a four-ring system, part of which is a benzomorphan nucleus.

In several synthetic studies of 6,7-benzomorphan derivatives,[1] it has been reported that the cyclization of 1-allyl-1,2,5,6-tetrahydro-2-benzyl-3,4-dimethylpyridine or the corresponding 1-(3′-methylallyl) derivatives with Lewis acid gives the 6,7-benzomorphan derivatives. We have discovered that cyclization of 1-(3′,3′-dimethylallyl) derivatives [I] with P_2O_5-85% H_3PO_4 does not give 3-(3′,3′-dimethylallyl)-1,2,3,4,5,6-hexahydro-6,11-dimethyl-2,6-methano-3-benzazocine [II], but another product in high yield, which shows analgesic activity. We failed to determine the molecular structure of the product by NMR, IR and Mass spectra. An X-ray diffraction investigation for its hydrochloride has been undertaken, and the chemical structure of the product established is [III].



Experimental

Preparation of 1,2,3,4,5,6-Hexahydro-6,11,12,12-tetramethyl-2,6-methano-3,11-propano-3-benzazocine[III]. A mixture of 40 g of [I], 262 g of phosphorus pentoxide and 329 g of 85%-phosphoric acid was kept at 135~140 °C (bath temperature 150~160 °C) for 20 hours under nitrogen atmosphere, cooled, poured into 500 ml of ice-water and basified with concentrated ammonium hydroxide. The oily product was extracted three times by 500 ml of ether and dried over anhydrous sodium sulfate. After removal of ether, the residue was distilled under reduced pressure. Bp: 144~147 °C (0.25~0.28 mmHg); Mp: 72~74 °C (uncorr.). Anal. Calcd for $C_{19}H_{27}N$: C(84.70); H(10.10); N(5.20%). Found: C (84.65); H(9.97); N(5.16%). IR: ν_{max}^{Neat} 2850~3050, 1600, 1580, 1480, 1440, 760, 740, 710, 700 cm^{-1}. NMR ($CDCl_3$);

Preparation of the Hydrochloride of III. To the ethereal solution of III was bubbled anhydrous hydrogen chloride gas at 0～5 °C for 10 minutes. The resulting crystals were filtered and recrystallized from acetone at room temperature. Colorless prisms, $C_{19}H_{27}N\cdot HCl\cdot H_2O$. Mp: 243.5～244.5 °C (uncorr.). Anal. Calc. for ($C_{19}H_{30}ONCl$): C(70.43); H (9.35); N(4.32); Cl(10.95%). Found: C(70.40); H(9.31); N(4.30); Cl(10.91%). IR: ν_{max}^{Nujol} 3500, 3450, 2500, 1640, 780, 740 cm^{-1}. $[\alpha]_D^{20°}$: 0°(c=1.316, MeOH).

The thermogravimetric analysis(TGA) scan showed a 5.20 % weight loss in the temperature region 65—149 °C (in comparison with 5.562% calculated for one water molecule of the monohydrate).

X-Ray Analysis of $C_{19}H_{27}N\cdot HCl\cdot H_2O$. Single crystals suitable for X-ray analysis were shaped to rectangular prism elongated along the c axis, by dissolving with methanol. The unit cell dimensions were calibrated with NaCl powder patterns superposed on Weissenberg photographs. The density was measured by flotation in a mixture of benzene and carbon tetrachloride. Crystal data was listed in Table 1. Crystal specimens of dimensions $0.44\times0.40\times0.51$ mm and $0.24\times0.29\times0.52$ mm were selected for data collection around the b and c axes respectively. Weissenberg photographs for layers of $h0l$-$h121$ and $hk0$-$hk5$ were taken with nickel-filtered Cu$K\alpha$ radiation. Intensities were esitmated visually, and corrected for Lorentz and polarization factors and for absorption. But no correction for spot shapes was applied. An absolute scale and overall temperature factor (B=3.122 Å^2) were determined by Wilson plot[2] and a total of 3211 independent reflections were obtained.

Solution and Refinement of the Structure

A symbolic addition procedure[3,4] was used to solve the phase problem. Normalized structure factors, $|E_h|$

were calculated and a set of Σ_2 relationships was tabulated. Three origin defining reflections and four reflections given symbols were selected by consideration of the magnitudes of the $|E_h|$ and the number of high probability Σ_2 relationships for each reflection, shown as in Table 2. The signs or symbols of 293 reflections out of 486 with $|E_h| \geq 1.4$ were determined by Σ_2 relationships. An E map was calculated based on these 293 signed E's with a=d=(+) and b=c=(−), and 21 of the 22 non-hydrogen atoms were located. The oxgen atom of water was revealed on a subsequent difference Fourier map. The R value, $\Sigma||F_o|-$

$|F_c|/\Sigma|F_0|$, at this stage was 0.469 with all 22 atoms assumed as carbon atoms. Refinement of the structure was done first by diagonal and then block-diagonal least-squares until $R=0.134$. A difference Fourier map using all reflections, indicated the positions of all 30 hydrogen atoms, which is shown in Fig. 1. The hydrogen atom coordinates used in further refinement, however, were calculated from geometrical considerations and were not refined. All hydrogen atoms were given isotropic temperature factors which were those of the atoms to which they are attached. The final R was 0.113 for all observed reflections. The final atomic parameters are shown in Table 3. Atomic scattering factors were taken from "International Tables for X-ray Crystallography".[5]

A list of the observed and calculated structure factors is kept by the office of the Chemical Society of Japan, (Document No. 7415). All calculations were done on a CDC 3600 and IBM 370 computers using the UNICS programs and those written by the present authors.

Results and Discussion

The molecule [III] consists of a four-ring system, the rings being named as A, B, C and D in Figs. 2 and 3. The molecular structure shown in Figures is one of the racemic paires. The bond distances and angles are shown in Table 4. The standard deviations in the distances and angles are estimated to be 0.049 Å and 2.8° respectively. The molecule of [III] is a new molecular skeleton, but it can be considered as a segment of morphine molecule,[6] since the corresponding parts (rings A, B and C) have the same configuration as the latter. The bond distances and angles are in good agreement with those in cyclazocine,[7] 2-allyl-2'-hydroxy-5,9-dimethyl-6,7-benzomorphan (AHDB).[8] The product [III] has analgesic activity as well as AHDB and cyclazocine. The averages of the aromatic C–C, saturated C–C and C–N bonds are 1.395, 1.541, and 1.499 Å respectively. The ring B attached to the benzene ring has a slightly distorted half-chair conformation with C(9) lying 0.66 Å above the benzene ring plane (Table 5). Two piperidine rings (C and D) assume a nearly regular chair form, and the conformations about the ten single bonds in C and D are staggered. The methyl groups C(16), C(17) and C(18) are in equatorial positions with re-

spect to the piperdine ring C and/or D. C(19) is in axial positions with respect to D. Figures 2 and 3 show the molecule viewed normal to and parallel to the benzene ring plane respectively. These figures show that the benzomorphan nucleus is approximately shaped. Intermolecular distances (<4 Å) are shown in Table 6. Hydrogen bonds exist between the N^+ and Cl^- ions and between the Cl^- ion and the water molecule, so that endless chains along c-axis are formed as seen from Figs. 4 and 5.

The authors wish to express their thanks to professor Kenji Osaki of the Pharmaceutical Department of Kyoto Univ. for discussions about this manuscript and to the staffs of Sumitomo Chemical Computer Center for computing.

The Crystal Structure of Pyrazinic Acid

Fusao TAKUSAGAWA, Taiichi HIGUCHI, Akira SHIMADA,†
Chihiro TAMURA,* and Yoshio SASADA**

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

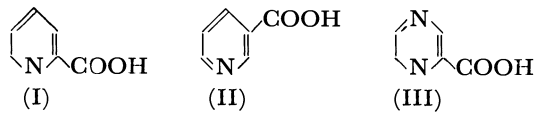
(Received December 27, 1973)

The crystal structure of pyrazinic acid has been determined by X-ray diffraction method. The crystal is orthorhombic, space group $Pna2_1$, $a=11.352$, $b=7.363$, $c=6.454$ Å, and $Z=4$. The structure was solved by inspecting the sharpened Patterson map. The final R value is 6.4% for all observed reflections. The molecule does not take a zwitter ion, but a neutral form. The dimensions of the pyrazine ring are close to those of pyrazine. Each molecule is joined, through the O–H···N hydrogen bond with distance of 2.669 Å, to two neighboring molecules forming the chain. These chains are linked by the weak C–H···O hydrogen bond to form the sheet parallel to the (0 0 1) plane. This hydrogen bonding scheme is quite similar to that of nicotinic acid. The hydrogen bonding type found in nicotinic acid is considered energetically favored more than that found in picolinic acid.

This work is a part of serial studies on the O–H···N hydrogen bonding in solids. The crystal structures of picolinic acid (I)[1] and nicotinic acid (II)[2] are quite different from each other. Each picolinic acid molecule is joined by two kinds of hydrogen bonds,



(I) (II) (III)

O—H—O and N—H—N, to two neighboring molecules forming the chain. On the other hand, the O–H···N hydrogen bonds between the carboxyl group and the pyridine ring link the nicotinic acid molecules to form an endless chain.

Pyrazinic acid(III) has a similar framework and isoelectronic structure to both of (I) and (II) and hence might form either types of hydrogen bonds mentioned above. The crystal data of (III),[3] however, indicate that it is isomorphous with neither of crystals (I) nor (II). Therefore, elucidation of the effect of nitrogen atoms on the hydrogen bond formation in solids should be interesting.

Experimental

The crystals were obtained in the form of light yellow prisms by recrystallization from a mixed solution of water and ethanol. Weissenberg photographs showed that the space group is $Pna2_1$ or Pnam(absent spectra: $0kl$ when $k+l$ is odd, $h0l$ when h is odd). The cell dimensions were measured from zero-layer photographs taken with a double radius Weissenberg camera($R=57.296$ mm). They are given, along with other crystal data, in Table 1. One of the crystals was shaped to a sphere with an average diameter of 0.4 mm. The intensity data were collected for the 0—6 layers around the c axis and for the 0—5 layers around the b axis using the equi-inclination integrating Weissenberg technique, with Cu$K\alpha$ radiation. The intensities were estimated visually by comparison with an intensity scale; 662 independent reflections were obtained. Absorption and extinction corrections were not applied.

† Deceased August 5, 1973.

Linear absorption coefficient	12.01
Number of independent reflections	662

Structure Determination and Refinement

The structure was solved by inspecting the sharpened Patterson map. Successful solution of the structure led to assignment of $Pna2_1$ as the appropriate space group. All the hydrogen atoms were found in a difference Fourier map. The structural parameters of the atoms including isotropic hydrogen were refined by a full-matrix least-squares, minimizing the function $\Sigma w(F_o-F_c)^2$, where

$$w = 1.0/[10(|F_o|-2.0)^2 + 1.0] \text{ for } |F_o| \leqq 2.0$$

and

$$w = 1.0/[(|F_o|-2.0)^2 + 1.0] \text{ for } |F_o| \geqq 2.0$$

The final agreement factors were:

$$R = \Sigma||F_o|-|F_c||/\Sigma|F_o| = 0.064$$
$$R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.090.$$

The atomic scattering factors used were those listed in the International Tables for X-ray Crystallography[4] for C, N, and O atoms, and those of Stewart *et al.*[5] for H atom. The observed and calculated structure factors are listed in Table 2.*** The fractional co-

*** Table 2 has been submitted to, and is kept by the office of the Chemical Society of Japan, 1-5, Kanda-Surugadai, Chiyoda-ku, Tokyo (Document No. 7412).

Table 3. The final parameters and their estimated standard deviations (in parentheses)

The coordinates of the non-hydrogen atoms have been multiplied by 10^4; those of the hydrogen atoms, by 10^3. The anisotropic thermal factors of non-hydrogen atoms are of the form of $\exp(-B_{11}h^2\cdots-B_{12}hl\cdots)$, and have been multiplied by 10^4. For the hydrogen atoms, the values are isotropic thermal factors B(Å^2).

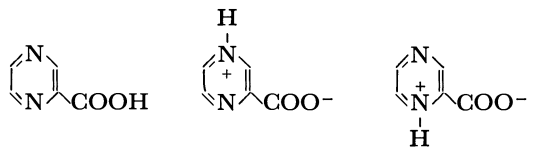
Results and Discussion

Molecular Structure. Figure 1 shows the difference Fourier map viewed along the c axis, in which there is no high peaks except for those due to the hydrogen atoms. Figure 2 shows the thermal ellipsoids of atoms, drawn with the 74% probability level. The bond lengths and angles are given in Fig. 3.

The pyrazinic acid molecule can take either of the following three forms;



(A) (B) (C)

From the position of the hydrogen atom in the difference Fourier map, however, it is evident that the molecule takes the neutral form (A) in the crystal. This is also concluded from the difference of 0.104(3) Å between the C(7)–O(1) and C(7)–O(2) bond lengths and the C(3)–N(4)–C(5) bond angle of 117.0(2)° (the values in parentheses denote the e.s.d.'s in the last digits).

A pyrazinic acid molecule is approximately planar with a maximum deviation of 0.044 Å, but close examination reveals that the pyrazine ring takes a chair form; the planes of C(2), N(1) and C(6) and of C(3), N(4) and C(5) make the dihedral angles of 7.2° and C(3), respectively, with the least-squares plane of C(2), 4.0°, C(5) and C(6). The least-squares planes and displacements of the atoms from them are given in Table 4.

The dimensions of the pyrazine ring are close to those of pyrazine.[7] The substitution of a carboxyl group at the C(2) atom may cause the small differences between the N(1)–C(2) and N(1)–C(6) bond lengths and between the C(2)–C(3) and C(5)–C(6) bond lengths. They are quite compatible with the difference in the π-bond orders calculated by the CNDO/2 method,[6] shown in Fig. 4. A small difference between the C(2)–N(1)–C(6) and C(3)–N(4)–C(5) bond angles may be

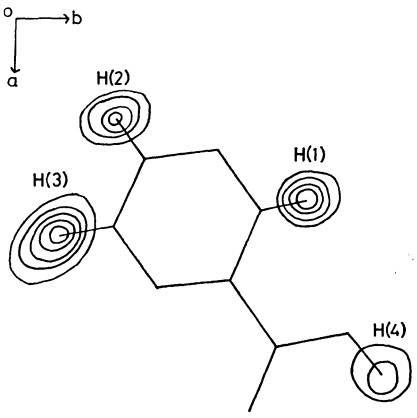


Fig. 1. A composite drawing of the electron density associated with the hydrogen atoms. The contours are at intervals of 0.1 e·Å^{-3}, beginning with the 0.2 e·Å^{-3}.

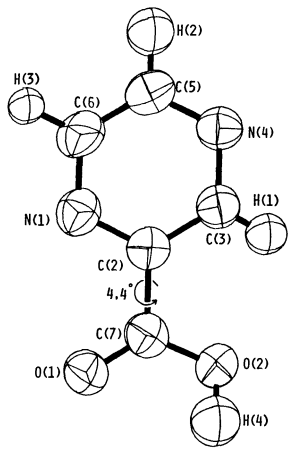

Fig. 2. The thermal ellipsoids of atoms.
The numeral indicates the dihedral angle between the planes of the pyrazine ring and the carboxyl group.

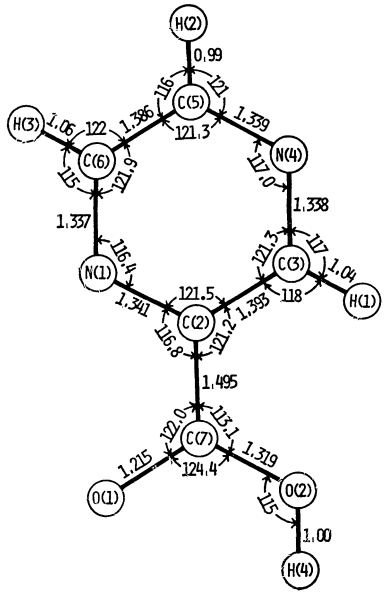

Fig. 3. Dimensions of pyrazinic acid molecule.
The estimated standard deviations are as follows: X-X=0.003~0.004 Å, X-H=0.03~0.04 Å, X-X-X=0.2°, X-X-H=2, where X and H represent the non-hydrogen atom and the hydrogen atom, respectively.

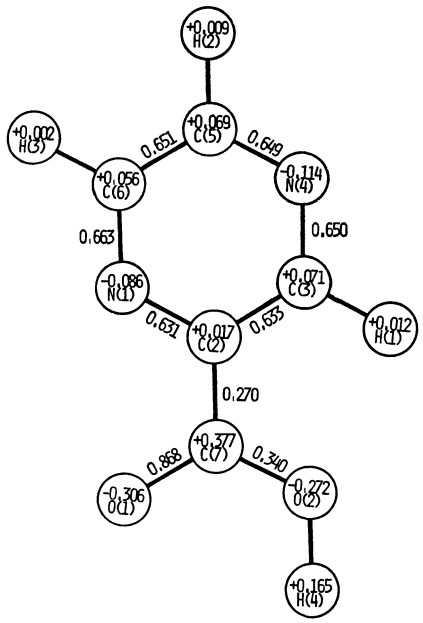

Fig. 4. The π-bond orders and net charges calculated by the CNDO/2 method.

explained by the fact that the N(4) atom participates in a hydrogen bond, while the N(1) atom does not. The 4.4(2)° difference between the N(1)–C(2)–C(7) and C(3)–C(2)–C(7) bond angles is significant judging from their estimated standard deviations. Similar differences are found in dipicolinic acid[8] and orotic acid.[9] When the hydroxyl oxygen of the carboxyl group at α-position of pyridine, pyrazine or pyrimidine ring is *s-cis* to the nitrogen atom in the ring, these two bond angles are approximately equal to each other,

Table 4. Deviations (Å) from the least-sequares planes

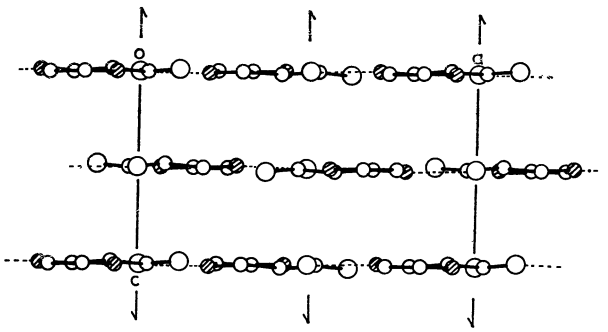

Fig. 5. A view of the crystal structure down the *b* axis. The hydrogen bonds are shown by broken lines.

but when it is *s-trans*, they are significantly different from each other.[1,8-11] The dihedral angle between the planes of the pyrazine ring and the carboxyl group is 4.4° and its direction is shown in Fig. 2.

Molecular Arrangement and Hydrogen-bond System. Figures 5 and 6 show the molecular arrangement viewed along the *b* and *c* axes, respectively. The molecules are arranged in layers parallel to the (001) plane with a spacing of 3.227 Å. The zig-zag chains along the *c* axis, consisting of the molecules linked by the O–H···N hydrogen bonds, on the same plane are joined by the weak C–H···O hydrogen bonds to form a sheet. There is no hydrogen bond between the sheets, but they are packed only by the van der Waals forces. This hydrogen bonding scheme is quite similar to that of nicotinic acid and the distance of the hydrogen bond of 2.669(3) Å is approximately equal to the 2.665 Å of nicotinic acid. Although the positions of hydrogen atoms are not determined in the crystal structure analysis of nicotinic acid, the difference between the two C–O bond lengths of the carboxyl group and the C–N–C bond angle of the pyridine ring suggest the existence of O–H···N hydrogen bond. However, the stacking of the pyrazinic acid molecule is considerably different from that of nicotinic acid, as shown in Fig. 7. There are two short contacts, 3.238(5) and 3.265(5)

Table 5. Distances of hydrogen bonds and short contacts

a) Closest contact between the layers (symmetry operation applied is given in parentheses)

Pyrazinc acid		Nicotinic acid	
N(1)···C(7)	$(1-x, 1-y, 1/2+z)$ 3.265(5) Å	C(6)···O(2)	3.405 Å
N(1)···C(7)	$(1-x, 1-y, -1/2+z)$ 3.238(5)	C(7)···N(4)	3.413
N(1)···O(1)	$(1-x, 1-y, -1/2+z)$ 3.273(5)		

b) Within a layer

X—H···Y	X···Y	X···Y
O(2)-H(4)···N(4)	2.669(3) Å	2.665 Å
C(3)-H(1)···O(1)	3.104(3)	3.265
C(5)-H(2)···O(1)	3.168(3)	3.259

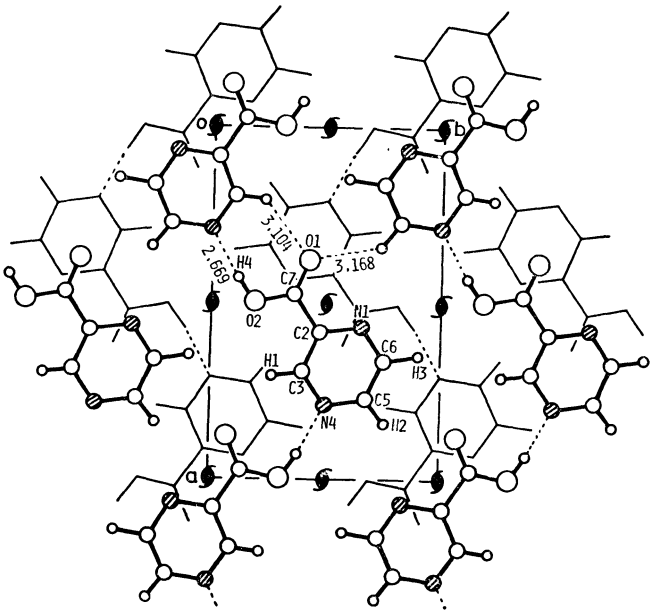

Fig. 6. A view of the crystal structure down the *c* axis, showing the relative orientation of the molecules in two adjacent layers parallel to the (001) plane. The hydrogen bonds are shown by broken lines.

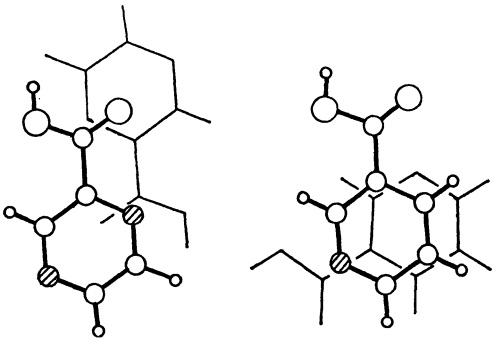
Å, between the N(1) and C(7) atoms in the different sheets. The net charges on the N(1) and C(7) atoms are −0.086 and +0.377, respectively; these values indicate some electrostatic attractive-forces between them. On the other hand, nicotinic acid molecule does not contain such electronegative atom. The closest interlayer contacts of pyrazinic acid are listed, along with those of nicotinic acid, in Table 5.

As for the hydrogen bond between the carboxyl group and the nitrogen atom in the pyridine ring, the $\overset{+}{N}$–H···$\bar{O}$ hydrogen bond is found in all the crystal structures of pyridine-carboxylic acids.[11-13] As mentioned above, hydrogen bonding types of pyrazinic acid and nicotinic acid are not the $\overset{+}{N}$–H···$\bar{O}$, but the O–H···N. This fact may be explained as follows: The carbonyl oxygen atom O(1) is surrounded with two hydrogen atoms, H(1) and H(2), as illustrated in Fig. 8. The distances and angles are: O(1)···H(1)=2.44(4) Å, O(1)···H(2)=2.43(4) Å, C(7)=O(1)···H(1)=120(2)°, C(7)=O(1)···H(2)=



(I) Pyrazinic acid (II) Nicotinic acid

Fig. 7. Stackings of pyrazinic acid and nicotinic acid molecules.

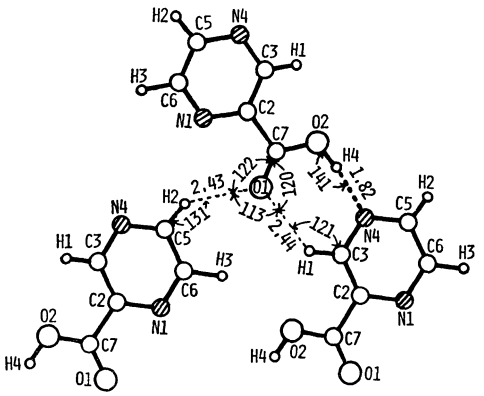


Fig. 8. Short intermolecular contacts within a molecular layer. The O-H···N and C-H···O hydrogen bonds are illustrated by heavy and thin broken lines, respectively.

122(2)°, and H(1)···O(1)···H(2)=113(5)°. These angles indicate that the H(1), H(2), O(1), and C(7) atoms are nearly on a plane. Since the O(1) atom takes the sp^2 hybrid orbitals, the two lone pairs of O(1) atom will interact with the H(1) and H(2) atoms. These may be considered as the weak C–H···O hydrogen bonds. If the H(4) atom moves from the O(2) atom to the N(4) atom, the O(1) atom no longer would take the sp^2 hybrid orbitals and the lone pairs would not be directed toward H(1) and H(2), so that the C–H···O hydrogen bonds are not formed. Therefore,

the C–H···O hydrogen bond formation and protonation on the nitrogen atom are competitive. The crystal structures of pyrazinic acid and nicotinic acid suggest that the formation of the two weak C–H···O hydrogen bonds is energetically favored more than the formation of zwitter ion.

The N(4) atom takes part in the hydrogen bond, while the N(1) atom is free from it. This may be explained by the facts that the N(4) atom is more electronegative than the N(1) atom, and that the N(1) atom is shielded by the carboxyl group from the donor group for the hydrogen bond. The melting point of nicotinic acid is higher than that of picolinic acid. These two experimental facts indicate that the hydrogen bonding type found in nicotinic acid is energetically favored more than that found in picolinic acid.

Computer Programs. All the calculations were performed on a FACOM 270–30 computer at the Computer Center of Osaka City University, using the UNICS[14] programs, SCALE(film factor, Lp and layer scaling),[15] BOND(bond length, bond angle and least-squares plane),[16] TE-I(thermal ellipsoid),[17] and CNINDO (CNDO and INDO calculations).[6]

The authors are greatly indebted to Dr. Kichisuke Nishimoto and to Mr. Ken Hirotsu of Osaka City University for their useful advice on the theoretical calculation and their valuable discussions and suggestions during this investigation.

Studies of Ruthenium Complexes. VII.[1] Photochemical Reactions of *cis*-Dihalogenotetraammineruthenium(III) Complexes in Aqueous Solutions

Akira OHYOSHI, Noriyuki TAKEBAYASHI, Yutaka HIROSHIMA, Kenichiro YOSHIKUNI, and Kazuhiko TSUJI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received September 13, 1973)

Studies have been made of the photochemistry of *cis*-dihalogenotetraammineruthenium(III) in aqueous solutions. For the *cis*-dichlorocomplex, no photochemical reaction has been observed by the irradiation of the visible light region. For *cis*-dibromo- and *cis*-diiodo-complexes, a simple aquation of halide ligand seems to occur in a solution with a pH lower than 2.5. The typical values of the quantum yields for the *cis*-$[RuX_2(NH_3)_4]^+ + H_2O \xrightarrow{h\nu}$ *cis*-$[RuX(OH_2)(NH_3)_4]^{2+} + X^-$ reaction were 0.27×10^{-2} (382 nm light) and 0.82×10^{-2}(408 nm light) for dibromo- and dichloro-complexes respectively. The quantum yield was dependent on the wavelength of light, but was independent of the concentrations of halide and hydrogen ions. The quantum yield seems to depend on the oxidizability of the ligand or on probability of the deactivation process in the primary excited state. In accounting for the low quantum yield, it seems most probable that the photoexcited complex species is converted to the ground state by non-radiative transitions.

Although there have been many studies of the photochemistry of 3d metal complexes,[2-7] those of 4d metal analogs, in particular of the ruthenium complexes, are scarce. A recent photochemical study of hexaammine- and chloropentaammineruthenium(III)[8] has demonstrated that both of the complex ions are largely unreactive when their ultraviolet absorption bands are irradiated and that the photoinduced aquation of the ammine ligand can be established for each complex with a low quantum yield ($\phi<0.1$). The detectable photoredox process has not been observed by the irradiation of light in the region of charge transfer from ligand to metal(CTTM-band). Qualitatively, it might be expected that absorption in the region of an electron-transfer band would lead to the oxidation-reduction process, while the absorption in the region of a ligand-field band would cause a substitution reaction of the ligand. This photochemical inertness of the t_{2g}^6 ruthenium(III) complexes has been interpreted on the assumption of a small distortion at the excited states with a t_{2g}^5 electronic configuration and on the assumption that the CTTM states are lower in energy than those of the d-d excited states.

In the present study, the photoaquation rates of *cis*-dihalogenotetraammineruthenium(III) complexes were determined as a function of the hydrogen and halide ion concentrations, and the dependence of the quantum yield on the wavelength of the incident radiation was investigated. The results were then discussed in comparison with those of the hexaammine and chloropentaammine complexes of ruthenium(III) and with those of the analogous complexes of cobalt(III) and chromium(III).

Experimental

Materials. All the chemicals used were of a reagent grade. The *cis*-dihalogenotetraammineruthenium(III) halogenides were prepared by the method of Gleu and Breuel.[9] These compounds were analyzed by the usual elemental analysis and were confirmed by means of their spectra.

Photolysis Procedures. The photolyses were performed using a JASCO CRM-FA spectral irradiator equipped with a 2 kW Xenon arc lamp. A known volume of a sample solution in a rectangular quartz cell with a 1-cm light path length was kept at 25 °C; purified argon gas was passed through the solution during irradiation to avoid an appreciable secondary photolysis or inner filter effects. The solution was then irradiated for a preset time period by monitoring the light flux using a JASCO RMI-1 integrating radiometer equipped with a thermopile. The absorbed light intensities (I_a) were determined using a ferrioxalate actinometer[10] ($\lambda<400$ nm) and a reineckate actinometer[11] ($\lambda>400$ nm). The concentration of the reactant was determined from the absorbance of the first absorption band at 352 nm (*cis*-dichlorocomplex), 441 nm (*cis*-dibromocomplex), and 646 nm (*cis*-diiodocomplex) using a Hitachi 124 spectrophotometer. The pseudo first-order plot gave a straight line for about 120 min at an irradiation rate of 2.5×10^3 photons l^{-1} min^{-1}. The initial slope of this plot was used to calculate the initial rate of complex decomposition. This rate was used along with the I_a values to calculate the quantum yield.

Results and Discussion

Qualitative Observation of Photoreaction. The progressive changes in the absorption spectrum are shown in Figs. 1 and 2 for two kinds of complexes in acidic and neutral solutions. The two absorption bands in the spectra for the original complexes can be assigned to the charge-transfer absorptions from ligand to metal ($\pi\rightarrow t_{2g}$)[12] from the facts that; (1) their molar absorption coefficients take large values (10^3 M^{-1} cm^{-1}); (2) the plot of the wave number (ν_{max}) of the CT band from ligand to metal *vs.* the redox potential value of the coordinated halide ligand indicates a linear relationship (Fig. 3); and (3) the ν_{max} values obtained from the electronic spectra of the complexes are in agreement with those calculated by Jørgensen's empirical formula.[13]

The changes in the absorption spectra in the neutral solution appear to be different from those in the acidic solutions. The first and second bands of the complexes decrease, and a new peak appears in the UV region. The wavelength of this peak (291 nm) is very close to that of the hydroxo-complex (293 nm) resulting from the base hydrolysis of the corresponding initial complex. Thus, the photochemical reactions presumably proceed as follows:

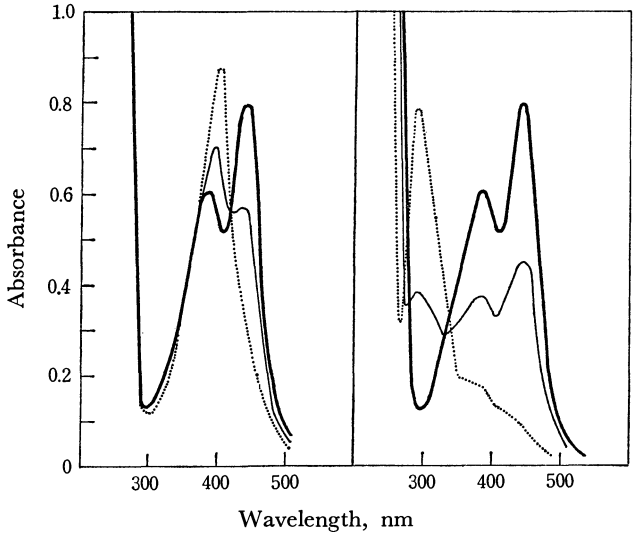

Fig. 1. Spectral change of *cis*-dibromotetraammineruthenium(III) in the photochemical reaction, at pH 2.0 (left), 7.0 (right), 434 nm light irradiation (2.5×10^3 photons l^{-1} min^{-1}), 25 °C.
——: initial, ——: intermediate (60 min), ·····: final (300 min). [complex]: 5×10^{-4} M, temp: 25 °C.

$$[RuX_2(NH_3)_4]^+ + 2OH^- \xrightarrow{h\nu} [Ru(OH)_2(NH_3)_4]^+ + 2X^- \quad (1)$$

On the other hand, the changes in the spectra in acidic solutions differ from those in the above case, *i.e.*, the first band decreases with the increase in the second band with the shift toward the longer wavelength as the reaction proceeds. The final spectra (Figs. 1 and 2) show a new peak different from those of the initial complex. In separate experiments where the acid hydrolysis of *cis*-dihalogenotetraammineruthenium(III) were carried out in the dark, similar changes in the absorption spectra were observed throughout the reactions. Similar observations have been reported in the aquation of dichlorobisethylenediammineruthenium(III),[14] and in the study of the preparation of dichlorotetraammine- and chloroaquotetraammineruthenium(II) complexes.[15] All the observations of the changes in the absorption spectrum gave evidence for the formation of a partially-aquated ruthenium(III) complex species, *cis*-$[RuX(OH_2)(NH_3)_4]^{2+}$. Thus, we concluded that the photoreaction took place mainly *via* the aquation process in the acidic solution:

$$cis\text{-}[RuX_2(NH_3)_4]^+ + H_2O \xrightarrow{h\nu} cis\text{-}[RuX(OH_2)(NH_3)_4]^{2+} + X^- \quad (2)$$

Determination of the Variables Affecting the Photoreaction Rate. Several experiments with various reaction parameters of the photolysis system were carried out in order to investigate their effects on the reaction rate or the quantum yield. The photoreaction rates were determined by measuring the decrease in the absorbance at the first absorption band of the respective complexes under different conditions of light irradiation. The plots of log C_t/C_0 *vs.* the reaction time are exemplified in Fig. 4, where C_t and C_0 denote the con-

centrations of the reactant complex at the reaction time t and at zero, respectively. The straight lines indicate that the photoaquation and thermal reaction are both first-order with respect to the complex concentration under given reaction conditions. The thermal reactions are somewhat observed at 25 °C; therefore, the net photoreaction rates were determined by subtracting these contributions. The photoreaction of the *cis*-dichlorotetraammine complex was found only in the case of ultraviolet light irradiation.

No effects of the halide-ion concentration or of the ionic strength on the reaction rate have been observed in acidic solutions. Three facts indicate that neither the halide ion nor a charged particle is concerned with the rate-determining step.

As is shown in Fig. 5, the effect of pH on the reaction rate has not been observed in a pH range lower than 2.2, while higher than 2.2, the apparent reaction rate increased with an increase in the pH values. Although this fact has not yet been investigated in detail, it may be considered that the base hydrolysis participates to some extent in the aquation reaction. The spectral observations provide evidence for this consideration (Figs. 1 and 2).

Quantum Yield for the Photochemical Aquation Reaction. The quantum yield for the photochemical aquation was determined with different light wavelengths. The results are given in Table 1, along with those of analogous and reference reactions and along with the available data on the thermal aquation reaction rates. The quantum yields for the photoaquation of *cis*-dihalogenotetraammineruthenium(III) complexes are dependent on the light wavelength and are small compared with those for the ammine ligand aquation of the hexaammine- and chloropentaammineruthenium-(III).[8] It was also found that the *cis*-dichlorotetraammine complex was photochemically unreactive and that *cis*-diiodotetraammine was more photosensitive than *cis*-dibromotetraammine in the wavelength region of visible light; for example, the quantum yield was 0.82×10^{-2} (at 408 nm) for the former and 0.27×10^{-2} (at 382 nm) for the latter complex, The relatively high yield observed at shorter wavelengths can be regarded as indicating a CTTM excited state with a different electronic configuration, for it is more populous than that produced by the light irradiation with longer wavelengths. The dependence of the irradiation wavelength on the quantum yield can be interpreted by the mechanism proposed by Adamson and Sporer,[3] which postulated that the first chemical consequence of light absorption is a homolytic bond fission of the metal-ligand bond. When a considerable excessive energy is available, the net quantum yield would be increased by the ease of nascent radicals in escaping their solvent cage. Thus, high quantum yields can be predicted to be favored by the use of the shorter-wavelength light. The homolytic bond fission of the metal ligand may be essentially different from that in the thermally-excited state, because there is no correlation between the photoreactivity and the instability towards thermal aquation as expressed by the rate constants (Table 1). The photoreactivity is rather correlated with the ease of the oxidation of the halide ligand and, hence, with the thermodynamic instability of the complexes towards redox reaction. A similar trend is more evidently observed in the photoreaction of the halogenopentaamminecobalt(III) complexes.[16] The oxidation potential of the halide ligand seems to play the dominant role in determining the photolytic behavior of the halogenoammine complex.

As is shown in Table 1, most studies of the photochemistry of ammine complex ions have dealt with the cobalt(III), chromium(III), and ruthenium(III) systems. These metal complexes differ from each other in photochemical behavior; the photoreactions of cobalt(III) complexes can be either substitution reactions or redox reactions, whereas for chromium(III) and ruthenium(III) complexes only substitution reactions are observed. Although there is no direct comparison of complexes with the same

ligand, the photoreaction type of the ruthenium(III) complex is the same as that of the chromium(III) complex except that the quantum yield depends on the light wavelength. These differences are presumably due to the greater difficulty of reduction from the trivalent to the divalent state or to the greater instability of the divalent state metal complex.

Photoreaction Mechanism of the cis-*dihalogenotetraammineruthenium(III) Complex.* According to the three-stage mechanism proposed by Adamson and Sporer,[3] the present photochemical reactions can be well interpreted. The first stage is homolytic-bond-breaking:

$$Ru^{III}X_2(NH_3)_4 \xrightarrow{h\nu} Ru^{II}X(NH_3)_4\cdot X^{\cdot} \quad (3)$$

and

$$Ru^{III}X_2(NH_3)_4 \xrightarrow{h\nu} Ru^{I}(NH_3)_4\cdot X_2^{\cdot\cdot} \quad (4)$$

where X denotes the halide ligand. These intermediate products have not yet been confirmed in our experiment; however, they can react in one of two ways. They can return to the ground state:

$$Ru^{II}X(NH_3)_4\cdot X^{\cdot} \rightarrow Ru^{III}X_2(NH_3)_4 \quad (5)$$

or

$$Ru^{I}(NH_3)_4\cdot X_2^{\cdot\cdot} \rightarrow Ru^{II}X(NH_3)_4\cdot X^{\cdot} \rightarrow Ru^{III}X_2(NH_3)_4 \quad (6)$$

In another path, they can react with a water molecule in an acidic solution or with the hydroxide ion in neutral and basic solutions:

$$Ru^{II}X(NH_3)_4\cdot X^{\cdot} \begin{cases} \rightarrow + H_2O \rightarrow \\ \quad Ru^{II}X(OH_2)(NH_3)_4\cdot X^{\cdot} \quad (7) \\ \rightarrow + OH^- \rightarrow \\ \quad Ru^{II}X(OH)(NH_3)_4\cdot X^{\cdot} \quad (8) \end{cases}$$

$$Ru^{I}(NH_3)_4\cdot X_2^{\cdot\cdot} \begin{cases} \rightarrow + 2H_2O \rightarrow \\ \quad Ru^{I}(OH_2)_2(NH_3)_4\cdot X_2^{\cdot\cdot} \quad (9) \\ \rightarrow + 2OH^- \rightarrow \\ \quad Ru^{I}(OH)_2(NH_3)_4\cdot X_2^{\cdot\cdot} \quad (10) \end{cases}$$

The species formed in Reactions (7), (8), and (9), (10) may be ruthenium(II) and ruthenium(I) complexes respectively, with an $X^{\cdot}$ radical in the second coordination sphere; however, the formation of the latter complexes may be difficult in view of the coordination ability of ruthenium(I). If the electron transfer from ruthenium(II) to X is energetically favorable, aquation or base hydrolysis proceeds:

$$Ru^{II}X(OH_2)(NH_3)_4 \cdot X^{\cdot} \rightarrow Ru^{III}X(OH_2)(NH_3)_4 + X^- \quad (11)$$

$$Ru^{II}X(OH)(NH_3)_4 \cdot X^{\cdot} \rightarrow Ru^{III}X(OH)(NH_3)_4 + X^- \quad (12)$$

Wells and Endicott[8] reported that the quantum yield for the photoaquation of the chloropentaammineruthenium(III) is independent of the wavelength. This has been interpreted by assuming that the over-all reaction rate is controlled by the step of ligand-exchange reaction in the lowest-energy excited state formed by the CTTM-band irradiation.

To account for the variation in the quantum yield with the wavelength in our results, it may be reasonable to assume that the probability of the deactivation process (5), (6) of the primary excited state increases with the decrease in the excitation energy, unless the probability of the primary excitation (3), (4) decreases with a decrease in the excitation energy. In particular, the fact that the low quantum yields are different from those for the other metal complexes may be supported by the instability of the radical containing ruthenium-(II) or (I) in the deactivation processes (5) and (6).

A Solubility Study of Coacervates of Magnesium, Calcium and Aluminum Highpolyphosphates in Acid Solutions

Takafumi KANAZAWA, Takao UMEGAKI, Yōzō KITAJIMA, and Takeshi OGAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo, 158

(Received October 9, 1973)

Dissolution of the highpolyphosphate coacervates of magnesium, calcium and aluminum was studied in order to understand the conformational feature of polyphosphate chains in the coacervates. Electrical conductivity and viscosity of the coacervate solutions were measured. Paper chromatographic technique was employed for the analysis of the solutions. It was concluded that the polyphosphates dissolve into acid solvents without cleavage of phosphate chains, the degree in the extension of the chains being considerably small. Dissolution processes of the three coacervates were compared. Optimum conditions on the syntheses of the threadforming coacervates are given.

Magesium highpolyphosphate coacervate (MPC), calcium highpolyphosphate coacervate (CPC) and aluminum highpolyphosphate coacervate (APC) with high viscosity (10—10^3 poise) and transparency were prepared from mixed solutions of sodium highpolyphosphate and metal chlorides.

The main purpose of this study was to clarify the dissolution processes of the three coacervates from the results of electrical conductivity and viscosity. Paper chromatography was utilized to examine whether cleavage of the chain phosphate anions occurred during the course or after the completion of the dissolution process.

The degradation of some highpolyphosphates has been investigated by Thilo and Wieker[1,2] and Gill and Riaz.[3] However, a detailed study of the dissolution process of polyphosphates into acid solvents does not seem to have been dealt with.

The synthetic conditions of CPC and APC are briefly described in the present report. The preparation of MPC and its thermal change were discussed in previous papers.[4–6]

Experimental

Materials. The synthetic conditions for CPC and APC were partly the same as those for MPC.[4] CPC was obtained from a mixture of 15% sodium highpolyphosphate solution (400 parts) and 20% calcium chloride solution (166 parts) by the addition of ethyl alcohol. In the synthesis of APC, the threadforming property of the coacervates changes with the molar ratio of P to aluminum ion. Acids such as HCl (0.05%, 0.1%) and citric acid (H_3Cit) (2%, 10%) were used as solvents.

Measurements. Viscosities of the coacervate solutions were measured with an Ostwald capillary viscometer with efflux time of ca. 120 s for distilled water. The conductivities of the coacervate solutions of various concentrations were measured with an apparatus consisting of an alternating current bridge and a conductivity cell. All the measurements of viscosities and conductivities were carried out in a bath maintained at 30±0.02 °C.

Paper chromatography. Each strip of filter paper (Toyo Roshi No. 51A) on which 25 μl of sample solution was spotted was immersed in Kolloff solvent No. 92-D5.[7] The filter paper was left at about 5 °C for 7—10 hr during which time the solvent rose 10—15 cm.

TABLE 1. SPINNABILITY AND RATIO OF METAL ION(M) TO P IN THE MIXED SOLUTIONS

Coacervate	M : P(mole ratio)	Note
MPC	1 : 2	spinnability
CPC	1 : 2	spinnability
APC	1 : 3	no spinnability
APC	1 : 6	
APC	1 : 12	spinnability

Results and Discussion

A comparison of spinnability among the three coacervates is given in Table 1. Threadforming MPC and CPC were obtained when the metal chloride solution and the sodium highpolyphosphate solution were mixed in the molar ratio P : metal=2 : 1. Threadforming APC formed from the mixture with a lower ratio of aluminum chloride to sodium polyphosphate. The optimum conditions for the synthesis of threadforming coacervate seem to be related to the acidity of the mixtures and the content of sodium ion in the coacervates.

No cleavage of highpolyphosphates occurred in the course of dissolution since such short chain phosphates as orthophosphates, pyrophosphates and tripolyphosphates were not detected by the paper chromatography. In a few hours after the complete dissolution of APC, orthophosphate ions were formed in the APC solution by the hydrolysis of polyphosphates, which was accelerated by the hydrogen ion and aluminum ion[1,2] in the coacervate solution. Consequently, all the

highpolyphosphates of magnesium, calcium and aluminum dissolved without degradation.

Figure 1 shows the electrical conductivity-concentration curves of the aqueous solutions of MPC and sodium highpolyphosphate used as a starting material of the coacervates. The coordination of magnesium ions to polyphosphate chains seems to depress the ionic dissociation of MPC. The conductivities of MPC solution were lower than those of the sodium highpolyphosphate solution. Figures 2 and 3 show the electrical conductivity *versus* concentration curves of the acid solutions of MPC. The conductivities of the citric acid solutions of MPC increased monotonically and the conductivity-concentration curves nearly coincide in the same manner as in the case of the HCl solution of MPC.

The electrical conduction by hydrogen ion was predominant in the dilute HCl solutions of MPC. The bonding between the hydrogen ions in the HCl solution and the polyphosphate ions from the dissolved MPC caused a decrease of the hydrogen ions in the MPC solution, the conductivities decreasing with the concentration of MPC. The citrate ions in the citric acid solutions of MPC acted as a buffer and enhanced the concentration of hydrogen ion when the polyphosphate ion linked with the hydrogen ions in the acid solvent. Thus no conductivity decrease was observed at low concentrations of MPC in the case of citric acid. On both acid solvents the contribution of the dissolved ions to the conductivity increased with concentration of the MPC, the convergence of the conductivities to one curve occurring when the effect of the hydrogen ions in the acid solvents almost disappeared.

With the decrease in the concentration of polyelectrolyte the net charge on a polymer ion increases due to the increase of the ionic dissociation of the polyelectrolyte, and polymer chains extend owing to the intermolecular repulsive force among the charges with equal sign. Then the reduced viscosity of the polyelectrolyte solutions at low concentration often exhibits a curve considerably concave upward.[8]

Figure 4 gives a plot of the reduced viscosity of the MPC solution against concentration c. We see that the reduced viscosity of the MPC solution at low concentration does not increase with dilution although some curves indicate a slight extention of polymer coils of polyphosphates. Most of the polyphosphate chains of the MPC solutions were to some extent tightly coiled since the intermolecular repulsion was restricted owing to the neutralization of the charges on the chains by such cations as Mg^{2+}, H^{+} and Na^{+}. The results of the viscosity measurement confirmed the conclusion from the conductivity measurement that the initial conductivity lowering of the HCl solution of MPC (Fig. 2) was caused not by the extention of the polymer chains but by the depression in the ionic dissociation of hydrogen. The changes in the conductivity and the viscosity of the acid solutions of threadforming APC were similar to those of the MPC solution (Figs. 5 and 6). The electrical conductivity change of the CPC solutions (Fig. 7) was also similar to that of the MPC solutions indicating that the more CPC was introduced into a solvent, the more electrolytes dissolved. However, a very small amount of viscous substance remains undissolved in the solution at a concentration of about 0.5 g/100 ml. CPC might contain some undissolved species, none of which was identified in the present study.

From the results obtained so far it was concluded that MPC, APC and soluble part of CPC dissolved without degradation of polyphosphate chains, which do not extend so much in the solutions. The polyphosphate ions in the coacervates seem to be more tightly coiled than those in the solutions of the coacervates since polyphosphates and some other electrolytes were much more concentrated as compared with those in the coacervate solutions.

Hydration of such cations as Mg^{2+}, Al^{3+}, Ca^{2+} and Na^{+} and the coordination of these ions to polyphosphate ions should be clarified for more detailed discussion on the dissolution of the coacervates.

Some of the data in this report was cited from Ref. 4.

The work was supported by a grant from the Asahi Glass Foundation for Contribution to Industrial Technology.

Electron Transfer Reaction between Thallium(I) and Thallium(III) in the Presence of Cerium(IV) in Aqueous Solution

Goro WADA and Kyoko TAMAKI

Department of Chemistry, Nara Women's University, Nara 630

(Received November 12, 1973)

The kinetics of the electron transfer reaction between Tl(I) and Tl(III) was investigated in the presence of Ce(IV) by use of a radioactive tracer ^{204}Tl. The apparent rate constant of the reaction, k_{app}, was dependent upon $[H^+]$ and [Co(IV)] ($<0.6\times10^{-3}$ M) and can be expressed by

$$k_{app} = k_A + \frac{k_B}{[H^+]} + \left(k_C + \frac{k_D}{[H^+]}\right)[Ce(IV)].$$

k_{app} is gradually saturated to a limiting value according to $[H^+]$ at higher [Ce(IV)]. The observed values are $k_A=4.70\ M^{-1}\ h^{-1}$, $k_B=2.13\ h^{-1}$, $k_C=1.30\times10^3\ M^{-2}\ h^{-1}$, and $k_D=2.61\times10^3\ M^{-1}\ h^{-1}$ at 50 °C. Since Ce(IV) is a one-electron-oxidant, Tl(I) is oxidized by one-electron transfer to produce Tl(II) as an intermediate. However, in the absence of one-electron-oxidant or -reductant, two electrons are transferred from Tl(I) to Tl(III) not through double steps of one-electron transfer but predominantly through a single step of two-electron transfer.

The electron transfer reaction between thallium(I) and thallium(III) has been investigated on the effects of hydrogen ion,[1-6] anions such as NO_3^-,[1] Cl^-,[2,7-9] CN^-,[10] SO_4^{2-},[11,12] Br^-,[13,14] and N_3^-,[15] organic acids such as acetic,[16,17] succinic,[16,17] and mono-, di-, and tri-chloroacetic acids,[18] and various organic substances[19-21] by using a radioactive isotope ^{204}Tl as a tracer. The investigations clarified the roles of the effective substances on the electron transfer reaction.

An important feature of this "thallous-thallic" redox reaction is that two electrons in total are transferred between them. The occurrence of thallium(II) has been proposed as a reaction intermediate on the basis of kinetic studies of the redox reaction between iron(II) and thallium(III)[22] and between thallium(I) and cerium(IV)[23] and on the irradiation of X-rays[24] and ultraviolet rays[25] upon the thallium(I)-thallium(III) system. Consequently, the electron transfer reaction between thallium(I) and thallium(III) in the absence of catalyst has been considered to proceed not *via* a single step of "two-electron transfer" but *via* two successive steps of "one-electron transfer" with thallium(II) as an intermediate.

Recently, the acceleration due to the addition of iron(II) to thallium(I)-thallium(III) system[26] and of iron(III) to uranium(IV)-uranium(VI) system[27] was reported, the latter being also an overall reaction with a two-electron transfer. We have investigated the thallium(I)-thallium(III) system in the presence of cerium(IV), and the functions of thallium(II) when it occurs.

Experimental

Materials. Thallium(I) perchlorate was prepared by dissolving thallium metal of 99.99% purity in warm perchloric acid, crystallized, washed by ethanol and dried. The crystal thus obtained was in anhydrous form.

Thallium(III) perchlorate was prepared by dissolving Tl_2O_3 in 4 M perchloric acid at 60—70 °C for many hours. Both thallium(I) and thallium(III) salts were confirmed to be free of chloride ion.

$Ce_2(SO_4)_3\cdot8H_2O$ and $Ce(SO_4)_2\cdot nH_2O$ were used in aqueous perchloric acid as salts of cerium(III) and cerium(IV) respectively. The sulfate ion concentration was regulated with sodium sulfate. As a radioactive tracer, ^{204}Tl obtained in the form of $TlNO_3$ was converted into $TlClO_4$ in perchloric acid. The ionic strength of the reaction solutions was adjusted with sodium perchlorate.

Pure water was made by treating tap water with ion-exchange resin, followed by distillation of the alkaline permanganate solution.

Analyses of Thallium Concentrations. Thallium(III) was determined by titration with disodium ethylenediaminetetraacetate (EDTA) by use of Xylenol Orange as an indicator at pH 4—5 and 50—55 °C. Thallium(I) was oxidized by bromine to thallium(III), most of the excess bromine being removed by heating and the rest completely removed by addition of a few drops of methanolic solution of phenol. Thallium(III) was then titrated in a similar way. A mixture of thallium(I) and (III) was titrated before and after the treatment with bromine, and the concentration of thallium (I) was determined from the difference.

Rate of Oxidation of Thallium(I) by Cerium(IV). Cerium(IV) was spectrophotometrically observed to exhibit an absorption peak at a wavelength of 320 nm, while no absorption was observed in thallium(I), (III), or cerium(III) at wavelengths greater than 300 nm in perchloric and sulfuric acid solution. Thus, the rate of oxidation of thallium(I) by cerium(IV) could be followed by virtue of the decrease in the absorbance of cerium(IV). The absorbance was measured with a Hitachi UV-VIS spectrophotometer Model 139. The oxidation rate could be also followed by measuring the increase in the radioactivity of thallium(III), when thallium(I) was labeled, by a method similar to that for the electron transfer reaction.

Rate of Electron Transfer Reaction Between Thallium(I) and Thallium(III). A reaction mixture containing $TlClO_4$, $Tl(ClO_4)_3$, $Ce(SO_4)_2$, $HClO_4$, Na_2SO_4, and $NaClO_4$ was set in a thermostat in advance. The reaction was initiated at the instant the radioactive thallium(I) was added to the solution. The concentration of sulfate ion, the ionic strength, and temperature of the reaction were always maintained at $[SO_4^{2-}]=0.02$ M, $\mu=3$ M, and 50 °C, respectively.

An aliquot of the reaction solution was taken out into a quenching solution at appropriate time intervals. The quenching solution contained EDTA and was cooled in ice-water beforehand. Ten minutes after removal of an aliquot of the reaction solution, sodium chromate was added as a precipitating reagent for thallium(I), and the pH value was adjusted to about 4—5 with ammonia and ammonium acetate solution. Fifteen minutes later, the solution was filtered,

thallium(III) being separated from thallium(I) into the filtrate. A small portion of the filtrate was gently evaporated in a stainless-steel dish with irradiation by an infrared lamp and the β-radioactivity due to thallium(III) was counted with an Aloka G-M scaler Model TDC-102.

In earlier works on thallium(I)-thallium(III) systems, cyanide ion was usually used as a masking reagent for thallium(III). However, since cyanide ion is highly poisonous, EDTA was adopted in its place. The rate of masking of thallium(III) by EDTA is slower than that by cyanide ion, and EDTA has a masking action even toward thallium(I) in an alkaline medium. Thus, EDTA sometimes induced a zero-time exchange as much as 30—40%, which could be attributed to the accelerated exchange on the interface at the moment of precipitation, whenever EDTA was added at the same time as chromate ion and ammonia. In spite of these disadvantages of EDTA, the procedure described above was found to be accurate enough.

Results and Discussion

Oxidation of Thallium(I) by Cerium (IV). The standard redox potentials of Tl^{3+}/Tl^{+} and Ce^{4+}/Ce^{3+} are 1.28 V[28] and 1.74 V[29] at 25 °C, respectively. Thus, the reaction $Tl^{+}+2Ce^{4+}\rightleftharpoons Tl^{3+}+2Ce^{3+}$ occurs almost completely towards right with an equilibrium constant $\log K=15.6$. But the rate of the reaction is very small as observed photometrically at a wavelength of 360 nm (Fig. 1). In practice, the autoreduction of cerium(IV) takes place even in the absence of thallium(I) in the air, besides the reduction by thallium(I). Consequently, the values of [Ce(IV)] at time t employed in the figure are the observed ones corrected for the autoreduction.

If the reaction proceeds *via* the following two successive paths by stepwise reductions,

$$Tl(I) + Ce(IV) \rightleftarrows Tl(II) + Ce(III) \quad (k_1,\ k_{-1}) \qquad (1)$$

$$Tl(II) + Ce(IV) \rightarrow Tl(III) + Ce(III) \quad (k_2) \qquad (2)$$

Tl(II) is produced as an intermediate species. By the method of steady state applied to Tl(II), the following rate equation is obtained, when $[Tl(I)]_0$ is much greater than $[Ce(IV)]_0$.

$$\ln\frac{[Ce(IV)]}{[Ce(IV)]_0} - \frac{k_{-1}}{k_2-k_{-1}}\left(\frac{[Ce(IV)]_0}{[Ce(IV)]}-1\right) = \frac{-2k_1k_2[Tl(I)]}{k_2-k_{-1}}t \qquad (3)$$

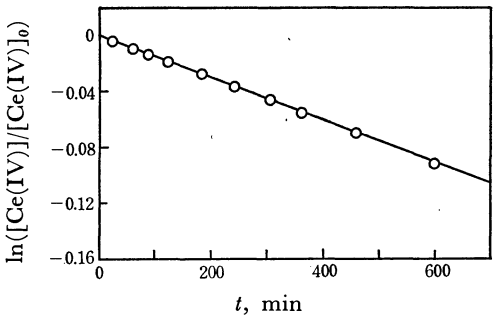

Fig. 1. Rate of oxidation of Tl(I) by Ce(IV) at $[H^+]=1.0$ M, $[SO_4^{2-}]=0.02$ M, $\mu=3$ M, and 50 °C, observed at 360 nm.
$[Tl(I)]_0=0.03$ M, $[Ce(IV)]_0=0.001$ M

Since k_{-1} is supposed to be negligibly small as compared with k_2, Eq. 3 may be simplified as follows.

$$\ln\frac{[Ce(IV)]}{[Ce(IV)]_0} = -2k_1[Tl(I)]t \qquad (4)$$

This is satisfied in Fig. 1, where the plot of $\ln([Ce(IV)]/[Ce(IV)]_0)$ against t shows a straight line, from the slope of which $k_1=0.17\ M^{-1}\ h^{-1}$ is obtained at 50 °C.

If k_{-1} were much greater than k_2, Eq. 3 would become the following equation, whose linear relationship does not hold in this case.

$$\ln\frac{[Ce(IV)]}{[Ce(IV)]_0} + \frac{[Ce(IV)]_0}{[Ce(IV)]} - 1 = \frac{2k_1k_2[Tl(I)]}{k_{-1}}t \qquad (5)$$

Electron Transfer Reaction Between Thallium(I) and Thallium(III). When $\log(x_\infty-x)$ was plotted against t, straight lines were always obtained irrespective of the presence or absence of cerium(IV), x and x_∞ being the specific radioactivities of thallium(III) in the reaction solution at time t and at time of equilibrium, respectively. Two typical plots in the absence and presence of cerium(IV) are shown in Fig. 2.

Since the reaction was very slow and it was too troublesome to determine x_∞ by observation for every kinetic run, x_∞ was estimated by calculation on the basis of statistical distribution of radioactivity between thallium(I) and thallium(III) at equilibrium as $x=x_t\cdot[Tl(III)]/([Tl(I)]+[Tl(III)])$, where x_t is the total radioactivity of ^{204}Tl.

Thus, the apparent rate constant k_{app} of the electron transfer reaction is given from McKay's relation,[30] since the reaction is of the first order with respect to both [Tl(I)] and [Tl(III)], $\text{Rate}=k_{app}[Tl(I)][Tl(III)]$.

$$k_{app} = \frac{0.693}{([Tl(I)]+[Tl(III)])t_{1/2}} \qquad (6)$$

Here $t_{1/2}$ is the half-life period of the reaction, which is easily obtained from the slope of the straight line in Fig. 2.

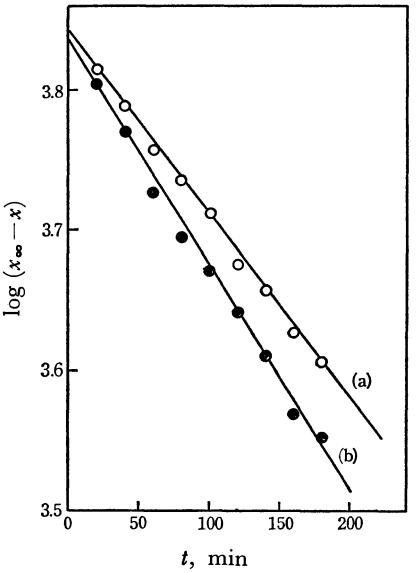

Fig. 2. McKay's plot of $\log(x_\infty-x)$ *vs.* time t at $[Tl(I)]=[Tl(III)]=0.01$ M, $[SO_4^{2-}]=0.02$ M, $[H^+]=0.50$ M, $\mu=3$ M, and 50 °C.
(a) $[Ce(IV)]=0$, (b) $[Ce(IV)]=0.001$ M

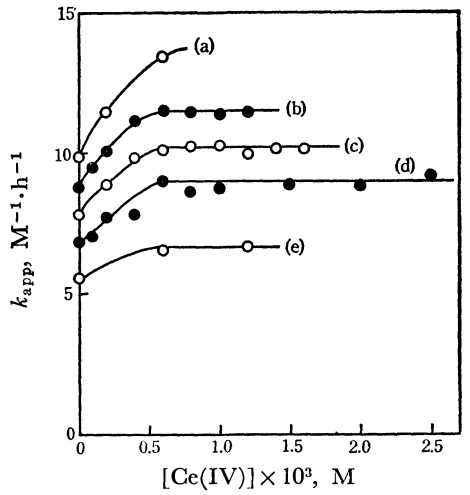

Fig. 3. Dependence of k_{app} upon [H⁺] and [Ce(IV)] at $[SO_4^{2-}]=0.02$ M, $\mu=3$ M, and 50 °C.
(a) [H⁺]=0.41 M, (b) [H⁺]=0.50 M, (c) [H⁺]=0.70 M, (d) [H⁺]=1.00 M, (e) [H⁺]=1.50 M

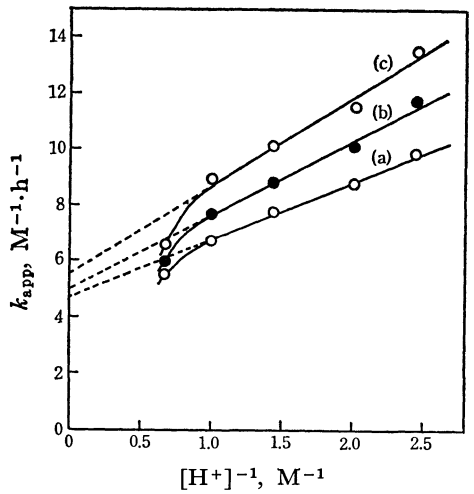

Fig. 4. Linear relationships between k_{app} and $[H^+]^{-1}$ at various [Ce(IV)] at $[SO_4^{2-}]=0.02$ M, $\mu=3$ M, and 50 °C.
(a) [Ce(IV)]=0, (b) [Ce(IV)]=0.2×10^{-3} M, (c) [Ce(IV)]=0.6×10^{-3} M

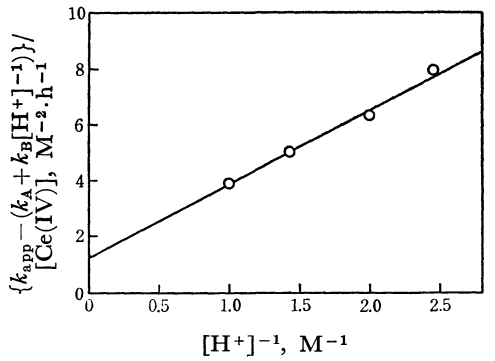

Fig. 5. Linear relationship between $\{k_{app}-(k_A+k_B/[H^+])\}/[Ce(IV)]$ and $[H^+]^{-1}$ at $[SO_4^{2-}]=0.02$ M, $\mu=3$ M, and 50 °C.

The results obtained in the concentration range [H⁺]=0.4—1.5 M and [Ce(IV)]=0—2.5×10^{-3} M are illustrated in Fig. 3. We see that k_{app} increases with decreasing [H⁺] at constant [Ce(IV)] and with increasing [Ce(IV)] at constant [H⁺] when [Ce(IV)] is less than 0.6×10^{-3} M. Above this concentration, k_{app} is saturated to a limiting value at respective [H⁺].

i. When [Ce(IV)]$\leqq0.6\times10^{-3}$ M: Linear relationships of k_{app} with $[H^+]^{-1}$ at [Ce(IV)]=0, 0.2×10^{-3}, and 0.6×10^{-3} M are shown in Fig. 4, and another linear relationship of (k_{app}-intercept in Fig. 3)/[Ce(IV)] with [H⁺] in Fig. 5. The following equation of k_{app} is thus established as functions of [H⁺] and [Ce(IV)], where k_A, k_B, k_C, and k_D are constants.

$$k_{app}=\left(k_A+\frac{k_B}{[H^+]}\right)+\left(k_C+\frac{k_D}{[H^+]}\right)[Ce(IV)] \qquad (7)$$

From the intercepts and slopes of these straight lines, the values of the individual rate constants at 50 °C can be determined as:

$$k_A = 4.70\ M^{-1}\,h^{-1}$$
$$k_B = 2.13\ h^{-1}$$
$$k_C = 1.30\times10^3\ M^{-2}\,h^{-1}$$
$$k_D = 2.61\times10^3\ M^{-1}\,h^{-1}$$

At least four sets of reactants, *viz.* oxidant, reductant, reductant, and catalyst, may be involved in parallel in the electron transfer reaction between thallium(I) and thallium(III) species; k_B and k_D may be connected with the hydrolyzed species of one of its participants. The sulfate ion is an accelerating ligand, bonding with thallium(I) and/or thallium(III).[11,12]

ii. When [Ce(IV)] exceeds 0.6×10^{-3} M: At increased cerium(IV) concentrations, k_{app} gradually deviates from the linearity in Eq. 7 but reaches a saturated value at respective acid concentrations.

According to the results of irradiation of ultraviolet rays on thallium(I)-thallium(III) system,[25] the rates of exchange of the following are very fast.

$$*Tl(I) + Tl(II) \rightleftarrows *Tl(II) + Tl(I) \qquad (k_I) \qquad (8)$$
$$*Tl(II) + Tl(III) \rightleftarrows *Tl(III) + Tl(II) \qquad (k_{III}) \qquad (9)$$

$k_I = 1.8\times10^8\ M^{-1}\,h^{-1}$ at 25°C
$k_{III} = 3.6\times10^8\ M^{-1}\,h^{-1}$ at 25°C

The acceleration of electron transfer in the thallium(I)-thallium(III) system by cerium(IV) is due to the initial occurrence of thallium(II) through Reaction 1, followed by the rapid exchanges through Reactions 8 and 9. Thus, the increased rate due to cerium(IV) might be proportional to [Tl(II)], which is approximately expressed as follows.

$$[Tl(II)]=\frac{k_1[Tl(I)][Ce(IV)]}{k_{-1}[Ce(III)]+k_2[Ce(IV)]} \qquad (10)$$

As [Ce(IV)] increases, [Tl(II)] increases at first, and attains a limiting value [Tl(II)]=(k_1/k_2)[Tl(I)]. This may qualitatively correspond to the saturation phenomenon of k_{app} at higher [Ce(IV)] as seen in Fig. 3.

How are the Two Electrons Transferred ? The two-electron transfer system between thallium(I) and thallium(III) is also known to be accelerated by the addition of a minute amount of iron(II),[22,26] which is a one-electron-reductant. In this case, the smaller

the concentration of iron(II), the larger the acceleration, as long as $[Fe(II)]>6.8\times10^{-5}$ M. A rate equation for the fact has been proposed.[26]

The reduction of thallium(III) by iron(II) was not affected by the addition of thallium(I) at all but retarded by the addition of iron(III).[22] Thus, the reduction was deduced to proceed in the following paths.

$$Tl(III) + Fe(II) \rightleftarrows Tl(II) + Fe(III) \quad (11)$$

$$Tl(II) + Fe(II) \rightarrow Tl(I) + Fe(III) \quad (12)$$

Thallium(II) is produced as an intermediate, and since Reaction 12 is rate-determining, Reaction 11 maintains partial equilibrium. It can therefore be reasonably said that the addition of iron(III) diminishes [Tl(II)] and consequently the total rate, but the addition of thallium(I) has no effect on the total rate.

It is worthwhile investigating the effect of the addition of iron(III) on the rate of thallium(I)-thallium(III) electron transfer reaction. If this electron transfer were to exactly undergo an initial production of thallium(II), as expressed by

$$Tl(I) + Tl(III) \rightleftarrows Tl(II) + Tl(II), \quad (13)$$

the addition of iron(III) should interfere with Reaction 13 on account of the promotion of the backward reaction of Reaction 11, resulting in the retardation of thallium(I)-thallium(III) electron transfer, which would have otherwise occurred through Reactions 8 and 9.

The results of addition of various metal ions to the thallium(I)-thallium(III) system are listed in Table 1. Although the concentration of iron(III) added in the reaction system seems to be high enough to interfere with the production of thallium(II) markedly, no actual retardation effect on the rate of the electron transfer but only a slight acceleration was observed. Attention should be paid to the fact that iron(III) has no ability to oxidize thallium(I) to thallium(II) and as a consequence to thallium(III), on account of its oxidation potential.

This suggests that the two electrons are transferred not through double one-electron transfer steps but mostly through a single step of two-electron transfer without thallium(II) species as the intermediate, when neither one-electron-oxidant nor one-electron-reductant exists in the thallium(I)-thallium(III) system; the chemical equation is as follows.

$$*Tl(I) + Tl(III) \rightarrow *Tl(III) + Tl(I) \quad (14)$$

A tentative check by ESR method for the occurrence of thallium(II) was negative in a mixture of thallium(I) and thallium(III) species, while thallium(II) was detected in the presence of one-electron-oxidant.[31] Since chromium exists in such oxidation states as II, III and IV, chromium(II) is known to reduce thallium(III) to thallium(I) as a two-electron-reductant, resulting in chromium(IV) which forms a binuclear complex with an unreacted chromium(II).[32,33] This supports the possibility of the direct two-electron transfer mechanism between thallium(I) and thallium(III) in the absence of one-electron catalyst.

Table 1. Effects of metal ions on the rate of Tl(I)-Tl(III) electron transfer reaction at $[Tl(I)]=[Tl(III)]=0.01$ M, $[H^+]=0.5$ M, $\mu=1.57$ M, and at 50°C

[Added ion], M	k_{app}, $M^{-1}\,h^{-1}$
None	2.77
Cu^{2+} 0.01	2.77
Fe^{3+} 0.1	2.98, 2.89, 2.65
Hg^{2+} 0.01	2.88

It might be concluded that thallium(I)-thallium(III) electron transfer reaction proceeds mainly *via* a single step of two-electron transfer in the absence of catalyst and *via* two steps of stepwise one-electron transfer in the presence of a one-electron-oxidant or a one-electron-reductant.

Kinetic Studies of the Reactions of the Ferricyanide Ion with Cobalt(II)-Aminopolycarboxylate Complexes

Hiroshi OGINO, Masatake TAKAHASHI, and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received November 26, 1973)

Kinetic studies of the reactions of the ferricyanide ion with cobalt(II)-aminopolycarboxylate complexes were carried out. The aminopolycarboxylates used in this study were trimethylenediaminetetraacetate (TRDTA), *trans*-1,2-cyclohexanediaminetetraacetate (CyDTA), propylenediaminetetraacetate(PDTA), and *N*-hydroxyethyl ethylenediaminetriacetate(HEDTA). The first step in the reaction is the rapid formation of a binuclear complex intermediate, [(aminopolycarboxylate)$Co^{III}NCFe^{II}(CN)_5]^{n-}$ ($n=5$ for TRDTA, CyDTA and PDTA and 4 for HEDTA), followed by the dissociation of the intermediate to ferrocyanide and Co(III)-aminopolycarboxylate ions. The equilibrium constant of the formation reaction and the rate constant of the dissociation reaction of the intermediate at an ionic strength of 0.66 were 6.2×10^{2} M^{-1} and 2.0×10^{-2} s^{-1} respectively for the TRDTA system at 5 °C, 3.3×10 M^{-1} and 2.7×10^{-2} s^{-1} for the CyDTA system at 25 °C, and 2.4×10^{3} M^{-1} and 3.0×10^{-3} s^{-1} for the PDTA system at 25 °C. The rate constant of the dissociation of [hedta $Co^{III}NCFe^{II}(CN)_5]^{4-}$ was found to be smaller than 1×10^{-4} s^{-1} at 25 °C and at an ionic strength of 0.66.

It has been reported that the reaction of the ferricyanide ion with ethylenediaminetetraacetatocobaltate(II) (cobalt(II)-EDTA) produced the ferrocyanide ion and the cobalt(III)-EDTA complex as the final products:[1,2]

$$Fe^{III}(CN)_6^{3-} + Co^{II}edta^{2-} \longrightarrow Fe^{II}(CN)_6^{4-} + Co^{III}edta^{-} \quad (1)$$

This reaction proceeds through two consecutive steps. The first step is the formation reaction of a metastable binuclear intermediate, $[edtaCo^{III}NCFe^{II}(CN)_5]^{5-}$, by an inner-sphere electron-transfer reaction between ferricyanide and cobalt(II)-EDTA. The second step is the dissociation of the intermediate to ferrocyanide and cobalt(III)-EDTA. Analogous reactions of the ferricyanide ion with cobalt(II) complexes containing *trans*-1,2-cyclohexanediaminetetraacetate (CyDTA) and diethylenetriaminepentaacetate (DTPA) were investigated by Huchital and Hodges very recently.[3,4]

This paper will describe kinetic studies of the reactions between the ferricyanide ion and cobalt(II) complexes with several aminopolycarboxylates,[5] studies which have been carried out in order to ascertain how the change in the nature of aminopolycarboxylates influences the features of the reactions.

Experimental

Materials. H_4pdta,[6] H_4trdta,[7,8] K[Co pdta]·H_2O,[6] K[Co cydta]·$3H_2O$,[9] and K[Co trdta]·$2H_2O$[7] were prepared by methods described previously. The solution of Co hedta-(H_2O) was prepared in a way similar to that which has been reported for the preparation of $Co^{III}trdta^{-}$.[7] The resulting solution was passed through a cation-exchange resin column, Dowex 50W-X8 (hydrogen-ion form). The effluent was then passed through an anion-exchange resin column, Dowex 1 X-4 (acetate-ion form). The resulting solution was evaporated to a small volume with a rotating evaporator and dried over a phosphorus pentoxide desiccator. Found: C, 32.21; H, 5.27; N, 7.72%. Calcd for $[Co(C_{10}H_{15}N_2O_7)(H_2O)]\cdot H_2O$: C, 32.45; H, 5.17; N, 7.57%.

Kinetic Measurements. Kinetic measurements were made by recording the change in the absorbance at a given wavelength as a function of the time, using a Hitachi EPS-3 pen-recording spectrophotometer. The solution containing given amounts of cobalt(II) ions, aminopolycarboxylate, and an acetate buffer was placed in a quartz spectrophotometer cell, which was then sealed with a serum cap. The reaction was initiated by the addition of a potassium ferricyanide solution using a syringe. The mixing was performed by the passage of a rapid stream of nitrogen gas. The concentration of aminopolycarboxylate was kept at five to ten times that of the cobalt(II) ions. The temperature of the optical cell was controlled at 25.0 °C for the PDTA, CyDTA, and HEDTA systems and 5.0 °C for the TRDTA system. The pH of the solution was adjusted to 5.0 with the acetate buffer solution, and the ionic strength was regulated at 0.66 with sodium acetate.

Results

Spectral Change in the Reactions of the Ferricyanide Ion with Cobalt(II)-Aminopolycarboxylates. Figure 1 shows the change in the absorbance at 550 nm with the time which was obtained for the reaction of $Fe^{III}(CN)_6^{3-}$ with $Co^{II}pdta^{2-}$. The absorbance at zero time which was calculated from the initial concentrations and the molar extinction coefficients of the two reactants is 0.196. However, this calculated value was much smaller than the actual value which was obtained from the extrapolation of the absorbance-time

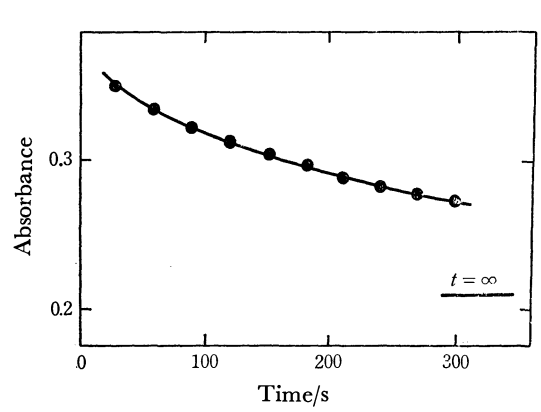

Fig. 1. Absorbance at 550 nm as a function of time obtained for the reaction of ferricyanide ion with cobalt(II)-PDTA complex. Initial concentrations are: $[Fe(CN)_6^{3-}]_{t=0}=0.500$ mM and $[Co^{II}pdta^{2-}]_{t=0}=8.63$ mM.

curve in Fig. 1 to zero time. This suggested that an intermediate was rapidly formed and then converted to the other species. The final reaction products were identified spectrophotometrically as $Fe^{II}(CN)_6^{4-}$ and $Co^{III}pdta^-$. Similar phenomena were also observed for the CyDTA and the TRDTA system. These observations mean that the reaction proceeds in a fashion similar to that of the EDTA system;[1,2] that is, it proceeds through two consecutive steps:

$$Fe^{III}(CN)_6^{3-} + Co^{II}Y^{2-} \overset{K_a}{\rightleftharpoons} YCo^{III}NCFe^{II}(CN)_5^{5-} \quad (2)$$

$$YCo^{III}NCFe^{II}(CN)_5^{5-} \overset{k}{\longrightarrow} Fe^{II}(CN)_6^{4-} + Co^{III}Y^- \quad (3)$$

where Y denotes the tetranegative anion of aminopolycarboxylates. The reaction of $Fe^{III}(CN)_6^{3-}$ with cobalt(II)-HEDTA, however, was found to be different; an intensely-colored species was formed when the reactants were mixed, and it remained unchanged for at least several hours. Figure 2 shows the spectra of the species related to the reaction of $Fe^{III}(CN)_6^{3-}$ with $Co^{II}hedta(H_2O)^-$. Curve A in Fig. 2 is the spectrum for the solution containing $Fe^{III}(CN)_6^{3-}$ and $Co^{II}hedta(H_2O)^-$. This does not coincide with the synthetic spectrum (Curve E in Fig. 2) which was calculated by assuming that the following reaction occurred:

$$Fe^{III}(CN)_6^{3-} + Co^{II}hedta(H_2O)^- \longrightarrow Fe^{II}(CN)_6^{4-} + Co^{III}hedta(H_2O) \quad (4)$$

The shape of Spectrum A is very similar to those of [edta $Co^{III}NCFe^{II}(CN)_5]^{5-}$ and [cydta $Co^{III}NCFe^{II}(CN)_5]^{5-}$.[1,3] These facts suggest that [hedta $Co^{III}NCFe^{II}(CN)_5]^{4-}$ is formed rapidly by the reaction between $Fe^{III}(CN)_6^{3-}$ and $Co^{II}hedta(H_2O)^-$ and that Spectrum A corresponds to the sum of the spectra of [hedta $Co^{III}NCFe^{II}(CN)_5]^{4-}$ and $Co^{II}hedta(H_2O)^-$, the latter of which is present in a large excess.

Kinetic Results. The dissociation of the intermediates was followed under pseudo-first order conditions. The rate constant, k_{app}, was obtained from the slope of plots of log $|D_t - D_\infty|$ *vs.* time, where D_t and D_∞ mean the absorbances at time t and at infinite, respectively. Adamson and Gonick[1] derived the following equation for k_{app} by assuming that the reaction proceeds by means of the mechanism indicated in Eqs. 2 and 3:

$$k_{app} = \frac{kK[Co^{II}Y^{2-}]}{1+K[Co^{II}Y^{2-}]} \quad (5)$$

This equation may be rewritten as:

$$\frac{1}{k_{app}} = \frac{1}{k} + \frac{1}{kK[Co^{II}Y^{2-}]} \quad (6)$$

As is shown in Fig. 3, the plots of $1/k_{app}$ *vs.* $1/[Co^{II}Y^{2-}]$ for various aminopolycarboxylate systems show linear relations which are consistent with the mechanism given in Eqs. 2 and 3. The values of k and K were obtained from the intercepts and slopes of these plots. The results are summarized in Table 1, along with the values reported previously. The values of k and K for the CyDTA system obtained in this work are in good agreement with those obtained by Huchital and Hodges.[3] In the case of the HEDTA system, only a lower limit of the rate constant could be determined.

Discussion

The rate constants of the dissociation of the intermediate, $[YCo^{III}NCFe^{II}(CN)_5]^{n-}$, were found to be

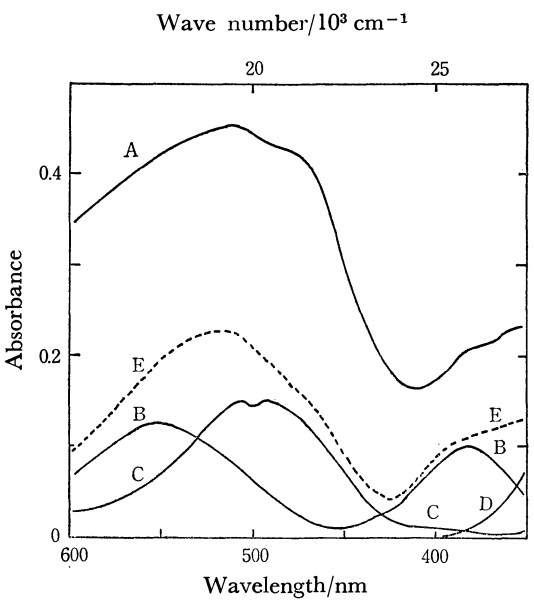

Fig. 2. Spectra of the species related to the reaction of ferricyanide ion with cobalt(II)-HEDTA.
(A) Spectrum obtained for the cobalt(II)-HEDTA solution upon the addition of ferricyanide: $[Co^{II}hedta(H_2O)^-]_{t=0}=8.63$ mM, $[Fe(CN)_6^{3-}]_{t=0}=0.500$ mM. (B) Spectrum of 0.500 mM $[Co^{III}hedta(H_2O)]$ (C) Spectrum of 8.13 mM $[Co^{II}hedta(H_2O)^-]$, (D) Spectrum of 0.500 mM $[Fe(CN)_6^{4-}]$, (E) Synthetic spectrum resulted from the sum of spectra (B), (C) and (D).

HEDTA	25	—	$<1\times10^{-4}$	This work
	—	$\sim5\times10^{3}$	—	4

a) The value was calculated from the data reported in Ref. 3 by the present authors.

in the following order with the natures of the aminopolycarboxylates:

$$\text{TRDTA} > \text{CyDTA} > \text{EDTA, PDTA} \gg \text{HEDTA}$$

where $n=5$ for TRDTA, CyDTA, EDTA, and PDTA, and 4 for HEDTA. This order is parallel to the tendency of aminopolycarboxylates to take a hexadentate structure in the cobalt(III) complexes. Several facts demonstrate that the hexadentate structures of the Co(III)CyDTA and Co(III)-TRDTA complexes are much more stable than the corresponding pentadentate structures, while the hexadentate structures of the Co(III)-EDTA and Co(III)-PDTA complexes are slightly more stable than the pentadentate structures. Complexes of the $Co^{III}Xedta^{2-}$ and $Co^{III}Xpdta^{2-}$ types, where X is Cl^-, Br^-, NO_2^- or OH^-, have also been prepared.[10-13] The ligand X in these complexes is slowly eliminated in a solution, and the complexes come to have the hexadentate structure.[14,15] Dwyer and Garvan observed a rapid conversion of Co^{III}-Clcydta^{2-} to $Co^{III}cydta^-$.[9] Van Saun and Douglas failed in preparing complexes in which TRDTA functions as a pentadentate ligand.[16] Therefore, the $[trdtaCo^{III}NCFe^{II}(CN)_5]^{5-}$ complex detected in this work is the first example of a complex in which TRDTA functions as a pentadentate ligand.

The equilibrium constant of the following acid dissociation reaction may also be a measure of the tendency of aminopolycarboxylates to take a hexadentate structure in cobalt(III) complexes:

$$Co^{III}HY(H_2O) \overset{K_a}{\rightleftharpoons} Co^{III}Y^- + H^+ + H_2O \qquad (7)$$

The value of K_a for the EDTA complex has been determined to be 1.31 M^{-1} at 25 °C and at an ionic strength of 2.0.[17] In this work, the K_a value for the PDTA complex was determined spectrophotometrically to be 1.04 M^{-1} at 25 °C and at an ionic strength of 2.0, this value is very close to that of the EDTA complex. The value of K_a for the CyDTA complex has not yet been reported. However, it was found in this work that $Co^{III}cydta^-$ did not show any spectral change with the increase in the hydrogen-ion concentration up to 5 M in nitric acid. This is the same result as for Co^{III} trdta$^-$.[17] Hence, the formations of $Co^{III}Hcydta(H_2O)$ and $Co^{III}Htrdta(H_2O)$ are considered to be very unfavored.

The increasing tendency to have a hexadentate structure of the CyDTA and TRDTA complexes compared with the EDTA and PDTA complexes holds also in the corresponding complexes of other metals. Both chromium(III)-EDTA[18] and PDTA[19] complexes contain one water molecule in the first coordination sphere, while both CyDTA[19] and TRDTA[20] function as hexadentate ligands in their chromium(III) complexes.

Higgison determined the proportions of several metal(II) complexes containing EDTA, PDTA, or CyDTA in the hexadentate form, the remaining part being the pentadentate form in which the sixth coordination position of the central metal(II) ion is occupied by an aqua ligand.[21] These data also show the increasing tendency to be of a hexadentate structure of the cobalt(II)-, nickel(II)- and copper(II)-CyDTA complexes compared with the corresponding EDTA and PDTA complexes.

The HEDTA system provides an extreme case in which HEDTA functions as a pentadentate ligand because of the very weak coordination ability of the *N*-hydroxyethyl group. The rate of the dissociation of $[hedta\ Co^{III}NCFe^{II}(CN)_5]^{4-}$ was very slow; this is consistent with the interpretation of the order of the dissociation rate of the intermediates presented above. Therefore, the dissociation of the intermediates, $[YCo^{III}$-$NCFe^{II}(CN)_5]^{n-}$, may be a S_N2 reaction, as has been proposed by Huchital and Hodges,[3] in which unbound carboxylate assists the elimination of $Fe^{II}(CN)_6^{4-}$ from the central cobalt(III) ion.

All the hexadentate EDTA, TRDTA, PDTA and CyDTA complexes of cobalt(III) contain two nonequivalent acetate rings. One is in the plane of the diamine chelate ring (in-plane acetate), and the other is perpendicular to the in-plane acetate rings (out-of-plane acetate). In a previous paper,[8] it was suggested that the trimethylenediamine chelate ring in Co^{III} trdta$^-$ takes a twist-boat form and that the in-plane acetate rings are more strained than the out-of-plane acetate rings. This was confirmed later by X-ray study.[22] The data revealed that the shape and size of the four acetate rings of $Co^{III}trdta^-$ are essentially identical to those of $Co^{III}edta^-$.[23] The in-plane acetate rings show considerable departure from planarity and are strained, while the out-of-plane acetate rings are nearly planar. It has been inferred that the conformational situations of acetate rings in $Co^{III}pdta^-$ and $Co^{III}cydta^-$ are similar to those in $Co^{III}edta^-$.[24,25] This may be true also for $Co^{III}hedta(H_2O)$, because HEDTA has a structure very similar to that of EDTA.

It is known that X in $Co^{III}Xedta^{2-}$ replaces an in-plane acetate.[26] Busch *et al.* investigated the reactions of ethylenediamine with $Co^{III}edta^-$ and Co^{III}-pdta$^-$ to produce the tris(ethylenediamine)cobalt(III) ion.[24,27,28] They found a satisfactory interpretation for the reaction mechanism on the assumption that the first step of the entry of ethylenediamine to the coordination sphere of the cobalt(III) ion is the replacement of an in-plane acetate group. Therefore, it is reasonable to consider that the cyano group coordinated to the

cobalt(III) ion in the intermediate given in Eq. 2 replaces an in-plane acetate group.

Huchital and Hodges reported that the higher value of k for the CyDTA complex than that for the EDTA complex was due to the steric hindrance between the methylene protons of the acetate ring and the axial proton in the 3 position of the cyclohexane ring.[3] However, this does not seem to be the cause of the higher value of k, because the acetate protons which interfere with the axial proton in the 3 position of the cyclohexane ring are out-of-plane protons. There is no steric interaction between the axial proton in the cyclohexane ring and the proton of the in-plane acetate ring which is replaced by the incoming cyano group. The molecular model for the $Co^{III}pdta^-$ complex reveals that there is a steric hindrance between the proton of the out-of-plane acetate ring and the methyl protons. This steric hindrance is similar to that between the proton of the out-of-plane acetate ring and the axial proton in the 3 position of the cyclohexane ring for the CyDTA complex. If the out-of-plane acetate group, which suffers steric hindrance from the proton of the methyl group, is replaced by a cyano group, the value of k for the PDTA system would be expected to be much different from that for the EDTA system. The results given in Table 1 show that this is not true and that the values of k for the two systems are essentially identical. Therefore, it may be concluded that the cyano group coordinated to the cobalt(III) ion in the intermediate replaces the in-plane acetate group.

The equilibrium constant of Reaction 2, K, was found to increase in the following order with the nature of the aminopolycarboxylates:

$$\text{CyDTA, TRDTA} < \text{EDTA, PDTA} < \text{HEDTA}$$

This order is not related to that of the magnitude of the oxidation-reduction potentials of the Co(III)-Y/Co(II)-Y sysetm,[29,30] but it is the reverse of the order found for the values of the rate constant, k, except for TRDTA and CyDTA. Hence, it can reasonably be concluded that the value of K becomes larger for aminopolycarboxylates, which have a stronger tendency to take a pentadentate structure.

The authors are grateful to the Ministry of Education for its financial support and to the Matsunaga Science Foundation for a grant to one of them (H. O.).

Kinetics of Multidentate Ligand Substitution Reactions. XVI. Substitution Reactions of 1,2-Cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic Acid (CyDTA) with the Zinc(II)–Ethylenediaminemonoacetate (EDMA) and –Ethylenediamine-*N*,*N*′-diacetate (EDDA) Complexes and That of Ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic Acid (EDTA) with the Nickel(II)–EDDA Complex

Mutsuo KODAMA

(Received November 26, 1973)

The kinetics of the substitution reactions of CyDTA with zinc(II)–EDMA and –EDDA complexes and that of EDTA with the nickel(II)–EDDA complex were studied systematically by using the polarographic technique. All the substitution reactions were found to be first-order with respect to the CyDTA or EDTA anion and also first-order with respect to the 1 : 1-ratio EDMA or EDDA complex. From a comparison of the observed rate constants with those estimated on the basis of the proposed reaction intermediates, the detailed reaction mechanisms were discussed. The rates of the reactions of zinc(II)–EDMA complex and nickel(II)–EDDA complex could be understood in terms of the ethylenediamine reaction mechanism, but that of the reaction of the zinc(II)–EDDA complex with the CyDTA anion could not. This discrepancy may be ascribed by the steric hindrance of the CyDTA anion to the formation of an ethylenediamine reaction intermediate in the reaction of the zinc(II)–EDDA complex.

In a previous paper,[1] the present author studied the steric effect of the cyclohexane ring on the rate of the substitution reactions of metal(II)–aminopolycarboxylate complexes. In this paper, the present author will deal with the kinetics of the substitution reactions of CyDTA with the zinc(II)–EDMA and –EDDA complexes as an extention of an earlier investigation of the steric effects of the CyDTA anion on the reaction of the metal(II)–aminopolycarboxylate complex. In order to describe more precisely the nature of the steric effect of the CyDTA anion, the substitution reaction of EDTA with the nickel(II)–EDDA complex will also be studied.

Experimental

Reagents. The preparation and standardization of zinc(II) and nickel(II) solutions were described in previous papers.[2,3] Reagent-grade EDDA, CyDTA, and glycine were recrystallized from their aqueous solutions by adding pure hydrochloric acid and ethanol. The preparation and recrystallization of EDMA were also described previously.[4] The other chemicals used in this study were of an analytical reagent-grade and were used without further purification.

Apparatus and Experimental Procedures. The apparatus and the experimental procedures were the same as those described previously.[1] In this study, all the measurements were conducted in solutions with an ionic strength of 0.30 ($NaClO_4$) at 25 °C. No buffer reagent was used, because the sample solutions always contained a large excess of uncomplexed EDMA, EDDA, or Gly, and had enough buffer capacity in the pH ranges studied ($9.50<pH<10.50$ in the EDMA system and $9.00<pH<10.20$ in the EDDA system). In the case of the zinc(II) system, the kinetic measurements were carried out in sample solutions containing large excesses of uncomplexed CyDTA and EDMA or EDDA over the complexed EDMA or EDDA. In the reaction of the nickel(II) complex, the kinetic measurements were carried out in solutions containing large excesses of complexed and uncomplexed EDDA over EDTA. Therefore, all the reactions could be treated as pseudo-first-order reactions. The rate of the substitution reaction of the zinc(II) complex was determined by measuring the change in the reduction wave-height of the zinc(II)–EDMA or –EDDA complex. On the other hand, the rate of the reaction involving the nickel(II)–EDDA complex was determined by observing the change in the dissolution wave due to the uncomplexed EDTA.

Results and Discussion

The reaction of CyDTA with the zinc(II)–EDMA complex showed the same kinetic behavior as that with the zinc(II)–*N*-(2-hydroxyethyl)iminodiacetate (HIDA) complex,[1] suggesting the following reaction mechanism (I):

$$MX_2^{(2-2m)+} \rightleftharpoons MY^{(2-m)+} + X^{m-} \quad (1_a) \text{ in a rapid equil.}$$

(I)

$$MX^{(2-m)+} + \begin{cases} HY^{3-} \overset{k_H}{\rightleftharpoons} MY^{2-} + HX^{(1-m)} & (1_b) \\ Y^{-4} \overset{k_0}{\rightleftharpoons} MY^{2-} + X^{m-} & (2_c) \end{cases} \text{ rds}$$

Therefore, the k_0 and k_H values were determined from the intercept and slope of the linear relation between $k_{ap}^{+}\cdot(1+K_2\cdot[X]_f/(\alpha_H)_x)\cdot(\alpha_H)_Y/[Y]_f$ and $[H^+]$ (Table 1). Here, all the symbols used have their usual meanings.[1] The substitution reactions of the nickel(II)–EDDA complex with EDTA was studied in sample solutions containing excess glycinate. In this reaction, the k_{ap}^{+} value determined from the slope of the linear relation between $\log(i_0/i_t)$ and t was independent of the concentration of the uncomplexed EDDA and of the initial concentration of EDTA. However, it decreased appreciably with an increase in the Glut concentration $[G]_f$, and the plot of the $[Ni(II)]/k_{ap}^{+}\cdot(\alpha_H)_Y$ against the concentration of the Glut anion, $[G]_f/(\alpha_H)_G$, gave a straight line with an intercept of a finite value (Fig. 1). This indicates the formation of a 1 : 1 : 1-ratio mixed ligand complex, MXG^-, corresponding to the following reaction mechanism (II):

$$MXG^- \rightleftharpoons MX^0 + G^- \quad (2_a) \text{ in a rapid equil.}$$

(II)

$$MX^0 + \begin{cases} HY^{3-} \overset{k_H}{\rightleftharpoons} MY^{2-} + HX^- & (2_b) \\ Y^{4-} \overset{k_0}{\rightleftharpoons} MY^{2-}. + X^{2-} & (2_c) \end{cases} \text{ rds}$$

TABLE 1. RATE CONSTANTS (μ=0.30, 25°C)

A) Ni(II) system

log K_{MX}	System	Observed rate constant		Rate constant ratio		
				Obsd		Calcd (En mechanism)
		k_0	k_H	k_0	k_H	
13.20	EDDA	7.0	3.72	1.0	1.0	1.0
10.44	EDMA[7]	1.5×10^3	3.90×10^2	$10^{2.30}$	$10^{2.02}$	$10^{2.26}$

B) Zn(II) system

log K_{MX}	System	Observed rate constant		k_0 ratio		
				Obsd	Calcd	
		k_0	k_H		En mecha.	Gly mecha.
8.02	HIDA	2.7×10^4	2.60×10^2	1.0	—	1.0
8.22	EDMA	5.6×10^2	3.20×10^1	$10^{-1.68}$	$10^{-1.74}$	—
10.79	EDDA	1.9×10^1	$6.0_0\times10^{-1}$	$10^{-3.15}$	$10^{-4.00}$	$10^{-2.77}$

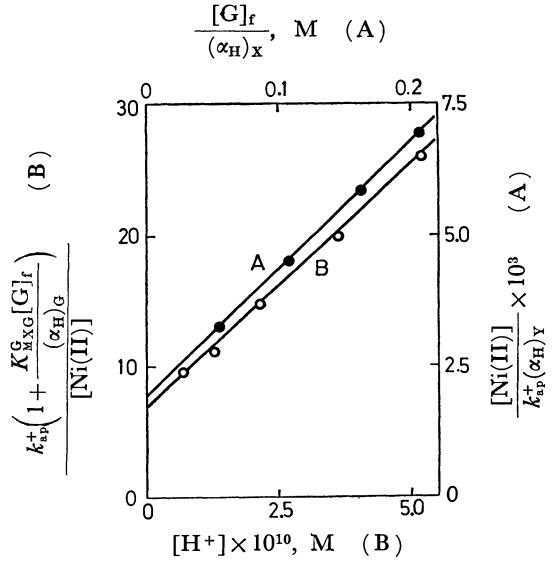

Fig. 1. The relation between $[Ni(II)]/k^+_{ap}\cdot(\alpha_H)_Y$ and $[G]_f/(\alpha_H)_G$ and that between $k^+_{ap}\cdot(\alpha_H)_Y\cdot(1+K^G_{MXG}\cdot[G]_f/(\alpha_H)_G)/[Ni(II)]$ and $[H^+]$.
μ=0.30, 25 °C
$[EDDA]_f$=28.3 mM, $[EDTA]_l$=0.566 mM
A) The relation between $[Ni(II)]/k^+_{ap}\cdot(\alpha_H)_Y$ and $[G]_f/(\alpha_H)_G$
pH=9.70, [Ni(II)]=5.66 mM
$[G]_f$ ranged from 80 to 290 mM
B) The relation between $k^+_{ap}\cdot(\alpha_H)_Y(1+K^G_{MXG}\cdot[G]_f/(\alpha_H)_G)/[Ni(II)]$ and $[H^+]$
[Ni(II)]=7.55 mM, $[G]_f$=28.3 mM
pH ranged from 9.20 to 10.20

Since the 1 : 1 : 1-ratio mixed ligand complex of the nickel(II)-ion involving the EDDA and Glut anions can be synthesized easily by mixing $NiCl_2$, EDDA, and Glut solutions and by evaporating the resulting mixture to dryness,[5] the above conclusion seems reasonable. From the ratio between the slope and the intercept of the above linear relation, the equilibrium constant, $K^G_{MXG}=[MXG^-]/[MX^0]\cdot[G^-]$, was determined to be 13.1. For the above reaction mechanism, the apparent rate constant, k^+_{ap}, is given by $[Y]_f(k_0+k_H\cdot[H^+]/K_4)/(\alpha_H)_Y\cdot(1+K^G_{MXG}\cdot[G]_f/(\alpha_H)_G)$. Therefore, the k_0 and k_H values were determined from the intercept and slope of the linear relation between $k^+_{ap}\cdot(\alpha_H)_Y\cdot(1+K^G_{MGX}\cdot[G]_f/(\alpha_H)_G)/[Y]_f$ and $[H^+]$ (Fig. 1). They are also listed in Table 1.

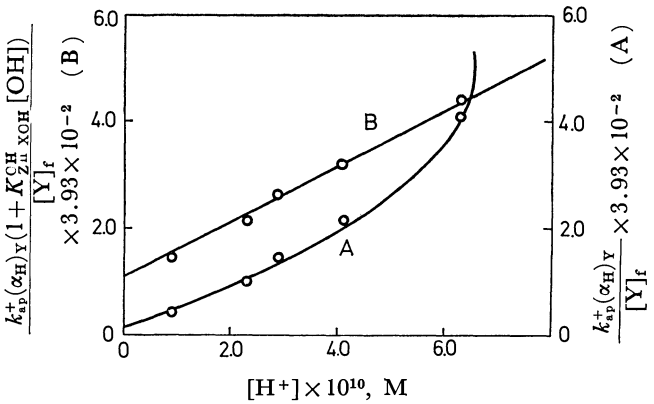

Fig. 2. The plot of $k^+_{ap}\cdot(\alpha_H)_Y/[Y]_f$ or $k^+_{ap}(\alpha_H)_Y(1+K^{OH}_{ZnX(OH)}[OH^-])/[Y]_f$ against $[H^+]$.
[Zn(II)]=1.0 mM, $[EDDA]_f$=20.0 mM
$[CyDTA]_l$=10 mM
μ=0.30, 25 °C
A) The plot of $k^+_{ap}\cdot(\alpha_H)_Y/[Y]_f$ against $[H^+]$
B) The plot of $k^+_{ap}\cdot(\alpha_H)_Y(1+K^{OH}_{ZnX(OH)}[OH^-])/[Y]_f$ against $[H^+]$

The substitution reaction of the zinc(II)-EDDA complex with CyDTA was studied in solutions not containing glycinate. As in the case of the nickel(II)-EDDA system, the k^+_{ap} value was independent of the cocentration of the uncomplexed EDDA and of the initial concentration of the zinc(II)-EDDA complex. However, the plot of k^+_{ap} multiplied by $(\alpha_H)_Y/[Y]_f$ against the hydrogen ion concentration, $[H^+]$, gave no linear relation (Fig. 2). This may suggest the formation of a mixed-ligand complex involving the hydroxide anion. Since the zinc(II)-EDDA complex forms a mixed-ligand complex, $ZnX(NCS)^-$,

with NCS^-,[6] it is natural to assume the formation of the 1 : 1 : 1-ratio mixed ligand complex, $ZnX(OH)^-$. If the slow reaction pathways, (2_b) and (2_c), are preceded by the rapid dissociation of $ZnX(OH)^-$ into ZnX^0, corresponding to the k_{ap}^+ value of $[Y]_f(k_0+k_H[H^+]/K_4)/(\alpha_H)_Y(1+K_{ZnX(OH)}^{OH}[OH^-])$, the equilibrium constant, $K_{ZnX(OH)}^{H}(=[ZnX(OH)^-]/[ZnX^0]\cdot[OH^-])$, should be given by Eq. (1):

$$k_{ZnX(OH)}^{OH}=\frac{1}{K_w}\frac{(P_1\cdot[H^+]_1-P_2\cdot[H^+]_2)([H^+]_1-[H^+]_2\cdot)-(P_1\cdot[H^+]_1-P_3\cdot[H^+]_3)\cdot([H^+]_1-[H^+]_3)}{(P_1-P_2)([H^+]_1-[H^+]_3)-(P_1-P_3)([H^+]_1-[H^+]_2)} \quad (1)$$

and the plot of $k_{ap}^+\cdot(1+K_{ZnX(OH)}^{OH}\cdot[OH^-])\cdot(\alpha_H)_Y/[Y]_f$ against $[H^+]$ should give a straight line with an intercept of a finite value. By using the $K_{ZnX(CH)}^{OH}$ value of 2×10^4 estimated with the aid of Eq. (1), the $k_{ap}^+\cdot(\alpha_H)_Y\cdot K_{ZnX(OH)}^{OH}\cdot[OH^-])/[Y]_f$ value was plotted against $[H^+]$. As is illustrated by the straight line (B) in Fig. 2, the above plot invariably gave a linear relation with an intercept of a finite value. From the intercept and the slope of the above linear relation, the k_0 and k_H values for the substitution reaction of the zinc(II)–EDDA complex with CyDTA were determined (Table 1). Previously,[1] the present author systematically studied the substitution reaction of the zinc(II)–HIDA complex with CyDTA at 0 °C and drew the conclusion that the reaction proceeds through the glycinate-reaction mechanism. In this paper, this reaction was studied at 25 °C, and the k_0 and k_H values were determined to be 2.7×10^4 and $2.6_0\times10^2$ respectively.

Previously,[7] the present author mentioned that the substitution reaction of the nickel(II)–EDMA complex with EDTA proceeds through the ethylene diamine(En)-reaction intermediate, where the leaving EDMA and entering EDTA anions are bonded to the nickel(II) ion through ethylenediamine- and glycinate-chelate rings respectively. Therefore, it is reasonable to assume the En mechanism for the substitution reaction of the nickel(II)–EDMA complex with EDTA. The relative rate constant for the reaction of the nickel(II)–EDDA complex with EDTA was calculated on the basis of the En-reaction intermediate by means of this relation; $k=k_{rds}\cdot K_L\cdot K_A\cdot K_{st}\cdot K_{elec}/K_{MX}$,[1] and was compared with the observed one (Table 1). Here, all the symbols in the above relation have their usual meanings.[1] The good agreement between the calculated and observed relative rate constants supports the above En-mechanism explanation. Since the steric hindrance to the CyDTA anion in its reaction with the zinc(II)–HIDA complex is considered to be quite the same as those of the reactions with the zinc(II)–EDMA and –EDDA complexes, one can also calculate the relative rate constants with reference to the zinc(II)–HIDA system on the basis of the proposed reaction intermediate. Since, in the substitution reaction, the zinc(II)-aminopolycarboxylate complex shows kinetic behavior very similar to that of the corresponding nickel(II) complex,[8] one can assume the En-reaction mechanism for the reactions of CyDTA with the zinc(II)–EDMA and –EDDA complexes. As is shown in Table 1, the k_0 ratio between the HIDA and EDMA systems calculated by assuming the En-reaction mechanism for the EDMA system agreed well with the observed one. However, the rate of the substitution reaction of the zinc(II)–EDDA complex with CyDTA cannot be understood by assuming the En mechanism. This discrepancy may be ascribed to the steric effect of the CyDTA anion on the reaction mechanism. The k_{rds} values for the Gly and En mechanisms were approximated by the dissociation rate constants of the 1 : 1-ratio zinc(II)–Gly and –En complexes respectively. The dissociation rate constant of the zinc(II)–Gly complex was estimated to be 1.5×10^3 from the formation rate constant, k_f, with the aid of the $K_{MX}=k_f/k_d$ relation. The k_f value was calculated by using the $k_{Zn}^{H_2O}$ value of 3.2×10^7 and the K_{os} value of 5 on the basis of the usual water-exchange mechanism.[9] The dissociation rate constant of the 1 : 1-ratio zinc(II)–En complex was evaluated as 3.0×10^2 from the dissociation constant of the 1 : 1-ratio zinc(II)–ammine complex[10] by correcting it for the rotational barrier around the C–N bond.[11] In order to explain more thoroughly the fact that the CyDTA reaction with the zinc(II)–EDMA complex proceeds through the En mechanism, whereas that with the zinc(II)–EDDA complex does not, the steric effect of the CyDTA on the formation of the reaction intermediate in the reactions of the EDMA and EDDA complexes was investigated by using the molecular model. A close molecular model examination revealed that the ethylenediamine reaction intermediate can be formed without any difficulty in the EDDA~EDTA and EDMA~CyDTA systems. However, it is almost impossible to build the En intermediate in the EDDA~CyDTA system because of the steric interaction of the CyDTA with the free carboxylate group of the EDDA anion. For this reason, the substitution reaction of CyDTA with the zinc(II)–EDDA complex could not proceed through the En reaction intermediate. As has been mentioned above, it is impossible to form the En-reaction intermediate from the EDDA and CyDTA anions. However, the glycinate reaction intermediate could be formed, although with some difficulty. The relative rate constant calculated on the basis of the Gly mechanism is also listed in Table 1 and compared with the observed one. The agreement between the two values can be regarded as satisfactory. This agreement and the conclusion obtained in the molecular-model examination suggest that the glycinate reaction mechanism can be assumed for the reaction of the zinc(II)–EDDA complex with with CyDTA.

A Polarographic Study of the Zinc(II)–Ethylenediamine-*N*,*N*′-diacetate (EDDA) and –Triethylenetetraamine (Trien) Complexes

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki, Aomori 036

(Received November 26, 1973)

Zinc(II)–EDDA and –Trien complexes produced kinetic waves. By conducting a systematic examination of the nature of the kinetic waves, the reaction mechanisms and the rates of the rate-determining step were determined. The kinetic wave of the zinc(II)–EDDA complex could be ascribed to the reduction of the zinc(II) aquo ion formed upon its slow dissociation at the electrode surface. From a comparison of the observed rate constant with that estimated on the basis of the proposed reaction intermediate, the dissociation of the zinc(II)–EDDA complex was found to proceed through a reaction intermediate in which the leaving EDDA anion is bonded to the zinc(II) ion through the ethylenediamine chelate ring. In the case of the Trien complex, the kinetic wave could be ascirbed to the reduction of the zinc(II)–Trien complex formed upon the slow configurational change of the tetrahedral zinc(II)–Trien complex at the electrode surface.

Previously,[1] the present author studied the dissociation reactions of zinc(II)–, lead(II)–, and cadmium(II)–aminopolycarboxylate complexes by examining the nature of the kinetic waves they gave. The zinc(II)–EDDA and –Trien complexes also produced kinetic waves. In this paper, the author will describe a systematic study of the nature of the above kinetic waves and will determine the reaction mechanism and reaction rates. The effect of the thiocyanate anion on the polarographic behavior of the zinc(II)–EDDA and –Trien complexes will also be investigated.

Experimental

Reagents. The previous paper[2] explained the preparation of a standard zinc(II) solution. An EDDA was recrystallized from its aqueous solution. Its standard solution was prepared by dissolving a known amount of recrystallized EDDA in redistilled water. The Trien was redistilled under reduced pressure. All the other chemicals were of an analytical reagent-grade and were used without further purification.

Apparatus and Experimental Procedures. The polarographs used for the measurement of the dc current-voltage cuvres were given previously.[2] The rate of the flow of mercury, m, and the drop time, t_d, of the dropping mercury electrode (DME) used in this study were 0.836 mg/s and 4.30 s respectively at a mercury height of 58.0 cm in an air-free 0.10 M sodium perchlorate solution at 0.0 V *vs.* SCE. All the other pieces of the apparatus and all the experimental procedures employed in this study were the same as those described in the previous paper.[2] For the EDDA system, an acetate buffer solution was used. In the case of the Trien system, no buffer reagent was used, because the sample solutions always contained a large excess of uncomplexed Trien and had a sufficient buffer capacity over the entire pH range covered ($6.00 < pH < 7.50$).

Results and Discussion

Under the experimental conditions where all the zinc(II) ions exist as complexes, the zinc(II) ions in EDDA and Trien solutions gave two- and one-step polarographic waves respectively. The first wave of the EDDA complex and the reduction step of the Trien complex showed a characteristic kinetic-controlled nature, while the second wave of the EDDA complex showed a diffusion-controlled nature. From the effects of the mercury pressure, the solution pH, and the uncomplexed ligand concentration on the limiting current, the second step of the EDDA complex could be ascribed to its direct reduction at the electrode surface.

As in the cases of the cobalt(II)–iminodiacetate (IDA) and –aspartate (Asp) complexes,[3] the first step of the zinc(II)–EDDA complex invariably gave a linear relation passing through the point of origin between $i_k/(i_d-i_k)$ and $(\alpha_H)_X^{1/2}$ (at a given EDDA concentration, $[X]_f$) or $[X]_f^{-1/2}$ (at a given solution pH) (Fig. 1). Here, $(\alpha_H)_X$ and i_k are, respectively, the (α_H) value of EDDA and the kinetic wave height. Provided that the other experimental conditions are kept constant, the plot of $i_k/(i_d-i_k)$ against $\beta_{Ac}^{1/2}$ $(=1+K_1^{Ac}\cdot[Ac^-]+K_1^{Ac}\cdot K_2^{Ac}\cdot[Ac^-]^2+\cdots]^{1/2})$[1] also gave a straight line which passes through the point of origin. Since the zinc(II) ion forms only a 1 : 1-ratio complex with EDDA[4], the above facts suggest that the following

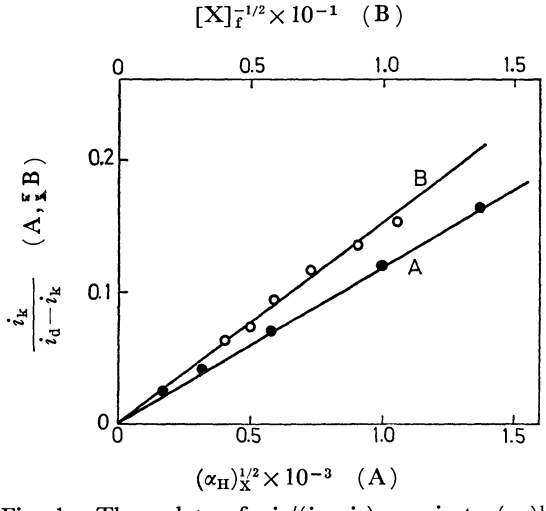

Fig. 1. The plot of $i_k/(i_d-i_k)$ against $(\alpha_H)_X^{1/2}$ or $[X]_f^{-1/2}$.
$\mu=0.30$, 25 °C
$[Zn(II)]=0.60$ mM, $]Ac]_f=0.060$ M
A) The plot of $i_k/(i_d-i_k)$ against $(\alpha)_X^{1/2}$
$[EDDA]_f=14.0$ mM
pH ranged from 4.60 to 5.90
B) The plot of $i_k/(i_d-i_k)$ against $[X]_f^{-1/2}$
$[EDDA]_f$ ranged from 9.0 to 40.0 M
pH=5.00

reaction mechanism can be assumed for the kinetic wave of the zinc(II)-EDDA complex:

$$ZnX^0 \overset{k_d}{\rightleftharpoons} Zn^{2+} + X^{2-} \quad (1)\ \text{rds}$$

$$\underbrace{Zn^{2+} + iAc^- \rightleftharpoons Zn(Ac)_i^{2-i}}_{Hg \downarrow 2e^-} \quad \text{in a rapid equil.}$$

$$Zn(Hg)$$

The k_d value was determined from the slope of the linear relation in Fig. 1; it is listed in Table 1, together with other numerical data. In the presence of the thiocyanate anion, the plot of $((i_d-i_k)/i_k)\cdot\beta_{NCS}^{1/2}$ against [NCS$^-$] gave a linear relation with an intercept of a finite value (Fig. 2). Here, β_{NCS} is defined as $1+K_1^{NCS}\cdot[NCS^-]+K_1^{NCS}\cdot K_2^{NCS}\cdot[NCS^-]^2+\cdots$, and [NCS$^-$] is the concentration of the uncomplexed thiocyanate anion. The above facts evidently suggest the formation of a mixed-ligand complex, ZnX(NCS)$^-$. Therefore, in view of the fact that the zinc(II)-thiocyanate complex is much more stable than the corresponding acetate complex, one can assume the following reaction mechanism for the kinetic wave of the zinc(II)-EDDA complex in solutions containing thiocyanate anions:

$$ZnX(NCS)^- \rightleftharpoons ZnX^0 + NCS^- \quad (2)\ \text{in a rapid equil.}$$

$$ZnX^0 \overset{k_d}{\rightleftharpoons} Zn^{2+} + X^{2-} \quad (1)\ \text{rds}$$

$$\underbrace{Zn^{2+} + jNCS^- \rightleftharpoons Zn(NCS)_j^{2-j}}_{Hg \downarrow 2e^-} \quad \text{in a rapid equil.}$$

$$Zn(Hg)$$

corresponding to Relation (1):

$$\frac{i_k}{i_d-i_k} = 0.886\cdot\sqrt{\frac{k_d\cdot t\cdot(\alpha_H)_X\cdot\beta_{NCS}}{K_{ZnX}\cdot[X]_f}}\cdot\frac{1}{1+K_{ZnX(NCS)}^{NCS}\cdot[NCS^-]} \quad (1)$$

Relation (1) was examined successfully by using some typical experimental data and the $K_{ZnX(NCS)}^{NCS}$ (=[ZnX(NCS)$^-$]/[ZnX^0]·[NCS$^-$]) value of 2.24 determined from the ratio between the intercept and the slope of the straight line (A) in Fig. 2. The good agreement of the k_d value estimated from the slope of the linear relation (B) in Fig. 2 with that determined from the slope of the straight line in Fig. 1 also supports the above explanation.

In the zinc(II)-Trien system, i_k also decreased with an increase in the solution pH, and the plot of $i_k/(i_d-i_k)$ against $K^H\cdot[H^+]^{1/2}/(1+K^H\cdot[H^+])$ gave a linear relation passing through the point of origin (Fig. 3). However, the $i_k/(i_d-i_k)$ ratio was almost independent of the concentration of the uncomplexed Trien, $[X]_f$. These facts suggest the following reaction mechanism

Table 1. Rate constants (μ=0.30, 25 °C)

6.62	−1.133	− 8	−6.5
6.88	−1.145	−15	−14.2
7.28	−1.165	−25	−26.0

anism is assumed for the zinc(II)-Trien system, the half-wave potential of the kinetic wave, $(E_{1/2})_k$, should be given by:[5]

$$(E_{1/2})_k = \text{constant} + \frac{0.0591}{4\alpha}\log [H^+] \qquad (3)$$

By using the α value of 0.51, the effect of the solution pH on the half-wave potential was examined with the aid of Eq. (3). The result is given in Table 2. The shifts of the half-wave potential observed agreed well with those calculated.

As was discussed in connection with the dissociation mechanism of the zinc(II)-aminopolycarboxylate complex, the structure of the reaction intermediate in the dissociation of the zinc(II)-EDDA complex was determined by comparing the observed k_d value with that calculated on the basis of the proposed reaction intermediate. The k_d value calculated with the aid of the well-known relation; $k=k_{rds}\cdot K_{inter}\cdot K_{st}\cdot K_{elec}/K_{MX}$,[3] on the basis of the ethylenediamine reaction intermediate was 1.0. Here, $K_{inter}=10^{6.15}$, $K_{st}=1.0\times 10^2$, $k_{rds}=3.1\times 10^2$, and $K_{MX}=10.$[10.79] The k_{rds} value used in the above calculation was estimated from the dissociation rate constant of the 1 : 1-ratio zinc(II)-ammine complex by making a correction for the rotational barrier around the C-N bond.[6] The agreement between the calculated and observed rate constants can be regarded as satisfactory. The rate constants calculated on the basis of the other reaction intermediates showed no satisfactory agreement with the observed one.

In the case of the zinc(II)-Trien complex, one can not determine the k value from the slope of the linear relation in Fig. 3, because the K value is unknown. With regard to the nature of the electroactive zinc(II)-Trien complex, two explanations are possible. One is that electroactive zinc(II)-Trien complex, ZnX^{2+}*, is the species produced upon the partial dissociation of the original complex, ZnX^{2+}. The other is that ZnX^{2+}* is the Trien complex formed upon the configurational change of the original complex. Generally, protonation of a metal complex always involves a partial dissociation of the metal complex. Therefore, the fact that the rate-determining step includes the deprotonation of the protonated zinc(II)-Trien complex eliminates the former explanation. On the basis of the ΔS value of the formation reaction, Sacconi *et al.*[7] concluded that the zinc(II)-Trien complex in a solution is tetrahedral. This could be confirmed by the finding that the thiocyanate anion had practically no effect on the polarographic behavior of the zinc(II)-Trien complex. If the zinc(II)-Trien complex in solution is octahedral, the thiocyanate anion will form a mixed ligand complex with ZnX^{2+} and will have a remarkable effect on the kinetic wave. Therefore, it must be reasonable to believe that the rate-determining step in the zinc(II)-Trien system is the configurational change of the zinc(II)-Trien complex from tetrahedral to octahedral or square pyramid. In order to describe the nature of the above configurational change more precisely, a further systematic investigation should be conducted.

Copper(II) Complexes of Glycyl-L-histidine, Glycyl-L-histidylglycine, and Glycylglycyl-L-histidine in Aqueous Solution

Hiroji AIBA, Akira YOKOYAMA, and Hisashi TANAKA

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received November 29, 1973)

The complex formation of glycyl-L-histidine, glycyl-L-histidylglycine, and glycylglycyl-L-histidine with copper (II) ion in aqueous solutions containing equimolar amounts of copper(II) and the respective ligand was investigated by potentiometric and visible spectrophotometric methods. The presence of the following copper (II) complex species was assumed: $CuLH^{2+}$, CuX, and $Cu_nY_n^{n-}$ for glycyl-L-histidine-copper(II) and glycyl-L-histidylglycine-copper(II) systems, and $CuLH^{2+}$, CuY^-, and CuZ^{2-} for glycylglycyl-L-histidine-copper(II) system, where LH is the neutral species of the ligand and $LH=XH_2=YH_3=ZH_4$. The formation and ionization constants were obtained graphically, and the distribution of copper(II) among the complex species was calculated for each system. The results indicate that copper(II) ions are bound to the imidazole and carboxyl (or carbonyl) groups in $CuLH^{2+}$ and to the amino, imidazole, and deprotonated amide groups in CuX, CuY^-, and CuZ^{2-}. The spectral blue shift accompanying a deprotonation in the region from $a=4$ to 5 in the glycyl-L-histidine and glycyl-L-histidylglycine copper(II) systems indicates the formation of a polymer complex $Cu_nY_n^{n-}$ in which the imidazole ring acts as a bridge to connect copper atoms, where a represents moles of KOH added per completely protonated ligand.

In previous papers,[1,2] we discussed the complex species formed in the reaction of L-histidylglycine and L-histidylglycylglycine with copper(II) ion in an aqueous solution. Since the histidyl residue in the peptides plays an important role in their complex formation with metal ions, the position of the histidyl residue in the peptide molecule may cause remarkable differences in the modes of their complex formation. In an attempt to obtain further information on the interaction of the histidyl residue in the peptides with metal ion, the complex formation of glycyl-L-histidine, glycyl-L-histidylglycine, and glycylglycyl-L-histidine (abbreviated as GH, GHG, and GGH hereafter) with copper(II) ion was studied in aqueous solutions containing equimolar amounts of copper(II) and the ligand by potentiometric and spectrophotometric methods.

The copper(II) complexes of GH and GGH in aqueous solution have been investigated by various physico-chemical methods, and the binding sites of copper(II) have been deduced.[3-7] The structure of the neutral 1 : 1 GH-copper(II) complex was elucidated by X-ray diffraction analysis.[8] Recently, copper(II) complex of GHG was also studied in both aqueous solution and crystalline state.[9-11] However, the complex formation of these peptides with copper(II) ion in aqueous solution has not been elucidated completely, and there remain problems on the quantitative interpretation of the experimental results, the complex species formed in the reaction, and their structures.

Experimental

Materials. The preparation of the peptides were described previously.[12] Other reagents were commercial products.

Methods. The potentiometric and visible absorption spectral measurements were carried out as described previously.[1,12]

Results

Potentiometric Titration of GH-copper(II) and GHG-copper(II) Systems. The titration curves for the solutions containing $CuCl_2$ and GH or GHG (molar ratio 1 : 1) are shown in Fig. 1, together with those for the ligands in the absence of copper(II). Each curve shows the onset of pH fall at a point near $a=1$ and an extensive overlap of the ionization, giving a strong pH inflection at $a=4$, where a represents the number of moles of KOH added per completely protonated ligand. The same titration curve has been reported by Martin and Edsall,[3] and Bryce *et al.*[4] for the GH-Cu(II) system. From these titration behaviors, coordination is presumed to occur initially at the imidazole group with subsequent release of the protons from the amino and the peptide amide groups. Accordingly, the following equilibria are assumed in the region between $a=1$ and $a=4$,

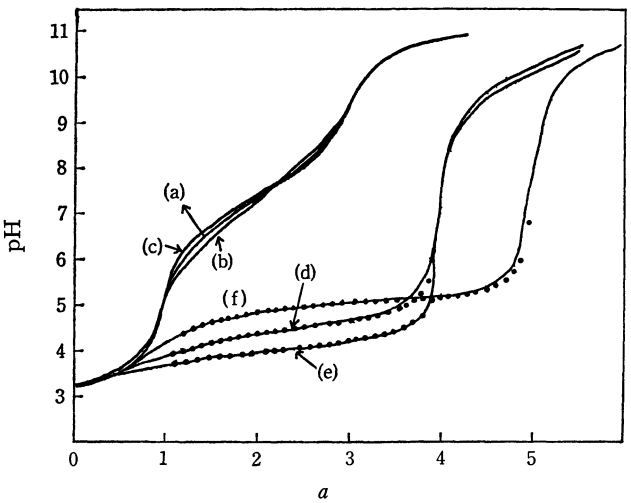

Fig. 1. Titration curves of GH, GHG, and GGH in the absence and presence of $CuCl_2$.
(a) GH+2HCl, (b) GHG+2HCl, (c) GGH+2HCl, (d) GH+2HCl+$CuCl_2$, (e) GHG+2HCl+$CuCl_2$, (f) GGH+2HCl+$CuCl_2$; ligand concentration is 10^{-3} M (at $a=0$).
The lines are experimental curves. Each point was calculated from the equilibrium constant.

TABLE 1. FORMATION AND IONIZATION CONSTANTS FOR COPPER(II)-PEPTIDE SYSTEMS

Ligand	pK_{COOH}[a)]	pK_{Im}[a)]	pK_{NH_3}[a)]	$\log K_1$	pK_{2c}	pK_{3c}	"pK_c"[b)]
GH	2.75	6.85	8.33	5.08	8.40	—	9.65
GHG	3.19	6.63	8.17	4.94	7.10	—	9.55
GGH	2.84	6.99	8.23	5.33	—	14.81	10.69

a) The acid dissociation constants of ligands were reported previouly (Ref. 12). b) The values of "pK_c" are pH values at the half-neutralization points.

$$LH_3^{2+} \rightleftharpoons LH_2^+ + H^+$$
$$K_{COOH}=[LH_2^+][H^+]/[LH_3^{2+}] \quad (1)$$
$$LH_2^+ \rightleftharpoons LH + H^+$$
$$K_{Im}=[LH][H^+]/]LH_2^+] \quad (2)$$
$$Cu^{2+} + LH \rightleftharpoons CuLH^{2+}$$
$$K_1=[CuLH^{2+}]/[Cu^{2+}][H^+] \quad (3)$$
$$CuLH^{2+} \rightleftharpoons CuX + 2H^+$$
$$K_{2c} = [CuX][H^+]^2/[CuLH^2] \quad (4)$$

where LH is the neutral species of the ligand and LH=XH_2. For the sake of electroneutrality we have

$$2[Cu^{2+}] + 2[CuLH^{2+}] + 2[LH_3^{2+}] + [LH_2^+] + [K^+] + [H^+] = [OH^-] + [Cl^-]. \quad (5)$$

The total concentrations of the ligand and the copper(II) ion are given as follows.

$$[Cu]_T = [Cu^{2+}] + [CuLH^{2+}] + CuX] \quad (6)$$
$$[L]_T = [LH_3^{2+}] + [LH_2^+] + [LH] + [CuLH^{2+}] + [CuX] \quad (7)$$

From Eq. (1)—(7), the following relationship between K_1 and K_{2c} is derived.

$$K_1 = (ABC+2\alpha B^2+ABDK_{2c})/(\gamma C^2+2\gamma CDK_{2c}+\gamma D^2K_{2c}^2) \quad (8)$$

where A, B, C, D, α, β, and γ are defined as follows.

$$A = 2\alpha + \beta$$
$$B = \alpha\gamma - A[Cu]_T$$
$$C = 2\alpha[Cu]_T - \alpha\gamma$$
$$D = -\alpha\gamma/[H^+]^2$$
$$\alpha = 1 + [H^+]/K_{Im} + [H^+]^2/K_{COOH}K_{Im}$$
$$\beta = [H^+]/K_{Im} + 2[H^+]^2/K_{COOH}K_{Im}$$
$$\gamma = [OH^-] + [Cl^-] - [H^+] - [K^+]$$

The acid dissociation constants, K_{COOH} and K_{Im}, have been reported.[12)]

The values of K_1 and K_{2c} were evaluated by the graphical method of Schwarzenbach *et al.*[13)] The results for the GH-copper(II) system are shown in Fig. 2. The equilibrium constants obtained are listed in Table 1. From the K_1 and K_{2c} values, the titration curves were recalculated and compared with those obtained experimentally in Fig. 1. In the region between $a=4$ and $a=5$, an additional deprotonation is observed. The apparent ionization constants "pK_c", which are the pH values at the half-neutralization point, are 9.65 and 9.55 for the GH-copper(II) and the GHG-copper(II) systems, respectively. The distribution of copper(II) among the complex species at various pH values was calculated. The results for the GH-copper(II) system are shown in Fig. 3.

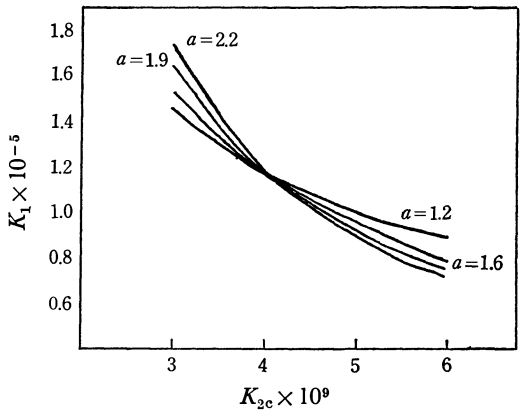

Fig. 2. Graphical calculation of K_1 and K_{2c} for GH-Cu(II) system.

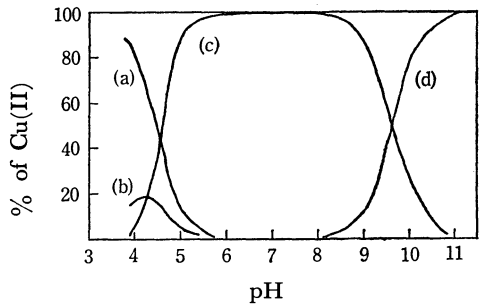

Fig. 3. Distribution of Cu(II) species for the 1 : 1 GH-Cu(II) system;
(a) Cu^{2+}, (b) $CuLH^{2+}$, (c) CuX, (d) $Cu_nY_n^{n-}$.

GGH-copper(II) System. The titration curve o the 1 : 1 GGH-copper(II) system is given in Fig. 1. The same curve has been reported by Bryce *et al.*[4)] The titration behavior in the GGH-copper(II) system is similar to that of the GH-copper(II) system, in the region between $a=1$ and $a=4$, but a remarkable pH inflection is observed at $a=5$. This indicates the deprotonation of the two amide groups of the peptide bonds. Accordingly, the following equilibria are assumed, with Eqs. (1) and (2), where LH=YH_3.

$$Cu^{2+} + LH \rightleftharpoons CuLH^{2+}$$
$$K_1 = [CuLH^{2+}]/[Cu^{2+}][LH] \quad (9)$$
$$CuLH^{2+} \rightleftharpoons CuY^- + 3H^+$$
$$K_{3c} = [CuY^-][H^+]^3/[CuLH^{2+}] \quad (10)$$

The values of K_1 and K_{3c} were calculated by the same method as in the case of GH-copper(II) system. The results are shown in Fig. 4 and Table 1. An additional deprotonation is observed in the region between $a=5$ and $a=6$, giving the apparent ionization constants 10.69. The value is a little higher than the values of

Table 2. Spectral characteristics of Cu(II)-peptide complexes

Ligand	*a* Value	λ_{max} (mμ)	ε ($M^{-1}cm^{-1}$)	Main species
GH	4	600	60	CuX
	5	557	70	$Cu_nY_n^{n-}$
GHG	4	602	60	CuX
	5	556	72	$Cu_nY_n^{n-}$
GGH	5	525	94	CuY^-
	6	525	95	CuZ^{2-}
GG[a)]	2	638	87	CuX
	3	641	83	$CuL(OH)^-$

a) GG=glycylglycine, and in this case *a* value represents moles of KOH added per neutral (monoprotonated) glycylglycine.

the GH-copper(II) and the GHG-copper(II) systems. The distribution of copper(II) among the complex species is shown in Fig. 5.

Absorption Spectra of the Peptide-copper(II) 1 : 1 Solutions. The characteristics of the visible absorption spectra of the GH-copper(II) and GGH-copper(II) complex has been reported,[5,6] but the relation between the absorption spectra and the pH of the solution has not been fully discussed. The spectra of the GHG-copper(II) complex has not been studied.

The spectra of the GGH-copper(II) and GHG-copper(II) systems are shown in Figs. 6 and 7, where *a* has the same meaning as those in titration. The spectra of the GH-copper(II) system are similar to those of GHG-copper(II) systems. The absorption characteristics of those spectra are given in Table 2. The spectrum at $a=2$ in the GGH-copper(II) system shows two absorption maxima at 750 nm and 525 nm. The absorption at 750 nm decreases whereas that at 524 nm increases, with the increase of *a*. The absorption maximum at 750 nm is presumed to be due to Cu^{2+} and $CuLH^{2+}$, and that at 525 nm to CuY^-. The spectral behavior corresponds reasonably to the equilibrium

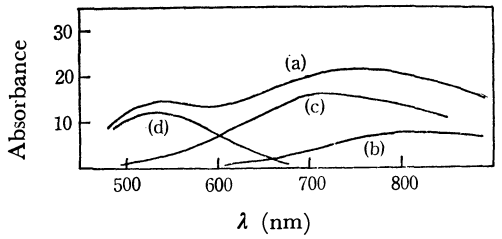

Fig. 8. Resolution of the spectrum at $a=2$ in the 1 : 1 GGH-Cu(II) system;
(a) GGH+Cu(II), (b) Cu^{2+} (45.6%), (c) $CuLH^{2+}$ (38.4%), (d) CuY^- (16.0%).

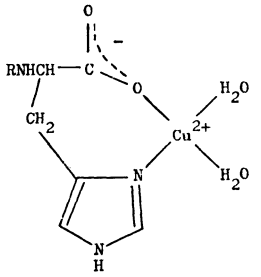
assumed from the titration curve. The spectrum at $a=2$ was resolved into three components corresponding to the three complex species by the use of the equilibrium constants. The results is shown in Fig. 8.

In the GH-copper(II) and GHG-copper(II) systems, the spectral behavior is similar to that in the GGH-copper(II) system up to $a=2$, the neutral complex CuX exhibiting a maximum at ~600 nm. However, the additional deprotonation causes a shift of the maximum to 555 nm.

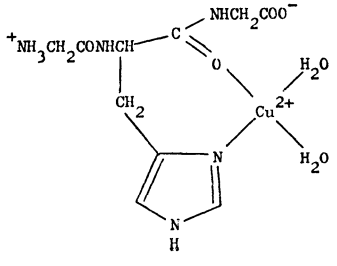
Discussion

The stepwise ionization constants of GH-copper(II) and GGH-copper(II) complexes have been reported.[3,4] However, the formation constants of these complexes have not been calculated because of the complexity of the titration behavior. The assumption in Eqs. (3) and (4) (or (9) and (10)) made the quantitative interpretation of the titration data possible.

In Table 1, the log K_1 values decrease in the order GGH, GH, and GHG, which agrees with that of the basicity of the imidazole group. This suggests the presence of a bond between the imidazole group and copper(II) in the complex $CuLH^{2+}$. The copper(II) ions will also be bound to the carboxyl or the carbonyl groups. The following structures are suggested for the complexes $CuLH^{2+}$.

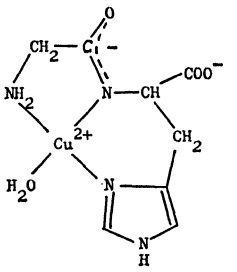


(I) $CuLH^{2+}$
R = $^+NH_3CH_2CO$: GH-Cu(II)
R = $^+NH_3CH_2$-$CONHCH_2CO$: GGH-Cu(II)

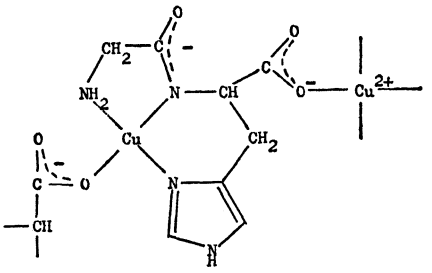


(II) $CuLH^{2+}$, GHG-Cu(II)

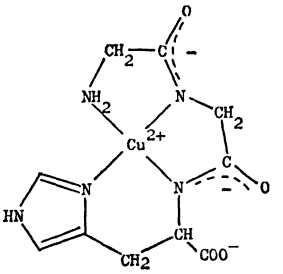
From the titration data it has been suggested that the copper(II) predominantly binds to the three nitrogens of the imidazole, amino, and deprotonated amide groups in the pH region 6—8 in the GH-copper(II) system. In the GH-copper(II) and GHG-copper(II) systems, the liberation of three protons and the remarkable blue shift of the absorption maxima in the region between $a=1$ and $a=4$ indicate that the copper(II) in the neutral complex CuX is bound to the three nitrogen atoms. In aqueous solutions the fourth coordination site of copper(II) is presumed to be mainly occupied by water molecule. The probable structure of CuX can be represented by III. However, the neutral chelate of the GH-copper(II) system precipitates on standing from the solution at $a=4$. Thus in the crystalline state, the fourth coordination site would be occupied by the carboxyl groups of a neighboring molecule to give a polymer Cu_nX_n as shown by IV. The structure of Cu_nX_n has been elucidated by X-ray diffraction analysis.[8] The same structure has been proposed to the GHG-copper-(II) complexes.[10,11]



(III) CuX



(IV) Cu_nX_n

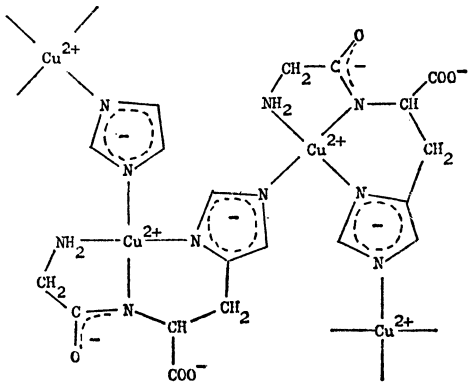


(V) CuY^-

As in the case of the GH-copper(II) system, it is apparent that the copper(II) in the anionic species CuY^- of the GGH-copper(II) complex is bound to the nitrogen atoms of the amino, imidazole, and two deprotonated amide groups as shown in V.

A further spectral blue shift caused by an additional deprotonation at $a=5$ in the GH-copper(II) and GHG-copper(II) systems suggests important changes in the coordination sphere of the copper(II) ion. The fol-

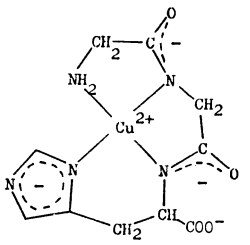
lowing three possibilities have been taken into account for the deprotonation for the GH–copper(II) system: (1) the proton dissociation of the coordinated water molecule at the fourth position,[4,5] (2) the proton dissociation from the imino nitrogen of the imidazole ring,[3] (3) the coordination of the deprotonated imino nitrogen to the fourth position of another copper(II).[6] The dissociation of the water molecule at the fourth position causes some red shift in the glycylglycine–copper(II) system, as indicated in Table 2. Deprotonation of the imino group in the GGH–copper(II) complex CuY^- does not occur below pH 10. The results exclude the possibilities (1) and (2). The most probable assumption is that a deprotonated imino nitrogen of the imidazole ring coordinates to the fourth position of another copper(II) to give a negatively charged polymer complex $Cu_nY_n^{n-}$. The structure of $Cu_nY_n^{n-}$ is shown as VI. The polymer is presumed to be a



(VI) $Cu_nY_n^{n-}$

tetramer from the molecular model, as suggested by Morris and Martin[6] but no evidence was obtained from the quantitative analysis of the titration curve.

Further addition of the base to CuY^- of the GGH–copper(II) system would cause the liberation of a proton from the imino nitrogen to give a dianionic chelate CuZ^{2-} as indicated by VII, where $LH{=}YH_3{=}ZH_4$. The spectral characteristic of CuZ^{2-} is similar to that of CuY^-.



(VII) CuZ^{2-}

The authors wish to express their thanks to the staff of Kyoto University Computer Center for the use of FACOM 230—60 Computer, and to the members of the Micro Analytical Center, Kyoto University, for elemental analysis.

Cobalt-59 Nuclear Magnetic Resonance Study of Cobalt(III) Complexes. Empirical Rules for the Cobalt-59 Chemical Shifts and Line Widths of $[Co^{III}(en)_x(NH_3)_{6-2x-y}L_y]$-type Complexes*

Fumikazu YAJIMA**, Yasuo KOIKE**, Akira YAMASAKI, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received December 15, 1973)

The cobalt-59 chemical shifts and line widths for about seventy cobalt(III) complexes of the $[Co^{III}(en)_x(NH_3)_{6-2x-y}L_y]$ (L=Cl, Br, NO_2, N_3, OH, H_2O, CO_3, and C_2O_4) type have been measured. The cobalt-59 chemical shifts of this type of complex are approximately represented by a simple relation:

$$\delta(\text{ppm}) = 360x + \sum_{i=1}^{y} \delta_i(\text{L}) \qquad (x=0,\ 1,\ \text{and}\ 2),$$

where $\delta_i(\text{L})$ is the i-th ligand shift parameter which represents the contribution of the i-th ligand, L, to the total chemical shift. Three empirical rules can be derived from experimental observations: I. The chemical shift of a *trans*-isomer is higher than that of the corresponding *cis*-isomer. II. The line width of the *trans*-CoA_4B_2 isomer is larger than that of the *cis*-CoA_4B_2 isomer. III. The line width of a *meridional* isomer is larger than that of the corresponding *facial* isomer. Illustrative examples are presented where cobalt-59 NMR is used to identify cobalt (III) complexes and to study the kinetics and equilibrium in solution.

The cobalt-59 chemical shifts and line widths have been reported for a variety of cobalt(III) complexes in solution.[1-8] However, the values of the chemical shifts of the same complexes as measured by different workers are not in good agreement with each other. This inconsistency is assumed to be due to the fact that all the works in the literature are based on one species of chemical shift standard, *i.e.*, $[Co(CN)_6]^{3-}$, which has the highest chemical shift among the cobalt(III) complexes studied so far. Hence, two other complexes ($[Co(en)_3]^{3+}$ and $[Co(acac)_3]$) have here been chosen as the standards besides $[Co(CN)_6]^{3-}$, and used as the standards of chemical shifts in the middle- and low-field regions respectively.

Experimental

Materials. Cobalt(III) complexes were synthesized by standard procedures and purified by recrystallization. Monoethylenediamine-cobalt(III) complexes of the $[Co(en)(NH_3)_2L_2]$ (L=OH, NO_2, and N_3) and $[Co(en)(NH_3)_3L]$ (L=Cl, Br, OH, NO_2, and N_3) types were prepared from $[Co(en)(NH_3)_2Cl_2]Cl$ and $[Co(en)(NH_3)_3H_2O]X_3$,[8] respectively according to the modification of the procedure for the preparation of the corresponding $[Co(NH_3)_{6-x}L_x]$ or $[Co(en)_2(NH_3)_{2-x}L_x]$ type complexes.

NMR Measurements. The cobalt-59 NMR measurements were made at 25.0 °C using a JEOL JNM-WB-20 spectrometer operating at 13.5550 MHz. Some measurements were carried out on a Varian Associates VF-16 spectrometer at several frequencies. For the chemical shift measurements, $[Co(CN)_6]^{3-}$, $[Co(en)_3]^{3+}$, and $[Co(acac)_3]$ were used as the internal or external reference in the high-, middle-, and low-field regions respectively. The difference in chemical shift between the internal and external references was less than 5 ppm. The resonant fields for the above three standards were determined separately from lithium-7 NMR of aqueous lithium chloride solutions using an autodyne oscillator. The standard deviation of the observed values of the chemical shifts was less than 0.5%. In the case of chloro-, bromo-, and aquo-complexes, the standard deviation of the chemical shifts was 2—3% for their large line widths. The line widths were obtained as the peak-to-peak intervals of the first derivatives of the absorption signals, which were recorded under a quite small amplitude of modulation at a frequency of 35 Hz.

Results and Discussion

Chemical Shift. All the cobalt(III) complexes studied were of the $[Co(en)_x(NH_3)_{6-2x-y}L_y]$ type, where L is Cl, Br, NO_2, N_3, OH, H_2O, CO_3, and C_2O_4. The chemical shifts and line widths of these complexes are listed in Table 1. The chemical shift of the $[Co(NH_3)_6]^{3+}$ ion is taken as zero in the present study. Figures 1-a—1-e show that the chemical shifts change regularly with the combination of ligands. On the basis of these results, the chemical shift of the complexes of the $[Co(en)_x(NH_3)_{6-2x-y}L_y]$ type can be approximately represented as follows:

$$\delta(\text{ppm}) = 360x + \sum_{i=1}^{y} \delta_i(\text{L}),\ (x=0,\ 1,\ \text{and}\ 2) \qquad (1)$$

where $\delta_i(\text{L})$ represents the contribution from the i-th ligand, L, to the total chemical shift. Hereafter, $\delta_i(\text{L})$ will be referred to as the i-th ligand shift parameter.

Table 1-a. Chemical shifts and line widths for $[Co(en)_x(NH_3)_{6-2x}]$ type of complexes

Fig. 1. The diagram for chemical shifts and line widths for $[Co(en)_x(NH_3)_{6-2x-y}L_y]$ type of complexes. The chemical shift and line width are represented by longitudinal and transverse bars, respectively. *Trans*, *cis*, *meridional*, and *facial* isomers are represented by t, c, m, and f, respectively.

The ligand shift parameters obtained are listed in Table 2.

The chemical shifts for ammine–ethylenediamine mixed complexes are listed in Table 1-a. The chemical shifts are proportional to the number of the ethylenediamine(or ammine) groups. The replacement of two NH_3 by one (en) results in a high-field shift of 360 ppm.

Figure 1-a shows the relation between the chemical shifts and the combinations of ligands for chloroammine complexes. From this diagram, the first and the sec-

TABLE 2. LIGAND SHIFT PARAMETER

Ligand	first (ppm)	second (ppm)	third (ppm)
NO_2^-	530± 20	420±100	—
N_3^-	−480± 50	−540± 50	−660± 50
Cl^-	−650± 50	−900± 50	—
Br^-	−620± 50	−900± 50	—
OH^-	−950±100	−950±100	−1100±100
H_2O	−900±100	−870±100	−830±100
Ligand	second (ppm)	fourth (ppm)	sixth (ppm)
CO_3^{2-}	−1500±100	−1900±100	−2200
$C_2O_4^{2-}$	−1200±100	−1500±100	−2000

ond ligand shift parameters are estimated as $\delta_1(Cl) = -(650+50)$ and $\delta_2(Cl) = -(900\pm50)$ ppm respectively. A quite similar diagram is obtained for bromoammine complexes, which show a slightly higher shift than to the chloroammine complexes.

The diagram for the carbonato species is shown in Fig. 1-b. The second, fourth, and sixth ligand shift parameters are estimated to be $-(1500\pm100)$, $-(1900\pm100)$, and -2200 ppm respectively. The absolute values for the ligand shift parameters become large with the increase in the number of substituted carbonato groups. Similar trends are observed for the Cl, Br, N_3, and C_2O_4 series. According to these results, it may be concluded that the absolute values of ligand shift parameters becomes smaller with an increase in the resonant fields of complexes. The diagrams for the NO_2 and N_3 series are shown in Figs. 1-c and 1-d respectively.

As Fig. 1-e shows, the contribution of the OH radical to the chemical shifts of cobalt-59 is additive: *i.e.*, the first, second, and third ligand shift parameters are almost equal ($\delta_1 \cong \delta_2 \cong \delta_3 \cong -(950\pm100)$ ppm). The chemical shifts of aquo-complexes also show a similar trend. The line width for aquo-complexes is much larger than that for the corresponding hydroxo-complexes: this certainly reflects the difference in the quadrupolar interactions of cobalt-59 between Co–OH and Co–OH_2 bonds.

Empirical Rules for the Chemical Shifts and Line Widths of Geometrical Isomers. The following rules have been deduced from the results of the present experiment concerning the relations between the geometrical isomers and their chemical shifts or line widths.

Rule I. The chemical shift of the trans-*isomer is higher than that of the corresponding* cis *isomer.* This rule holds for the complexes of the CoA_4B_2, $CoA_2A'_2B_2$, and CoA_4BC types, where A, B, and C refer to the different ligand atoms directly coordinate with cobalt, and where A and A′ represent the ligands of the same ligand atoms, such as NH_3 and (en). Shimura[9] presented an empirical rule for d-d absorption bands of *cis* and *trans* isomers of CoA_4B_2 type complexes: if A is in a higher rank than B in the spectroschemical series, $\nu_{max(cis)} - \nu_{max(trans)} > 0$, while if B is in a higher rank than A, $\nu_{max(cis)} - \nu_{max(trans)} < 0$. However, as has been described above, the chemical shift of a *trans* isomer, the chemical shift of a *trans* isomer is always higher than that of the corresponding *cis* isomer, regardless of the strength of the ligand fields for A and B. Simple calculation suggests that the difference in radial parameters and orbital reduction factors[10] is reponsible for the difference in chemical shifts between the *cis* and *trans* isomers.

Rule II. The line width of the trans-CoA_4B_2 *isomer is larger than that of the* cis-CoA_4B_2 *isomer.* It is well established that the cobalt-59 line widths for the species in solution are determined by quadrupolar interaction. A calculation based on a simple point-charge model has shown that the electric field gradient of a *trans* isomer is twice as that of the corresponding *cis* isomer.[6] The line widths of *cis*- and *trans*-$[Co(en)_2(NH_3)_2]^{3+}$, $[Co(en)_2(NO_2)_2]^+$, $[Co(en)_2Cl_2]^+$, $[Co(en)_2Br_2]^+$, $[Co(NH_3)_4(NO_2)_2]^+$, $[Co(NH_3)_4(N_3)_2]^+$, and $[Co(NH_3)_4Cl_2]^+$ are consistent with this rule. $[Co(en)_2(OH)_2]^+$ ion is the only exception among all the complexes studied which does not obey the general trends cited above. The relatively large line width of the *cis*-$[Co(en)_2(OH)_2]^+$ ion suggests a distortion of the field, resulting in a significant deviation from the regular octahedral structure.

Rule III. The line width of the mer-*isomer is larger than that of* fac-*isomer.* The electric field gradient at the site of the central cobalt nucleus in the *fac*-triaquotriamminecobalt(III) complex is estimated to be very small, as we see a sharp spectrum with a line width of 0.20 G. This value is in contrast to the broad spectra (about 2G) of the other aquoammine-complexes.[6] It can also be predicted from the point-charge model that *mer*-CoA_3B_2C complexes should give larger line widths than *fac*-CoA_3B_2C complexes. In fact, the line width of the *mer*-$[Co(en)(NH_3)_3NO_2]^{2+}$ ion is twice as large as that of the corresponding *fac*-isomer.

The Application of Cobalt-59 NMR to the Kinetics and Equilibria in Solution. The ligand shift parameters given in Table 2 can be used, along with the empirical rules presented above, to identify the cobalt(III) complexes and to study the kinetics and equilibria in solution. Illustrative examples will be presented and briefly discussed below.

Example 1. It is well established that the $[Co(NH_3)_5OH]^{2+}$, $[Co(NH_3)_4(OH)_2]^+$, $[Co(en)_2(NH_3)(OH)]^{2+}$, and $[Co(en)_2(OH)_2]^+$ ions exist in an alkaline solution.[11–13] However, the corresponding monoethylenediamine hydroxo-complexes, such as $[Co(en)(NH_3)_3(OH)]^{2+}$ and $[Co(en)(NH_3)_2(OH)_2]^+$ ions, have not yet been identified. In a concentrated alkaline solution, *trans*-$[Co(en)(NH_3)_2Br_2]Br$ shows two cobalt-59 NMR signals which do not coincide with that of the *trans*-$[Co(en)(NH_3)_2Br_2]^+$ ion (Fig. 2-a). The chemical shifts of these two signals are -1670 and -1580 ppm, which are very close to the value, -1540 ppm, estimated by means of Equation (1). This suggests that *trans*-$[Co(en)(NH_3)_2Br_2]^+$ is hydrolyzed to yield $[Co(en)(NH_3)_2(OH)_2]^+$ ion in an alkaline solution. On the basis of Rule I, the high- and low-field signals of the doublet can be assigned to the *trans*-dihydroxo and *cis*-dihydroxo isomers respectively. Figure 2-b shows an NMR spectrum of *trans*-$[Co(en)(NH_3)_2Br_2]$-Br dissolved in 10% aqueous ammonia and heated at 40 °C for 10 minutes. A high-field doublet in Fig. 2-b

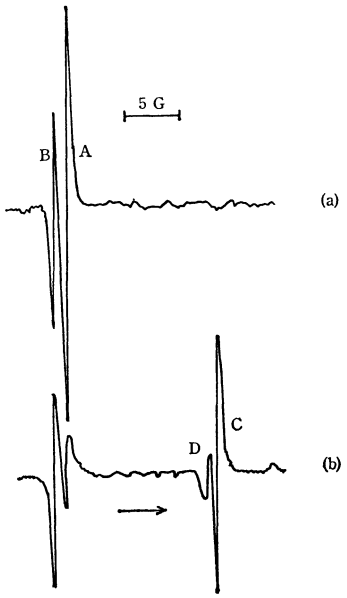

Fig. 2(a). Co-59 NMR spectra of *trans*-$[Co(en)(NH_3)_2Br_2]Br$ in concentrated ammonia solution. A and B correspond to *trans*- and *cis*-$[Co(en)(NH_3)_2(OH)_2]^+$ ions, respectively.
(b). Co-59 NMR spectra of *trans*-$[Co(en)(NH_3)_2Br_2]Br$ is ammonia solution which is heated at 40 °C for 10 minutes. C and D correspond to *fac*- and *mer*-$[Co(en)(NH_3)_3OH]^{2+}$ ions, respectively.

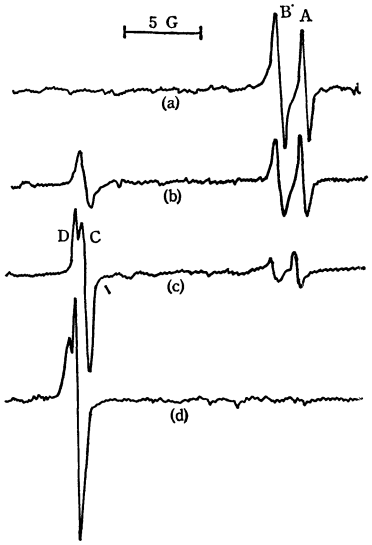

Fig. 3. Time variation of Co-59 NMR spectra of *cis*-$[Co(en)_2NH_3Br]Br_2$ in alkaline solution;
(a) at initial state, (b) after 5 min, (c) after 15 min, and (d) after 60 min.
The base hydrolysis reaction proceeded at 60 °C. NMR measurements were made at 25 °C after the reaction was quenched by cooling.
A, B, C, and D correspond to *trans*- and *cis*- $Co(en)_2NH_3OH]^{2+}$ and *trans*- and *cis*-$[Co(en)_2(OH)_2]^+$ ions, respectively.

with chemical shifts of −560 and −635 ppm is assigned to *mer*- and *fac*-$[Co(en)(NH_3)_3(OH)]^{2+}$. The chemical shift for $[Co(en)(NH_3)_3(OH)]^{2+}$ estimated from Equation (1) is −590 ppm. The broad and sharp signals of the doublet can be assigned to the *mer*- and *fac*-isomers respectively by means of Rule III.

Example 2. A doublet signal was observed in an alkaline solution of *cis*-$[Co(en)_2(NH_3)Br]Br_2$ which does not coincide with that of the *cis*-$[Co(en)_2(NH_3)Br]^{2+}$ ions itself. The high- and low-field signals of the doublet coincide with those of the *trans*- and *cis*-$[Co(en)_2(NH_3)(OH)]^{2+}$ ions respectively, suggesting that Br^- is replaced by OH^- to yield the *cis*- and *trans*-$[Co(en)_2(NH_3)(OH)]^{2+}$ ions. The fact that the initial concentrations of the *cis*- and *trans*-$[Co(en)_2(NH_3)(OH)]^{2+}$ ions (*cis* 80%, *trans* 20%) gradually change to reach the equilibrium concentrations (*cis* 70%, *trans* 30%) shows that the isomerization takes place between the *cis*- and *trans*-isomers.[8] If a large excess of the OH^- ion exists, the signal intensities of *cis*- and *trans*-$[Co(en)_2(NH_3)(OH)]^{2+}$ decrease and a new doublet corresponding to *cis*- and *trans*-$[Co(en)_2(OH)_2]^+$ appears (Fig. 3). These results clearly indicate that the *cis*- and *trans*-$[Co(en)_2(NH_3)(OH)]^{2+}$ ions are hydrolyzed to yield the *cis*- and *trans*-$[Co(en)_2(OH)_2]^+$ ions. The intensity measurements of each signal[8] would make it possible to determine the rate constants for the base hydrolysis. A quantitative treatment of this system is now under study and will be discussed in detail in a coming paper.

The authors wish to thank Prof. Yoji Arata and Prof. Takeo Yamamoto for their valuable discussions. Thanks are also due to Dr. Keikichi Nakamura, National Research Institute for Metals, for his assistance of measurement by Varian VF-16 spectrometer.

Crystal Structure of Bis(iminodiacetamide)copper(II) Perchlorate[1)]

Masao SEKIZAKI*

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received July 2, 1973)

Bis(iminodiacetamide)copper(II) perchlorate was newly synthesized, and the crystal structure was determined from three-dimensional X-ray data collected on a diffractometer. The structure was refined by block-diagonal least-squares methods to give $R=0.08$ for the 950 observed reflections. The crystals are monoclinic with the space group of $P2_1/c$. There are two formula units per unit cell with $a=6.183$, $b=17.617$, $c=8.900$ Å, and $\beta=110.2°$. The complex is centrosymmetric, in which the two ligand molecules coordinate to the central copper atom through two imino nitrogen atoms and two of the four amide oxygen atoms in *trans* positions, exhibiting a square-planar coordination. The other two amide oxygen atoms are weakly bonded to the copper atom above and below this square-plane, thus completing an *s-facial* distorted (elongated) octahedral coordination. The complex cations are held together through hydrogen bonds to form infinite chains along the *a* axis. These chains are connected with one another by perchlorate ions through hydrogen bonds, thus forming three-dimensional networks.

A number of bivalent copper complexes of bidentate ligands exhibit an elongated octahedral structure of D_{2h} symmetry.[2-7)] There are some complexes of terdentate ligands in which the length of the four coordination bonds in the same plane are longer than those of the other two coordination bonds, such as $[Cu(dien)_2](NO_3)_2$ (dien=diethylenetriamine).[8)] Such an unusual structure is sometimes called a "compressed" distorted octahedral structure.[9)] The complex of the other terdentate ligand, such as $[Cu(ida)_2]^{2-}$ (ida=iminodiacetate), was, however, reported on the basis of a spectroscopic investigation, to have an elongated octahedral structure.[10)] Two of the factors that differentiate the structures of these complexes may be as follows: the iminodiacetate ion[11)] has a smaller stability constant of complex formation than diethylenetriamine,[12)] and the force constant of Cu–O is generally smaller than that of Cu–N.[13)]

Iminodiacetamide, $HN(CH_2CONH_2)_2$, (abbreviated as $idaaH_2$) can act as a terdentate ligand. It can also function as a neutral ligand, forming a cationic complex like diethylenetriamine. It can coordinate to a metal atom through two oxygen and one nitrogen atoms like the iminodiacetate ion. It is difficult to decide by the spectroscopic method whether or not the distorted octahedral coordination around the copper atom is "compressed." A copper complex of iminodiacetamide, $Cu(idaaH_2)_2(ClO_4)_2$, was subjected to X-ray crystal analysis in order to clarify this point and to facilitate the assignments of the infrared spectra.

Experimental

Preparations. Iminodiacetamide was prepared as white needles by the reaction of diethyliminodiacetate and ammonia in ethanol. The melting point, 142 °C, and the results of chemical analysis agreed with the reported values.[14)]

The complex was prepared by mixing 0.07 g of the ligand with 0.09 g of copper(II) perchlorate dissolved in water and then by concentrating the mixture *in vacuo* at room temperature. The crystals thus obtained were washed with a small amount of water. Yield, 0.06 g.

Found: C, 18.00; H, 3.46; N, 15.67; Cu, 11.90%. Calcd for $C_8H_{18}N_6O_4Cu(ClO_4)_2$: C, 18.00; H, 3.56; N, 15.75; Cu, 11.92%.

Determination of the Cell Constants and Collection of the Intensity Data. The cell constants were determined by the least-squares methods based on the 2θ values measured on a single-crystal diffractometer using Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). A crystal with a diameter of about 0.2 mm was sealed in a glass capillary. The intensities were collected on a Hilger-Watts automatic four-circle diffractometer, using Ni-filtered Cu$K\alpha$ radiation. The ω-2θ step-scan technique with $\Delta\omega=0.02°$ and a counting time of 1 sec per step were used. The scan range was 0.8° in the 0—57° region and 1.2° in the 57—75° region. At each end of the scan, the backgrounds were measured for 10 sec in the $\theta\leqq57°$ region and for 15 sec in the $\theta>57°$ region. The fluctuations in intensity of the three standard reflections measured every 100 reflections were about 2% during the data collection. A total of 1600 independent reflections were measured up to $\theta=75°$; of them, 650 had an intensity less than σ's above the background. Thus, 950 independent non-zero reflections were used in the analysis. They were converted to $|F|$ by applying Lorentz and polarization corrections. No corrections were made for absorption or extinction ($\mu r=0.2$).

The crystal data are:
$Cu(C_4H_9N_3O_2)_2(ClO_4)_2$, *F.W.* 524.72, monoclinic, $a=6.183$ (2), $b=17.617(4)$, $c=8.900(2)$ Å, $\beta=110.2(1)°$, $U=908$ Å^3, $D_m=1.94$, $D_x=1.92$ g cm^{-3}, $Z=2$.
The systematic absences are $h0l$ with l odd and $0k0$ with k odd. Hence, the space group is $P2_1/c$.

Solution and Refinement of the Structure

The copper atoms must lie on a set of twofold special positions, since there are only two formula units in a unit cell. The complex must thus have a center of symmetry. The coordinates of the chlorine atoms were determined from the prominent peaks in a Patterson map; those of all the other atoms except the hydrogens were determined by a three-dimensional electron density map calculated on the basis of the copper and chlorine atoms.

The block-diagonal least-squares refinements were carried out for the 950 reflections with equal weights. After five cycles of refinement with isotropic thermal parameters, the R-value became 0.12. Further refinements with anisotropic thermal parameters finally reduced the R-value to 0.08.

The atomic scattering factors were taken from the "International Tables for X-ray Crystallography."[15)]

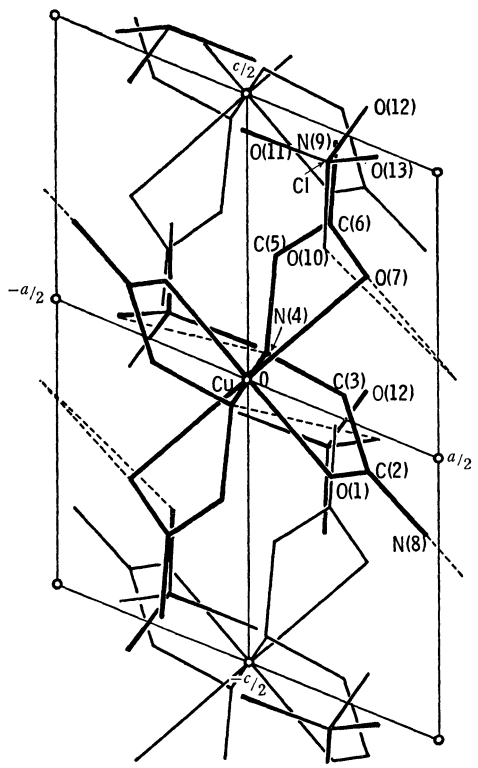

Fig. 1. Projection of the structure along the b axis. Dashed lines indicate hydrogen bonds.

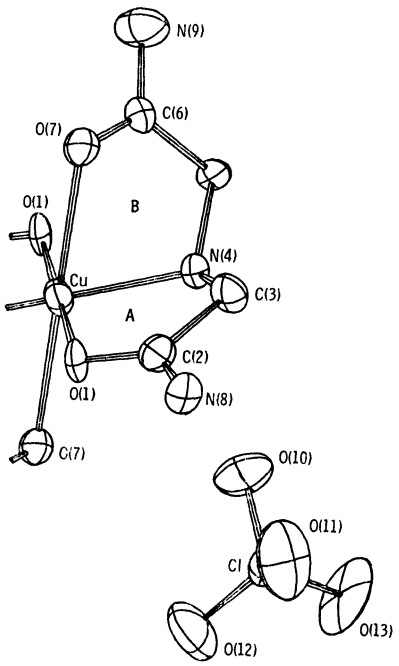

Fig. 2. Thermal ellipsoids of atoms at 50% probability level.

The calculations of the data reduction and the Fourier syntheses were carried out by means of programs written by Dr. Sasaki. The block-diagonal least-squares refinements and the calculations of the bond distances and angles were done with the HBLS-4 and DAPH programs written by Dr. Ashida. The thermal ellipsoids were drawn by means of the ORTEP program of Dr. Johnson. All the calculations were performed on a FACOM 230-60 computer at the Computation Center of Nagoya University.

The observed and calculated structure factors are listed in Table 1,** and the final atomic parameters, in Table 2.

Results and Discussion

A projection of the structure along the b axis is shown in Fig. 1. The anisotropic thermal ellipsoids of the

atoms are shown in Fig. 2. The bond distances and angles are listed in Table 3, and the intermolecular contacts, in Table 4.

The complex is centrosymmetric, with two ligand molecules coordinating in *trans* positions through two imino nitrogen atoms, N(4), and two of the four amide oxygen atoms, O(1). The other two amide oxygen atoms, O(7), lie above and below the plane defined by the N(4), O(1), and Cu atoms, thus completing an *s-facial* octahedral coordination.

The bond distances and angles of the two chelate rings, Cu–O(1)–N(4) (Chelate ring A in Fig. 2) and Cu–O(7)–N(4) (Chelate ring B), are shown in Fig. 3 along with those of *cis*-bis(glycinato)copper(II) monohydrate.[16] All the distances and angles except for the C(2)–O(1) double bond in the Chelate ring A agree with those of the glycinato complex. This indicates that no large influence due to terdentate coordination is introduced in the Chelate ring A.

The Cu–O(7) distance (2.47 Å) in the Chelate ring B is much longer than the Cu–O(1) distance in the ring A, indicating a weak bonding interaction, a "semi-

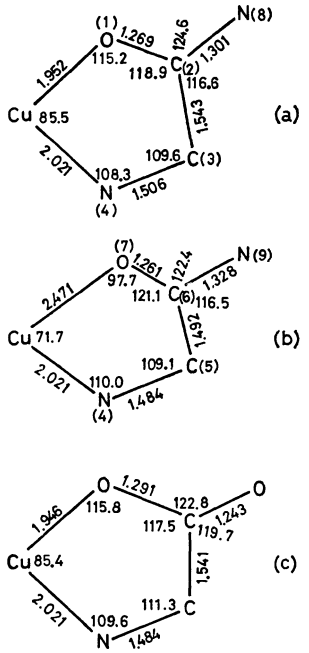

Fig. 3. Bond distances and angles of (a) Chelate ring A, (b) Chelate ring B and (c) *cis*-$Cu(H_2NCH_2COO)_2 \cdot H_2O$.[16]

coordination bond,"[6] between Cu and O(7). The O(7)–Cu–N(4) angle (71.7°) is too small to be a normal angle between the coordination bonds. Hence, the structure of the complex is not simply elongated but is distorted octahedral.

The equations of the planes defined by Cu and the coordinating atoms (coordination planes) are listed in Table 5. The Chelate rings, A and B, are not planar and show considerable deviations of carbon atoms from each of the coordination planes, while the chelate ring of the glycinato complex is almost coplanar.[16] Judging by the model, this difference may be due to the C=O double bond in these chelate rings rather than to fused-ring formation.

Table 5. Equations for the coordination planes in the chelate rings A and B, and the deviations of the atoms therefrom

Planes are expressed in the form: $DX+EY+FZ=0$, where X, Y, and Z are coordinates in Å measured along the a, b, and c^* axes respectively

Chelate ring	A	B
Atoms defining the plane	Cu, O(1), N(4)	Cu, O(7), N(4)
D	0.4911	−0.8925
E	0.2494	0.0831
F	0.8346	0.4434
Deviation of the atoms from the plane	C (2) 0.118 Å	C (5) 0.958 Å
	C (3) 0.316	C (6) 0.887

The complex cations are connected through hydrogen bonds between $N(8^{I})$ and $O(7^{V})$, forming infinite chains along the a axis. These chains are held with one another by perchlorate ions through hydrogen bonds of the N–H···O type between $O(13^{I})$ and $N(4^{III})$ and between $O(10^{I})$ and $N(8^{V})$ (Table 4). The crystal thus consists of three-dimensional networks of hydrogen bonds connecting the complex and perchlorate ions with one another.

The perchlorate ion is regularly tetrahedral, and the thermal motions of the four oxygen atoms are larger than those of the atoms in the complex ion.

The infrared and visible spectra of nickel(II) and cobalt(II) complexes of iminodiacetamide could be well assigned on the basis of the structural features of this complex. These results will be published elsewhere.[17]

The author wishes to acknowledge valuable discussions with Professor Kazuo Yamasaki of Nagoya University. He also wishes to thank Professor Jiro Tanaka, Dr. Noriyoshi Sakabe, and Dr. Kyoyu Sasaki of Nagoya University for the use of the Hilger-Watts four-circle automatic diffractometer and the computation programs. Part of the expenses were met by a grant from the Matsunaga Science Foundation, to which the author's thanks are due.

The Reaction of *N*-Chlorocarbamoylethyl Starch with Amines in an Aqueous Alkaline Medium; Reactions of An Isocyanate Group[1]

Mitsuo HIGUCHI, Kenji TAKESHITA,* and Ryoichi SENJU

Department of Forest Products, Faculty of Agriculture, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received September 12, 1973)

The reactions of *N*-chlorocarbamoylethyl starch with simple monoamines were investigated in order to elucidate the mechanism of the reaction of an isocyanate group with amines in an aqueous alkaline medium. It was confirmed that the *N*-chloroamide group reacts with amines through the formation of an isocyanate group. The reactions of the isocyanate with amines in the presence of sodium hydroxide obeyed the following equation: (rate of isocyanate–amine reaction)/(rate of isocyanate–OH^- reaction)$=k_u$[amine]/k_a[OH^-] showing no catalytic effects of reactants or products. The reactivities of most of the primary amino groups attached to primary carbon with the isocyanate are comparable to that of the hydroxide ion. The relative rates of the reactions of amines with the isocyanate are not always correlated to their basicities, even when differences in steric hindrance are not great. Both the enthalpy and entropy of activation for the isocyanate–amine reactions are smaller than those for the isocyanate–OH^- reaction.

Polymers bearing *N*-chloroamide groups are of interest because of the variety of reactions of the *N*-chloroamide groups. It is well known that *N*-haloamides in acid form (RCONHX) react as oxidizing agents or as halogenating agents,[2] and that, in salt form or in ionized form ($RCONX^-$), they produce isocyanate groups through the Hofmann rearrangement.[3]

The *N*-chlorocarbamoylethyl derivatives of polysaccharides can be readily synthesized and have some possibilities of practical use. With regard to the utilization of these derivatives, it may be most promising to exploit the reactions of the isocyanate group which is formed through the Hofmann rearrangement of the *N*-chloroamide group, leading to the syntheses of novel derivatives of polysaccharides.

On the reactions of isocyanates with active hydrogen compounds, although numerous papers have been published[4] and some papers have dealt with the reaction of water with isocyanates, nothing is yet known concerning the reactions of isocyanates in aqueous medium. Therefore, the reactions of *N*-chlorocarbamoylethyl starch with amines were investigated in an attempt to elucidate the mechanism of the reaction of the isocyanate group with amines in an aqueous alkaline medium.

Results and Discussion

Course of the Reaction of the N*-chloroamide Group with Amines.* First, as it was possible that the *N*-chloroamide would not always react with amines only through the formation of the isocyanate group, the effects of amines on the rate of decomposition of the *N*-chloroamide and the material balance in the reaction were investigated in order to make the course of the reaction clear.

It is well known that the rate of the Hofmann rearrangement of *N*-chloroamides obeys a first-order equation:[5]

$$-\mathrm{d[RCONCl^-]}/dt = k[\mathrm{RCONCl^-}] \qquad (1)$$

All the runs for various combinations of *N*-chlorocarbamoylethyl starch with amines employed in this study followed Eq. (1), and the concentration of the amines had no effect on the rate of the decomposition of *N*-chloroamide above pH 11.

The rate constants and energies of activation for the decomposition of *N*-chloroamide in the presence of amines were almost identical with those for the *N*-chloroamide–NaOH system, a typical case of Hofmann rearrangement.

Table 1 shows the material balance in the reaction of *N*-chlorocarbamoylethyl starch with methylamine. The amount of the *N*-chloroamide group decomposed is in agreement with the increase in the nitrogen content of the starch derivative and with half of the amount of methylamine consumed. This result is in accord with the following reaction sequence:

$$\mathrm{RCONHCl + R'NH_2} \xrightarrow{\text{instantaneous}} \mathrm{(RCONCl)^-(R'NH_3)^+}$$

$$\mathrm{(RCONCl)^-(R'NH_3)^+} \xrightarrow{\text{slow}} \mathrm{RN{=}C{=}O + R'NH_3{+}Cl^-}$$

$$\mathrm{RN{=}C{=}O + R'NH_2} \xrightarrow{\text{very fast}} \mathrm{RNHCONHR'} \qquad (2)$$

The results on other amine–*N*-chloroamide systems were essentially identical with this.

From the facts discussed above, it may be concluded that the *N*-chloroamide reacts with amines through the formation of an isocyanate, and that any side reactions are negligible in these systems.

Table 1. Material balance in the reaction of *N*-chlorocarbamoylethyl starch with methylamine[a]

Reaction time (min)	Relative[b] amount of *N*-chloroamide decomposed	Relative[c] amount of amine consumed	Relative[d] increase in nitrogen content

1: Amount of the *N*-chloroamide group decomposed.
2: Amount of the urea derivative formed (evaluated from the increase in nitrogen content of the starch derivative).
3: Amount of the aminoethyl group formed.

Reaction of the Isocyanate Group with Amines in the Presence of Sodium Hydroxide. As can be seen from the results shown in Table 1, in the absence of caustic alkalies almost all of the reaction products consisted of the corresponding urea derivatives when more than a four-~fivefold excess of amines was employed. This fact indicates that the reactivity of H_2O with the isocyanate group is negligible in comparison with those of amines.

In the presence of sodium hydroxide, however, a considerable amount of the aminoethyl group was produced. Figure 1 shows a typical case of the reaction course. The sum of the amounts of the aminoethyl group and the urea derivative (evaluated from the increase in nitrogen content of the starch derivative) is in good agreement with the amount of the *N*-chloroamide decomposed, though a slight discrepancy appears in the late stage of the reaction. This discrepancy was significant when the concentration of amines was too low or when the reactivities of amines were too low, as in the cases of aniline and *tert*-butylamine. This may be attributed to the formation of an intramolecular urea derivative, *i. e.*, the product of the reaction of the isocyanate group with the aminoethyl group formed by the Hofmann degradation.

The relative rate of the isocyanate–amine reaction to the isocyanate–OH^- reaction, R_u/R_a, can be readily calculated from the ratio of the amount of the urea derivative to that of the aminoethyl group formed.

As Fig. 2 shows, a linear relationship was observed between R_u/R_a and [Amine]/[NaOH] when the concentrations of amine and sodium hydroxide were not too low or not too high. This result indicates that the catalytic effects of reactants or products, which have often been observed in the reactions of isocyanates in some nonaqueous media,[4] are absent in this isocyanate–amine–NaOH system, and that the reactions obey simple second-order kinetics;

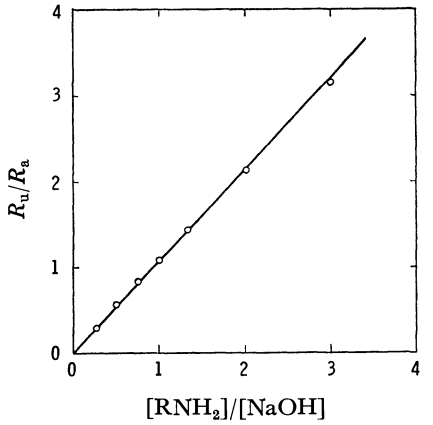

Fig. 2. Relation between R_u/R_a and $[RNH_2]/NaOH]$.
$[N\text{-chloroamide}]_{t=0}$: 0.02 mol/l, [Ethylamine]: 0.125—0.5 mol/l, [NaOH]: 0.125—0.5 mol/l, temp: 30 °C.

$$\text{d[Urea derivative]/d}t = k_u[\text{Isocyanate}][\text{Amine}] \quad (3)$$

$$\text{d[Aminoethyl group]/d}t = k_a[\text{Isocyanate}][OH^-] \quad (4)$$

$$\frac{\text{d[Urea derivative]/d}t}{\text{d[Aminoethyl group]/d}t} = \frac{R_u}{R_a} = \frac{k_u}{k_a}\frac{[\text{Amine}]}{[OH^-]} \quad (5)$$

The k_u/k_a ratio represents the relative reactivity of amine to the hydroxide ion in the reaction with the isocyanate.

The Arrhenius plots of k_u/k_a are shown in Fig. 3. The energies of activation for the isocyanate–amine reactions are smaller than that for the isocyanate–OH^- reaction.

Relative Reactivities of Amines. The rate constant ratios, k_u/k_a, at 30 °C and the derived activation parameters are summarized in Table 2. The relative reactivities of primary amines are in this order: amino groups attached to primary carbon>attached to secondary carbon>attached to tertiary carbon; this result is in agreement with the order in the extent of steric hindrance. It is noteworthy that the reactivities of most of the primary amino groups attached to primary carbon are comparable to that of the hydroxide ion, and that the

a) Calculated from the slopes of the lines for Arrhenius plots of k_u/k_a (Fig. 3). $\Delta\Delta H^{\neq} = \Delta H_u^{\neq} - \Delta H_a^{\neq} = E_u - E_a$. b) $\Delta\Delta S^{\neq} = \Delta S_u^{\neq} - \Delta S_a^{\neq} = 2.303\,R \log (k_u/k_a) + \Delta\Delta H^{\neq}/T$. c) Taken from the paper of H. K. Hall, Jr., *J. Amer. Chem. Soc.*, **79**, 5441 (1957).

relative reactivities of amines are not always in agreement with the concept, accepted for the reactions in some nonaqueous media, that the more basic amines react faster when the differences in steric hindrance are not great.

The negative values of $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ suggest that the hydration of the reactants plays an important role in the reaction of the isocyanate group with amines in aqueous alkaline media. It is conceivable that, in forming the transition-state complex with the isocyanate, the hydroxide ion requires a larger energy than amines do because of the greater extent of hydration, in spite of its greater basicity. The larger value of the entropy of activation for the isocyanate–OH^- reaction in comparison with those for the isocyanate–amine reactions may be attributed to the larger amount of the water molecule released on the formation of the transition-state complex. Differences in the extent of hydration of amines may also be reflected in their relative reactivities.

Experimental

Materials. Carbamoylethyl starch was prepared by means of a Michael reaction of acrylamide with corn starch; the degree of substitution was 0.9.[6]

Amines purchased from commercial sources were purified by distillation under a N_2 atmosphere. Ethyl aminoethyl ether (a model for the aminoethyl group attached to polysaccharide) was prepared by means of the Hofmann degradation of ethyl carbamoylethyl ether; $C_2H_5OC_2H_4NH_2$=89, bp 108.5 °C.

Reaction Procedure. The chlorination of carbamoylethyl starch was carried out under these conditions: amide group concentration: 0.2 mol/l; sodium hypochlorite concentration: 0.22 mol/l; temperature: 0 °C, and reaction time: 7 hr. The degree of *N*-chlorination was 99% on the basis of the amide group. After this process, acetone was added to the reaction mixture (1 vol%) in order to eliminate the excess hypochlorite.[7] After 10 hr the solution was neutralized to pH 5.5 with dilute HCl and diluted to 0.1 mol/l on the basis of the *N*-chloroamide group.

Adequate portions of this solution and an amine solution and/or a NaOH solution were mixed under cooling with ice-water, and 15-ml portions of the mixture were enclosed in 20-ml Pyrex ampoules. The ampoules were immersed in a constant-temperature bath under vigorous shaking for the desired times, then cooled with ice–water and subjected to analysis.

Analytical Methods. The *N*-chloroamide group was analyzed by iodometry. The nitrogen contents of the starch derivatives were determined by the following procedure.

A 10-ml portion of the reaction mixture was pipetted out and transferred into a 200-ml beaker containing 50 ml of methanol, 100 ml of acetone, and 1 ml of acetic acid. The mixture was then agitated by a magnetic stirrer until the starch derivative had been precipitated completely. Then the supernatant liquid was removed, and the precipitate was redissolved with 10 ml of a 1 M acetic acid aqueous solution and reprecipitated by the addition of 100 ml of acetone. After the completion of the precipitation, the supernatant liquid was removed and the precipitate was washed with ethanol and dissolved with 30 ml of 20% sulfuric acid and then subjected to Kjeldahl analysis. The complete precipitation of starch derivatives and the complete removal of the unreacted amine were confirmed by testing the samples of zero reaction time.

The amino-group contents of the starch derivatives were determined by colloid titration;[8] a 2-ml (or 5-ml) portion of the reaction mixture was pipetted out, put into 150 ml of 0.1 M acetic acid aqueous solution, and then titrated with a M/400 potassium polyvinyl sulfate solution, using toluidine blue as an indicator.

The authors wish to express their thanks to Professor Isao Sakata, Kyushu University, for his helpful suggestions.

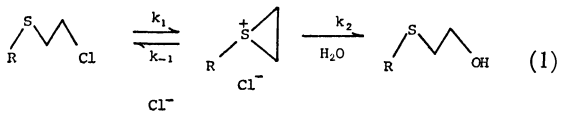
A Mechanistic Study of the Acetolyses of 3-Chloropropene Sulfide and 2-Chloroethyl Methyl Sulfide

Iwao TABUSHI,* Yoshinao TAMARU, and Zen-ichi YOSHIDA
Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received September 22, 1973)

Forming a marked contrast to hydrolysis, the first-order rate constant in the acetolyses of 3-chloropropene sulfide (I) and 2-chloroethyl methyl sulfide (II) has been observed to be seriously decreased; this may be ascribed to the return to the starting material of the sulfonium intermediate (III′ or IV) by the chloride ion liberated in the course of the reaction. The reaction has substantially obeyed first-order kinetics, giving exclusively and quantitatively skeletally-rearranged 3-acetoxy-thietane (the first-order rate constant; $k_1=2.1\times10^{-5}$ s^{-1}, at 55.0 °C) and 2-acetoxyethyl methyl sulfide ($k_1=4.8\times10^{-4}$ s^{-1}, at 55.0 °C) from I and II respectively.

On the hydrolyses of 2-chloroethyl alkyl (or aryl) sulfides, the kinetics (of the profound acceleration due to sulfur participation) and mechanism (S_N1) involving the rate-determining formation of the episulfonium ion (III), followed by the facile destruction of III to alcohol, as is expressed in Eq. 1, have been well established.[1]

Making a marked contrast to the mechanistic and/or kinetic simplicities in hydrolysis, in acetolysis some complex observations have been reported.[2]



(1)

(III)

$k_2[\mathrm{III}][H_2O]>k_{-1}[\mathrm{III}][Cl^-]>k_1[RSCH_2CH_2Cl]$
R=alkyl, aryl, *etc.*

For example, one report has stated that the rate of decrease of 3-chloropropene sulfide in acetic acid follows the apparent first-order kinetics to give many kinds of unidentified products containing C–Cl bonds.[4]

Another report says that the acetolysis of 3-chloropropene sulfide gives 3-acetoxythietane only in a 33% yield.[5] Along with these intricate observations, the conspicuous mechanistic change in the acetolysis of 2-*endo*-chloro-7-thiabicyclo[2.2.1]heptane[6] (the rate-determining acetoxy ion attack on the sulfonium intermediate, S_N2) constrained us to investigate the mechanism and kinetics of the acetolysis of 3-chloroethyl alkyl sulfide, taking 3-chloropropene sulfide (I) and 2-chloroethyl methyl sulfide (II) as typical models.

Results

The acetolyses of 3-chloropropene sulfide (I) and 2-chloroethyl methyl sulfide (II) were performed in anhydrous acetic acid buffered with varying amounts of sodium acetate ([I], [II]=0.05 M, [NaOAc]=0.0, 0.065, 0.25, and 1.00 M). The rate of solvolysis was followed by means of the Volhard method for the liberated chloride ion. In several runs, the rate was also followed by means of vpc, where the amount of the acetate produced was in accord with the results of the titrimetric determination. The reuults for I and II are plotted in Figs. 1 and 2 respectively.

* Present address: Faculty of Pharmaceutical Science, Kyushu University, Katakasu, Fukuoka, 812.

The apparent first-order rate constants of I and II drifted downward, especially in the runs with low concentrations of sodium acetate. The same result was obtained for the acetolysis of II in the one-tenth concentrations involving with II and sodium acetate

○: [II[=0.05 M, [NaOAc]=0.25 M
◑: [II]=0.05 M, [NaOAc]=0.25 M, [NaCl]=0.0041 M
The plots, obtained in the presence of added chloride ion, were slided by 8.1% reaction.

([II]=0.005 M, [NaOAc]=0.0065 M).

In the absence of sodium acetate, no appreciable amount of acetate was produced or of the chloride ion was liberated within 5 hr for I and within 64 min for II at 55.0 °C, indicating that no reaction proceeded under those conditions.

The marked retardation of the reaction was observed in the presence of initially-added sodium chloride (8.1% to substrate; 0.0041 M). However, the time-conversion curve obtained in the presence of an added chloride ion could be just superimposed on the curve (at 8.1% conversion) obtained under the corresponding conditions where the chloride ion was not added (see Fig. 3).

On the basis of the vpc, NMR, and IR spectra of the reaction mixture of I, the exclusive and quantitative formation of skeletally-rearranged 3-acetoxythietane was observed, but the recovered sulfur chloride was not contaminated with the skeletally-rearranged 3-chlorothietane. From 2-chloroethyl methyl sulfide, 2-acetoxyethyl methyl sulfide was obtained in a quantitative yield (see Experimental section).

Discussion

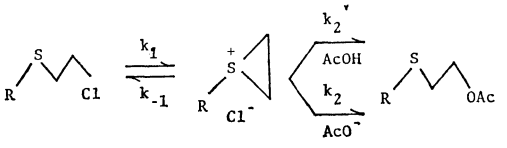
Our observation that no appreciable amount of liberated chloride ions was detected in the absence of sodium acetate is quite in accord with the observation reported by Morita and Oae[4] that, in the absence of a base, the acetolysis (at 105 °C) of 3-chloropropene sulfide (I) gave mainly many kinds of unidentified products containing C–Cl bonds, along with small amounts of acetates (3-acetoxypropene sulfide and 3-acetoxythietane).

An examination of Fig. 2 will make it clear that, under the conditions of ([KOAc]/[II]=1.45, on a steam bath for 20 hr) which Adams *et al.*[5] employed to obtain 33% of 3-acetoxythietane, the reaction practically ceases at around a 30~40% reaction.

The result in the run of a high dilution ([II]=0.005 M, [NaOAc]=0.0065 M) indicates that the direct displacement reaction by the acetoxy ion (S_N2) is not operative.

Figures 1 and 2 indicate that, in the initial period of reaction, the reaction proceeds at practically the same rate, with a small but appreciable amount of the salt effect of sodium acetate. This seems to indicate that the reaction proceeds *via* the rate-determining formation of the carbonium ion (delocalized by sulfur, S_N1 mechanism) and that the retardation is due to the liberated chloride ion (Eq. (2)). This explanation is supported by the quantitative retardation caused by the added chloride ion (Fig. 3) and can be reconciled with the fact of no reaction in the absence of a base (Eq. (2)).

The validity of this explanation is also reflected by the numerical treatment of the data (see the section on the numerical treatment of the rate data), by which the first-order rate constants, together with the ratios of the competition factors of the chloride ion to the acetoxy ion (k Cl^-/k OAc^-, given in parentheses) were determined to be 4.8×10^{-4} s^{-1} (*ca.* 30) for II and 2.1×10^{-5} s^{-1} (*ca.* 30)[7] for I.



(2)

(III')

$k_{-1}[III'][Cl^-]>k_2[III'][AcO^-]>k_1[RSCH_2CH_2Cl]$

$k_{-1}[III'][Cl^-]>k_2'[III][AcOH]$

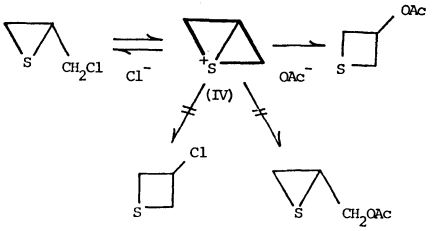
The apparent difference between the behavior in water and in acetic acid may partly be explained in terms of the differences in nucleophilicities of these solvents. Using the ratio of nucleophilicities[10] among acetic acid, water, and the chloride ion, the following relation may be drawn:

$$v_{H_2O} : v_{Cl^-} = 1 \quad : \quad 0.016 \text{ for hydrolysis} \tag{3}$$

$$v_{Cl^-} : v_{AcOH} = 1 \quad : \quad 0.0013 \text{ for acetolysis} \tag{4}$$

Thus, in a less nucleophilic solvent, as in acetic acid, the reaction seems to be governed exclusively by the chloride ion liberated, thus returning the sulfonium ion to the starting chlorosulfide (See Eqs. (2) and (4)).

The exclusive formation of the skeletally-rearranged 3-acetoxythietane and the absence of 3-acetoxypropene sulfide or 3-chlorothietane[12] in the reaction mixture (at 10% and 66% reactions), as monitored by means of vpc and NMR spectra, indicate that the acetoxy ion and the chloride ion reacted regioselectively with 1-thiabicyclo[1.1.0]butonium ion (IV) to produce 3-acetoxythietane and 3-chloropropene sulfide respectively. (See Eq. (5))



(5)

The rate of I is about seventy times the published

combined acetolysis-rearrangement constant for cyclopropylmethyl chloride.[15] This is typical of enhanced rate data supporting delocalization as the driving force for ionization. In view of the observed product, sulfur participation to form IV would seem to be a reasonable explanation for the reactivity of I. The moderately diminished reactivity of I compared with that of II may be due to the remarkable strain in the intermediate, IV, and/or to the expected poorer electron donation of episulfide.[16]

Numerical Treatment of Rate Data[17]

The most plausible reaction pathway for the acetolysis of II is illustrated in Eq. (6).

$$CH_3SCH_2CH_2Cl \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} CH_3\overset{+}{S}\!\!\triangleleft \xrightarrow[OAc^-]{k_2} CH_3SCH_2CH_2OAc \qquad (6)$$

Cl^- Cl^-

II V

where $k_{-1}[Cl^-][V]$ and $k_2[OAc^-][V]$ are assumed to be much larger than $k_1[II]$. The rate of the disappearance of the substrate can, then, be written as:

$$-\frac{d[R\text{-}Cl]}{dt} = \frac{k_1k_2[R\text{-}Cl][OAc^-]}{k_{-1}[Cl^-]+k_2[OAc^-]} \qquad (7)$$

The substitution of 1-x for R–Cl, x for Cl^-, $a-x$ for OAc^-, and x for ROAc gives:

$$-\frac{d(1-x)}{dt} = \frac{k_1k_2(1-x)(a-x)}{k_{-1}x+k_2(a-x)} \qquad (8)$$

where x: conversion expressed in terms of the fraction.

a: molar ratio of the sodium acetate to the substrate.

Integration gives:

$$k_1t = \ln\frac{1}{1-x} + \frac{k_{-1}}{k_2(a-1)}\left(\ln\frac{1}{1-x} - a\ln\frac{a}{a-x}\right) \qquad (9)$$

The k_{-1}/k_2 term is the ratio of the competition factors of the chloride ion to the acetoxy ion. Figure 4 shows the results calculated according to Eq. (9), with the value of k_{-1}/k_2 varying from 0 to 90, in which a systematic change could be observed; when the value of k_{-1}/k_2 was overestimated, an upward derivation of the calculated k_1 with the time was observed. An underestimation of the k_{-1}/k_2 value results in downward deviations of k_1. The first-order rate constant, k_1, and the ratio of the competition factors of the chloride ion to the acetoxy ion in the acetolysis of II at 55.0 °C were determined from Fig. 4 to be $(4.8\pm0.7)\times10^{-4}$ s^{-1} and *ca.* 30 respectively. Similarly, k_1 and k_{-1}/k_2 for the acetolysis of I at 55.0 °C were determined to be $(2.1\pm0.30)\times10^{-5}$ s^{-1} and *ca.* 30 respectively (see Fig. 5).

Effect of Added Chloride Ions. The rate constant, k_1, in the presence of added chloride ions was similarly expressed as:

$$k_1t = \ln\frac{1}{1-x} + \frac{k_{-1}}{k_2(a-1)}\left\{(\alpha+1)\ln\frac{1}{1-x} + (\alpha+a)\ln\frac{a}{a-x}\right\} \qquad (10)$$

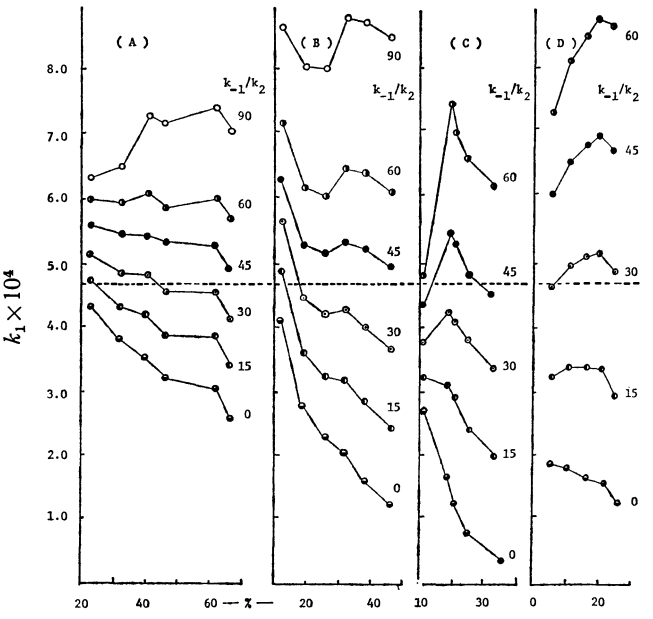


Fig. 4. Acetolysis of 2-chloroethyl methyl sulfide at 55.0 °C; The plots obtained from Eqs. (9) and (10), varying the value of k_{-1}/k_2 from 0 to 90.
(A): [NaOAc]=1.00 M, (B): [NaOAc]=0.25 M, (C): [NaOAc]=0.065 M, (D): [NaOAc]=0.25 M, [NaCl]=0.004 M.

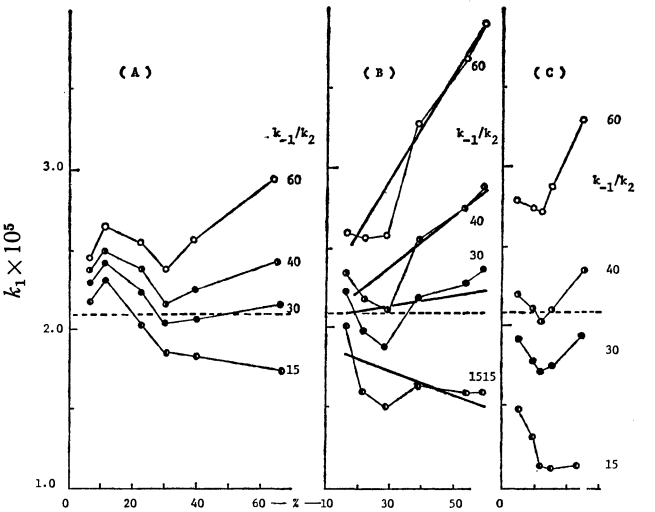

Fig. 5. Acetolysis of thiaepichlorohydrin at 55.0 °C; The plots obtained from Eqs. (9) and (10), varying the value of k_{-1}/k_2 from 0 to 60.
(A), [NaOAc]=1.00 M, (B): [NaOAc]=0.25 M, (C): [NaOAc]=0.065 M.

where α is the molar ratio of the added sodium chloride to the substrate. The k_1 value calculated on the basis of Eq. (10) is plotted in Fig. 4.

Experimental

All the boiling points are uncorrected. The NMR spectra were recorded with a Varian T 60 spectrometer, while chemical shifts were reported in δ values relative to the TMS internal standard. The infrared spectra were measured with a Hitachi Model EPI-G3 grating spectrophotometer, and

the mass spectra were recorded with a Hitachi Model RMU 6C mass spectrometer.

The acetic acid was used after distillation from a mixture containing 5% of acetic anhydride (118.0—118.3 °C). The sodium acetate was used without further purification after drying by means of Abderhalden at the toluene reflux temperature.

2-Chloroethyl Methyl Sulfide (II). Into a solution of 20.0 g of β-hydroxyethyl methyl sulfide in 100 ml of benzene we vigorously stirred dry hydrogen chloride at room temperature for 3 hr. The reaction mixture was diluted with 100 ml of pentane, and the excess hydrogen chloride was neutralized with sodium bicarbonate. After washing with saturated sodium chloride, the organic layer was dried over magnesium sulfate. After the distillation of the solvent through a 10-cm Vigreux column, II was distilled twice under reduced pressure (66.5—67.2 °C/70 mmHg, 87.0—87.8 °C/138 mmHg), 22.0 g of II was thus obtained (the yield was 82%). $\delta_{CCl_4}^{TMS}$ 3.56 (2H, triplet, J=9Hz), 2.70 (2H, triplet, J=9 Hz) and 2.08 (3H, singlet). ν_{max}^{neat} 1220 (s), 705 (s) and 680 cm^{-1} (s).

3-Chloropropene Sulfide (I). I was prepared according to the method of Culvenor.[18] Thus, into a solution of 92 g (1.0 mol) of epichlorohydrin in 300 ml of methanol, chilled with ice, 84 g (1.1 mol) of thiourea was gradually dropped as a crystalline over a period of 1 hr: the reaction mixture was then stirred at 0~5 °C for an additional 2 hr and then at room temperature for an additional 2 hr.

The reaction mixture was subsequently poured onto 2 l of ice-water and extracted with two 300-ml portions of ether. The combined ether extracts were washed twice with saturated sodium chloride and dried over calcium chloride. After the distillation of the ether through a 10-cm Vigreux column, the residue was distilled twice under reduced pressure (77.0 °C/93 mmHg, 81.0 °C/112 mmHg). Sixty grams of I were thus obtained (the yield was 55%). 3-Chloropropene sulfide should be stored in refrigerator to prevent decomposition. At room temperature, I decomposes at a moderate speed to give an amorphous white solid. $\delta_{CDCl_3}^{TMS}$ 3.9 (1H, multiplet), 3.2 (2H, multiplet), 2.6 (1H, multiplet and 2.25 (1H, multiplet). ν_{max}^{neat}, 1260 (s), 1040 (s) and 705 cm^{-1} (s).

3-Acetoxythietane. A reaction mixture consisting of 500 ml of acetic acid, 62 g (0.75 mol) of sodium acetate, and 10 g (0.093 mol) of I was heated at about 60 °C for 5 day.

The reaction mixture was then poured into 3 l of water and extracted with two 250-ml portions of petroleum ether; the combined petroleum ether extracts were washed with saturated sodium bicarbonate until the evolution of carbon dioxide had ceased and then washed with saturated sodium chloride. After the evaporation of the solvent, 3-acetoxythietane was distilled under reduced pressure (83.5 °C/23 mmHg) (the yield was 82%). $\delta_{CCl_4}^{TMS}$ 5.56 (1H, quintet, J=8 Hz), 3.46 (2H, triplet, J=8 Hz), 3.26 (2H, triplet, J=8 Hz) and 2.00 (3H, singlet). ν_{max}^{neat} 1740 (s), 1370 (m), 1240 (s), 1040 (s) and 905 cm^{-1} (w). *m/e* 132 (P^+), 89, 72 and 43.

β-Acetoxyethyl Methyl Sulfide. A mixture consisting of 50 ml of acetic acid, 2 g of II, and 10 g of sodium acetate was heated at 60 °C for 8 hr. The reaction mixture was then poured into 300 ml of water and extracted with two 50-ml portions of petroleum ether. The combined extracts were neutralized with sodium bicarbonate, washed with saturated sodium chloride, and then dried over calcium chloride. After the evaporation of the solvent, the β-acetoxyethyl methyl sulfide was distilled under reduced pressure (125 °C/133 mmHg). (Yield, *ca.* 90%). $\delta_{CCl_4}^{TMS}$ 4.20 (2H, triplet, J= 7 Hz). 2.65 (2H, triplet, J=7 Hz), 2.08 (3H, singlet) and 2.00 (3H, singlet). ν_{max}^{neat}; 1755 (s), 1396 (m), 1240 (s) and 1040 cm^{-1} (m), *m/e*; 74 (100), 61 (75), 43 (90).

Procedure for Titration. In a 25-ml measuring flask, 1.25 mmol of the substrate was dissolved with acetic acid containing some sodium acetate, heated to 55.00±0.05 °C beforehand, up to 25 ml; this flask was immersed immediately into a bath maintained constant at 55.00±0.05 °C. At desired intervals of time, 3-ml samples were measured out and dropped into a separatory funnel containing 15 ml of distilled water and 10 ml of carbon tetrachloride. After vigorous shaking, the aqueous portion was washed once more with 10 ml of carbon tetrachloride and then transferred into a flask quantitatively. (The separatory funnel was washed off with 2 ml of distilled water). To a combined aqueous layer, we then added 2.00 ml of 0.100 M of silver nitrate, two drops of fuming nitric acid, and a few drops of a saturated ferric ammonium sulfate solution, after which this solution was back-titrated with 0.116 M ammonium thiocyanate (Volhard method).

Photo-induced Polar Addition of Protic Solvents to Cycloalkenones. Evidence for the Ground-state *trans* Isomers as Chemically-reactive Intermediates[1]

Ryoji NOYORI and Masao KATÔ

Department of Chemistry, Nagoya University, Chikusa, Nagoya 464

(Received October 5, 1973)

The photo-induced reaction of cyclic α,β-unsaturated ketones with protic media is described. The irradiation of 2-cycloheptenone or 2-cyclooctenone in various protic solvents (alcohols, acetic acid, water, and diethylamine) results in the formation of Michael-type solvent adducts. The chemically-reactive species have been demonstrated to be the highly strained *trans* isomers in a ground state. The irradiation of *cis*-2-cyclononenone affords the stable *trans* isomer, which reacts in the dark with methyl alcohol at an elevated temperature to give 3-methoxycyclononanone. The irradiation of 2-cyclohexenone in methyl alcohol yields 3-methoxycyclohexanone in a poor yield. The possible existence of *trans*-2-cyclohexenone is discussed.

In recent decades the photochemistry of cyclic α,β-unsaturated ketones has received considerable attention.[2] Particularly interesting is the fact that the reaction course is profoundly influenced by the ring size. Diphenylcyclopropenone, the smallest cyclic enone, suffers photochemical decarbonylation to give tolan.[3] Cyclobutenone derivatives afford ketenes under electrocyclic ring opening.[4] The five- and six-membered homologs can undergo intermolecular photoreactions. 2-Cyclopentenone, upon irradiation, leads to the cyclobutane dimers in good yields,[5] while in the presence of an excess of cyclopentene [2+2] cross-cycloaddition takes place.[6] 2-Cyclohexenone shows a reactivity qualitatively parallel to that of 2-cyclopentenone in cycloaddition.[7] Certain 4,4-disubstituted 2-cyclohexenones are known to rearrange to the bicyclo[3.1.0]hexan-2-ones with group migration.[8] Throughout these intra- and intermolecular reactions, two points are noteworthy: (1) mechanistically, most of these reactions have been believed to occur in an electronically-excited state (either a singlet or a triplet), and (2) formally, the reactions are regarded as being a nonpolar (nonionic) process. In striking contrast, as will be shown below, upon irradiation seven- and eight-membered cyclenones can undergo polar (ionic) reactions arising from a highly reactive ground-state molecule. The mechanisms of the related polar reactions of 2-cyclohexenones are also a subject of our interest.

Results and Discussion

The photo-induced reactions of alcohols across a carbon—carbon double bond may be divided into the two classes depicted in Chart 1. Path *a* is a radical process and involves a fission of a weak C–H bond bearing an OH function (bond energy ~92 kcal/mol[9]). The second pathway, *b*, defined as a polar addition, involves a rupture of the stronger (~102 kcal/mol[9]), more ionic O–H bond.[10]

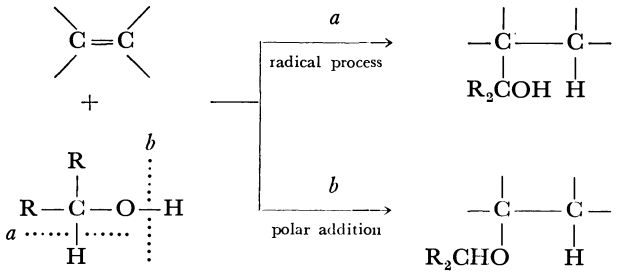

Chart 1.

The irradiation of 2-cycloheptenone (I)[11] with a high-pressure mercury arc in such protic solvents as alcohols, acetic acid, water–acetonitrile, and diethylamine at room temperature afforded the corresponding polar adducts, II. The results are given in Table 1. In certain cases, considerable amounts

Table 1. Irradiation of 2-cycloheptenone in protic solvents[a]

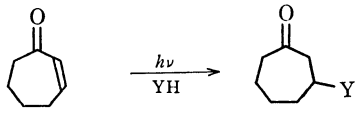
Solvent	Conversion %[b]	Yield of II %[b,c]
Methyl alcohol	68	86
Ethyl alcohol	66	73
Isopropyl alcohol	54	50[d]
tert-Butyl alcohol	40	3[d]
Acetic acid	34	23[d]
Water–acetonitrile (1 : 5)	61	27[d]
Diethylamine	80	55[e]

a) Irradiation was effected on 1.0% solution at room temperature for 15 min. b) Determined by glpc. c) Based on the consumed enone. d) Considerable amounts of cyclodimers were obtained.[12] Irradiation of I in cyclohexane gave cyclobutane dimers in 88% yield. e) Photolysis was performed at 0 °C and yield was determined by NMR analysis.

Table 2. Photolysis of 2-cyclooctenone in protic solvents[a]

Solvent	Irradiation time, min	Conversion %[b]	Yield of IV %[b,c]
Methyl alcohol	10	92	72
Isopropyl alcohol	150	90	43
Acetic acid	150	58	76
Water–acetonitrile (1 : 5)	75	81	25
Diethylamine	30[d]	85	66[e]

a) All photolyses were performed in a 1.0% solution at room temperature. b) Determined by glpc. c) Based on the consumed III. d) Irradiation was carried out at 0°C. e) Determined by NMR analysis.

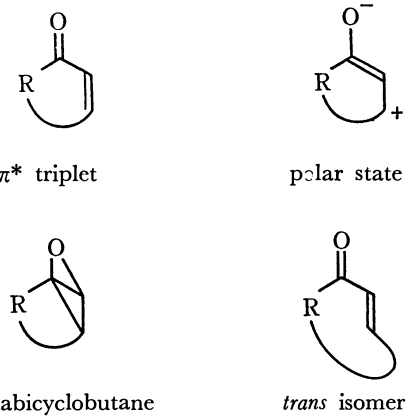


I II a: Y=OCH_3 e: Y=$OCOCH_3$
b: Y=OC_2H_5 f: Y=OH
c: Y=$OCH(CH_3)_2$ g: Y=$N(C_2H_5)_2$
d: Y=$OC(CH_3)_3$

of cyclodimers[12] were also formed. No products were obtained *via* a radical process. A similar photo-induced polar addition of protic solvents was observed for 2-cyclooctenone (III),[11] as is summarized in Table 2. The structural determination of the photoproducts was made on the basis of elemental analyses and spectral data (Table 3). The structure of the β-ketols, IIf and IVd, was confirmed by converting them to the acetates, IIe and IVc, respectively.

The photo-induced polar addition reaction of the protic solvents mentioned here provides a new synthetic means of introducing oxygen or nitrogen functions to the β position of a carbonyl group under neutral or comparatively mild reaction conditions.

The observed photo-induced reaction could be interpreted in various ways. As the product-forming species, the π,π^* triplet states of the enones[13,14] or, alternatively, the highly strained ground-state molecules derived therefrom may be involved. Oxabicyclobutanes[7b,12a,15] or enones containing a *trans* double bond[1,12,14,16] would be the candidates in the latter case (Chart 2). The



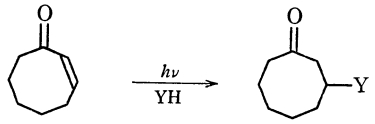
π,π^* triplet polar state

oxabicyclobutane *trans* isomer

Chart 2. Possible reactive species.

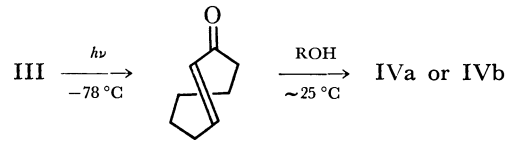
reaction could also be accounted for by assuming the intervention of the polar state, a hypothetical dipolar species first suggested by Chapman.[17] We have examined in detail the behavior of I and III and found that their *trans* isomers are the product-determining intermediates.

Eaton and Lin observed that the photolysis of the medium-sized enone III causes a *cis-trans* isomerization, thus establishing an equilibrium between III and V (*ca.* 20 : 80 ratio).[16] The moderate thermal stability of the *trans* cyclenone, V, permitted low-temperature studies of its chemical behavior. The enone III was irradiated in 2-methyltetrahydrofuran at −78 °C for 15 min. After the light source had then been turned off, the photolysate was poured into an excess of cold (−78 °C) methyl alcohol and allowed to warm up to



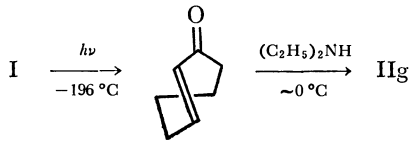
III IV a: Y=OCH_3 d: Y=OH
b: Y=$OCH(CH_3)_2$ e: Y=$N(C_2H_5)_2$
c: Y=$OCOCH_3$

room temperature in the dark, thus producing the corresponding alcohol adducts, IVa, in a 43% yield. The starting enone, III, was recovered in a 41% yield. When isopropyl alcohol was used in place of methyl alcohol, IVb was obtained in a 24% yield. The irradiation of III in isopropyl alcohol under the same conditions, followed by treatment with a large excess of methyl alcohol in the dark, gave almost exclusively the methyl alcohol adduct, IVa (80%). Only a very small amount of the isopropyl alcohol adduct, IVb (<1%), if any, was formed. Apparently the polar addition to the photo-excited states is not significant.



V

The more strained *trans*-2-cycloheptenone (VI) can also be generated by the irradiation of the *cis* enone I.[12] Because of the much reduced stability, however, it was difficult to demonstrate that the ground-state molecule, VI, is involved in the photo-induced polar addition of alcohols. The irradiation of I in EPA at the temperature of liquid nitrogen was followed by turning the lamp off, the addition of cold (−78 °C) methyl alcohol, and a gradual warming to room temperature. Only cyclodimers of I[12] were obtained, however. No methyl alcohol adduct could be detected in the reaction mixture. The irradiation of I in methyl alcohol at −196 °C, followed by warming up to room temperature, also failed to produce the adduct IIa. Fortunately, however, a proof was obtained using diethylamine, a more efficient nucleophile. Thus, the addition of diethylamine to the photolysate of I at −196 °C (EPA glass), followed by warming up to 0 °C, led to the formation of the Michael-type adduct IIg in a 25% yield. A control experiment showed that the *cis* enone I gives no trace of the adduct IIg under these thermal conditions.[18]



VI

The irradiation of a nine-membered cyclenone, *cis*-2-cyclononenone (VII) in methyl alcohol or cyclohexane below room temperature afforded a mixture of VII and the *trans* isomer, VIII. The latter was stable enough to be isolated by a usual work-up. The enone VIII in methyl alcohol remained unchanged at

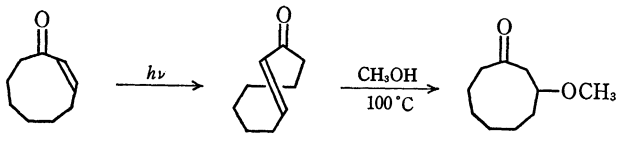
a) Neat liquid film. b) Taken in 5—10% CCl_4 solutions. Splitting patterns are designated as s, singlet; t, triplet; q, quartet; m, multiplet. The number n is 6 (II), 7 (III), 8 (IX), or 5 (XI). c) An AB part of ABX system. d) J=7 Hz. e) J=6 Hz. f) J=5 Hz. g) NMR spectrum was measured in $CDCl_3$ solution.



VII VIII IX

0 °C, but heating the solution at 100 °C gave rise to the adduct IX in a high yield. The spectral data are given in Table 3.

Thus, the photo-induced polar addition of cyclic enones proved to consist of two chemical reactions, *i. e.*, a prior *photochemical* isomerization to the *trans* isomers and a subsequent *thermal* reaction with nucleophilic solvents. The protic solvent addition to six-,[19] seven-,[19] and eight-membered cycloalkenes[20] under irradiation has been previously reported. The reaction was proposed to proceed by a sequence; (1) a photochemical *cis-trans* isomerization of the olefins, (2) protonation to the strained *trans* olefins to produce cycloalkyl cations, and (3) nucleophilic capture by the solvent. In the present case, however, the nucleophilic attack of the solvent takes place directly on the carbon—carbon double bond of the strained enones.

The relationship between the reactivity and the ring size of cyclic enones could be inferred from the potential energy curves of the twisted olefins (Fig. 1). The twist angle, ϕ, indicates the deviation from the normal $C(sp^2)=C(sp^2)$ plane. An electronically-excited olefin (either S_1 or T_1) should prefer a rotation about the $C(sp^2)-C(sp^2)$ single bond to afford an orthogonal geometry (ϕ=90°), thus minimizing the mutual repulsive interactions of the π and π^* electrons.[21] Decay by either internal conversion[22] or intersystem crossing leads to the *cis* or *trans* ground state, in which ϕ is 0° or 180° respectively. With rather small ring olefins,

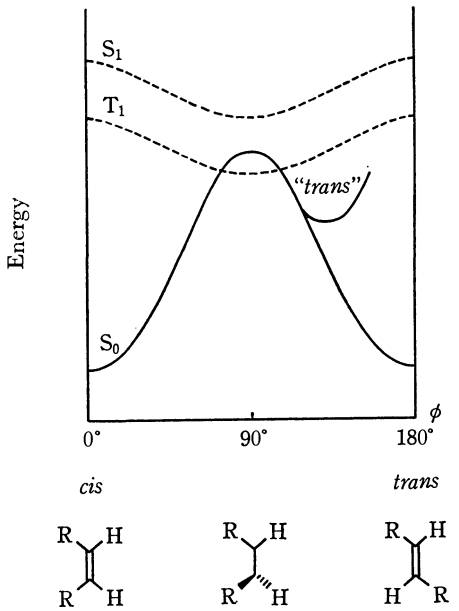

Fig. 1. Energy for the twisting of various electronic states of 1,2-disubstituted olefin. $\phi = \angle C(sp^2) - C(sp^2)$

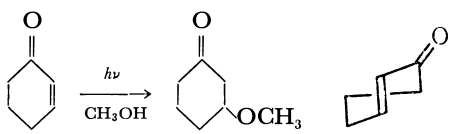
however, a complete twisting ($\phi > 90°$) is sterically impossible; consequently, their *cis* to *trans* isomerization is precluded. In contrast, open-chain or sufficiently large-membered cyclic olefins undergo the geometrical isomerization facilely. Seven- and eight-membered cyclic olefins are located intermediate between the two extremes. Obviously, a coplanar *trans* double bond ($\phi = 180°$) could not be accommodated, but a 90°-twisted conformation can be adopted and further twisting to a ground-state isomer ($90° < \phi < 180°$) with minimized energy could occur. Such molecules are conventionally referred to as *trans* isomers. Table 4 compares the spectral data of certain *cis* and *trans* cyclenones. The degree of the conjugation of the C=C bond with the C=O group in the seven- and eight-membered *trans* enones (VI and V) is markedly decreased as compared with that of the *cis* isomers. These *trans* double bonds suffer enough torsional strain to provide effective strain-releasing reactions. Apparently the nine-membered *trans* enone VIII is sterically less constrained and, consequently, undergoes the addition of methyl alcohol under only forcing thermal conditions. Both *cis*- and *trans*-2-cyclododecenones,[23] enones free from torsional strain, were inert under these reaction conditions. Electron-deficient olefins including α,β-unsaturated ketones are susceptible to nucleophilic reagents (alcohols, water, primary and secondary amines, *etc.*) under basic conditions and afford Michael-type addition products.[24] A similar type of the addition of acids is also known.[25] Therefore, the above findings are not surprising. The *trans* cyclenones, even though torsionally strained, conform electronically to a ground-state singlet; therefore, they exhibit reactivities understandable on the basis of our knowledge of classical organic chemistry.

In principle, the reactivities of *cis* and *trans* double bonds are identical in type; they are different from each other only in a quantitative way. If this were generally the case for cyclenones, the photolysis in turn in protic solvents might serve as a probe for the chemical detection of the elusive *trans*-2-cyclohexenone. This assumption prompted us to examine the behavior of 2-cyclohexenone (X). In the dark X did not react



X XI XII

with freshly-distilled methyl alcohol below 100 °C. Upon the irradiation of a 0.1% solution of X in methyl alcohol at room temperature, 3-methoxycyclohexanone (XI) was obtained, though in a low yield (0.7%) (see Table 3). The major products were its cyclodimers.[7] Thus, the formation of the polar adduct, XI, may suggest the existence of *trans*-2-cyclohexenone (XII),

Table 5. Analytical data of the polar adducts[a]

Compound	Bp, °C/mmHg (mp, °C)	Molecular formula	Found (Calcd), % C	H
3-Ethoxycycloheptanone (IIb)	65/3	$C_9H_{16}O_2$	69.43 (69.19)	10.37 (10.32)
3-Isopropoxycycloheptanone (IIc)	70/3	$C_{10}H_{18}O_2$	70.47 (70.54)	10.94 (10.66)
3-*tert*-Butoxycycloheptanone (IId)	110—120/10	$C_{11}H_{20}O_2$	71.88 (71.69)	10.82 (10.94)

3-Acetoxycyclooctanone (IVc)	105—110/3	$C_{10}H_{16}O_3$	65.27 (65.19)	8.85 (8.75)
3-(*N*,*N*-Diethylamino)cyclooctanone (IVe) picrate[b]	(102—106)	$C_{18}H_{26}O_8N_4$	50.89 (50.70)	6.07 (6.15)

a) Microanalyses were performed at the Elemental Analyses Center of Kyoto University. b) IIg (bp, 83 °C/3 mmHg) and IVe (bp, 90 °C/3 mmHg) afforded a correct molecular peak in mass spectrum at *m/e* (70 eV) 183 and 197, respectively.

though attempted low-temperature experiments had failed to demonstrate the formation of the highly-reactive enone.[12] Although Hammond showed that the photodimerization of X proceeded *via* the triplet state,[7c] the problem of whether or not the ground-state molecule, XII, can be derived therefrom has remained unsolved. In the literature, we can find various examples of a similar type of polar photoreaction: the alcohol addition to Pummerer's ketone,[26] the reaction of cyclohexenone derivatives in aqueous acetic acid,[17] the *tert*-butyl alcohol addition to 5,5-dimethyl-2-cyclohexenone,[27] and the alcohol addition to acetylcyclohexene.[14] As to the behavior of 2-cyclohexenone (X) itself, irradiation in a phosphate buffer solution forming 3-hydroxycyclohexanone has been recorded.[13] Finally, it is worth pointing out that 2-cyclopentenone reacts with alcohols photochemically *via* only a radical process (*cf.* Chart 1).[28]

Experimental

Instrumentation. The IR spectra were taken on a JASCO DS-402G or a Shimadzu IR-27-G spectrophotometer. The UV spectra were recorded on a Perkin-Elmer Model 202 spectrophotometer. The NMR spectra were measured with a Jeol JNM C-60H spectrometer, using tetramethylsilane (TMS) as the internal standard. The mass spectra were obtained with a Hitachi RMU-6C spectrometer. The gas-chromatographic analyses (glpc) were performed on a Yanagimoto Model G-8 chromatograph equipped with a column of Apiezon L on Chromosorb (10% or 30%, 2 mm × 2 m) or one of PEGS on Neosorb (5%, 2 mm × 2 m), and a flame ionization detector, using nitrogen as the carrier gas. The preparative work was done on a Yanagimoto Model GCG-3D instrument with a thermal conductivity detector and using helium as the carrier gas. Columns of Apiezon L on Chromosorb (30%, 5 mm × 2 m) and of PEGS on Neosorb (5%, 5 mm × 2 m) were employed. Analytical and preparative thin-layer chromatography (tlc) was carried out on silica-gel plates (Merck silica gel GF_{254}, buffered at pH 7; 0.25 mm and 1.00 mm thickness respectively).

Materials and Solvents. The 2-cyclohexenone, 2-cycloheptenone, and 2-cyclooctenone were prepared as has been reported by Garbisch.[11] The 2-cyclononenone[29] was obtained by the oxidation[30] of 3-hydroxycyclononene.[31] S.P.- (methyl alcohol, acetonitrile, and cyclohexane) or G.R.-grade solvents (other alcohols, acetic acid, diethylamine, and isopentane) were purchased from Nakarai Chemicals, Ltd., Kyoto, and were used for photochemical studies without further purification. The 2-methyltetrahydrofuran, ether, and water were used after distillation.

General Procedure for Preparative Scale Irradiations. A solution of the cyclic enones (3.6—15 mmol) in various solvents (10—400 ml) was placed in Pyrex tubes (15 × 180 mm), flushed with purified nitrogen for 15 min, and then irradiated externally using a 200 W high-pressure mercury arc for 0.5—24 hr at room temperature. The progress of the reaction was monitored by the glpc analysis of aliquots removed from the reaction vessel. The removal of the solvent, followed by rough distillation, gave a crude oil. Pure materials were obtained by preparative glpc (Apiezon L 30%, 150—180 °C). The spectral properties of the polar adducts are given in Table 3, while the analytical data of new compounds are summarized in Table 5. The fairly unstable adducts, IIg and IVe, were analyzed after their conversion to crystalline picrates.

The treatment of two labile hydroxy ketones, IIf and IVd (0.5—1.6 mmol), with a 1 : 3 mixture of acetic anhydride and pyridine (1.3—2.5 ml) at 100 °C for 1.5 hr, followed by a usual work-up, gave the respective acetoxy ketones, IIe and IVc; they were identified by means of the IR spectra and the retention times of glpc.

All the 3-methoxycycloalkanones were compared with authentic samples.[29b,c]

Irradiation for Analytical Purposes (Tables 1 and 2). A

1.0% solution (2.5—20 ml) of the enones was placed in a quartz tube (10×80 mm) or a Pyrex tube (15×180 mm) and irradiated externally with a 200 W high-pressure mercury lamp through a Pyrex filter at a distance of 15 mm at room temperature or 0 °C under a nitrogen atmosphere. The irradiation was continued for the stated time, and then the yield of polar adducts was determined by glpc (Apiezon L 30% or 10%).

Low-temperature Photolysis of 2-Cyclooctenone (III). *(a) In 2-Methyltetrahydrofuran*: The enone III (13.6 mg, 0.11 mmol) was dissolved in 2-methyltetrahydrofuran (1.5 ml) containing cyclododecane (14.9 mg, 0.09 mmol) as an internal standard for glpc analysis. The solution was then divided into two parts and irradiated in Pyrex tubes (10×80 mm) at −78 °C (Dry Ice–CH_3OH bath) for 15 min under nitrogen, using a 200 W high-pressure mercury arc. After the lamp had then been turned off, each photolysate was poured into methyl alcohol and isopropyl alcohol (1.0 ml), respectively, each of which had been cooled to −78 °C and flushed with dry nitrogen. The methyl alcohol solution was then allowed to warm spontaneously to room temperature in the dark. The solvent was removed *in vacuo*,. The glpc analysis of the residue showed two peaks of retention times identical with those of the starting ketone, III, (41%) and IVa (43%). A similar work-up of the isopropyl alcohol solution, followed by glpc analysis, demonstrated the existence of III (60%) and IVb (24%).

(b) In Isopropyl Alcohol: A solution of III (10.2 mg, 0.08 mmol) and cyclododecane (11.0 mg, 0.07 mmol), an internal reference for glpc analysis, in isopropyl alcohol (1.0 ml) was flushed with dry nitrogen and irradiated at −78 °C as has been described above. After 15 min, the lamp was turned off and the photolysate was treated with an excess of cold methyl alcohol (5.0 ml) in the dark. The mixture was then allowed to warm up to room temperature. Subsequent glpc analysis revealed the existence of only two components, with reaction times identical with those of III and IVa (17 and 80% yields respectively). The isopropyl alcohol adduct, IVb, could not be detected over 1%, if at all.

Low-temperature Photolysis of 2-Cycloheptenone (I). *(a) In Methyl Alcohol*: A solution of the enone I (100 mg, 0.91 mmol) in a 1 : 1 mixture of methyl alcohol and 2-methyltetrahydrofuran (10.0 ml) was irradiated at −196 °C (liq. nitrogen) for 3 hr. After the lamp had then been turned off, the reaction mixture was allowed to warm up to room temperature. The residue obtained after the removal of the solvents was analyzed by glpc and mass analyses. Although the starting material was consumed (30%), no methyl alcohol adduct was obtained.

(b) In EPA: A solution of I (142 mg, 1.29 mmol) in a 5 : 5 : 2 mixture of ether, isopentane, and ethyl alcohol (EPA) (2.0 ml) was irradiated at −196 °C for 3 hr, after which the lamp was turned off. To the cold photolysate we then quickly added diethylamine (1.8 ml) in EPA (4.0 ml) which had been chilled at −78 °C. The solution was allowed to warm to 0 °C while the vessel was caused to vibrate. The subsequent careful removal of the solvents at 0 °C *in vacuo* gave an oily residue; an NMR analysis of this residue showed that 3-(*N*,*N*-diethylamino)cycloheptanone (IIg) was afforded in a 25% yield (40%, based on the consumed enone I).

The treatmcnt of I (116 mg, 1.05 mmol) with a 1 : 10 mixture of diethylamine and EPA (11.0 ml) at 0 °C for 3 hr in the dark did not produce IIg, as ascertained by NMR analysis. The heating of I in diethylamine at 60 °C for 3 hr gave IIg in a 30% yield.

Irradiation of cis*-2-Cyclononenone (VII) in Cyclohexane.* A solution of VII (1.0 g, 7.25 mmol) in cyclohexane (100 ml) was divided into five portions, and each aliquot was irradiated in a Pyrex tube (15×180 mm) affixed to the extension of the lamp at room temperature. After 30 min, the solvent was removed at room temperature under reduced pressure. The residual oil was shown by NMR analysis to consist of the starting enone, VII, and a *trans* isomer, VIII (45 : 55 ratio). Preparative scale tlc (*n*-hexane : ether=4 : 1, three developments) afforded pure VIII. Mass spectrum: *m/e* 138 (M^+). The IR-, UV-, and NMR-spectral data are given in Table 4.

The heating of a solution of VIII (200 mg, 1.47 mmol) in methyl alcohol at 100 °C for 1 hr, followed by the evaporation of the solvent, gave 65 : 35 mixture of 3-methoxycyclononanone (IX) and the *cis* enone, VII (by glpc analysis). The IR and NMR spectra (Table 3) were identical with those of an authentic sample.[29c]

Irradiation of VII in Methyl Alcohol. A solution containing VII (42.6 mg, 0.32 mmol) in methyl alcohol (5.0 ml) was irradiated at 0 °C for 30 min. The subsequent careful removal of the solvent at 0 °C under reduced pressure gave a residue which was found, by NMR and glpc analyses, to contain no methyl alcohol adduct, IX. The oil consisted of only VII and VIII (46 : 54 ratio).

Photolysis of 2-Cyclohexenone (X) in Methyl Alcohol. A dilute solution of X (345 mg, 3.69 mmol) in freshly-distilled methyl alcohol (400 ml) was irradiated in an immersion well at room temperature under nitrogen for 3 hr. By glpc, 70% of the enone X was found to be consumed. The subsequent careful removal of methyl alcohol at 0 °C *in vacuo*, followed by distillation, afforded an oily product (45 mg). Glpc and NMR analyses showed that 3-methoxycyclohexanone (XI) was produced in a 0.7% yield. Glpc examination revealed that no trace of XI was found in the dark under the above-described conditions.

An authentic sample of XI was obtained according to the known procedure.[29c] The IR and NMR spectral data are given in Table 3.

The authors wish to thank Professor H. Nozaki for his encouragement throughout this work. They are also indebted to Mr. M. Kurita for carrying out preliminary studies with regard this investigation. Moreover thanks are due to Messrs. Y. Ohnishi and A. Watanabe for their skillful assistance. Financial support from the Kurata Science Foundation is also acknowledged.

The Cationic Oligomerization of 2-Methylfuran and the Characteristics of the Oligomers

Akira ISHIGAKI and Toshiyuki SHONO*

Nara Technical College, Yata, Yamato-Kōriyama-shi

** Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita-shi 565*

(Received October 11, 1973)

The treatment of 2-methylfuran with phosphoric acid yields the 2,4,4-tris(5′-methyl-2′-furyl)-1-pentanol (**1**) as a tetrameric product. This product gives its acetate (**2**) on acetylation with acetic anhydride, and forms a equimolar adduct (**3**) after treatment with maleic anhydride. The structural formula of **1** is supported by the IR, UV, NMR, and mass spectral data and by the other experimental facts. The other oligomers are separated as a product (**4**) which contains tetra-, penta-, hexa-, and heptamer. The structure of these oligomers discussed, and some possible reaction mechanisms for oligomerization are suggested.

Furan and alkylfurans are polymerized to resins by the action of acidic catalysts. The structures of these polymeric substances have been the subject of a number of investigations.[1-7] However, the structures of these substances have still not been completely elucidated.

A tetramer of 2-methylfuran formed by the catalytic action of BF_3 was noted by Dunlop and Peters in 1953.[8] As the structure of this tetramer they suggested a large ring compound linked with four 5-methyl-2,5-furylene units.

In a previous paper[9] we reported the formation of 2-methylfuran tetramer by the catalytic action of phosphoric acid. We also suggested another structure for this product.

In the further investigation reported here we will present the most reliable structure of this product and will point out the presence of the other 2-methylfuran oligomers, *i.e.*, penta-, hexa-, and heptamer, in the reaction mixture. We believe that the investigation of these oligomers will provide valuable information for clarifying the structure of the 2-methylfuran polymer and the other polymeric compounds of furan and alkylfurans.

Results and Discussion

Tetramer of 2-Methylfuran and Its Related Compounds. The treatment of 2-methylfuran with phosphoric acid under reflux results in the formation of 2,4,4-tris(5′-methyl-2′-furyl)-1-pentanol **1** in a good yield. The product can be separated as a slightly colored viscous liquid by fractional distillation. Product **1** gives its acetate (**2**) after treatment with acetic anhydride in pyridine. A maleic anhydride adduct of **1** can be separated as a colorless crystalline product. Elementary analyses data indicate that this product (**3**) is an equimolar adduct of **1** and maleic anhydride.

The structural formula of **1** is based on its spectral data, elementary analyses, and other experimental facts. The elementary analysis data of **1**, **2**, and **3** correspond to their calculated values. Moreover the mass numbers of their molecular ions also correspond to their calculated molecular weights. These facts indicate that (**1**) is a tetramer of 2-methylfuran.

Several IR characteristic bands (3100, 1610, 1560, and 775 cm^{-1}) suggest the presence of a furan nucleus which reacts with a dienophile (*e.g.*, maleic anhydride).

The treatment of **1** with alkaline hydrogen peroxide results in an aqueous solution of an oxidation product mixture. This mixture contains 5-methyl-2-furoic acid as an oxidation product. This indicates the presence of 5-methyl-2-furyl groups in the structure.

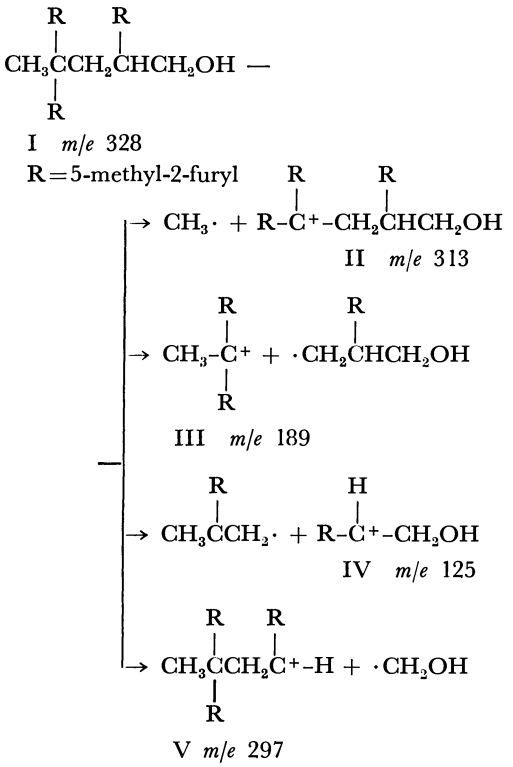
The UV absorption maximum of **1** in hexane appears at 222 nm. This absorption maximum is similar to the π-π transition absorption maximum of alkylfurans (at 215 nm for 2-methylfuran and at 218 nm for 2,5-dimethylfuran in hexane). This indicates that the π electron system of the furan nucleus does not conjugate with any other π electron system in the structure of **1**.

The NMR spectrum of **1** reveals six heteroaromatic protons at τ 4.2—4.4. These protons correspond to the ring protons of three 5′-methyl-2′-furyl groups.[10]

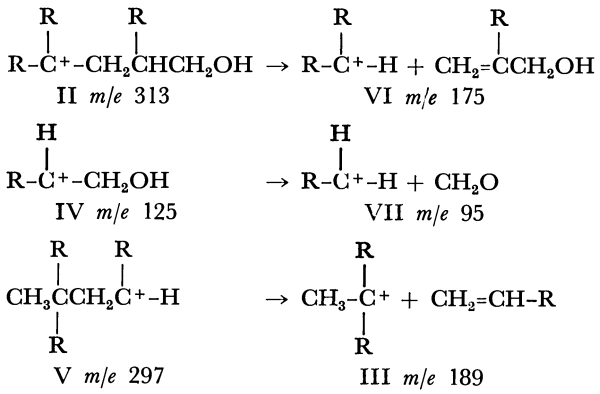
Therefore the signals which appear as two singlets at τ 7.80 (6H) and 7.82 (3H) must correspond to the protons of three methyl groups attached to the 5′-position of the furan nucleus. The other signals correspond to the following functional groups; the methyl group attached to tertiary aliphatic carbon (τ 8.56, 3H), the hydroxyl group (τ 8.42, 1H; this signal disappears after treatment with D_2O), the methylene group attached to the hydroxyl group (τ 6.72, 2H; this signal is shifted to τ 6.10 in the spectrum of the acetate **2**), the methine group attached to the hydroxymethyl group (τ 7.30, 1H, quintet; this signal is shifted to τ 7.80 in the spectrum of **2**), and another methylene group between tertiary aliphatic carbon and the methine group (τ 7.72, 2H; this signal overlaps with the broad singlet at τ 7.80).

The mass spectrum of **1** indicates a possible fragmentation mechanism, as is shown in the following schemes. Most heterocyclic-system fragmentation occurs by means of β-fission. The fission process is initiated by the loss of one of the non-bonded electrons of the heteroatom, which induces the "*onium ion*". Therefore, it is possible to form four fragment ions (II—V) on the β-fission process from the molecular ion (I), as is shown in Scheme I. The fragment ion III is a tertiary carbonium ion which is stabilized by two furan nuclei. Therefore, it appears as a predominant peak at *m/e* 189. This fragment ion is also possibly forms by the successive fragmentation of V

Scheme I.



Scheme II.



(Scheme II). The other fragment ions (II and IV) may be changed to minor fragment ions (VI and VII) with the elimination of neutral molecules (Scheme II). The mass spectrum of **1** indicates the presence of these ions (III, IV, VI and VII). The peak at *m/e* 43 may be due to CH_3CO^+, which is generally found in the mass spectra of 5-methyl-2-substituted furan compounds.

The facts presented above support the idea that the 2-methylfuran tetramer (**1**) definitely corresponds to 2,4,4-tris(5'-methyl-2'-furyl)-1-pentanol. This structure present a clue to elucidating the reaction mechanism of oligomerization.

Meisel and others reported the trimer of thiophene in 1950.[11] They indicated the structure of this compound and presented a reaction mechanism. This investigation will suggest a possible reaction mechanism to form **1** from 2-methylfuran; it is shown in Fig. 1.

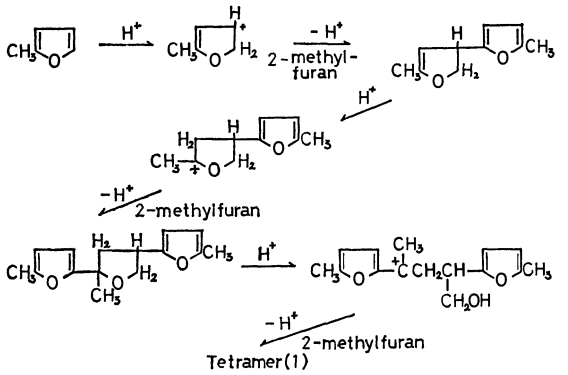


Fig. 1. A possible reaction mechanism for tetramerization.

The Other 2-Methylfuran Oligomers. The other 2-methylfuran oligomers can be separated as product **4** by the molecular distillation of the residue remaining after the removal of **1**. This product **4** is a slightly colored waxy substance. The elementary analysis data indicate that **4** correspond to the oligomer. The mass spectrum of **4** reveals the presence of a number of oligomers, *i.e.*, tetra-, penta-, hexa-, and heptamer.

Product **4** resembles **1** very closely in IR, UV, and NMR spectral patterns. These facts indicate a considerable structural resemblance between them. However, one of the appreciable differences between **1** and **4** is the ratio of the heteroaromatic proton signal intensities to the total one; **1** has a value of 6H/24H, but **4** has a value of 6H/30H. In addition, **4** has a strong IR characteristic band at 1700 cm^{-1}. This indicates the presence of a carbonyl group in the structure of **4**. These facts suggest that the pentamer is formed from **1** or another tetrameric precursor, accompanied by the ring cleavage of the furan nucleus. Some possible reaction routes illustrating this idea are shown in Fig. 2.

The structure of the tetrameric precursor is not necessarily the same as **1**. It is possible that the tetramer contained in **4** is another precursor for oligomerization. The tetramer contained in **4** could not be separated in this work. Therefore, we can not elucidate the structural difference between **1** and the tetramer in **4**. This problem is an interesting subject for investigation in the future.

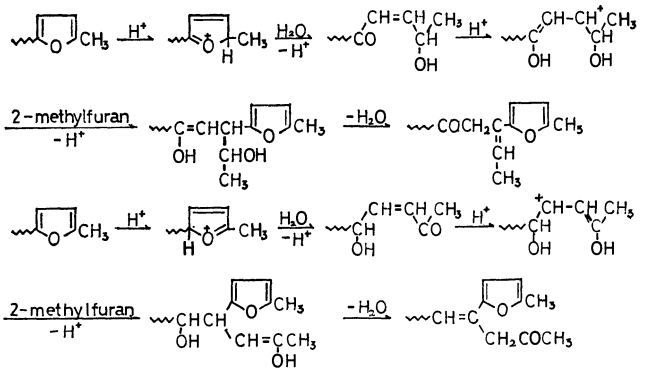

Fig. 2. Some possible propagation mechanisms for oligomerization.

Experimental

The elementary analyses were performed by the microanalytical division in the Department of Applied Chemistry of Osaka University. The infrared spectra were obtained with JASCO IR-G infracord as a neat liquid. The ultraviolet spectra were obtained with a Hitachi model 124 spectrometer. The mass spectra were obtained with a Hitachi RMU-6E spectrometer at 70 eV. The nuclear magnetic resonance spectra at 100 MHz were obtained with a Nippon Denshi JNM-P-100 instrument. The molecular distillation was carried out in a micro pot still in order to separate the oligomeric product.

The 2-methylfuran was prepared by the Wolff-Kishner reduction of 2-furaldehyde and was purified by fractional distillation; bp 62.8 °C (750 mmHg).

Oligomerization Reaction of 2-Methylfuran with Phosphoric Acid. One hundred and fifty grams of 2-methylfuran were stirred vigorously under reflux; then 8 g of phosphoric acid were added, drop by drop over a 10-minute period. The dark brown reaction mixture was stirred for an additional 30 min; then the reaction mixture was poured into a potassium carbonate solution and extracted with ether. The extract was dried over anhydrous magnesium sulfate, the ether and unchanged 2-methylfuran were removed by fractional distillation, and then it was concentrated under vacuum at room temperature. About 110 g of a brown viscous liquid was obtained as a residue.

*2,4,4-Tris(5'-methyl)-2'-furyl-1-pentanol (**1**).* The residual liquid was distilled, giving 57 g (38%) of **1** as a slightly colored viscous liquid; bp 200 °C (3 mmHg); n_D^{20} 1.5290. This product gave a satisfactory elementary analysis for **1**.

Found: C, 73.05; H, 7.35%. Calcd for $C_{20}H_{24}O_4$: C, 73.17; H, 7.31%.

UV max (hexane) 222 nm (ε 25100); IR (liquid film) 3400 (OH), 3100, 1608, 1555, and 775 cm^{-1} (a series of characteristic bands due to 2,5-disubstituted furan nuclei); NMR (CCl_4) τ 4.2—4.4 (m, 6H, β,β'-ring protons of furan nuclei), 6.68 (d, 2H, J=7 Hz, $C\underline{H}_2OH$), 7.30 (quintet, 1H, J=7 Hz, $CH_2C\underline{H}CH_2OH$), 7.72 (d, 2H, $-C\underline{C}H_2\underline{C}H-$, overlapped with a broad singlet at τ 7.80), 7.80 (s, 6H, $C\underline{H}_3$ of 5-methyl-2-furyl groups), 7.82 (s, 3H, $C\underline{H}_3$ of another 5-methyl-2-furyl group), 8.42 (s, 1H, $CH_2O\underline{H}$, washed out with D_2O) and 8.56 (s, 3H, $CH_3\underline{C}CH_2$); mass spectrum (70 eV) *m/e* (rel. intensity) 328 (9), 190 (16), 189 (100), 175 (10), 125 (5), 122 (5), 95 (7), 43 (12).

*Oxidation of the Tetramer (**1**) with Alkaline Hydrogen Peroxide.* One gram of **1** was added to a mixture of 1.2 g of potassium hydroxide and 40 ml of hydrogen peroxide (30% aqueous solution) with vigorous stirring, after which the mixture was left to stand four weeks. Then the mixture was treated with manganese (IV) oxide to decompose the excess hydrogen peroxide and filtered. The firtrate was neutralized with phosphoric acid and extracted with ether. According to thin-layer chromatographic separation (5 cm × 10 cm Wakogel UA Plate and Polyamide UA Plate; solvent: benzene: acetic acid, 40 : 1), 5-methyl-2-furoic acid was found in the extract as an oxidation product. An authentic sample of 5-methyl-2-furoic acid was prepared from 5-methyl-2-furaldehyde.

*2,4,4-Tris(5'-methyl-2'-furyl)-1-pentyl Acetate (**2**).* We dissolve 8.2 g of **1** in 50 g of pyridine and cooled in ice bath; then 36.5 g of acetic anhydride were added, and the mixture was left standing for eight days at room temperature. The reaction mixture was then treated with 1.6 liter of water and extracted with 300 ml of ether. The extract was thoroughly washed with water and distilled under reduced pressure, giving 6.4 g (70%) of **2** as a slightly colored viscous liliquid; bp 182 °C (2 mmHg); n_D^{23} 1.5135.

Found: C, 71.15; H, 7.35%. Calcd for $C_{22}H_{26}O_5$: C, 71.33; H, 7.07%.

IR (liquid film) 1725 (C=O, ester), 3100, 1608, 1555, and 775 cm^{-1} (a series of characteristic bands due to 2,5-disubstituted furan nuclei); NMR (CCl_4) τ 4.2—4.4 (m, 6H, β,β'-ring protons of furan nuclei), 6.02 (d, 2H, J=7 Hz, $C\underline{H}_2OAc$), 7.08 (quintet, 1H, J=7 Hz, $CH_2C\underline{H}CH_2OAc$), 7.72 (d, 2H, overlapped with a broad singlet at τ 7.80), 7.80 (s, 6H, $C\underline{H}_3$ of 5-methyl-2-furyl groups), 7.82 (s, 3H, $C\underline{H}_3$ of another 5-methyl-2-furyl groups), 8.10 (s, 3H, $C\underline{H}_3CO$) and 8.56 (s, 3H, $C\underline{H}_3CCH_2$); mass spectrum (70 eV) *m/e* (rel. intensity) 370 (2), 310 (2), 228 (4), 190 (15), 180 (100), 175 (4), 167 (2), 145 (3), 125 (4), 122 (2), 43 (13).

*Maleic Anhydride Adduct (**3**).* One gram of maleic anhydride and 1.0 g of **1** were dissolved in 10 ml of ether under reflux; then the solution was cooled to room temperature and left to stand for two weeks. A colorless, transparent, crystalline product was obtained; 0.13 g (10%); mp 151.7 °C.

This product gave a satisfactory elementary analysis for an equimolar adduct of **1** and maleic anhydride.

Found: C, 67.11; H, 6.10%. Calcd for $C_{24}H_{26}O_7$: C, 67.60; H, 6.10%.

Mass spectrum (70 eV) *m/e* (rel. intensity) 426 (trace), 328 (9), 190 (18), 189 (100), 175 (5), 125 (9), 98 (7), 95 (9), 54 (9), 43 (18), 28 (11), 26 (7).

This spectrum reasonably represents the superimposed spectrum of **1** and maleic anhydride (molecular weight, 98). This compound can appear from the adduct **3** as the result of the retro-Diels Alder process.

Separation of a Mixture of 2-Methylfuran Oligomers. Fifty-two grams of a hard brown brittle substance remained in the vacuum distillation flask after the removal of **1**. From 5.2 g of this substance, 2.1 g of an oligomeric product **4** was separated by molecular distillation; bp 195—200 °C (10^{-4} mmHg). The product **4** is a yellow, waxy substance and gave a satisfactory elementary analysis for the 2-methylfuran oligomers.

Found: C, 72.58; H, 7.38%. Calcd for $(C_5H_6O)_n$: C, 73.17; H, 7.31%.

UV max (methanol) 221 nm (ε 23,200); IR (thin film) 3400 (OH), 1700 (C=O), 3100, 1608, 1555, and 775 cm^{-1} (a series of characteristic bands due to 2,5-disubstituted furan nuclei); NMR (CCl_4) τ 4.1—4.4 (m, 6H, β,β'-ring protons of furan nuclei), 6.68 (d), 7.30 (quintet), 7.72, 7.80 (s), 7.82 (s), 7.85 (m), 8.60 (s) and 8.4—8.7 (m); mass spectrum (70 eV) *m/e* (rel. intensity) 328 (5), 410 (9), 492 (3), 574 (trace), 189 (100) and others.

The authors wish to thank Dr. Yoshikazu Hachihama, President of Nara Technical College, for his support of this work. (This report was present at the 28th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1973).

The Diazotization of 2-Aminoazulene Derivatives. The Formation of 2-Diazo-2,6-azulenoquinone Derivatives[1]

Tetsuo NOZOE,* Toyonobu ASAO,** Hiroshi SUSUMAGO,*** and Masayoshi ANDO

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received October 29, 1973)

The Diazotization of 2-amino-6-bromo (or alkoxy)-azulene, with alkoxycarbonyl or cyano groups at the 1 and 3-positions, by sodium nitrite in dioxane-sulfuric acid afforded mainly the corresponding 2-diazo-2,6-azulenoquinone derivatives (**2a**, **2b**, **16**). The catalytic hydrogenation of these compounds gave 1,3-disubstituted 6-hydroxyazulenes (**4a**, **4b**, **18**), from which 1,3-disubstituted 6-alkoxy- or 6-acetoxy-azulenes were obtained. The diazotization of diethyl 2-amino-6-bromoazulene-1,3-dicarboxylate (**1a**) in dry benzene with isoamyl nitrite in the presence of hydrogen chloride afforded the 2,6-dichloroazulene derivative (**20**) and the 5-bromo-2-diazo-2,6-azulenoquinone derivative (**21**); the latter, accompanied by a bromine addition product (**22**), was also obtained by the bromination of **2a**. The diazotization of diethyl 2-aminoazulene-1,3-dicarboxylate (**25**) afforded **2a** and a deamination product (**26**). The structure and mechanism of the formation of these diazoazulenoquinones are discussed.

It has long been known that 1,3-disubstituted 2-aminoazulene derivatives easily undergo a diazo reaction similar to benzenoid amines, by way of which deamination products or 2-haloazulenes are obtained.[2]

However, it has also been found that the deamination of diethyl 2-amino-6-bromoazulene-1,3-dicarboxylate does not proceed well under the same reaction conditions.[3] We have studied the reaction for 2-aminoazulene derivatives and have found that the reaction afforded 2-diazo-2,6-azulenoquinone derivatives in good yields. The results will be reported in this paper.

Results and Discussion

When a solution of diethyl 2-amino-6-bromoazulene-1,3-dicarboxylate (**1a**)[4] in dioxane containing concentrated sulfuric acid was diazotized with sodium nitrite, Compound **2a**, with a molecular formula of $C_{16}H_{14}O_5N_2$, was obtained, besides a small amount of diethyl 6-bromoazulene-1,3-dicarboxylate (**3**).[3] We first assigned the structure of (A) (azulene diazocarboxylate derivative) to the compound **2a** formed by the intramolecular elimination of bromine by the ethoxyl group.[1] However, from the facts that diethyl 6-acetoxy- and 6-chloroazulene-1,3-dicarboxylates were formed from **2a**, as will be described below, the structure of (A) was found to be incorrect.

Compound **2a** shows a UV absorption pattern similar to those of azulene derivatives, an IR (KBr) spectrum at 2165 cm^{-1} (diazonium group), and NMR ($CDCl_3$) signals at δ 6.61 ppm (2H) and 8.29 (2H), with an A_2B_2-type pattern. When Compound **2a** was submitted to catalytic hydrogenation in the presence of 5% Pd–C, no hydrogen absorption could be observed; however, the reaction yielded an acidic compound (**4a**), $C_{16}H_{16}O_5$, which gave methyl ether (**5a**), ethyl ether (**6**), and acetate (**7**) upon reaction with diazomethane, ethyl iodide with a silver salt of **4a**, and acetic anhydride respectively. Furthermore, Compound **4a** reacted with thionyl chloride to give a 6-chloro derivative (**8**), and it has already been reported that the hydrolysis, followed by the decarboxylation of **4a** with acid, afforded 6-hydroxyazulene.[5]

Compound **6** was found to be identical with the known diethyl 6-ethoxyazulene-1,3-dicarboxylate obtained by the reaction of **3** with ethoxide;[3] therefore, Compound **2a** must be diethyl 2-diazo-2,6-azulenoquinone-1,3-dicarboxylate or its inner salt. This compound is presumably formed by the nucleophilic attack of water on the 6-position of the initially-formed diazonium compound **9**, followed by the elimination of hydrogen bromide from an intermediate **10**. The attack at the 6-position must occur easily, because the position is activated by an electron-attractive diazonium group at the 2-position and by ethoxycarbonyl groups at the 1- and 3-positions, especially under acidic conditions.

The fact that the apparent hydrogen absorption could not be observed in the catalytic hydrogenation of **2a** can be explained by the liberation of an equimolar amount of nitrogen probably through an intermediate **11** when hydrogen is absorbed.

The nucleophilic substitution of Compound **1a** afforded the corresponding azulenes, the 6-ethoxy (**12**), 6-ethylthio (**13**), and 6-*p*-tolylthio (**14**) derivatives. However, the reaction of **1a** with methoxide in methanol afforded dimethyl 2-amino-6-bromoazulene-1,3-dicarboxylate (**1b**) as insoluble precipitates.

The similar diazotization of **12** and **13** yielded the same compound **2a** in good yields. The diazotization of **1b** afforded dimethyl ester (**2b**) in a good yield. The catalytic reduction of **2b** gave the 6-hydroxyazulene derivative (**4b**), the reaction of which with diazomethane afforded the corresponding methyl ether (**5b**). The heating of these diazoazulenoquinones (**2a** and **2b**) in isopropyl alcohol in the presence of HCl or H_2SO_4 for a short time yielded the corresponding 6-hydroxyazulene derivatives (**4a** and **4b** respectively) and acetone by disproportionation, followed by the extrusion of N_2.

The diazotization of the 2-amino-6-bromo-1,3-

* Present address: No 811, 2-5-1, Kamiyoga, Setagaya-ku, Tokyo 158.

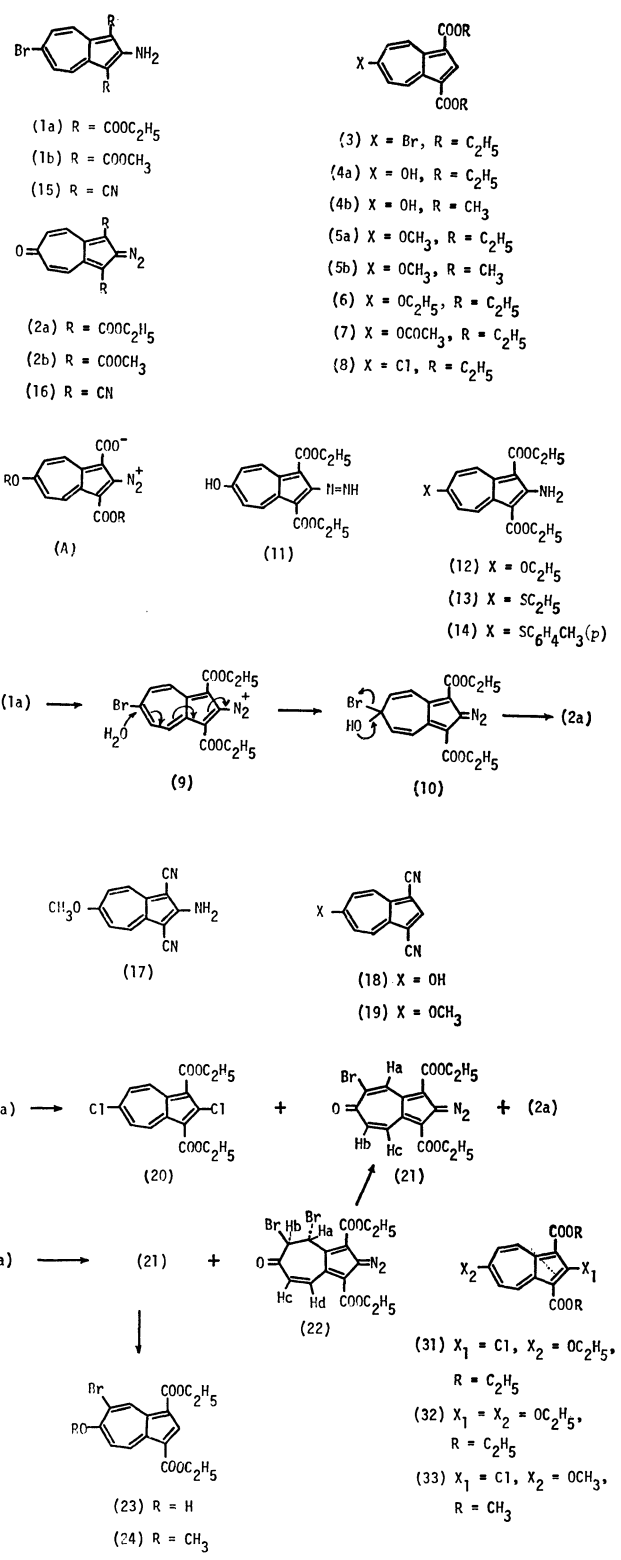
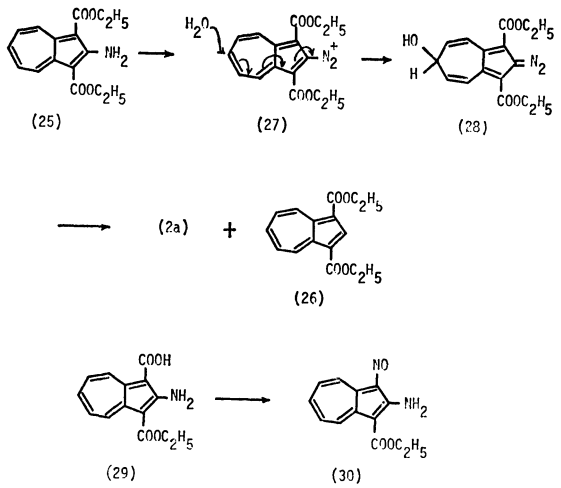
*** Present address: Asahi Chemical Industries Ltd., Ukishima, Kawasaki 210.





dicyanoazulene (**15**) obtained by the bromination of 2-amino-1,3-dicyanoazulene[2] in acetic acid at an elevated temperature afforded a similar diazo compound, 1,3-dicyano-2-diazo-2,6-azulenoquinone (**16**), which was also obtained by the diazotization of 2-amino-6-methoxy-1,3-dicyanoazulene (**17**). The structure of **16** was confirmed by reduction to yield unstable 6-hydroxy-1,3-dicyanoazulene (**18**), followed by methylation which gave 6-methoxy-1,3-dicyanoazulene (**19**), and by the IR spectrum of **16**, which shows a diazonium band at 2155 cm^{-1} and a cyano band at 2217 cm^{-1}.

On the other hand, when a solution of **1a** in dry benzene containing dry hydrogen chloride was diazotized with isoamyl nitrite, diethyl 2,6-dichloroazulene-1,3-dicarboxylate (**20**), a compound **21** with the molecular formula of $C_{16}H_{13}O_5N_2Br$, and a small amount of **2a** were obtained. Compound **21** shows an UV absorption curve similar to that of **2a**; IR (KBr) 2175 cm^{-1}; NMR ($CDCl_3$) δ 6.71 ppm (d, J=12.5 Hz, Hb), 8.01 (d, J=12.5 Hz, Hc), and 9.08 (s, Ha). From the above data, as well as on the basis of following reactions, Compound **21** was assumed to be diethyl 5-bromo-2-diazo-2,6-azulenoquinone-1,3-dicarboxylate, which must be formed by the bromination of the initially-formed diazoazulenoquinone (**2a**); the bromine might have been produced by the oxidation of liberated hydrogen bromide under these conditions. Therefore, it is reasonable that a similar diazotization of the 6-ethoxyazulene derivative (**12**) in benzene–HCl with isoamyl nitrite afforded only Compound **2a**.

The bromination of **2a** with bromine in $CHCl_3$ actually afforded Compound **21**, accompanied by a bromine addition product (**22**), and the treatment of **22** with triethylamine afforded **21** in a quantitative yield. The dibromide (**22**) was assumed to have the structure shown in the scheme on the basis of its derivation to **21**, the results of elemental analysis, and NMR spectrum ($CDCl_3$) δ 4.82 ppm (d, d, J=6.0, 1.8 Hz, Hb), 6.12 (d, d, J=13.0, 1.8 Hz, Hc), 6.56 (d, J=6.0 Hz, Ha), and 8.06 (d, J=13.0 Hz, Hd).

Compound **21** was catalytically hydrogenated to yield the 5-bromo-6-hydroxyazulene derivative (**23**), which was then reacted with diazomethane to give the methyl ether (**24**).

The formation of the dichloro compound (**20**) can be explained by a nucleophilic replacement of the bromine of the diazonium compound (**9**) by the chloride ion, followed by a Sandmeyer reaction at the 2-position. No change was observed in the reaction of **1a** and hydrogen chloride; therefore, it is clear that halogen exchange occurred after diazotization.

When diethyl 2-aminoazulene-1,3-dicarboxylate

(**25**)[2] was diazotized in dioxane containing sulfuric acid with sodium nitrite, diazoazulenoquinone (**2a**) and a deamination product, diethyl azulene-1,3-dicarboxylate (**26**), were unexpectedly obtained, although in low yields. This reaction may be explained as follows; at first the diazotization of **25** occurs to yield diazonium compound (**27**), which is easily attacked by water at the 6-position to give the quinol compound (**28**); then dispropotionation occurs between **27** and **28** to afford **26** and **2a** respectively.

The fact that the diazonium compound (**27**) undergoes a nucleophilic attack at the 6-position, in contrast with the reactivity of azulene itself, which preferentially occurs at the 4-position,[6] may be attributable to the steric hindrace of ethoxycarbonyl groups at the 1 and 3 positions.

The diazotization of 2-amino-3-ethoxycarbonylazulene-1-carboxylic acid (**29**) was attempted in the anticipation of obtaining a diazoazulenecarboxylate derivative; however, only a violet powder was obtained, and upon treatment with sodium carbonate it yielded ethyl 2-amino-3-nitrosoazulene-1-carboxylate (**30**), which had been synthesized by the nitrosation of ethyl 2-aminoazulene-1-carboxylate.[7]

When the dichloroazulene derivative (**20**) was treated with ethoxide in ethanol, 2-chloro-6-ethoxyazulene and 2,6-diethoxyazulene derivatives (**31** and **32**) were obtained, depending on the amount of the reagent used. The alkaline hydrolysis of **20** afforded 2-chloro-6-hydroxyazulene-1,3-dicarboxylic acid as an amorphous powder, which then gave dimethyl 2-chloro-6-methoxyazulene-1,3-dicarboxylate (**33**) upon reaction with diazomethane.

The 2-diazo-2,6-azulenoquinone derivatives obtained in this paper are very stable, with definite melting points; they are soluble in non-polar solvents such as $CHCl_3$ and benzene, less soluble in alcohol, and insoluble in water.

The electronic spectra of the diazoazulenoquinones in MeOH, acidic, and basic media (Fig. 1 and see Experimental section) show that the spectra are little changed by the solvent used and do not show any absorption maxima over 450 nm.

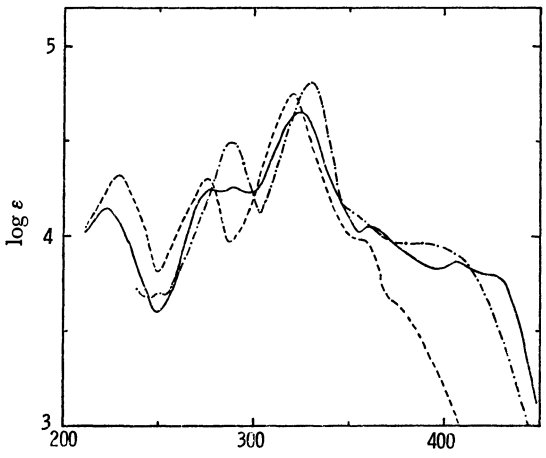


Fig. 1. UV absorption spectra of compound (**2a**) in MeOH (——), in MeOH-HCl (----) and in MeOH-NaOH (—·—·—).

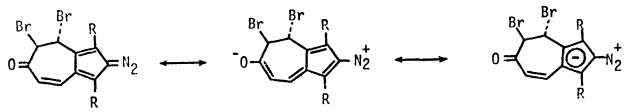
The infrared spectra of the compounds show strong diazonium bands at 2155—2175 cm^{-1}, a frequency a little higher than those of *p*-diazobenzoquinone, 2100 cm^{-1},[8] and diazocyclopentadiene, 2082 cm^{-1},[9] but considerably lower than that of benzene diazonium tetrafluoroborate, 2298 cm^{-1}.[8]

These facts would indicate that the compounds exist in the following resonance hybrids:

The ultraviolet absorption spectrum of the rather stable dibromo compound (**22**) is completely different from those of azulene compounds, and the infrared spectrum shows a diazonium band at 2135 cm^{-1} and a broad carbonyl band at 1690—1655 cm^{-1}. The compound seems to be stabilized by the contribution of the following resonance forms, as is also observed in diazocyclopentadiene.[9]



Experimental[10]

*The Diazotization of Diethyl 2-Amino-6-bromoazulene-1,3-dicarboxylate (**1a**) and Related Compounds (**1b**, **12**, **13**, **15**, and **17**).* *a) In Dioxane*: To a stirred solution of **1a** (300 mg) in purified dioxane (7 ml) and concentrated sulfuric acid (1 ml), a solution of sodium nitrite (150 mg) in water (1 ml) was added over a 3-hr period under cooling with ice. After the mixture had been stirred for 2 hr, water (20 ml) was added and the separated precipitates were collected, washed, and recrystallized from benzene to give 190 mg of diethyl 2-diazo-2,6-azulenoquinone-1,3-dicarboxylate (**2a**). The filtrate of the recrystallization was chromatographed on an alumina column and eluted with benzene. From the first effluent 10 mg of 6-bromoazulene-1,3-dicarboxylate (**3**) was obtained; it was identified by a direct comparison of the infrared spectrum with that of an authentic specimen.[3]

In a similar manner, five compounds (**1a**, **12**, **13**, **15**, and **17**) gave the corresponding 2-diazo-2,6-azulenoquinones (**2b**, **2a**, and **16**). The analytical and physical data of the products are as follows.

2a: orange needles, mp 148—149 °C (decomp.).
Found: C, 61.45; H, 4.27; N, 8.94%. Calcd for $C_{16}H_{14}O_5N_2$: C, 61.14; H, 4.49; N, 8.91%.
λ_{max}^{MeOH} nm (log ε); 223 (4.15), 277 (4.25), 289 (4.26), 324 (4.65), 360 (4.05), 406 (3.87) and 426^{sh} (3.80).
$\lambda_{max}^{MeOH-HCl}$ nm (log ε); 229 (4.32), 276 (4.30), 321 (4.75), 358^{sh} (3.98) and 373^{sh} (3.66).
$\lambda_{max}^{MeOH-NaOH}$ nm (log ε); 250 (3.84), 288 (4.39), 330 (4.81), 358^{sh} (4.14) and 390 (3.97).

2b: orange needles (from benzene), mp 173—175 °C.
Found: C, 58.66; H, 3.70; N, 9.86%. Calcd for $C_{14}H_{10}O_5N_2$: C, 58.74; H, 3.52; N, 9.79%.
λ_{max}^{MeOH} nm (log ε); 223 (4.11), 278 (4.20), 289 (4.20), 325 (4.69), 360 (3.98), 406 (3.90) and 426 (3.85).
$\lambda_{max}^{MeOH-HCl}$ nm (log ε); 228 (4.32), 275 (4.29), 320 (4.76),

359 (3.98), and 374 (3.63).
$\lambda_{max}^{MeOH-NaOH}$ nm (log ε); 250 (3.60); 287 (4.37), 329 (4.81), 360^{sh} (4.11), and 390 (3.92).

16: brown prisms (from dioxane), mp 155 °C (explosively decomp.).

Found: C, 65.17; H, 2.03; N, 25.63%. Calcd for $C_{12}H_4ON_4$: C, 65.44; H, 1.83; N, 25.44%.
λ_{max}^{MeOH} nm (log ε); 235 (3.97), 262^{sh} (3.94), 274^{sh} (4.01), 315^{sh} (4.27), 323 (4.29), 375^{sh} (3.86), and 400 (3.93).
$\lambda_{max}^{MeOH-HCl}$ nm (log ε); 225 (4.21), 265 (3.88), 315^{sh} (4.39), 319 (4.40), 374 (3.82), 396 (3.79), and 420 (3.70).
$\lambda_{max}^{MeOH-NaOH}$ nm (log ε); 246 (4.07), 262 (3.96), 271 (3.92), 324 (4.50), and 399 (3.86).

b) In dry benzene: A solution of **1a** (2 g) in dry benzene (100 ml) was saturated with dry hydrogen chloride gas under cooling with ice, and then isoamyl nitrite (1.5 ml) was added to the solution. After the mixture had been allowed to stand in an ice box overnight, benzene (100 ml) was added and the solution was washed with water five times. After the benzene solution had then been dried over anhydrous sodium sulfate, the solution was concentrated to about 30 ml under reduced pressure. The solution was submitted to column chromatography on an alumina and then eluted with benzene. From the first effluent, 300 mg of diethyl 2,6-dichloroazulene-1,3-dicarboxylate (**20**) as reddish-purple crystals (mp 160—161 °C (from benzene-cyclohexane)) were obtained.

Found: C, 56.02; H, 3.95%. Calcd for $C_{16}H_{14}O_4Cl_2$: C, 56.30; H, 4.13%.
λ_{max}^{MeOH} nm (log ε); 237 (4.31), 266 (4.05), 305 (4.54), 315 (4.60), 349^{sh} (3.68), 362 (3.77), and 500 (2.54).

The latter effluents were combined and rechromatographed on an alumina column; 1.1 g of diethyl 5-bromo-2-diazo-2,6-azulenoquinone-1,3-dicarboxylate (**21**) as orange needles (mp 166—168 °C (decomp.) (from benzene)) were thus obtained.

Found: C, 49.05; H, 3.28; N, 7.26%. Calcd for $C_{16}H_{13}O_5N_2Br$: C, 48.87; H, 3.33; N, 7.13%.
λ_{max}^{MeOH} nm (log ε); 229 (4.11), 280 (4.20), 292 (4.25), 323^{sh} (4.55), 334 (4.62), 264^{sh} (4.01), 382^{sh} (3.83) and 410^{sh} (3.42).
$\lambda_{max}^{MeOH-HCl}$ nm (log ε); 232 (4.19), 277 (4.19), 322 (4.64), 356^{sh} (3.95), 383 (3.81) and 430^{sh} (3.22).
$\lambda_{max}^{MeOH-NaOH}$ nm (log ε); 245 (4.01); 289 (4.35), 333 (4.73), 360^{sh} (4.12), and 398^{sh} (3.88).

From the latter effluent, 80 mg of Compound **2a** (mp 148 °C (decomp.)) were obtained.

A similar diazotization of Compound **12** in dry benzene afforded only **2a**.

The Diazotization of Diethyl 2-Aminoazulene-1,3-dicarboxylate (25) in Dioxane. To a solution of Compound **25** (500 mg) in dioxane (5 ml) and concentrated sulfuric acid (1.5 ml), a solution of sodium nitrite (250 mg) in water (1 ml) was added under cooling with ice. The solution was then stirred overnight, water (30 ml) was added, and the solution was extracted with benzene. The extract was washed with water, dried, and submitted to chromatography on an alumina column. From the first effluent 50 mg of reddish crystals (mp 120 °C) were obtained; their infrared spectrum was superimposable upon that of authentic diethyl azulene-1,3-dicarboxylate (**26**).[2b] From the next effluent, 70 mg of Compound **2a** were obtained. From the latter effluents, a dark brown oil was obtained; however, its structure could not be clarified.

The Reaction of 2-Amino-3-ethoxycarbonylazulene-1-carboxylic Acid (29) with Nitrous Acid. To a stirred solution of **29** (140 mg) in dioxane (5 ml) and concentrated sulfuric acid (0.5 ml), isoamyl nitrite (0.1 g) was added under cooling with ice. After the mixture had been stirred for 30 min, the resulting precipitate was filtered to give black violet crystals (mp 199—201 °C (decomp.)). The crystals were dissolved in water, and the solution was neutralized by sodium hydrogen carbonate to afford ethyl 2-amino-1-nitrosoazulene-3-carboxylate (**30**) in a quatitative yield. The infrared spectrum of Compound **30** was superimposable upon that of an authentic sample.[7]

The Hydrogenation of 2-Diazo-2,6-azulenoquinones to 6-Hydroxyazulenes. A solution of **2a** (300 mg) in ethanol (100 ml) was submitted to catalytic hydrogenation in the presence of 5% Pd–C (30 mg), after which the solution was shaken for 3 hr. Hydrogen was not takenup, to all appearances. The catalyst was then filtered off, the solvent was removed, and the residue was recrystallized from benzene to give 200 mg of diethyl 6-hydroxyazulene-1,3-dicarboxylate (**4a**) as yellow needles (mp 171—172 °C).

Found: C, 66.79; H, 5.46%. Calcd for $C_{16}H_{16}O_5$: C, 66.65; H, 5.59%.
λ_{max}^{MeOH} nm (log ε); 225 (4.33), 278 (4.42), 323 (4.75), 330^{sh} (4.67), 356^{sh} (4.12), 374 (3.90), 395^{sh} (3.56) and 464 (2.74).

A similar hydrogenation of **2b** and **21** afforded the corresponding 6-hydroxyazulenes (**4b** and **23**).

4b: yellow needles, mp 235—237 °C (decomp.).

Found: C, 64.73; H, 4.40%. Calcd for $C_{14}H_{12}O_5$: C, 64.61; H, 4.65%.

23: dark yellow needles, mp 203—205 °C (decomp.).

Found: C, 52.51; H, 4.03%. Calcd for $C_{16}H_{15}O_5Br$: C, 52.30; H, 4.12%.
λ_{max}^{MeOH} nm (log ε); 235 (4.28), 280 (4.35), 293 (4.26), 326 (4.71), 383 (4.01), 410^{sh} (3.55) and 475^{sh} (2.95).

6-Methoxyazulenes from 6-Hydroxyazulenes. Thirty mg of Compound **4a** was methylated with diazomethane in methanol. The crystals obtained by the removal of the solvent were dissolved in benzene, and the solution was passed through an alumina column and then recrystallized from a mixture of benzene and cyclohexane to give 25 mg of **5a** as reddish prisms (mp 140—141 °C).

In a similar manner, two compounds (**4b** and **23**) gave the corresponding 6-methoxyazulenes (**5b** and **24**); the hydrogenation of **16**, followed by its methylation afforded 1,3-dicyano-6-methoxyazulene (**19**). The analytical and physical data of the products are as follows.

5a: Found: C, 67.60; H, 5.78%. Calcd for $C_{17}H_{18}O_5$: C, 67.54; H, 6.00%.
λ_{max}^{MeOH} nm (log ε); 228 (4.46), 276 (4.40), 310^{sh} (4.65), 321 (4.77), 349 (4.06), 376 (3.75), and 456 (3.00).

5b: orange needles, mp 144—146 °C.

Found: C, 65.92; H, 5.31%. Calcd for $C_{15}H_{14}O_5$: C, 65.69; H, 5.15%.
λ_{max}^{MeOH} nm (log ε); 233 (4.40), 276 (4.36), 307^{sh} (4.60), 320 (4.76), 348 (4.03), 374 (3.81), and 453 (3.04).

24: reddish crystals, mp 133—134 °C.

Found: C, 53.71; H, 4.30%. Calcd for $C_{17}H_{17}O_5Br$: C, 53.56; H, 4.49%.
λ_{max}^{MeOH} nm (log ε); 237 (4.32), 270^{sh} (4.27), 279 (4.34), 312^{sh} (4.65), 325 (4.84), 355 (4.04), 386 (4.08), and 470 (3.03).

19: orange needles, mp 245 °C (decomp.).

Found: C, 74.76; H, 4.17; N, 13.17%. Calcd for $C_{13}H_8ON_2$: C, 74.99; H, 3.87; N, 13.46%.
λ_{max}^{MeOH} nm (log ε); 220 (4.38), 227 (4.38), 265 (3.94), 306^{sh} (4.55), 313^{sh} (4.68), 318 (4.71), 352 (3.96), and 460 (2.98).

6-Methoxyazulenes from 6-Haloazulenes. a): A solution of 2-amino-6-bromo-1,3-dicyanoazulene (**15**) (816 mg) in methanol (40 ml) containing 200 mg of sodium was refluxed for 5 hr. After cooling, greenish-yellow needles (640 mg) were obtained. Recrystallization from dioxane gave 2-amino-6-methoxy-1,3-dicyanoazulene (**17**) as yellow needles (mp 285 °C (decomp.)).

Found: C, 69.52; H, 4.04; N, 18.67%. Calcd for $C_{13}H_9ON_3$: C, 69.94; H, 4.06; N, 18.83%.

b): A solution of **20** (100 mg) in 50% ethanol (10 ml) containing potassium hydroxide (1 g) was refluxed for 2 hr. Water (20 ml) was then added, and the solution was acidified by the addition of 2M hydrochloric acid. A dark yellow solid was filtered off, washed with water, and dried. A suspended solution of the solid in methanol was methylated with diazomethane, the solvent was removed, and the residue was recrystallized from ethanol to give dimethyl 2-chloro-6-methoxyazulene-1,3-dicarboxylate (**33**) (30 mg) as orange needles (mp 140—142 °C).

Found: C, 58.58; H, 4.15%. Calcd for $C_{15}H_{13}O_5Cl$: C, 58.33; H, 4.23%.

λ_{max}^{MeOH} nm (log ε); 228 (4.38), 275 (4.32), 310^{sh} (4.71), 320 (4.82), 364 (4.11), and 440 (3.16).

6-Ethoxyazulenes. *a)*: A dried silver salt obtained from 130 mg of **4a** was suspended in dry benzene (20 ml), and the solution was refluxed with ethyl iodide (500 mg) for 3 hr. The black precipitate was then filtered off, and the solvent was removed from the filtrate to leave orange crystals. Recrystallization from a mixture of benzene and methanol gave 45 mg of diethyl 6-ethoxyazulene-1,3-dicarboxylate (**6**) as orange needles (mp 139—141 °C).

Found: C, 68.31; H, 6.36%. Calcd for $C_{18}H_{20}O_5$: C, 68.34; H, 6.37%.

λ_{max}^{MeOH} nm (log ε); 228 (4.41), 276 (4.37), 308^{sh} (4.62), 320 (4.78), 349 (4.07), 375 (3.85), and 454 (3.04).

b): After a solution of Compound **1a** (300 mg) in anhydrous ethanol (20 ml) containing 200 mg of sodium had been refluxed for 2 hr, orange crystals which were precipitated out by cooling the reaction mixture were recrystallized from benzene to afford diethyl 2-amino-6-ethoxyazulene-1,3-dicarboxylate (**12**) (160 mg) as yellow needles (mp 160—161 °C).

Found: C, 65.52; H, 6.11%. Calcd for $C_{18}H_{21}O_5N$: C, 65.24; H, 6.39%.

λ_{max}^{MeOH} nm (log ε); 232^{sh} (4.28), 245^{sh} (4.37), 255 (4.39), 281 (4.27), 325^{sh} (4.66), 336 (4.77), 370^{sh} (3.90), 410 (3.89) and 460 (3.86).

c): A solution of Compound **20** (100 mg) in anhydrous ethanol (10 ml) containing sodium ethoxide prepared from 7 mg of sodium was refluxed for one hour. A usual working up afforded 65 mg of diethyl 2-chloro-6-ethoxyazulene-1,3-dicarboxylate (**31**) as orange needles (from benzene) (mp 137—138 °C).

Found: C, 61.52; H, 5.30%. Calcd for $C_{18}H_{19}O_5Cl$: C, 61.63; H, 5.46%.

λ_{max}^{MeOH} nm (log ε); 229 (4.38), 276 (4.30), 311^{sh} (4.71), 321 (4.82), 365 (4.02), and 445 (3.10).

d): A solution of Compound **20** (100 mg) in anhydrous ethanol (10 ml) containing sodium ethoxide prepared from 60 mg of sodium was refluxed for 2 hr. A usual working up gave diethyl 2,6-diethoxyazulene-1,3-dicarboxylate (**32**) as orange needles (from benzene) (mp 148—149 °C).

Found: C, 66.85; H, 6.82%. Calcd for $C_{20}H_{24}O_6$: C, 66.65; H, 6.71%.

λ_{max}^{MeOH} nm (log ε); 229 (4.44), 273 (4.34), 313^{sh} (4.71), 323 (4.82), 365 (4.07), and 436 (3.10).

*Diethyl 2-Amino-6-ethylthioazulene-1,3-dicarboxylate (**13**).* A solution of **1a** (200 mg) and ethylmercaptane (45 mg) in anhydrous ethanol (5 ml) containing 14.5 mg of sodium was refluxed for one hour. The orange crystals which precipitated out were filtered, washed with water, and recrystallized from ethanol to give 170 mg of **13** as orange crystals (mp 104—105 °C).

Found: C, 62.42; H, 5.87; N, 3.95%. Calcd for $C_{18}H_{21}O_4NS$: C, 62.24; H, 6.10; N, 4.03%.

λ_{max}^{MeOH} nm (log ε); 246 (4.50), 277 (4.17), 345 (4.73), 432 (4.18), and 485 (3.66).

*Diethyl 2-Amino-6-(p-tolylthio)azulene-1,3-dicarboxylate (**14**).* The reaction of **1a** (200 mg) and *p*-thiocresol in anhydrous ethanol in the presence of sodium ethoxide afforded 190 mg of **14** as orange needles (from ethanol) (mp 129—130 °C).

Found: C, 67.57; H, 5.49; N, 3.32%. Calcd for $C_{23}H_{29}O_4NS$: C, 67.46; H, 5.66; N, 3.42%.

λ_{max}^{MeOH} nm (log ε); 246 (4.54), 277 (4.23), 344 (4.73), 433 (4.22), and 480 (3.70).

*Dimethyl 2-Amino-6-bromoazulene-1,3-dicarboxylate (**1b**).* The refluxing of a solution of Compound **1a** (300 mg) in anhydrous methanol containing 200 mg of sodium afforded orange crystals, which were subsequently purified by chromatography and recrystallization from chloroform to give **1b** (220 mg) as orange needles (mp 203—204 °C).

Found: C, 50.05; H, 3.40; N, 4.12%. Calcd for $C_{14}H_{12}O_4NBr$: C, 49.72; H, 3.57; N, 4.14%.

λ_{max}^{MeOH} nm (log ε); 244 (4.57), 276 (4.18), 320 (4.69), 333 (3.90), 404^{sh} (3.96), 416 (3.97), and 473 (3.58).

*2-Amino-6-bromo-1,3-dicyanoazulene (**15**).* A mixture of 2-amino-1,3-dicyanoazulene (1.76 g), bromine (3.5 g), and sodium acetate (1.23 g) in acetic acid (50 ml) was heated at 60 °C for 7 hr. The crystals (2.3 g) which separated out were filtered and recrystallized from dioxane to give 2-amino-6-bromo-1,3-dicyanoazulene (**15**) (2.3 g) as yellowish-brown needles (mp over 300 °C).

Found: C, 52.84; H, 2.45; N, 15.14%. Calcd for $C_{12}H_6N_3Br$: C, 52.99; H, 2.24; N, 15.45%.

λ_{max}^{MeOH} nm (log ε); 231 (4.59), 252^{sh} (4.08), 270 (3.83), 315 (4.79), 328 (4.86), 416^{sh} (4.00), and 418 (4.01).

*The Bromination of Diethyl 2-Diazo-2,6-azulenoquinone-1,3-dicarboxylate (**2a**).* To a stirred solution of Compound **2a** (200 mg) in chloroform (5 ml), a solution of bromine (105 mg) in chloroform (1 ml) was added at room temperature over a 30-min period. After having been stirred a further hour, the solution was washed with water, dried, and chromatographed on a silica gel column. The first effluent, obtained by the use of $CHCl_3$–CCl_4 (2 : 1), gave 100 mg of a dark yellow viscous oil, and the second effluent, obtained by the use of $CHCl_3$, gave 80 mg of diethyl 5-bromo-2-diazo-2,6-azulenoquinone-1,3-dicarboxylate (**21**); these substances were identified by a comparison of their infrared spectra. From the last effluent, the starting azulene (**2a**) (30 mg) was recovered. The dark yellow viscous oil obtained from the first effluent could not be crystallized; it was found to be the bromine addition compound **22** from the spectroscopic data.

Found: N, 5.64%. Calcd for $C_{16}H_{14}O_5N_2Br_2$: N, 5.91%.

λ_{max}^{MeOH} nm (log ε); 217 (4.33), 295 (4.16), 335 (4.20), and 385 (4.17). A solution of Compound **22** (70 mg) in chloroform (3 ml) was treated with 5 drops of triethylamine; the solution was thus immediately changed to dark yellow, and from it 40 mg of Compound **21** were obtained.

*Diethyl 6-Acetoxyazulene-1,3-dicarboxylate (**7**).* The acetate **7** was obtained as reddish-purple needles by the reaction of Compound **4a** with acetic anhydride in the presence of pyridine (mp 133—134 °C).

Found: C, 65.22; H, 5.60%. Calcd for $C_{18}H_{18}O_6$: C, 65.44; H, 5.49%.

λ_{max}^{MeOH} nm (log ε); 233 (4.45), 271 (4.36), 296^{sh} (4.54), 307 (4.65), 331 (4.05), 362 (3.90), 373 (3.97), and 497 (3.80).

*Diethyl 6-Chloroazulene-1,3-dicarboxylate (**8**).* A solution of Compound **4a** (480 mg) and thionyl chloride (3 ml) in anhydrous benzene (50 ml) was allowed to stand overnight and was then gently refluxed for 30 min. After the solvent

had been removed, a solution of the residue in benzene was chromatographed on an alumina column to give Compound **8** (290 mg) as reddish-purple needles (mp 200—201 °C).

Found: C, 62.76; H, 5.05%. Calcd for $C_{16}H_{15}O_4Cl$: C, 62.65; H, 4.93%.

λ_{max}^{MeOH} nm (log ε); 236 (4.54), 270 (4.29), 300 (4.69), 311 (4.81), 337^{sh} (3.88), 345 (3.93), 375 (4.00) and 510 (3.08).

The Relative *cis/trans* Reactivity in the Hydrochlorination of 1-Arylpropenes

Kunisuke IZAWA, Tadashi OKUYAMA, and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received November 5, 1973)

Hydrochlorination of *cis*- and *trans*-1-phenylpropenes and their ring-substituted derivatives (*p*-CH_3O, *p*-CH_3, and *p*-Cl) has been studied in acetic acid at 16—35°C. 1-Phenylpropene gave predominantly a *cis*-adduct while the *p*-CH_3O derivative yielded a non-stereospecific product. For the *p*-CH_3O and *p*-CH_3 derivatives, the *cis* isomer was found to be more reactive than the corresponding *trans* isomer, while for the *p*-Cl derivative the opposite relative reactivity was observed. The origins of these *cis/trans* reactivities have been discussed in terms of the electronic and steric effects on stability of the solvated transition state.

The question of the relative reactivity of the geometrical isomers of an olefin in addition reactions is one of the problems remaining to be solved. We have studied the acid-catalyzed hydrolyses of various alkenyl alkyl ethers and found that all the *cis* isomers are more reactive than the corresponding *trans* isomers.[1] Since most of the *cis* ethers are thermochemically less stable than the *trans* isomers, the reactivity difference was at first ascribed to the difference in the ground-state stability.[2] A similar reasoning of the relative reactivities in some electrophilic additions was presented previously.[3] However, we have later found that *cis*-β-chlorovinyl ethyl ether[4] and *cis*-1,2-dialkoxyethylenes,[5] which are more stable than the *trans* isomers, are more reactive than the *trans* isomers. An alternative explanation for this reactivity has tentatively been presented but is not general.[4,5] Furthermore, we have found that *trans*-styryl ethyl ether is less reactive than the *cis* isomer at ordinary temperatures but the activation enthalpy for the former is smaller than that for the latter, despite the greater stability of the former at the ground state.[6] The reactivity difference in this case is controlled by the entropy term at higher temperatures and the origin of this observation is still ambiguous.

Addition reactions of various electrophiles have already been studied with *cis*- and *trans*-1-phenylpropenes (**1c** and **1t**).[7–11] The reactivity difference between **1c** and **1t** was found to be very small and vary depending on the electrophile. Thus, the *trans* isomer is slightly more reactive in bromination[7] and sulfenylation[8] but less reactive in methoxymercuration[9] and hydrobromination.[10] Results on cationic polymerization are not definite.[11]

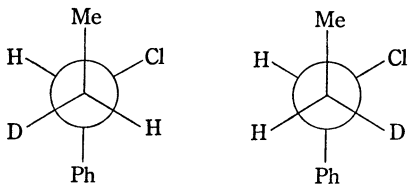
In the present investigation, the relative reactivities of *cis* and *trans* isomeric pairs of **1c** and **1t** and their ring-substituted derivatives have been measured for their hydrochlorination in acetic acid in the temperature range of 16—35 °C. Possible origins of these reactivities are discussed.

Results

The hydrochlorination of both **1c** and **1t** in glacial acid acetic gave predominantly 1-phenylpropyl chloride (**2**) with a contamination by 1-phenylpropyl acetate (**3**).

In order to confirm the stereochemistry of the present reaction, the deuteriochlorination was carried out in acetic acid-*O*-*d*. The *cis* isomer **1c** gave predominantly an *erythro* adduct **2c** while **1t** yielded a *threo* adduct **2t**, in agreement with the results obtained in hydrobromination.[10] The most favorable conformations of **2c** and **2t** are shown below.

$$\underset{\mathbf{1}}{C_6H_5CH{=}CHCH_3} + HCl \xrightarrow[CH_3COOH]{} \underset{\mathbf{2}}{C_6H_5\overset{\displaystyle Cl}{\overset{|}{C}}H\text{-}CH_2CH_3} + \underset{\mathbf{3}}{C_6H_5\overset{\displaystyle OCOCH_3}{\overset{|}{C}}H\text{-}CH_2CH_3} \quad (1)$$



2c **2t**

The stereochemistry of the adducts was determined by NMR spectra. The vicinal H-H coupling constants were 7.5 and 4.5 Hz for **2c** and **2t**, respectively. It is known that the spin-spin coupling constant between vicinal hydrogens is greatly dependent on the dihedral angle of their bonds.[12] The coupling constant between trans protons is greater than that between gauche protons. Consequently, **2c** should have a greater coupling constant than **2t**. A similar pair of compounds, *erythro*- and *threo*-1-phenyl-2-methylaminopropyl alcohols, have $J=8.2\pm0.2$ and 4.0 ± 0.2 Hz, respectively.[13]

By contrast, the products from both the *p*-methoxy derivatives of **1c** and **1t** gave the same NMR spectrum, suggesting the formation of nonstereospecific adducts. This observation is consistent with the observation that the geometrical isomerization of *p*-CH_3O-**1c** to *p*-CH_3O-**1t** is taking place during the reaction. Other derivatives suffered little geometrical isomerization under the reaction conditions adopted here.

During the reaction of **1c**, no trace of the *trans* isomer **1t** was found by vpc. With the *p*-CH_3 derivative, the relative concentration of the *trans* isomer (*ca.* 5%) concomitant with the *cis* isomer did not increase during the reaction. But geometrical isomerization of *p*-CH_3-**1c** to *p*-CH_3-**1t** seems to take place to some extent. However, it did not affect rate-determination under low conversion.

The kinetic measurements were carried out gas-chromatographically with a pure isomer or with a

p-Cl		0.30	0.35	$+2.8_2$	$+7.0_5$

a) By the competitive method. b) Calcd from the k_1 values listed in Table 1. c) $2.303\,R \log (k_{cis}/k_{trans}) = -\delta\Delta H^{\neq}(1/T)+\delta\Delta S^{\neq}$, $\delta\Delta H^{\neq}=\Delta H^{\neq}(cis)-\Delta H^{\neq}(trans)$ $\delta\Delta S^{\neq}=\Delta S^{\neq}(cis)-\Delta S^{\neq}(trans)$

mixture of isomeric olefins. Because of the complexity of kinetic order in [HCl],[14] the pseudo-first order rate constants were determined under low conversion (5—10 %) for isomerically pure *p*-CH_3O and *p*-CH_3 derivatives. The results are given in Table 1. Although the isomerization accompanied the reaction of *p*-CH_3O-**1c**, the rate of decay of the substrate is considered to be that of protonation and recorded as such in Table 1.

The relative rates of geometrical isomers were measured mostly by the competitive method with an isomeric mixture. The results are given in Table 2. The *cis* isomers are more reactive in the case of 1-phenylpropenes bearing an electron-donating group (*p*-CH_3O and *p*-CH_3) while the *trans* isomer of the *p*-Cl derivative is more reactive than its *cis* isomer. Unsubstituted **1c** and **1t** are similar in reactivity; relative reactivity is reversed between 25 and 35 °C.

The relative *cis/trans* reactivity tends to increase with the rise in temperature except for the *p*-CH_3O derivative. The differences in activation enthalpy $\delta\Delta H^{\neq}$ and activation entropy $\delta\Delta S^{\neq}$ between the *cis* and *trans* isomers were calculated and are listed in Table 2. The activation enthalpies of *cis* isomers are greater than those for the corresponding *trans* isomers except for the *p*-CH_3O derivative. The apparently greater reactivity of the *cis* isomer of the *p*-CH_3 derivative in the present temperature range is entropy-controlled. Negative $\delta\Delta H^{\neq}$ obtained for the *p*-CH_3O derivative implies that the *cis* isomer is energetically more reactive.

Discussion

Stereochemistry. Deuteriochlorination of **1c** and **1t** in DCl-DOAc gave mainly *erythro*- and *threo*-adducts, respectively. That is, hydrochlorination of **1c** and **1t** takes place preferentially through *syn*-addition. Similar results were obtained in the hydrobromination of **1c** and **1t** and interpreted in terms of the mechanism involving carbonium halide ion-pair intermediates.[10]

The *p*-CH_3O derivative reacts non-stereospecifically, being accompanied by geometrical isomerization. The intermediate carbonium ion, which should be stabilized by *p*-CH_3O group, would be reluctant to collapse by the attack of the chloride ion and hence could rotate freely before completion of the reaction. Thus, the isomerization accompanies the reaction of the *cis* isomer.

Relative cis/trans *Reactivities.* Relative reactivities of geometrically isomeric pairs vary depending on the ring substituent and reaction temperature. As has been described above,[7,8,11] *trans* isomers are often more reactive in styryl compounds. Similar observations were previously made for another class of styryl derivatives, styryl ethyl ether.[6] On the other hand, it was found that the *cis* isomers of α,β-unsaturated ethers are usually more reactive than the corresponding *trans* isomers toward some electrophiles, irrespective of ground-state stability.[1,2,4,5,15] Clearly, relative reactivities cannot be interpreted by the ground-state stability differences alone.

Yamaguchi *et al.*[16] have theoretically made general considerations on the origin of the *cis/trans* reactivities of olefins. It was concluded that the *cis* isomer should generally be more reactive in ionic reactions irrespective of the ground-state stability and that the Coulombic interaction in the transition state plays a predominant role in determining the greater reactivity of *cis* isomer relative to the *trans* counterpart. The observations on styryl compounds are however outside this scope, and another factor has to be taken into account to interpret the reactivities.

Relative *cis/trans* reactivity increases with increasing electron-donating character of a ring substituent as is seen in Table 2. This implies that the *cis* isomer is more sensitive to the electronic effects of ring substituents. It was suggested earlier that the diminished reactivity of **1c** is due to steric hindrance against electrophilic attack because of nonplanar conformation of **1c**.[11] This view implicitly presumes that the transition state for **1c** is less bonding (between an electrophile and the reaction site of olefin) than that for **1t**. However, this interpretation seems to contradict the present result that **1c** is more sensitive to the substituent effects than **1t**.

Alternatively, a steric effect against solvation of intermediate ion-pair in the *cis* isomers seems to account for all the results available. Effective solvation of intermediate carbonium-chloride ion-pair derived from the *trans* isomer stabilizes the transition state and hence enhances the reactivity of **1t** on one hand. Charge dispersion by solvation, on the other hand, would result in lower sensitivity of **1t** to substituent effects.[17] For very reactive derivatives like *p*-CH_3O-**1**, the electronic effects will overcome the steric effects, thus allowing the *cis* isomer to be more reactive.

In conclusion, the *cis* isomers of any olefins including styryl compounds should be intrinsically (or electro-

nically) more reactive in protonation than are the *trans* counterparts. The Coulombic interaction at the transition state contributes mainly to this reactivity. In the protonation and probably in other types of reactions also, the steric inhibition against intermediate solvation should more or less reduce the reactivity of *cis* isomers. The relative *cis/trans* reactivities experimentally observed are probably a reflection of the relative importance of these two opposing contributions.

Experimental

Materials. Preparation of *cis*- and *trans*-1-phenylpropenes (**1c** and **1t**) and their derivatives will be described elsewhere.[8]

1-Phenylpropyl chloride was prepared as an authentic sample by treatment of 1-phenylpropyl alcohol with thionyl chloride. NMR (CCl_4); δ 1.02 (3H, t, J=7.5 Hz, CH_3), 2.10 (2H, q, J=7.5 Hz, CH_2), 4.70 (1H, t, J=7.5 Hz, CH–Cl), 7.3 (5H, s, C_6H_5).

Hydrochlorination. Procedure of the reaction and the method of kinetic measurements were described previously.[18] The reaction procedure for deuteriochlorination was also described before.[19]

NMR spectra of the products were recorded on a JNM-4H-100 spectrometer. NMR (CCl_4): **2t**. δ 0.96 (3H, d, J=7 Hz, CH_3), ~2.0 (1H, m, CH–Me), 4.63 (1H, d, J=4.5 Hz, CH–Cl), ~7.25 (5H, m, C_6H_5). **2c**: δ 0.98 (3H, d, J=7 Hz, CH_3), ~2.0 (1H, m, CH–Me), 4.66 (1H, d, J=7.5 Hz, CH–Cl), ~7.22 (5H, m, C_6H_5). Product from *p*-CH_3O-**1t**; δ 0.96 (3H, d, J=7 Hz, CH_3), ~2 (1H, m, CH–Me), 3.73 (3H, s, CH_3O), 4.63 (1H, d, J=6.0 Hz, CH–Cl), 6.7—7.25 (4H, m, C_6H_4). Product from *p*-CH_3O-**1c**; δ 0.96 (3H, d, J=7 Hz, CH_3), ~2 (1H, m, CH–Me), 3.70 (3H, s, CH_3O), 4.65 (1H, d, J=6.0 Hz, CH–Cl), 6.72—7.27 (4H, m, C_6H_4).

The Addition of 2,4-Dinitrobenzenesulfenyl Chloride to *cis*- and *trans*-1-Arylpropenes and Some Other Olefins

Kunisuke IZAWA, Tadashi OKUYAMA, and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received November 5, 1973)

Kinetic investigations were carried out on the addition of 2,4-dinitrobenzenesulfenyl chloride to the geometrically isomeric pairs of various 1-arylpropenes as well as some related olefins. All the *trans* isomers of 1-arylpropenes were more reactive than the corresponding *cis* isomers and the Hammett correlations were observed for respective isomers with $\rho = -2.64$ (*trans*) and -2.3 (*cis*). By contrast, *cis*-alkenes were more than 10 times as reactive as the corresponding *trans* isomers. The reactivities of various unsaturated compounds in this reaction were found to be correlated with their ionization potentials constituting two lines accodring to the type of substrates. It was concluded that the greater reactivity of *trans*-1-arylpropene as compared with the *cis* isomer is ascribable to the difference in the charge-transfer interaction between the electrophile and a substrate at the transition state. The conclusion is contrasting to the generalization that the relative *cis*/*trans* reactivity of alkenes is determined mainly by the Coulombic interaction at the transition state.

The addition of sulfenyl halide to olefins is known to proceed through an episulfonium ion intermediate.[1] The influence of electronic effects on the rate of this reaction has been extensively studied with various olefins; ring-substituted styrenes,[2] cyclic olefins,[3-5] and alkenes.[6,7] However, little attention has ever been paid to the relative reactivities of geometrical isomers. Available data seem to suggest complexity of the reactivity.

cis-Alkene was found to react faster than the *trans* isomer[7] and the latter deviates from the Hammett-Taft correlation.[6] *cis*-Stilbene, on the other hand, is less reactive than *trans*-stilbene; this observation was explained in terms of the steric effects against electrophilic attack to the former.[8]

In the present study, we have investigated the reaction of 2,4-dinitrobenzenesulfenyl chloride (**1**) with *cis*- and *trans*-1-phenylpropenes (**2c** and **2t**) and their ring-substituted derivatives, *cis*- and *trans*-2-heptenes (**3c** and **3t**) and *cis*- and *trans*-4-methyl-2-pentenes (**4c** and **4t**) in order to clarify the relationship between relative *cis*/*trans* reactivities and olefin structure. The reaction rates of some other related olefins have been measured for the sake of comparison. Possible factors that influence these reactivities have been discussed.

Results

Reaction Products. The reaction of **1** with **2t** in glacial acetic acid led to a high yield of 1 : 1 adduct which was shown to be *erythro*-1-phenyl-1-chloro-2-(2,4-dinitrophenylthio)propane by NMR specroscopy. That is, the addition is specifically of Markownikoff-type and *anti* fashion. On the other hand, the reaction with **2c** under the same conditions yielded *ca.* 30% of the anti-Markownikoff isomer together with 70% the normal adduct. Both adducts were *threo*-type; the addition is, therefore, specifically *anti*. Stereochemistry of the adducts was determined by comparing the NMR spectra (see Experimental) with the compilation of spectra of related compounds.[9,10]

Kinetic Measurements. The rates of addition of **1** to **2c** and **2t** and their ring-substituted derivatives were determined in dry acetic acid solution. The reactions were followed by measuring the rates of disappearance of the sulfenyl chloride by the titration method. The rate is first order in each reactant as was found for other olefins.[2-6] Initial reactant concentrations were varied in the different rate runs but there was found no indication of deviations from the simple second-order kinetics.

The second-order rate constants k_2 for phenylpropene derivatives are summarized in Table 1. All the *trans* isomers of phenylpropenes are several times more reactive than the corresponding *cis* isomers. From the temperature dependence of k_2, activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, were calculated in a usual way. Although they may not be precise enough because of a limited range of temperature variation, they are included in Table 1 for the sake of comparison between *cis*-*trans* isomeric pairs.

The Hammett $\rho\sigma$ correlation for the reaction of the derivatives of **2c** and **2t** at 25 °C are shown in Fig. 1. The reaction constants ρ were evaluated excluding *p*-methoxy derivatives, which show apparent

deviation from the linearities: $\rho=-2.64$ for the *trans* isomers and $\rho\sim-2.3$ for the *cis* isomers.

Listed in Table 2 are the kinetic data for styrene (**5**), indene (**6**) and some alkenes. The *cis* isomer of an alkene is significantly reactive than its *trans* isomer.

Discussion

Specific *anti*-additions of **1** to both **2c** and **2t** are explained as usual by the mechanism involving an episulfonium ion intermediate.[1] The anti-Markownikoff-type adduct was found only for the *cis* isomer (30 %). This trend was observed earlier in the addition of *p*-chlorobenzenesulfenyl chloride.[10] In this reaction, **2c** gave 66% of anti-Markownikoff product. The reduced yield of anti-Markownikoff product in the present reaction is consistent with the general observation[11] that the *ortho*-nitro substitution of sulfenyl chloride tends to increase Markownikoff adduct.

The *trans* isomers of aryl-substituted olefins were found to be more reactive than the *cis* counterparts, while *trans*-alkenes were found to be less reactive than the *cis* isomers. These results are seemingly similar to those obtained for the protonation in which *cis* isomers are more reactive in the case of aliphatic olefins but are less reactive in the case of most of 1-phenylpropene derivatives.[12]

However, the effect of ring substituents on the protonation rate of **2** is contrasting to the present results. In the hydrochlorination of **2**, the relative *cis*/*trans* reactivity increases with increasing electron-donating character of the ring substituent. That is, the ring substitution exerts more influence on the reactivity of the *cis* isomer ($|\rho_{cis}|>|\rho_{trans}|$).[12] From these observations, the reduced reactivity of the *cis* isomers was interpreted by the steric inhibition of intermediate solvation.[12] On the other hand, the substituent effects observed in the present reaction are just opposite to those observed in the hydrochlorination. The relative *cis*/*trans* reactivity tends to diminish with the increasing electron-donating character of ring substituents. Correspondingly, the magnitude of the reaction constant ρ is greater for the *trans* isomers than for the *cis* isomers (Fig. 1). Furthermore, all the values of $\Delta H^{\neq}$ are greater for the *cis* isomers. These results seem to suggest, in contrast to the hydrochlorination, that the *trans* isomers are electronically more reactive in sulfenylation of 1-phenylpropenes. If the steric factor were important to the reaction,[13] its effect would be analogous to that in the hydrochlorination.[12]

Electronic interactions controlling the reactivity may divided into two factors, Coulombic and charge-transfer interactions.[14,15] It was concluded that the former predominates in the greater reactivity of *cis* isomers in protonation.[13,14] The latter factor of charge transfer interaction seems to contribute to the greater

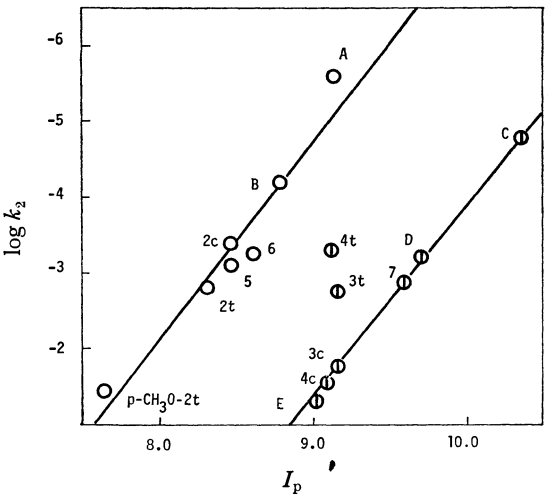

Fig. 2. Correlation of the reaction rates (k_2 for the addition of **1** in acetic acid at 25 °C) with ionization potentials. Ionization potential data are taken from Y. Morino, *et al.*, "Kagaku Binran (Handbook of Chemistry)" Ed. by Chem. Soc. Japan, Maruzen, Tokyo, 1966 and K. Yamaguchi, Doctor thesis, Osaka Univ., 1972. For Nos., see Tables 1 and 2. (A) Phenylacetylene (Ref. 8); (B) 1-phenylpropyne; (C) 1-hexyne; (D) 2-heptyne (T. Okuyama, K. Izawa, and T. Fueno, *J. Org. Chem.*, **39**, 351 (1974)); (E) cyclohexene (Ref. 4).

reactivity of the *trans* isomers in the present reaction. Importance of the charge transfer interaction is in accord with the tendency of episulfonium intermediate formation.

The charge-transfer controlled reactivity might be ascribed to the softness of electrophilic sulfur. The correlation between the reactivity of an olefin or an acetylene and its ionization potential (I_p) is substantiated in Fig. 2 as expected for the charge-transfer controlled reaction. Two classes of compounds, aromatic and aliphatic, constitute different lines. This fact might arise from the different contributions from other factors to the respective class of unsaturated compounds.

The greater reactivity of **2t** seems to reflect the lower ionization potential of **2t** as compared with **2c**. The large magnitude of the ρ value for the *trans* isomers compared with that for the *cis* isomers is consistent with the greater contribution of charge-transfer interaction to the reactivities of the former.

As for the alkene series, the difference in ionization potential is negligibly small between *cis* and *trans* isomers. Thus, the reactivity difference does not seem to reflect charge-transfer contribution. The reduced reactivity of the *trans* isomers as compared with the *cis* counterparts will be accounted for in terms of different Coulombic interaction as in the case of protonation.

The observed Hammett-Taft correlation for sulfenyl chloride addition to alkenes[6] may have some bearing on this log k_2—I_p correlation. The rate enhancement by *cis*-β-methyl substitution corresponds to the decrease in I_p (**7** and **3c**). The points for the *trans*-alkenes (**3t** and **4t**) are deviated from the line in Fig. 2. This type of deviations of *trans*-alkenes were pointed out also in the Hammett-Taft correlations not only for sulfenylation[6] but bromination.[16]

In conclusion, the contribution of charge-transfer interaction is considerably great in the reaction of "soft" reagent like sulfur with a substrate of low I_p even if the reaction is ionic. Relative *cis*/*trans* reactivities of aromatic olefins are ascribed to this factor.

Experimental

All boiling points and melting points are uncorrected. The nuclear magnetic resonance spectra were obtained on a JNM-4H-100 spectrometer operating at a frequency of 100 MHz. All vpc analyses were performed with a Shimadzu gas chromatograph Model 4APT.

Materials. Glacial acetic acid was dried according to the literature.[17] 2,4-Dinitrobenzenesulfenyl chloride (**1**) was prepared by the method of Kharasch and Langford[18] and recrystallized from carbon tetrachloride; mp 95.0—95.5 °C (lit,[18] 95.0—95.5 °C).

trans-1-Phenylpropene (**2t**) and its ring-substituted derivatives were prepared by prototropic rearrangement[19] of corresponding allylbenzenes, which were obtained by the Grignard coupling between allylbromide and bromobenzenes.[20] *cis*-1-Phenylpropene (**2c**) and its ring-substituted derivatives were prepared by decarboxylation of corresponding α-methylcinnamic acids, which were obtained by the Perkin reaction of appropriate benzaldehydes.[21] All the 1-phenylpropenes obtained were geometrically pure over 95% and were further purified by preparative vpc whenever necessary. The isomer thus purified were pure in >99%. IR spectra of **2t** and **2c** agreed well with those reported in the literature. Their boiling points and spectral data were as follows: **2t**, bp 48 °C(8 mmHg) (lit,[22] 105 °C (80 mmHg)); NMR (CCl_4) δ 1.84 (3H, d, J=6 Hz, CH_3), 5.96—6.40 (2H, m, -CH=CH-) 7.07—7.73 (5H, C_6H_5). *p*-CH_3O-**2t**, bp 108 °C (12 mmHg); NMR (CCl_4) δ 1.83 (3H, d, J=6 Hz, CH_3), 3.67 (3H, s, OCH_3), 5.8—6.33 (2H, m, -CH=CH-), 6.61—7.15 (4H, C_6H_4). *p*-CH_3-**2t**, bp 58 °C (4 mmHg); NMR (CCl_4) δ 1.83 (3H, d, J=6 Hz, CH_3), 2.27 (3H, s, CH_3), 5.85—6.37 (2H, m, -CH=CH-), 6.9—7.13 (4H, C_6H_4). *m*-CH_3-**2t**, bp 67 °C (8 mmHg); NMR (CCl_4) δ 1.85 (3H, d, J=6 Hz, CH_3) 2.30 (3H, s, CH_3), 5.95—6.38 (2H, m, -CH=CH-), 6.85—7.07 (4H, C_6H_4). *p*-Cl-**2t**, bp 79 °C (7 mmHg); NMR (CCl_4) δ 1.84 (3H, d, J=6 Hz, CH_3), 5.95—6.36 (2H, m, -CH=CH-), ~7.15 (4H, C_6H_4). *m*-Cl-**2t**, bp 80.5 °C (7 mmHg); NMR (CCl_4) δ 1.86 (3H, d, J=7 Hz, CH_3), 5.96—6.40 (2H, m, -CH=CH-), 7.05-7.15 (4H, C_6H_4). **2c**, bp 45°C (10 mmHg) (lit,[22] 95—96 °C (80 mmHg); NMR (CCl_4) δ 1.85 (3H, dd, J=7 and 1.5 Hz, CH_3), 5.5—5.85 (1H, m, =CH-Me), 6.85 (1H, dd, J=11 and 1.5 Hz, Ph-CH=), 7.1—7.2 (5H, C_6H_5). *p*-CH_3O-**2c**, bp 88 °C (10 mmHg); NMR (CCl_4) δ 1.85 (3H, dd, J=7 and 1.5 Hz, CH_3), 3.72 (3H, s, OCH_3), 5.42—5.75 (1H, m, =CH-Me), 6.29 (1H, dd, H=11 and 1.5 Hz, Ph-CH=), 6.67—7.20 (4H, C_6H_4). *p*-CH_3-**2c**, bp 66 °C (10 mmHg); NMR (CCl_4) δ 1.84 (3H, dd, J=7 and 1.5 Hz, CH_3), 2.30 (3H, s, CH_3), 5.45—5.80 (1H, m, =CH-Me), 6.83 (1H, dd, J=11 and 1.5 Hz, Ph-Ch-), ~7.06 (4H, C_6H_4). *p*-Cl-**2c**, bp 72 °C (8 mmHg); NMR (CCl_4) δ 1.84 (3H, dd, J=7 and 1.5 Hz, CH_3), 5.5—5.85 (1H, m, =CH-Me), 6.35 (1H, dd, J=11 and 1.5 Hz, Ph-CH=), 7.1—7.2 (4H, C_6H_4).

Styrene (**5**), indene (**6**), 1-hexene (**7**), *trans*- and *cis*-2-heptenes (**3t** and **3c**), and *trans*- and *cis*-4-methyl-2-pentenes

(**4t** and **4c**) were commercially obtained (Nakarai Chemicals) and distilled under nitrogen atmosphere immediately before use.

*Reaction of **1** with **2t**.* A sample of 2.50 g of **1** was mixed with 1.75 g of **2t** in 50 ml dry acetic acid and allowed to react for two days at room temperature. Yellow precipitates were separated and recrystallized from absolute alcohol to give 3.14 g of yellow prisms, mp 91° (83.5% yield as a 1 : 1 adduct). Found: C, 51.34; H, 3.57; N, 7.94; Cl, 9.94; S, 9.14. Calcd for $C_{15}H_{13}O_4N_2ClS$: C, 51.06; H, 3.72; N, 7.95; Cl, 10.06; S, 9.09. NMR ($CDCl_3$) δ 1.63 (3H, d, J=7 Hz, CH_3), 3.95 (1H, double quartet, J=7 and 8 Hz, S-CH-Me), 5.0 (1H, d, J=8 Hz, Ph-CH-Cl), 7.17—7.36 (5H, m, C_6H_5), 7.5—8.78 (3H, m, $C_6H_3(NO_2)_2$). By comparing the spectrum with those of related compounds,[9,10] the adduct was assigned to be *erythro*-1-phenyl-1-chloro-2-(2,4-dinitrophenylthio)propane.

*Reaction of **1** with **2c**.* The reaction product was obtained in the same way as in the case of **2t**. One to one adducts were isolated in *ca.* 80% yield. NMR spectrum in $CDCl_3$ showed that the product is a mixture of isomers. Two doublet signals were observed at δ=1.47 and 1.71 in an integral ratio of 7 : 3. They were attributed to the methyl groups of the *thero*-Markownikoff (δ 1.47) and the *threo*-anti-Markownikoff (δ=1.71) adducts, respectively.

Separation of isomers was carried out by liquid chromatography with silica gel column using ethanol as eluent. The Markownikoff adduct was obtained in 65% yield as yellow needles melting at 113.5 °C. Found: C, 50.95; H, 3.54; N, 8.03; Cl, 9.90; S, 9.18%. Calcd for $C_{15}H_{11}O_4N_2ClS$: C, 50.99; H, 3.68; N, 7.93; Cl, 10.21; S, 9.08%. NMR ($CDCl_3$) δ 1.47 (3H, d, J=6 Hz, CH_3), 4.10 (1H, m, Me-CH) 5.09 (1H, d, J=5 Hz, CHCl), ~7.40 (5H, m, C_6H_5), 7.56 (1H, d, J=8 Hz, 6-H of $C_6H_3(NO_2)_2$), 8.32 (1H, dd, J=8 and 2 Hz, 5-H of $C_6H_3(NO_2)_2$), 8.97 (1H, d, J=2 Hz, 3-H of $C_6H_3(NO_2)_2$).

Kinetic Measurements were made by essentially the same method as used by Orr and Kharasch.[2] Stock solutions of **1** and unsaturated compounds were respectively prepared by dissolving weighed amounts of freshly purified materials in the desired volume of dry acetic acid at the temperature of each run.

Total Syntheses of Holomycin, Thiolutin, and Aureothricin

Katsuaki HAGIO and Naoto YONEDA

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka 532

(Received November 9, 1973)

The reactions of 4-benzylthio-5-benzylthiomethyl-3-hydroxy-2-oxo-2,5-dihydrofuran with ammonia and primary amines gave 3-amino-4-benzylthio-5-benzylthiomethyl-3-pyrrolin-2-one derivatives. 3-Acylamino-4-benzylthio-5-benzylthiomethylene-3-pyrrolin-2-one derivatives, including the intermediate of the synthesis of holomycin by Büchi, were prepared by the treatment of the 3-acylaminolactams derived from the 3-aminolactams with chloranil or DDQ. Thiolutin and aureothricin were also synthesized from 3-acetamido- and 3-propionamido-4-benzylthio-5-benzylthiomethylene-1-methyl-3-pyrrolin-2-one respectively.

Holomycin (**1**),[1] thiolutin (**2**),[2] aureothricin (**3**),[2] and isobutyropyrrothine (**4**)[3] are antibiotics produced by certain *Streptomyces* species. Their structures have been shown by degradative studies to have pyrrolinonodithiole nucleus.[1,2] Furthermore, two antibiotics (**5** and **6**) bearing a formamide group at the side chain were also isolated.[4] These substances are effective against Gram-positive and Gram-negative bacteria, fungi, and ameboid parasites. The total syntheses of **1** and **2** was first reported by Schmidt and Geiger.[5] Somewhat later, an alternate total synthesis of **1** was presented by Büchi and Lukas.[6]

Scheme 1.

In the course of studies of the sulfonium ylides, we have developed a synthesis of a new lactone, 4-benzylthio-5-benzylthiomethyl-3-hydroxy-2-oxo-2,5-dihydrofuran (**7**), which is expected to be a useful intermediate for the synthesis of **1**—**3**.[7] This paper will describe how a new route for the synthesis of **1**—**3** was successfully established in three stages from **7**; this route involves the formation of five-membered lactams, dehydrogenation, and the final ring closure to the desired antibiotics.

Formation of Five-membered Lactams. The reaction of **7** with methylamine and acetic acid in refluxing ethanol gave 4-benzylthio-5-benzylthiomethyl-1-methyl-3-methylamino-3-pyrrolin-2-one (**9**) (mp 106—108 °C), which was then purified by a chromatographic separation on silica gel G. The IR spectrum showed absorptions at 3310, 1693, and 1645 cm^{-1} due to NH stretching, five-membered lactam carbonyl, and a double bond respectively. The NMR spectrum ($CDCl_3$) exhibited signals at δ 2.80 (3H, s, N-CH_3), 2.90 (2H, m, the methylene protons attached to C_5), 2.93 (3H, s, N-CH_3), 3.65 (1H, m, the methine proton at C_5), 3.64 (2H, s, S-CH_2-Ph), 3.68 (2H, s, S-CH_2-Ph), 3.9—4.6 (1H, D_2O-exchangeable, NH), 7.21 and 7.29 (two phenyl groups). By the reaction of **7** with methylamine in water or ethanol in a sealed tube at 80 °C, **9** was also obtained in a comparable yield. The prolonged reaction in the absence of acetic acid resulted in the decomposition of **7**. Similarly, 3-aminolactams (**8** and **10**—**13**) were synthesized from **7** (see Table 1).

However, the attempted isolation of 3-aminolactone (**14**), another product anticipated in this reaction, was unsuccessful.[8]

Contrary to ordinary methods for the transformation of lactones into lactams, the formation of 3-aminolactams (**8**—**13**) from **7** proceeded under relatively mild conditions. The low yield in the reaction with *p*-toluidine may be due to the low basicity or the steric

hindrance.

The treatment of **9** with hydrochloric acid in boiling ethanol afforded 4-benzylthio-5-benzylthiomethyl-3-hydroxy-3-pyrrolin-2-one (**16**) as colorless needles (mp 123—124 °C); they turned blue with ferric chloride. Under similar conditions, 3-aminolactams (**8** and **10**—**13**) were converted readily into the corresponding 3-hydroxy derivatives in good yields.

3-Hydroxy lactam (**16**) was refluxed in ethanol with ammonium acetate to give 3-amino-4-benzylthio-5-benzylthiomethyl-1-methyl-3-pyrrolin-2-one (**22**) in an 84% yield; the substance turned violet upon treatment with ninhydrin. Analogous reactions of 3-hydroxy derivatives yielded the corresponding 3-aminolactams.

Thus, the introduction of the desired substituents of 3-amino group was achieved through the hydrolysis of 3-aminolactams, followed by the condensation of the resulting 3-hydroxylactams with appropriate amines.

In contrast to the assumption that the reactivity of the 3-amino group in a conjugated system would be low, the acylation of the 3-aminolactams proceeded easily, yielding the acyl derivatives. The treatment of **22** with acetic anhydride in boiling benzene furnished 3-acetamido-4-benzylthio-5-benzylthiomethyl-1-methyl-3-pyrrolin-2-one (**25**) in an 86% yield (mp 140—142 °C). By a similar treatment of 3-aminolactams, several 3-acylamino derivatives were obtained in good yields.

Dehydrogenation. The reaction of **24** with chloranil and DDQ in refluxing benzene afforded the dehydrogenated product (**30**) as yellow needles (mp 178—179 °C) in 63 and 67% yields respectively. The melting point and the spectral properties were consistent with those of 3-acetamido-4-benzylthio-5-benzylthiomethylene-3-pyrrolin-2-one, as reported by Büchi[6] in his holomycin synthesis. On the contrary, the reaction with thionyl chloride, which had been successfully used by Büchi[6] for the dehydrogenation of the side chain of 3-acetyl-4-hydroxy-5-benzylthiomethyl-3-pyrrolin-2-one, gave **30** only in a 7% yield. The resulting product in both the reactions was a single isomer, though its geometric configuration was not clarified.

The dehydrogenation of **26** with chloranil or DDQ in boiling benzene or *t*-butyl alcohol gave a mixture of *cis* and *trans* isomers (**32a** and **32b**) as yellow microcrystals (mp 120—125 °C). Separation by preparative thin-layer chromatography on silica gel G gave **32a** (mp 154—156 °C) and **32b** (mp 128—129 °C). On the basis of the elemental analyses and spectral data (see Table 3), both of them were confirmed to be the geometric isomers with an exocyclic methylene group. Considering the deshielding effect of the phenyl groups, the lower-shifted signals of the vinylic proton and the *N*-methyl protons in the NMR spectrum of **32b** suggest that both the benzylthio groups are *trans*. From the peak areas of the vinylic and *N*-methyl protons, **32** was found to be a mixture of *cis* and *trans* isomers in the ratio of 1 : 5.

Although the interconversion of **32a** and **32b** was attempted under various conditions, no useful method for the isomerization was obtained.

Under similar conditions, **31** and **33** were obtained in good yields as mixtures of geometric isomers (see Table 2). The mixture (**31**) was treated by preparative thin-layer chromatography (silica gel G) to separate the *cis* and *trans* isomers, but attempts to sepearte

the isomers (**33**) were unsuccessful.

The dehydrogenation of **28** yielded one (**34**) of the isomers, though its geometric configuration remained unclear.

Together with the interconversion between 3-aminolactams (*e. g.* **9** and **22**), the success in the dehydrogenation of the side chain with chloranil or DDQ made this synthetic line an advantageous method.

Debenzylation and Ring Closure. At the final stage of the synthesis, the reductive debenzylation of both benzylthio groups was carried out by a slight modification of Büchi's method[6] using 4 equivalent of lithium in liquid ammonia. The subsequent air-oxidation of the crude dithiol (**35**) thus obtained in aqueous methanol at pH 2 afforded aureothricin (**3**) as yellow needles (mp 260—270 °C (dec)). The similar treatment of **31** gave thiolutin (**2**) (mp 270—275 °C (dec)). The NMR spectra of **2** and **3** were consistent with the structural assignment made. The IR, UV spectra, and the thin-layer chromatographic behavior were identical with those of the natural antibiotics.

Experimental

All the melting points are uncorrected. The IR spectra were obtained on a Shimadzu IR-27G spectrophotometer. The NMR spectra were recorded on a Hitachi R-20A instrument, using TMS as the internal standard. The UV spectra were determined with a Hitachi EPS-3F spectrophotometer. The elemental analyses of the new compounds are listed in Table 8.

Preparation of 3-Amino-4-benzylthio-5-benzylthiomethyl-3-pyrrolin-2-one Derivatives (8-13). The reactions were achieved in the following two fashions. The results and spectral data are listed in Tables 1 and 4 respectively.

a) By Reaction in the Presence of Acetic Acid: To a cooled solution of **7** (10.0 g) and methylamine (8.5 g) in ethanol (50 ml) was added acetic acid (16 ml) with stirring. After refluxing for 2 hr, the reaction mixture was evaporated and the residue was extracted with ethyl acetate. The extract was washed with 1% hydrochloric acid, with a 5% sodium bicarbonate solution, and with water, and then dried over sodium sulfate. After the removal of the solvent, the tarry residue was chromatographed on silica gel G, using chloroform as the eluent, to give 4.10 g (38%) of **9** as colorless needles, (mp 106—108 °C); it was subsequently recrystallized from 2-propanol.

b) By Reaction in the Absence of Acetic Acid: A solution of **7** (3.58 g) and methylamine (0.93 g) in water (5 ml) was heated in a sealed tube for 30 min and then poured into water. The mixture was extracted with ethyl acetate, and the organic layer was worked up to afford 1.20 g (31%) of **9** by a procedure similar to that described above.

Hydrolysis of 3-Aminolactams. A solution of **9** (1.50 g) in ethanol (25 ml) was refluxed with 10% hydrochloric acid (5 ml) for 1 hr and then evaporated. The residue was extracted with ethyl acetate, and the extract was washed with water, dried over sodium sulfate, and evaporated. The recrystallization of the residue from 2-propanol gave 1.41 g (96%) of **16** as colorless needles (mp 123—124 °C).

In a similar manner, **8** and **10—13** were treated with hydrochloric acid to afford hydrolysis products: **15**, 71%, yellow syrup; **17**, 64%, mp 96—98 °C; **18**, 94%, mp 128—129 °C; **19**, 71%, mp 130—131 °C; **20**, 83%, mp 129—130 °C. The spectral data are shown in Table 5.

Conversion of 3-Hydroxylactams into 3-Aminolactams. a) By Reaction with Ammonium Acetate: A solution of **16** (4.14 g) and ammonium acetate (4.0 g) in ethanol (50 ml) was refluxed for 2 hr and then evaporated to give a syrup, which was subsequently extracted with ether. The extract was washed with water, dried and evaporated to dryness. The addition of cyclohexane to the residue, followed by recrystallization from isopropyl ether, afforded 3.05 g (84%) of **22** as colorless needles (mp 69—71 °C). The product gave a violet color with ninhydrin.

Similarly, **18** reacted with ammonium acetate to furnish **23** (mp 66—67 °C) in an 81% yield.

29	1695, 1670	2.18(3H, s), 2.75(2H, d), 3.4—3.8(2H, m), 3.57(2H, s), 3.63(2H, s), 4.99(2H, s), 5.08(1H, d), 6.6—7.5(20H, m)

a) Measured as a film. b) Sh, shoulder absorption. c) D_2O-exchangeable peak.

b) By Reaction with Primary Amines: A solution of **18** (500 mg) and benzylamine (655 mg) in benzene (6 ml) was refluxed for 5 hr. After cooling, the reaction mixture was washed with 1% hydrochloric acid and with water, and dried. The removal of the solvent gave **11** (570 mg, 78%) (mp 121—122 °C), which was subsequently recrystallized from ethanol. In this way, **15** was allowed to react with *p*-toluidine for 7 hr to afford **21** as colorless needles in a 23% yield (mp 110—111 °C).

The spectral data are shown in Table 4.

*Preparation of 3-Acylamino-3-pyrrolin-2-one Derivatives. a) Preparation of **24***: A solution of **8** (2.12 g) and acetic anhydride (6 ml) in benzene (20 ml) was refluxed for 2 hr and evaporated to dryness. The residue was extracted with ethyl acetate, and the extract was washed with a 5% sodium bicarbonate solution and with water, and dried. The removal of the solvent left a syrup; this syrup was then chromatographed over silica gel G, using benzene–ethyl acetate (4 : 1) as the eluent, to give 1.33 g (56%) of **24** as a pale yellow syrup. The structure of **24** was confirmed by the spectral properties shown in Table 6.

*b) Preparation of **25**—**27** and **29***: A solution of **22** (2.92 g) and acetic anhydride (6 ml) in benzene (20 ml) was refluxed for 2 hr and then evaporated to give a syrup, which was subsequently crystallized by the addition of ether. Filtration and recrystallization from ethanol afforded 2.78 g (86%) of **25** as colorless needles (mp 140—142 °C). By the procedure described above, **26** (72%, mp 142—144 °C), **27** (88%, mp 128—129 °C), and **29** (88%, mp 95—96 °C) were obtained. The spectral data are listed in Table 6.

*c) Preparation of **28***: A solution of **23** (1.0 g) and benzoyl chloride (1.0 g) in benzene (5 ml) was stirred for 2 hr at room temperature. By the procedure described in the preparation of **24**, the resulting reaction mixture afforded 0.87 g (71%) of **28** as a pale yellow syrup. The structural assignment was made on the basis of spectral properties shown in Table 6.

Dehydrogenations of 3-Acylamino-5-benzylthiomethyl-3-pyrrolin-2-one Derivatives. a) With Chloranil or DDQ: A solution of **24** (0.63 g, 1.6 mmol) and chloranil (0.43 g, 1.8 mmol) in benzene (6 ml) was refluxed for 30 min and then diluted with methylene chloride. The solution was washed with 1% aqueous sodium hydroxide and with water, and dried. The removal of the solvent and recrystallization of the residue from ethanol gave 0.39 g (62%) of **30** as pale yellow needles: mp 178—179 °C; λ_{max}^{EtOH} 361 nm (ε 23500); M^+ ion at *m/e* 396. The IR and NMR spectra shown in Table 7 were consistent with the published data.[6] When DDQ was employed, **24** (0.40 g) yielded 0.27 g (67%) of **30**.

Similarly, **25**—**28** were treated with chloranil or DDQ to afford the corresponding exocyclic methlene compounds (**31**—**34**). The reactions in *t*-butanol also gave the dehydrogenated products in yields comparable to those in benzene. The results and the spectral properties are shown in Tables 2 and 7.

b) With Thionyl Chloride: Thionyl chloride (0.32 g, 3.8 mmol) was added to a cooled solution of **24** (1.50 g, 3.8 mmol) in chloroform (15 ml) with stirring. The resulting dark solution was allowed to stand overnight, and then washed with water and dried. After the evaporation of the solvent, the residue was chromatographed on silica gel G, using benzene–ethyl acetate (1 : 1) as the eluent, to give 103 mg (7%) of **30**. The reaction of 1-substituted lactams (**25**—**28**) with thionyl chloride led to the formation of unidentified products.

Separation of Geometric Isomers. The mixture (**32**, 500 mg) was treated by thin-layer chromatography (benzene–ethyl acetate, 1 : 1 on silica gel G) to give **32a** (70 mg, yellow leaflets) and **32b** (255 mg, yellow needles), which were recrystallized from 2-propanol. Similarly, the mixture (**31**, 300 mg) was separated into **31a** (60 mg, yellow leaflets) and **31b** (145 mg, yellow needles). The spectral properties are shown in Table 3.

*Thiolutin (**2**) and Aureothricin (**3**).* A solution of **31** (215 mg, 0.53 mmol) in tetrahydrofuran (2 ml) was introduced to liquid ammonia (20 ml). To the solution was added small pieces of lithium (15 mg, 2.2 mg. atom) with vigorous stirring. After 5 min, ammonium chloride (0.2 g) was added to the resulting orange-colored suspension. Evaporation left a yellow solid which was subsequently dissolved in methanol (20 ml). The solution was adjusted to pH 2 with 10% hydrochloric acid. After air was bubbled through the solution for 3 hr, evaporation gave a solid which was chromatographed on alumina, using chloroform–ethyl acetate (4 : 1), to give a yellow powder. Recrystallization from *n*-butanol afforded 13 mg (11%) of thiolutin (**2**) as yellow needles: mp 270—275 °C (dec); IR (KBr) 3270, 3060, 1670, 1640, 1605, 1550, 1235, 825 and 740 cm^{-1}; λ_{max}^{MeOH} 250, 312, 390 nm (6200, 5200, 11100); NMR (DMSO-d_6) δ

34	$C_{33}H_{28}N_2O_2S_2$	72.23	5.14	5.10	11.68	71.96	5.29	5.07	11.62

2.05 (3H, s), 3.92 (3H, s), 7.19 (1H, s) and 9.85 (1H, broad s).

By a similar procedure, **32** (1.04 g) yielded 37 mg (6%) of aureothricin (**3**) as yellow needles: mp 260—270 °C (dec); IR (KBr) 3250, 3050, 1670, 1640, 1605, 1545, 1230, 815 and 730 cm^{-1}; λ_{max}^{MeOH} 246, 313, 390 nm (6300, 4000, 11100); NMR (DMSO-d_6) δ 1.02 (3H, t), 2.40 (2H, q), 3.25 (3H, s), 7.28 (1H, s) and 9.8 (1H, broad s).

Both substances showed no depression on a mixed-melting-point determination with an authentic sample. The IR, UV spectra, and the thin-layer chromatographic behavior on silica gel G and alumina using benzene–ethyl acetate (1 : 1), benzene–methanol (9 : 1) and chloroform–ethyl acetate (4 : 1) could not distinguish between the synthetic and natural antibiotics (**2** and **3**).

The authors wish to thank Professor Teruaki Mukaiyama and Associate professor Hisashi Takei for their valuable suggestions. They also thank Director Dr. Ichiro Chibata and Dr. Muneji Miyoshi for their encouragement in this work.

A Polarographic Study of Aryl-substituted Tetra-aza- and Hexa-aza-pentalenes in Dimethylformamide

Akira MATSUMOTO, Joung Hee LEE, Masayuki YOSHIDA, and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113

(Received November 27, 1973)

The polarographic reduction potentials of aryl-substituted 1,2,4,5-tetra-aza- and 1,2,3,4,5,6-hexa-aza-pentalenes were shown to be approximately governed by the numbers of nitrogen atoms and aryl-substituents. Such effect of nitrogen atoms was discussed in terms of the orbital energies of parent azapentalenes obtained by HMO calculations.

The preparations and properties of aryl-substituted 1,2,4,5-tetra-aza- (I) as well as 1,2,3,4,5,6-hexa-aza- (V–X) pentalenes were described previously,[1,2] and these compounds were shown to be very stable. In the present work the polarographic reduction of a number of 1,2,4,5-tetra-aza- and 1,2,3,4,5,6-hexa-aza-pentalenes (including compounds I and V–X) has been studied to examine any correlation between the half-wave reduction potentials and the chemical properties.

Results and Discussion

Polarograms of polyazapentalenes in dimethylformamide containing tetra-*n*-butylammonium iodide (0.155 M) as supporting electrolyte showed two well-defined reduction waves; polarographic data are given in Table 1. Plots of polarographic potential E *versus* log $[(i_d - i)/i]$ give straight lines with a slope in good agreement with the theoretical value of 0.0585 V at 22 °C according to Heyrovsky and Ilkovic's derivation.[3] This result, therefore, indicates that these reduction waves correspond to reversible one-electron reduction of polyazapentalenes to radical anions.

A plot of the potentials for the first reduction waves ($E_{1/2}$) against the number (N) of aryl-substituents in each molecule (Fig. 1) gives two parallel straight lines, one ($E_{1/2}=0.36\,N\,-2.60$ (V)) for tetra-aza- and the other ($E_{1/2}=0.36\,N\,-1.32$(V)) for hexa-aza-pentalenes. These correlations clearly show that the number of nitrogen atoms in the azapentalene nucleus is important in determining the reduction potential. On the other hand, the fact that the slopes of the straight lines are found identical shows that the effect of an aryl substituent on the potential is additive and the same, giving rise to an elevation by 0.36 V for one substituent, irrespective of the nature of the nucleus. The effects of other factors such as the orientation of substituents or the replacement of a phenyl with a *p*-chlorophenyl group (V–VI) are small in comparison with the above major effects.

—○— Tetra-azapentalenes
—●— Hexa-azapentalenes

The plot corresponding to compound VIII does not fall on the straight line for hexa-azapentalenes; the reason is obviously the difference in the type of electronic structure, because compound VIII is not mesoionic, carrying a methyl and a phenyl group at positions 1 and 5, respectively, while the other hexa-azapentalenes examined are mesoionic carrying substituents at positions 2 and 5.

As regards the regression line for tetra-azapentalenes,

a) Values of only k_m's are shown. b) Occupied levels are distinguished from unoccupied ones by underline.

the correlation can not be regarded as excellent, as is apparent, for example, from the discrepancy between the plots for compounds III and IV. This is probably because the type of electronic structure may be slightly different in the compounds examined, the orientations of the four substituent groups being different except between compounds II and III, and furthermore, compound I is mesoionic.

If a straight line is drawn through the two points representing compounds II and III, the slope will be decreased to 0.24 V/N, indicating thus a weaker effect of the aryl substituent in this type of compounds. The reason may be attributable to non-coplanarity of the phenyl group with the azapentalene nucleus owing to the juxtaposition of substituent groups.[4]

The polarographic reduction potentials of aromatic hydrocarbons are known to be correlated linearly with the energy of their lowest vacant molecular orbitals as calculated by the simple HMO method.[5] This is found to be the case also with 2,5-disubstituted hexa-azapentalenes as is shown in Fig. 2. In the present calculations, aryl substituents were thought

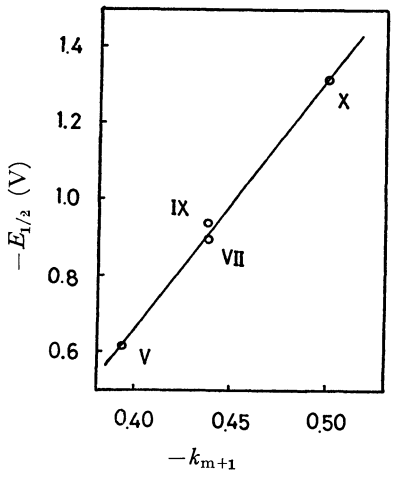

Fig. 2. Half-wave reduction potentials for hexa-azapentalenes in dimethylformamide *versus* energies of lowest vacant orbitals.
The axis of abscissa shows energy in terms of coefficient k_{m+1} in energy expression $E_{m+1}=\alpha+k_{m+1}\beta$ of lowest vacant orbital.[7]

to be coplanar with the hexa-azapentalene nucleus, as is supported by UV and NMR spectroscopic measurements.[6]

Hückel molecular orbital calculations were also carried out for some mesoionic azapentalene parent rings[7] in order to compare the effect of the number and positions of nitrogen atoms on the π-electron energy with that on the chemical behaviour. The results are summarized in Table 2. 2,5-Diaza- (XI) and 3a,6a-diaza- (XII)[8] pentalenes have an occupied non-bonding orbital, and the total π-electron energy is nearly the same for the two rings, but the lowest vacant orbital lies lower in ring XI than in ring XII. Introduction of two nitrogen atoms into these diazapentalenes to give 1,2,4,5-tetra-aza-(XIII) and 1,3a,4,6a-tetra-aza-(XIV) pentalenes results in lowering of the energies of all the orbitals, but again the energy of the highest occupied orbital and the total π-electron energy are nearly the same for (XIII) and (XIV), and the energy of the lowest vacant orbital of (XIII) is lower than that of (XIV). Introduction of two more nitrogen atoms into XIII to give 1,2,3,4,5,6-hexa-azapentalene (XV) causes further decrease in the energy of each of the molecular orbitals and hence in the total energy.

Thus, in the series of the azapentalenes, XI, XIII, and XV, the effect of the number of nitrogen atoms on the energy of the lowest vacant orbital, to which the polarographic reduction potential should be related, is in harmony with the earlier mentioned result that introduction of two more nitrogen atoms into positions 3 and 6 of the 1,2,4,5-tetra-azapentalene nucleus causes elevation of the reduction potentials by 2.60—1.32=1.28 V.

The HMO calculations also show that the energy of the highest occupied orbital and the stability of azapentalenes as judged by the total π-electron energy seem to be approximately governed by the number of nitrogen atoms, their position in the nucleus exerting insignificant influence.

Irrelevance of the position of nitrogen atoms appears to be the case also with the chemical behaviour relating to the highest occupied orbital; the reactivity of 2,3,5,6-tetra-aryl-1,2,4,5-tetra-azapentalene in reaction such as electrophilic substitution and oxidation parallels closely that reported for dibenzo-1,3a,4,6a-tetra-aza- and dibenzo-1,3a,6,6a-tetra-aza-pentalenes.[4,9]

Comparison of the energy values shown in Table 2 predicts that 1,2,3,4,5,6-hexa-azapentalene (XV) should be subjected to more facile reduction, but not to more facile oxidation than 1,2,4,5-tetra-azapentalene (XIII). This view is supported by the finding that 2,5-diphenyl-1,2,3,4,5,6-hexa-azapentalene (V) is easily reduced by sodium to the corresponding anion radical, but does not undergo any oxidation with potassium permanganate in boiling pyridine, whereas the reverse is the case with the tetra-azapentalene (I).[10]

Experimental

The syntheses of compounds I and V—X were reported previously.[1,2] Non-mesoionic tetra-azapentalenes II—IV are new compounds and their syntheses were reported in a separate paper.[4] Commercial tetra-*n*-butylammonium iodide was twice recrystallized from a mixture of ethanol and ethyl acetate and stored under nitrogen. Dimethylformamide was boiled under reflux with calcium hydride and distilled under nitrogen.

Polarographic measurements were carried out with a Yanagimoto Model P-8 apparatus. The dropping mercury electrode was operated at 60 cm pressure and had a drop-time of 4.36 sec in dimethylformamide (open circuit).

The authors are grateful to Prof. S. Fujiwara and Dr. Y. Umezawa for allowing them to use their polarographic facilities.

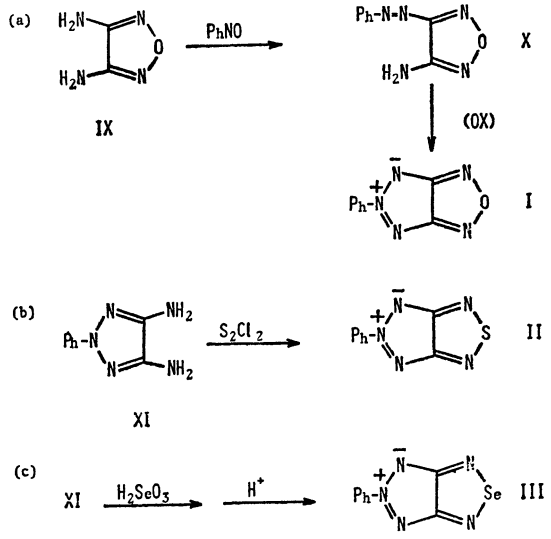
Preparations and Properties of 5-Phenyl-5*H*[1,2,3]-triazolo[4,5-*c*][1,2,5]-oxadiazole, -thiadiazole, and -selenadiazole

Akira MATSUMOTO, Masayuki YOSHIDA, and Osamu SIMAMURA
Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113
(Received November 27, 1973)

The title compounds have been synthesized, and their chemical reactivities and spectroscopic properties are discussed in comparison with those of 2,5-diphenyl-*v*-triazolo[4,5-*d*]-*v*-triazole.

The preparations and properties of some meso-ionic 1,2,4,5-tetra-aza- as well as 1,2,3,4,5,6-hexa-aza-pentalenes were described previously.[1,2] These investigations and a polarographic study of azapentalenes have shown that the major factor affecting the properties of the above polyazapentalenes is the number of nitrogen atoms in the azapentalene nucleus.[3] Thus, it seemed of interest to examine the physical and chemical consequences of replacing one of the nitrogen atoms in the polyazapentalene nucleus with another electronegative atom such as oxygen, sulphur, and selenium. This paper presents the syntheses and properties of a series of new heteropentalenes, 5-phenyl-5*H*[1,2,3]-triazolo[4,5-*c*][1,2,5]-oxadiazole (I), -thiadiazole (II), and -selenadiazole (III), in which a hetero atom at position 2 contributes two π-electrons to the π-electronic system of the nucleus.

The preparative routes to these compounds are summarized in Scheme 1. The details of the synthetic procedures are given in the Experimental Part.



Scheme 1. The Preparative Routes to Heteropentalenes.

The behaviour of these heteropentalenes under oxidizing or reducing conditions is particularly interesting. Whereas 2,3,5,6-tetra-aryl-1,2,4,5-tetra-azapentalenes are readily oxidized or reduced with ring-opening,[1,3] 2,5-diphenyl-hexa-azapentalene (V) is entirely resistant to oxidation and is catalytically hydrogenated to yield products with the azapentalene nucleus being left intact, *viz.*, 2,5-dicyclohexyl-(VIII) and 2-cyclohexyl-5-phenyl-hexa-azapentalene (VI).[2] These results caused us to examine the reactions of the triazolothiadiazole (II) under similar conditions. It was resistant to oxidation with *m*-chloroperoxybenzoic acid in chloroform or with hydrogen peroxide in acetic acid. Heated at 95 °C for 9 hr with potassium permanganate in a mixture of pyridine and water (10 : 1), however, it underwent extensive oxidation giving no isolable compounds. On the other hand, the triazolothiadiazole (II) was not hydrogenated at 1 atm of hydrogen with platinum catalyst under acidic conditions. Possible poisoning of the catalyst by the sulphur-containing substrate was suspected, but an excess of catalyst did not effect the reduction. However, reduction with lithium aluminium hydride in tetrahydrofuran occurred readily at room temperature, giving 4,5-diamino-2-phenyl-*v*-triazole (XI) in 90% yield.

The triazolooxadiazole (I) was resistant to attack by *m*-chloroperoxybenzoic acid, a result not unexpected in view of the stability of II described above.

The ultraviolet and NMR spectral characteristics and the half-wave reduction potentials of these heteropentalenes (I–III) as well as those of phenyl-substituted hexa-azapentalenes (IV–VII) are listed in Tables 1 and 2. All of these compounds exhibit two ultraviolet absorption maxima without vibrational structure. It is noteworthy that the absorption peaks of compounds I, II, and and III show an appreciable shift to longer wavelength regions according as the atom at position 2 varies from O to S to Se; this effect is particularly pronounced with the maxima of the longer wavelength. Obviously, electronic conjugation occurs between the nitrogen-containing system and the hetero atom at position 2.

In view of the apparent similarity in reactivity observed between compounds II and V, the polarographic reduction of these compounds was examined. As shown in Table 2, the half-wave potentials of compounds II and III are strikingly higher than those of the hexa-azapentalenes, IV–VII. Apparently, the difference is attributable to the effect of a sulphur or selenium atom present in the nucleus in place of a nitrogen, although

nitrogen is more electronegative than sulphur.[4]

In these phenyl-substituted heteropentalenes, the phenyl group may be regarded as almost coplanar with the bicyclic nucleus, since large bathochromic shifts are observed in the ultraviolet absorption spectra of phenyl substituted hexa-azapentalenes when compared to those of the corresponding cyclohexyl derivatives.[2] This conclusion is further supported by the fact, shown in Table 2, that the NMR signals of the *ortho*-protons of the substituent phenyl group occur in lower field regions than those of the *meta*- and *para*-protons. Finar and Rackham attributed similar deshielding observed with 1-phenyl-substituted aza-aromatic compounds such as 1-phenylpyrazole to the interaction due to a large electric field associated with the lone pair of electrons of the nitrogen atom at position 2, this effect being operative only when both rings are coplanar.[5] Thus, the large difference in chemical shift (0.81—0.93 ppm) between the *o*-protons and the *m*- and *p*-protons in 5-phenyl heteropentalenes (I–VII, Table 2) can be attributed to the coplanarity of the phenyl-substituent and the presence of two lone pairs at 4- and 6-positions. Similar strong deshielding was observed with the NMR spectrum of 2-phenyl-*s*-triazolo[1,5-*a*]pyridine.[6]

Experimental

3-Amino-4-phenylazo-1,2,5-oxadiazole (X). 3,4-Diamino-1,2,5-oxadiazole (IX)[7] (2.9 g, 29 mmol) was suspended in a mixture of aqueous sodium hydroxide (50%, 60 ml) and benzene (2 ml). Nitrosobenzene (3.1 g, 29 mmol) was added in small portions to the stirred mixture kept at 60 °C over a period of 7 min, and the mixture was stirred for an additional 7 min. The solution was poured onto *ca.* 500 ml of ice-water, and the orange solid deposited was collected by filtration, washed with water, and recrystallized from benzene to give 1.5 g (27%) of X as orange crystals, mp 172.4—174.0 °C (Found: C, 50.61; H, 3.81; N, 37.07%. Calcd for $C_8H_7N_5O$: C, 50.79; H, 3.73; N, 37.02%), ν_{max} (Nujol) 3450, 3300, 1610, 1020, 770, 735, and 680 cm^{-1}, *m/e* 189 (M^+, 29%), 105(20), 91(3), 78(10), and 77(100).

5-Phenyl-5H[1,2,3]-triazolo[4,5-c][1,2,5]oxadiazole (I). 3-Amino-4-phenylazo-1,2,5-oxadiazole (X) (1.1 g, 58 mmol) was heated under reflux with 3.5 g of lead tetraacetate in 50 ml of benzene for 23 hr. After filtration of insoluble solid and evaporation of the solvent, the residue was eluted through a column of silica-gel (Wakogel C-200) with benzene. The solvent was evaporated from the eluate, and the residue recrystallized first from benzene and then from ethanol (with active charcoal) yielded 0.3 g (28%) of the triazolooxadiazole (I) as yellow crystals, mp 165.5—166.5 °C (Found: C, 51.59; H, 2.44; N, 37.59%. Calcd for $C_8H_5N_5O$: C, 51.34; H, 2.69; N, 37.42%), ν_{max} (Nujol) 1580, 1300, 1185, 1110, 1070, 930, 830, 800, 765, and 670 cm^{-1}, *m/e* 187 (M^+, 27%), 131(6), 105(13), 78(11), 77(100), and 51(33).

5-Phenyl-5H[1,2,3]-triazolo[4,5-c][1,2,5]thiadiazole (II). To a mixture of 0.57 g (3.3 mmol) of 4,5-diamino-2-phenyl-*v*-triazole[8] (XI) and 14 ml of benzene was slowly added 0.88 g (6.6 mmol) of sulphur monochloride to give a dark violet solution. The mixture was heated under reflux for 18 hr and the solvent was evaporated, yielding a brownish black solid mixture. Column chromatography on silica-gel (Wakogel C-200) in benzene gave a yellowish crystalline mixture containing sulphur. The mixture was freed from sulphur by percolating a dilute benzene solution of the mixture through a chromatographic tube packed with copper powder treated with 30% sulphuric acid at room temperature. Evaporation of the solution and recrystallization of the residue from benzene gave 0.26 g (38%) of the triazolothiadiazole (II) as yellow crystals, mp 181.0—182.5 °C (Found: C, 47.44; H, 2.21; N, 34.72%. Calcd for $C_8H_5N_5S$: C, 47.28; H, 2.48; N, 34.46%), ν_{max} (KBr) 1610, 1480, 1450, 1290, 1180, 1095, 1065, 915, 855, 800, 760, 680, and 660 cm^{-1}, *m/e* 203(M^+, 50%), 105(7), 78(5), and 77(100).

5-Phenyl-5H[1,2,3]-triazolo[4,5-c][1,2,5]selenadiazole (III). To a solution of 3.4 g (19 mmol) of 4,5-diamino-2-phenyl-*v*-triazole (XI) in 75 ml of ethanol was added 2.75 g (21 mmol) of selenous acid.[9] The solution was kept at 40 °C for 10 hr, giving black precipitate. The precipitate was collected by filtration, washed with water and then added to a mixture of 50 ml of benzene and 5 ml of concd hydrochloric acid in 100 ml of water. The mixture was heated under reflux for 4 hr, and the resulting yellow benzene layer was separated and replaced with 50 ml of fresh benzene. Heating and separation in the same way were repeated additional three times each with addition of 50 ml of benzene, and the combined benzene solutions (200 ml), on evaporation, gave 0.6 g of dark-red crystals. Recrystallization from benzene and column chromatography on silica-gel (Wakogel C-200) in benzene gave 0.35 g (7.2%) of the triazoloselenadiazole as yellow crystals, mp 203.8—204.5 °C (Found: C, 38.56; H, 2.01; N, 28.04%. Calcd for $C_8H_5N_5Se$: C, 38.42; H, 2.02; N, 28.00%), ν_{max} (Nujol) 1330, 1290, 1190, 1095, 1070, 925, 770, 750, 680, and 670 cm^{-1}, *m/e* 251 (M^+, 12%), 105(20), 78(13), 77(100), and isotopic peaks (due to the isotopes of selenium) at 253, 249, 248, and 247.

Oxidation of 5-Phenyl-5H[1,2,3]-triazolo[4,5-c][1,2,5]thiadiazole (II). *(a) With m-Chloroperoxybenzoic Acid*: Phenyltriazolothiadiazole (II) (0.102 g, 0.50 mmol) was refluxed with *m*-chloroperoxybenzoic acid (0.42 g, 2.44 mmol in 40 ml of of dichloromethane) for 18 hr. Acidic matter was removed with aqueous sodium carbonate solution and the residual solution was dried (Na_2SO_4). Removal of dichloromethane left 0.082 g (80%) of the starting material.

(b) With Hydrogen Peroxide: A mixture of 0.086 g (0.42 mmol) of II, 13 ml of hydrogen peroxide (30%), 1 ml of diluted sulphuric acid (1%), 30 ml of acetic acid, and 10 ml

of chloroform was heated at 60 °C for 20.5 hr. The mixture was neutralized with dilute sodium carbonate solution and the chloroform layer was separated, which, on evaporation, gave back 0.081 g of the starting material.

(c) With Potassium Permanganate: A mixture of 0.103 g (0.51 mmol) of II, 0.1 g of potassium permanganate and 0.50 ml of water in 5 ml of pyridine was stirred at 95 °C for 1.5 hr. Stirring was continued for a further 2 hr at 95 °C with an additional 0.1 g of potassium permanganate, but most of compound II remained unoxidized. The oxidation was complete after further heating for 5 hr with an additional 0.2 g of the oxidizing agent. The manganese dioxide was removed by filtration and the filtrate was concentrated to give only a trace amount of reddish black tarry matter.

*Reduction of 5-Phenyl-5*H[*1,2,3*]-*triazolo*[*4,5*-c][*1,2,5*]*thiadiazole (II).* *(a) Catalytic Hydrogenation*: The phenyltriazolothiadiazole (II) (0.506 g, 2.4 mmol) in 30 ml of dioxane was hydrogenated with 0.106 g of platinum oxide catalyst at 1 atm of hydrogen for 5 days. The starting material was recovered (91%) from the reaction mixture.

(b) With Lithium Aluminium Hydride (LAH): A mixture of 0.46 g (2.2 mmol) of II and 0.1 g of LAH in 30 ml of anhydrous tetrahydrofuran was stirred for 18 hr at room temperature, followed by heating under reflux for 4.3 hr with an additional 0.2 g of LAH. Water (2 ml) was added carefully to the mixture and the solvent was removed under reduced pressure. Organic products were extracted with ethanol and evaporation of the solvent from the extract gave 4,5-diamino-2-phenyl-*v*-triazole (XI) in 90% yield.

Polarographic Measurements. Polarographic measurements of the heteropentalenes (I, II, and III) were carried out in a similar manner to that described in the literature.[10] No distinct polarogram was obtained for compound I.

Formation and Conformation of Benzoyloxylated Sulfur-containing Heterocycles

Tadashi SUGAWARA, Hiizu IWAMURA, and Michinori ŌKI
Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113
(Received December 18, 1973)

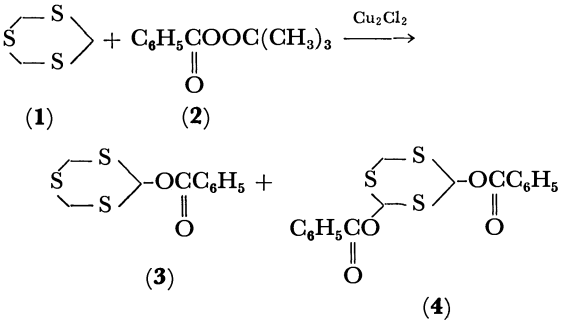
Thiane, 1,3-dithiane, and 1,3,5-trithiane were treated with *t*-butyl peroxybenzoate in the presence of cuprous chloride to yield benzoyloxylated products. Methylenes placed between two sulfur atoms were found to be more reactive than those next to one sulfur atom. Introduction of two benzoyloxy groups into 1,3,5-trithiane afforded *cis*-2,4-dibenzoyloxy-1,3,5-trithiane only. PMR spectra of benzoyloxylated products at various temperatures indicate that benzoyloxy-axial conformation is overwhelming for all the compounds investigated.

Some stereospecific reactions of anions derived from dithianes and trithianes have been reported.[1,2] As an extension of these works, it was thought of interest to study the reactions of sulfur-heterocycles taking place *via* carbonium ions. In order to carry out such studies, it is necessary to synthesize sulfur-heterocycles which carry electronegative substituents.

The synthesis of these compounds was found to be tedious halogenation of 1,3,5-trithiane under either basic or neutral conditions gave intractable materials, attempts to introduce a hydroxyl group being unsuccessful. Acyloxylation of ethers and sulfides by peroxy esters with the aid of cuprous salt is known.[3] The reaction should introduce a benzoyloxy group to the sulfur-heterocycles if *t*-butyl peroxybenzoate is used and the products could be used for the nucleophilic reactions. A benzoyloxy group itself is not a good leaving group in solvolytic reactions but the presence of sulfur atoms may enhance the reactivity of the compound. This paper concerns the benzoyloxylation of thiane, 1,3-dithiane, and 1,3,5-trithiane, the stereoselectivity of the reaction, and the conformation of the products.

Results and Discussion

Benzoyloxylation and Stereoselectivity. When 1,3,5-trithiane (**1**) was treated with *t*-butyl peroxybenzoate (**2**) in benzene, the number of benzoyloxy groups introduced into the trithiane skeleton was found to depend on the molar ratio of **1** to **2**. The results are summarized in Table 1.



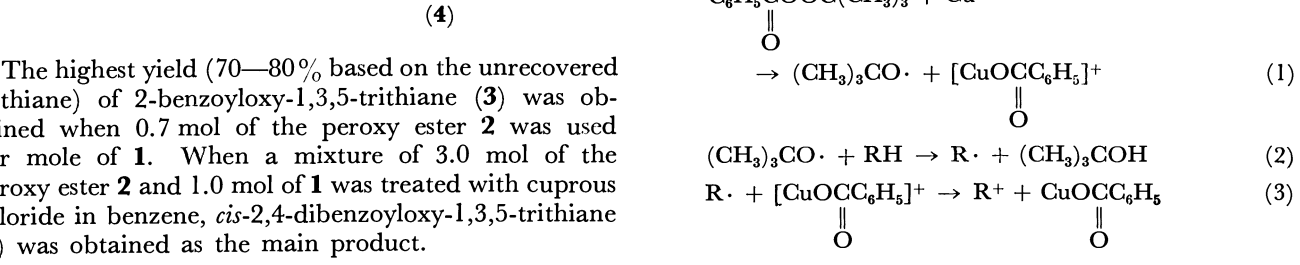
The highest yield (70—80% based on the unrecovered trithiane) of 2-benzoyloxy-1,3,5-trithiane (**3**) was obtained when 0.7 mol of the peroxy ester **2** was used per mole of **1**. When a mixture of 3.0 mol of the peroxy ester **2** and 1.0 mol of **1** was treated with cuprous chloride in benzene, *cis*-2,4-dibenzoyloxy-1,3,5-trithiane (**4**) was obtained as the main product.

TABLE 1. DISTRIBUTION OF PRODUCTS IN THE REACTION BETWEEN *t*-BUTYL PEROXYBENZOATE AND 1,3,5-TRITHIANE OR ITS DERIVATIVES

Substrate	Peroxy ester (mol/mol substrate)	Relative yield including recovery		
		1	**3**	**4**
1	0.5	1.5	1.0	—
1	0.7	0.4_5	1.0	0.1
1	1.0	1.0	1.0	0.25
1	2.0	0.01	1.0	1.5
1	3.0	—	1.0	4.0
3	1.0	—	1.0	1.2

Assignment of the stereochemistry of the product is straight-forward. The PMR spectrum of compound **4** in deuteriochloroform shows a quartet (δ 3.74 and 5.32, J=15.0 Hz) for the ring methylene group, indicating that the two protons are magnetically nonequivalent, and a singlet for the methine protons indicating that they are equivalent. The features are not significantly altered when the solution is cooled to −80 °C. If the compound were of *trans* form, the spectra would show sharp singlets for the methylene and methine protons at room temperature, and two kinds each of methylenes and methines would be observed at low temperatures as bis(phenylthio)trithiane did.[4]

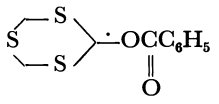
The absence of 2,2-dibenzoyloxy-1,3,5-trithiane or other geminally disubstituted products and the sole formation of the *cis*-disubstituted isomer deserves special attention.[5] Benzoyloxylation with *t*-butyl peroxybenzoate has been extensively studied and the mechanism has been established as follows.[6] **2** is decomposed catalytically by cuprous ion to *t*-butoxy radical and cupric benzoate at the initial step. The *t*-butoxy radical thus formed abstracts a hydrogen from the substrate to form a radical R· and *t*-butyl alcohol. The radical R· is oxidized by cupric ion to the corresponding carbonium ion which then reacts with the benzoate ion to form a benzoate ester.



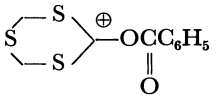
$$R^+ + CuOCC_6H_5 \rightarrow ROCC_6H_5 + Cu^+ \quad (4)$$

Although the rate-determining step is generally step 2, if the free radical formed is reluctant to release an electron, the net reaction would hardly proceed at all.[7] Thus steps 2 and 3 are important in determining whether the reaction occurs easily or with difficulty. The lack of *gem*-dibenzoyloxy compound in the product may be interpreted by assuming either a slow step 2 due to the electron-defficient hydrogen to be removed by an electron-demanding *t*-butoxy radical or a slow step 3 because of the possible instability of a carbonium ion which possesses electronegative substituents. Either case seems possible but we prefer the former for the following reasons.

Firstly, if benzoyloxytrithianyl radical (**5**) is formed easily but step 3 is very slow, **5** may abstract hydrogen from other sources. This indicates that products like **4** have a strong possibility of existing as a *cis-trans* mixture but none of the isomers of **4** was detected.[8] Secondly, the carbonium ion (**6**) to be formed may not be too unstable because of the participation of p-electrons of oxygen and sulfur atoms. Nakai and Okawara reported such stable tri-hetero-substituted carbonium ions.[9]

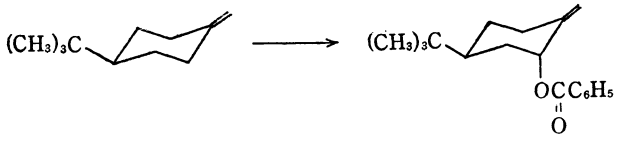


(**5**)



(**6**)

The stereoselectivity of the reaction may be explained on the basis of either thermodynamic or kinetic control. The thermodynamic control of the products cannot be ruled out because of the failure in an equilibration experiment. However, the authors are inclined to consider that the stereoselectivity is of the kinetic origin. The stereospecific formation of 2-methylene-*trans*-5-*t*-butylcyclohexyl benzoate (**8**) is known for the reaction between 4-*t*-butyl-1-methylenecyclohexane (**7**) and *t*-butyl peroxybenzoate and is interpreted by assuming the preferred axial-side attack with the benzoate anion on a carbonium ion produced by the oxidation of the radical.[10]



(**7**) (**8**)

Since the benzoyloxy group in 1,3,5-trithiane takes axial conformation as will be discussed later, the benzoate anion attacking from the axial side should form the *cis*-dibenzoate. It is not yet clear whether the cause for the preferred axial attack is the same in the cases of cyclohexane and trithiane series.

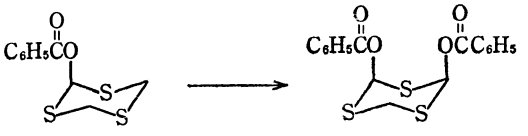


Table 2. Comparison of the reactivities of sulfides toward *t*-butyl peroxybenzoate[a]

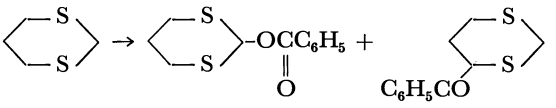
Substrate	Total yields of benzoates (%)	Half-Lives of peroxybenzoate[b] (min)
1	70—80	2
9	70	8
12	50	75

a) Molar ratios were 0.5 and 0.07 for the peroxybenzoate and cuprous chloride, respectively, per mole of substrate. b) The half-lives were determined by iodometric titration.

Reaction of 1,3-dithiane (**9**) and thiane (**12**) with *t*-butyl peroxybenzoate was carried out as in the case of 1,3,5-trithiane. Yields and half-lives of the peroxy ester as revealed by iodometry are summarized in Table 2. It is evident that thiane is the least reactive among the compounds tested, and dithianes and trithianes react more easily. It was also noted that the reaction with thiane gave 15% methyl benzoate and 2—3% biphenyl in contrast to the absence of these by-products in the cases of dithiane and trithiane. This means that the methylene between two sulfur atoms is much more reactive than the others and the following product analysis is consistent with the idea.



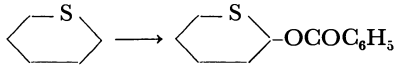
(**9**) (**10**) (**11**)

Since dithiane has three kinds of methylene groups, three kinds of mono-benzoyloxylated products are expected. The structural assignment for the isomers should be easy from the PMR spectra. 2-Benzoyloxy-1,3-dithiane (**10**) was too unstable to be isolated in the air. Thus the reaction mixture was treated with benzenethiol for conversion into 2-phenylthio-1,3-dithiane which was characterized. Identification and estimation of the yields of **10** were performed with a PMR signal at 6.68 ppm which is close to the chemical shift of the methine proton of 2-benzoyloxy-1,3,5-trithiane and thus is assigned to the proton at the foot of the benzoyloxy group. Similarly 4-benzoyloxy-1,3-dithiane was identified by a signal at 6.08 ppm; this chemical shift is close to that of the methine proton of 2-benzoyloxythiane.

The product ratio seems to reflect the reactivities of the methylenes[11] since the reverse of the final reaction, coupling of the ions, is assumed to be very slow. Thus, the relative reactivity of position 2 of 1,3-dithiane is found to be 10.0±1.0 after correction was made as regards the statistical factor, the reactivity of position 4 of 1,3-dithiane being taken as unity and that of 5 practically zero. Thus the methylene between two sulfur atoms is more reactive than the methylene next to one sulfur atom and the methylene beta to a sulfur atom is still less reactive. The smaller half-life of the peroxy ester, when mixed with trithiane, can be attributed to the presence of three methylene groups of the enhanced reactivity.

One of the reaction products from thiane (**12**) and *t*-butyl peroxybenzoate was found to be 2-benzoyloxy-

thiane (**13**) and was purified by chromatography. However, the reaction gave another product which was not identified.



(**12**) (**13**)

Conformation of the Benzoyloxy Derivatives. The PMR spectrum of 2-benzoyloxythiane in carbon tetrachloride showed a near-triplet signal for the methine proton at position 2 at 5.98 ppm from the internal TMS. The half-band width of the signal was 7.2 Hz. These features of a methine proton in six-membered rings are characteristic of equatorially oriented ones.[12] The benzoyloxy group should be axial at least mainly at room temperature. The signal shape of the methine proton, as measured in a mixture of chloroform and carbon disulfide, was not altered even though the temperature was lowered from the ambient to −90 °C. The results are best interpreted by assuming that the conformation of 2-benzoyloxythiane is almost fixed in the benzoyloxy-axial form even at room temperature. No evidence for the presence of the benzoyloxy-equatorial form was obtained even though the spectra were determined in various solvents.

Studies were carried out on the anomeric effect in oxane derivatives. The alkoxy-equatorial form was reported by some authors to be present to the extent of 20—30%[13] but in very small amount by others.[14] The result presented here corresponds to an extreme case even in the oxane series and indicates that no significant difference is caused by replacing an oxygen atom by a sulfur in the heterocyclic system. The only report on the anomeric effect in thiane series also suggests that the alkoxy-axial form is present to the extent of *ca.* 80%.[15]

The PMR spectrum of 2-benzoyloxy-1,3,5-trithiane in deuteriochloroform at 34 °C is shown in Fig. 1 together with an expanded spectrum of the methylene region. The signals at the higher field, assigned to equatorial protons of the methyl groups,[16] appear as triplets with coupling constant of 0.9 Hz and are smaller in height than the counterparts of the AB signal. The phenomenon can be attributed to the W-letter coupling and may be taken as evidence supporting the view that this compound exists solely in the benzoyloxy-axial form, since if the ring were to invert rapidly, the small couplings would have been averaged out to disappear. Another piece of evidence for the assignment of the conformation is obtained by comparing the chemical shifts of the methylene protons: the chemical shift difference, 1.24 ppm, is much greater than that for the methylene protons of 1,3,5-trithiane, 0.76 ppm,[17] and this variation is only explainable by assuming the insertion of an axial benzoyloxy group to trithiane. Thus 2-benzoyloxy-1,3,5-trithiane is seen to exist in the benzoyloxy-axial conformation. The PMR spectrum of this compound in a mixture of deuteriochloroform and acetone-d_6 at −80 °C shows no significant variation from that at room temperature. Thus the conformation of 2-benzoyloxy-1,3,5-trithiane is almost exclusively the benzoyloxy-axial form. No evidence for the presence of the benzoyloxy-equatorial conformation was obtained.

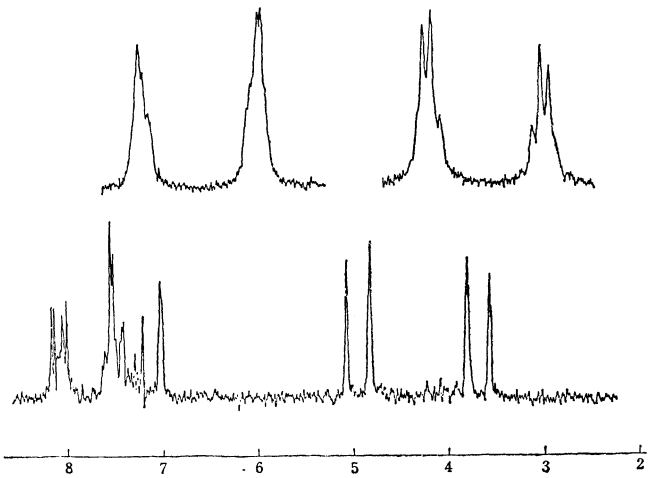


Fig. 1. Below: PMR spectrum of 2-benzoyloxy-1,3,5-trithiane in $CDCl_3$-CS_2 at 34 °C.
Above: Expanded (× 5) spectrum of the AB part for the ring methylenes.

PMR spectra of 2-benzoyloxy-1,3-dithiane in a mixture of deuteriochloroform and carbon disulfide showed a similar feature. A broad signal at 6.68 ppm, assigned to the methine proton at position 2, showed no temperature dependency. The expanded spectrum revealed that the signal was of triplet nature. These results suggest that this compound also exists in the benzoyloxy-axial conformation.

The methine proton signal of 4-benzoyloxy-1,3-dithiane appeared at 6.08 ppm as a near-triplet with a coupling constant of *ca.* 3 Hz and a half-band width of 9 Hz. These results can best be interpreted by assuming the equatorial proton at position 4. This indicates the predominance of the axial benzoyloxy group. The spectral feature was essentially unchanged, though the temperature was lowered to −80 °C.

The PMR spectrum of *cis*-2,4-dibenzoyloxy-1,3,5-trithiane showed similar features to those of the monobenzoyloxy compound. Two signals due to the equatorial proton of the methylene group showed a triplet nature, the coupling constant being estimated to be *ca.* 1 Hz. The spectrum was not significantly altered even at −80 °C. The shape of the signal was practically the same in various solvents. The difference in the chemical shift of the AB protons in deuteriochloroform was 1.58 ppm and greater than that for the methylene protons of 1,3,5-trithiane: compared with the difference between 2-benzoyloxy-1,3,5-trithiane, it almost doubles and the results are expected because two benzoyloxy groups are inserted to trithiane this time. Thus it is concluded that *cis*-2,4-dibenzoyloxy-1,3,5-trithiane exists solely in the benzoyloxy-axial form. The 1,3-diaxial conformation is strongly disfavored in cyclohexane series[18] but, in trithiane series, the diaxial interaction may be relieved to some extent because of the longer distance of the C-S than the C-C and also the strong anomeric effect.[19]

Experimental

Reaction of Cyclic Sulfides with t-Butyl Peroxybenzoate. To a refluxing solution of 0.04 mol of the substrate in 350 ml of anhydrous benzene was added an appropriate amount of a 50 vol% solution of *t*-butyl peroxybenzoate in benzene and 0.05—0.1 equivalent of cuprous chloride. The resulting mixture was heated under nitrogen. The reaction was monitored by checking the decrease in carbonyl absorption of the peroxybenzoate (1760 cm^{-1}) and was stopped when the carbonyl band disappeared. It took about 40 min for trithiane and dithiane, and about 4 hr for thiane. After the mixture had been cooled to room temperature, it was quickly filtered through a potassium carbonate layer to remove the cupric-cuprous salt and acidic materials. Evaporation of the solvent under reduced pressure below 40 °C gave a crude product which was purified by either chromatography or recrystallization.

*2-Benzoyloxy-1,3,5-trithiane (**3**)*, mp 137—138 °C, was best prepared by treating 1,3,5-trithiane with 0.7 molar peroxy ester and was purified by recrystallization from 1 : 1 benzene–hexane. Found: C, 46.49; H, 3.90; S, 37.23%. Calcd for $C_{10}H_{10}O_2S_3$: C, 46.63; H, 3.86; S, 37.06%. IR (Nujol): 1720 cm^{-1}. NMR ($CDCl_3$, δ from TMS): 3.71 and 4.95 (quartet, J=15.0 Hz, 4H), 7.05 (broad singlet, 1H), 7.30—8.20 (multiplet, 5H).

The compound slowly deteriorated in the air unless stored in a desiccator.

cis-*2,4-Dibenzoyloxy-1,3,5-trithiane (**4**)*, mp 156 °C, was best prepared by treating 1,3,5-trithiane with 3 molar peroxy ester and was purified by recrystallization from 7 : 3 benzene–hexane. Found: C, 53.92; H, 3.73%. Calcd for $C_{17}H_{14}O_4S_3$: C, 53.78; H, 3.93. IR (Nujol): 1720 cm^{-1}. NMR ($CDCl_3$, δ from TMS): 3.74 and 5.32 (quartet, J= 15.0 Hz, 2H), 7.17 (broad singlet, 2H), 7.50—8.20 (multiplet, 10H).

*2-Benzoyloxy-1,3-dithiane (**10**)* was found to be labile. It decomposed in the air with a half-life of *ca.* 5 min at 20 °C, unless prevention against moisture was provided. The reaction mixture was therefore treated under a dry atmosphere. 1,3-Dithiane was treated with an equimolar peroxybenzoate and the mixture was treated as above. After evaporation of the solvent, the mixture was heated at 60 °C under 2 mmHg pressure to remove unchanged dithiane as far as possible. Thus **10** with a purity of *ca.* 80% was obtained, the main impurity being 4-benzoyloxy-1,3-dithiane (**11**). IR (neat): 1720 cm^{-1}. NMR(CCl_4, δ from TMS): 2.0—3.6 (multiplet, 6H), 6.68 (broad singlet, 1H), 7.30—8.20 (multiplet, 5H).

*4-Benzoyloxy-1,3-dithiane (**11**)* was obtained as a by-product of the reaction between 1,3-dithiane and the peroxy ester. IR (neat): 1720 cm^{-1}. NMR (CCl_4, δ from TMS): 4.41 and 3.40 (quartet, 2H), 6.01 (triplet, 1H), 7.30—8.20 (multiplet, 5H).

Since both **10** and **11** were unstable compounds, they were converted into phenylthiodithianes for the sake of confirmation by the following procedure. Three molar excess of benzenethiol was added to a freshly prepared solution of benzoyloxylated dithianes in benzene and the mixture was heated at 80 °C for 3 hr. After removal of the solvent, the residue was chromatographed on alumina. 2-Phenylthio-1,3-dithiane, mp 59—60 °C, was eluted with 3 : 7 benzene–hexane and 4-phenylthio-1,3-dithiane, a glass, was eluted with 1 : 1 benzene–hexane. 2-Phenylthio-1,3-dithiane: Found: C, 52.31; H, 5.29; S, 41.87%. 4-Phenylthio-1,3-dithiane: Found: C, 52.86; H, 5.28; S, 41.92%. Calcd for $C_{10}H_{12}S_3$: C, 52.58; H, 5.29; S, 42.11%.

*2-Benzoyloxythiane (**13**)* was obtained as the main product when an equimolar mixture of thiane and the peroxy ester was treated as above. The compound deteriorated unless chromatography was carried out on neutral alumina at low temperature (−4∼−6 °C). Elution with 2 : 8 benzene–hexane gave the desired compound as a colorless oil. IR (neat). 1720 cm^{-1}. NMR (CCl_4, δ from TMS): 5.98 (near triplet, 1H): 1.20—1.35 (multiplet, 8H), 7.20—8.12 (multiplet, 5H).

The compound was unstable and thus was converted into 2-phenylthiothiane, an oil, by the above procedure. The following analytical data were obtained for a substance after purification by chromatography. Found: C, 63.08; H, 6.42; S, 30.33%. Calcd for $C_{11}H_{14}S_2$: C, 62.80; H, 6.71; S, 30.48%.

PMR Measurement. The PMR spectra were recorded on a Hitachi R-20B spectrometer equipped with a temperature variation accessory operating at 60 MHz. Temperature was read by the difference in chemical shift of methyl and hydroxy protons of methanol.

Reactions of Iodocarbenoid of Zinc. II.[1] The Iodocyclopropanation of Olefins with Diethylzinc and Iodoform[2]

Sotaro MIYANO and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Arakami, Sendai 980

(Received December 20, 1973)

The iodocyclopropanation of olefins by the iodocarbenoid of zinc generated from diethylzinc and iodoform was investigated. When the reaction was carried out in a neat olefin, cyclohexene, 1-hexene, *cis*-2-butene, isobutene, and styrene gave the corresponding iodocyclopropanes in yields of 70, 34, 63, 55, and 44% respectively, showing that the CHI_3–Et_2Zn system is a convenient route for iodocyclopropanes. The reaction with cyclohexene was investigated in some detail. *syn*-7-Iodonorcarane easily gave 3-ethylcycloheptene upon treatment with diethyl zinc in the presence of zinc iodide.

Various carbene and carbenoid reagents are available for the cyclopropanation of olefins.[3] However, there seem to be only a few reports describing the iodocyclopropanation of olefins by iodocarbene or iodocarbenoids.[4-6] In 1971, Nishimura and Furukawa reported the formation of 7-iodonorcaranes from cyclohexene in trace amounts by a reaction with diethylzinc and iodoform in a light petroleum medium.[5] In the preceding paper,[1] we ourselves reported that, in the ring-expansion of benzene by the CHI_3–Et_2Zn system, the dilution of the substrate (benzene) with hexane caused a remarkable reduction in the yield of 7-ethyltropilidene. This was ascribed to the consumption of the iodocarbenoid reagent of zinc in the formation of propylene. These observations prompted us to examine the iodocarbenoid reaction with diethylzinc and iodoform in neat olefins; in this paper we wish to describe a convenient synthetic route for iodocyclopropanes.

Results and Discussion

Reaction of Diethylzinc and Iodoform in Neat Cyclohexene. The addition of iodoform to an equimolar quantity of diethylzinc in cyclohexene resulted in an exothermic reaction, with the precipitation of white solids. Hydrolysis with aqueous hydrogen chloride gave an organic layer which was analyzed on glc. The results are summarized in Eq. (1):

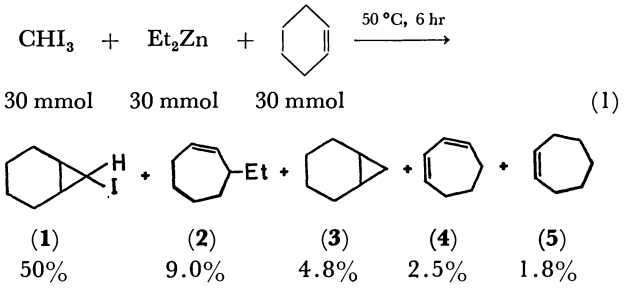

Figure 1 shows the effects of the amount of diethylzinc on the reaction. The quantitative formation of ethyl iodide and the consumption of a part of the reagents in the formation of propylene upon the treatment of diethylzinc and iodoform were reported in the previous paper.[1]

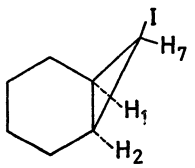
The 7-iodonorcaranes (**1**) were separated as a mixture of *syn*- and *anti*-isomer[7] after a usual work-up of the reaction mixture. The structures were confirmed by elemental analysis, by studying the NMR spectra, and by the formation of norcarane by the Na–MeOH–H_2O reduction according to the method described by Dale and Swartzentruber.[8] The *syn*- and *anti*-7-iodonorcarane were assigned on the basis of the facts that: (1) the alkylsubstituents on a cyclopropane ring would shield the *cis* H_7 more than the *trans* H_7,[9] (2) in cyclopropanes a coupling constant of vicinal-ring protons is generally $J_{cis} > J_{trans}$,[10] and (3) halocarbenoids tend to yield the more sterically-crowded *syn*-isomers.[7,11] The assignment is consistent with that for 7-bromonorcaranes reported by Seyferth *et al.*[10]



syn-**1**

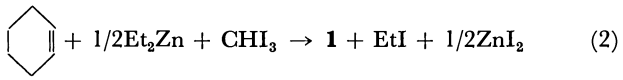
$J_{1,7}$; 4.2 Hz

Diethylzinc reacts with a 2-molar amount of iodoform in the iodocyclopropanation of cyclohexene, since when the molar ratio of diethylzinc to iodoform is less than 1/2, the molar amount **1** is greater than that of the diethylzinc used (Eq. (2)):



3-Ethylcycloheptene (**2**), norcarane (**3**), 1,3-cycloheptadiene (**4**), and cycloheptene (**5**) were characterized by comparing their retention times on glc and on the basis of their NMR and IR spectra. Magid *et al.* reported the stereospecific formation of 7-methylnorcarane from **1** upon treatment with methyllithium.[6a] On the contrary, **1** was almost inactive toward diethylzinc in benzene. It may be concluded, however, from the effects of the amount of diethylzinc on the product composition shown in Fig. 1 and from the following results, that the **2**, **4**, and **5** were formed in the subsequent reactions of *syn*-**1** in the presence of an excess of EtZnX (X=Et or I). Diethylzinc was allowed to react with a mixture of *syn*- and *anti*-**1** in the presence of zinc iodide in benzene at 50 °C for 5 hr. Almost all of the latter was recovered unchanged, but the former was consumed to give **2**, **4**, and **5**, **2** being the major product. These results are consistent with

Table 1. Reaction of several Olefins with Et_2Zn-CHI_3

Olefin	ml	Et_2Zn mol×10	CHI_3 mol×10	Reaction temp. (°C)	Iodocyclopropane yield (%)[a]	*Syn*/*Anti* ratio

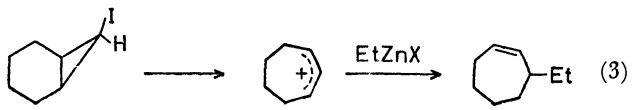
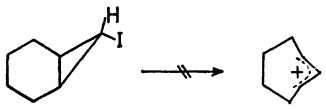
the assumption that, in a concerted cyclopropane ring-opening, a preferred inward rotation of *cis* groups to the leaving iodide leads to a stable allylic cation from the *syn*-**1**, as was suggested by DePuy *et al.*[12] In the *anti*-**1**, the outward rotation of the *trans* groups is prevented and a concerted ring-opening may also be forbidden (Eqs. (3) and (4)):



(3)



(4)

The *syn*-**1** was thermally less stable than the *anti*-isomer, and it easily gave **4** even during a glc analysis when a glc apparatus was operated at a high temperature. Ando *et al.* reported a similar transformation of *syn*-1-chloronorcarane into **4** upon treatment in quinoline at 200 °C.[13] The precise mechanism for the formation of the reduced products (**3** and **5**) is not yet clear.

Iodocyclopropanation of Several Olefins. Table 1 shows the results of the iodocyclopropanation of several olefins. Cyclohexene gave **1** in the yield of as much as 70% when diethylzinc was allowed to react with iodoform in cyclohexene at 0 °C. The reaction temperature is one of the important reaction variables; Nishimura and Furukawa reported that the yield of **1** was 10% when the reaction was carried out in refluxing cyclohexene.[5] On the other hand, when the reaction temperature was kept at —5—0 °C; 1-hexene gave the 1-iodo-2-*n*-butylcyclopropanes in only a 9.8% yield, and methylene iodide was obtained as the major product. It seems to be formed by the hydrolysis of the iodocarbenoid of zinc (Eq. (5)):

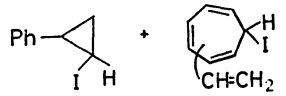
$$EtZnX + CHI_3 \xrightarrow{-EtI} I_2CHZnX \xrightarrow{H_2O} CH_2I_2 \qquad (5)$$

cis-2-Butene afforded the corresponding epimeric pair of 1-iodo-*cis*,*cis*- and 1-iodo-*trans*,*trans*-2,3-dimethylcyclopropane, and no 1-iodo-*cis*,*trans*-dimethyl isomer was detected in the reaction mixture, showing a stereospecific[14] CHI addition to *cis*-2-butene.

n-Butyl vinyl ether was polymerized vigorously upon treatment with diethylzinc and iodoform at room temperature,[15] and it failed to produce the cyclopropanated products.

When styrene was subjected to a reaction, the iodocyclopropanation of ethylene linkage preceded the ring-expansion of the benzene nucleus,[1] but it was accompanied by the formation of a large amount of polystyrene (Eq. (6)):

$$CHI_3 + Et_2Zn + PhCH{=}CH_2 \longrightarrow$$



(6)

44% 8.7%

The isolated iodocyclopropanated product[16] seemed to be a mixture of *syn*- and *anti*-1-iodo-2-phenylcyclopropane, but the two isomers were not differentiated from each other because of their complex NMR spectrum.

We proposed a free-radical-chain mechanism involving the homolytic abstraction of the iodo radical from CH_2IX for the formation of a zinc-carbenoid

reagent from diethylzinc and CH_2IX (X=I, Cl).[9] It may be concluded that a similar mechanism is also applicable to the CHI_3–Et_2Zn system for the formation of iodocarbenoid of zinc, in view of the facts that the system is known to catalyze the radical polymerization of vinyl monomers, such as styrene and methyl methacrylate,[15] and that the iodide in CHI_3 seems to be more easily abstracted homolytically than that in CH_2IX.

Several methods have been reported to afford iodocycloproanes,[4-6,18-20] but where sufficient amounts of the starting olefins are available the CHI_3–Et_2Zn system is the preferred method in view of the simplicity of its reaction procedure and the easiness of the isolation of the products.

Experimental

The glc analysis was carried out on a Shimadzu GC 3AF apparatus equipped with hydrogen-flame detectors and two 3 m×3 mm stainless steel columns packed with Diasolid M coated with Silicone DC 550 and Silicone DC 410 respectively. The infrared spectra were obtained with a JASCO Model IR-E spectrophotometer. The NMR data were obtained with a Varian Associates Model A-60D instrument. All the chemical shifts are relative to an internal TMS or benzene reference (*ca.* 5 wt% solution in CCl_4 or benzene). Elemental analysis was performed at the Elemental Analysis Center, Chemical Research Institute of Nonaqueous Solutions, Tohoku University.

Materials. The diethylzinc and iodoform were purified as has been reported before.[1] The 1,3-cycloheptadiene (bp 69.3—70.2 °C/140 mmHg, lit,[21] 121—122 °C/760 mmHg), phenylcyclopropane,[9] and norcarane[9] were prepared according to the methods in the literature. Reagent-grade commercial olefins were purified by the usual methods before use. The materials were stored under nitrogen.

Reaction of Cyclohexene with Diethylzinc and Iodoform. The reaction procedure was almost analogous to that reported for the reaction of benzene with diethylzinc and iodoform.[1] For the identification of the reaction products, a controlled reaction was carried out as follows. Iodoform (40.0 g, 0.102 mol) was added, portion by portion, to a diethylzinc (10 ml, 0.10 mol) solution in cyclohexene (100 ml) over a 2-hr period at 50 °C. The reaction mixture was stirred at 50 °C for another 4 hr, and was then hydrolyzed in an ice-water bath with a dilute aqueous hydrogen chloride solution. After the usual work-up, the distillation of the organic layer gave three fractions: (1) 0.16 g, boiling range 55—56 °C/78 mmHg, (2) 0.71 g, bp 68—68.5 °C/28 mmHg, (3) 6.3 g, 65.5—71 °C/3 mmHg. Glc analysis showed that Fraction 1 was composed of almost equal amounts of cycloheptene (**5**) (NMR: δ 5.85—5.65 (m) for olefinic protons, 2.3—1.9 (br) for allylic protons, IR: 3020 cm^{-1} (>C=CH–), 1650 cm^{-1} (>C=C<)) and norcarane (**3**) (characteristic absorptions of the cyclopropane ring, IR: 3060, 1020 cm^{-1}, NMR: δ 0.8——0.2), plus a trace amount of 1,3-cycloheptadiene (**4**). The retention times of these three substances in glc increased in this order: **5**<**3**<**4** (Silicone DC 550, 110 °C). Fraction 2 was 3-ethylcycloheptene contaminated with a small amount of an unidetified material. NMR: δ 5.7—5.5 (2H, m), 2.3—1.8 (4H, br), 1.8—1.1 (7H, m), 1.1—0.3 (3H, t). IR (liq. film): 3020 cm^{-1} (>C=CH–), 1645 cm^{-1} (>C=C<).

Fraction 3 was essentially pure 7-iodonorcaranes (**1**), and redistillation gave 4.0 g of an analytical sample of a 46 : 54 mixture of *syn*- and *anti*-**1** boiling at 68.5—69.5 °C/3 mmHg. Found: C, 38.04; H, 4.90%. Calcd for $C_7H_{11}I$: C, 37.86; H, 4.99; I, 57.15%. IR (liq. film, cm^{-1}): 3000(m, sh), 2900 (s), 2850(s), 1460(m, sh), 1445 (s), 1355 (m), 1340 (m), 1270(m), 1240(s), 1205(s), 1180(w), 1155(w, sh), 1140(m), 1080(w, sh), 1070(w), 1005(m), 960(w), 950(w), 920(w), 895(w), 830(w), 765(w), 725(w). The *syn*- and *anti*-isomer ratio was determined on the basis of the NMR spectrum and the peak areas on glc (Silicone DC 410 column, 110 °C), the former giving a longer retention time than the latter. When a glc analysis was carried out on a Silicone DC 550 column operated at 170 °C, the *syn*-isomer completely disappeared, giving a new peak the retention time of which coincided with that of 1,3-cycloheptadiene.

Reduction of ***1*** *with Na–MeOH–H_2O.* A 46 : 54 mixture of *syn*- and *anti*-**1** (1.30 mmol) in wet methanol (0.5 ml of water to 10 ml of methanol) was treated with 1.0 g of sodium metal. The reaction mixture was then neutralized with hydrogen chloride and extracted with ether. Glc analysis showed the presence of 0.82 mmol of norcarane (63% based on **1**), 0.17 mmol of unchanged *syn*-**1**, and 0.25 mmol of *anti*-**1**.

The Reaction of ***1*** *with Diethylzinc in the Presence of Zinc Iodide.* To a 43 : 57 mixture of *syn*- and *anti*-**1** (2.06 mmol) and 1.03 mmol of zinc iodide in 10 ml of benzene, we added 0.50 ml of diethylzinc (5.0 mmol). The reaction mixture was then stirred at 50 °C for 5 hr. Glc analysis showed that 98.4% of the *anti*-**1** was recovered unchanged, but 50% of the *syn*-**1** reacted to leave a 27 : 73 mixture of *syn*- and *anti*-**1**, and 0.40 mmol of **2**, 0.064 mmol of **5**, and 0.022 mmol of **4** were detected in the reaction mixture. Upon the similar treatment of **1** with diethylzinc in the absence of zinc iodide, the **1** was recovered almost unchanged and trace amounts of **5** and **4** were detected after the reaction.

Reaction with Styrene. Iodoform was allowed to react with diethylzinc in styrene according to the above procedure except that the iodoform was added over a 1-hr period, after which the reaction was continued for another 5 hr. The distillation of the reaction mixture gave a portion boiling at 74.5—76 °C/6.5 mmHg (0.5 g), which was characterized as a mixture of vinyl-7-ethyltropilidenes on the basis of its NMR and IR spectra. IR (liq. film, cm^{-1}): 985, 900 (vinyl), 1630, 1613, 1595 (polyene structure). After the distillation, 20.5 g of a viscous, dark brown residue remained; this was dissolved in 10 ml of acetone and precipitated with 300 ml of methanol. The precipitate (8.2 g) gave IR absorption spectra (KBr) identical with those of polystyrene film over the wave range from 650 to 3200 cm^{-1}. The methanol solution was distilled to give 5.3 g of 1-iodo-2-phenylcyclopropane (**6**) as a slightly pale yellow liquid boiling at 100—102 °C/3 mmHg (lit,[18] bp 80—81 °C/0.4 mmHg). Found: C, 44.23; H, 3.56%. Calcd for C_9H_9I: C, 44.29; H, 3.72; I, 52.00%. IR (liq. film, cm^{-1}): 3080 (m, sh), 3060(s), 2930(m, sh), 2850(m, sh), 1605(s), 1580(w, sh), 1505(s), 1455(s), 1440(m, sh), 1370(w), 1240(s), 1220(m), 1185(w), 1165(w), 1160—1070(m), 1045(m), 1030(m), 995(m), 960(w), 915(m), 820(m), 770(m), 735(m), 700(s). NMR: δ 7.3—7.0 (5H), 3.1—1.0 (4H, m).

6 (0.40 mmol) in wet methanol (0.5 ml of water to 10 ml of methanol) was treated with 1 g of sodium metal to give phenylcyclopropane in a yield of 77%.

*1-Iodo-2-*n*-butylcyclopropanes (****7****).* Bp 68—71 °C/7 mmHg (5.0 g). Found: C, 37.02; H, 5.96%. Calcd for $C_7H_{13}I$: C, 37.52; H, 5.85; I, 56.64%. IR (liq. film, cm^{-1}): 2950(s, sh), 2925(s), 2855(s), 1460—1440(m, br), 1380(m), 1235(s), 1192(m), 1035(m), 822(m), 735(w). NMR: δ 2.8—2.4 (m, H_1 for *syn*-**7**), 2.3—1.8 (m, H_1 for *anti*-**7**).

In a separate run, diethylzinc (15 ml) was added to iodoform (60 g) in 1-hexene (100 ml) which had been kept at —5—0 °C over a 1-hr period, after which the reaction mix-

ture was kept at 0 °C for 5 hr with stirring. Glc analysis showed that the yield of **7** was reduced to 9.8%; 10.4 g of methylene iodide were recovered by distillation.

1-Iodo-2,3-dimethylcyclopropanes (8). *cis*-2-Butene (*ca.* 20 ml) was distilled into a sealed tube which contained 12 g of iodoform. From the side arm of the tube, 2 ml of diethylzinc were added to the mixture, drop by drop, over a 2-hr period with occasional cooling in an ice-water bath. The reaction mixture was then allowed to stand at room temperature for 1 hr with stirring. After the unchanged butene had been distilled off, the reaction mixture was diluted with ether and treated as usual. A portion boiling at 63—64 °C/29 mmHg was collected as a mixture of *syn*- and *anti*-**8** (2.0 g) (lit,[18] bp 50—52 °C/40 mmHg). Found: C, 29.50; H, 4.79%. Calcd for C_5H_9I: 30.63; H, 4.63; I, 64.74%. IR (liq. film, cm^{-1}): 3025(m, sh), 3000(s, sh), 2950(s), 2925(s), 2870(s, sh), 1455(s, br), 1390(s), 1240(s), 1220(s), 1165(m), 1115(s), 1060(m), 910(w), 750(s). The NMR spectrum was consistent with that of **8**[18]; H_1 for the *syn*-**8**, δ 2.85, $J_{1,3}=7.7$ Hz.

1-Iodo-2,2-dimethylcyclopropane (9). Bp 56—57 °C/51 mmHg (1.5 g) (lit,[18] bp 40—41 °C/20 mmHg). Found: C, 30.97; H, 4.23%. Calcd for C_5H_9I: C, 30.63; H, 4.63; I, 64.74%. IR (liq. film, cm^{-1}): 2950(s), 2840(s, sh), 1465(m, sh), 1450(s), 1440(s), 1380(m), 1280(m), 1195(s), 1123(w), 1086(w), 1035(m), 950(w), 900(m), 825(w). NMR spectrum was consistent with **9**.[18]

Spin Trapping of Free Radicals Generated from Arylazo *p*-Tolyl Sulfones[1]

Michio KOBAYASHI, Eri AKIYAMA, Hiroshi MINATO, and Noboru KITO*

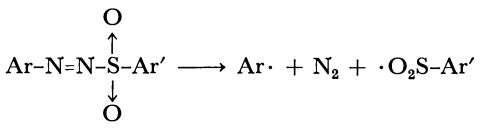
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

**Sagami Chemical Research Center, 3100 Sagamihara, Ohnuma, Sagamihara, Kanagawa 229*

(Received December 21, 1973)

Arylazo *p*-tolyl sulfones(I) were thermolyzed or photolyzed in the presence of trapping agents such as α,*N*-diphenyl nitrone(II), α-phenyl *N*-*t*-butyl nitrone(III) and 2-methyl-2-nitrosopropane(X). ESR studies showed that phenyl radical or *p*-methoxyphenyl radical is produced from the decomposition of I and adds to II or III. The adduct of phenyl radical to II and that of *p*-methoxyphenyl radiacl to III were synthesized for comparison by separate pathways. The photolysis of phenyl *p*-tolylazo sulfone(Ia) in the presence of III yielded benzhydryl *t*-butyl nitroxide, benzoyl *t*-butyl nitroxide and *t*-butyl *p*-toluenesulfonyl nitroxide(XVI) radicals. The photolysis of Ia in the presence of X gave di-*t*-butyl nitroxide(XII) and XVI. The photolysis of phenylazotriphenylmethane in the presence of X yielded XII and *t*-butyl nitroxide radical. The mechanisms of the formation of these radicals are discussed. The formation of arenesulfonyl radicals from the decomposition of I has been proved indirectly (analyses of the products of the combination of nitroxide radicals with arenesulfonyl radicals) and directly (detection of *t*-butyl *p*-toluenesulfonyl nitroxide radical).

Arylazo *p*-tolyl sulfones(I) decompose when they are heated in neutral or weakly basic media[2] or when they are irradiated by UV light,[3] and the generation of aryl radicals has been proposed on the basis of kinetic studies[4] or product studies (orientation and partial rate factors in arylating various aromatics).[5]



(I)

Ia: Ar=Ph, Ar′=*p*-Tolyl

Ib: Ar=*p*-MeO-C_6H_4, Ar′=*p*-Tolyl

However, no evidence has been presented indicating the formation of arenesulfonyl radicals, since they do not attack aromatics easily.[6,7] Consequently, mechanisms involving only aryl radicals (*i. e.*, not arenesulfonyl radicals) cannot be excluded. A plausible example is the following mechanism, which is similar to the diazoanhydride–acetic anhydride mechanism proposed for the decomposition of N-nitrosoacetanilide by Rüchardt *et al.*[8]

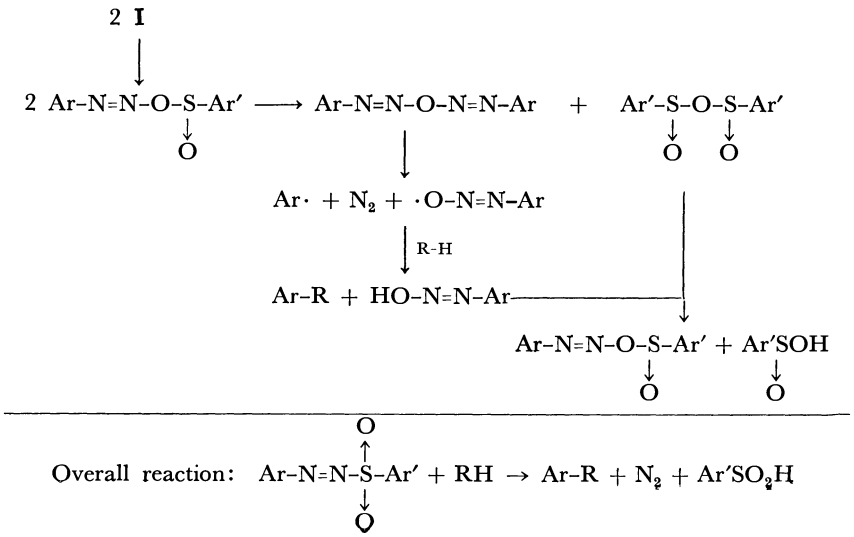
Even the formation of aryl radicals from I has not been proved by physical methods. Spin trapping of aryl and arenesulfonyl radicals has therefore been investigated, and the results are descirbed in this paper.

Results and Discussion

When benzene solutions of phenylazo *p*-tolyl sulfone (Ia) or *p*-methoxyphenylazo *p*′-tolyl sulfone (Ib) were heated or irradiated, ESR spectra did not indicate the presence of aryl radicals. The reactivities of aryl radicals are probably so great that the steady-state concentrations of aryl radicals produced are not large enough for ESR detection.

Trappings[9] of aryl radicals by reactions with α,*N*-diphenyl nitrone (II) or α-phenyl *N*-*t*-butyl nitrone (PBN) (III) were attempted. When benzene solutions of Ia and II (or Ib and II) were mixed at room temperature in the dark, ESR signals were observable. This indicates that free radicals are slowly produced by thermolysis of Ia or Ib at room temperature. When these mixtures were irradiated with a 100-W high pressure mercury lamp, very strong ESR signals composed of 40 hyperfine splittings (shown in Fig. 1a) were observed. The ESR signal patterns of the radicals produced by photolysis were the same as those observed for the radicals produced by thermolysis at room temperature. Thus, the radicals produced by photolysis and thermolysis should be the same.

The following hyperfine splitting constants were cal-



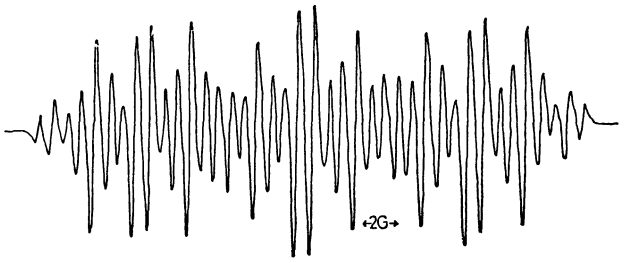


Fig. 1(a). The ESR spectrum of an irradiated mixture of *p*-$MeOC_6H_4N{=}NO_2SC_6H_4Me$-*p* and PhCH=N-Ph (O) in benzene.

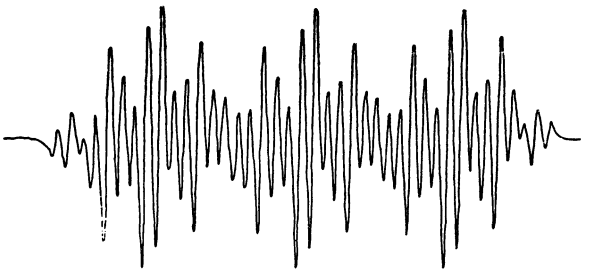

Fig. 1(b). An ESR spectrum obtained by simulation using $A_N=10.01$, $A_{\beta\text{-H}}=3.41$, $A_{o\text{-H}}=2.51$, $A_{m\text{-H}}=0.88$, and $A_{p\text{-H}}=2.51$G.

culated from analysis of the hyperfine splittings.

$A_N = 10.01$	$A_{o\text{-H}} = 2.51$
$A_{\beta\text{-CH}} = 3.41$	$A_{m\text{-H}} = 0.88$
	$A_{p\text{-H}} = 2.51$
	$g = 2.0056$

Simulation was carried out by using these hyperfine splitting constants, the result (Fig. 1b) being in excellent agreement with what was experimentally observed. Thus the radical responsible for the ESR pattern is benzhydryl phenyl nitroxide radical (IVa) shown below.

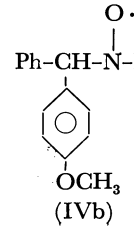
Ia ⟶ Ph·

Ph· + Ph-CH=N-Ph (O) → Ph-CH(Ph)-N-Ph (O·)

(II) (IVa)

Bluhm and Weinstein[10] trapped the phenyl radical, produced from phenylazotriphenylmethane, by the reaction with II, and the hyperfine splitting constants they reported for radical IVa are approximately the same as those described above.

When Ib was decomposed by irradiation or by heating in the presence of II, ESR signals ascribable to nitroxide radical IVb were observed. The following hyperfine splitting constants were obtained from the analysis of the ESR pattern.



(IVb)

$A_N = 10.0$ $A_{o\text{-H}} = 2.5$

$A_{\beta\text{-H}} = 3.4$ $A_{m\text{-H}} = 0.9$

$A_{p\text{-H}} = 2.5$

When the samples were irradiated at room temperature and the ESR signals were examined after the light was turned off, they were observable for about 15 min. This indicates that radicals IVa and IVb are fairly stable.

ESR studies on the reaction between Ia and nitrone III and that between Ib and III showed the presence of nitroxide radicals Va and Vb, respectively. The following hyperfine splitting constants were obtained.

t-Bu-N=CH-Ph (O) + Ph· ⟶ t-Bu-N(Ph)-CH-Ph (O·)

(III) (Va)

t-Bu-N=CH-Ph (O) + p-MeO-C_6H_4· ⟶ t-Bu-N(·O)-CH(Ph)-C_6H_4-OMe-*p*

(Vb)

	A_N	$A_{\beta\text{-CH}}$	g
Va	13.93	2.09	
Vb	13.91	2.15	2.0061

Concerning Va, Janzen and Blackburn reported that $A_N=13.73$ and $A_{\beta\text{-CH}}=2.08$ G.[11]

In order to prove the structure of IVa, *N*-benzhydryl-*N*-phenylhydroxylamine (VIa) was synthesized from nitrone II and phenylmagnesium bromide, and was oxidized with air in a weakly alkaline (NaOH) aqueous ethanol. The ESR signals observed were exactly the same as those observed when Ia was photolyzed in the presence of II. When VIa was treated with *n*-BuLi in benzene and then irradiated with a high pressure mercury lamp in the presence of air, similar ESR signals ascribable to nitroxide radical IVa were observed.

Ph-N(OH)-$CHPh_2$ $\xrightarrow{OH^-}$ Ph-N(O⊖)-$CHPh_2$ $\xrightarrow{O_2}$ Ph-N(O·)-$CHPh_2$

(VIa) (IVa)

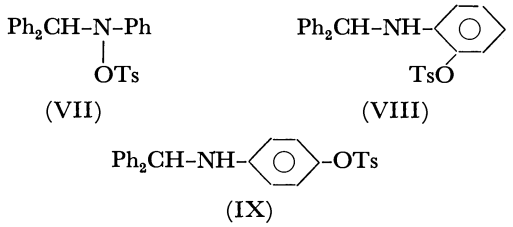
In a similar manner, when an alkaline ethanol solution of *N*-*t*-butyl-*N*-(phenyl-*p*-methoxyphenylmethyl)hydroxylamine (VIb) was oxidized with air or irradiated in the presence of air, nitroxide radical Vb was formed and its ESR signals were identical with those obtained from azosulfone Ib and nitrone III.

t-Bu-N(OH)-CH(Ph)-C_6H_4-OMe-*p* $\xrightarrow[\text{or } h\nu]{OH^-,\ O_2}$ t-Bu-N(O·)-CH(Ph)-C_6H_4-OMe-*p*

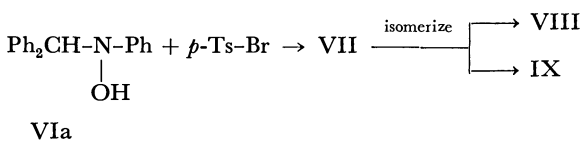
(VIb) (Vb)

These data obtained by means of ESR have established that aryl free radicals are formed by thermolysis or photolysis of azosulfones Ia or Ib.

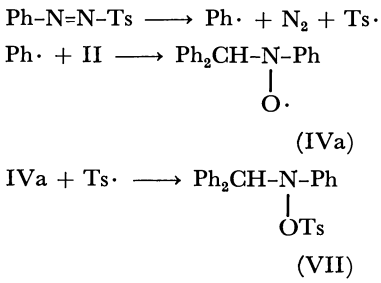
In order to determine the final products from nitroxide radicals IV and V, a mixture of Ia, pyridine (3 mol/mol Ia; added in order to keep the medium weakly alkaline) and nitrone II (1.5 mol/mol Ia) was thermolyzed. Recrystallization of the products gave a compound, which appeared to be *N*-benzhydryl-*N*-phenylhydroxylamine *O*-*p*-toluenesulfonate (VII). It was very unstable, readily isomerizing to *o*- and *p*-benzhydrylaminophenyl *p*-toluenesulfonates (VIII) and (IX), when allowed to stand at room temperature. When the products of thermolysis of Ia-II-pyridine in benzene were separated by column chromatography, VII was not detected and VIII and IX were isolated in 17% and 1% yields (per 100 mol Ia), respectively.



When *N*-benzhydryl-*N*-phenylhydroxylamine (VIa) was allowed to react with *p*-tosyl bromide in pyridine at room temperature, VII was not obtained; isomerization took place during the course of recrystallization and the product isolated was VIII. A similar rearrangement of hydroxylamine-O-esters has been reported.[12]

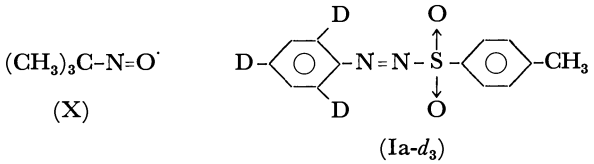


The formation of VII can be ascribed to a combination of nitroxide radical IVa and *p*-toluenesulfonyl radical.

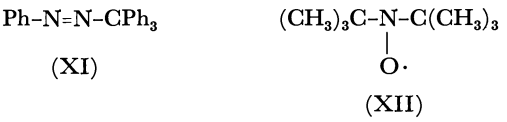


The fact that VII is formed proves indirectly that the decomposition of azosulfone Ia yields *p*-toluenesulfonyl radical in addition to phenyl radical.

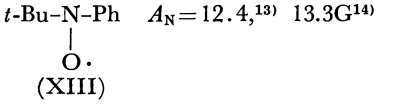
In an attempt to trap *p*-tosyl radical with nitrone III, Ia was photolyzed in the presence of excess III at room temperature under various conditions. The presence of two new nitroxide radicals in addition to Va were detected by ESR; A_N=12.5 G and 7.67 G (for Va, A_N=13.93 G). Since these two radicals showed simple triplets without hyperfine splittings due to β-hydrogens, addition of radicals on some nitroso compounds containing only *t*-butyl groups was suspected. When an ethereal solution of Ia was irradiated at 366 nm in the presence of 2-methyl-2-nitrosopropane(X), ESR signals of two radicals were observed; A_N=12.5 G and 15.5 G, and g=2.0060 for both. In order to determine whether or not these radicals arose from trapping of phenyl radical, *p*-tolyl 2,4,6-trideuteriophenylazo sulfone (Ia-d_3) was photolyzed in the presence of X. Since the radicals detected were identical with those formed in the case of Ia, they cannot be the products of trapping of phenyl radical with X.



When phenylazotriphenylmethane (XI), another phenyl radical source, was photolyzed in ether in the presence of X, two radicals were detected; one with A_N=12.8 G and $A_{\beta\text{-CH}}$=2.6 G and the other with A_N=15.5 G. When X was irradiated in ether with a sodium lamp (589 nm), the ESR signals obtained were a simple triplet with A_N=15.5 G. Therefore, the radical with A =15.5 G must be di-*t*-butyl nitroxide radical (XII).

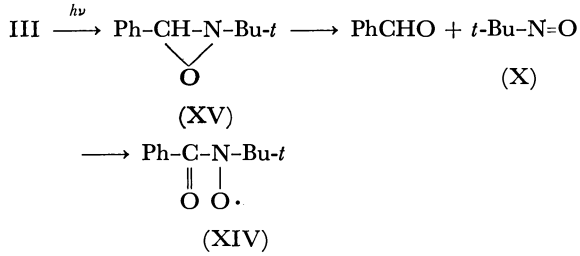


It has been reported that XII is formed by the photolysis of X; A_N=15.7 G[13] or 15.5 G,[14] and also that *t*-butyl phenyl nitroxide (XIII) formed by the trapping of phenyl radical with X shows hyperfine splittings due to *ortho* and *para* hydrogens of the benzene ring.[13,14]

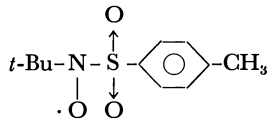


The fact that no XIII was found in the photolysis of Ia in the presence of X can be ascribed to the consumption of phenyl radical by abstraction of α-hydrogens of ether.

The radical with A_N=7.67 G formed in the photolysis of Ia in the presence of III is probably benzoyl *t*-butyl nitroxide radical[11] (XIV) produced by the photolysis of III. It has been reported[15] that upon irradiation nitrone III isomerizes to α-phenyl-*N*-*t*-butyloxazirane (XV), which then yields 2-methyl-2-nitrosopropane (X) and XIV.



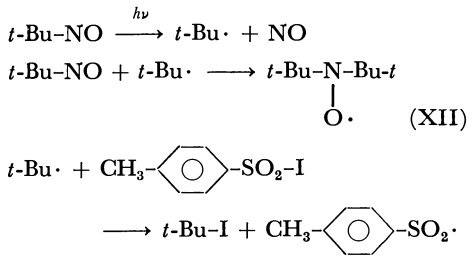
Thus, of the three radicals produced from the photolysis of Ia in the presence of III, the one with A_N=13.93G is Va, that with A_N=7.67 G is XIV, and that with A_N=12.5 G remains to be explained. If this is not XIII, the only possibility seems to be nitroxide radical XVI, which can be formed by the trapping of *p*-toluenesulfonyl radical with X. In order to confirm the



(XVI)

possibility, *p*-toluenesulfonyl iodide, another *p*-tosyl radical source, was irradiated at 589 nm in the presence of X. A nitroxide radical with $A_N=12.5$ G was observed, which is identical with that obtained in the photolysis of Ia or Ib in the presence of X.

The rate of decrease of the ESR signals of XVI was determined after light was turned off, and the nitroxide radical XVI was found to be a fairly stable radical with a half-life of 44 seconds. When an ethereal solution of X was irradiated in the absence of *p*-tosyl iodide, ESR signals observed were those of di-*t*-butyl nitroxide (XII) alone. The following reaction sequence is therefore plausible.



(XII)

Fig. 2(a). The ESR spectrum of an irradiated mixture of PhN=$NO_2SC_6H_4$-Me-*p* and *t*-Bu-N=CH-Ph (O) in benzene ($A_N=13.13$, $A_{\beta\text{-H}}=2.09$; $A_N=12.5$; $A_N=7.67$G).

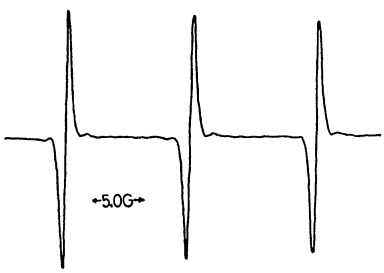


Fig. 2(b). The ESR spectrum of an irradiated solution of *t*-Bu-N=O in ether ($A_N=15.5$G).

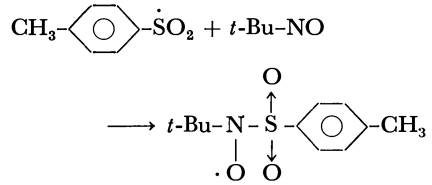
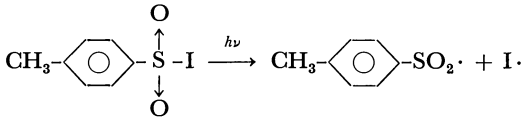


It is possible that *p*-toluenesulfonyl radical is produced by direct photolysis of *p*-toluenesulfonyl iodide itself.[6]



However, since X absorbs at longer wavelength region (near 589 nm), it seems more probable that the *t*-butyl radical produced by photolysis of X abstracts the iodine atom from *p*-tosyl iodide, yielding *p*-tosyl radical and *t*-butyl iodide.

When an ethereal solution of iodobenzene was irradiated in the presence of X, two sets of ESR signals were observed; a triplet with $A_N=15.5$ G and a triplet with $A_N=12.5$ G and with hyperfine splittings. The former is due to XII, and the latter can be ascribed to *t*-butyl phenyl nitroxide (XIII). The formation of XIII can be explained in terms of the following reaction steps: 1) photolysis of X gives *t*-butyl radical, 2) *t*-butyl radical abstracts the iodine atom from iodobenzene, and 3) the phenyl radical formed is trapped

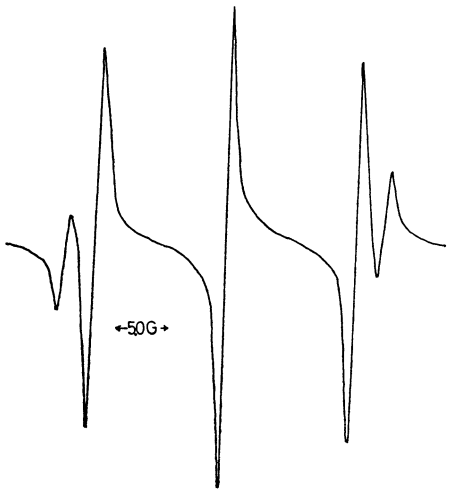


Fig. 2(c). The ESR spectrum of an irradiated mixture of PhN=$NO_2SC_6H_4$Me-*p* and *t*-Bu-N=O in ether ($A_N=12.5$, and $A_N=15.5$G).

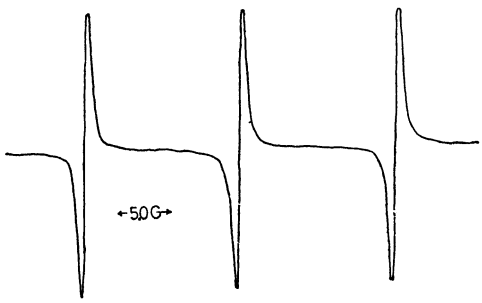

Fig. 2(d). The spectrum of an irradiated mixture of *p*-$MeC_6H_4SO_2I$ and *t*-Bu-N=O in ether ($A_N=12.5$ G).

by X. In contrast with the case of the photolysis of azosulfone Ia in the presence of X, phenyl radical was trapped by X in the photolysis of iodobenzene. In this case, iodobenzene was used in a high concentration, and therefore not all of the phenyl radicals produced were consumed by the reaction with ether.

Thus, the spin trapping experiments with nitrones II, III and 2-methyl-2-nitrosopropane (X) have proved that aryl radicals and sulfonyl radicals are produced by the thermolysis or photolysis of azosulfones Ia or Ib.

Experimental

Materials. Arylazo *p*-tolyl sulfones were synthesized by the addition of aqueous solutions of *p*-toluenesulfinate to aqueous solutions of arenediazonium salts,[4] and recrystallized from methanol. Nitrone II was produced by the condensation of phenylhydroxylamine with benzaldehyde, and recrystallized from ethanol. Nitrone III was synthesized by the following two steps; 1) H_2O_2(90%)-Ac_2O-oxidation of benzylidene-*t*-butylamine to 2-*t*-butyl-3-phenyloxaziridine and 2) isomerization of the oxaziridine by refluxing in acetonitrile for 2 days.[16] It was recrystallized from hexane; mp 76 °C.

ESR Measurements. ESR signals were observed by use of a JES-ME-1X.

Formation of Benzhydryl Phenyl Nitroxide Radical IVa. Benzhydryl bromide, phenylhydroxylamine and sodium acetate were ground in a porcelain mortar. When the mixture was washed with water and then with hexane and the residue was recrystallized from benzene-hexane, *N*-benzhydryl-*N*-phenylhydroxylamine (VIa) was obtained. This hydroxylamine was also synthesized from α,*N*-diphenyl nitrone II and phenylmagnesium bromide.

Oxidation of VIa with HgO or 2,6-dichlorophenol-indophenol sodium was attempted, but was not successful. However, when air was bubbled through a weakly alkaline (NaOH) aqueous ethanol solution of VIa, ESR signals were observed. The same ESR signals were observed when a benzene solution of VIa containing some *n*-butyl lithium was irradiated with a high pressure mercury lamp. The hyperfine splittings of the ESR signals were identical with those obtained from azosulfone Ia and nitrone II, and are ascribable to benzhydryl phenyl nitroxide radical IVa.

Formation of t-*Butyl Phenyl*-p-*methoxyphenylmethyl Nitroxide Radical IVb.* *N*-*t*-Butyl-*N*-(phenyl-*p*-methoxyphenylmethyl) hydroxylamine (VIb) was prepared from α-phenyl *N*-*t*-butyl nitrone and *p*-methoxyphenylmagnesium bromide, and was oxidized by air in a weakly alkaline (NaOH) aqueous ethanol solution. The ESR signals observed were identical with those obtained in the reaction between azosulfone Ib and nitrone III, and are ascribable to *t*-butyl phenyl-*p*-methoxyphenylmethyl nitroxide radical IVb.

Products of the Reaction between Azosulfone Ia and Nitrone II. A mixture of Ia (2.5 g), II(4.0 g), pyridine (4.0 g) and benzene (130 ml) was heated at 91 °C for 3 hr (the half-life of Ia under these conditions is 46 min). The reaction mixture was washed with water and with dilute HCl for removal of pyridine, and then concentrated. The column chromatography (Florisil) of the residue gave biphenyl 10.8, azobenzene 6.1, *o*-benzhydrylaminophenyl *p*-toluenesulfonate (VIII) 17.2 and *p*-benzhydrylaminophenyl *p*-toluenesulfonate (IX) 1.0 mol/100 mol Ia.

Synthesis of VIII. *o*-Nitrophenyl *p*-toluenesulfonate was reduced with $SnCl_2$-HCl, and the *o*-aminophenyl *p*-toluenesulfonate obtained (1.5 g) was heated with benzhydryl chloride (1.0 g) and pyridine (5 ml) at 90 °C for 3 days. The reaction mixture was washed with water and then with dilute HCl, and pyridine was distilled off under reduced pressure. Recrystallization of the residue from hexane-benzene gave VIII; mp 122—123 °C.

Synthesis of IX. A mixture of *p*-aminophenyl *p*-toluenesulfonate (1.5 g), benzhydryl chloride (1.0 g) and pyridine (5 ml) was refluxed for 13 hr and then treated in a manner similar to that described for VIII. Recrystallization from hexane-benzene gave IX; mp 133—134 °C.

Analysis:	C	H	N	M.W.
VIII (authentic)	72.38	5.37	3.13%	
VIII (from Ia and II)	72.87	5.43	3.09	419
IX (authentic)	71.21	5.31	2.99	
IX (from Ia and II)	69.85	5.31	3.41	421
Calcd.	72.8	5.4	3.3	429

Molecular weights were determined by use of the vapor pressure method with a Hitachi-Perkin Elmer Molecular Weight Apparatus 115.

The Reaction of the Hydroxamic Acid Group in Polymer with *p*-Nitrophenyl Acetate[1]

Toyoki KUNITAKE, Yoshio OKAHATA, and Reiko ANDO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka, 812

(Received February 12, 1974)

Water-soluble copolymers containing protected hydroxamate groups were prepared by radical copolymerization of acetyl *N*-phenylacrylohydroxamate and acrylamide, and the hydroxamic acid group (PHA) was unmasked by treating it with hydroxylamine. In acetylation with *p*-nitrophenyl acetate (1.4 v/v% CH_3CN-H_2O, 30 °C) the PHA unit was less reactive than the corresponding monomeric compound. When the PHA content was low (3 mol%), the reactivity of a given PHA anion (true reacting species) was invariant (9.1 M^{-1} s^{-1}) over a wide range of the dissociation of the PHA unit. However, in the case of the copolymer of a higher PHA content (11 mol %) the reactivity decreased as the neutralization of the PHA anion progressed. This phenomenon was attributed to the intramolecular aggregation of the undissociated PHA side chain. The deacylation rate of the acetylated PHA unit was comparable to those of the monomeric counterparts, in contrast with the acylation process. Finally, the probable role of the PHA unit as catalyst for the ester hydrolysis was discussed.

In the past several years, we have studied the catalytic hydrolysis of phenyl esters by imidazole-containing polymers.[2] Apart from a few exceptional cases,[3] the efficiency of the imidazole catalysis is limited by the rate-determining acylation step.

The hydroxamate anion is known to be highly nucleophilic toward phenyl esters,[4-9] and attempts to use it as catalyst for the hydrolysis of phenyl esters have been carried out by Bender and coworkers in small-molecule systems.[10,11] However, in polymeric systems, introduction of hydroxamic acid groups has not been necessarily straight-forward, and their nucleophilic reactivity was not examined. Thus, in the present study the hydroxamic acid group was introduced into water-soluble polymers and characterized unambiguously, and the reaction with *p*-nitrophenyl acetate(PNPA) was investigated in order to evaluate the usefulness of the hydroxamic acid group in polymer as a catalyst for the ester hydrolysis.

Experimental

All melting points are uncorrected. The UV-visible spectroscopic measurements were made with a Hitachi 124 spectrophotometer. NMR spectra were obtained with a Varian A60 instrument.

Materials. *p*-Nitrophenyl acetate was prepared by acylation of *p*-nitrophenol with acetic anhydride and recrystallized from cyclohexane, mp 78 °C (lit,[12] 81—82 °C). Acrylamide was purified by repeated recrystallizations from benzene, mp 83.5—84.5 °C.

N-Phenylacrylohydroxamic acid (**1**) was prepared according to Barda and Manole from *N*-phenylhydroxylamine and acryloyl chloride.[13] Repeated recrystallizations from cyclohexane gave pale yellow plates; yield 46—58%, mp 90—91 °C (lit,[13] 88—89 °C).

Similar procedures were employed in ether or chloroform solvent for the preparation of the following hydroxamic acids.

N-Phenylisobutyrohydroxamic acid (**2**); yield 60%, colorless plates from a cyclohexane-*n*-hexane mixture, mp 49—50 °C. Found: C, 67.01; H, 7.26; N, 7.86%. Calcd for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82%.

N-Methylisobutyrohydroxamic acid (**3**); yield 45%, bp 91—95 °C/5 mmHg. Found: C, 51.18; H, 9.57; N, 11.81 %. Calcd for $C_5H_{11}NO_2$: C, 51.25; H, 9.46; N, 11.95%.

N-Methyl-α-naphthohydroxamic acid (**4**); yield 52%, colorless plates from acetone, mp 133—134 °C. Found: C, 71.52; H, 5.43; N, 6.86%. Calcd for $C_{12}H_{11}NO_2$: C, 71.53; H, 5.53; N, 6.96%.

Acetyl *N*-phenylacrylohydroxamate (**1a**); *N*-phenylacrylohydroxamic acid (38 g, 0.23 mol) and 24 g (0.24 mol) of triethylamine were dissolved in a mixture of 700 ml of ether and 100 ml of chloroform. To this solution was added dropwise 17.7 g (0.23 mol) of freshly-distilled acetyl chloride in 100 ml of ether with stirring at −10 °C over 30 min, and stirring was continued for an additional hour at room temperature. The reaction mixture was washed with 100 ml of saturated aqueous NaCl and with three 50-m*l* portions of a dilute Na_2CO_3 solution, and dried over Na_2SO_4. The solvent was evaporated and the tan-brown residue was distilled *in vccuo*. The distillate (dark yellow oil, bp 100—110 °C/0.08 mmHg) was recrystallized from petroleum ether in a dry ice-methanol bath; pale yellow oil, yield 52—65%. Found: C, 64.19; H, 5.53; N, 6.60%. Calcd for $C_{11}H_{11}NO_3$: C, 64.38; H, 5.40; N, 6.83%.

Similar procedures were applied to the preparation of the following acetyl hydroxamates.

Acetyl *N*-phenylisobutyrohydroxamate (**2a**); yield 80%. colorless plates from *n*-hexane. mp 77—78 °C. Found: C, 65.14; H, 6.31; N, 6.31%. Calcd for $C_{12}H_{15}NO_3$: C, 65.03; H, 6.83; N, 6.33%.

Acetyl *N*-methylisobutyrohydroxamate (**3a**); yield 53%. bp 95—98 °C/20 mmHg. Found: C, 52.78; H, 8.26; N, 8.81%. Calcd for $C_7H_{13}NO_3$: C, 52.82; H, 8.23; N, 8.80%.

Copolymerization. The radical copolymerization of acetyl *N*-phenylacrylohydroxamate and acrylamide was performed with azobisisobutyronitrile as an initiator in acetonitrile. The polymerization mixture was placed in an ampoule, which was sealed under nitrogen. After given polymerization periods, water was added to the reaction mixture, and the polymer was recovered by precipitation in excess methanol and dried *in vacuo*. The polymerization results are summarized in Table 1.

Deacetylation. A copolymer sample was dissolved in a small amount of water which contained a large excess of hydroxylamine, and was allowed to stand for 24 hr. The product polymer was recovered by precipitation in excess methanol, washed with methanol and dried *in vacuo*. Completion of deacylation was confirmed by disappearance of an IR peak at 1800 cm^{-1} due to the acetyl hydroxamate group ($\nu_{C=O}$). IR spectra of the copolymer before and after deacetylation are compared in Fig. 1. The corresponding spectra of the model compound are shown for comparison.

Determination of Copolymer Composition. The composition of the deacetylated copolymer was determined by NMR

TABLE 1. COPOLYMERIZATION[a]

spectroscopy and by the UV titration of the hydroxamate group. In the first method, the copolymer composition was determined from the relative peak area of the phenyl protons and the methine and methylene protons. In the second method, the UV absorption characteristics of the hydroxamic acid unit (PHA) in the polymer was assumed to be the same as that of *N*-phenylisobutyrohydroxamic acid, and the copolymer composition was calculated by using the absorption of the hydroxamate anion at 300 nm (ε 1230). The PHA homopolymer prepared by radical polymerization was not utilized for this purpose because of its insolubility in water. The copolymer compositions thus determined are included in Table 1. The UV method appears to be more reliable particularly for samples of the low PHA content.

Determination of pK_a *Value.* The pK_a value of the hydroxamic acids (including the PHA unit in polymer) was determined by the UV spectroscopic and potentiometric titrations. The UV titration was conducted by using the absorbance of the hydroxamate anion at 300 nm in 1.4 vol% CH_3CN–H_2O at 30 °C (0.1 M KCl, 0.05 M Tris buffer), and the potentiometric titration was carried out in 1.4 vol% CH_3CN–H_2O at 30 °C, 0.1 M KCl. The UV titration data for the polymer hydroxamic acids were plotted according to the modified Henderson-Hasselbach equation[14]

$$pK_a = pH + n'\log\frac{1-\alpha}{\alpha} \qquad (1)$$

where α is the fraction of the dissociated hydroxamic acid group. The pK_a value corresponds to pH at the half neutralization, and the deviation of the n' value from unity is a qualitative measure of the electrostatic repulsion between the negatively-charged groups.

These titration data are summarized in Table 2. The agreement between the two methods is satisfactory.

Rate Measurements. The rate of acetylation of hydroxamic acids with *p*-nitrophenyl acetate was determined by following the increase in the absorption of the *p*-nitrophenolate anion at 401 nm. The hydrolysis of acetyl hydroxamates was followed in 1.4 vol% CH_3CN–H_2O (0.1 M KCl) at 30 °C by observing the increase in the absorption of the hydroxamate anion at 300 nm. Tris and phosphate buffers

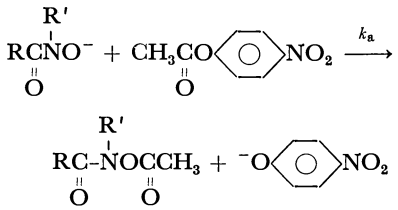
were used. The pH of the reaction mixture was confirmed not to vary from pH measurements (Toa Digital pH Meter Model HM-15A) before and after the reaction.

Results

Electronic Spectra. Electronic spectra of the copolymer are shown in Fig. 2. The absorption of the hydroxamate anion is shifted to the longer wavelength compared with those of the acid and the acetate. The spectral characteristics are summarized in Table 3 together with those of the model compound. It is apparent that the PHA unit gives almost identical spectra with those of the model compound. These results are not inconsistent with those of other hydroxamic acids.[15]

The extinction coefficient of the PHA anion at 300 nm (ε 1250) is much greater than those of the corresponding acid or ester ($\varepsilon<100$). Therefore, the alkaline hydrolysis of acetyl hydroxamates can be followed by the use of the absorption difference at 300 nm, as mentioned above.

Reaction of Hydroxamic Acids with PNPA. The reaction of hydroxamic acids with PNPA leads to the release of *p*-nitrophenol as follows.



(2)

This was confirmed for the polymer hydroxamic acid employed. A solution of PHA-AAm-1 (1×10^{-3} baseM of the PHA unit) in 20 vol% EtOH–H_2O was made alkaline and treated with 0.01 M of 3-nitro-4-acetoxybenzoic acid at room temperature. After 4 hrs, the mixture was poured into excess methanol. The polymer recovered possessed an IR peak at 1800 cm^{-1} which indicated the presence of the acetyl hydroxamate group and the validity of Eq. (2) for the polymeric system.

·—· *o*-acetyl PHA-AAm-1 in CH_3CN
---- PHA-AAm-1 in 0.01 M HCl
—— PHA-AAm-1 in 0.01 M NaOH

The nitrophenol release due to spontaneous hydrolysis, v_{H_2O}, was corrected: $v_a=v_{total}-v_{H_2O}$. Figures 3 and 4 show the dependence of the rate of nitrophenol release on the concentrations of hydroxamic acid (HA) and PNPA.

$$v_a = k_{a,obs}[HA][PNPA] \quad (3)$$

When the concentrations of hydroxamic acid and PNPA are comparable as in these experiments, the reaction rate, v_a, follows the overall second-order kinetics. On the other hand, the spontaneous hydrolysis

Hydroxamic acid	pH of the reaction medium	$k_{a,obs}$ $M^{-1}s^{-1}$	
		A[b]	B[c]
2	8.57	9.18	9.30
	8.99	14.9	15.2
3	8.57	7.35	7.40
	9.00	14.1	13.9

a) Reaction condition: 30 °C; 0.05 M Tris buffer; 0.1 M KCl; 1.4 vol% CH_3CN-H_2O. b) Obtained from the initial rate. [PNPA]$=3.15\times10^{-5}$ M. [HA]$=5.28\times10^{-5}$ M. c) Obtained from the first-order plot. [PNPA]$=3.15\times10^{-5}$ M. [HA]$=6.28\times10^{-3}$ M.

is a pseudo-first-order process. Therefore, the initial rate of the phenol release was employed for calculating $k_{a,obs}$ values from these data.

The total phenol release adheres strictly to the pseudo-first-order kinetics up to more than 90% reaction, when a large excess of the hydroxamic acid was used. In this case, the rate constant ($k_{a,obs}=k_{total}-k_{H_2O}$) was determined by the Guggenheim method.[16] In Table 4 are compared the rate constants obtained with and without large excesses of hydroxamic acids. The agreements are satisfactory. The use of excess hydroxamic acid concentrations was difficult in the polymeric system, because of the limitation in solubility.

Subsequently, the reaction of hydroxamic acids with PNPA was carried out at the pH range of 7 to 9. The apparent rate constants $k_{a,obs}$ at different pH's are plotted against α(degree of dissociation of hydroxamic acids). Linear relationships were obtained except for PHA-AAm-1, as shown in Fig. 5. An upward curvature was obtained for PHA-AAm-1. This result will be discussed later. It is clear that the hydroxamate anion is the true reacting species and that the reaction rate can be expressed as follows for the first three cases.

$$v_a = k_a\cdot\alpha\cdot[HA][PNPA] \quad (4)$$

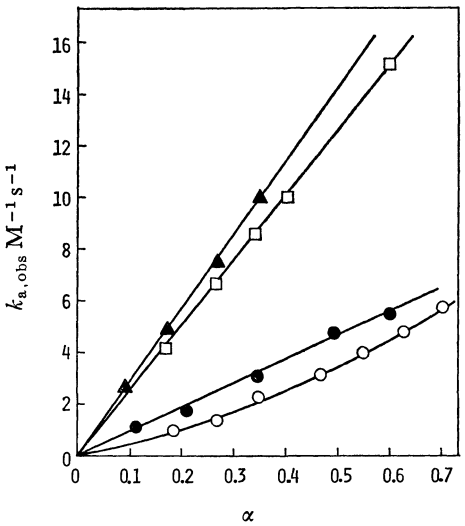

Fig. 5. Reaction of PNPA with a series of hydroxamic acids.
○ PHA-AAm-1, ● PHA-AAm-2, □ **2**, ▲ **3**
30 °C, 1.4vol%CH_3CN-H_2O, 0.1 M KCl, 0.05 M Tris.

where [HA] is the total concentration of the hydroxamic acid employed, and k_a is the true second-order rate constant of acylation.

It is to be noted that the rate of acylation of the polymeric hydroxamate anion was much smaller than that of the model compounds. The k_a value was also calculated for the PHA-AAm-1 case, from the slope at $\alpha=0$. The k_a values are summarized in Table 2.

Hydrolysis of Acetyl Hydroxamates. The hydrolyses of polymeric and monomeric acetyl hydroxamates were performed at three buffer concentrations (0.05, 0.10, 0.15 M) over the pH range between 8.8 and 9.6. The ionic strength was maintained at 0.1 by adding necessary amounts of a KCl solution. The apparent first-order rate constants were calculated by the method of Guggenheim and they were extrapolated to the zero buffer concentration, giving the observed first-order rate constant of deacetylation, $k_{d,obs}$.

$$k_{d,obs} = k_{OH}[OH^-] + k_w \quad (5)$$

The rate constants for the hydroxide and water hydrolyses were determined from the slope and intercept of the linear relationships shown in Fig. 6, and summarized in Table 5.

The k_{OH} values of acetyl *N*-methylhydroxamates were greater than those of the *N*-phenyl counterparts. It is interesting that there is not much difference in k_{OH} values between the corresponding polymeric and small-

Table 5. Hydrolysis of acetyl hydroxamates[a]

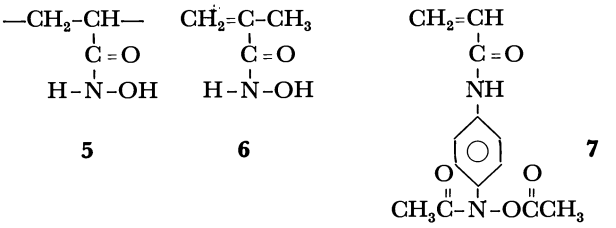
molecule acetyl hydroxamates. This result is in sharp contrast with that observed in the acylation process.

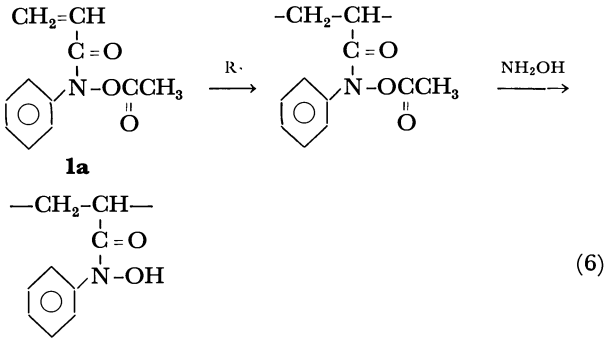
Discussion

Preparation of Polymers Containing the Hydroxamic Acid Group. The introduction of the hydroxamic acid group into polymer has been investigated by several groups. For example, Reiz[17] and Hatano *et al.*[18] prepared polymers containing the hydroxamic acid group (**5**) by reaction of poly(methyl acrylate) with NH_2OH. The conversion was, however, not quantitative. Okawara and coworkers reported a quantitative conversion of the *p*-nitrophenyl ester unit to the hydroxamic acid group in a crossed-linked copolymer. However, the radical polymerization of methacrylohydroxamic acid (**6**) was not successful.[19] Previously we copolymerized a new monomer (**7**) with acrylamide. The hydroxamic acid unit was generated by hydrolysis.[20]



5 **6** **7**

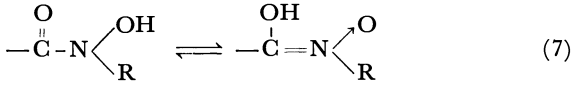
Incorporation of the functional group by polymer reactions often leads to ambiguous results. This is particularly true for rather labile functional groups like hydroxamic acid. Therefore, we synthesized a new monomer (**1a**) which possessed the acetyl hydroxamate group. The hydroxamic acid group was regenerated by NH_2OH treatment of the original polymer.



1a

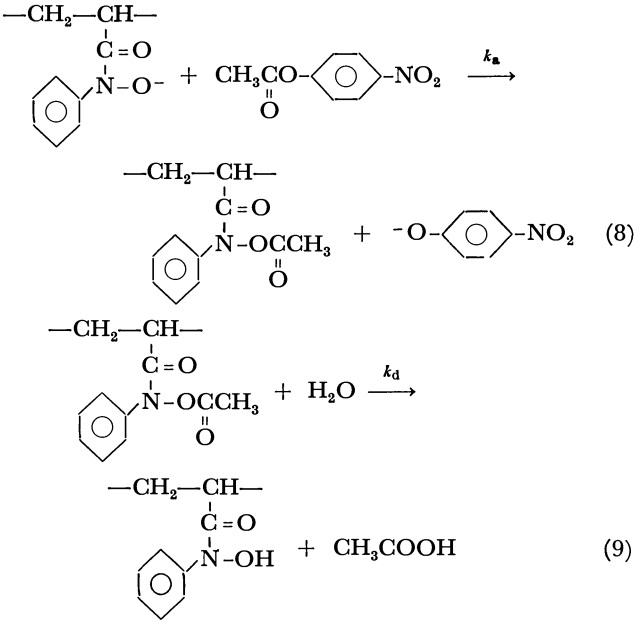
PHA unit (6)

The polymerization of monomers with unprotected hydroxamic acid groups seems difficult, probably because the hydroxamic acid group is tautomeric with the nitrone structure. Nitrones are known to be very efficient trapping agents of the propagating free radical.[21]



a nitrone (7)

Reactions of Hydroxamic Acids with Phenyl Esters. It has been confirmed by several research groups that the reaction of simple hydroxamate anions with phenyl esters yields acyl hydroxamates and phenols.[6,22] The acyl hydroxamate formed can undergo the Lossen rearrangement to isocyanates under strongly basic conditions if the nitrogen of the hydroxamate group is not substituted.[23,24] On the other hand, the Lossen rearrangement can be suppressed by alkyl substitution on the hydroxamic acid nitrogen, and the hydrolysis of acyl hydroxamate to regenerate hydroxamic acid occurs exclusively under basic conditions.[10,25] Thus, Bender and coworkers[10,11] employed *N*-alkylhydroxamic acids as catalysts for the hydrolysis of some phenyl esters. That the same sequence of reactions occurs for polymeric hydroxamic acids (Eqs. (8) and (9)) was established by the present study.



(8)

(9)

Acylation Step. As is clear from Fig. 5, the reaction of the PHA unit in polymer was much slower than that of the monomeric counterpart **2**. Furthermore, two polymer hydroxamic acids show different dependence of the acylation rate on α. This different acylation behavior is interesting. The $k_{a,obs}$ value increases linearly with the increase in α in the case of PHA-AAm-2, whereas the same relation for PHA-AAm-1 is not linear; instead a concave curve is observed. The $k_{a,obs}$ values for PHA-AAm-1 are somewhat lower than those for PHA-AAm-2 at small α values, but they become closer at higher α values.

The n' value determined by the UV titration was 1.35 for PHA-AAm-1 (PHA unit content: 11%) and 1.04 for PHA-AAm-2 (PHA unit content: 3.9%). Therefore, there must be considerable electrostatic repulsion among the hydroxamate anion when the PHA unit content is high. The electrostatic repulsion is conceivably intensified by intramolecular aggregation of the hydrophobic PHA unit. When the content of the PHA unit is small as in PHA-AAm-2, there is not observed noticeable electrostatic repulsion ($n'=1.04$): the dissociation behavior of a given PHA unit is almost the same throughout titration.

The acylation behavior of the polymer hydroxamic

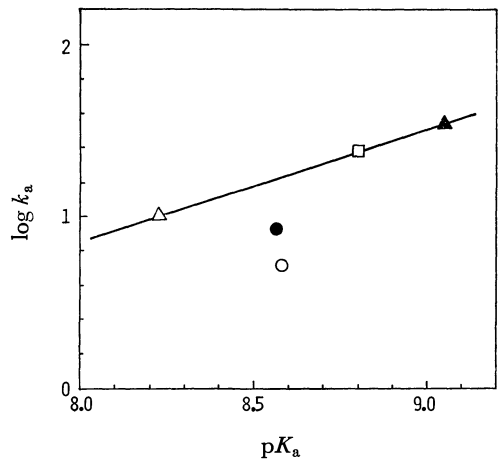


Fig. 7. Brønsted plots.
○ PHA-AAm-1, ● PHA-AAm-2, □ **2**, ▲ **3**, △ **4**
The pK_{int} value was used instead of pK_a for the polymers

acid can be explained by referring to the titration data. The reactivity of the hydroxamate anion in PHA-AAm-2 is invariant since the electrostatic interaction promoted by the side-chain aggregation is negligible. In the case of PHA-AAm-1, the reactivity of a given hydroxamate anion is lessened because of intramolecular aggregation probably with the undissociated PHA unit. As the degree of dissociation increases, the side-chain aggregation is destroyed by expansion of the polymer coil due to increasing electrostatic repulsion among the negatively-charged groups. Therefore, the reactivity of the individual hydroxamate anion increases with α, approaching that of PHA-AAm-2 at higher α values. In the latter polymer, the electrostatic interaction among the PHA unit is considered to be negligible.

The difference in the nucleophilic reactivity between the polymeric and small-molecule systems is also apparent in the Brønsted plot shown in Fig. 7. The three plots for the monomeric hydroxamic acid fall on a straight line, which is expressed by the following equation.

$$\log k_a = 0.62\, pK_a - 4.0 \qquad (10)$$

The slope of the line, the so-called β value in the Brønsted correlation, is 0.62, in fair agreement with those obtained by other workers. Dessolin, *et al.* found β=0.72 for the reaction of PNPA with series of benzohydroxamic acids and cinnamohydroxamic acids.[6] Hershfield and Bender obtained a β value of 0.68 for the reaction of PNPA with three *N*-methylhydroxamic acids.[11] Therefore, it is concluded that the structure variation in the acyl portion and in the *N*-substituent exerts simply the ordinary electronic influence on the nucleophilic reactivity of the hydroxamate group in these systems. The deviation of Brønsted plots for the PHA unit in polymer is, thus, reasonably ascribed to the steric hindrance of the polymer chain on the acylation, rather than to its electronic influence.

Deacylation. The deacylation results are contrasting with the acylation data, in that there is no polymer effect. Thus, the rate constants of deacylation k_{OH} are very similar for three acetyl hydroxamates studied. It might be expected that the hydrolysis rate would decrease with the increase in the basicity of the corresponding hydroxamic acid. However this is not the case, as is clear from the data given in Table 5. It is to be noted that the acetyl hydroxamate unit in polymer possesses a little higher k_{OH} values than the model compound, **2a**. Apparently, the polymer chain does not interfere with the hydroxide attack contrary to the acylation by PNPA. The probable electrostatic repulsion between the partially hydrolyzed O-acetyl-PHA-AAm copolymers and OH^- seemingly does not affect deacylation of the remaining acetyl hydroxamate unit, since the pseudo-first order plot holds well in the deacylation process up to at least 90% completion.

Concluding Remark. As described above, the hydroxamic acid group in polymer undergoes clean acylation and deacylation reactions, as are the monomeric counterparts.* Therefore, polymer hydroxamic acids are potential catalysts for the hydrolysis of phenyl esters. However, the deacylation process is not efficient and the acetyl intermediate is accumulated under the ordinary reaction condition. In fact, the k_{OH} value of PNPA (9.5 $M^{-1}\,s^{-1}$, 25 °C, 1.0 M KCl)[25] is in the same range as those of acetyl hydroxamates. This behavior of the hydroxamic acid is quite contrasting with that of imidazole. In the catalytic hydrolysis of PNPA with imidazole, the acylation process is rate-limiting[26] and the deacylation process is much more efficient than that of acetyl hydroxamates. Therefore, it appears that the catalytic efficiency of the hydroxamic acid can be enhanced by introduction of the intramolecular imidazole unit which assists deacylation of acetyl hydroxamates. This has been accomplished to some extent in a polymeric system.[27]

Synthetic Study of Colchicine

Michiharu KATO, Fusao KIDO, Ming-Der WU, and Akira YOSHIKOSHI

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received February 16, 1974)

An efficient route based upon solvolytic fragmentation of a cyclopentadiene-dichloroketene adduct **4c** has been investigated for the synthesis of trimethoxyphenylpropyltropolone **2b**, a synthetic intermediate of colchicine **1a**. Attempted synthesis of the corresponding unsaturated tropolones **8a** and **10** is also discussed.

Many synthetic approaches have been reported for colchicine **1a**[1] because of its characteristic biological activity on cell divisions and because of the rarely encountered tricyclic tropolone structure. The synthetic goals in many of these studies were desacetamidocolchiceine **1b** since the conversion of the latter compound into natural colchicine has been accomplished by Corrodi and Hardegger.[2] In some instances 4-substituted tropolones, **2a** and **2b**, were used as precursors for **1b**, and the formers were cyclized by intramolecular oxidative coupling[1d] or by Pschorr cyclization[1g] to tricyclic derivatives. In this paper we describe an efficient route to **2b** and attempted synthesis of the related unsaturated systems, such as **8a** and **10**.

Results and Dicussion

4-*t*-Butyltropolone[3a] and 4-isopropyltropolone (hinokitiol)[3b] were regiospecifically synthesized by the addition of the corresponding 1-alkylcyclopentadienes with dichloroketene followed by solvolytic fragmentation. These results imply that a similar synthetic route *via* 1-(trimethoxyphenylpropyl)cyclopentadiene **4a** and its dichloroketene adduct **4c** would be useful for the regiospecific preparation of 4-(trimethoxyphenylpropyl)tropolone **2b**, although the latter was previously synthesized in devious paths from 4-formyltropolone.[4]

Methyl *trans*-3,4,5-trimethoxycinnamate[5] **3a** was hydrogenated to he cortresponding hydrocinnamate **3b** (91% yield). Reduction of **3b** with lithium aluminum hydride gave hydrocinnamyl alcohol **3c** quantitatively. Tosylation of the alcohol in pyridine at an ice bath temperature afforded tosylate **3d**. By treatment with sodium cyclopentadienide in tetrahydrofuran, the tosylate yielded an oily product. The product showed a single spot on tlc, but it was not so sufficiently stable as to give an analytically pure sample. The NMR spectrum of the product displays an overlapped signal corresponding to three protons at δ 5.92—6.50 ppm, proposing **4a** or **4b** as the possible structure of the product. In view of the selective formation of 4-isopropyltropolone upon isopropylation of cyclopentadienylmagnesium bromide,[3b] the selected reaction conditions seemed favorable to the formation of **4a**. Without further examination of the structure, the crude product was immediately allowed to react with equimolar dichloroketene generated from dichloroacetyl chloride and triethylamine in *n*-hexane, giving an oil (42% yield from **3c**) as homogeneous product (tlc). An intense carbonyl absorption at 1805 cm^{-1} in the IR spectrum and a one-proton multiplet at 5.55 ppm in the NMR spectrum are indicative of an α,α-dichlorocyclobutanone structure and a trisubstituted double bond, respectively. The known regiospecificity in the addition reaction of ketenes with conjugated dienes[6] allows to assign the structures **4c** or **4d** to the adduct. On the basis of the known regiospecific formation of substituted tropolones upon acetolysis,[7] **4c** or **4d** should provide the desired 4-(trimethoxyphenylpropyl)tropolone (**2b**) or the corresponding 5-substituted derivative, respectively. The adduct was refluxed in aqueous acetic acid containing potassium acetate, and the tropolonic product was extracted with alkali to give **2b** (67% yield). No formation of other tropolonic products was observed. The physical data of the tropolone were identical with those reported, and the identity was finally ascertained by direct comparison with an authentic sample.[8] The results demonstrates that the aforementioned substituted cyclopentadiene and its dichloroketene adduct must be **4a** and **4c**, respectively. We thus ensured a brief route of good overall yield (25% from **3a**) for the preparation of the tropolone **2b**.

The first successful Pschorr cyclizations of aminotropolones **5a**—**5c** into tricyclic tropolones **6a**—**6c** were achieved by Nozoe *et al.*[9] Kaneko and Matsui[1g] also submitted aminotropolone **7b**, obtained from **2b** *via* azo compound **7a**, to the Pschorr cyclization leading to desacetamidocolchiceine **1b**. We followed the above results and obtained **1b** in a poor yield as reported. The product was reaffirmed by comparison with the au-

thentic compound derived from colchicine according to Eschenmoser *et al.*[1a] In Pschorr cyclization, the fixation of participated aryl groups in *cis* gives better yields of cyclization products than free-rotational systems, *e.g.*, *cis*-2-aminostilbene yielded phenanthrene in 61% yield while 1-phenyl-2-*o*-aminophenylethane gave only a trace of of 9,10-dihydrophenanthrene.[10] In our case *cis*-stilbene type derivative **8b** was presumed to give better yield in the cyclization. We then endeavored to synthesize **8b**.

The cinnamic acid **3e** was brominated in chloroform to give crystalline dibromo acid **3f** (95% yield). The dibromo acid was then heated with sodium bicarbonate in dry acetone yielding a mixture of *cis*- and *trans*-bromostyrenes **3g** (91% yield). The mixture showed two peaks in a ratio of 2 : 1 in glc, and the major product was separated by silver nitrate–silica gel tlc. The NMR spectrum of the major product exhibited two olefin proton signals of an AB-pattern, and their coupling constants (8.8 Hz) demonstrate, in accordance with the findings of Grovenstein and Lee,[11a] and Cristol and Norris,[11b] the major decarboxylative dehydrobromination product to be the *cis*-bromostyrene. Upon treatment with sodium amide in liquid ammonia, the mixture of the bromostyrenes **3g** produced phenylacetylene **3h** (85% yield), whose Grignard reagent was then treated with excess formaldehyde in tetrahydrofuran. The reaction afforded two products (68% yield in total), which were separated by silica gel chromatography in a ratio of 3 : 1. The major product ($C_{12}H_{14}O_4$) was identified as the desired compound **9a** by its spectra, while the minor one ($C_{13}H_{14}O_5$) exhibited a strong absorption at 1720 cm^{-1} and a one-proton triplet signal (J=1.5 Hz) at 8.15 ppm in the IR and NMR spectra, respectively. Since these spectra seemed to suggest that the compound is a formate **9b**, the minor product was hydrolyzed with aqueous alkali. The hydrolysis product was found to be identical with the major product **9a**. It was proved by decoupling experiments that the observed splitting of the formate proton signal are due to a spin-spin coupling between this proton and the propargylic methylene protons. The spin-spin coupling through two C-H and two C-O bonds of formate grouping seems to be uncommon. The formation of **9b** may be accounted for oxymethylenation of the initially formed alcoholate **9c** with formaldehyde leading to **9d**, followed by Oppenauer oxidation with excess formaldehyde. The abnormal Grignard reactions of this type have also been reported for some sterically hindered arylmagnesium bromides.[12]

The alcohol **9a** was converted into bromide **9e** with phosphorus tribromide and a catalytic amount of pyridine (83% yield). Upon treatment with sodium cyclopentadienide under conditions similar to those used for the saturated system **4a**. The bromide gave an oil after passing through a short silica gel column (66% yield), which was nearly homogeneous on tlc. The NMR signals of the product at 3.00 (a two-proton multiplet), 3.51 (a two-proton multiplet), and 6.22—6.62 ppm (a three-proton multiplet) are attributable to propargylic methylene, cyclopentadiene methylene, and olefin protons, respectively. Formula **9f** or **9g**, therefore, may be given to the product. Without further investigation on the structure, the product was allowed to react with dichloroketene leading to an oily adduct (32% yield from the substituted cyclopentadiene). The UV spectrum of the adduct (**9h** or **9i**) shows a maximum absorption at 263 nm, and no IR absorption at near 1785 cm^{-1}, a characteristic carbonyl absorption of α,α-dichlorocyclobutenone and its derivatives,[13] was observed. These spectral data demonstrate that the acetylenic bond was unaffected in the course of the addition with dichloroketene. Solvolytic fragmentation of the adduct in acetic acid containing potassium acetate gave a solid product after extraction with aqueous alkali. Despite of some characteristic IR absorptions at 3150, 1610, and 1550 cm^{-1} of the crude product, attempted separation of the desired tropolone **10** was unsuccessful. Catalytic hydrogenation of the crude product over palladium-carbon gave **2b** in only 11% yield.

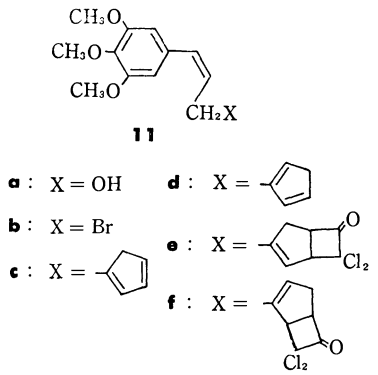
10

Since the pure tropolone **10** was unavailable, we then turned to another approach. The propargyl alcohol **9a** was hydrogenated over Lindlar catalyst to an olefinic alcohol (77% yield), whose NMR spectrum is consistent with the anticipated structure **11a**. Two olefin proton signals of an AB-pattern (J=12 Hz) at 5.80 and 6.50 indicates a cis disubstituted olefin bond. Reaction of **11a** with phosphorus tribromide yielded an unstable bromide **11b**. The crude bromide was submitted to the reaction with sodium cyclopentadienide under conditions similar to those employed for **4a** to give a substituted



cyclopentadiene derivative (36% yield from **11a** after brief purification). The spectra is consistent with the proposed structure **11c** or **11d**. Since the product was also unstable to obtain analytically pure compound, the roughly purified product was immediately submitted to the addition reaction with dichloroketene. A homogeneous oily adduct was obtained on chromatography (5% from **11a**). A UV absorption maximum at 260 nm and an AB-patterned *cis* disubstituted ethylene protons (J=14 Hz) in the NMR spectrum, as disclosed by decoupling (*cf.* Experimental), obviously demonstrate a cis β-substituted styrene moiety. An α,α-dichlorocyclobutanone structure was shown in the IR spectrum (1807 cm^{-1}). These results are in accordance with the structure **11e** or **11f**. The solvolytic fragmentation of the adduct gave an acidic oil, which shows IR absorptions typical of tropolones at 3180, 1615, and 1550 cm^{-1}. The oil, however, was an inseparable mixture. Hydrogenation of the oil, followed by chromatography, gave **2b** in a low yield.

It has still been unclarified why, while the dichloroketene adduct **4c** smoothly yielded the desired tropolone **2a**, the solvolysis of the unsaturated systems resulted in the formation of intractable mixtures.

Experimental

All melting points and boiling points were uncorrected. The spectra were taken with the following instruments: UV, Cary Model 14 spectrophotometer; IR, Hitachi EPI-S2 spectrophotometer; NMR, JEOL Model C-60-HL (60 MHz) and JEOL Model PS-100 (100 MHz). Unless otherwise stated, NMR spectra were recorded in deuterochloroform solutions containing tetramethylsilane (δ=0 ppm) as internal standard. Coupling constants were given in Hz.

*Methyl 3-(3,4,5-Trimethoxyphenyl)-propionate (**3b**).* A solution of methyl *trans*-3,4,5-trimethoxycinnamate[5] **3a** (10 g) in methanol (250 ml) was hydrogenated over 10% palladium-carbon (0.7 g) under atmospheric pressure at room temperature. After hydrogen uptake ceased, the solution was filtered and concentrated to leave an oily **3b** (9.1 g, 91%), which was homogeneous in tlc. IR (Liquid film): 1735 cm^{-1}. NMR: 2.77 (2H, octet), 3.70 (3H, s), 3.81 (3H, s), 3.83 (6H, s), and 6.43 (2H, s).

An analytical sample was obtained by distillation *in vacuo* [bp 110 °C (bath temperature)/0.2 mmHg].

Found: C, 61.24; H, 6.72%. Calcd for $C_{13}H_{18}O_5$: C, 61.40; H, 7.14%.

*3-(3,4,5-Trimethoxyphenyl)-propyl Alcohol (**3c**).* A solution of the hydrocinnamate **3b** (20 g) in dry ether (150 ml) was added dropwise into a suspension of lithium aluminum hydride (2.3 g) in the same solvent (350 ml) over 4 hr with stirring in an ice bath. After the reaction mixture was allowed to stand overnight at room temperature, the excess reagent was destroyed by adding moist ether and then water. The organic layer was dried and evaporated to give an oily **3c** (17 g), which was homogeneous in tlc. IR (liquid film): 3300 cm^{-1}. NMR: 1.96 (2H, q, J=6), 2.70 (2H, t, J=6), 3.73 (2H, t, J=6), 3.88 (9H, s), and 6.49 (2H, s).

An analytical sample was obtained by distillation *in vacuo* [bp 120—130 °C (bath temperature)/1 mmHg (lit.[14] bp 136—139 °C/0.3 mmHg) as colorless oil.

Found: C, 63.47; H, 7.92%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*1-[3-(3,4,5-Trimethoxyphenyl)-propyl]-cyclopentadiene (**4a**).* A solution of tosyl chloride (17.2 g) in dry pyridine (50 ml) was added dropwise to a solution of **3c** (18.5 g) in the same solvent (200 ml) over 2 hr with stirring in an ice bath. The mixture was kept in a refrigerator overnight and then filtered. The filtrate was diluted with cold ether (500 ml) and then washed with cold 10% hydrochloric acid to remove the pyridine. The organic layer was washed with water and brine, and dried. Evaporation of the solvent gave oily tosylate **3d** (27.1 g), which was homogeneous in tlc. The tosylate was used, without further purification, in the next step. IR (liquid film): 1360 and 1180 cm^{-1}.

A solution of freshly distilled cyclopentadiene (380 mg) in dry tetrahydrofuran (3 ml) was added dropwise to a stirred suspension of sodium hydride (126 mg) in the same solvent (4 ml) under nitrogen in an ice bath. After hydrogen evolution ceased, a solution of the crude tosylate (985 mg) in dry tetrahydrofuran (7 ml) was added dropwise to the above cyclopentadienide solution with stirring. Stirring was continued for an additional 3 hr, and the reaction mixture was poured into cold water. The mixture was extracted with ether, and the extracts were washed with water and brine, and dried. Removal of the solvent left a yellow oil (715 mg). The oil was chromatographed on silica gel. Petroleum ether–ether (1 : 1) eluted a small amount of an olefin fraction and then **4a** (576 mg) as a yellow oil. NMR: 1.55—3.05 (8H, m), 3.82 (3H, s), 3.86 (6H, s), 6.43 (2H, s), and 5.92—6.50 (3H, m). Further purification was attempted to obtain an analytically pure sample, but removal of a small amount of impurity from the main fraction was unsuccessful. Thus the roughly purified product was used in the next step.

*7,7-Dichloro-3-[3-(3,4,5-trimethoxyphenyl)-propyl]-bicyclo[3.2.0]-hept-2-en-6-one (**4c**).* Dichloroacetyl chloride (73 mg) was added to a stirred solution of **4a** (137 mg) in *n*-hexane (4 ml), and then the solution was cooled in an ice bath. A solution of triethylamine (60 mg) in the same solvent was added to the above solution over 2 min with stirring. The mixture was stirred for an additional 5 hr. Cold water was added, and the mixture was extracted with ether. The extracts were washed with water and brine, and dried. An oil obtained by evaporation of the solvent was chromato-

graphed on silica gel. Petroleum ether–ether eluted the unreacted **4a** (30 mg) and then the oily adduct **4c** (114 mg, 42% from **3c**). IR: 1805 and 1640 cm^{-1}. NMR: 1.5—2.8 (8H, m), 3.82 (3H, s), 3.85 (6H, s), 4.25 (1H, d.t., J= 7.5 and 2.5, assigned to the proton adjacent to carbonyl[3b]), 5.55 (1H, m), and 6.38 (2H, d, J=2.2).

Found: C, 58.94; H, 5.46%. Calcd for $C_{19}H_{22}O_4Cl_2$: C, 59.21; H, 5.75%.

*4-[3-(3,4,5-Trimethoxyphenyl)-propyl]-tropolone (**2b**).* A mixture of **4c** (4.16 g), potassium acetate (10.6 g), acetic acid (60 ml), and water (0.5 ml) was refluxed for 2 days. The reaction mixture was concentrated *in vacuo*, and the residue was diluted with water. The product was extracted with ether. The organic layer was extracted with dilute sodium hydroxide, and the aqueous layer was acidified with dilute hydrochloric acid. The precipitate was filtered and recrystallized from ethanol to give **2b** (2.40 g, 66%), mp 111—112.5 °C (lit.[1d] 113—115 °C). UV (methanol): 238 nm (log ε, 4.81) and 338 (3.93). IR (KBr): 3180, 1606, 1590, and 1540 cm^{-1}. NMR:[15] 2.00 (2H, m), 2.64 (2H, t, J=8), 2.70 (2H, t, J=8), 3.86 (3H, s), 3.88 (6H, s), 6.44 (2H, s), and 6.8—7.4 (6H, m).

The spectra were identical with those of the authentic compound[1d] provided by Professor Scott.

*4-[3-(3,4,5-Trimethoxyphenyl)-propyl]-5-p-tolylazotropolone (**7a**) and 4-[3-(3,4,5-Trimethoxyphenyl)-propyl]-5-aminotropolone (**7b**).* These compounds were prepared according to the known procedure,[1g] and similar results were obtained. The unreported NMR data of **7a** are given below. NMR of **7a**: 2.00 (2H, m), 2.45 (3H, s), 2.75 (3H, t, J=7), 3.32 (3H, t, J=7), 3.37 (3H, s), 6.43 (2H, s, assigned to the aromatic protons of trimethoxyphenyl), 7.37 and 8.20 (1H, d, J=12 each, assigned to the C-6 and C-7 tropolone protons), 7.40 nad 7.80 (1H, d, J=6 each, assigned to the aromatic protons of tolylazo group), and 7.51 (1H, s, assigned to the C-3 tropolone proton).

*Desacetamidocolchiceine (**1b**).* The cyclization reaction was performed under reaction conditions essentially identical with those described by Kaneko and Matsui,[1g] except that no copper catalyst was used in decomposition of the diazonium salt of **7b**.

Thus a solution of isoamyl nitrite (0.1 ml) in dioxane (1 ml) was added dropwise to a stirred solution of **7b** (69 mg) and sulfuric acid (0.1 ml) in dioxane (1.5 ml) at room temperature. After stirring for an additional 2 hr, the mixture was heated at 55—57 °C for 1 hr. The mixture was diluted with water and extracted with methylene chloride. After usual work-up, the crude product was chromatographed on phosphoric acid impregnated Celite. After an unidentified product was eluted with a mixture of *n*-hexane and benzene, **1b** was eluted with benzene as crystals, which was recrystallized from ethanol giving 2 mg (3%) of the pure product melting at 167—169 °C (lit. 168—169 °C,[1a] 165—167 °C[1b]). The IR and NMR spectra of the product were identical with those of an authentic sample of desacetamidocolchiceine.

*3-(3,4,5-Trimethoxyphenyl)-2,3-dibromopropionic Acid (**3f**).* A solution of bromine (176 mg) in chloroform (1 ml) was added dropwise to an ice-cooled solution of **3a** (238 mg) in the same solvent (2 ml) over 2 min with stirring. The reaction mixture was filtered to separate the precipitate after 30 min, and the filtrate was concentrated to give an additional solid. The combined solids were recrystallized from benzene–ligroin to afford colorless crystals (377 mg, 95%), mp 153—155 °C. IR(KBr): 1745 cm^{-1}. NMR (acetone-d_6): 3.80 (3H, s), 3.91 (6H, s), 5.22 and 5.52 (1H, d, J=12 each), and 7.04 (2H, s).

Found: C, 35.77; H, 3.78%. Calcd for $C_{12}H_{14}O_5Br_2$: C, 36.11; H, 3.51%.

*3,4,5-Trimethoxy-β-styrene (**3g**).* A suspension of **3f** (100 mg) and sodium bicarbonate (252 mg) in dry acetone (10 ml) was refluxed with stirring for 2 hr. The acetone was removed *in vacuo*, and water (3 ml) was added to the residue. The mixture was extracted with ether. The combined extracts were washed with water and brine, and dried. Removal of the solvent left an oil, which was distilled *in vacuo* [120—130 °C (bath temperature)/1 mmHg] giving a colorless oil (62 mg, 91%).

Found: C, 48.81; H, 4.73%. Calcd for $C_{11}H_{13}O_3Br$: C, 48.47; H, 4.79%.

The mixture of the isomers showed two peaks in glc (SE-30 column) in an approximate ratio of 1 : 2. The major isomer was separated by silver nitrate-silica gel preparative tlc. IR (liquid film): 3050 and 1615 cm^{-1}. NMR (carbon tetrachloride):[15] 3.70 (3H, s), 3.75 (6H, s), 6.35 (2H, s), and 6.55 and 6.85 (1H, d, J=8.8 each).

*3,4,5-Trimethoxyphenylacetylene (**3h**).* A solution of the isomeric mixture of **3g** (27.3 g) in dry ether (100 ml) was added dropwise to a stirred sodium amide solution, prepared from sodium (2.7 g) and liquid ammonia (500 ml), over 20 min. A vigorous reaction took place and appeared to complete when the addition finished. Stirring was continued for an additinal 30 min, and ammonium chloride was added. After removal of the liquid ammonia, water was added, and the mixture was extracted with ether. The combined extracts were washed with dilute hydrochloric acid and water, and then brine. Evaporation of the solvent left crystals, which was recrystallized from ether–petroleum ether to give colorless crystals melting at 68—68.5 °C (16.3 g, 85%). IR (KBr): 3250 cm^{-1}. NMR (carbon tetrachloride): 2.93 (1H, s), 3.81 (3H, s), 3.89 (6H, s), and 6.74 (2H, s).

Found: C, 68.79; H, 6.03%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

*3-(3,4,5-Trimethoxyphenyl)-propargyl Alcohol (**9a**) and Its Formate (**9b**).* A solution of **3h** (192 mg) in dry tetrahydrofuran (0.5 ml) was added dropwise to a Grignard reagent solution prepared from ethyl bromide (131 mg) and magnesium (29 mg) in the same solvent (0.5 ml). Excess formaldehyde vapor was passed through the above acetylenic Grignard reagent solution with stirring at room temperature, and then water was added to quench. The organic layer was separated and washed with water and brine, and dried. Evaporation of the solvent left an oil, which showed three spots in tlc. The oil was chromatographed on silica gel. Petroleum ether–ether (3 : 2) eluted the unreacted **3h** (33 mg) and then the formate **9b** (40 mg, 16%). Petroleum ether–ether (2 : 3—1 : 4) eluted **9a** (115 mg, 52%).

An analytical sample of **9a** was obtained by recrystallization from ether–petroleum ether as colorless crystals melting at 89—91 °C. IR (KBr): 3300, 2210, and 1127 cm^{-1}. NMR:[15] 3.85 (9H, s), 4.51 (2H, s), and 6.71 (2H, s).

Found: C, 64.55; H, 6.45%. Calcd for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

An analytical sample of **9b** was obtained by recrystallization from *n*-hexane–benzene as colorless crystals melting at 89—90 °C. IR (KBr): 2200, 1720, and 1210 cm^{-1}. NMR: 3.86 (9H, s), 5.00 (2H, d, J=1.5), 6.71 (2H, s), and 8.15 (1H, t, J=1.5). The doublet at 5.00 or the triplet at 8.15 ppm collapsed to a singlet on decoupling of the other signal.

Found: C, 62.59; H, 5.87%. Calcd for $C_{13}H_{14}O_5$: C, 62.39; H, 5.64%.

A solution of the formate **9b** (50 mg) and sodium hydroxide (16 mg) in ethanol (10 ml) was allowed to stand overnight. After evaporation of the solvent, the residue was diluted with water and extracted with chloroform. A usual work-up

gave **9a** (41 mg, 93%).

*3-(3,4,5-Trimethoxyphenyl)-propargyl Bromide (**9e**).* A solution of phosphorus tribromide (300 mg) in dry tetrahydrofuran was added dropwise to a stirred solution of **9a** (889 mg) and a catalytic amount of pyridine in the same solvent (8 ml) over a period of 10 min in an ice bath. After stirring for an additional 2 hr, the mixture was poured into cold water and extracted with ether. The combined extracts were washed with water and brine, and dried. Removal of the solvent left an oil, which was chromatographed on silica gel. Petroleum ether–ether eluted **9e** (1.14 g, 83%) as crystals, which was recrystallized from petroleum ether–ether to afford colorless crystals, mp 48—50 °C. IR (KBr): 2200 cm^{-1}. NMR (carbon tetrachloride): 3.75 (3H, s), 3.81 (6H, s), 4.11 (2H, s), and 6.60 (2H, s).

Found: C, 50.27; H, 4.58%. Calcd for $C_{12}H_{13}O_3Br$: C, 50.53; H, 4.58%.

*1-[3-(3,4,5-Trimethoxyphenyl)-2-propynyl]cyclopentadiene (**9f** or **9g**).* A solution of **9e** (550 mg) in dry tetrahydrofuran (5 ml) was added dropwise to a stirred cyclopentadienide solution, prepared from cyclopentadiene (152 mg) and sodium hydride (53 mg) in the same solvent (5 ml), over 10 min in an ice bath. Stirring was continued for an additional 3 hr, and the reaction mixture was extracted with ether. The extracts were washed with water and brine, and dried. Removal of the solvent *in vacuo* gave a yellow oil, which was chromatographed on a short silica gel column. A mixture of petroleum ether–ether eluted an oil (344 mg, *ca.* 66%), whose tlc showed it to be nearly homogeneous. Further purification, however, was unsuccessful owing to its instability. IR (liquid film): 2300 cm^{-1}. NMR:[15] 3.00 (2H, m), 3.51 (2H, m), 3.85 (9H, s), 6.22—6.62 (3H, m), and 6.65 (2H, s).

*Dichloroketene Adduct of the Propargylcyclopentadiene (**9h** or **9i**).* Dichloroacetyl chloride (888 mg) was added to a stirred solution of the above propargylcyclopentadiene (1.48 g) in *n*-hexane (40 ml), and the mixture was cooled in an ice bath. A solution of triethylamine (638 mg) in the same solvent was added to the above mixture over 5 min with stirring at the same temperature. The mixture was stirred for an additional 5 hr, and then water was added. The organic layer was washed with water and brine, and dried. Removal of the solvent gave an oil. Petroleum ether containing ether eluted an oily adduct (668 mg, 32%). UV (methanol): 218 nm (log ε, 4.60) and 263 (4.23). IR (liquid film): 1807 cm^{-1}. NMR: 2.77 (2H, m), 3.10—3.80 (2H, m), 3.85 (9H, s), 3.95—4.50 (2H, m), 5.95 (1H, m), 6.70 (1H, s), and 6.75 (1H, s).

Found: C, 59.34; H, 4.90%. Calcd for $C_{19}H_{18}O_4Cl_2$: C, 59.69; H, 4.75%.

*Solvolysis of the Adduct (**9h** or **9i**) and Hydrogenation of the Product.* A solution of the adduct (**9h** or **9i**) (215 mg), potassium acetate (320 mg), and water (2 drops) in acetic acid (5 ml) was refluxed for 2 days. The solvent was removed *in vacuo*, and the residue was diluted with water and extracted with chloroform. The combined extracts were washed with dilute sodium hydroxide solution. The aqueous layer was acidified with dilute hydrochloric acid and extracted with chloroform. The extracts were washed with water and brine. Evaporation of the solvent left a solid (72 mg), which could not be purified by recrystallization or chromatography.

The crude product (70 mg) dissolved in ethyl acetate (5 ml) was hydrogenated over 10% palladium-carbon (5 mg). After hydrogen uptake ceased, the catalyst was filtered off. The filtrate was evaporated to give a solid (61 mg), which was then dissolved in hot methanol (10 ml). The solution was filtered, and the filtrate was concentrated and cooled to give **2b** (8 mg).

*3-(3,4,5-Trimethoxyphenyl)-allyl Alcohol (**11a**).* A mixture of **9a** (66 mg), 5% palladium-barium sulfate (20 mg), quinoline (0.4 ml), and methanol (2 ml) was treated with hydrogen under atmospheric pressure at room temperature. After hydrogen uptake ceased (1 molar equivalent), the catalyst was filtetered off, and then the filtrate was passed through a 5% silver nitrate-silica gel column to remove the quinoline. The solvent was removed, and the residue was submitted to preparative tlc using petorleum ether–ether (1 : 1) as eluent. The allylic alcohol (**11a**) was obtained (51 mg, 77%) as an oil. IR (liquid film): 3400 and 1640 cm^{-1}. NMR: 3.83 (9H, s), 4.42 (2H, q, J=6 and 1.5), 5.80 (1H, d.t, J=12 and 6), 6.50 (1H, br. d, J=12), and 6.45 (2H, s).

Found: C, 64.12; H, 7.25%. Calcd for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19%.

*Dichloroketene Adduct(**11e** or **11f**).* Phosphorus tribromide (1.39 g) was added dropwise to a stirred solution of **11a** (3.12 g) and pyridine (0.2 ml) in dry tetrahydrofuran (70 ml) over 5 min in an ice bath, and stirring was continued for an additional 1 hr. The mixture was poured into water and extracted with ether. The combined extracts were washed with water and brine, and dried. Removal of the solvent gave an unstable oil (4.09 g), whose IR spectrum showed no hydroxyl absorptions. The freshly prepared bromide was used, without further purification, in the next step.

A solution of the crude bromide (4.09 g) in dry tetrahydrofuran (70 ml) was added dropwise to a stirred cyclopentadienide solution, prepared from cyclopentadiene (1.06 g) and sodium hydride (370 mg) in the same solvent (70 ml), over 10 min at an ice-bath temperature. After stirring for an additional 2 hr, the mixture was poured into water and extracted with ether. A usual work-up gave a yellow oil, which was chromatographed on a short silica gel column. Petroleum ether–ether (2 : 1) eluted an oily product (1.37 g, 36% from **11a**), which was homogeneous in tlc. NMR: 3.02 (2H, m), 3.36 (2H, m), 3.87 (3H, s), 3.91 (6H, s), 6.12—6.60 (5H, m), and 6.67 (2H, s).

Owing to its instability, no analytical sample of the product was obtained.

Dichloroacetyl chloride (54 mg) was added to a stirred solution of the roughly purified product (100 mg) in *n*-hexane (5 ml) in an ice bath. A solution of triethylamine (38 mg) in the same solvent (3 ml) was added dropwise to the above mixture. After stirring for an additional 2 hr, the mixture was poured into water and extracted with ether. A usual work-up gave an oil, which was purified twice by preparative silica gel tlc using petroleum ether–ether (1 : 1) as eluent. A homogeneous product **11e** (or **11f**) (20 mg, 5% from **11a**) was obtained. UV (methanol): 260 nm (log ε, 4.22). IR (liquid film): 1807 cm^{-1}. NMR:[15] 2.67 (2H, m), 3.00 (2H, br. d, J=6), 3.81 (3H, s), 3.84 (6H, s), 3.95 (1H, m, assigned to the C-1 proton[16]), 4.25 (1H, d. t, assigned to the C-5 proton[16]), 5.48 (1H, br. s), 6.04 (1H, q, J=14 and 6), 6.32 (1H, d, J=14), and 6.45 (2H, s). On irradiation at 3.00 ppm, the quartet signal at 6.04 ppm changed into a doublet (J=14).

Found: C, 59.66; H, 4.61%. Calcd for $C_{19}H_{20}O_4Cl_2$: C, 59.31; H, 4.82%.

*Solvolysis of the Adduct (**11e** or **11f**) and Hydrogenation of the Product.* A mixture of the adduct (**11e** or **11f**) (95 mg), potassium acetate (200 mg), water (2 drops), and acetic acid (2 ml) was refluxed for 2 days. The solvent was evaporated *in vacuo*, and the residue was poured into water and extracted with ether. The extracts were washed with aqueous sodium hydroxide, and the aqueous layer was acidified with dilute hydrochloric acid. The acidic product was extracted with chloroform. The organic layer was extracted

with 85% phosphoric acid, and the phosphoric acid extracts were diluted with water. The liberated product was collected with ether. An oil (27 mg) was obtained by evaporation of the solvent. The oil was a mixture and gave no homogeneous product upon attempted purification.

A mixture of the crude solvolysis products (20 mg), 10% palladium-carbon (3 mg) and ethyl acetate (2 ml) was hydrogenated under atmospheric pressure at room temperature. After usual work-up, an oil obtained was passed through a phosphoric acid-Celite column. Benzene eluted crystals, which were recrystallized from methanol to give **2b** (4 mg), as identified by IR.

The Base-induced Reactions of 2-Halogeno-1,3-diketones in a Variety of Solvents

Tadahiro WAKUI, Yoshio OTSUJI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received February 20, 1974)

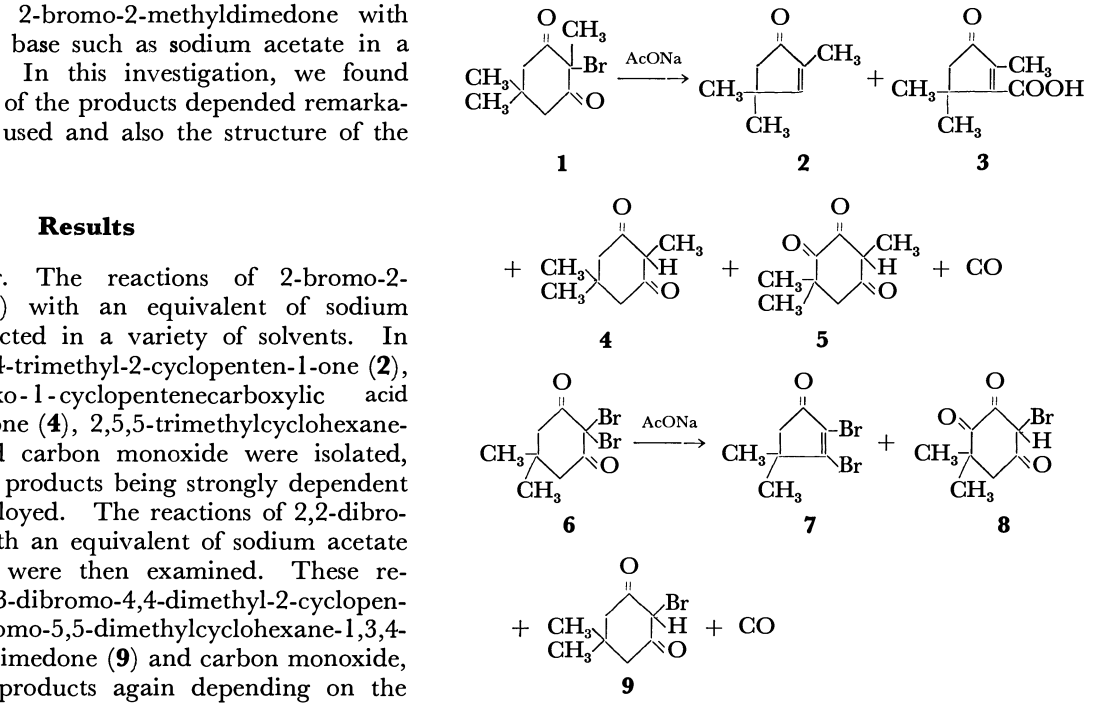
The reactions of 2-bromo-2-methyldimedone (**1**), 2,2-dibromodimedone (**6**), 2-bromo- and 2-chloro-2-methylcyclohexane-1,3-dione (**10a** and **10b**) and 2-acetyl-2,6-dibromocyclohexanone (**14**) with an equivalent of sodium acetate in a variety of solvents were studied. The constitutions and proportions of the products obtained by these reactions depended strongly on the structure of 2-halogeno-1,3-diketones and the solvents employed. The results were discussed in terms of the mechanisms proposed.

In a previous paper,[1] we have reported that 2-alkyl-2-bromodimedones undergo various types of reactions upon treatment with bases in aprotic solvents such as benzene and THF, and the mode of reactions strongly depends on the bases employed. This paper deals with the reactions of various 2-halogeno-1,3-diketones including 2-bromo-2-methyldimedone with a weak nucleophilic base such as sodium acetate in a variety of solvents. In this investigation, we found that the proportions of the products depended remarkably on the solvents used and also the structure of the 1,3-diketones.

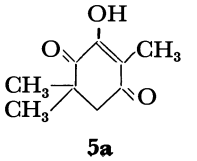
Results

Effects of Solvents. The reactions of 2-bromo-2-methyldimedone (**1**) with an equivalent of sodium acetate were conducted in a variety of solvents. In these reactions, 2,4,4-trimethyl-2-cyclopenten-1-one (**2**), 2,5,5-trimethyl-3-oxo-1-cyclopentenecarboxylic acid (**3**), 2-methyldimedone (**4**), 2,5,5-trimethylcyclohexane-1,3,4-trione (**5**) and carbon monoxide were isolated, proportions of these products being strongly dependent on the solvents employed. The reactions of 2,2-dibromodimedone (**6**) with an equivalent of sodium acetate in various solvents were then examined. These reactions afforded 2,3-dibromo-4,4-dimethyl-2-cyclopenten-1-one (**7**), 2-bromo-5,5-dimethylcyclohexane-1,3,4-trione (**8**), 2-bromodimedone (**9**) and carbon monoxide, proportions of the products again depending on the solvents used.

The structures of the products **2**—**4** and **7**—**9** were assigned as previously reported,[1] and the evolution of carbon monoxide was confirmed by vpc analysis of the evolved gas collected during the reaction. The structure of **5** was established from its elemental analysis and spectral data. The IR spectrum (KBr) showed a hydrogen-bonded hydroxyl absorption at 3200 cm^{-1}, three carbonyl absorptions at 1705, 1685, and 1650 cm^{-1}, and an absorption due to the C=C bond at 1640 cm^{-1}. The NMR spectrum ($CDCl_3$) exhibited a singlet (6H, two CH_3's attached at the 5-position) at δ 1.27, a singlet (3H, CH_3 attached at the 2-position) at δ 1.92, a singlet (2H, $-CH_2-$ at the 4-position) at δ 2.73, and a broad singlet (1H, an enol proton) at δ 7.0. The mass spectrum showed a parent peak at *m/e* 168. These spectral data indicate that **5** exists essentially in the form of **5a** under the conditions where the spectra were measured. The yields of the products **2**—**9** obtained by the above reactions are summarized in Table 1.

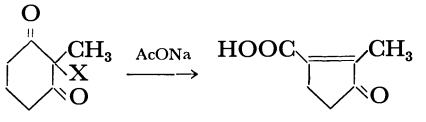


1 **2** **3** **4** **5** **6** **7** **8** **9**



5a

Effects of the Structure of 1,3-Diketones. Treatment of 2-bromo-2-methylcyclohexane-1,3-dione (**10a**) with an equivalent of sodium acetate in THF under reflux afforded 2-methyl-3-oxo-1-cyclopentenecarboxylic acid (**11**), its mixed anhydride (**12**) and 2-methylcyclohexane-1,3-dione (**13**). Similar treatment of 2-chloro-2-methylcyclohexane-1,3-dione (**10b**) with an equivalent of sodium acetate in THF gave the same products. However, the reaction of 2-acetyl-2,6-dibromocyclohexanone (**14**) with an equivalent of sodium acetate in THF afforded a mixture of 2-acetyl-1-cyclopentenecarboxylic acid (**15**) and its mixed anhydride (**16**). The yields of the products obtained by the above reactions are summarized Table 2.

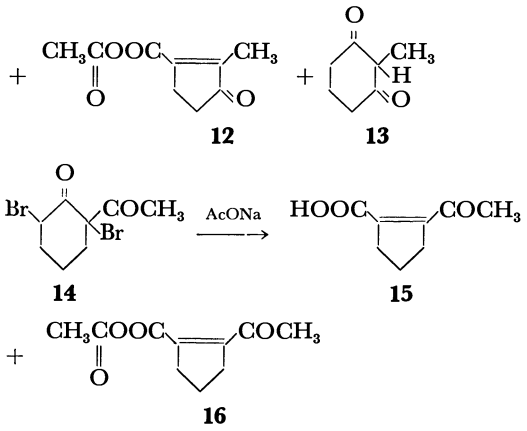


10a; X=Br
b; X=Cl

11

Table 1. Reactions of **1** and **7** with sodium acetate

Compd	Solvent	Reaction temp., °C	Time hr	Products			Recovered starting material
1	Benzene	80	5	**2**(4)	**3**(3)	**4**(Trace)	**1**(57)
1	Ether	35	5	**2**(4)		**4**(5)	**1**(42)
1	THF	65	5	**2**(20)	**3**(37)	**4**(20)	**1**(6)
1	*t*-BuOH	83	5	**2**(20)	**3**(13)	**4**(20)	
1	CH_3CN	80	5	**2**(28)	**3**(18)	**4**(8)	
1	EtOH	78	5	**2**(50)	**5**(22)	**4**(2)	
1	MeOH	65	5	**2**(58)	**5**(20)		
1	MeOH	0—5	5	**2**(20)			
1	THF-water (3 : 2)	70	5	**2**(22)	**3**(15)	**4**(15)	
1	Benzene-water (6 : 1)	80	5				**1**(88)
6	THF	65	5	**7**(25)	**8**(16)	**9**(32)	
6	THF-water (6 : 1)	70	5	**7**(12)	**8**(25)	**9**(33)	
6	DMF	80	5	**7**(3)	**8**(75)		



The structure of **13** was confirmed by the comparisons of IR and NMR spectral data with those of the authentic sample and also by the mixture melting-point test. The structure of **11** was assigned by its spectral data. The IR spectrum (KBr) showed multiple absorptions characteristic of a carboxyl group at 3200—2800 cm^{-1}, carbonyl absorptions at 1720 and 1670 cm^{-1}, and an absorption due to the C=C bond at 1630 cm^{-1}. The NMR spectrum ($CDCl_3$) exhibited a singlet (3H, $-CH_3$ attached at the 2-position) at δ 1.76, a multiplet (4H, $-CH_2-CH_2-$ at the 4- and 5-positions) at δ 2.1—3.0, and a singlet(1H, –COOH at the 3-position) at δ 8.37. The UV spectrum (95% ethanol) had a maximum absorption at 243 nm (ε 13000). This spectrum was similar in shape to that of 3-oxo-1-cyclopentenecarboxylic acid (λ_{max}^{EtOH} 243 nm(ε1 5000)).[2] The mass spectrum showed a parent peak at *m/e* 140. The structure of **12** was confirmed by its spectral data (see Experimental) and chemical modification; the mild treatment of **12** with sodium hydroxide solution gave **11**. The structure of **15** was also established by its spectral data. The IR spectrum showed a carbonyl absorption at 1700 cm^{-1}, a carboxyl absorption at 1690 cm^{-1}, and an absorption due to the C=C bond at 1630 cm^{-1}. The NMR spectrum ($CDCl_3$) exhibited a singlet (3H, $-COCH_3$) at δ 2.45, a multiplet (6H, $-CH_2-CH_2-CH_2-$ at the 3-, 4- and 5-positions) at δ 2.0—2.91, and a singlet (1H, –COOH) at δ 12.4. The mass spectrum showed a parent peak at *m/e* 154. The structure of **16** was deduced by its spectral data (see Experimental) and by the fact that the mild treatment of **16** with NaOH solution gave **15**.

Table 2. Reactions of various 2-halogeno-1,3-diones with sodium acetate in THF under reflux

1,3-Dione	Reaction time, hr	Products (%)		
10a	5	**11**(25)	**12**(12)	**13**(18)[a]
10b	4	**11**(18)	**12**(4)	**13**(20)[b]
14	5	**15**(40)	**16**(17)	

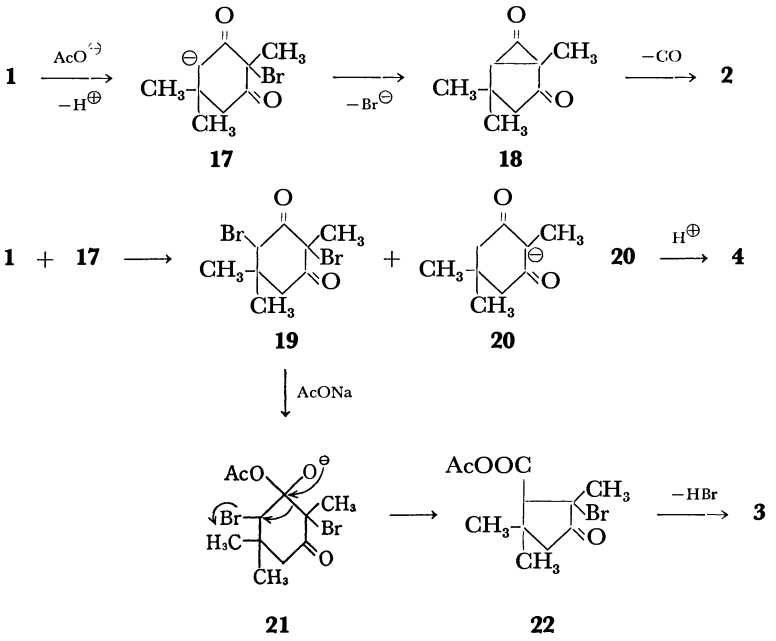
a) The starting material, **10a**, was recovered in 11% yield. b) The starting material, **10b**, was recovered in 15% yield.

Discussion

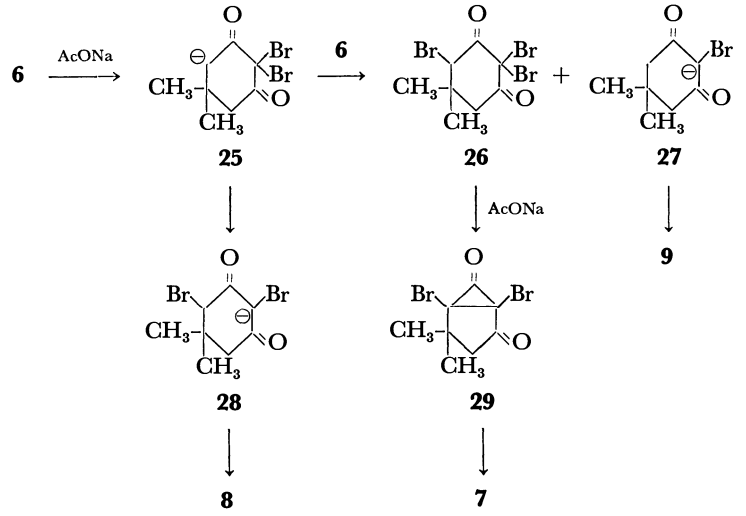
Effects of Solvents. A striking feature of the reaction of **1** with sodium acetate is that the proportion and constitution of the products are largely dependent on the solvents employed. The results of Table 1 indicate that the yields of the products increase with increase in the polarity of the solvents. Specifically, the use of alcohols caused pronounced effects on the constitution of the products; *i. e.*, (1) the yield of **2** increased remarkably with a marked decrease in the yields of **3** and **4**, and (2) the formation of the trione **5** was observed.

These results could be interpreted in terms of the mechanism proposed in the previous paper,[1] which is outlined in Scheme 1.

A key intermediate in the formation of **2** is the cyclopropanone **18** which is produced by an elimination of bromide ion from the carbanion **17**. The carbanion **17** reacts also with **1** to produce the dibromide **19** and the carbanion **20** which affords **4** on protonation. The dibromide **19** is converted by the semibenzylic type-rearrangement to **22** and then to **3** upon treatment with sodium acetate. The polar solvents may facilitate these ionic reactions, thus leading to an increase in the yields of the products. The use of alcohols may favor the formation of **18** by assisting the elimination of

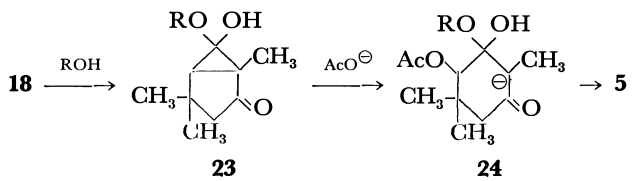


Scheme 1.



Scheme 2.

bromide ion from **17**, probably through a hydrogen bonding between the solvents and bromine, which is depicted as -Br···HOR. Thus, the reactions in alcohols result in the increase in the yield of **2**, accompanied by the decrease in the yield of other products which are produced from **17**. It is conceivable that in an alcohol **18** forms the alkyl acetal which is stable.[3] The reaction of **23** with sodium acetate may result in the formation of **5**.

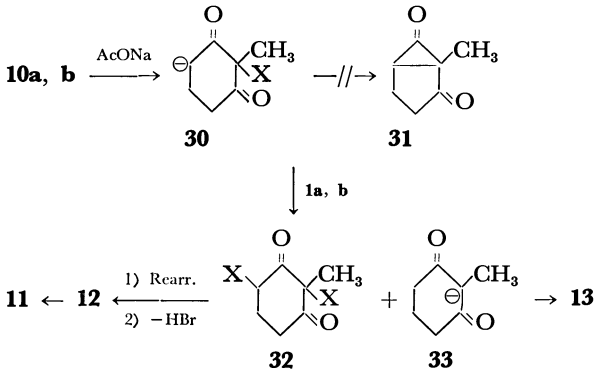


The behavior of **6** for the reaction with sodium acetate could also be explained by the mechanism proposed previously[1] (Scheme 2).

Effects of the Structure of 2-Halogeno-1,3-diketones. Another striking feature of the results of this investigation is that the mode of the reaction of 2-halogeno-1,3-diketones with sodium acetate is strongly influenced by the structure of the 1,3-diketones. The reaction of **10a** and **10b** with sodium acetate led to the formation of **11**, **12**, and **13**. However, in these reactions the cyclopentenone corresponding to **2** could not be isolated.

These results suggest that two methyl substituents attached at the 5-position of cyclohexane-1,3-dione plays an important role for the formation of the cyclopropanone intermediate. In the case of the reaction of **1**, the reaction of the carbanion **17** with **1** is more or less interfered by a steric interference caused by two methyl substituents at the 5-position, thus **17** can partly be transformed to the cyclopropanone **18** (see Scheme 1). On the other hand, in the reactions of **10a** and **10b**, the carbanion **30** is readily converted to **32** and **33** upon

the reaction with **10a, b** without the formation of the cyclopropanone **31** (see Scheme 3).



Scheme 3.

Similarly, the reaction of **14** with sodium acetate in THF lead preferentially to the formation of the rearranged products **15** and **16** in accordance with the mechanism proposed.

Experimental

2-Bromo-2-methyldimedone (**1**) and 2,2-dibromodimedone (**6**) were prepared by the methods previously reported.[1]

*Reactions of **1** with Sodium Acetate in Benzene, Ether, THF, THF–Water (3 : 2), t-Butyl Alcohol, and Acetonitrile.* A mixture of 0.5 g (2.2 mmol) of **1** and 0.2 g (2.5 mmol) of AcONa in 30 ml of a solvent was refluxed for 5 hr. The reaction mixture was poured into water, neutralized with 1M HCl, and then extracted with ether. The ether extract was washed with a 5% aqueous Na_2CO_3 solution, dried over Na_2SO_4, and evaporated to leave an oil. Distillation of the oil gave 2,4,4-trimethyl-2-cyclopenten-1-one (**2**); bp 160—165 °C. The yield of **2** was determined by vpc analysis of the reaction mixture.

The Na_2CO_3 solution was neutralized with 1 M HCl and extracted with ether. The ether extract was dried over Na_2SO_4 and evaporated. The residue was chromatographed on a silica gel with benzene–CCl_4 (1 : 3). The earlier fraction gave 2,5,5-trimethyl-3-oxo-1-cyclopentenecarboxylic acid (**3**); mp 189—191 °C. The latter fraction afforded 2-methyldimedone (**4**); mp 160—162 °C. The yields of **2**, **3** and **4** are given in Table 1.

*Reaction of **1** with Sodium Acetate in Methanol.* A mixture of 0.5 g (2.2 mmol) of **1** and 0.2 g (2.5 mmol) of AcONa in 30 ml of MeOH was refluxed for 5 hr. The reaction mixture was worked up as described above and separated into two fractions (the neutral fraction and the Na_2CO_3 soluble fraction). From the neutral fraction, crude **2** was obtained as an oil. Vpc analysis of the reaction mixture indicated that the mixture contained 0.15 g (58%) of **2**.

From the Na_2CO_3 soluble fraction, a solid was obtained. Recrystallization of the solid from $CHCl_3$ gave 0.07 g (20%) of 2,5,5-trimethylcyclohexane-1,3,4-trione (**5**); mp 161—162 °C.

Found: C, 64.35; H, 7.33%. Calcd for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

*Reaction of **6** with Sodium Acetate.* A mixture of 1.0 g (3.4 mmol) of **6** and 0.3 g (3.7 mmol) of AcONa in 50 ml of DMF was heated at 70 °C for 5 hr. The reaction mixture was poured into 50 ml of water, neutralized with 1 M HCl, and then extracted with two 30 ml portions of ether. The ether extracts were washed with 5% aqueous Na_2CO_3 solution, dried over Na_2SO_4 and evaporated to leave an oil. The oil was chromatographed on a silica gel with *n*-hexane–CCl_4 (5 : 1) to give 27 mg (3%) of 2,3-dibromo-4,4-dimethyl-2-cyclopenten-1-one (**8**); mp 85—86 °C.

The Na_2CO_3 solution was neutralized with 1M HCl and extracted with ether. The ether solution was dried over Na_2SO_4, and evaporated to give a solid. Recrystallization of the solid from CCl_4–$CHCl_3$ (1 : 3) gave 0.59 g (75%) of 2-bromo-5,5-dimethylcyclohexane-1,3,4-trione (**8**); mp 188—190 °C.

The reactions of **6** with AcONa in other solvents were carried out similarly, and the products shown in Table 1 were isolated.

*2-Bromo-2-methylcyclohexane-1,3-dione (**10a**).* To a stirred mixture of 4.5 g (36 mmol) of 2-methylcyclohexane-1,3-dione[5] and 4.2 g (36 mmol) of AcONa in 60 ml of $CHCl_3$–H_2O (6 : 1), 5.7 g (36 mmol) of bromine was added dropwise below 5 °C. After the addition, the mixture was further stirred for 1 hr, and then the $CHCl_3$ layer was separated. The aqueous layer was extracted with 30 ml of $CHCl_3$. The combined $CHCl_3$ solutions were dried over Na_2SO_4 and evaporated under reduced pressure. The residue was chromatographed on a silica gel with CCl_4 to give 4.5 g (62%) of **10a**; bp 65—66 °C/2 mmHg. IR(film): 1735 and 1710 cm^{-1}. NMR(CCl_4): δ 1.75 (s, 3H, CH_3) and 1.90—3.60 ppm (m, 6H, $-CH_2CH_2CH_2-$).

Found: C, 41.33; H, 4.68%. Calcd for $C_7H_9O_2Br$: C, 41.00; H, 4.42%.

*Reaction of **10a** with Sodium Acetate.* A mixture of 1.5 g (7.3 mmol) of **10a** and 0.6 g (7.4 mmol) of AcONa in 50 ml of THF was refluxed for 5 hr. The reaction mixture was poured into water, neutralized with 1M HCl and then extracted with two 30 ml portions of ether. The combined ether extracts were washed with 5% aqueous Na_2CO_3 solution. The ether layer was separated, dried over Na_2SO_4 and evaporated to give an oil. The oil was separated into two fractions by chromatography on a silica gel with CCl_4. The earlier fraction gave 0.16 g (12%) of acetic 1-oxo-2-methyl-2-cyclopentene-3-carboxylic anhydride (**12**). IR(film): 1770, 1720, 1680 and 1630 cm^{-1}. NMR($CDCl_3$): δ 1.56 (s, 3H, $-CH_3$), 2.18 (*s*, 3H, $-OCOCH_3$), and 1.95—2.85 ppm (m, 4H, $-CH_2CH_2-$). Mass spectrum: *m/e* 182 (M^+).

Found: C, 59.72; H, 5.83%. Calcd for $C_9H_{10}O_4$: C, 59.34; H, 5.53%.

The mild treatment of **12** with an aqueous NaOH afforded 2-methyl-3-oxo-1-cyclopentenecarboxylic acid (**11**). The latter fraction of the chromatography gave 0.2 g (13%) of **10a**.

The aqueous Na_2CO_3 solution was neutralized with 1M HCl, and then extracted with ether. The ether extract was dried over Na_2SO_4, and evaporated. The solidified residue was subjected to fractional recrystallizations from CCl_4–$CHCl_3$ (4 : 1), which afforded 0.2 g (22%) of 2-methylcyclohexane-1,3-dione (**13**); mp 200—202 °C (lit,[5] mp 204 °C and 0.26 g (25%) of 2-methyl-3-oxo-1-cyclopentenecarboxylic acid (**11**). An analytical sample of **11** was obtained by recrystallization from $CHCl_3$; mp 168—170 °C.

Found: C, 59.82; H, 5.51%. Calcd for $C_7H_8O_3$: C, 59.99; H, 5.75%.

*2-Chloro-2-methylcyclohexane-1,3-dione (**10b**).* To a stirred suspension of 3.0 g (24 mmol) of **13** in 100 ml of $CHCl_3$, 2.7 g (25 mmol) of *t*-butyl hypochlorite was added gradually under nitrogen atmosphere at −10 °C. After the addition was completed, the reaction mixture was further stirred for 2 hr at −10 °C, and washed with 20 ml of 5% aqueous Na_2CO_3 solution, then with water. The $CHCl_3$ solution was dried over Na_2SO_4 and evaporated. The residue was chromatographed on a silica gel with CCl_4 to give 2.2 g (58%)

of **10b**; bp 70—71 °C/4 mmHg. IR(film): 1740 and 1715 cm^{-1}. NMR (CCl_4): δ 1.60 (s, 3H, CH_3) and 2.00—3.60 ppm (m, 6H, $-CH_2CH_2CH_2-$).

Found: C, 52.58; H, 5.33%. Calcd for $C_7H_9O_2Cl$: C, 52.35; H, 5.65%.

*Reaction of **10b** with Sodium Acetate.* A mixture of 1.5 g (9.3 mmol) of **10b** and 0.78 g (9.5 mmol) of AcONa in 50 ml of THF was refluxed for 4 hr. The reaction mixture was worked up according to the procedures similar to those described for the reaction of **10a** with AcONa, and separated into the neutral fraction and the Na_2CO_3 soluble fraction. The oil obtained from the neutral fraction was chromatographed on a silica gel with CCl_4. The earlier fraction gave 0.07 g (4%) of **12**. The latter fraction afforded 0.23 g (15%) of the recovered starting material (**10b**). The solid obtained from the Na_2CO_3 soluble fraction was subjected to fractional recrystallizations from CCl_4–$CHCl_3$ (4 : 1), which afforded 0.24 g (18%) of **11** and 0.24 g (20%) of **13**.

*2-Acetyl-2,6-dibromocyclohexanone (**14**).* To a stirred mixture of 5.0 g (36 mmol) of 2-acetylcyclohexanone[6] in 80 ml of $CHCl_3$, 5.7 g (36 mmol) of bromine was added gradually below 5 °C. A solution of 4.9 g (36 mmol) of AcONa, and then 5.7 g (36 mmol) of bromine were added successively to the above mixture below 5 °C. After the addition was completed, the reaction mixture was stirred further for 2 hr at 5 °C, and then the $CHCl_3$ layer was separated. The $CHCl_3$ solution was washed with water, dried over Na_2SO_4 and evaporated under reduced pressure. The residual oil decomposed upon distillation, but could be chromatographed on a silica gel with CCl_4 to give (7.2 g (68%) of **14**. IR(film): 1720 and 1730 cm^{-1}. NMR (CCl_4): δ 24.2 (s, 3H. $-COCH_3$) and 1.2—4.0 (m, 7H, $-BrCH-CH_2-CH_2-CH_2-$).

Found: C, 32.56; H, 3.67%. Calcd for $C_8H_{10}O_2Br_2$: C, 32.25; H, 3.38%.

*Reaction of **14** with Sodium Acetate.* A mixture of 1.0 g (3.3 mmol) of **14** and 0.3 g (3.6 mmol) of AcONa in THF was refluxed with stirring for 5 hr. The reaction mixture was worked up as described above and separated into two fractions. An oil obtained from the neutral fraction was chromatographed on a silica gel with *n*-hexane–benzene (1 : 1) to give 82 mg (12%) of acetic 2-acetyl-1-cyclopentene-1-carboxylic anhydride (**16**); bp 85—90 °C/1 mmHg. IR(film): 1770, 1730, 1700 and 1630 cm^{-1}. Mass spectrum: *m/e* 196 (M^+).

Found: C, 61.58; H, 6.42%. Calcd for $C_{10}H_{12}O_4$: C, 61.22; H, 6.17%.

The mild treatment of **16** with an aqueous NaOH solution afforded 2-acetyl-1-carboxy-1-cyclopentene (**15**). The chromatography gave also 0.15 g of a tarry material which could not be purified.

An oily material, which was obtained from the Na_2CO_3 soluble fraction, was triturated with ice-water. A solid thus obtained was recrystallized from $CHCl_3$ to give 0.2 g (40%) of **15**; mp 75—76 °C.

Found: C, 62.31; H, 6.48%. Calcd for $C_8H_{10}O_3$: C, 62.33; H, 6.54%.

Fractionation of Polyvinyl Chloride Pitch by Vacuum Sublimation

Mutsukazu KAMO, Hisao KANDA, Yoichiro SATO, and Nobuo SETAKA

National Institute for Researches in Inorganic Materials, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received July 23, 1973)

Pitch prepared by heating polyvinyl chloride at 400 °C (PVC pitch) was fractionated by vacuum sublimation. The fractions were studied by means of elementary analysis, determination of molecular weight, IR spectroscopy and NMR spectroscopy. It was found that each fraction has a characteristic constituent as follows: 1) Zones 1 and 2 are composed of some aromatic nuclei with 3—4 rings and 3—5 rings linked with aliphatic chains, respectively; 2) Zones 3 and 4 are composed of condensed aromatic nuclei with 6—8 rings and 6—7 rings, respectively; 3) In zone 5, aromatic nuclei have 2—4 aromatic rings on an average, and the ratio of the aliphatic group is higher than that of other zones; 4) The sublimation residue is mainly composed of condensed aromatic nuclei, and the ratio of aromatic hydrogen to aliphatic hydrogen in the residue is the highest.

The initial stage of carbonization of pitch can be studied by chemical methods until the optically anisotropic phase insoluble in usual organic solvents develops.[1] Since pitch is a multi-component system, solvent extraction and chromatographic methods are utilized for fractionation or separation in order to study the mechanism of carbonization.

In this work, vacuum sublimation was used for fractionation. The fractionation is carried out by the difference in vapor pressure. The vapor pressure decreases with increasing molecular weight in a homologous series.

Polyvinyl chloride(PVC) pitch was chosen, since investigations of the carbonization of PVC[2-6] show it to be suitable for examining the utility of vacuum sublimation. Aromatization of aliphatic components is an important process in carbonization and PVC pitch is a typical system prepared from aliphatic compound.

Each fraction obtained by vacuum sublimation was studied by means of elementary analysis, determination of molecular weight, IR spectroscopy and NMR spectroscopy. The results are discussed as regards size of aromatic nuclei, because carbonization is considered to be a process of the growth of aromatic nuclei.

Experimental

Preparation of PVC Pitch. PVC pitch was prepared by heating commercial polyvinyl chloride (Wako Pure Chem. Ind.) under a nitrogen stream at 400 °C. Heat treatment was carried out for 5 hr at 400 °C until the weight loss became constant. The yield was 23%.

Vacuum Sublimation. The heater of the vacuum sublimation furnace consists of two parts, one for sample heating and the other for separation, both of which can be controlled independently. The sublimation column made of a Pyrex glass tube, 8 mm inner diameter and sealed at one end, is connected to a vacuum system consisting of a rotary vacuum pump and monitored by a Pirani guage. Powdered sample, 300—400 mg, was charged in each run. Sublimation was performed at 390—395 °C at $5—6\times10^{-3}$ Torr as vacuum was attained at the end of each run.

Measurement of Molecular Weight. Number-average molecular weights of sublimed fractions in chloroform were determined at 34 °C with a Hitachi 115 vapor-pressure osmometer. Zone-refined benzil (Tokyo Chemical Industry Co., Ltd.) was used as reference material. The stationary value $(\Delta R)_s$ of the difference of thermister resistance ΔR was defined to be the value when the change of ΔR with time was nearly zero ($d\Delta R/dt \simeq 0$). The change was found to be less than 1.3×10^{-2} ohm/min. The value of $\lim_{c\to0}(\Delta R)_s/c$ was estimated from the intercept of the plot of $\Delta R/c$ *versus* concentration c at zero concentration.[7] The cryoscopic method using anthracene as a solvent was employed for the original pitch and the sublimation residue, which contained chloroform-insoluble components. The number-average molecular weights obtained will henceforth be referred to as mean molecular weight.

Instruments. Infrared spectra were measured with a Hitachi spectrometer (EPI-G3) by the usual KBr-disk method. Nuclear magnetic resonance spectra were obtained with a Hitachi spectrometer (R-24) using $CDCl_3$ as a solvent.

Results and Discussion

The temperature gradient curves of the sublimation furnace and each deposition zone are given in Fig. 1. Zones 1, 2, 3, 4, and 5 are numbered with decreasing temperature. Oily deposition product was obtained in the region between temperature 5 and room temperature, but the deposition was not sufficient for analysis. The relations between the yield of each fraction and heating temperatures of samples are given in Fig. 2. Sublimation yields tend to be constant at temperatures higher than 420 °C. However, the difference (indicated by □) has a tendency to increase with temperature. This indicates the possibility of degradation of the pitch at temperatures higher than 400 °C. As

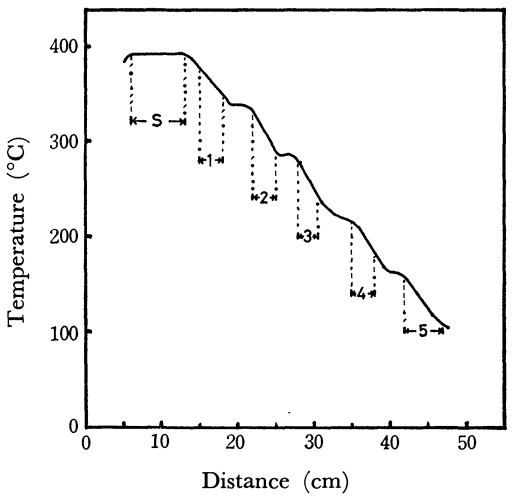

Fig. 1. Temperature gradient of sublimation furnace. S: sample, 1: 1st zone, 2: 2nd zone, 3: 3rd zone, 4: 4th zone, 5: 5th zone.

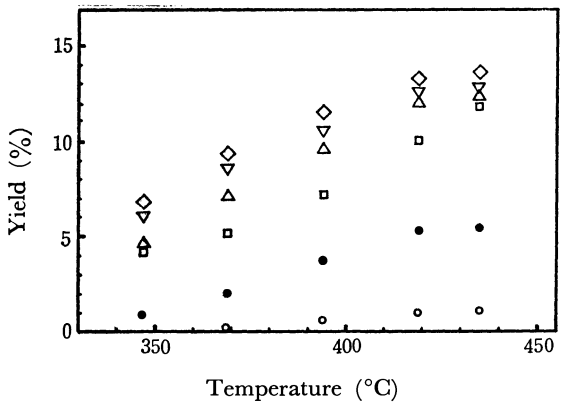

Fig. 2. Relations between yield of each zone and sample temperatures.
○: 1st zone, ●: 2nd zone, △: 3rd zone, ▽: 4th zone, ◇: 5th zone, □: difference between the sublimation yield of sample and the total of the yield of each zone from 1 to 5.

high an yield as possible is desirable, but degradation and/or reaction in pitch during sublimation should be avoided. The sublimation was therefore performed in the temperature range 390—395 °C, at a temperature lower than that of the preparation of the pitch (400 °C). The yields were 42—45%.

Sublimation of the mixture of the following eight compounds was performed: ovalene, violanthrene, decacyclene, coronene, 1,12-benzoperylene, perylene, pyrene, and anthracene. The results are given in Table 1. Each zone is divided into two parts, high temperature and low temperature except for zone 5. The high temperature side is similar to the low temperature side of the neighboring higher temperature zone. Results of elementary analysis of PVC pitch and mean molecular weights are given in Table 2. Mean molecular weights of sublimation products increase with rise in temperature of deposition zones. However, the mean molecular weight of the first zone is greater than that of the residue. This indicates the difference in structure of the main constituents.

NMR data are analyzed according to Brown *et al.*[8,9] and the results are given in Table 3. R denotes the number of condensed aromatic rings per average aromatic unit estimated from H_{aru}/C_{ar}. R′ values indicate actual numbers of aromatic rings per average aromatic unit obtained by the correction of R values with mean molecular weights and chemical formulas.

In the case of the unsubstituted aromatic hydrocarbons, vapor pressure and hydrogen content are usually lowered with increase in the number of rings, *i.e.*, with increase in molecular weight. The tendency is also observed with the aromatic compounds used in this work as seen from Table 1. In contrast, a considerable discrepancy from this trend is noted for PVC pitch fractions of zones 1 and 2.

The deposition of zone 1, though highest in molecular weight, exhibits higher H/C and smaller R than those of zones 2—4 as shown in Tables 2 and 3. It is

H_a/H_t; Ratio of aromatic hydrogen(H_a) to the total hydrogen(H_t).
H_α/H_t; Ratio of hydrogen in saturated groups α to aromatic rings (H_α) to H_t.
H_0/H_t; Ratio of hydrogen on other saturated carbon atoms(H_0) to H_t.
F_a; Aromaticity defined as the ratio of the aromatic carbon to the total carbon.
H_{aru}/C_{ar}; The atomic hydrogen to carbon ratio of the hypothetical unsubstituted aromatic material.
R; Number of condensed aromatic rings per average aromatic unit estimated from H_{aru}/C_{ar}.
R′; Corrected value of R with mean molecular weight and chemical formula.

estimated that the average aromatic unit consists of 3—4 rings, corresponding to the unit weight of 180—220. The observed molecular weight indicates that the average molecule should contain about 4 aromatic units. Taking the chemical composition into account and allowing for the contribution of alkyl groups to the molecular weight, the average molecular structure may be described as a cluster of 3—4 aromatic units linked with aliphatic chains, each unit containing 3—4 condensed rings.

The fraction of zone 2 also shows an anomalous tendency exhibiting a smaller R than that of the fractions of zones 3 and 4 in spite of higher molecular weight. This suggests that the components of zones 1 and 2 are similar in chemical structure. The analysis shows that the average molecule consists of 2—3 aromatic units each having 3—5 fused rings on an average.

The results obtained with the fractions of zones 3 and 4 are almost the same except for molecular weight. Both fractions show lower H/C and H_{aru}/C_{ar} than those of other zones. Their molecular weights and chemical formula indicate that the average molecular structure can be described by the single aromatic unit, in contrast to the case of zones 1 and 2. The analysis shows that the average components of zones 3 and 4 are aromatic hydrocarbons containing 6—8 and 6—7 rings, respectively. NMR parameters and the molecular weights indicate that the aromatic compounds have alkyl substituents.

The deposition of zone 5 exhibits higher H/C and H_{aru}/C_{ar}, and lower F_a than those of other zones. It is estimated that the aromatic unit consists of 2—4 rings on an average. The mean molecular weight indicates that the average components are these aromatic units each having a few alkyl groups. It should be noted that the fraction is somewhat oily, which implies that it contains aliphatic compounds, since aromatic hydrocarbons with molecular weight near 300 are usually solid at room temperature.

The residue has the smallest H/C and as seen from the IR spectra (Fig. 3), the relative intensity of aromatic CH stretching (3060 cm^{-1}) to aliphatic CH stretching (2920 cm^{-1}) is the highest in all the fractions. It is thus inferred that the residue consists mainly of highly condensed aromatic compounds.

* *Department of Chemistry, Faculty of General Education, Hiroshima University, Hiroshima 730*

(Received March 2, 1974)

Synopsis. Sesquirosefuran (I) was synthesized by the coupling of geranyl bromide with 2,2′-bis(3-methylfuryl)-mercury in 29% yield.

Quite recently, Chakravarti *et al.* reported the synthesis[1] of sesquirosefuran (I), one of the components isolated from *Actinodaphne longifolia* Nakai by two of us[2] who also established the structure of other component, longifolin (II). The Chakravarti's paper prompted us to report our own result. Although identity of both natural and synthetic sesquirosefuran (I) was ascertained,[3] the result of the synthesis was kept unpublished since our effort was then directed toward the synthesis of longifolin (II) by the similar method.

As in the case of 2-farnesyl-3-methylfuran (III),[4] coupling of geranyl bromide with 3-methylfurano moiety was achieved using 2,2′-bis(3-methylfuryl)mercury[5] in the presence of zinc-copper powder as described below. Although Chakravarti *et al.* carried out the coupling using 3-methyl-2-furyllithium in 40% yield, our trials with the same reagent gave no satisfactory results.

To an ice cooled anhydrous benzene solution (6 ml) of 2,2′-bis(3-methylfuryl)mercury (1.45 g, 4 mmol) was added 0.87 g (4 mmol) of geranyl bromide in 2 ml of anhydrous benzene. After an addition of zinc-copper powder (15 mg) to the mixture, the reaction mixture was stirred at room temperature for 15 hr, and poured into ice–water. Extraction with ether and a usual work up afforded crude product which was purified by passing through silica gel column with mixed solvents of *n*-hexane: cyclohexane (1 : 1) to give 243 mg (29%) of oily sesquirosefuran (I). IR, NMR, mass fragmentations and analysis were in accord with those of natural product.

A New Lanthanoid Double Trifluoride Compound $(Er_{0.3}Nd_{0.7})F_3$

Kiyohito OKAMURA and Seishi YAJIMA

The Oarai Branch, The Research Institute for Iron, Steel and Other Metals, Tohoku University, Oarai, Ibaraki 311-13

(Received March 30, 1973)

Synopsis: A new compound, $(Er_{0.3}Nd_{0.7})F_3$, in the ErF_3–NdF_3 system was prepared by the solid state reaction of NdF_3 (hexagonal LaF_3-type) and ErF_3 (orthorhombic YF_3-type). It was found to be of an isostructure with ErF_3 of the space group Pnma. Structural data are compared with those of ErF_3.

The lanthanoid trifluorides from LaF_3 to NdF_3 have the hexagonal phase of LaF_3-type structure in the temperature range, from room temperature to melting.[1-2] Trifluorides of elements from Sm to Lu, with orthorhombic YF_3-type structure, exhibit equilibrium dimorphic transformation at high temperatures. Compounds from SmF_3 to HoF_3 turn into the hexagonal LaF_3-type, and compounds from ErF_3 to LuF_3 into the hexagonal YF_3-type[1-2] (trifluoride with the hexagonal LaF_3-type and that with the orthorhombic YF_3-type are abbreviated as $(LnF_3)_{hex}$ and $(LnF_3)_{orth}$, respectively). The lanthanoid trifluorides of the same structure have a wide solid solubility range,[3] while the solubility of $(LnF_3)_{orth}$ in $(LnF_3)_{hex}$ differs with the lanthanoid element in $(LnF_3)_{orth}$. However, lanthanoid double trifluoride compounds, such as $(Er_x \cdot Nd_y)F_3$, are not found in the $(LnF_3)_{orth}$–$(LnF_3)_{hex}$ system.

The present work was carried out in order to find new lanthanoid double fluoride compounds consisting of components $(LnF_3)_{orth}$ and $(LnF_3)_{hex}$. Such a compound could be obtained by a solid phase reaction at high temperatures between the lanthanoid trifluorides having a similar radius of the Ln^{3+} ions. Of the $(LnF_3)_{orth}$ type compounds, ErF_3 has the highest transition temperature 1075 °C, and of the $(LnF_3)_{hex}$ compounds, the radius of Nd^{3+} is closest to that of Er^{3+} in ErF_3, compound NdF_3 having a hexagonal phase up to its melting temperature 1380 °C. Thus, ErF_3 and NdF_3 were considered to be the most suitable combination.

Experimental

Erbium and neodymium trifluorides were prepared as described previously.[4] Powders (325 mesh under) of ErF_3 and NdF_3 were mixed in various molar ratios and pressed into pellets of 10 mm diameter and 10 mm height. These were placed in a platinum boat kept in an electric furnace, heated at 1000 °C for five hours in a highly pure argon stream, and cooled slowly to room temperature. Equilibrium was considered to have been established when the X-ray diffraction patterns showed no change on further heating. The crystal structure of the heated specimen was determined from X-ray diffraction patterns taken at room temperature, using Ni-filtered Cu$K\alpha$ radiation (λ=1.5418 Å) and an NaI(Tl) counter connected to a pulse-height analyzer.

Results and Discussion

A new compound was obtained by heating a powder mixture of ErF_3 and NdF_3 with molar ratio 3 : 7. The X-ray diffraction patterns are assigned to an orthorhombic unit cell; the lattice constants are a=6.660±0.003 Å, b=7.053±0.005 Å and c=4.393±0.002 Å. Chemical analysis of the compound was made by the X-ray fluorescence method since ErF_3 and NdF_3 were found to evaporate slightly during the course of heat treatment. The analysis shows the ratio Er : Nd to be 3.06±0.10 : 6.94±0.09. The compound is represented by $(Er_{0.3}Nd_{0.7})F_3$. The crystal is isostructural with ErF_3. The relative intensities of the X-ray diffraction patterns for $(Er_{0.3}Nd_{0.7})F_3$ and ErF_3 are almost the same, but the lattice constants a and b of the former are greater by 5% and 3%, respectively, while c is greater by only 0.2%. The positional and isotropic thermal parameters of $(Er_{0.3}Nd_{0.7})F_3$ were refined by the least-squares by means of powder reflections. The initial atomic parameters of ErF_3[5] with space group Pnma were used. The occupancies of Er and Nd at the lanthanoid atomic sites (abbreviated as $\overline{Ln}$) were fixed at the ratio 3.06 : 6.94. The atomic scattering factors were corrected for the anomalous dispersion effect due to $\Delta f'$ and $\Delta f''$ values (International Tables for X-Ray Crystallography, Vol. II). The final structure is given in Table 1 with that of ErF_3. The final calculated intensities are compared with the observed values (I_0) in Table 2. The reliability factor, $R=(\sum_{hkl}|I_0-I_c|)/\sum_{hkl}I_0$, is 10.10% for the observed reflections.

The fluorine atoms are displaced to some extent from their sites in ErF_3, while the lanthanoid atoms are only slightly displaced from the erbium atom sites in ErF_3. The distances between the $\overline{Ln}$ and fluorine

atoms lie in the range 2.234 Å—2.771 Å, and those between fluorine atoms in the range 2.398 Å—3.083 Å. The corresponding distances in ErF_3 are 2.248 Å—2.589 Å, and 2.552 Å—2.846 Å. The fluctuations of the interatomic distances from the average ($\overline{Ln}$-F; 2.332 Å, F-F; 2.679 Å) are larger than the corresponding deviations from the mean values ($\overline{Ln}$-F; 2.284 Å, F-F; 2.686 Å) in ErF_3. It seems that the atomic arrangement in $(Er_{0.3}Nd_{0.7})F_3$ is more strongly distorted than that in ErF_3.

The Direct-current Conductivity of Silica Gel†

Masa-aki MUROYA and Seiichi KONDO*

Osaka Electro-Communication University, Neyagawa-shi, Osaka 572

** Osaka University of Education, Tennoji-ku, Osaka 543*

(Received June 16, 1973)

Synopsis. The study of the effect of heat-treatment on the direct-current conductivity of silica gel showed that the conductivity changed in response to the dehydration of the adsorbed water and of various kind of silanols. The temperatures of dehydration by this experiment seems to coincide with other experiments such as IR spectroscopy.

The study of direct-current conductivity is useful in investigating the surface of a colloid such as high specific-surface-area silica, since a major part of the measured current is considered to be due to the surface current in such material[1] and, since the behavior of the charge carriers lying on its surface may play a central role in the conductivity. According to the recent studies of this material, several types of silanol groups dehydrate from the surface in various temperature ranges.[2,3] Therefore, the thermal behaivor of these silanol groups is expected to influence the conductivity of this material sensitively. Similar points of view have been presented in several investigations of the conductivity of silica gel.[4,5] In this kind of experiment, however, such impurities as alkali ions generally have a marked influence not only on the drastic thermal changes of the properties of silica gel,[6] but also on the values of the conductivity. Therefore, the thermal effect of the surface conductivity of silica gel was studied in this investigation using high-purity silica gel with high-purity gold electrodes.

Experimental

Material. Ethyl orthosilicate was hydrolyzed to silica sol and gelled on a plastic plate. When the hydrogel thus formed was dried in air, a glass-like plate about 1 mm thick and about 3 cm^2 in area was obtained. The organic substances remaining in the silica gel were oxidized by hydrogen peroxide. No alkali and alkaline earth impurities were detected within our range of experimental error (about ± 1 ppm) in the case of sodium ion. The BET N_2 specific surface area of this sample, S_A, was about 650 m^2/g, and the pore volume was 0.33 ml/g.

Conductivity Measurement. Gold films about 99.999% pure and of 10^{-5} cm thick, and 0.28 cm^2 in area were vacuum-deposited as the electrodes on the same plate which had been sufficiently preheated at about 150 °C and 10^{-5} Torr. This sample was then placed between platinum electrodes placed in a furnace, whose temperature range was from room temperature to 650 °C under a vacuum of 10^{-3} Torr. All these parts were then placed in a vacuum cell made of quartz and Pyrex glass. The applied voltage was mostly 1.000 ± 0.001 V, which was sufficiently low enough to maintain the Ohm's law, and the error of the current measurement was about $\pm 1\%$ or 10^{-3} A. More details of the experiment will be described elsewhere.[7]

According to a simple pore structure model of silica gel in which all the pores lie uniformly in the directions parallel to x, y, and z axes (the z axis is the direction of the electric field, and the x and y axes are perpendicular to the z axis), one third of the total pores in the z axis, which has one third of the total surface area, contribute to the surface conductivity. With this model, the value of the surface conductivity, σ_s, can be calculated as follows;

$$\sigma_s = \frac{l^2}{r} \cdot \frac{3}{S_A \cdot \rho \cdot v} \qquad (\text{ohm}^{-1})$$

where l is the electrode distance; r, the resistance; ρ the apparent density, and v, the volume between the electrodes. The experimental error of the relative value of the resistance was $\pm 1\%$, that of the absolute value was about $\pm 5\%$, and the minimum observable value was about 1×10^{-21} ohm^{-1}.

Results and Discussion

Figure 1 shows the relation between the surface conductivity, log σ_s, and the reciprocal temperature of the heat-treatment of silica gel. The surface conductivity increased gradually and irreversibly when the heat-treatment temperature was elevated in the range from room temperature to about 160 °C, as is shown by the white circles in the figure. When this sample was then cooled from 160 °C, the conductivity decreased linearly along a different route from the original one, as is shown by Curve *a* of this figure. With this thermal history, the conductivity change was reversible along Curve *a*. This difference seems to be caused by the desorption of adsorbed water. From

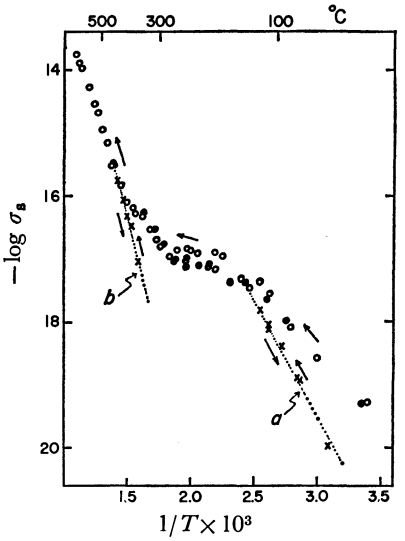

Fig. 1. Log σ_s (the surface conductivity) *versus* reciprocal temperature relation of silica gel.

† Presented at the 26th annual meeting of the Chemical Society of Japan, 1972.

about 170 °C, at which the desorption of water was completed, to about 350 °C, the conductivity curve deviated largely from linearity. As is shown by black and white circles in this figure, the conductivity in this range showed an analogous thermal behavior, but has different absolute values from sample to sample. On the other hand, the infrared study[8] revealed the existence of four types of silanols (b, c, d, and e), and the b-type silanol, whose absorption band is the largest and has the maximum at 3260 cm^{-1}, starts to decrease at 170 °C and disappears at 350 °C. Therefore, the dehydration of this b-type silanol may be responsible for the large decrease in the conductivity. From about 350 to 650 °C, the conductivity increased when the heating temperature was elevated. When the sample cooled after heating at about 450 °C, for example, the conductivity decreased with a different temperature coefficient from that of the heating curve along reversibly Curve *b* in Fig. 1, while it increased reversibly within the range of Curve *b* when the sample was heated. The reason for this difference seems to be that the c-type silanol, which has the 3470 cm^{-1} absorption band, begins to dehydrate at 350 °C. Although still more silanol groups stable at temperatures higher than 650 °C are known to exist,[2,3,8] measurements at such high temperatures in a vacuum were not possible in the present experiment.

The Alkylation of Phenol over the $ZnO-Fe_2O_3$ Catalyst

Takeshi KOTANIGAWA and Katsuyoshi SHIMOKAWA

The Government Industrial Development Laboratory, Hokkaido, Higashi-Tsukisamu, Toyohira-ku, Sapporo 061-01

(Received September 14, 1973)

Synopsis. The highly selective alkylation at the *ortho* position of phenol was caused by the dissociative adsorption of phenol; it was discussed by taking account of the acidic and the basic properties of the $ZnO-Fe_2O_3$ catalyst.

The catalytic alkylation of phenol with alcohols by means of a vapor-phase reaction is well known. A large number of related papers have been reported. Enomoto *et al.* have studied the alkylation at the *meta* position of phenol, using a condensed phosphoric acid-Kieselguhr[1] and Al_2O_3–SiO_2[2] as catalysts. Ogata *et al.* have reported the alkylation of phenol with various types of alcohol by means of vapor-phase reactions.[3] The alkylation over solid acidic catalysts is considered to proceed *via* phenyl ether as the intermediate.

It was found in our previous work that the selective methylation at the *ortho* position of phenol over the $ZnO-Fe_2O_3$ catalyst proceeded by means of a reaction between the *ortho* position of the phenoxide surface species and the methyl cation which is formed on the surface of the catalyst.[4] In this paper, we wish to report the results of the selective alkylation of phenol with various alcohols over the $ZnO-Fe_2O_3$ catalyst.

Experimental

Materials. The phenol, ethanol, 1-propanol, 2-propanol, and *t*-butyl alcohol were also of an analytical reagent grade. These alcohols were used after one distillation.

Catalyst. The catalyst was prepared as follows: after the dissolution of 1 mol of ferric nitrate and 1 mol of zinc nitrate in 2.2 l of water, a 14% aqueous ammonium solution was added to the solution until it gave a pH value of 6.85. The coprecipitate was washed several times with water, dried at 150 °C in an oven, calcined in air at 400 °C for 3 hr, and sieved to 12-14-mesh-size particles.[5]

Acidic and Basic Properties of the Catalyst. As the catalyst was colored, the acidic and basic properties were measured by means of gas chromatography, as was illustrated in a previous work.[4] The acidity and the basicity were defined as the saturated amounts of the adsorption of pyridine and phenol respectively.

Reaction Apparatus and Conditions. A conventional flow-type reaction apparatus (reactor : Pyrex glass, i.d. 18 mm) was used. A mixture of 1 mol of phenol and 5 mol of alcohol was introduced into the vaporizer; the reaction vapors were carried by nitrogen gas onto the catalyst bed. The partial pressures of phenol, alcohol, and nitrogen gas in the reaction system was 0.058 atm 0.288 atm, and 0.654 atm respectively. The time factor, W/F, was 53.3 g-cat. h/mol-feed. The vaporizer was maintained at about 300 °C, and the temperature of the catalyst bed was controlled at 350 °C.

Analysis of Products. The reaction products were identified by means of infrared, NMR, and mass spectrometry. The content of each component was quantitatively determined by gas chromatography (column: active carbon, Silicon DC 550, and Porapak Q).

Results and Discussion

The catalyst possesses the following properties: the surface area is 26.6 m^2/g, the pore volume is 0.094 ml/g, and the component is analyzed as $ZnO-ZnFe_2O_4$ by X-ray analysis (Fe-Kα radiation). Moreover, the acidic and the basic properties of the catalyst are shown in Fig. 1. Figure 1 shows that: (1) the acidity and the basicity are 91.3 μmol/g-cat. and 98.0 μ mol/g-cat. respectively, (2) the amounts of the adsorption of pyridine on the catalyst after the saturated adsorption of phenol are 3.8 μ mol/g-cat., and (3) the amounts of the adsorption of pyridine decrease from 91.3 μmol/g-cat. to 3.8 μmol/g-cat. with an increase in the amounts of of the pre-adsorbed phenol.

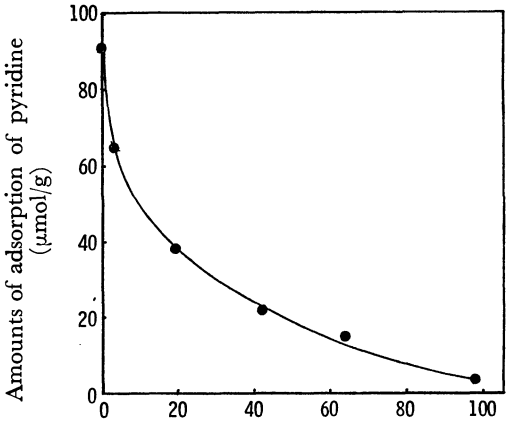

Fig. 1. Acidic and basic properties of the $ZnO-Fe_2O_3$ catalyst.

From these results, it may be considered that the adsorbed phenol lies on both the acid site and the base site. This seems to mean that a dissociative adsorption of phenol takes place on the catalyst.[4] The products of the reaction between phenol and various alcohols are shown in Table 1. The reaction may be divided into the alkylation of phenol and the decomposition of alcohols.

Alkylation of Phenol: The alkylation of phenol over such a solid acidic catalyst as alumina is said to proceed by means of the rearrangement of alkyl phenyl ether.[2] The ratio of alkylphenol to alkyl phenyl ether in the reaction products depends on the structure of the alcohol.[6] However, the alkylation of phenol over the present catalyst proceeds selectively at the *ortho* position even with various alcohols, as is shown in Table 1. Ogata *et al.* reported that phenol was not only alkylated by the rearrangement of alkyl phenyl ether, but also by the direct nuclear alkylation.[3] The present catalyst

Table 1. Products by the reaction between phenol and various types of alcohols

Alcohol	Ethanol	1-Propanol	2-Propanol	*t*-Butyl alcohol
Conversion of phenol (mol %)	33.1	23.9	12.0	trace

Composition of gaseous products (mol %)				
Carbon dioxide	16.8	18.5	—	—
Hydrogen	78.7	77.1	100	—
Carbon monoxide	4.5	4.5	—	—

can, therefore, be considered to catalyze the nuclear alkylation of phenol directly without the rearrangement of alkyl phenyl ether. For the nuclear alkylation, phenol must be dissociated on the surface of the catalyst. In the previous work, it was described that selective methylation at the *ortho* position of phenol was carried out by the reaction between the phenoxide surface species and the methyl cation.[4] If this mechanism is applied in this study, the alkylation of phenol with various alcohols may also be effected to take place at the *ortho* position. The high selectivity for the alkylation at the *ortho* position of phenol may be concluded to be caused by the dissociative adsorption of phenol on the acid site and the base site of the present catalyst.

Decomposition of Alcohols: The ethanol and 1-propanol decomposed to form gaseous products and ketones. The gaseous products from primary alcohols were composed of 17% of CO_2, 78% of H_2, and 4.5% of CO. From these facts, the path of the decomposition of primary alcohols may be considered to be as follows;

$$2\,RCH_2OH \longrightarrow 2\,RCHO + 2\,H_2 \quad (1)$$

$$2\,RCHO \longrightarrow \begin{matrix}R\\R\end{matrix}\!\!>\!C{=}O + CO + H_2 \quad (2)$$

$$CO + H_2O \longrightarrow CO_2 + H_2 \quad (3)$$

where R denotes a methyl or ethyl group. 2-propanol decomposed to form hydrogen, acetone, and small amounts of unsaturated ketone (C_4H_7-CO-CH_3). From these facts, the reaction may be considered to proceed as follows;

$$\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!CHOH \longrightarrow \begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!C{=}O + H_2 \quad (4)$$

$$CH_3\text{-}CO\text{-}CH_3 + O{=}C\!<\!\begin{matrix}CH_3\\CH_3\end{matrix} \longrightarrow$$

$$CH_3\text{-}CO\text{-}CH{=}C\!<\!\begin{matrix}CH_3\\CH_3\end{matrix} + H_2O \quad (5)$$

t-butyl alcohol decomposed to form *iso*-butylene and water by dehydration, which is said to proceed in an acidic medium.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(6), 1537—1538 (1974)

The Effect of Ion Exchange on the 1,2-Epoxybutane-Isomerization Activity[1,2]

Shigemi MATSUMOTO, Masahiro NITTA, and Kazuo AOMURA
Faculty of Engineering, Hokkaido University, Sapporo 060

(Received September 27, 1973)

Synopsis. The isomerization of 1,2-epoxybutane was studied over NaA-type zeolite and its zinc-exchanged forms in a flow system. The catalytic activity increased from 31 to 92% upon the replacement of Na^+ by Zn^{2+}. This increase may be the consequence of the enlargement of the zeolite pore size and the increase in the surface acidity.

We reported previously that the synthetic A-type zeolites exchanged with various cations are effective as catalysts in 1,2-epoxybutane (EB) isomerization.[1] It was shown that the catalytic activity depends upon the surface acidity, which varies with the kind of cation. It may, then, be expected that the degree of ion exchange also has an influence on the acidity and activity.

In this paper we will deal with the effects of the degree of ion exchange on the EB isomerization activity and on acidity of zinc-exchanged A-type zeolite.

Table 1 shows various properties of A-type zeolites exchanged with the zinc ion. The X-ray diffraction patterns and specific surface areas of all the catalysts (ZnA=sample II-VIII) were similar to those of the original Linde 4A(NaA=sample I) and showed ZnA to be highly crystalline.

The products of the EB isomerization reaction were BA, CA_c, CA_t, EMK, and a small amount of *n*-butyl alcohol (NB). Sample I showed no catalytic activity under the conditions studied here. Figure 1 shows the correlation between the catalytic activity and the extent of zinc ion exchanged on ZnA. As is evident from Fig. 1, ZnA begins to show the catalytic activity slightly when the extent of exchange exceeds 30%, the activity increases rapidly as the extent of exchange exceeds 50%, and then becomes almost constant in the range above 80%. This suggests that any comparison of the catalytic activity among zeolites exchanged with various cations, which are of widely differing degrees of ion exchange, should be done with extra care. The order of activity of cation-exchanged A-type zeolites will be effective only when the degree of ion exchange is either the same or $\geq 80\%$.

Many authors have already reported on the influence of the degree of ion exchange on the activity of zeolite catalysts.[4-6] All of their studies, however, have been of X- and Y-type zeolites. Type-A zeolites have hardly been investigated at all.[7] X- and Y-type zeolites with large pores (9—10 Å) also show an activity change with the degree of ion exchange similar to that described above. Those zeolites have three kinds of cation sites.[6] When the replacement of cations at inactive sites is achieved, *i.e.*, when the degree of ion exchange exceeds *ca.* 50%, the activity increases suddenly.

In the case of the A-type, however, the effective pore size of zeolite should be considered aside from the above interpretation, because the cation sites of the A-type differ from those of the X- and Y-types and the size of the reactant molecule is close to the pore size. The molecular size of EB** is larger than the effective pore size of NaA(4.2 Å). The reactant molecules cannot, therefore, pass the pore and are not adsorbed on the internal surface(cavity of zeolite). Consequently, Samples I, II, III, and IV, which are Na-rich forms, are inactive for isomerization. The effective pore size of the A-type is determined by the number and species of cations at the 8-membered oxygen-ring sites, as has been pointed out by Breck *et al.*[8] and Takaishi and Yusa.[9] Takaishi and Yusa have proposed cation-exchange scheme as below to account for the adsorption phenomena of ZnA. The A-type zeolite has two types of cation sites; that is, there are 3 of the 8-membered oxygen ring sites and 8 of the 6-membered oxygen ring sites per unit cell. A total of 12 mon ovalent cations per unit cell are distributed among those sites (see Ref. 9). When 2 Zn ions are introduced (*i.e.*, when the Na ions at the 8-ring sites and the 2 Na ions at the 6-ring sites are replaced (4/12=33%)), the effective pore size becomes 5 Å since 2 Zn ions are located at the 6-ring sites and one of the 8-ring sites is vacant, and the adsorption of *n*-butane begins to occur.[10] At a point corresponding to the replacement of 4 Zn ions for 8 Na ions(8/12=67%) all the 8-ring sites become vacant and molecules of about 5Å size can freely

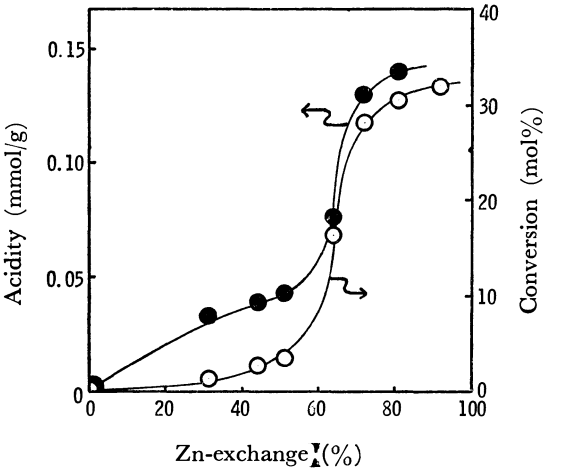

Fig. 1. Change of catalytic activity and acidity with degree of ion exchange.
○: Conversion of EB, ●: Acid amount at $H_0 \leqq +4.8$

* In our paper the "4A" zeolite, which contains only sodium as a cation, is designated as NaA, while forms in which sodium has been exchanged to even a slight degree with the zinc ion are designated "ZnA,"

** About 4.9 Å; estimated from *n*-butane: 4.89 Å; tehane: 4.2 Å; ethylene oxide: 4.2 Å.

Table 1. Various properties of ZnA type zeolites

Sample	Zn-exchanged (%)	Surface area (m^2/g)	Diffraction peak intensity[b]	ΔE_a[c] (kcal/mol)	Selectivity (BA+CA)/EMK	Acid strength[d] (H_0)
I	0	659[a]	144	0	—	$>+4.8$
II	31	—	128	11.2	39.2	-5.6
III	44	—	133	23.6	37.5	-5.6
IV	51	643	—	22.1	40.0	-5.6

VI	72	—	—	—	38.0	-5.6
VII	81	619[e]	121	31.6	41.2	-5.6
VIII	92	631	124	—	42.3	-5.6

a) Using O_2; b) Sum of peak heights for (311), (321) and (410, 322) planes; c) Apparent activation energy; Reaction temp.: 180—240 °C; d) Maximum value which the catalyst shows; e) After reaction.

go in and out of the cavity. Thus, the catalytic activity of Samples V and VI increases. Beyond this point Zn ions occupy the 8-ring sites, but do not disturb the passage of molecules since one of the 8-ring sites is still vacant and since the Zn ion(ionic radius, 0.74Å) is smaller than the Na ion (0.97 Å); hence, Samples VII and VIII are highly active, much like V and VI.

The constitution of the products is almost the same in all the catalysts except I. The selectivity, (BA+CA)/EMK, is about 40; this indicates that BA is preferentially produced. This implies that the "molecular sieve action" characteristic of A-type zeolite does not change with the degree of ion exchange for this reaction.

The acidic character of the catalysts is given in Table 1. Sample I has no acidity at $H_0 \leqq 4.8$. It is known from the results of spectroscopic study that the Na-forms in X- and Y-type zeolites are also nonacidic.[11] As may be seen in Table 1, the strong acid sites as $H_0 = -5.6$ appear rapidly, as the degree of ion exchange is about 30%. When the degree of exchange rises, the total amount of acid sites increase, although the strength of the acid sites does not change further. A previous study clarified that those acid sites are the active sites for EB isomerization.[1] The inertness of Sample I (NaA) is due to both the absence of acid sites and the small pore size. The rise in activity with the growing zinc content can be explained as an increase in the total amount of acid sites and an enlargement of the effective pore size. On the low-exchanged ZnA(II, III, IV) the activity is considerably smaller than that expected from the amount of acid, as is shown in Fig. 1. This is due to the diffusion hindrance, as has been mentioned above.

The apparent activation energy changes are shown in Table 1. The apparent activation energy of EB isomerization over low-exchanged ZnA(II, III, IV) was smaller than that of the high-exchanged sample, VII. A similar dependence of the activation energy was noted by Balandin *et al.* for A-type zeolite (CoA) in a 1-butanol dehydration study.[7] The low activation energy may be a result of diffusion hindrance because of the small effective pore size; this would be in agreement with the conclusion of Balandin.

Experimental

Materials. The original sodium-form zeolite(NaA)* was Linde Molecular Sieves 4A, which is in a binder-free powder form. The zinc chloride used for ion-exchange was of a guaranteed grade. The EB was of an extra pure grade, and the heart-cut after distillation was chromatographically pure. The nitrogen deoxygenated and dehydrated was used as a carrier gas.

Ion-exchange. The ion-exchange experiment was carried out at 85 °C ±1 for 5 hr in a thermostat.

The NaA was treated as has been described in Part II.

The degree of ion exchange was determined by flame photometry after dissolution in dilute hydrochloric acid.

The X-ray powder diffraction patterns of the hydrated samples were obtained using filtered copper K_α radiation. The specific surface areas of the samples were measured by the BET method using N_2 and O_2. The crystallinity of the ion-exchanged zeolites was judged by a comparison of these results.

Reaction and Analysis. For estimating the catalytic activity, a flow reactor was used.[1] The zeolite catalysts were heat-treated at 400 °C for 3 hr in a reactor. The reaction was carried out at 220 °C in a nitrogen carrier. The activity of the catalyst was given in terms of EB conversion. The selectivity of the catalyst was expressed in terms of the mole ratio of butyraldehyde (BA) and crotyl alcohol (*cis*=CA_c, *trans*=CA_t) to ethyl methyl ketone(EMK).

Acidity. The acidic properties of the catalysts, which were heated at 400 °C for 3 hr in air, were determined by the titration method with *n*-butylamine and using a series of Hammett indicators.[3]

Solid Complex Formation of Malonic Acid with Glycine

Jujiro NISHIJO

Kobe Women's College of Pharmacy, Higashinada-ku, Kobe 658

(Received October 2, 1973)

Synopsis. A solid complex in a molar ratio of 1 : 1 was inferred to be formed by means of an intermolecular hydrogen bond between the hydrogen atom of the -COOH of malonic acid and the $-COO^-$ of glycine.

As a part of a series of studies of the interaction of organic acid with amino acid, we previously reported[1] that oxalic acid forms a solid complex at a molar ratio of 1 : 1 with a large number of α-amino acids and also at a molar ratio of 1 : 2 with some of the α-amino acids. Therefore, it was presumed that the formation of the complexes was promoted by proton-transfer from the carboxyl group in oxalic acid to the carboxyl ion of amino acid in the case of the 1 : 1 complex and by the intermolecular hydrogen bond between two hydrogen atoms of the carboxyl groups in oxalic acid and the carboxyl ions of two molecules of amino acid in the case of the 1 : 2 complex. To investigate further the factors affecting the formation of a solid complex of organic acids with α-amino acid, we have chosen malonic acid, which is a weaker acid than oxalic acid and glycine, and studied it with respect to the formation of a solid complex between them.

Experimental

Preparation of the Solid Complex. A mixture of malonic acid (special-grade chemicals) and glycine (special-grade chemicals) in a molar ratio of 1 : 1 was dissolved into purified water. By evaporating the solvent at 60 °C under a pressure of 30—40 mmHg, a viscous residue was obtained. The residue gradually crystallized when left standing at room temperature. This substance will hereafter be called M_1-G_1, where M and G stand for malonic acid and glycine respectively where the subscripts refer to the molar ratio. The crystalline substance was dried at 60 °C for 10 hr, pulverized in an agate mortar, and then used as the sample. The same procedure was followed to prepare samples of different molar ratios.

Measurements. The X-ray analysis and DTA-TG were carried out using the apparatus previously reported.[1] The infrared absorption spectra were measured with a Hitachi spectrophotometer, Model EPI-G2. The Nujol-mull method was used in the measurements. The pH value was measured by means of a Toa Denpa HM-5A-type apparatus. The determination of malonic acid and glycine by X-ray diffractometry was carried out by the method reported previously.[1]

Results and Discussion

The X-ray diffraction patterns of malonic acid, γ-glycine, and M_1-G_1 are shown in Fig. 1. In the case of M_1-G_1, a new diffraction pattern, diffrent from those of the component, malonic acid, and glycine, was obtained. On the other hand, M_2-G_1, M_3-G_2, and M_4-G_3 gave patterns of M_1-G_1 and malonic acid, while

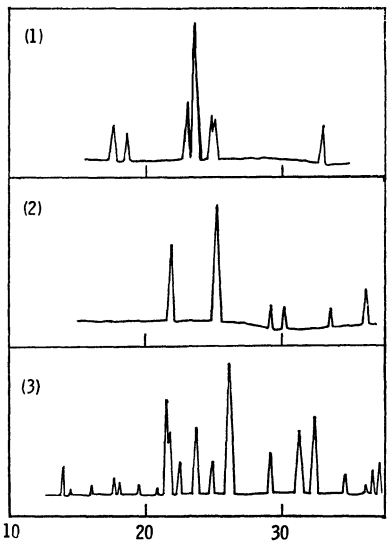

Fig. 1. X-Ray diffraction patterns of malonic acid (1), γ-glycine (2) and M_1-G_1 (3).

M_1-G_2, M_2-G_3, and M_3-G_4 gave those of M_1-G_1 and γ-glycine. The determination of the mole ratio of malonic acid to glycine in the complex was carried out by the method reported previously;[1] it was concluded that malonic acid reacts with glycine in a 1 : 1 molar ratio to produce a solid complex which gives the diffraction pattern of M_1-G_1.

The infrared spectrum of M_1-G_1 is shown in Fig. 2. For comparison, the infrared spectra of the components, malonic acid and glycine, are shown in Fig. 2. The infrared spectrum of M_1-G_1 is diffrent from the sum; this fact indicates the presence of an interaction between

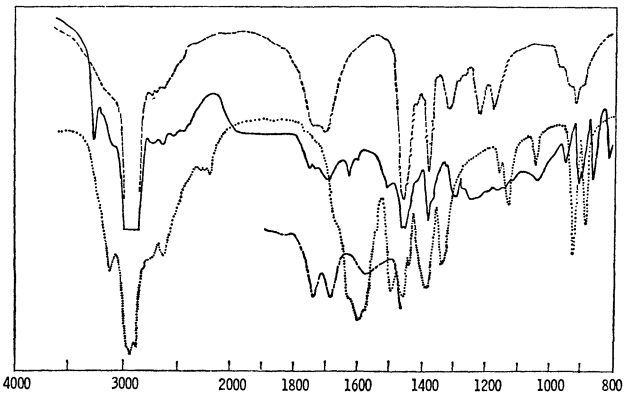

Fig. 2. Infrared absorption spectra of M_1-G_1 (——), malonic acid (----), γ-glycine (·····) and deuterated M_1-G_1 (— — — —) in Nujol.

malonic acid and glycine. The absorption bands which are observed at 3250—2300 cm^{-1}, 1620 cm^{-1}, and 1510 cm^{-1} in M_1-G_1 shift toward lower wave numbers upon deuteration. Therefore, NH_3^+ is present in M_1-G_1. An absorption band assigned to COOH is observed in the region of 1750—1695 cm^{-1}, and it is inferred from the shape of the absorption band and the wave number that there exists a COOH group of a different type of intermolecular hydrogen bond in M_1-G_1. Also, an absorption band appearing near 1575 cm^{-1} in the deuterated M_1-G_1 seems to be assignable to $-COO^-$. The X-ray diffraction pattern of M_1-G_1 was identical with that of the deuterated M_1-G_1.

The DTA-TG of M_1-G_1 and malonic acid are shown in Fig. 3. In the case of malonic acid, a small endothermic peak due to a transition and a large endothermic peak due to fusion are observed near 92 °C and 132 °C respectively. Following this sharp endothermic peak, a broad endothermic change due to the decomposition of malonic acid into acetic acid and carbon dioxide was observed. Now, in the case of M_1-G_1, a sharp, large endothermic peak due to fusion and a small but sharp exothermic peak due to the crystallization of the dissolved glycine to α-glycine were observed near 113 and 145 °C respectively. The gradually increasing endothermic change shown by M_1-G_1 after fusion is similar to that shown by malonic acid alone and is

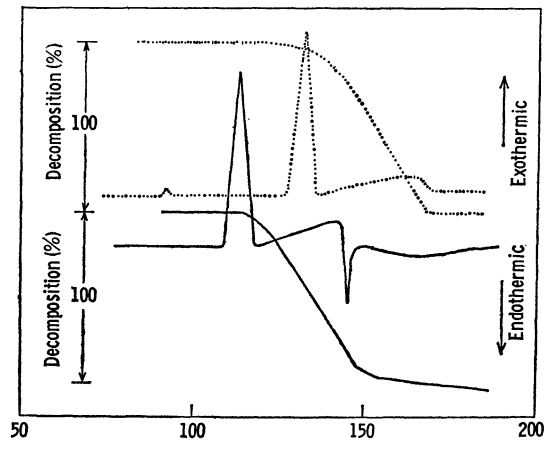

Fig. 3. DTA-TG curves of M_1-G_1 (——) and malonic acid (·····), in air. heating rate: 1.25 °C/min, sensivility: ±50 μV, reference: α-alumina powder.

considered to be the energy required for the decomposition of M_1-G_1 into glycine, acetic acid, and carbon dioxide. The slight exothermic change observed after the exothermic peak due to the crystallization to α-glycine indicates a possibility that glycine in part undergoes thermal polymerization in this temperature range.[2]

The driving force in the formation of a solid complex of malonic acid with glycine was considered. The pK_1 and pK_2 of malonic acid are 2.76 and 5.29 respectively, whereas the pK_1 of glycine is 2.35.[3] Hence, the formation of the so-called salt in aqueous solution would not be extensive. The pH of an aqueous solution of mixture of malonic acid and glycine, 0.1 mol/l in respect to each component, was 2.60 at room temperature. The ratio of $G^{\pm}(NH_3^+CH_2COO^-)$ to $G^+(NH_3^+CH_2COOH)$ in the aqueous solution was determined by means of the following equation:

$$\frac{[G^{\pm}][H^+]}{[G^+]} = 10^{-2.35}, \quad \frac{[G^{\pm}]}{[G^+]} = 1.8$$

Therefore, G^+ is about one half of $G^{\pm}$. It is known that the shape of the infrared absorption band of -COOH in M_1-G_1 differs from that of -COOH in malonic acid alone, but is similar in wave number, that the stretching vibration of NH_3^+ is shifted toward the higher wave-number side compared with that of glycine alone, that M_1-G_1 undergoes a breakdown to malonic acid and γ-glycine upon treatment with methanol or ethanol and malonic acid dissolves in an organic solvent while γ-glycine remains undissolved. On the basis of these experimental results, it is difficult to consider that the proton of -COOH of malonic acid has transferred to the $-COO^-$ of glycine in M_1-G_1. It has, hence, been inferred that the solid complex is formed as a result of formations of an intermolecular hydrogen bond between the hydrogen atom of malonic acid and the $-COO^-$ of glycine.

The author wishes to thank Professor Toshio Kinugasa, Professor Isamu Imanishi and Doctor Genzo Hashizume for their encouragement.

The ESR Spectra of Michler's Ketone Anion Radicals

Hideo FUJITA, Saburo KAKO, Jun YAMAUCHI*, Hiroaki OHYA-NISHIGUCHI**, and Yasuo DEGUCHI

College of Liberal Arts and Sciences, Kyoto University, Kyoto 606

** Institute for Chemical Research, Kyoto University, Uji 611*

*** Faculty of Science, Kyoto University, Kyoto 606*

(Received November 12, 1973)

Synopsis. The ESR spectra of Michler's ketone anion radicals reduced by alkali metal in solution consist of five groups of lines at +20 °C, but change into three groups of lines at −50 °C. The assigned hyperfine splitting constants are $A_H^o=3.22$, $A_H^m=0.43$, $A_N=0.72$, $A_{H^3}^{CH_3}=0.29$ gauss at +20 °C.

Since Müller[1] reported the complete 1 : 1 metal ketyl monomer fomation of Michler's ketone with counter cations on the basis of magnetic-susceptibility measurements, the cation radicals of this ketone[2] in solution have been investigated by ESR and characterized as similar to those of Wuerster's blue[3] and *N,N'*-tetramethylbenzidine[4] in the relative magnitudes of their hyperfine splitting constants among nitrogen and differrent sorts of protons. The results of the first observation of the ESR spectra of anion radicals of this ketone will be presented in this report.

Experimental

Anion radicals of Michler's ketone were prepared by the standard alkali metal reduction method.[5] The ESR spectra were measured with a JEOL X-band spectrometer equipped with 100 kHz modulation (MODEL ME-3) over the temperature range from +90 to −120 °C. Spectral simulations were carried out with a JEOL Spectral Computer (MODEL JEC-6).

Results and Discussion

The ESR spectra of the anion radicals obtained by potassium metal reduction on a mixed solvent (75%-DME and 25%-MeTHF) consisted of five groups of lines in the temperature range from 0 to +40 °C; a typical example at +20 °C is shown in Fig. 1a. Upon cooling to a lower temperature range (from −30 to −60 °C), the spectral structures were changed into those of three groups of lines with an approximate intensity ratio of 1 : 2 : 1; a representative spectrum at −50 °C is shown in Fig. 2. No appreciable line broadening has been detected in this temperature region, and the overall spectral width was constant at a value of around 21.2 gauss. The temperature dependency was found to be reproducible even when the temperature was changed to the reverse. The slightly broader linewidth on the high-field side than on the low-field side seems to be attributable to the contribution from the anisotropic *g*-tensor.[6]

A satisfactory simulation spectrum for Fig. 1a is shown in Fig. 1b, while the splitting constants used are compiled in Table 1 together with the corresponding spin densities calculated by H.M.O. procedures (using the hyperconjugation model[7] for the methyl-group

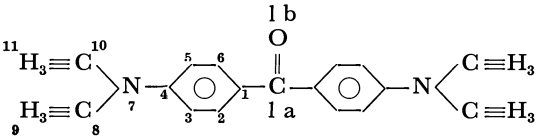
a) The parameters used for the calculation were cited from Ref. 7.



b) These values were calculated by using McLachlan spin densities in the table with Q values:
$|Q_{C-H}^H| = 24$, $|Q_{C-N}^N| = 20$, $|Q_{CH_3}^H| = 508/3$

contributions). The 3.22 gauss splitting from *o*-proton frames the characteristic five-group structure. The structure in the groups is accounted for by the contribution of the nitrogen and the other proton splittings. The potassium metal splitting constant is estimated to be less than 0.08 gauss; thus, the spectral patterns have not been affected significantly.

The change in the spectral structures around −30 °C to −60 °C has not yet been explained satisfactorily. However, the present authors assume that either a non-equivalency in a pair of *o*- or *m*-protons on the respective phenyl rings in the molecule or the presence of a linewidth alternation[8] similar to those found in the case of benzophenone[9] is responsible for this peculiar change. Many simulations for Fig. 2 have been carried out following a couple of the aforementioned mechanisms, but no statisfactory agreements have yet been found.

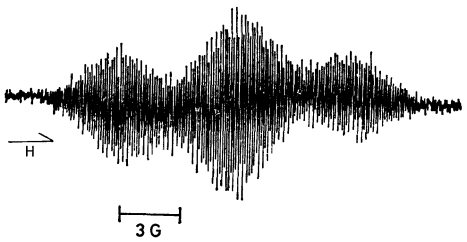


Fig. 2. The ESR spectrum of Michler's ketone anion radical in mixture of DME(75%) and MeTHF (25%) at −50 °C.

Recently the triplet-state ESR spectra of Michler's ketone ketyl have been observed; they suggest the formation of a metal ketyl similar to that of benzophenone.[10] These results will be reported in detail elsewhere.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(6), 1543—1544 (1974)

Energized Vinyl Radical Formation in the Photolysis of Ethylene

Hiroshi HARA and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received January 31, 1974)

Synopsis. Energized vinyl radical formation was found in the primary process of the 1634 Å photolysis of ethylene in the pressure region up to about 1 atm. The energized vinyl radical either decomposes unimolecularly to give acetylene and a hydrogen atom, or is deactivated to a stable vinyl radical at collision.

The primary processes in the photolysis of ethylene had been reported to be (1) and (2) in Scheme 1.[1-4] In recent years, however, another process, vinyl radical formation (3) was found on the basis of the formation of 1-butene as a product.[5,6]

$$C_2H_4 + h\nu \longrightarrow C_2H_2 + H_2 \quad (1)$$
$$\longrightarrow C_2H_2 + 2H \quad (2)$$
$$\longrightarrow C_2H_3 + H \quad (3)$$

Scheme 1.

More detailed mechanisms of the primary processes are still open to further investigation. In the present report, the mechanism involving two kinds of vinyl radical is proposed from the photolysis of high pressure ethylene (up to about 1 atom) at 1634 Å.

Experimental

The experimental procedures used in this experiment were almost the same as described previously.[6]

Results and Discussion

Ethylene was photolyzed at 1634 Å with and without nitrogen as a deactivator. The reaction products were the same as reported previously.[6] The ratio of formation rate of 1-butene to that of *n*-butane was plotted as a function of ethylene pressure, and as a function of nitrogen pressure with a fixed ethylene pressure in Figs. 1 and 2, respectively. In each case, the ratio follows a straight line with intercept against ethylene or nitrogen pressure.

As reported previously, 1-butene and *n*-butane are formed through recombination reactions of vinyl and ethyl radicals and of two ethyl radicals, respectively.[6]

It might be also possible that 1-butene is formed through Reaction (4).

$$C_2H_4^* + C_2H_4 \longrightarrow 1\text{-}C_4H_8 \quad (4)$$

But this process is ruled out in this experiment since 1-butene could not be detected in the photolysis of 360 Torr of ethylene with 19 Torr of nitric oxide added as a free radical scavenger. Thus, 1-butene is formed only by the recombination of vinyl and ethyl radicals. The product ratio evidently shows the pressure dependence, and it strongly suggests that the formation of the vibrationally excited vinyl radical, which either

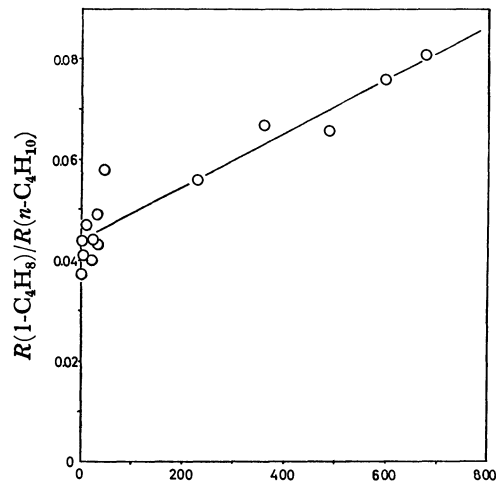

Fig. 1. $R(1\text{-}C_4H_8)/R(n\text{-}C_4H_{10})$ *vs.* the pressure of ethylene (Torr).

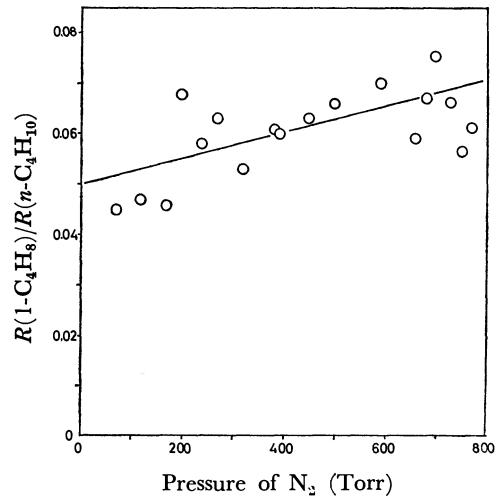

Fig. 2. $R(1\text{-}C_4H_8)/R(n\text{-}C_4H_{10})$ *vs.* the pressure of nitrogen (Torr) (C_2H_4: 25 Torr)

decomposes to give acetylene and a hydrogen atom, or is stabilized at collision to yield a stable vinyl radical. This mechanism has been proposed by Back and Griffith as follows.[4]

$$C_2H_4 + h\nu \longrightarrow H + [C_2H_3^*] \longrightarrow 2H + C_2H_2 \quad (5)$$

The details of the mechanism would be Reaction (6)

$$C_2H_4^* \longrightarrow C_2H_3^{\neq} + H \quad (6)$$

followed quickly by Reaction (7)

$$C_2H_3^{\neq} \longrightarrow C_2H_2 + H \quad (7)$$

provided the lifetime of $C_2H_3^{\neq}$ for dissociation is short enough to preclude any reactions requiring a bimolecu-

lar collision. But they have no direct evidence of the existence of the energized vinyl radicals. If this mechanism were the case, the ratio of 1-butene to *n*-butane would be extrapolated to zero at zero pressure. As seen in Figs. 1 and 2, the intercepts are, however, not zero. Thus, an additional path forming stable vinyl radicals should be considered. Namely two kinds of vinyl radicals must be formed in the primary process; one undergoes the unimolecular decomposition into acetylene and a hydrogen atom competing with collisional deactivation to a stable vinyl radical, and the other does not decompose even at very low pressures.

In the light of these arguments, the following scheme is proposed with the aid of our previous study.

$$C_2H_4 + h\nu \xrightarrow{\phi_1} C_2H_2 + H_2 \quad (8)$$

$$\xrightarrow{\phi_2} H + C_2H_3^{**} \xrightarrow{k_d} C_2H_2 + H_2 \quad (9)$$

$$\xrightarrow{\phi_3} H + C_2H_3^{*} \xrightarrow{k_s[M]} C_2H_3 \quad (10)$$

$$H + C_2H_4 \longrightarrow C_2H_5 \quad (11)$$

$$C_2H_5 + C_2H_5 \longrightarrow C_2H_4 + C_2H_6 \quad (12)$$

$$\longrightarrow n\text{-}C_4H_{10} \quad (13)$$

$$C_2H_3 + C_2H_5 \longrightarrow 2C_2H_4 \quad (14)$$

$$\longrightarrow C_2H_2 + C_2H_6 \quad (15)$$

$$\longrightarrow 1\text{-}C_4H_8 \quad (16)$$

Scheme 2.

Steady state treatment leads to the relationship

$$\frac{R(1\text{-}C_4H_8)}{R(n\text{-}C_4H_{10})} = A\left\{\frac{\phi_3}{\phi_2} + \left(1+\frac{\phi_3}{\phi_2}\right)\frac{k_s^{C_2H_4}}{k_d}[C_2H_4] + \left(1+\frac{\phi_3}{\phi_2}\right)\frac{k_s^{N_2}}{k_d}[N_2]\right\} \quad (17)$$

where $A=k_9(k_5+k_6)/k_6(k_7+k_8+k_9)$. The value of A was obtained in the previous study as 0.45 at 1634 Å.

From the intercepts and the slopes of the plots in Figs. 1 and 2, the values of ϕ_3/ϕ_2, $k_s^{C_2H_4}/k_d$ and $k_s^{N_2}/k_d$ can be determined. The results are summarized in Table 1.

Table 1. ϕ_3/ϕ_2, k_s^M/k_d, and β

M	ϕ_3/ϕ_2	k_s^M/k_d Torr^{-1}	β
C_2H_4	0.098±0.08	1.1 ±0.1	1.0
N_2	—	0.47±0.1	0.43

It is concluded that at least some portion of acetylene in Scheme 1 may be formed through $C_2H_3^{**}$ from ϕ_2 in Scheme 2.

The rate constant of stabilization, k_s, is written as follows:

$$k_s = \frac{\beta Z^{C_2H_3^{**}-M}}{[M]} \quad (18)$$

where β is the collisional deactivation efficiency and $Z^{C_2H_3^{**}-M}$ is the collision frequency between the energized vinyl radical and the deactivator, M. The latter was calculated by means of the gas kinetic theory on the assumption that the collisional diameter of vinyl radical was the same as that of ethylene. If the unit probability of energy transfer per collision is assumed for ethylene, the experimental value of $k_s^{C_2H_4}/k_d$ and the collisional frequency yield an upper limit of the dissociative rate constant, k_d, 1.0×10^{11} s^{-1}. Using this value of k_d, the collisional deactivation efficiency is obtained. These values are also shown in Table 1.

Calculation using a simple RRKM theory was carried out to compare with the dissociative rate constant obtained experimentally.

It is generally accepted that k_d corresponds to the specific rate constant k_E for the energies ranging from 50 to 80% of the maximum available energy for the decomposition. In this study, the specific rate constant for the decomposition of the vinyl radical was calculated. The computation was carried out for four models of activated complexes by the usage of the program by Akimoto *et al.*[7] The result is shown in Fig. 3. The experimental value of k_d, 1.0×10^{11} s^{-1} corresponds to the k_E at 48—57 kcal mol^{-1}, which is 70—80% of the available energy (70 kcal mol^{-1}). Thus the experimental value and our proposed mechanism are quite reasonable.

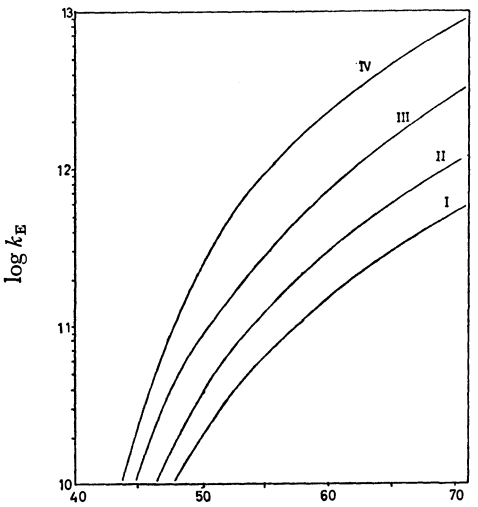

Fig. 3. log k_E *vs.* E. The numbering of the models is taken in order of rigidness.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 47(6), 1545—1546 (1974)

Polarized Raman Spectra of $(NH_4)_2SO_4$ Single Crystals

Katsuo UCHIDA, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, School of Science and Engineering, Waseda University, Tokyo 160

(Received February 5, 1974)

Synopsis. Polarized Raman spectra of $(NH_4)_2SO_4$ single crystals were measured at room temperature. The symmetry species of the observed Raman bands due to the internal vibrations of SO_4^{2-} as well as the lattice modes were determined.

Several articles have appeared on the vibrational spectra of $(NH_4)_2SO_4$.[1-5] In spite of the importance of this crystals as one of the improper ferroelectrics, the vibrational problem does not seem to have been solved. The most thorough study is that by Torrie *et al.*[5] who measured infrared and Raman spectra of $(NH_4)_2SO_4$ and $(ND_4)_2SO_4$ powder at temperatures above and below the Curie point (−50 °C). Their results are convincing but do not determine the symmetry species of the infrared and Raman bands.

It is the purpose of this note to report the polarized Raman spectra of $(NH_4)_2SO_4$ single crystals in the paraelectric phase and to give the symmetry species of the Raman bands.

Experimental

Single crystals of $(NH_4)_2SO_4$ were grown from an aqueous solution by slow evaporation at room temperature. The crystals were obtained as thick plates (about 10 mm × 10 mm × 3 mm) with the broad face parallel to the (010) plane and the cleavage plane perpendicular to the *a*-axis. The crystal axes were checked by X-ray oscillation photographs. The polarized Raman spectra were recorded with a Shimadzu R-2D double monochrometer using photon counting detection. The 5145 Å line of an Ar^+ laser was used as the excitation wavelength with 700 mW power output. A polarization scrambler was placed between analyzer and slit and the wave numbers of the Raman bands were calibrated using spontaneous emission lines from the laser.

Results and Discussion

The crystal structure of $(NH_4)_2SO_4$ in the paraelectric phase is orthorhombic P_{nam}-D_{2h}^{16}, with four units of $(NH_4)_2SO_4$ in a Bravais unit cell.[6] All the ions occupy the sites with C_s symmetry.

Internal vibrations of the NH_4^+ ions are expected to appear between 3100 and 1400 cm^{-1}. However, because of their weak intensities in the Raman spectrum, polarization measurements were not successful. According to the factor group analysis, the Raman-active internal vibrations of the SO_4^{2-} ions are classified as $6A_g(\nu_1, \nu_2, 2\nu_3, 2\nu_4)+6B_{1g}(\nu_1, \nu_2, 2\nu_3, 2\nu_4)+3B_{2g}(\nu_2, \nu_3, \nu_4)+3B_{3g}(\nu_2, \nu_3, \nu_4)$ and the Raman-active lattice modes as $9A_g$(6 trans., 2 NH_4^+ lib., SO_4^{2-} lib.)+$9B_{1g}$(6 trans., 2NH_4^+ lib., SO_4^{2-} lib.) + $9B_{2g}$ (3 trans., 4 NH_4^+ lib., 2 SO_4^{2-} lib.)+$9B_{3g}$(3 trans., 4 NH_4^+ lib., 2 SO_4^{2-} lib.).

Polarized Raman spectra below 1200 cm^{-1} are shown in Fig. 1. The bands which appear between 1120 and 440 cm^{-1} are undoubtedly due to the internal modes (ν_1, ν_2, ν_3 and ν_4) of the SO_4^{2-} ions. In spite of the fact that ν_1 is inactive in B_{2g} and B_{3g} species, a very weak band is observed at 976 cm^{-1} in the spectra of both species. Imperfection in the crystal or the polarizer may be responsible for this. It should be noted that the relative intensity of the same vibrational mode belonging to A_g species can vary remarkably in the polarized spectra with different Raman tensor component. As can be seen in Fig. 1, the splitting of the internal modes of the SO_4^{2-} ions is not large. This is in accord with the result of the neutron diffraction study by Schlemper and Hamilton[6] that the SO_4^{2-} ions are not much distorted from tetrahedral symmetry.

The neutron inelastic scattering study at 172 K by Rush and Taylor[7] and the infrared study at 77 K by Torrie *et al.*[5] indicate that the librational modes of the NH_4^+ ions should appear around 330 cm^{-1}. In the present work, however, no band was observed between 440 and 200 cm^{-1}. This is probably because the NH_4^+ ions are almost in free rotation at room temperature.

The liberational modes of the SO_4^{2-} ions and the

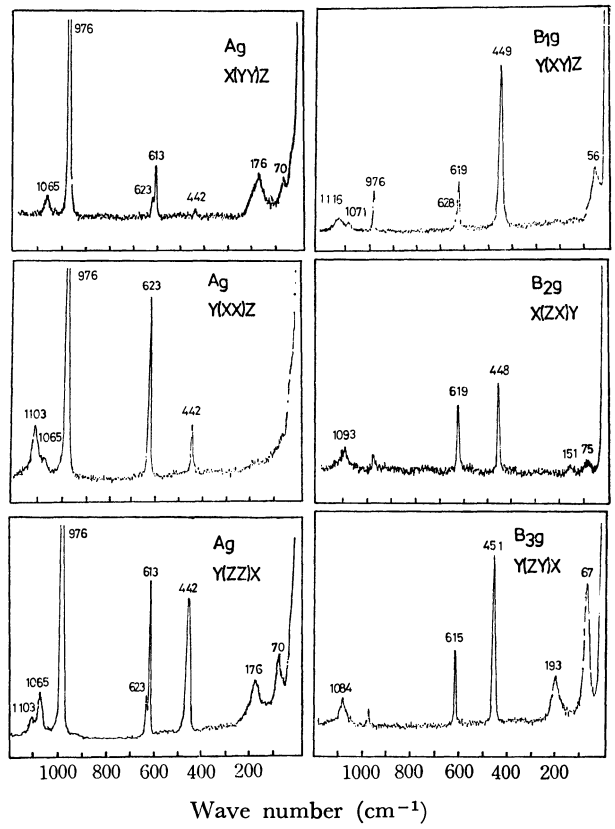

Fig. 1. Polarized Raman spectra of $(NH_4)_2SO_4$ single crystals. The Raman tensor components are expressed according to Porto's notation.[8]

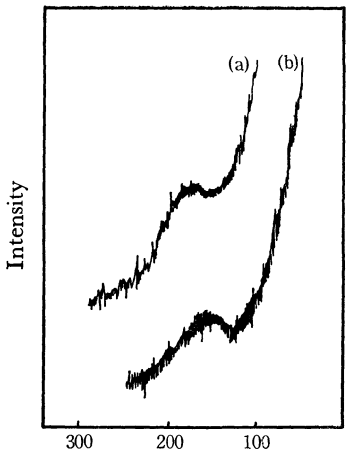

Fig. 2. Low frequency Raman spectra of (a) $(NH_4)_2SO_4$ and (b) $(ND_4)_2SO_4$ powder.

translational modes of the NH_4^+ and SO_4^{2-} ions are expected to appear below 200 cm^{-1}. The Raman spectra below 300 cm^{-1} of $(NH_4)_2SO_4$ and $(ND_4)_2SO_4$ powder are shown in Fig. 2. The band at 185 cm^{-1} of $(NH_4)_2SO_4$ shifts to 167 cm^{-1} by deuteration. The frequency ratio 185/167 is almost equal to $(22/18)^{1/2}$. This means that the band is attributed to the translational modes of the NH_4^+ ions. Thus, the bands at 176(A_g), 151(B_{2g}) and 193(B_{3g}) cm^{-1} in the polarized Raman spectra were assigned to the translational modes of the NH_4^+ ions.

Since the SO_4^{2-} ions do not differ significantly from the regular tetrahedral,[6] it is highly probable that the Raman intensity of the librational modes of the SO_4^{2-} ions is too weak to be detected. The bands at 70(A_g) 56(B_{1g}), 75(B_{2g}) and 67($B3_g$) cm^{-1} in the polarized Raman spectra were therefore assigned to the translational modes of the SO_4^{2-} ions (Table 1).

Table 1. Observed Raman frequencies (cm^{-1}) and assignment of $(NH_4)_2SO_4$

Assignment	A_g	B_{1g}	B_{2g}	B_{3g}

A Polarographic Study of the Complex Formation Equilibria of Lead(II) Ions with Glutamate and Ethylenediamine-*N*,*N*′-diacetate Anions

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki, Aomori 036

(Received November 26, 1973)

Synopsis. In this experiment, the complex formation equilibria of the lead(II) ions with glutamic and ethylenediamine-*N*,*N*′-diacetic acids were studied by using the polarographic method. The lead(II) ion forms 1 : 1- and 1 : 2-ratio complexes with glutamic acid, while, with ethylenediamine-*N*,*N*′-diacetic acid, it forms only a 1 : 1-ratio complex, PbX⁰.

Previously,[1] the present author reported in his polarographic study of the lead(II) ions in aspartate and iminodiacetate solutions that the lead(II) ion forms 1 : 1- and 1 : 2-ratio complexes with aspartate and iminodiacetate anions. The lead(II) ion also can form stable complexes with Glut* and EDDA* anions. However, no systematic equilibrium study of the complex formation reactions of the lead(II) ion with Glut and EDDA anions had been reported. In this connection, it seemed to be worthwhile to determine the equilibria of the lead(II) ion with Glut and EDDA anions. In this paper, the present author will determine the solution equilibria of the lead(II) ion with Glut and EDDA anions by using a polarographic technique.

Experimental

Reagents. The preparation of a lead(II) nitrate solution has been described previously.[1] The Gult and EDDA were recrystallized from their aqueous solutions. The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate amount of $NaClO_4$. The other chemicals used were of an analytical reagent-grade and were used without further purification.

Apparatus and Experimental Procedures. All the apparatus and the experimental procedures employed in this study were the same as those described previously.[1] The characteristic feature of the DME used was also described previously.[2] For the EDDA system, an acetate buffer solution was used. In the Glut system, no buffer reagent was used, because all the sample solutions contained an appropriate amount of uncomplexed Glut and had enough buffer capacity.

Results and Discussion

Lead(II) ions in Glut ($8.50<pH<9.40$) and EDDA ($3.00<pH<4.00$) solutions exhibited single reversible waves, which are diffusion-controlled in nature. In Glut solutions of pH's higher than 9.50, the 1.0 mM lead(II) ion yielded a white precipitate. Therefore, the equilibrium study of the Glut system was conducted in sample solutions containing the 0.30 mM lead(II) ion at pH's lower than 9.50. Since the Glut anion can act as a bidentate or tridentate ligand in the complexation reaction, the lead(II) ion will form 1 : 1- and 1 : 2-ratio complexes with the Glut anion. Therefore, the following relation can be derived for the lead(II)-Glut system:[1]

$$\mathrm{Antilog}\left(\frac{\Delta E_{1/2}}{0.0296}+\log\frac{k_{Pb}}{k_{PbG}}\right) = K'_{PbG}\cdot[\mathrm{Glut}]_f+K'_{PbG}\cdot K^{G'}_{PbG_2}\cdot[\mathrm{Glut}]_f^2 \quad (1)$$

where $\Delta E_{1/2}$ indicates the shift of the half-wave potential by the complex formation and where K'_{PbG} and $K^{G'}_{PbG}$ are, respectively, the conditional first and second successive formation constants of the lead(II)-Glut complex. By using the above relation, the solution equilibrium between the lead(II) ion and the Glut anion was studied. A typical result obtained is reproduced in Fig. 1. From the intercept and slope of the straight line in Fig. 1, K_{PbG} and $K^{G}_{PbG_2}$ were estimated to be 5.0×10^4 and $7.0_0\times10^2$ respectively.

The limiting current of the lead(II) ion in the EDDA solution decreased with an increase in the concentration of the uncomplexed EDDA, $[X]_f$. This decrease can be ascribed to the formation of a lead(II)–EDDA complex. If the aquo lead(II) ion coexists with the 1 : 1-ratio EDDA complex, one can derive the following equation for the conditional formation constant of a 1 : 1-ratio lead(II)-EDDA complex, K'_{PbX}, by combining the relation given by Kacena and Matousek[3] and the Ilkovic equation:

$$K'_{PbX}[X]_f=\frac{(i_d)^2_{Pb}-(i_d)_0^2}{(i_d)_0^2-(i_d)^2_{PbX}} \quad (2)$$

where $(i_d)_{PbX}$ and $(i_d)_{Pb}$ are the diffusion currents of complexed and uncomplexed lead(II) ions respectively,

Solvolytic Reactions in Dipolar Aprotic Solvents. Reaction Rates of the Tertiary Aralkyl System

Takane UCHIDA, Sumie MARUI, Yo MIYAGI,* and Kazuhiro MARUYAMA*

Department of Chemistry, Faculty of Education, Fukui University, Bunkyo, Fukui 910

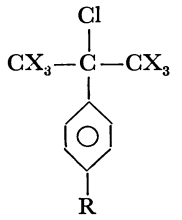
**Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606*

(Received September 14, 1973)

Synopsis. Solvolytic reaction rates of 2-aryl-2-chloropropanes in dipolar aprotic solvents were determined in order to obtain activation parameters, ρ-values, and β-deuterium effect. The results are compared with those in protic solvents.

Solvolytic reactions in protic media proceed through S_N1, El, S_N2, and E2 routes depending on the structure of substrate and the nature of solvent. In some cases several reaction routes occur concurrently, while in other cases only one appears to occur. Relative ionizing powers of protic solvents have been determined so far[1] without determination of the partitions of each route. In aprotic media most reactions can proceed through the El route because of the slight nucleophilic character of the solvents.[2] Thus the solvolytic reaction in aprotic media may reflect the characteristics of carbonium ion type intermediates more precisely than in protic media. A few such reactions have been studied for the tertiary system, such as reactions of triphenylmethyl chloride in benzene[3] and nitromethane,[4] *t*-butyl chloride in nitromethane,[5] acetonitrile[6] and dimethylformamide,[7] and *t*-butyl nitrate in acetonitrile.[8]

We have studied the reaction rates of 2-chloro-2-phenylpropanes (cumyl chlorides) in dimethyl sulfoxide (DMSO), nitromethane, acetonitrile and dimethylformamide (DMF). The reaction was carried out in the presence of pyridine and the acid liberated was titrated with methanolic sodium methoxide solution. Constant first-order rate coefficients were obtained up to 60% reaction. Rate constants (k_H) of 2-chloro-2-phenylpropane (**1**), with activation parameters, are given in Table 1, and rate constant (k_{Br}) of 2-(4'-bromophenyl)-2-chloropropane (**2**) and their rate ratios to **1** (k_{Br}/k_H) in Table 2. Rate constants (k_D) of 2-chloro-1,1,1,3,3,3-hexadeuterio-2-phenylpropane (**3**) and sixth roots of their ratios to **1** ($\sqrt[6]{k_H/k_D}$) are also shown in Table 2. The corresponding values obtained in protic media are given in Table 3.



1; R=X=H
2; R=Br, X=H
3; R=H, X=D

The effect of solvents on the reaction rate of **1** is in the order, DMSO>nitromethane>acetonitrile>DMF. Paucity of substituents might give unreliable ρ-values. However, the fact that **1** shows almost the same ρ-values in aprotic solvents indicates a sufficient reliability.

If we compare the results obtained in aprotic solvents with those in protic media, characteristics observed can be summarized as follows. i) ρ-values are similar in both media, ii) although k_H/k_D-values are almost constant in both media, they are slightly larger in aprotic, iii) $\Delta S^{\neq}$-values in aprotic media are negatively larger.

Experimental

Materials. Chlorides were prepared from the corresponding alcohols by the method of Brown and Rei:[9] 2-phenyl-2-propanol,[10], bp 94—96 °C/19 mmHg; 2-(4'-bromophenyl)-2-propanol, mp 40.1 °C (lit,[11] 45.6 °C); 1,1,1,3,3,3-hexadeuterio-2-phenyl-2-propanol was prepared from acetone-d_6 and phenylmagnesium bromide,[10] bp 65 °C/2.5 mmHg, no detectable methyl H-signals in NMR. Dimethyl sulfoxide was refluxed over calcium hydride under reduced pressure and distilled (bp 48.5—50.0 °C/2.5 mmHg). Nitromethane was dried over Drierite and distilled (bp 100.5—101.8 °C). Acetonitrile was refluxed over phosphorus pentoxide and distilled (bp 80.9—82.3 °C). Dimethylformamide was distilled with benzene (about 5%) to remove impurities azeotropically. A fraction boiling at 150—152 °C was collected. Pyridine was dried over potassium hydroxide and distilled (bp 115 °C).

Rate Measurements. About 0.5 mmol of chloride was

Brown and Y. Okamoto, *ibid.*, **79**, 1913 (1957). i) S. G. Smith and D. J. W. Goon, *J. Org. Chem.*, **34**, 3127 (1969). j) R. L. Buckson and S. G. Smith, *ibid.*, **32**, 634 (1967).

weighed in a 10 ml volumetric flask and 0.05 M solution of pyridine in an aprotic solvent was added. The flask was immersed in a thrmostatt. At an appropriate interval an aliquot of 1 ml was drawn out, poured into 20 ml of acetone, and titrated with a standard solution of sodium methoxide in methanol with lacmoid as an indicator.

Products. Quantitative isolation of 2-phenylpropene (**4**) was difficult because of polymerization. In the case of acetonitrile solution, the yields of **4** determined by an ultraviolet absorption at 243 nm of diluted reaction solutions with ethanol were almost quantitative based on acid formation. The yields of **4** in the other solvents derermined by ultraviolet absorption were less reproducible.

Reaction Paths in the Photochemical Isomerization between *cis*-Butadiene and Cyclobutene

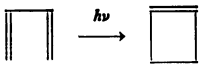
Osamu KIKUCHI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received October 29, 1973)

Synopsis. During the disrotatory process of the photoinduced cycloaddition of *cis*-butadiene, two lower symmetric states play an important role and the ground state of cyclobutene is formed directly through a radiationless transition between these two states.

One of the most important questions in photochemical reactions is the actual path along which the excited molecule travels to the product. van der Lugt and Oosterhoff[1] have proposed an interesting reaction path related to this problem. They have calculated the potential curves of the lowest and excited singlet states in the cyclo-addition of *cis*-butadiene to form cyclobutene:



(I)

and concluded that, for the disrotatory process of (I), the generation of the excited state of cyclobutene derived from the Woodward-Hoffmann rule[2] can not be expected and that the ground state of cyclobutene is formed directly through the excited singlet state, which has a symmetric (not an anti-symmetric) property with respect to the symmetry plane. In their calculations, however, only four electrons, π electrons of butadiene, were included. In this note, the potential curves for (I) will be obtained by an all-valence-electron SCF-CI method, and the reaction processes will be discussed.

The potential curves were calculated for the ideal paths, in which the molecule has C_s and C_2 symmetries for the disrotatory and the conrotatory processes respectively. In the course of doing so, the C-C distances and bond angles were varied from the values of *cis*-butadiene to those of cyclobutene. The rotation angle of the methylene groups, θ, was varied from 0° to 90° in steps of 15°. The energies of the lowest and excited (singlet and triplet) states were calculated by the MINDO/2 method[3], followed by CI calculations in which 38 singly- and doubly-excited configurations were included. One of the deficiencies of the MINDO/2 method is its underestimation of the strain energies of small-membered cyclic compounds. This deficiency was adjusted by adding strain energy to the system which increases with the θ and which is about 1 eV[3] at $\theta=90°$, cyclobutene.

The potential curves are shown in Fig. 1. In the conrotatory process, the potential curve for the ground state has a maximum point which did not appear in the potential curve obtained by van der Lugt and Oosterhoff[1] and was not expected in the qualitative diagram of Longuest-Higgins and Abrahamson.[4] The barrier was 1.8 eV,[5] as compared with an experimental estimation, 1.4 eV,[6] and with a theoretical estimation obtained by Hsu *et al.*, 2.0 eV.[7]

In the disrotatory process, the spectroscopic excited singlet state (A″, $\pi\rightarrow\pi^*$) of *cis*-butadiene[8] crosses an excited state (A′) at $\theta\simeq30°$, and two lower singlet states have the same symmetry (A′) at $\theta\simeq45°$, in contrast with Longuet-Higgins–Abrahamson's diagram. The approach of the two lower A′ states in the intermediate of the disrotatory process is caused by the change in the lowest closed-shell electron-configuration in this area. Thus, an appreciable non-adiabatic transition caused by a finite velocity of the rotational motion of CH_2 groups can be expected from the upper A′ state to the lowest A′ state. This has been pointed out by van der Lugt and Oosterhoff.[1]

The probability, P, of the non-adiabatic transition between two states can be estimated by Zener's formula:[9]

$$P = \exp\left\{-\frac{4\pi^2}{h}\varepsilon_{12}^2\Big/\left|\frac{\mathrm{d}}{\mathrm{d}t}(\varepsilon_1-\varepsilon_2)\right|\right\}$$

where the ε's are the energies calculated with two configuration functions whose linear combinations describe the two states in question.[10] Zener's formula can be used for the system in which ε_{12} is independent of the time and in which $\varepsilon_1-\varepsilon_2$ is a linear function of time. In the region of $\theta=30°$—$60°$ of the present

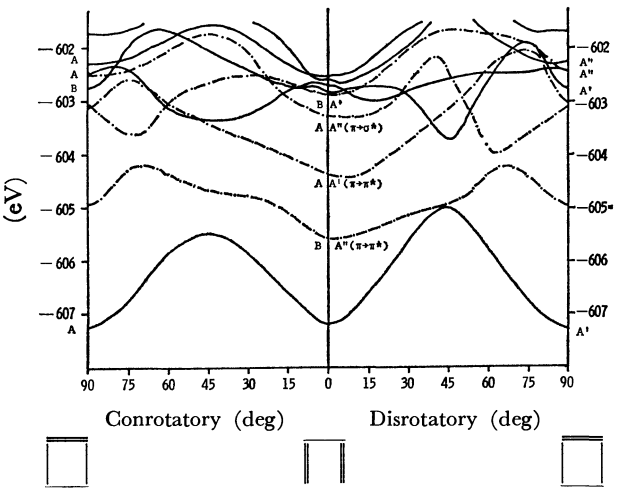


Fig. 1. Potential energy curves ploted as a function of the rotation angle θ of methylene groups.
Solid lines: Singlet states whose electronic symmetry properties are shown at both sides of the figure. The characters of excited states are given in the Ref. 8.
Broken lines: Triplet states whose electronic symmetry properties are shown at the center of the figure. The characters of excited states are given in parentheses.

disrotatory process, $\varepsilon_1-\varepsilon_2$ is approximately a linear function of θ and ε_{12} is almost constant. The probability of the non-adiabatic transition from the upper A′ singlet state to the lowest A′ one within the half-period of the oscillation was estimated as $P\simeq\exp\{-25\}$, a value which corresponds to the mean lifetime, $\simeq 10^{-3}$ s, of the upper A′ state. Between the two corresponding A states of the conrotatory process, no appreciable non-adiabatic transition can be expected because of the lack of interaction between the two A states, as in the two A′ states of the disrotatory process. We feel that the path proposed by van der Lugt and Oosterhoff is reasonable: *cis*-butadiene excited into the A″ singlet state changes its electronic symmetry property near $\theta=30°$,[12] and then the ground state of cyclobutene is formed directly through a radiationless transition at $\theta\simeq 45°$ from the upper A′ state to the lowest A′ state.

The potential curves of the triplet states indicate that the excited triplet states of *cis*-butadiene have no driving force for Reaction (I). This agrees with the experimental facts.[13] A photochemical ring opening of cyclobutene occurs from the upper excited triplet state (not the excited singlet states or the lowest triplet state) of cyclobutene.[13-14] The potential curves of the triplet states in Fig. 1 indicate that the photoinduced ring opening of cyclobutene is possible if cyclobutene is excited into the upper triplet state, T_2, and if the non-adiabatic transition from T_2 to T_1 is appreciable near $\theta=70°$. This path, however, involves the generation of the excited triplet state (A″) of *cis*-butadiene, which may be inconsistent with the experimental facts.[13] Moreover, the absence of the ring-opening path *via* the excited A″ singlet state of cyclobutene[13] can not be understood from the potential curves in Fig. 1.

The calculations were carried out on a HITAC 8700 computer at the Computer Center, The University of Tokyo. The author wishes to thank Professor K. Suzuki for his useful suggestions.

8) The four lower excited singlet states of *cis*-butadiene are $\sigma\rightarrow\pi^*$(B,A′), $\sigma\rightarrow\pi^*$(A,A″), $\pi\rightarrow\pi^*$(B,A″), and $\pi\rightarrow\pi^*$(A,A′), lying in this order within the range of 4.4—4.6 eV above the ground state. At $\theta=15°$ for the disrotatory process, the lowest excited stinglet state (A″) has the $\pi\rightarrow\pi^*$ character. At $\theta=15°$ for the conrotatory process, the second excited singlet state has the $\pi\rightarrow\pi^*$ character.
9) C. Zener, *Proc. Roy. Soc., Ser. A*, **137**, 696 (1932). The limits within which Zener's formula is valid have been discussed by C. A. Coulson and K. Zalewski, *ibid., Ser. A*, **268**, 437 (1962).
10) The electron configuration functions, $\Psi_1=|\cdots(7a')^2(5a'')^0|$ and $\Psi_2=|\cdots(7a')^0(5a'')^2|$, contribute effectively to the two A′ states in $\theta=30°$—$60°$ of the disrotatory process. In this region, $d|\varepsilon_1-\varepsilon_2|/d\theta=0.5$ eV/degree and $\varepsilon_{12}=1.5$ eV.
11) $\varepsilon_1-\varepsilon_2$ is not a linear function of the time but of the θ in $\theta=30°$—$60°$, and the value of $d|\varepsilon_1-\varepsilon_2|/dt$ was estimated from the value of $d|\varepsilon_1-\varepsilon_2|/d\theta$.
12) Two states, A′ and A″, will mix with only a small distortion of the molecular symmetry property, and the non-crossing curves enable the symmetry property of the system to change from A″ to A′.

The Reactions of Several Carbonyl Compounds with Hexamethylphosphoric Triamide

Seiji ARIMATSU, Ryohei YAMAGUCHI, and Mituyosi KAWANISI*

Department of Indnstrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received December 19, 1973)

Synopsis. Non-enolizable carbonyl compounds were found to undergo intriguing reaction upon heating with hexamethylphosphoric triamide; benzophenone gave 1,1,2,2-tetraphenylethane and benzophenone methylimine, while fluorenone afforded 9-methylfluorene, 9-dimethylaminofluorene, and fluorene. In contrast, anthrone, an enolizable compound, was completely recovered unchanged under the the same reaction conditions.

Hexamethylphosphoric triamide (HMPT), an excellent dipolar aprotic solvent,[1] has also been widely utilized as a reagent in organic synthesis.[2] In line with this tendency, Monson and his co-workers reported an intriguing chemical process in which cycloalkanones were converted by thermal treatment with HMPT into pyridine derivatives *via* 1-dimethylaminocycloalkenes.[2g] They were successful in explaining the reaction by assuming a cationic species derived from the enamines.

With this in mind, we hoped that the reaction of non-enolizable carbonyl compounds with HMPT might lead to a yet unexplored mode of reaction, since enamine formation is unlikely in this case. This proved to be the case, and 1,1,2,2-tetraphenylethane was obtained from benzophenone, and 9-methylfluorene from fluorenone.

Upon thermal treatment with HMPT at 230—240 °C for 2 hr, benzophenone afforded 1,1,2,2-tetraphenylethane (**1**) by a formally deoxygenative condensation, together with diphenylmethane (**2**), benzhydryldimethylamine (**3**), and benzophenone methylimine (**4**), as is shown in Table 1. On the other hand, a similar treatment of fluorenone gave mainly the reduction product, fluorene (**5**), together with 9-methylfluorene (**6**) and 9-dimethylaminofluorene (**7**). All these compounds gave satisfactory spectral data, and **1**,[3] **4**,[4] and **6**[5] were identical with the authentic specimens independently prepared. In the case of benzaldehyde, a complex mixture containing at least eleven products resulted, from which bibenzyl (**8**), benzyldimethylamine (**9**), and dibenzylmethylamine (**10**) were isolated.

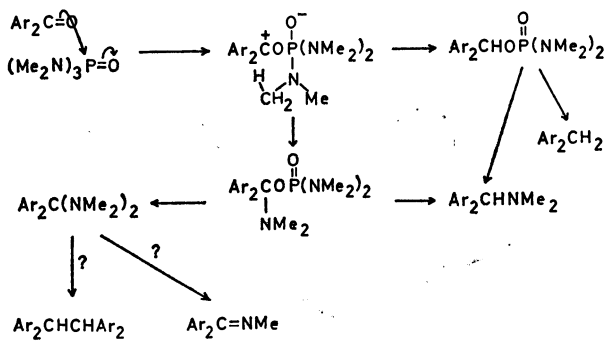
Furthermore, xanthone was converted to xanthene in a 47% yield, but anthrone, an enolizable compound, was completely recovered under these conditions, in accordance with the fact that phenol was converted only slightly to phenyl tetramethylphosphorodiamidate[6] by treatment with HMPT for 5 hr.

When an equimolar mixture of benzophenone and HMPT was heated at 230—240 °C for 2 hr, both the benzophenone and the HMPT were fully consumed. In this case, benzophenone methylimine (**2**) was obtained in a 49% yield after the vacuum distillation of the reaction mixture, although trace amount of **2** and **3** were included as impurities.

Additionally, as is shown in Table 1, the reaction of deoxybenzoin and benzopinacol with HMPT gave peculiar compounds (Runs 7 and 8). In both examples, a cleavage of the central C-C bond of the starting materials took place, although the detailed mechanism is yet unclear.

An inspection of the results listed in the Table (Runs 1 to 4) and the results for the corresponding alcohols[7] indicates that a mechanism similar to that of the reaction of alcohols with HMPT might operate also in the reaction of non-enolizable carbonyl compounds with HMPT, though including some different factors.

Thus, we tentatively propose Scheme 1 with regard to the first step of the reaction.



Scheme 1.

Since benzophenone methylimine (**4**) which had been independently prepared was unchanged even if it was treated with HMPT at 230—240 °C for 2 hr, **4** was the final product in this reaction. The presumed intermediate, an aminal, was prepared in the case of benzaldehyde[8] and was treated *without* a solvent at 230—240 °C, affording only a trace amount of bibenzyl, while the starting material was almost entirely recovered. The detailed mechanism for the formation of the peculiar products, such as **1**, **4**, **7**, and **8**, is not yet understood.

The formation of 2,3,5,6-tetraphenylpyridine (**11**) from deoxybenzoin was well explained by Monson's mechanism.[2g] The compound (**11**) was identical with an authentic specimen independently prepared.[9]

Finally an additional observation might be noted. Throughout Runs 1—3 and 5—7, octamethylpyrophosphoramide[10] was formed.

Experimental

All the temperatures are uncorrected. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The mass spectra were taken by using a Hitachi RMS-4 mass spectrometer. The NMR spectra were obtained on an EM-360

Table 1. The reaction with HMPT

Run	Substrate	Products (%)
1	Benzophenone	$Ph_2CHCHPh_2$(13), Ph_2CH_2(3), Ph_2CHNMe_2(9), $Ph_2C{=}NMe$(12)
2	Benzaldehyde	$PhCH_2CH_2Ph$(1), $PhCH_2NMe_2$(11), $(PhCH_2)_2NMe$(8), etc.
3	Fluorenone	fluorene(68), 9-methylfluorene(6), 9-dimethylaminofluorene(13)
4	9-Fluorenol	fluorene(11), 9-methylfluorene(1), 9-dimethylaminofluorene(35)
5	Xanthone	xanthene (47, based on unrecovered xanthone) xanthone was recovered in 52%.
6	Anthrone	no reaction
7	Deoxybenzoin	$PhCH{=}C(NMe_2)Ph$(34), $PhCONMe_2$(13), 2,3,5,6-tetraphenylpyridine(3)
8	Benzopinacol	$Ph_2CHCHPh_2$(15), Ph_2CH_2(4), Ph_2CHNMe_2(49), $Ph_2C{=}NMe$(7)

spectrometer, TMS being chosen as the internal standard.

Starting Materials. The benzophenone, benzaldehyde, fluorenone, xanthone, and anthrone were commercially-available products. The following compounds were prepared by the reported method; 9-fluorenol,[11] deoxybenzoin,[12] and benzopinacol.[13]

Hexamethylphosphoric Triamide (HMPT). Commercially-available HMPT was refluxed for 5 hr under N_2 over calcium hydride, and then distilled; bp 110—115 °C/15 mmHg.

General Procedure for the Reaction with HMPT. The substrate (0.01 mol) was dissolved in HMPT (10 ml) and heated at 230—240 °C under N_2 for 2 hr. The reaction mixture was then distilled under reduced pressure. After the HMPT had been distilled off at 110—115 °C/15 mmHg, the residue was separated to a single product by a combination of vacuum distillation, column chromatography, and preparative glc.

Preparation of Benzophenone Methylimine (4).[14] A mixture of benzophenone dichloride (6 g, 0.025 mol) and 30% aqueous methylamine (60 ml) was stirred for 4 hr. After an additional methylamine solution (20 ml) had been added and stirring had been continued for 1 hr, the organic material was extracted with ether and dried (Na_2SO_4). The removal of the ether and distillation at 133—135 °C/5 mmHg gave 4.3 g (88%) of benzophenone methylimine, which was identical with the product of the reaction of benzophenone with HMPT.

The authors wish to thank Professor Hitosi Nozaki for his valuable advice and continuous encouragement.

Determination of Enantiomeric Purity of 1-Phenylalkanols Using a Chiral NMR Shift Reagent

Keiji YAMAMOTO, Tamio HAYASHI, and Makoto KUMADA
Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received December 27, 1973)

Synopsis. Addition of tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III) to solutions of partly active (*S*)-1-phenylalkanols caused large enantiomeric-shift differences ($\Delta\Delta\delta$) in their ^{1}H NMR spectra, which permitted a direct determination of enantiomeric compositions of these alkanols.

Recently, chiral lanthanide shift reagents[1] have been applied to the direct determination of enantiomeric purity of certain organic Lewis bases.

We wish to record a quantitative determination of enantiomeric compositions of a series of partly active 1-phenylalkanols (excess (*S*) isomer), obtained *via* catalytic asymmetric hydrosilylation of the corresponding alkyl phenyl ketones[2] (Eq. 1).

$$\begin{matrix} R \\ \diagdown \\ \quad C{=}O \\ \diagup \\ Ph \end{matrix} + Me_2PhSiH \xrightarrow[\text{catalyst}]{\text{chiral Rh}^+} RPhC^*HOSiMe_2Ph \xrightarrow{OH^-} RPhC^*HOH \qquad (1)$$

(R=Me, Et, *iso*-Pr, and *tert*-Bu)

In ^{1}H NMR spectra of the alkanols, addition of tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]europium(III) (**1**) to the solutions examined caused large enantiomeric-shift differences ($\Delta\Delta\delta$) in the α-proton signals, as for 1-phenylethanol ($\Delta\Delta\delta$=0.30 ppm).[1b,3] The effect of this chiral shift reagent on the alkanol spectra is shown in Table 1.

It is interesting to note that a systematic decrease in the magnitude of downfield paramagnetic-induced shifts ($\Delta\delta$) of alkanol proton signals (*tert*-Bu<*iso*-Pr<Et) can reflect differences in the bulkiness of these alkanols, showing a relationship parallel to the reverse of the degree of asymmetric induction by the hydrosilylation of alkyl phenyl ketones. The fact that all the protons of (*R*)-alkanols resonate definitely at lower fields than those of (*S*)-enantiomers supports the view that the enantiomeric-shift difference can result from the difference in the stability constants of forming diastereoisomeric complexes of **1** with the alkanols[1a] rather than that in magnetic environments of the complexes.[1b,d]

The enantiomeric compositions of the respective alkanols have been determined on the basis of peak areas of completely separated signals due to their α-proton in the lanthanide-assisted spectra. The results are summarized in Table 2, showing exact agreement with those determined from maximum rotations.[4]

Experimental

Complex **1** was prepared by the reaction of 3-trifluoromethylhydroxymethylene-*d*-camphor (**2**) with europium(III) chloride according to the procedure of Goering *et al.*[1b] Diketone **2** was prepared by the following Grignard reaction of *d*-3-bromocamphor with ethyl trifluoroacetate.[5]

A mixture of 23.3 g (0.10 mol) of *d*-3-bromocamphor, 14.5 g (0.105 mol) of ethyl trifluoroacetate, and 2.56 g (0.105 g-atom) of magnesium in 230 ml of anhydrous ether was heated at reflux for 2 hr. The reaction mixture was then hydrolyzed with 10% hydrochloric acid. The organic layer was separated and the aqueous layer was extracted with ether. The combined ether solution and extracts were washed twice with saturated sodium chloride solution, and the solvent was

Radiation Synthesis of Methylal from Methanol Solution of Ferric Chloride

Yasumasa IKEZOE, Shoichi SATO, and Keichi OSHIMA*

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11

(Received December 28, 1973)

Synopsis. The gamma radiolysis of $FeCl_3$–CH_3OH solution was studied by measuring the *G*-values of the products. The mechanism of the selective formation of the main product methylal (G=8.3) was discussed.

The radiolysis of methanol has been studied by several workers.[1] In this paper, the γ-radiolysis of methanol solution of ferric chloride at high absorbed dose is described from the viewpoint of preparative radiation chemistry. The products of radiolysis, in the presence of ferric ion in high concentration known to act as a radical scavenger,[2-4] were analyzed in order to explain the main reaction scheme. The additive was found to act not only as a scavenger but also as a reactant.

Experimental

Preparation of Sample. Reagent grade methanol was distilled twice, first with magnesium and then with tribromobenzoic acid on a 2 m column. Anhydrous ferric chloride (E.P. grade) was dissolved without further purification in methanol under dry nitrogen atmosphere. The irradiation sample (1 ml) was sealed in a 7 ml ampoule after evacuation at liquid nitrogen temperature.

Irradiation. Samples were irradiated by a 16 kCi ^{60}Co gamma source mostly at an exposure rate of 3.2×10^5 R/hr. Before and after irradiation, the samples were kept at Dry Ice temperature to suppress thermal reactions.

Dose rates were determined by Fricke dosimetry with correction for the difference in the electron densities of water and methanol, the energy absorbed by the additive being neglected.

Analysis. The evolved gas, consisting of hydrogen, methane and carbon monoxide, was analyzed by volumetry after being passed through a liquid nitrogen trap, and by mass spectrometry. Two μl of liquid condensed in the liquid nitrogen trap was sampled and injected into a capillary column gas chromatograph with a 60 m column of PEG-400 and a 30 m column of 3,3′-iminodipropionitrile in series connection for the determination of yields of dimethyl ether, methyl chloride, and methylal (dimethoxymethane). The remaining liquid was titrated for induced acidity with 1/10 M sodium hydroxide solution, using methyl red as an indicator. 20 ml of saturated dimedone solution, with pH adjusted to 4.5, was then added to determine formaldehyde yield by precipitation. The filtrate and residue of vacuum distillation were jointly dissolved in distilled water, and the yield of ferrous ion was determined by colorimetry at 552 mμ, after the addition of α,α'-dipyridyl and sodium acetate solution for pH adjustment.

Results and Discussions

The *G*-values of products from the methanol–ferric chloride system are shown in Table 1. The selective formation of methylal[5] at high ferric chloride concentration should be noted. The mechanism could be considered as follows.

$$CH_3OH \rightsquigarrow \cdot CH_2OH,\ H,\ CH_3O\cdot,\ e_s^-,\ etc. \quad (1)$$

$$CH_3O\cdot + CH_3OH \longrightarrow \cdot CH_2OH + CH_3OH \quad (2)$$

Hydroxymethyl radical $\cdot CH_2OH$ is produced directly and indirectly, and is oxidized by ferric ion producing formaldehyde:[4]

$$\cdot CH_2OH + Fe^{3+} \longrightarrow HCHO + Fe^{2+} + H^+ \quad (3)$$

The hydroxymethyl radical, the precursor of ethylene glycol in the absence of ferric ion, is thus converted into formaldehyde, which subsequently reacts in acid solutions with methanol molecules to produce methylal. The thermal reaction between formaldehyde and methanol proceeds through hemiacetal as an intermediate:[7]

$$HCHO + CH_3OH \xrightarrow[acid]{} CH_2(OH)(OCH_3) \quad (4)$$

$$CH_2(OH)(OCH_3) + CH_3OH \longrightarrow CH_2(OCH_3)_2 + H_2O \quad (5)$$

Thus, formaldehyde and ethylene glycol are not formed in the presence of large quantities of ferric ions and methylal is obtained instead. If the above mechanism holds, G(methylal) should be equal to the sum of G(formaldehyde) and twice G(ethylene glycol) in the absence of the scavenger. G(methylal) in this experiment is 8.3, which is consistent with the sums calculated from literature values, 6.3—9.5.[1] The approximate agreement of the calculated and experimental *G*-values as well as the disappearance of formaldehyde caused

Calculation of the Carbon-13 NMR Chemical Shifts of Linear and Branched Paraffins and Saturated Cyclic Hydrocarbons

Kitsuma TAKAISHI, Isao ANDO, Masahiro KONDO, Riichirô CHÛJÔ, and Atsuo NISHIOKA

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 13, 1973)

The carbon-13 NMR chemical shifts of linear and branched paraffins have been calculated by means of Pople's theory, particularly using the averaged excitation energy method. The calculation was carried out based on the CNDO/2 molecular orbital method. The values calculated by means of the averaged excitation energy method deviate extremely from the experimental ones; therefore, the energies most suitable for giving good agreement are investigated and determined for linear and branched paraffins. The suitable energies are expressed by an empirical formula, correlated to the molecular structure. The results obtained may be briefly expressed by;

$$\Delta E = 11.30 \times 1.015^a \times 0.958^b \times 1.010^c \times S$$
$$S = 1.011^d \times 1.009^e \times 1.029^f \times 1.009^g \times 1.030^h \times 1.031^i$$

(see Results and Discussion for the notations used).

This empirical averaged excitation energy expression is applied to cyclic hydrocarbons, such as cyclohexane, methylcyclohexane, and dimethylcyclohexane. Further, the γ-effect is estimated on the basis of these results.

The carbon-13 (C-13) NMR chemical shifts of saturated hydrocarbons have been studied systematically by Grant *et al.*[1-5]

Pople *et al.*[6-8] have developed a theory of the C-13 chemical shift and have calculated the C-13 shielding constants of simple hydrocarbons using an averaged excitation energy method (AEE method). It is very convenient to use the AEE method for the calculation of the C-13 shielding constants with the Pople expression. Since the AEE method is, however, a severe approximation, its use makes it difficult to obtain a suitable value for the averaged excitation energy (ΔE), and the calculated chemical shifts are not in good agreement with the experimental values. For example, when the value of 10 eV is used for the ΔE of linear and branched hydrocarbons, the calculated chemical shifts deviate from the experimental values by about 10 or 20 ppm. The C-13 chemical shifts depend on the electronic states of molecules which are influenced by their molecular structures, and the ΔE which largely contributes to the C-13 chemical shifts should be correlated to the molecular structures; *i.e.*, the values of ΔE are not equal to each other for various carbons in a molecule.

Okada *et al.*[9] proposed an empirical expression for ΔE in which ΔE was influenced by adjacent carbons until γ-carbon and by the difference in the molecule. This expression is very simple and convenient; however, it is theoretically limited because it uses an extended Hückel theory (EHT) method. The idea that one tries to determine the values of ΔE unified for various molecular structures is based on the fact that the C-13 chemical shifts depend on the molecular structure, though this is ambiguous theoretically. Nevertheless, the empirical ΔE expression is a useful method for calculating the chemical shifts of many molecules. In order to improve this method and to obtain a wider adoptability, a new empirical expression for ΔE will be proposed. This expression is based on the idea of Okada *et al.*, but the method of computation is a CNDO/2 MO one[10,11] instead of an EHT one. The expression obtained is parameterized for linear and branched paraffins, and then is applied to saturated cyclic compounds, such as cyclohexane and its derivatives. Further, the γ-effect will be estimated on the basis of these results.

Theory

The C-13 shielding constants of any specified carbon atom, A, in a molecule may be approximated as follows;[6,12,13]

$$\sigma^A = \sigma_d{}^A + \sigma_p{}^A + \sum_{B(\neq A)} \sigma^A + \sigma^A_{ring} \quad (1)$$

where $\sigma_d{}^A$ and $\sigma_p{}^A$ are the diamagnetic and paramagnetic contributions on the specified carbon atom, A, respectively, where $\sum_{B(\neq A)} \sigma^B$ is sum of the contributions from the neighbouring atoms bonded to the A atom and where σ^A_{ring} is the contribution from the ring current. Usually the effects of $\sum\sigma^B$ and σ^A_{ring} in the C-13 chemical shifts are known to be very small and contribute less than a few parts per million (ppm). With Slater atomic orbitals, the increase in $\sigma_d{}^A$ when a 2p electron is added is 14 ppm, only about 10% of the entire observed range of the C-13 chemical shifts. The differences in C-13 chemical shifts among various carbon atoms are mostly due to the difference in $\sigma_p{}^A$. In this paper, in order to discuss the C-13 chemical shifts in detail we will take $\sigma_d{}^A$ and $\sigma_p{}^A$ into account and will neglect the contributions from $\sum\sigma^B$ and σ^A_{ring}. The value of $\sigma_d{}^A$ is given by the following formula:

$$\sigma_d{}^A = \frac{e^2}{3mc^2} \sum_i \left\langle \frac{1}{r_i} \right\rangle \quad (2)$$

where $\langle r_i^{-1} \rangle$ is the mean inverse distance of the i-th electron from a nucleus, m is its mass, e is its charge, and c is the light velocity, and where the sum is taken over all the electrons on the atoms being considered.

According to the Pople theory, $\sigma_p{}^A$ is given by the following equations:

$$\sigma_p{}^A = -2N^{-1}\langle r^{-3}\rangle_A \chi_p{}^A \quad (3)$$

$$(\chi_p{}^A)_{zz} = \frac{Ne^2\hbar^2}{m^2c^2} \sum_i^{occ} \sum_j^{unocc} (E_j - E_i)^{-1} (C_{ixA}C_{jyA} - C_{iyA}C_{jxA}) \times \sum (C_{ixB}C_{jyB} - C_{iyB}C_{jxB}) \quad (4)$$

In order to calculate these equations, some approximations are introduced; therefore,[12]

$$\sigma_d^A = 4.45z^*q \tag{5}$$

where:

$$z^* = 3.25-0.35(q-4) \tag{6}$$

in which q is the total electron density around the particular carbon atom and in z^* which is the "effective nuclear charge" estimated according to Slater's rules.

$$\sigma_p^A = -\frac{e^2\hbar^2}{2m^2c^2\Delta E}\left\langle\frac{1}{r^3}\right\rangle_{2p}\sum_B Q_{AB} \tag{7}$$

where;

$$Q_{AB} = \frac{4}{3}\delta_{AB}(P_{X_AX_B}+P_{Y_AY_B}+P_{Z_AZ_B}) - \frac{2}{3}(P_{Y_AY_B}P_{Z_AZ_B}+P_{Z_AZ_B}P_{X_AX_B}+P_{X_AX_B}P_{Y_AY_B}) + \frac{2}{3}(P_{Y_AZ_B}P_{Z_AY_B}+P_{Z_AX_B}P_{X_AZ_B}+P_{X_AY_B}P_{Y_AX_B}) \tag{8}$$

$$\left\langle\frac{1}{r^3}\right\rangle_{2p} = \frac{1}{24a_0^3}\{3.25-0.35(q_{2p}-3)\}^3 \tag{9}$$

$$q_{2p} = P_{X_AX_A} + P_{Y_AY_A} + P_{Z_AZ_A} \tag{10}$$

In these formulae, ΔE is an averaged excitation energy, $\langle r^{-3}\rangle_{2p}$ is the mean inverse cube radius for carbon 2p orbitals and depends on the local electron density on the particular carbon atom, $\sum$ is a sum over all the atoms, δ_{AB} is a Kronecker symbol, and a_0 is a Bohr radius.

$P_{X_AX_B}$ is the matrix element for the $2p_X$ atomic orbitals on the A and B atoms. When A=B, it is the electron density in $2p_X$ on the A atom and when A≠B, it is the bond-order between the two atomic orbitals.

To estimate the bond-order matrix, as the molecular orbital method the CNDO/2 MO method was used.

Results and Discussion

The carbon-13 chemical shifts were calculated for linear and branched paraffins, using the Pople theory for the shielding constants by means of the AEE method and the CNDO/2 MO method.

As a result of using the value of 10 eV for ΔE, the calculated chemical shifts were found to deviate from the experimental values by more than 10 ppm for paraffins. In an *n*-pentane, for example, the experimental carbon-13 chemical shifts of two secondary carbons differ from each other by about 12 ppm, while the calculated values are almost indistinguishable from each other. The total electron densities of the two secondary carbons are nearly identical when calculated by the CNDO/2 MO method. In molecules which have π-electrons and/or lone pair electrons, such as aromatic and azine compounds, it has been reported that there is a correlation between the C-13 chemical shifts and the charge distributions.[14] Sichel *et al.*[15] have reported empirically on the apparent correlation between the C-13 chemical shifts and the electron-charge densities on the carbon atoms in hydrocarbons; they worked on the basis of the extended Hückel method. On the other hand, if the calculation is carried out by the CNDO/2 MO method, there is no obvious correlation between the C-13 chemical shifts and the electron densities for the same compounds.

In the calculation of the C-13 chemical shift of saturated hydrocarbons, one of the most important factors is the averaged excitation energy. Various values have been proposed for ΔE.[7,8,14,16] It should be noted that, in the vacuum UV spectra of *n*-paraffins the wavelengths at the most intense absorption peak become larger as the chain length increases. This suggests that the averaged excitation energies depend on the molecular structures. The tendency for the C-13 chemical shifts to increase as the carbon numbers of hydrocarbons decrease can be barely explained, using the excitation energy values from the UV spectra as ΔE.

Okada *et al.*[9] obtained an empirical averaged excitation energy expression for linear and branched paraffins using the extended Hückel method:

$$\Delta E = 10.0 \times \alpha^a \times \beta^b \times \gamma^c \times c^d \tag{9}$$

where α, β, and γ are the parameters showing the effects of α, β, and γ-carbons respectively, where a, b, and c are the numbers of α, β, and γ-carbons respectively, where c is the parameter showing the conformational effect, and where d is the number of the possible gauche conformation. The numerical values for the α, β, γ, and c parameters are 0.974, 0.960, 1.009, and 1.009 respectively. The value of 10.0 is adopted as the ΔE coefficient for all the carbons. Using this expression, the calculated C-13 chemical shifts are considerably improved. However, this expression is based on an extended Hückel method, so there is a substantial limitation. Nevertheless, this method is important because it is convenient for calculating ΔE from the structural parameters. In order to improve this expression, we proposed the new empirical one with a similar form and more structural parameters, using the CNDO/2 MO method. The new ΔE expression has the following form:

$$\Delta E = K \times \alpha^a \times \beta^b \times \gamma^c \times S \tag{10}$$

$$S = [1°(4°)]^d \times [2°(3)°]^e \times [2°(4°)]^f \times [3°(2°)]^g \times [3°(3°)]^h \times [4°(2°)]^i \tag{11}$$

where K is a coefficient and would be a ΔE of methane when there are no α, β, and γ-carbons, where S is a structural parameter [1°(4°)] showing the effect of the primary carbon adjacent to the quaternary carbon, and where d is the number of [1°(4°)] carbons. These parameters were determined for linear and branched paraffins by the least-squares multiple method.

Contrary to the modified ΔE expression given above, there is another method which represents ΔE by means of the sum of the contributions from all the carbons. Considering that these are all empirical expressions, we must choose a simplified formula.

The coefficient of this expression, K, has an important influence on the improvement of the calculated values. Instead of the value of 10 eV, we tried to adopt 9.705 eV,[17] which was obtained from a vacuum UV spectrum, for the averaged excitation energy of methane, but we did not get any improvement in the calculated values. Strong[18] got the value of 11.30 eV for the ΔE of methane by statistically averaging the excitation energies between the ground states and the excited states.

It has been found that the deviation of the calculated values from the experimental values is considerably influenced by varying the K, *i.e.*, the coefficient of the ΔE expression. Therefore, we can expect at least to get the most preferable K which makes the difference between the calculated and experimental values. The equation representing the relation between the experimental chemical shifts and the calculated ones is as follows:

$$\delta_i = \delta_c + \delta_{di} - \frac{K_i}{\Delta E_i} \qquad (12)$$

where δ_i is the experimental chemical shift of the i-th carbon, δ_{di} is a calculated diamagnetic contribution from the i-th carbon, $K_i/\Delta E_i$ is a paramagnetic one, and δ_c is a constant that is common to all the carbons. Then, the ΔE of each n-paraffin can be determined from this equation because δ_c and δ_i are known and δ_{di} and K_i can be calculated. We plotted such ΔE's for various n-paraffin's carbons against the number of carbon atoms in n-paraffins in Fig. 1. In this figure, three kinds of ΔE values are adopted as follows: (a) 10.0, (b) 9.705, and (c) 11.30eV. Comparing the curves in Fig. 1, we can conclude that the value of 11.30 eV is the most suitable for the calculation by using an empirical expression, because in Curve (c) the slopes between the nearest and second nearest carbons from an end are all equal to one another, irrespective of the increase in n, and because the ΔE's of the nearest and second nearest carbons are equal to each other when n is larger than 4. Using the above-determined ΔE, we can determine the parameters for n-paraffins having

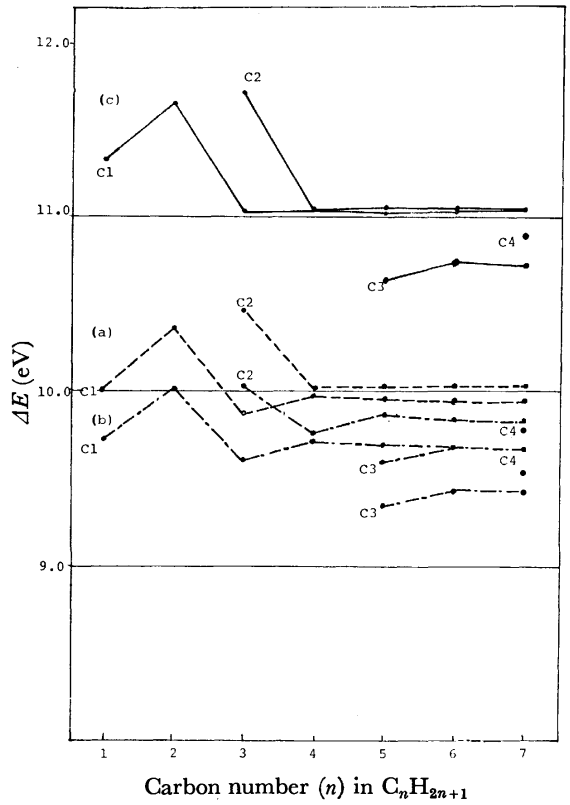

Fig. 1. The averaged excitation energies of linear paraffins when (a) 10.0, (b) 9.705, and (c) 11.30 eV are adopted as the reference values for methane.

Table 1. Calculated values of C-13 chemical shifts in linear and branched paraffins

Compound		ΔE (eV)	Error[a]	Chem. shift[b] (ppm)	Error[c]

a) (Error) = − (ΔE when calculated chemical shift coincide with observed one) + (ΔE calculated by the empirical formula) b) From benzene c) (Error) = (calculated value) − (observed value)

the carbons of from 1 to 7.

Next, using the above empirical expression, we obtain:

$$\Delta E = 11.30 \times 1.015^a \times 0.958^b \times 1.010^c \times S \qquad (13)$$

$$S = 1.011^d \times 1.009^e \times 1.029^f \times 1.009^g \times 1.030^h \times 1.031^i \qquad (14)$$

as the most suitable empirical formula for the estimation of the C-13 chemical shift in n-paraffin. We tried to calculate inversely the C-13 chemical shifts in the compounds which were used for parameterization. These results are listed in Table 1. The differences between the experimental and calculated values are extremely small for most paraffins. A considerable discrepancy was seen in ethane, isobutane, 2,2-dimethylbutane, *etc.* In the case of ethane, there is only an α-effect; it is, therefore, difficult to estimate the absolute value of the α-effect instead of a relative value. The discrepancy in ethane may be due to this circumstance. For isobutane and 2,2-dimethylbutane, the principal source for the discrepancy is probably due to their steric hindrances.

Table 2. Calculated values of C-13 chemical shifts in cyclohexane derivatives

Compound		ΔE (eV)	Chem. shift[a] (ppm)	Error[b]

a) From benzene. b) (Error) = (calculated value) − (observed value).

Further, we calculated the C-13 chemical shifts of cyclohexane and its methyl derivatives, using the above empirical expression. The cyclohexane system has the least steric hindrance among the cyclic hydrocarbons. The calculated values are listed in Table 2 and are illustrated by the schematic stick spectrum models in Fig. 2. The stick spectra calculated by Grant's additive rule are also shown in Fig. 2 for purposes of comparison. In cyclohexane, the calculated value is lower than the experimental one by 4.09 ppm. In various kinds of dimethylcyclohexane, *trans*-1,2-, *cis*-1,3-, and *trans*-1,4-dimethylcyclohexanes deviate a little from the experimental values. On the other hand, 1,1-, *cis*-1,2-, *trans*-1,3-, and *cis*-1,4-dimethylcyclohexane deviate from the experimental values by more than about 3 to 4 ppm (see Table 2). By comparing the values calculated by Pople's method using the ΔE expression and the values

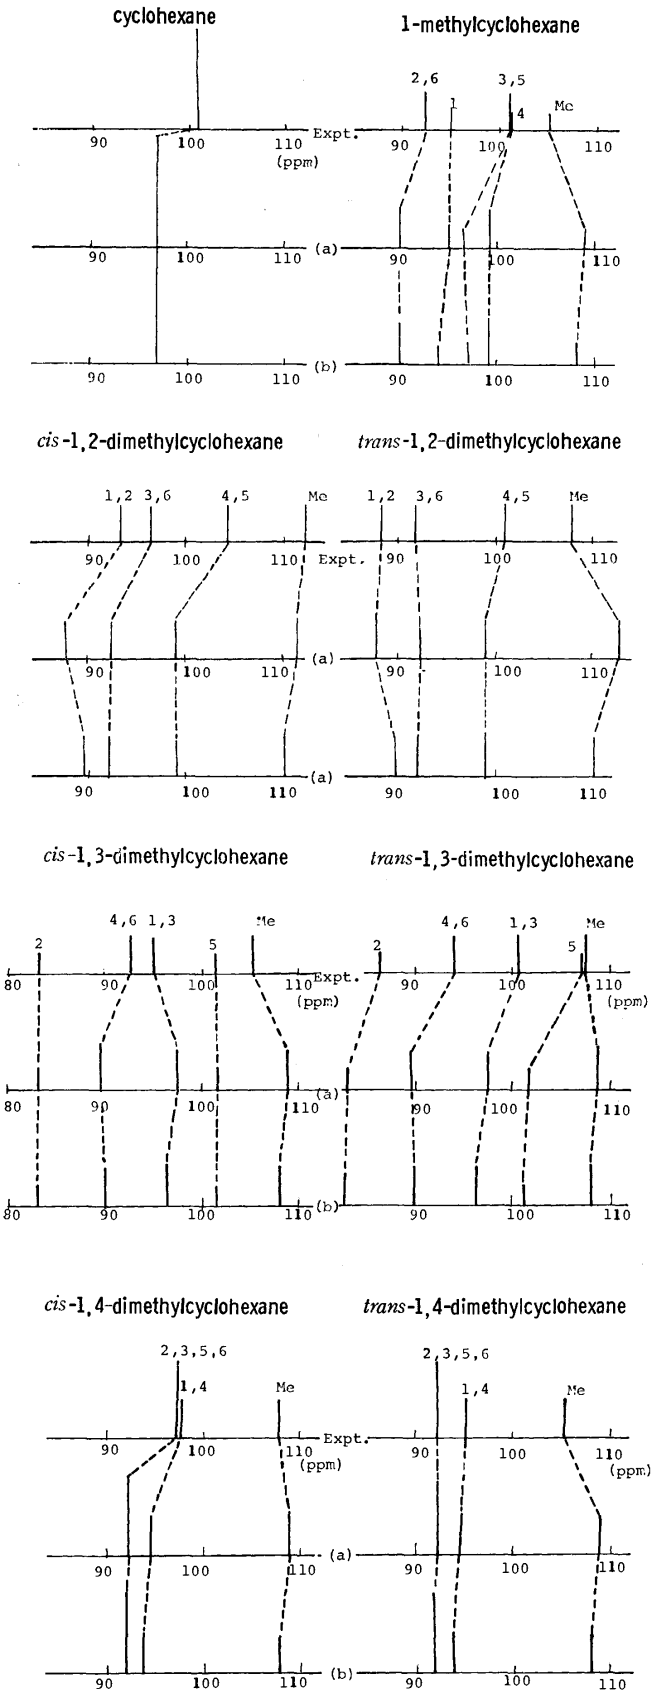

Fig. 2. Experimental and calculated C-13 chemical shifts of cyclohexane derivatives. Expt. shows the experimental values. (a) and (b) are calculated ones by Grant's additive rule and the empirical ΔE formula, respectively.

calculated by Grant's method, we find that the former are more improved than the latter in methylcyclohexane and *cis*-1,2-, *trans*-1,2-, *cis*-1,3-, and *trans*-1,4-dimethylcyclohexanes. On the other hand, the former are nearly equal to the latter in *trans*-1,3- and *cis*-1,4-dimethylcyclohexanes. In cyclohexane their values are equal to each other. Consequently, it can be said that Pople theory, in which ΔE is calculated by the empirical ΔE expression, can predict the most exact C-13 chemical shift of non-constrained cyclic saturated hydrocarbons, such as cyclohexane and its methyl derivatives.

In cyclohexane, however, the deviation of about 4 ppm suggests that the ΔE expression cannot include the steric factor. The C-13 chemical shift of cyclohexane is higher than the value of the central carbon of *n*-hexane by 4.3 ppm. Furthermore, the calculated values agree fairly with the experimental ones when both methyl groups are in equatorial positions, while the agreement is not so good when the methyl groups are in axial positions. However, if about 4 ppm is added to the values of dimethylcyclohexane of which the methyl groups are in axial positions, the results are excellently improved. We can conclude that about 4 ppm is the contribution from the steric effect in the cyclohexane system.

In the carbons of methyl groups, the deviations are about 2 to 3 ppm. This is due to the steric influence of the cyclohexane ring. This steric effect is almost thought to equal the γ effect. In a cyclohexane system, all the ring carbons are in a *gauche* conformation, the axial methyl groups are *gauche* to the γ-carbons of the cyclohexane ring. γ-Effects in *gauche* conformations are estimated by comparison with various hydrocarbons, such as norbornane,[19] its methyl derivatives, and methylcyclohexane. The correlation between the γ-effect and a dihedral angle between C_1 and C_4 carbons is illustrated in Fig. 3.

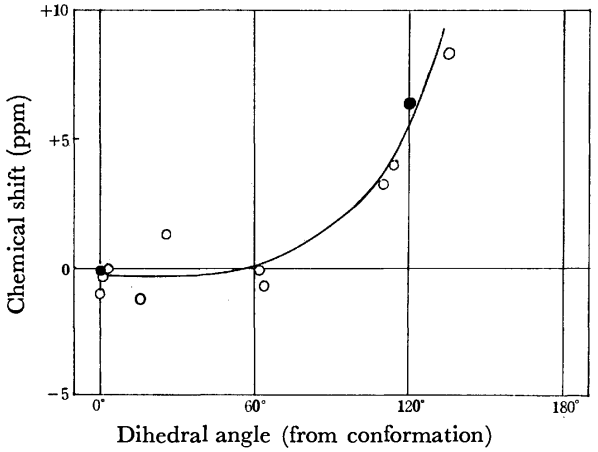

Fig. 3. Correlation between γ-effect and dihedral angle. ○ and ● correspond to the values obtained from norbornane and a methyl derivatives of cyclohexane, respectively.

As is shown in Fig. 3, the γ effect in a *trans* conformation is -0.4 ppm, and the γ-effect in which a dihedral angle is 60° is nearly zero and the γ-effect in which a dihedral angle is 120° (*gauche* conformation) is almost 6 ppm. These results show that, in equatorial methyl groups, the γ-effect are very small, while in axial methyl groups the cyclohexane ring's influence about comprises the γ-effects.

Since the ΔE expression includes the averaged γ-effect, there is no difference in the calculated C-13 chemical shifts between compounds with the same framework, such as *cis*-1,3- and *trans*-1,3-dimethylcyclohexane. By showing the improved calculated value of the C-13 chemical shift in cyclohexane and its derivatives it is proved that the empirical ΔE expression is useful for cyclics and that the C-13 chemical shift of saturated hydrocarbons may be explained with regard only to the influence of α-, β-, and γ-carbons. In the future, it will be interesting to apply this method to the cyclic strained hydrocarbons and to examine the steric effects.

On the Behavior of O_2^- and O^- Radicals over V_2O_5–SiO_2 Catalyst

Satohiro YOSHIDA, Tokuo MATSUZAKI, Tomonori KASHIWAZAKI, Kozo MORI, and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received September 20, 1973)

The behavior of oxygen, O_2^- and O^- radicals adsorbed on the partially reduced V_2O_5–SiO_2 catalysts has been investigated. Oxygen is adsorbed mainly in a molecular state at room temperature, the sum of amounts of paramagnetic adsorbed species O_2^- and O^- being less than 10% of total amount of adsorbed oxygen. High degree of reduction, high content of V_2O_5 and low pressure of oxygen at adsorption equilibrium are favorable for the formation of O^- radical. It was confirmed by the quantitative analysis of reaction products and the adsorbed species that O_2^-, not O^-, is the active species in the oxidation of propylene at room temperature. A mechanism involving an intermediate of an epoxide structure was proposed.

In the last decade, many works have been carried out mainly by ESR technique on the formation of O_2^- and/or O^- on the surface of partially reduced metal oxide. It has been established that O^- is very reactive to carbon monoxide, while O_2^- seems to be unreactive to such gases as hydrogen and carbon monoxide at room temperature.[1] In most works, zinc oxide and titanium oxide were chosen as adsorbents, which exhibit poor activity for the oxidation of hydrocarbons. No reports seem to have been given on the oxidation of hydrocarbons by O_2^- or O^- over these oxides.

Schvets *et al.*[2] and Tarama *et al.*[3] found that O_2^- and/or O^- were formed on partially reduced vanadium oxide used as a commercial catalyst for oxidation, when the oxide was supported on silica. Kazansky *et al.* have established the high reactivity of O^- to carbon monoxide and claimed that O_2^- is inactive in oxidation reactions.[4]

In a previous paper[5] a report was given on the stability and reactivity of O_2^-. It was found that propylene is oxidized to propionaldehyde by adsorbed oxygen species over this catalyst, a hypothesis being proposed that O_2^- is the active species in the reaction. Kazansky *et al.* reported that O^- was formed on the reduced vanadium oxide[4] but they gave no favorable conditions for its formation, and this could not be confirmed in the previous work. The first aim of the present work is the establishment of favorable conditions for the formation of O^-. The second aim is clarification of the active species in the oxidation of hydrocarbons. A large amount of diamagnetic oxygen species are coexistent on the surface.[5] The possibility of participation of these species can not be excluded from ESR investigation only. We attempted to solve the problem by investigation of the quantitative correlation between the amount of products and oxygen species.

Experimental

Materials. Carrier (SiO_2); Silica gel obtained from ethyl orthosilicate hydrolyzed in a water–ethanol mixture at boiling point was calcined at 500 °C for 5 hr in a dry stream of air and was ground to powder of less than 100 mesh.

Catalysts (V_2O_5–SiO_2): Silica gel impregnated with 0.3 M ammonia solution containing ammonium metavanadate was dried and calcined at 500 °C for 10 hr in dry stream of air. The amounts of vanadium oxide (V_2O_5) supported on SiO_2 were 2 and 5 wt%.

Gases: Commercial oxygen and propylene were used. Carbon monoxide was obtained by the decomposition of sodium formate. All gases were purified by vacuum distillation at a low temperature.

Apparatus and Procedure. Measurements of oxygen adsorption were carried out by the usual volumetric method. ESR spectra were recorded with a JES-3BSX type ESR spectrometer (X-band). Amounts of O_2^- were determined by means of a TE105 cavity using DPPH as a standard. Amounts of O^- were estimated from the amount of CO_2 produced by its reaction with CO at room temperature. The reaction of propylene with adsorbed oxygen was carried out in a similar manner to that described previously.[5] The reaction mixtures were recovered with a liquid N_2 trap and analyzed by a gas chromatograph with 3m column (PEG 1500 20% Celite) at 80 °C. Partial reduction of catalysts was carried out at 420 °C for a given time with CO. The degree of reduction was calculated from the amount of CO_2 produced and given in terms of the percentage of V^{4+} produced to the total V ions.

Results and Discussion

Adsorption of Oxygen. Adsorption isotherms* of oxygen on partially reduced V_2O_5(5 wt%)–SiO_2 cata-

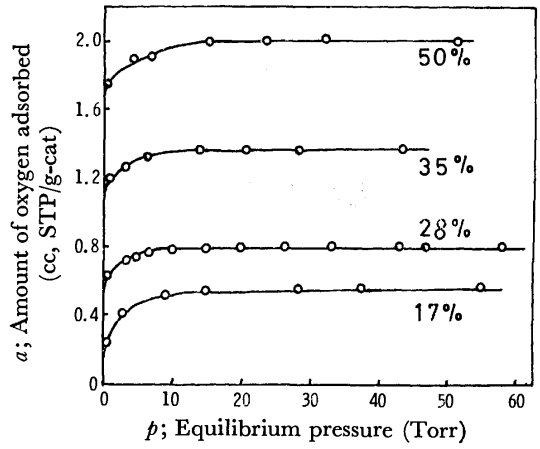

Fig. 1. Adsorption isotherms of oxygen on partially reduced V_2O_5(5 wt%)–SiO_2 (%; reduction degree)

* V_2O_5–SiO_2 catalyst before reduction adsorbed a small amount of oxygen at room temperature. The adsorbed amount of oxygen on partially reduced catalysts was corrected by subtracting the amount.

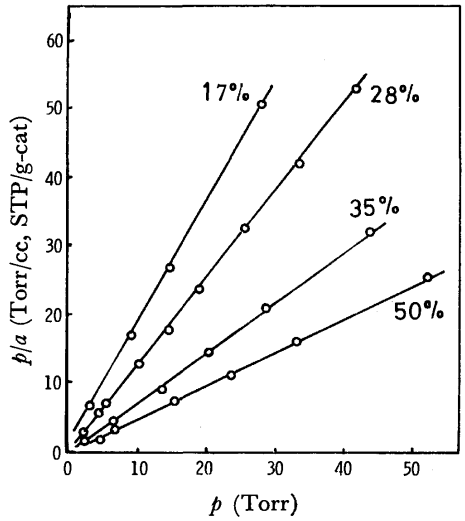

Fig. 2. Langmuir plot for oxygen adsorption isotherm (%; degree of reduction)

Table 1. Variation of a_s/V^{4+} by reduction

Degree of reduction (%)	16.7	20.0	22.1	28.5	34.7	49.6	50.1
a_s/V^{4+} (%)	26.9	23.6	27.1	22.7	32.2	25.8	33.7

a_s: Saturated adsorption amount of oxygen (mol/g-cat)
V^{4+}: Amount of V^{4+} produced by reduction (mol/g-cat)

lysts at room temperature are shown in Fig. 1. Since the Langmuir equation for non-dissociative adsorption fits the isotherms (Fig. 2), oxygen should be mainly adsorbed in a molecular state on these catalysts at room temperature. The saturated amount of adsorption of oxygen (a_S) increases with the increase in the reduction degree of the catalyst and the ratio of a_S to V^{4+} produced by reduction falls in the range 23—34% (Table 1).

ESR Spectra of Adsorbed Oxygen. Figure 3 shows the ESR spectrum of oxygen radical species adsorbed on the 17% reduced V_2O_5(5 wt%)–SiO_2 catalyst at room temperature. This spectrum with hfs of $A_{//}$= 9.3 G and $A_\perp$=5.8 G at $g_{//}$=2.022 and $g_\perp$=2.004 can

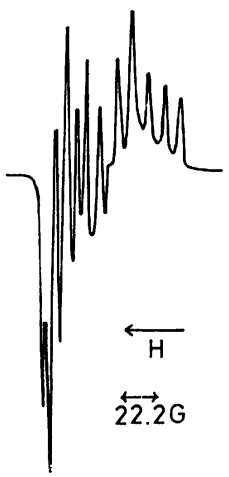

Fig. 3. ESR spectrum of oxygen adsorbed on 17% reduced V_2O_5 (5 wt%)–SiO_2.

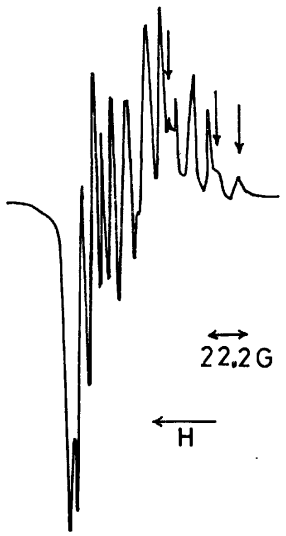

Fig. 4. ESR spectrum of oxygen adsorbed on 22% reduced V_2O_5 (5 wt%)–SiO_2.

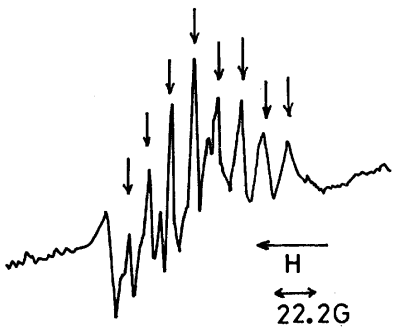

Fig. 5. ESR spectrum of oxygen adsorbed on 51% reduced V_2O_5 (5 wt%)–SiO_2.

be assigned to O_2^- radical.[2,3] Figures 4 and 5 show the ESR spectra of oxygen radical species adsorbed on the 22 and 51% reduced V_2O_5(5 wt%)–SiO_2 catalyst, respectively. In these spectra, a new signal (marked by arrows) is superimposed on the O_2^- signal. The new signal g=2.027, A=13 G corresponds to that assigned to the O^- radical by Kazansky.[4]

The signal assignable to the O^- radical was detected on catalysts more highly reduced than 20% for V_2O_5-(5 wt%)–SiO_2 and 30% for V_2O_5(2 wt%)–SiO_2, the ratio of O^-/O_2^- increasing with the increase in the reduction degree of catalysts (Fig. 6).

The influence of adsorption pressure of oxygen on the formation of oxygen radical species was investigated, the results being given in Table 2. Increase in the pressure of oxygen resulted in the increase in relative signal intensity of O_2^- and decrease in that of O^-, regardless of degree of reduction of the catalysts. This evidently shows that high degree of reduction, high content of V_2O_5 and low pressure of oxygen at equilibrium are favorable for the formation of O^- radicals.**

Both signals of O_2^- and O^- radicals are stable *in*

** In the former study,[5] the O^- radical was not detected for the catalyst of 1—45% reduction, which seems to have been due to high oxygen pressure.

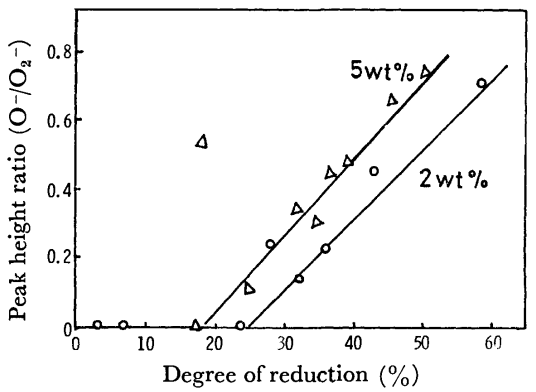

Fig. 6. Variation of O^-/O_2^- by reduction (wt%; V_2O_5 content in catalyst)

Table 2. Relative intensity of O_2^- and O^-

Catalyst	Equilibrium pressure p (Torr)	Amount of oxygen adsorbed 10^{-6} mol/g-cat	a/V^{4+}	Relative intensity of ESR signal O_2^-	O^-	O^-/O_2^-
50% reduced V_2O_5(5 wt%)-SiO_2	<0.1	63.1	22.8	29	20	0.69
	2.1	76.5	27.6	49	15	0.31
	7.5	78.0	28.2	43	11	0.26
	15.2	91.3	33.2	49	7.4	0.15
	25.3	92.7	33.7	52	4.6	0.09
35% reduced V_2O_5(5 wt%)-SiO_2	<0.1	53.8	27.6	20	6.0	0.30
	4.4	57.3	29.4	24	4.0	0.17

vacuo at room temperature even after 16 hr, but heating for 15 min at 150 °C caused a decrease of O_2^- by 80% and O^- by 30%. This shows that O^- is more stable than O_2^- at high temperatures in agreement with the result of Shvets *et al.*[6]

Quantitative Measurement of O_2^- and O^-. 17% reduced V_2O_5(5 wt%)-SiO_2 catalyst adsorbed 2.6×10^{-5} mol oxygen/g-cat at room temperature. The amount of O_2^- on this catalyst was determined to be 1.6×10^{-6} g ion/g-cat by the ESR method. On the other hand, both ESR signals of O_2^- and O^- were observed for 20% reduced V_2O_5(5 wt%)-SiO_2 catalyst adsorbing 2.62×10^{-5} mol oxygen/g-cat, the ratio of O^- to O_2^- being 0.59 from the relative signal intensity. Addition of CO at room temperature caused instantaneous disappearance of the ESR signal of O^- and formation of CO_2, as reported by Kazansky *et al.*[4] It was confirmed that the ESR signal intensity of O_2^- radical is not affected by either the addition of CO or the recovery of the resulting CO_2. This can be utilized for the evaluation of the amount of O^- by measuring the amount of CO_2 produced by reaction of O^- with CO. The amount of O^- radical adsorbed on 20% reduced V_2O_5(5 wt%)-SiO_2 was evaluated to be 9.6×10^{-7} g-ion/g-cat. The amount of O_2^- calculated from these values of O^- and O^-/O_2^- was 1.6×10^{-6} g-ion/g-cat. Thus, the values from the two different methods agree. In the following experiments, the amounts of O_2^- and O^- were estimated by the latter method.

Table 3. Amount of adsorbed species

Reduction degree %	V^{4+} $10^{-4}\times$ mol/g-cat	Amount of oxygen adsorbed $10^{-5}\times$ mol/g-cat	$\frac{O^-}{O_2^-}$	O^- $10^{-6}\times$ mol/g-cat	O_2^- $10^{-6}\times$ mol/g-cat	$\frac{\frac{1}{2}O^-+O_2^-}{a}$ %
17	1.12	2.60	—	—	1.6	6.2

50	2.75	9.27	0.09	0.42	4.8	5.4

The amounts of V^{4+}, total adsorbed oxygen (a), O_2^- and O^- for several catalysts are given in Table 3. In all cases, the values of $[O_2^-+(1/2)O^-]/a$ are smaller than 10%. From the fact that paramagnetic adsorbed species are only a small part of total adsorbed oxygen and the Langmuir equation for non-dissociative adsorption fits the isotherms, a large part of oxygen seems to be adsorbed as a neutral molecule.

Reaction with Propylene. Some olefins are oxidized by adsorbed oxygen, accompanied by the simultaneous disappearance of O_2^- signal in ESR spectra.[5] Since large amounts of adsorbed oxygen besides O_2^- are existent together with O^- on the catalyst surface, it seems that the previous results can not exclude the possibility of oxidation of olefins by adsorbed oxygen species other than O_2^-. In order to specify the oxidative species unambiguously a correlation between amounts of consumed O_2^- and oxidation products of propylene was quantitatively investigated.

At room temperature, propylene was brought into contact with catalysts, on which O^- had been removed by CO treatment to exclude the possibility of oxidation by O^-. After 1 hr, the reaction mixture was recovered in a liquid N_2 trap. For the desorption of products, the catalyst was evacuated at 200 °C during the course of recovery (1 hr). The results of gas chromatographic analysis of reaction products are given in Table 4. The amounts of recovered oxidation products (p_{ox}) for the A-series experiments are in the same order as that of consumed O_2^-, the ratios of p_{ox} to O_2^- being nearly in the range 0.8—1. Case B shows the result for the 46.5% reduced V_2O_5(5 wt%)-SiO_2 catalyst, on which both O_2^- and O^- initially coexist and O^- mainly remains after heating at 150 °C for 15 min. Although both O^- and O_2^- rapidly diminish in contact with propylene, the amount of oxidation product is in the same order as that of O_2^- rather than that of O^-. This probably means that in spite of reaction of O^- with propylene, the oxidation products resists the desorption from catalyst surface,[7] where oxidation products of propylene on zinc oxide are too tightly adsorbed to remove and are recovered as CO_2 only at a higher temperature than 200 °C. The oxidation products (Table 4) can be regarded to result from the reaction of O_2^- but not from other oxygen species.

Propionaldehyde, acetaldehyde and acrolein were detected with small amounts of acetone and propylene oxide in the oxidation products. Since these products except acrolein are not expected from the allylic intermediate, it is suggested that low temperature oxidation

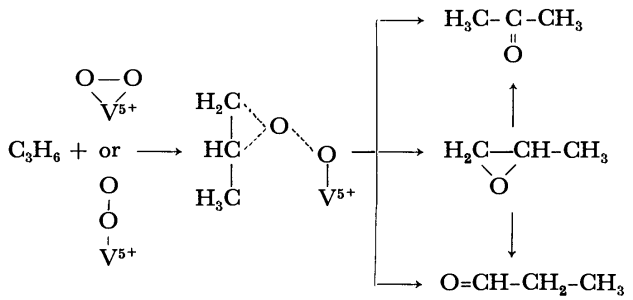
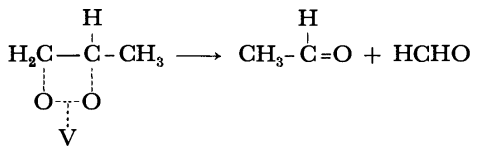
a) O^- was removed by reaction with CO. b) Catalyst adsorbing oxygen was heated at 150 °C for 15 min. c) 1.5×10^{-5} mol propylene oxide was introduced at room temperature on the 10% reduced V_2O_5(5 wt%)-SiO_2 and then evacuated. The reaction products were recovered by the same method as for Expt. A and B. *) Reduction degrees of catalysts in A-1, A-2, A-3, A-4 and B were 22.1, 34.7, 47.6, 50.1 and 46.5%, respectively.

of propylene with O_2^- radical occurs mainly through the intermediate of an epoxide structure as follows.



Propionaldehyde and acetone are also formed by the isomerization of propylene oxide on this catalyst. (Expt. No. C, Table 4).

The mechanism of formation of acetaldehyde is not clear, but the following mechanism might be partially cooperative with the above one.



However, we could not detect any formaldehyde in reaction products, nor could be elucidate the reaction products of O^- with propylene.

In conclusion, the respective amounts of total oxygen, O_2^- and O^- adsorbed on partially reduced V_2O_5-SiO_2 catalyst were quantitatively determined. It was confirmed that O_2^- on the catalyst oxidized propylene at room temperature by a mechanism involving the intermediate of an epoxide structure.

A New Pyrochlore System, $Pb(Ti_x \cdot Sn_{1-x})O_3$, and Its Transition to a Perovskite System

Shin-ichi SHIRASAKI, Hiroshi YAMAMURA, Kunitaka MURAMATSU, and Kōichiro TAKAHASHI

(Received October 19, 1973)

A series of pyrochlore compounds of $Pb(Ti_x \cdot Sn_{1-x})O_3$, was aqueously prepared. They were characterized in terms of inhomogeneously distributed Ti and Sn ions in the equivalent lattice positions. In the composition range where the value x was between 0.00 and 0.45, monophasic pyrochlore was crystallized. In the composition range of $x \gtrsim 0.45$, however, the pyrochlore phase more or less coexisted with a noncrystalline substance whose composition was supposed to be Pb/(Ti+Sn) mole ratio <1.0. The process of thermal transition from the pyrochlore-type $Pb(Ti_{0.4} \cdot Sn_{0.6})O_3$ to the perovskite-type system was traced by two lines of measurements of the pyrochlore, *i.e.*, the lattice constant and the degree of fluctuation of interplanar spacings, and by measurements of the tetragonal lattice strain of the resultant perovskite. The results showed that the transition occurred preferentially at Ti-rich microregions in the matrix lattice, in which a measurable fluctuation of the Sn: Ti ratio was detected.

The pyrochlore family, like the perovskite group, draw our attention in view of its ferroelectricity and/or high permittivity. The ferroelectric properties of cadmium pyroniobate, $Cd_2Nb_2O_7$, were discovered some time ago.[1] Recently it has been reported that the anion-deficient pyrochlore $Bi_2Zn_{4/3}Ta_{2/3}O_6$ is ferroelectric below 570 °C,[2] and unusual dielectric properties have been found at low temperatures for the Pb_2BiNbO_6 pyrochlore.[3] On the other hand, numerous studies have been successful in preparing $A^{2+}B^{4+}O_3$ perovskites (A: Ba, Pb, Sr, Cd, and Ca; B: Ti, Zr, Sn, and Hf). Among them, however, no attempts to prepare any single phases with a composition of $PbSnO_3$ have yet been successful under an atmospheric pressure. In the present study, two new pyrochlore compounds, $PbSnO_3$ and $Pb(Ti_x \cdot Sn_{1-x})O_3$ were aqueously prepared with a strong expectation as to their ferroelectricity. The present interest was directed to the thermal transition from the solid-solution-type pyrochlore into the perovskite. The degree of the inhomogeneous distribution of Ti and Sn ions in the equivalent lattice positions of the pyrochlore during the transition was estimated; it could be a useful parameter for the analysis of the transition characteristics.

Experimental

Materials. $Pb(CH_3CO_2)_2 \cdot 3H_2O$ was dissolved into a 5 M NaOH solution, and then this solution was neutralized by means of a 3 M HNO_3 solution. A mixed solution of $TiCl_4$ and $SnCl_4$ with a desired mole ratio was added to the neutralized solution to obtain a white precipitate. After this mixture has stood for a while, a light yellow precipitate appeared. This precipitate was repeatedly washed with water to remove any adsorbed Na^+ and Pb^{2+} and was then oven-dried at 130 °C for 1 day. Experiments were repeated by varying the mole ratio of $TiCl_4/SnCl_4$; more than 30 types of materials were thus obtained.

Chemical Analyses. Chemical analyses for Pb and Na were undertaken for one specimen of $x=0.4$ as-dried, which was readily soluble in a dilute HCl solution. In the determination of its composition on the basis of the chemical analysis data, therefore, the presence of its adsorbed water was taken into account. The Na content in the specimen solution was analyzed using a frame photometer (type EP-3, Shimadzu Co.). The drop-by-drop addition of a 0.3 M solution of cupron (α-benzoinoxime) to the specimen solution led to the quantitative formation of a pale-yellow mixed precipitate of cupron-Ti and cupron-Sn, leaving the cupron-Pb complex solution behind. The resultant precipitate was filtered and washed with diluted acid until all the adsorbed cupron-Pb complex had been removed. The collected solution of the cupron-Pb complex was then titrated with a standard EDTA solution in order to determine the Pb content. The water content in the dried specimen was determined from the weight loss up 650 °C.

Determination of a, (c/a)-1, and $\Delta d/d$. X-Ray diffraction patterns were obtained at room temperature using a JEOL diffractometer (Nihondenshi Co.) with Cu$K\alpha$ radiation in order to determine the lattice constant of pyrochlores and the tetragonal lattice strain, (c/a)-1, of perovskites transformed from a pyrochlore. The lattice constants of the pyrochlores were calculated for typical specimens using 8 of the well-resolved diffraction lines. The result indicated that the estimated accuracy of the lattice constant was ± 0.01 Å (see Tables 2 and 3). The lattice constant for other materials was conveniently calculated using the {622} reflection. The tetragonal strain of the perovskites was determined using the {111} and (002) diffraction lines. Further experiments were designed to determine whether each composition of solid-solution-type pyrochlores was microscopically uniform. For this purpose, the magnitude of the fluctuation of the interplanar spacings, $\Delta d/d$, was calculated by observing the reflection angle, θ, and the pure diffraction line broadening, β, relative to a silicon standard according to the $\Delta d/d = \beta\cos\theta/\sin\theta$ equation; for the determination of this, 4 of the well-resolved reflection, {222}, {400}, {440}, and {622}, were chosen. The crystallite size, r, was determined simultaneously using the Walker equation: $\beta = 0.9/r \cdot \cos\theta$, with $\beta\cos\theta$ extrapolated to $\sin\theta = 0$.

Determination of Degree of Transition. A quantitative determination of the relative amounts of the pyrochlore- and perovskite-phases was made by X-ray diffraction. The perovskite {111} and pyrochlore {222} reflections were used, and their integrated intensity ratio was planimetrically determined. This was compared with the corresponding ratios for a series of pyrochlore-perovskite mixtures.

Thermogravimetry. TG was undertaken at a temperature elevation speed of about 10 °C under the sensitivities of 50 mg/full-scale (Chō Keiryoki Co.) and of 2 mg/full-scale (Rigaku Denki Co.).

Infrared Absorption. The infrared absorption in the wave number range of 1500—4000 cm^{-1} is a way to directly observing the presence of OH^- and H_2O in specimens. A

spectrometer (type EPI-S_2, Hitachi Co.) was used to record the spectra of KBr plus specimen disks which were formed after a prolonged evacuation at room temperature to eliminate water adsorbed on KBr and specimen powders.

Results and Discussion

The X-ray diffraction indicated that no crystalline phases other than the pyrochlore one were found in any of the specimens prepared by varying the Ti/(Ti+Sn) mole ratio, x, in the starting mixed solution. TG of all the dried specimens under the sensitivity of 50 mg/full-scale revealed that the majority of dehydration was completed up to about 300 °C, thereafter, no considerable weight changes occurred up to about 1000 °C, at which the temperature volatilization of PbO started (Fig. 1). The DTA profiles of the dried specimens of $x \lesssim 0.45$ gave only heat absorption due to the removal of water, whereas those of $x \gtrsim 0.45$ showed, besides the heat absorption, an exothermic peak at about 550 °C, in which its intensity increased with an increase in the value of x. The latter fact was in harmony with the fact that the intensity of the background of X-ray diffraction also increased with an increase in the value of x. These facts strongly suggest that each specimen of $x \gtrsim 0.45$ more or less involves noncrystalline material, and that its exothermic peak of interest is due to its crystallization to perovskite and/or pyrochlore. Our previous reports[4-7] indicated that in the present manner of aqueous synthesis under the condition of $x=1.0$, "pure" noncrystalline material with a composition of $Pb_{1-y}TiO_{3-y}$ ($y \lesssim 0.3$) resulted, and that this crystallized to the perovskite at about 550 °C. It is thus believed that the compositions of noncrystalline materials coexisting with the pyrochlores are all Pb/(Ti+Sn) mole ratio <1.0. No further discussion will be undertaken of the specimens of $x \gtrsim 0.45$ in the present study.

The foregoing results allow us to regard the materials of $x \lesssim 0.45$ as roughly monophasic, even if a very small amount of a noncrystalline substance coexists. The results of chemical analyses for the material of $x=0.4$ as a typical example gave $Pb_{1.05}(Ti_{0.4} \cdot Sn_{0.6})O_3$ as its composition; no measurable content of Na was detected. Thus, its $Pb/(Ti_{0.4}+Sn_{0.6})$ and hence $Pb/(Ti_x+Sn_{1-x})$

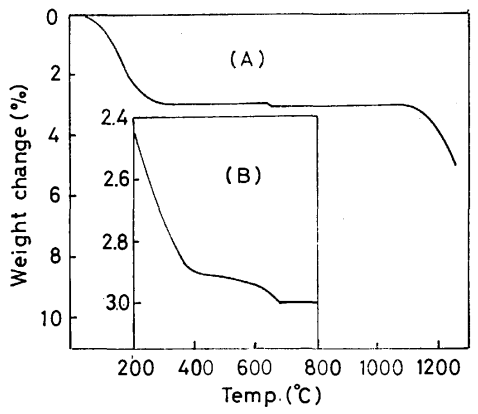

Fig. 1. Thermogravimetric trace of pyrochlore Pb $(Ti_{0.4} \cdot Sn_{0.6})O_3$ under the sensitivities of 50 mg/full-scale (A) and 2 mg/full-scale (B).

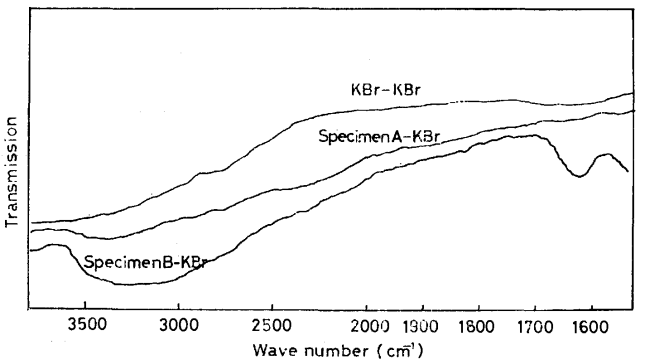

Fig. 2. Infrared absorption spectra of specimens A and B which were obtained by firing pyrochlore $Pb(Ti_{0.4} \cdot Sn_{0.6})O_3$ at 800 and 550 °C.

mole ratio in general may be taken to be unity within the limits of experimental error. Here we may need to further examine the possibility of the $Pb_2(Ti_{0.4} \cdot Sn_{0.6})_2(O,OH)_7$ composition besides $Pb(Ti_{0.4} \cdot Sn_{0.6})O_3$, since the two compositions may both lie within the accuracy of chemical analyses. Fortunately, as will be described later, the pyrochlore of $x=0.4$ was transformed to monophasic perovskite at elevated temperatures. Therefore, a composition of $Pb^{2+}(Ti_{0.4} \cdot Sn_{0.6})_2[O_5 \cdot (OH)_2]$ where the electroneutrality is maintained would be an accepted possibility, since only this composition can be transformed to the $Pb^{2+}(Ti_{0.4} \cdot Sn_{0.6})_2O_6$ by losing one molecule of water from the pyrochlore composition. A close examination was, therefore, done of the weight change at elevated temperatures using a microthermobalance. The results for a thermogravimetric trace of the specimen under the senstivity of 2 mg/full-scale is shown in Fig. 1; a slight weight change occurs over the temperature range from 300 to 620 °C. To ascertain the constituent species which causes the weight change, the infrared absorption spectra of two specimens of $x=0.4$ fired at 800 °C (Specimen A) and 550 °C (Specimen B) were recorded, (Fig. 2). For Specimen B, two kinds of absorptions, in the vicinity of 3400 cm^{-1} due to the stretching vibration mode of OH^{-1} and in the vicinity of 1600 cm^{-1} due to its bending vibration mode, are obvious. For Specimen A, whose relative mole ratio of perovskite/pyrochlore was 0.50, no absorption was detected over the wavelength range of interest. However, it should be stressed that the percent weight change in the temperature range of 300—620 °C ($\approx$0.1 wt%) was far less than the calculated H_2O percentage in $Pb_2(Ti_{0.4} \cdot Sn_{0.6})_2[O_5 \cdot (OH)_2]$ (=2.54 wt%). This fact shows the possible existence of pyrochlore with a composition of $Pb(Ti_{0.4} \cdot Sn_{0.6})O_3$ over a temperature range of at least 300—600 °C; the very small amounts of OH^- detected by the infrared absorption technique may arise from either zeolitic water or strongly-absorbed water present. Remarks will be necessary, for dehydration occurred up to $\approx$300 °C. The lattice constants of two specimens of $x=0.4$ before and after the dehydration were equal within the limits of experimental error. This fact gives negative evidence for the occurrence of pyrochlore with a composition of $Pb_2(Ti_{0.4} \cdot Sn_{0.6})_2[O_5(OH)_2]$.

Recently a number of the anion-deficient pyrochlores,

TABLE 1. COMPOSITIONS AND PHASES OF MATERIALS AT 300 AND 900°C
Compositions are indicated without taking the presence of "water" into consideration

$x=\frac{Ti}{Ti+Sn}$ (Mole fraction)	Phases present	
	Specimen fired at 300 °C	Specimen fired at 900 °C

$0.45\lesssim x<0.85$	Pyro.—$Pb(Ti_{x'}\cdot Sn_{1-x'})O_3$ +Noncryst.—$Pb_{1-y}(Ti_{x''}\cdot Sn_{1-x''})O_{3-y}$	Pero.—$Pb(Ti_{x'}\cdot Sn_{1-x'})O_3$ +Pero.—$Pb_{1-y}(Ti_{x''}\cdot Sn_{1-x''})O_{3-y}$
$x\gtrsim 0.85$	Noncryst.—$Pb_{1-y}(Ti_x\cdot Sn_{1-x})O_{3-y}$	Pero.—$Pb_{1-y}(Ti_x\cdot Sn_{1-x})O_{3-y}$

such as Pb_2BiNbO_6,[8] and $Bi_3A_2^{2+}TaO_9$, where A=Mg, Zn, and Ca,[8] and $Pb_2Cd_{1/2}Mn_{1/2}TaO_6$[8] and $Pb_2Sb^{3+}B^{5+}O_6$, where B=Nb and Ta,[8] have been reported. In view of the fact that many of these pyrochlores involve Pb, the existence of the oxygen-deficient pyrochlore system $Pb(Ti_x\cdot Sn_{1-x})O_3$ in the present study may be accepted. The $Pb(Ti_x\cdot Sn_{1-x})O_3$ composition in general indicates that the structure is oxygen-deficient with respect to a standard type of pyrochlore, $A_2B_2O_7$, where lattice positions available are fully occupied. In the standard pyrochlore structure, the configuration of the BO_6 octahedral is complicated, the O–B–O chains lying on a zig-zag line along the <110> direction. In this structure the seventh set of oxygen are not essential to the stability of the structure. Therefore, the number of oxygen ions in the $A_2B_2O_7$ pyrochlore may be reduced to 6. Our pyrochlores can also be such a case.

In summary, the compositions and phases of materials prepared aqueously and then fired at 300 °C are summarized in Table 1 in relation to the mole ratio, x. The X-ray diffraction data of $PbSnO_3$ and $Pb(Ti_{0.45}\cdot Sn_{0.55})O_3$, both fired at 300 °C, are listed in Table 2. It may be seen from the table that they have cubic symmetry, for which more strict proof will be presented later. Figure 3 shows the lattice constant, a, as a function of the x value. No anomaly is found in the plot. The materials precipitated aqueously and then dried were heat-treated at elevated temperatures, and then quenched in air down to room temperature. The

results of phase analyses for the materials fired at 900 °C are shown in the third column in Table 1. The pyrochlore of x=0.0, *i.e.*, $PbSnO_3$, decomposed into Pb_2SnO_4 and SnO_2 at about 800 °C. This fact indicates that if a solid-solid reaction between PbO and SnO_2 could occur in the vicinity of 800 °C, there can be no single stable phases of the $PbSnO_3$ composition. On the other hand, restricted monophasic pyrochlores of $0.35\lesssim x\lesssim 0.45$ were transformed into monophasic perovskites, the starting temperature being about 600 °C.

The $Pb(Ti_{0.4}\cdot Sn_{0.6})O_3$ composition was chosen to study the transition characterisitics of a solid-solution-type pyrochlore. The material was fired at a series of temperatures in order to measure the lattice constant of the pyrochlore phase. Table 3 gives the lattice constants of the pyrochlores fired at 720 and 870 °C, at which temperatures the extents of the transition were about 50 and 90% respectively. The pyrochlore phase held cubic symmetry during the transition. It is noticeable that the lattice constant, a, varies continuously during the transition. (Fig. 4). To ascertain the cause of such "anomalous" transition characteristics,

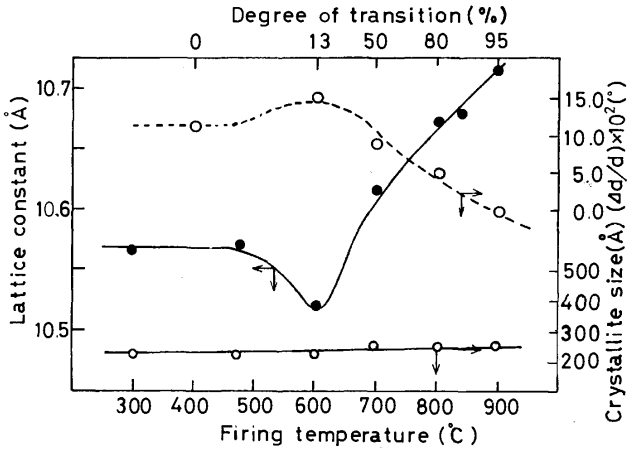

Fig. 4. Variations of $\Delta d/d$ and a of materials of pyrochlore-type obtained by firing pyrochlore $Pb(Ti_{0.4} \cdot Sn_{0.6})O_3$, with firing temperature.

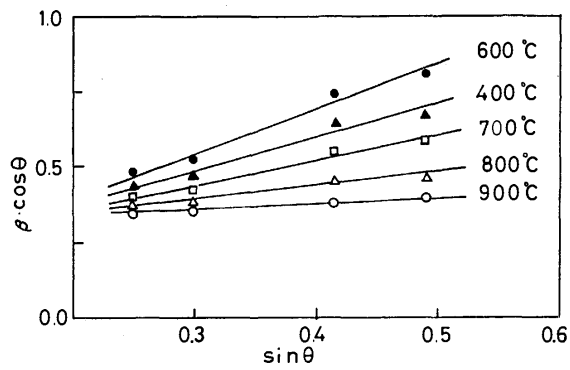

Fig. 5. Plots of $\beta cos\ \theta$ vs. $sin\ \theta$ of materials of pyrochlore-type obtained during transition from pyrochloro $Pb(Ti_{0.4} \cdot Sn_{0.6})O_3$ into perovskite one.

the magnitude of the fluctuation of the interplanar spacings and crystallite size of pyrochlores were determined. Figure 5 shows the plots of $\beta\cos\theta$ *vs.* $\sin\theta$ for the pyrochlores. The linearity of the plots is fairly good; the slopes give the $\Delta d/d$ value. Care must be taken that no diffraction line broadening due to crystallite size reduction contributes to the $\Delta d/d$ value. The $\Delta d/d$ value and the crystallite size are shown together in Fig. 4 as a function of the firing temperature. The $\Delta d/d$ value decreases continuously with the progress of the transition after a slight increase at an early stage of the transition. It should be noted that the $\Delta d/d$ value of the pyrochlore at the final stage of the transition is nearly zero, mainly because its diffraction lines are very sharp. Therefore, the interpretation of the pyrochlore fired at 870 °C in terms of cubic symmetry (Table 3) is valid. Accordingly, one might expect that all the pyrochlores treated in the present study have an exactly cubic symmetry even if their diffraction lines were unsharp in some cases.

It is very important to note that a decrease in $\Delta d/d$ follows an increase in a during the transition. There are two ways of interpreting the fluctuation of the interplanar spacings characteristic of the materials. One is based on the presence of an inhomogeneous strain, and the other, on its composition fluctuation. The literature[9,10] has indicated that the application of mechanical stress to polycrystalline solids causes an inhomogeneous strain. Throughout the formation process of the pyrochlores, however, there are not external environments enough for any residual stress or microstress to occur so as to create an inhomogeneous strain. One possibility to be considered is an internal stress stemming from a difference in the ionic radii of Ti^{4+} and Sn^{4+} ions. However such a stress, even if could be developed, may be quickly removed *via* free surfaces during the formation process of the materials. Therefore, it seems reasonable to give the interpretation in terms of composition fluctuation for $\Delta d/d$. A more rigorous proof for this will be described later. The majority of the composition fluctuation may occur as a result of the clustering of Sn ions in the B-positions of the $A_2B_2O_6$ pyrochlore in the formation process, by which an inhomogeneous distribution of Sn and Ti ions may result. The clustering tendency of Sn ions seems in harmony with the fact that an Sn-rich composition was apt to crystallize in a pyrochlore-type structure. The foregoing discussion suggests that a decrease in $\Delta d/d$ above 600 °C (see Fig. 4) occurs as a result of either Sn-rich or Ti-rich sides of the composition being missing. The accompanying increase in the lattice constant, a, above that temperature allows us to choose a preferential lack of a Ti-rich composition in the pyrochlore phase from among the two possibilities; a Sn-rich composition thus comes to predominate in the pyrochlore phase remaining. This feature of the two parameters, a and $\Delta d/d$, during the transition is also indicative of the validity of the interpretation based on composition fluctuation for $\Delta d/d$, because if the $\Delta d/d$ value is due to an inhomogeneous strain, its decrease has to proceed without varying the lattice constant. Here it is important to evaluate the actual range of the composition fluctuation of pyrochlores. The $\Delta d/d$ value was used with the data of Fig. 3 for this purpose. The composition range of, for example, $Pb(Ti_{0.4} \cdot Sn_{0.6})O_3$ fired at 300 °C was calculated as $x=0.364$—0.436 (average of $x=0.4$). In summary, it seems reasonable that the transition from the solid-solution-type pyrochlore to the perovskite occurs favorably in Ti-rich microregions. To confirm this line of thought definitely, it is useful to trace the tetragonal lattice strain, $(c/a)-1$, of the resultant

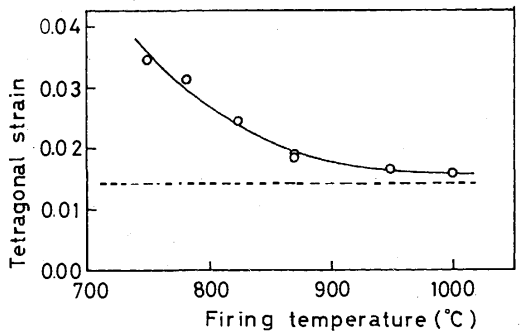

Fig. 6. Tetragonal lattice strain of materials of perovs kite-type obtained during transition from pyrochlore $Pb(Ti_{0.4}\cdot Sn_{0.6})O_3$ to perovskite one.

perovskite during the transition. Figure 6 shows the result; the dotted line shows the literature value[11] of the tetragonal strain of $Pb(Ti_{0.4}\cdot Sn_{0.6})O_3$ perovskite. As may be seen, the tetragonal strain of our perovskite lies in the vicinity of 0.04 at an early stage of the transition and then goes down to the literature value, 0.014, as the transition proceeds. This means that the composition of the resultant perovskite is Ti-richer at an early stage of the transition, thus fitting the foregoing interpretation of the transition characteristics of the solid-solution-type pyrochlore.

It is noticeable that a slight increase in $\Delta d/d$ occurs up to 600 °C, along with a slight decrease in the lattice constant, a (Fig. 4). A probable interpretation for this may be worked out by postulating that the as-dried solid solution contains a very small quantity of a noncrystalline material with a value of x slightly higher than that of the host. This line of thought may be supported by the fact that material with a high value of x is apt to become amorphous (Table 1). If this consideration is valid, and if its crystallization to pyrochlore proceeds near 500—600 °C, there can occur an increase in $\Delta d/d$ accompanying a decrease in the lattice constant, a, in the restricted temperature range of interest.

Some discussion may be needed regarding the displacement of the constituent ions, especially that of the Pb ions of the pyrochlore during the transition. Only when the displacement is "inhomogeneous", it can contribute to the $\Delta d/d$ value. Even if such a type of displacement could occur during the transition, however, the $\Delta d/d$ value has to go to a higher level than that before the transition without the lattice constant being varies. The results show in Fig. 4 and contrary to this requirement.

Further examinations were designed to trace the thermal-decomposition process of the monophasic pyrochlore $PbSnO_3$ by measurements along the same lines. These examinations may serve for checking whether the

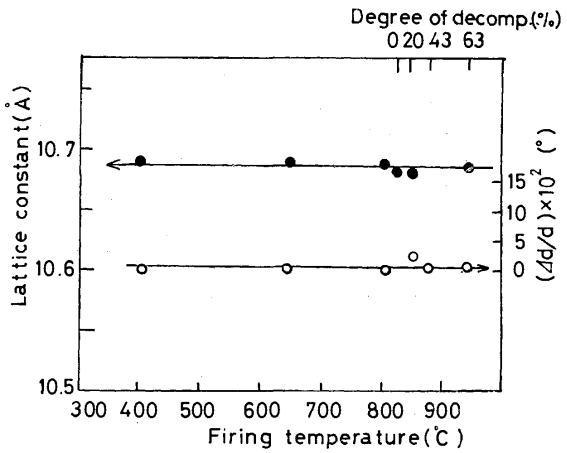

Fig. 7. Trace of $\Delta d/d$ and a of pyrochlore $PbSnO_3$ during thermal decomposition.

"anomalous" transition behavior is characteristic of the solid-solution-type pyrochlore. Figure 7 shows the two parameters, a and $\Delta d/d$, of the pyrochlore phase as a function of the firing temperature or of the extent of decomposition. No variations in the two are found up to at least 950 °C, at which temperature the extent of the decomposition reached about 63%; the $\Delta d/d$ value was zero before and throughout the transition, as had been expected. This fact can be taken as positive evidence for the foregoing way of understanding of the transition characterisitics of the solid-solution-type pyrochlore $Pb(Ti_x\cdot Sn_{1-x})O_3$ in general, and also as negative evidence for the occurrence of the displacement of the constituent ions of the pyrochlore during thetransition.

A Study of the Thermal Degradation of Several Halogen-containing Polymers by Torsional Braid Analysis

Noboru FURUSHO, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received October 20, 1973)

The thermal degradation of several halogen-containing polymers in air was studied by means of the TBA (Torsional Braid Analysis) method and IR spectroscopy. The samples were poly(vinyl chloride)(PVC), vinylidene chloride-vinyl chloride copolymer(PVdC-VC), poly(vinyl fluoride)(PVF), poly(vinylidene fluoride)(PVdF), poly(vinyl bromide)(PVB), and poly(vinylidene bromide)(PVdB). The dynamic mechanical properties of these polymers are complicated at higher temperatures because of the thermal degradation, by, for example, dehydrohalogenation. The relative shear modulus (G_r) increases and then decreases through a maximum, accompanied by changes in the logarithmic decrement. The temperatures at which the changes in G_r occur become higher in the order of PVdB<PVB<PVdC-VC<PVC<PVdF<PVF. This order agrees with that of the bond energy in carbon-halogen bonds. The apparent activation energies of these reactions were obtained from the changes in G_r and from the relative absorbance ratio of the carbon-carbon double bond with time, respectively. In general, the values estimated by these two procedures agreed well in each case.

The thermal degradation of polymers has been studied widely by various methods, by, for instance, thermogravimetric analysis and pyrolysis gas chromatography. On the other hand, relatively few studies have been carried out on the basis of measurements of the mechanical properties, which are much more sensitive to the changes in the state of the material. This situation may be attributed to the difficulties in the measurements of the mechanical properties of polymers at higher temperatures because of softening and fluidity. Gillham and Lewis[1] have established a new procedure, called the Torsional Braid Analysis (TBA) method, in which a composite system composed of a polymer and a mechanically-inactive supporting material (usually glass braids) is used.

Previously, using this TBA method, we have studied the change in the dynamic mechanical properties of several polymers during the thermal degradation and concluded that the TBA method can be used as a convenient tool for the kinetic study of the thermal degradation of polymers.[2,3]

In the present paper, we will report some results on the thermal degradation of several halogen-containing polymers: poly(vinyl halide) and poly(vinylidene halide). The halides are chloride, fluoride, and bromide. We will also report on the correlation between the changes in the dynamic mechanical behavior at higher temperatures and the chemical reactions with the aid of the results of the thermogravimetric analysis and the IR spectra.

The purpose of this work is to elucidate the effects of the various halogens and the types of substitution on the thermal stabilities of polymers on the basis of the measurements of the mechanical properties. Also, we intend to examine the applicability of these mechanical procedures to the kinetic studies by comparing the data obtained from the mechanical measurements with the values obtained from the IR spectra.

Experimental

The poly(vinyl chloride)(PVC), vinylidene chloride-vinyl chloride copolymer(PVdC-VC), poly(vinyl fluoride)(PVF), and poly(vinylidene fluoride)(PVdF) were commercial materials. The poly(vinyl bromide)(PVB) and poly(vinylidene bromide)(PVdB) were obtained as the starting materials from the 1,2-dibromoethane in the ordinary way;[4] the polymers were identified by elementary analysis and by IR spectroscopy. The known parameters relating to the molecular dimensions of the present samples are as follows. The viscosity-average molecular weights are 1.0×10^5 for PVC and 1.2×10^5 for PVB. The intrinsic viscosity in *N,N*-dimethylformamide at 20 °C is 1.8 (dl/g) for PVdF. The number-average degree of polymerization is 1000 for PVdC-VC, and the weight ratio of the components is 82: 18.

The details of the TBA method have been described elsewhere.[2] The relative shear modulus ($G_r=(T_0/T)^2$) and the logarithmic decrement ($\lambda=(1/n)\ln(A_{2n+1}/A_1)$) are obtained from the frequencies and the amplitudes of the damped oscillations. The measurements of G_r and λ are carried out under the conditions of a constant heating rate and under isothermal conditions. In the former case, the moduli at room temperatures, and in the latter case, the values 10 min after the setting of the specimen, were used as standards of the relative shear moduli. The test specimens were prepared by the impregnation of the polymer solutions into the glass braids and by the subsequent evaporation of the solvents. The frequency range is about 0.13—0.35 Hz.

The measurements of the IR spectra were carried out as follows. At first, KBr pellets with a known concentration of these polymers were prepared and then heated in air for the desired periods under isothermal conditions. The pellets were made again from those heat-treated materials and then used in the IR experiment. The relative absorbance ratios for the C–C double bond and the C–H group were calculated from the heights of the absorption peaks.

The thermogravimetric analysis(TGA) and the differential thermal analysis(DTA) were carried out in the air at a constant heating rate by using an apparatus made by the Rigaku Denki Co.

Results and Discussion

Temperature Dependence of G_r and λ. The dynamic mechanical properties of these polymers are shown in Figs. 1, 2, and 3. In these figures, the ordinates are arbitrarily shifted in order to avoid the overlapping of the curves. As is shown in Fig. 1, the G_r and λ of PVC behave in a complicated way. The curves of the

temperature dependence of G_r and λ consist of several parts. These features can be explained by assuming the following mechanism. The first abrupt decrease in G_r and the corresponding maximum of λ at about 90 °C are due to the glass transition. The gradual decrease in G_r and, presumably, the corresponding maximum of λ at about 180 °C may be due to the flow or the fusion. The successive increase in G_r (and the corresponding shoulder of λ at about 250 °C) and the last decrease in G_r through the maximum at about 300 °C may be attributed to the thermal degradation. The assumption about the last stage of the thermo-mechanical change is supported by the results of the thermogravimetric analysis shown in Fig. 4. In the case of PVC, as is shown in the figure, the weight loss accompanied by the dehydrochlorination reaction begins at about 230 °C and becomes intense between 250 and 290 °C; this temperature range is the same as that in which the values in G_r increase considerably. Considering the difference in the heating rates, it is reasonable to assume that these results correspond to each other.

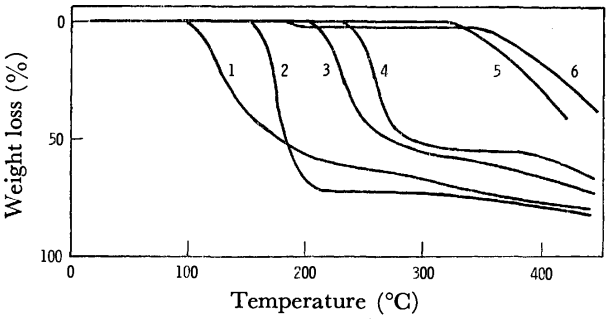

Fig. 4. TGA thermograms of halogen-containing polymers in air. Heating rate: 2.5 °C/min (1,2), 3 °C/min (3,4,5,6). (1): PVdB, (2): PVB, (3): PVdC–VC, (4): PVC, (5): PVF, (6): PVdF.

In the cases of the other polymers, the features in the dynamic mechanical properties can be also explained in the same way as in the case of PVC. For PVdC-VC, as is shown in Fig. 1, the decrease in G_r at the lower temperatures, the shoulder of λ at about 70 °C, and the successive decrease in G_r accompanied by the small peak (110 °C) and the shoulder (160 °C) of λ may be attributed to the physical relaxations. Such a situation is in agreement with the results obtained by Schmieder and Wolf.[5] The successive increase in G_r (and the corresponding small peak of λ at about 230 °C) and the last decrease in G_r through the maximum at about 270 °C are the results of the thermal degradation. It may be noticed that the values of G_r sharply decrease through a maximum in spite of the relatively slight loss of weight. Similar behavior is observed in the other systems. This result may be attributed to the destruction of the network structure by the oxidative chain scission, because the mechanical properties are very sensitive to the change in the network structure.

In the case of PVF, as is shown in Fig. 2, the decrease in G_r, the corresponding shoulder of λ at 40 °C, and the maximum of λ at 90 °C may be attributed to the molecular motions in the amorphous region and to those in the crystalline region, respectively. Considering our finding that the endothermic peak exists at about 190 °C, the small drop in G_r and the maximum of λ at 190 °C are due to the melting. These considerations

are supported by the results of Kawasaki and Hashimoto,[6] and Nielsen[7] with regard to its mechanical dispersion. The successive increase in G_r (and the corresponding shoulder of λ at about 320 °C) and the decrease in G_r through the maximum at 360 °C come from the thermal degradation. The nature of the small peak of λ at 260 °C has not been elucidated.

For PVdF (Fig. 2), the decrease in G_r and the corresponding peaks of λ at 90 and 150 °C may be attributed to the molecular motion in the crystalline region and to the melting, respectively. These assumptions are supported by the results of Kakutani[8] and Ota *et al.*[9] and by our finding that the endothermic peak exists at about 150 °C. The successive increase in G_r is due to the thermal degradation. However, the correlation between the gradual increase in G_r at about 200 °C and the chemical process is not clear at present. A slight weight loss is observed at about 180 °C. Ishii found a similar weight loss and stated that it was the result of the dehydrofluorination.[10] It should be pointed out here that the increase in G_r is greater than that to be expected from the curve of the weight loss; moreover, G_r continues to grow without showing any plateau.

For PVB (Fig. 3), the decrease in G_r and the corresponding maximum at 100 °C in λ relate to the glass transition. This agrees with the results obtained by Zutty and Whitworth.[11] The successive increase in G_r (and the corresponding shoulder of λ at 180 °C) and the decrease in G_r above 300 °C through the high plateau arise from the thermal degradation.

For PVdB (Fig. 3), the decrease in G_r, the corresponding maximum at 50 °C, and the shoulder at about 80 °C in λ are the results of the physical relaxation. The successive increase in G_r (and the corresponding shoulder of λ at 160 °C) and the decrease in G_r above 280 °C through a high plateau come from the thermal degradation. It may be noted that the values of G_r remain constant at a high plateau, irrespective of the continuous weight loss. This fact can be explained by assuming that the crosslinked network is formed at the first stage of the thermal degradation and that the so-formed polymeric structure remains unchanged in spite of the escape of small molecules, resulting in a continuous weight loss. In the case of epoxy resins during the curing process, the changes in G_r with time are similar to those of the present case (Fig. 6), and so an analogous mechanism of the formation of crosslinkage may be proposed.

These results concerning the thermal degradation are summarized in Table 1. The temperatures at which the values of G_r begin to increase become higher in the order of PVdB<PVB<PVdC-VC<PVC<PVdF<PVF. This order agrees well with that of the bond energy in the carbon-halogen bonds. Considering these features, together with the relation between the dynamic mechanical and the thermogravimetric results, and considering the appearance of the peak of the C-C double bond in the IR spectra, the increase in G_r seems to be attributable mainly to the dehydrohalogenation and the crosslinking reaction. The temperatures of the maximum of G_r become higher in the order of PVdB≈PVB<PVdC-VC<PVC<PVF<PVdF. In the cases of PVB and PVdB, those of the left-hand side of the plateau were taken as the maxima. The order of the temperatures at which G_r begins to decrease is PVdC-VC≈PVdB<PVC<PVB<PVF<PVdF.

These features are attributable to the difference in the stability of the dehydrohalogenation products against the oxidation which proceeds at the relatively higher temperatures, though the details have not been elucidated.

Time Dependence of G_r and λ. In order to study the kinetics of the thermal degradation, the G_r and λ are measured under isothermal conditions. Two typical results are shown in Figs. 5 and 6. Assuming that the

a) G_r increases or decreases.

order of the reaction is zero or first, the plots of the G_r *versus* the time and of the log G_r *versus* the time were made. In the case of PVC (Fig. 5), these two curves are linear at the initial stage. The order of the reaction has not yet been determined. At any rate, the slopes of these curves are a measure of the velocity constants, irrespective of the order of the reactions. The time dependence of λ is very slight and has been omitted from the figure. For other polymers, behavior was observed similar to that in the case of PVC. In the case of PVdB (Fig. 6), on the other hand, the curves are each composed of the two stages, and, at the same time, there exists a maximum in λ corresponding to the transition between the two stages. These phenomena have been found for polystyrene in our previous work[2] and for many cases of epoxy resins during the curing process. The time corresponding to the maximum of λ, therefore, may be regarded as a measure inversely proportional to the velocity constants.

The logarithms of the initial slopes and the time of the maximum λ were plotted against the reciprocal temperature (K^{-1}). From this analysis, the apparent activation energies are obtained as is shown in Table 2. These values agree well with those obtained by the other methods. For example, in the case of PVC, the value estimated from G_r, 24.7 kcal/mol, agrees well with 24 kcal/mol obtained by Talamini and Pezzin by TGA method.[12]

Furthermore, as was done in the previous work, a superposition procedure for the temperature dependence of G_r-reaction time curves was made. A typical composite curve is shown in Fig. 7. As was pointed out by Tobolsky[13] and shown in our previous work, the apparent activation energies can be obtained from the Arrhenius plot of the so-called shift factor in this procedure. The values are shown in Table 2. Except for a few cases, the agreement of the values estimated by various procedures is excellent; this fact confirms the validity of the analysis mentioned above.

The Changes in the Relative Absorbance Ratio. In order to substantiate the above discussion about the correlation between the changes in the dynamic mechanical properties and the chemical processes, and also

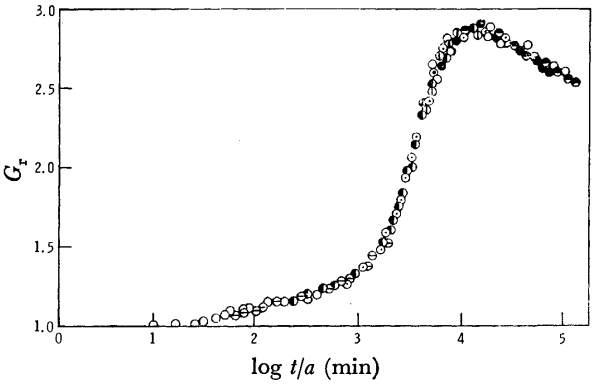

Fig. 7. Composite curve for relative shear modulus of PVC. (T_0=172 °C)
○: 172 °C, ⊖: 196 °C, ◐: 221 °C, ⊙: 246 °C, ⓘ: 271 °C, ●: 294 °C, ○: 319 °C, ◓: 343 °C.

in order to carry out the kinetic study, the IR spectra were measured. The change proceeds as follows; first, the peak of C-X bond disappears and the peak of C-C double bond appears in consequence of the dehydrohalogenation; second, the peaks of the carbonyl and ether groups resulting from the oxidation reaction appear. Otani suggested that the appearance of the peak of the ether group is the result of a crosslinking formation by the oxidation reaction.[14] These features support the considerations mentioned above of the mechano-chemical processes.

A typical example of the changes in the relative absorbance ratio (A_r) is shown in Fig. 8. A procedure of kinetic study similar to that used in the time dependence of G_r was used. The A_r *vs.* time and log A_r *vs.* time curves are linear at the initial stage. The slopes of these curves are, therefore, a measure of the velocity constant.

The logarithmic initial slopes in their curves were plotted against the reciprocal temperature (K^{-1}). From this analysis, the apparent activation energies were obtained as is shown in Table 2. These values agree well with the values obtained from the several other procedures of analysis. For example, in the case of PVdC-VC, the values are 26.0 kcal/mol from the G_r

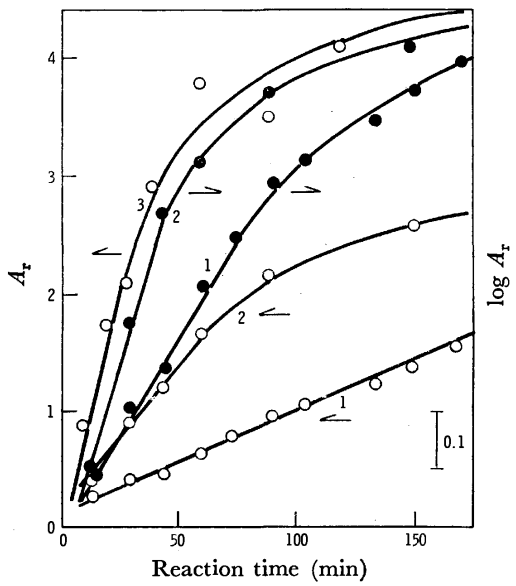

Fig. 8. A_r vs. t and log A_r vs. t plots of heat-treated PVdC–VC. (1): 184 °C, (2): 201 °C, (3): 221 °C. ○: A_r, ●: log A_r.

vs. t curves, 26.5 from log G_r *vs.* t, 26.5 from the shift factor of the composite curve, 27.5 from A_r *vs.* t curves, and 20.7 from log A_r *vs.* t. These agreements support also the considerations mentioned above of the correlation between the mechanical processes and the chemical reactions. There are, however, some deviations in several cases in the table. The problem of these deviations remains unsolved.

Conclusion

The changes in the mechanical properties at higher temperatures are associated with such chemical reactions as dehydrohalogenation, crosslinking and oxidation. The effect of the different halogen species on the thermal stability was elucidated. The stability of the polymers studied lies in the order of PVdB<PVB<PVdC-VC<PVC<PVdF<PVF.

Kinetic studies of these reactions were carried out, and the apparent activation energies were obtained by several ways of analysis. These values agree well each other except for a few cases. Finally, composite curves for the relative shear modulus were obtained for all the polymers studied.

The authors wish to thank Mr. Yoshio Takahashi (Electrotechnical Laboratory) and Associate Professor Yoshio Shibazaki (Saitama University) for affording the facilities for the use of the TGA and DTA apparatus.

A Study of the Upper and Lower Bounds of the Second-order Perturbation Energy

Tokio YAMABE, Kazuyoshi TANAKA, Shingo ISHIMARU, and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 31, 1973)

A method of calculation for the upper and lower bounds of the second-order perturbation energy is investigated. The expression for the upper bound is based on Hylleraas's variation perturbation condition and is an improved version of that obtained by Goodisman. The lower bound is based on the Temple-type inequality and is an improved version of that by Prager and Hirschfelder. The result is numerically tested for examples of the polarizability of a hydrogen atom and the coefficients (C_6 and C_8) of the dispersion force between two separated hydrogen atoms, yielding fairly good results. Particularly, the results of the upper bound for C_8 are the best so far calculated in a non-empirical way.

The second-order perturbation energy, E_2, is given by:

$$E_2 = -\sum_{i>0}^{\infty}|H_{1i}|^2/\varepsilon_i, \tag{1}$$

where $H_{1i}=\langle\phi_0^{(i)}|H_1|\phi_0^{(0)}\rangle$ and $\varepsilon_i=E_0^{(i)}-E_0^{(0)}$, in which H_1 is the perturbation, and $\phi_0^{(i)}$ and $E_0^{(i)}$ are the i-th eigenfunction and eigenvalue of the unperturbed Hamiltonian H_0 respectively. In the following, we will denote $\phi_0^{(0)}$ and $E_0^{(i)}$ as ϕ_0 and E_0 respectively, since we will deal with only the ground state in this paper.

Generally it is difficult to calculate the summation of Eq. (1); therefore, many approximate methods have been devised. Among them, the most useful method is Hylleraas's variation condition for the second-order perturbation energy:[1]

$$\langle\tilde{\phi}_1|H_0-E_0|\tilde{\phi}_1\rangle+\langle\tilde{\phi}_1|H_1-E_1|\phi_0\rangle+\langle\phi_0|H_1-E_1|\tilde{\phi}_1\rangle \geqq E_2, \tag{2}$$

in which $\tilde{\phi}_1$ is an arbitrary function corresponding to the first-order perturbation function. One of the effective forms which have been applied for $\tilde{\phi}_1$ is that of Goodisman,[2] who, using Eq. (2), obtained the upper bound of the second-order energy for the case in which first n excited states of unperturbed system are known. On the other hand, neglecting energies of a higher order than the second-order, Prager and Hirschfelder[3] found the lower bound of the second-order energy based on the Temple principle:[4]

$$\langle(H-E^{(0)})\tilde{\Psi}|(H-E^{(1)})\tilde{\Psi}\rangle \geqq 0, \tag{3}$$

where $E^{(i)}$ is the i-th eigenvalue associated with i-th eigenfunction, $\Psi^{(i)}$, of the total Hamiltonian, $H=H_0+H_1$, and where $\tilde{\Psi}$ is a variational function for $\Psi^{(0)}$, which may be divided into $\phi_0+\tilde{\phi}_1$.

Other theories estimating the upper and lower bounds were developed by Lindner and Löwdin[5] and subsequently by Miller.[6] They utilized operator techniques in the direction of using a finite arbitrary basis set for $\tilde{\phi}_1$. Especially Miller extended the theory of Lindner and Löwdin, who treated only the second-order energy in the ground state, to a theory which can be adopted to the second-order energy in the arbitrary excited state.

It seems, however, that the form of $\tilde{\phi}_1$ used by Goodisman is rather tractable for performing the calculation. Therefore, in the present paper, we will try to improve both the upper bound of Goodisman and the lower bound of Prager and Hirschfelder by the use of a form of $\tilde{\phi}_1$ similar to that of Goodisman.

Derivation of the Upper Bound

Let us consider the following first-order variational function:

$$\tilde{\phi}_1(n,\lambda,\{\mu_i|i\geqq n+1\}) = -\sum_{i>0}^{n}H_{1i}\phi_0^{(i)}/\varepsilon_i + \lambda\sum_{i=n+1}^{\infty}\mu_i H_{1i}\phi_0^{(i)}, \tag{4}$$

where λ and each μ_i are arbitrary real parameters. Substituting this function into Hylleraas's condition in Eq. (2), one obtains:

$$E_2^{\mathrm{up}}(n,\lambda,\{\mu_i|i\geqq n+1\}) = (\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i)\lambda^2 + 2(\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2)\lambda + A_n, \tag{5}$$

where:

$$A_n = -\sum_{i>0}^{\infty}|H_{1i}|^2/\varepsilon_i. \tag{6}$$

$E_2^{\mathrm{up}}(n,\lambda,\{\mu_i|i\geqq n+1\})$ in Eq. (5) is a quadratic formula with regard to λ and takes the minimum value:

$$E_2^{\mathrm{up}}(n,\{\mu_i|i\geqq n+1\}) = A_n-(\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2)^2/(\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i), \tag{7}$$

when λ is:

$$\lambda = -(\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2)/(\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i). \tag{8}$$

After modifying μ_i into some more convenient form, as will be shown below, we can further optimize $E_2^{\mathrm{up}}(n,\{\mu_i|i\geqq n+1\})$ with respect to $\{\mu_i\}$ for each n to get the desired upper bound, $E_2^{\mathrm{up}}(n)$. If the simplest form of μ_i is chosen, *i.e.*, $\mu_i=1$ for any i, the result is just that obtained by Goodisman.

It can easily be proved that the upper bound thus obtained really satisfies the relation that $E_2^{\mathrm{up}}(n-1)\geqq E_2^{\mathrm{up}}(n)$. In order to prove this, let us calculate the following subtraction between $E_2^{\mathrm{up}}(n,\{\mu_i|i\geqq n+1\})$ and $E_2^{\mathrm{up}}(n-1,\{\mu_i|i\geqq n\})$ of Eq. (7), keeping $\{\mu_i\}$ in common for both:

$$E_2^{\mathrm{up}}(n,\{\mu_i|i\geqq n+1\}) - E_2^{\mathrm{up}}(n-1,\{\mu_i|i\geqq n\}) = -|H_{1n}|^2/\varepsilon_n-(\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2)^2/(\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i) + (\sum_{i=n}^{\infty}\mu_i|H_{1i}|^2)^2/(\sum_{i=n}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i). \tag{9}$$

The right-hand side in Eq. (9) becomes:

$$-|H_{1n}|^2\{\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2(\mu_i\varepsilon_i-\mu_n\varepsilon_n)\}^2/$$
$$\{\varepsilon_n(\sum_{i=n}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i)(\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i)\}\leqq 0,$$

and is always nonpositive, since all of ε_i values are nonnegative. Consequently, when n becomes infinite, $E_2^{\mathrm{up}}(n,\{\mu_i|i\geqq n+1\})$; hence, $E_2^{\mathrm{up}}(n)$ also approaches to E_2 in Eq. (1) from the upper side.

Next, we set the modified form of μ_i as $\mu_i=1+\mu E_0^{(i)}/E_0$ to get the optimal value, $E_2^{\mathrm{up}}(n)$.[7] Substituting this μ_i into Eq. (7) and optimizing with respect to μ, one gets:

$$\begin{aligned}E_2^{\mathrm{up}}(n) = {} & A_n-\{\langle\phi_0|H_1^2|\phi_0\rangle+(\mu_{\mathrm{opt}}/E_0)\langle\phi_0|H_1H_0H_1|\phi_0\rangle\\ & -\sum_{i>0}^{n}(1+\mu_{\mathrm{opt}}E_0^{(i)}/E_0)|H_{1i}|^2\}^2/\{\langle\phi_0|H_1(H_0-E_0)H_1|\phi_0\rangle\\ & +(2\mu_{\mathrm{opt}}/E_0)\langle\phi_0|H_1H_0(H_0-E_0)H_1|\varphi_0\rangle\\ & +(\mu_{\mathrm{opt}}^2/E_0^2)\langle\phi_0|H_1H_0(H_0-E_0)H_0H_1|\phi_0\rangle\\ & -\sum_{i>0}^{n}(1+\mu_{\mathrm{opt}}E_0^{(i)}/E_0)^2|H_{1i}|^2\varepsilon_i\},\end{aligned}\tag{10}$$

where:

$$\begin{aligned}\mu_{\mathrm{opt}} = {} & [-(a^2e-b^2c)-\{(a^2e-b^2c)^2\\ & -(a^2d-2abc)(2abe-b^2d)\}^{1/2}]/(a^2d-2abc)\\ = {} & (bd-2ae)/(ad-2bc),\end{aligned}\tag{11}*$$

and where:

$$\left.\begin{aligned}a &= \langle\phi_0|H_1H_0H_1|\phi_0\rangle/E_0-\sum_{i=0}^{n}(E_0^{(i)}/E_0)|H_{1i}|^2,\\ b &= \langle\phi_0|H_1^2|\phi_0\rangle-\sum_{i=0}^{n}|H_{1i}|^2,\\ c &= \langle\phi_0|H_1H_0(H_0-E_0)H_0H_1|\phi_0\rangle/E_0^2\\ &\quad -\sum_{i>0}^{n}(E_0^{(i)}/E_0)^2|H_{1i}|^2\varepsilon_i,\\ d &= 2\{\langle\phi_0|H_1H_0(H_0-E_0)H_1|\phi_0\rangle/E_0\\ &\quad -\sum_{i>0}^{n}(E_0^{(i)}/E_0)|H_{1i}|^2\varepsilon_i.\end{aligned}\right\}\tag{11'}$$

and:

$$e=\langle\phi_0|H_1(H_0-E_0)H_1|\phi_0\rangle-\sum_{i>0}^{n}|H_{1i}|^2\varepsilon_i.$$

Derivation of the Lower Bound

If the variational function $\tilde{\Psi}$, which is divided into $\phi_0+\tilde{\phi}_1$, as has previously been mentioned, is orthogonal to the first several excited eigenfunctions of the total Hamiltonian, *i.e.*:

$$\langle\tilde{\Psi}|\Psi^{(k)}\rangle=0\quad(k=1,2,\cdots,n),\tag{12}$$

the following Temple-type inequality:

$$\langle(H-E^{(0)})\tilde{\Psi}|(H-E^{(n+1)})\tilde{\Psi}\rangle\geqq 0,\tag{13}$$

is easily established and can be utilized as the base to get the lower bound. Here we try to employ the same form as in Eq. (4) for $\tilde{\phi}_1$; namely, $\tilde{\Psi}$ is:

$$\tilde{\Psi}=\phi_0+\tilde{\phi}_1=\phi_0-\sum_{i>0}^{n}H_{1i}\phi_0^{(i)}/\varepsilon_i+\lambda\sum_{i=n+1}^{\infty}\mu_iH_{1i}\phi_0^{(i)},\tag{14}$$

which satisfies Eq. (12) as far as the second-order energy is considered.[8] Substituting this $\tilde{\Psi}$ into Eq. (13) and neglecting the energies of a higher order than the second-order one, we obtain a lower bound for the second-order energy:

$$\begin{aligned}E_2 \geqq {} & \{\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i(1-\varepsilon_i/\varepsilon_{n+1})\}\lambda^2\\ & +2\{\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2(1-\varepsilon_i/\varepsilon_{n+1})\}\lambda\\ & +\{A_n-\sum_{i=n+1}^{\infty}|H_{1i}|^2/\varepsilon_{n+1}\}\\ \equiv {} & E_2^{\mathrm{low}}(n,\lambda,\{\mu_i|i\geqq n+1\}),\end{aligned}\tag{15}$$

which takes the maximum value:

$$\begin{aligned}E_2^{\mathrm{low}}(n,\{\mu_i|i\geqq n+1\}) = {} & -\{\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2(1-\varepsilon_i/\varepsilon_{n+1})\}^2/\\ & \{\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i(1-\varepsilon_i/\varepsilon_{n+1})\}+\{A_n-\sum_{i=n+1}^{\infty}|H_{1i}|^2/\varepsilon_{n+1}\},\end{aligned}\tag{16}$$

when:

$$\begin{aligned}\lambda = {} & -\{\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2(1-\varepsilon_i/\varepsilon_{n+1})\}/\\ & \{\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i(1-\varepsilon_i/\varepsilon_{n+1})\}.\end{aligned}\tag{17}$$

$E_2^{\mathrm{low}}(n,\{\mu_i|i\geqq n+1\})$ can be further optimized with regard to $\{\mu_i\}$ to obtain $E_2^{\mathrm{low}}(n)$ much as in the previous section. If $n=0$ and $\mu_i=1$, the result coincides with that obtained by Prager and Hirschfelder.

Furthermore, the relation that $E_2^{\mathrm{low}}(n)\geqq E_2^{\mathrm{low}}(n-1)$ can be proved by calculating the following subtraction with the use of Eq. (15), keeping λ and $\{\mu_i\}$ in common for both $E_2^{\mathrm{low}}(n,\lambda,\{\mu_i|i\geqq n+1\})$ and $E_2^{\mathrm{low}}(n-1,\lambda,\{\mu_i|i\geqq n\})$:

$$\begin{aligned}& E_2^{\mathrm{low}}(n,\lambda,\{\mu_i|i\geqq n+1\})-E_2^{\mathrm{low}}(n-1,\lambda,\{\mu_i|i\geqq n\})\\ & = \{(\varepsilon_{n+1}-\varepsilon_n)\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i^2/\varepsilon_n\varepsilon_{n+1}\}\lambda^2\\ & \quad +2\{(\varepsilon_{n+1}-\varepsilon_n)\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2\varepsilon_i/\varepsilon_n\varepsilon_{n+1}\}\lambda\\ & \quad +\{(\varepsilon_{n+1}-\varepsilon_n)\sum_{i=n+1}^{\infty}|H_{1i}|^2/\varepsilon_n\varepsilon_{n+1}\}.\end{aligned}\tag{18}$$

Equation (18) is a quadratic formula of λ and is always positive, since the coefficient of λ^2 is positive and since the discriminant of Eq. (18):

$$\begin{aligned}D = {} & (\varepsilon_{n+1}-\varepsilon_n)^2\{(\sum_{i=n+1}^{\infty}\mu_i|H_{1i}|^2\varepsilon_i)^2\\ & -(\sum_{i=n+1}^{\infty}\mu_i^2|H_{1i}|^2\varepsilon_i^2)(\sum_{i=n+1}^{\infty}|H_{1i}|^2)\}/(\varepsilon_{n+1}^2\varepsilon_n^2),\end{aligned}$$

is always negative, which is ensured by the Schwartz inequality. Therefore, when n becomes infinite, $E_2^{\mathrm{low}}(n,\lambda,\{\mu_i|i\geqq n+1\})$; hence, $E_2^{\mathrm{low}}(n)$ also approaches to the true E_2 value from the lower side.

As a special case, by substituting $\mu_i=1$[7] into Eq. (16) one gets the lower bound, $E_2^{\mathrm{low}}(n)$:

$$\begin{aligned}E_2^{\mathrm{low}}(n) = {} & -\{\sum_{i=n+1}^{\infty}|H_{1i}|^2(1-\varepsilon_i/\varepsilon_{n+1})\}^2/\\ & \{\sum_{i=n+1}^{\infty}|H_{1i}|^2\varepsilon_i(1-\varepsilon_i/\varepsilon_{n+1})\}+\{A_n-\sum_{i=n+1}^{\infty}|H_{1i}|^2/\varepsilon_{n+1}\},\end{aligned}\tag{19}$$

which can then be rewritten by using the a, b, d, and e defined in the previous section:

$$\begin{aligned}E_2^{\mathrm{low}}(n) = {} & -[b-(a-b)E_0/\varepsilon_{n+1}]^2/\\ & [(a-b)E_0-(d/2-2e+aE_0-bE_0)E_0/\varepsilon_{n+1}]\\ & +(A_n-b/\varepsilon_{n+1}).\end{aligned}\tag{20}$$

* We are indebted to the referee for the final result of Eq. (11).

Results and Discussion

Polarizability of a Hydrogen Atom in the Ground State. The value of the polarizability, α, is twice the absolute value of E_2 caused by the perturbation, H_1, which, in this case, is z (in a.u.), the coordinate of the direction of the electric field (we will always use the atomic unit hereafter). Then,

$$\alpha = -2E_2 = 2\sum_{i>0}^{\infty}|\langle\psi_0^{(i)}|z|\psi_0\rangle|^2/(E_0^{(i)}-E_0). \quad (21)$$

In order to examine the usefulness of the present theory for the upper and lower bounds, we must calculate Eqs. (10), (11), and (20). In the calculation, the following values of integrals are required:

$$\left.\begin{aligned}&\langle\psi_0|z|\psi_0\rangle = 0,\\ &\langle\psi_0|z^2|\psi_0\rangle = 1,\\ &\langle\psi_0|zH_0z|\psi_0\rangle = 0,\\ &\langle\psi_0|zH_0^2z|\psi_0\rangle = 1/12,\\ &\text{and}\\ &\langle\psi_0|zH_0^3z|\psi_0\rangle = 5/12,\end{aligned}\right\} \quad (22)$$

in which ψ_0 is the 1s-function of a hydrogen atom and in which E_0 is $-1/2$.

In Table 1, the results for n=0, 1, 2, 3, and 4 are shown. The values of λ and μ are also shown, since they are the parameters corresponding to $1/E_0$ and $E_0/(E_0-E_0^{(i)})$ respectively.[7] Compared with the results of the lower bounds of α reported by Goodisman (μ_i=1), the present lower bounds are fairly well improved because of the existence of the μ_i parameter; the upper bounds are also better than that reported by Prager and Hirschfelder. For both the upper and lower bounds, the improvement from n=0 to n=1 is meaningful, but for $n\geqq 2$ the improvement does not seem to be substantial.

The Dispersion Force between Two Hydrogen Atoms. When the internuclear distance, R, between two hydrogen atoms in the ground state is large enough, the overlap and, hence, the exchange are insignificant; we can take $\psi_0=\psi_A(1)\psi_B(2)$ as the unperturbed wavefunction for this system, where $\psi_A(1)$ and $\psi_B(2)$ are the isolated atomic wavefunctions of the two hydrogen atoms. Besides, the perturbation, H_1, in usual notations:[9]

$$H_1 = -1/r_{B1} - 1/r_{A2} + 1/R + 1/r_{12}, \quad (23)$$

can be expanded in an inverse power series of R, and the second-order energy is generally represented by:

$$-E_2 = C_6/R^6 + C_8/R^8 + \cdots, \quad (24)$$

where:

$$C_6 = \sum_{i>0}^{\infty}|\langle\psi_0^{(i)}|H_{dd}|\psi_0\rangle|^2/(E_0^{(i)}-E_0),$$
$$H_{dd} = x_1x_2 + y_1y_2 - 2z_1z_2, \quad (25)$$

and

$$C_8 = \sum_{i>0}^{\infty}|\langle\psi_0^{(i)}|H_{qd}|\psi_0\rangle|^2/(E_0^{(i)}-E_0),$$
$$H_{qd} = (3/2)\{r_1^2z_2 - r_2^2z_1 + (2x_1x_2+2y_1y_2-3z_1z_2)(z_1-z_2)\}. \quad (26)$$

In the calculation of the bounds for C_6, we need various kinds of integrals, which are evaluated as follows:

$$\left.\begin{aligned}&\langle\psi_0|H_{dd}|\psi_0\rangle = 0,\\ &\langle\psi_0|H_{dd}^2|\psi_0\rangle = 6,\\ &\langle\psi_0|H_{dd}H_0H_{dd}|\psi_0\rangle = 0,\\ &\langle\psi_0|H_{dd}H_0^2H_{dd}|\psi_0\rangle = 1,\\ &\text{and}\\ &\langle\psi_0|H_{dd}H_0^3H_{dd}|\psi_0\rangle = 5.\end{aligned}\right\} \quad (27)$$

In Table 2, the results for C_6 using n=0, 1, 2, 3, 4, 5, 6, and 7 are shown. As in the case of polarizability, the improvement from n=0 to n=1 is remarkable, but for $n\geqq 2$ the effect is not so large.

When calculating the bounds for C_8, the following integrals are required:

$$\left.\begin{aligned}&\langle\psi_0|H_{qd}|\psi_0\rangle = 0,\\ &\langle\psi_0|H_{qd}^2|\psi_0\rangle = 135,\\ &\langle\psi_0|H_{qd}H_0H_{qd}|\psi_0\rangle = 45/2,\\ &\langle\psi_0|H_{qd}H_0^2H_{qd}|\psi_0\rangle = 207/8,\\ &\text{and}\\ &\langle\psi_0|H_{qd}H_0^3H_{qd}|\psi_0\rangle = 12501/160.\end{aligned}\right\} \quad (28)$$

In Table 3, the results for C_8 are presented in the case of n=0 and 1. It can also be seen that the improvement of the lower bound is remarkable when variable parameters, μ_i, are used in comparison with that obtained by using a constant $\mu_i=1(\mu=0)$; moreover, the improvement for both bounds from n=0 to n=1 is appreciable. The present result for the upper bound for C_8 is the best so far calculated in a non-empirical way.

From the above numerical results, it is clear that the present treatment is very tractable because of the convenient form of the variational function used. Although the numerical results are rather inferior to those in Refs. 5 and 10, the average of the both bounds for each n gives good approximations to the exact values as may be seen in Tables 1, 2, and 3. Hence, the

present treatment may be expected to be effective for larger molecular systems.

Appendix A

In deriving the upper bounds, we considered the following form of $\tilde{\phi}_1$:

$$\tilde{\phi}_1(n,\lambda,\mu) = -\sum_{i>0}^{n}(H_{1i}/\varepsilon_i)\phi_0^{(i)} + \lambda\sum_{i=n+1}^{\infty}(1+\mu E_0^{(i)}/E_0)H_{1i}\phi_0^{(i)}. \quad \text{(A-1)}$$

Now, let us refer to the first-order function derived by Lennard-Jones in order to compare it with the $\tilde{\phi}_1$ of Eq. (A-1). The function derived by Lennard-Jones is:[11]

$$\phi_1 = (H_1-E_1)\phi_0/E_0 + \sum_{i>0}^{\infty}E_0^{(i)}H_{1i}\phi_0^{(i)}/\{E_0(E_0-E_0^{(i)})\}, \quad \text{(A-2)}$$

which is reduced to:

$$\phi_1 = -\sum_{i>0}^{n}(H_{1i}/\varepsilon_i)\phi_0^{(i)} + (1/E_0)\sum_{i=n+1}^{\infty}\{1+E_0^{(i)}/(E_0-E_0^{(i)})\}H_{1i}\phi_0^{(i)}. \quad \text{(A-3)}$$

When we compare Eq. (A-1) with Eq. (A-3), it may be seen that λ and μ are taken to correspond to $1/E_0$ and the average of $E_0/(E_0-E_0^{(i)})$ respectively. If we also choose $\mu_i=1+\mu E_0^{(i)}/E_0$ for the derivation of lower bounds, there appears an integral such as $\langle\phi_0|zH_0^4z|\phi_0\rangle$ which diverges. Hence, the simplest form, $\mu_i=1$, is adopted for any i.

Appendix B

The inequality in Eq. (13) can be established not for a completely arbitrary function, but for a restricted one, under the conditions of Eq. (12). Since our variational function satisfies Eq. (12) only approximately, there remains the necessity of estimating the resulting error.

Using an arbitrary $\tilde{\Phi}$ function, Θ, which strictly satisfies the next relation:

$$\langle\Theta|\Psi^{(k)}\rangle = 0 \quad (k=1,2,\cdots,n), \quad \text{(B-1)}$$

may be rewritten as follows:

$$\Theta = \tilde{\Phi} - \sum_{i>0}^{n}\langle\Psi^{(i)}|\tilde{\Phi}\rangle\Psi^{(i)}. \quad \text{(B-2)}$$

Then, instead of Eq. (13), the inequality;

$$\langle(H-E^{(0)})\tilde{\Phi}|(H-E^{(n+1)})\tilde{\Phi}\rangle \geqq \sum_{i>0}^{n}|\langle\Psi^{(i)}|\tilde{\Phi}\rangle|^2(E^{(i)}-E^{(0)})(E^{(i)}-E^{(n+1)}), \quad \text{(B-3)}$$

may easily be obtained. Setting the exact $\Psi^{(i)}$ as:

$$\Psi^{(i)} = \phi_0^{(i)} + \phi_1^{(i)} + \cdots = \phi_0^{(i)} + \sum_{j\neq i}^{\infty}\{\langle\phi_0^{(j)}|H_1|\phi_0^{(i)}\rangle/(E_0^{(i)}-E_0^{(j)})\}\phi_0^{(j)} + \cdots, \quad \text{(B-4)}$$

ans setting $\tilde{\Phi}$ as $\tilde{\Psi}$ in Eq. (14), we obtain:

$$\langle\tilde{\Phi}|\tilde{\Psi}^{(k)}\rangle = \langle\tilde{\Psi}|\Psi^{(k)}\rangle = \langle\phi_0|\phi_0^{(k)}\rangle + \langle\phi_0|\phi_1^{(k)}\rangle + \langle\tilde{\phi}_1|\phi_0^{(k)}\rangle + \langle\tilde{\phi}_1|\phi_1^{(k)}\rangle + \cdots \quad (k=1,2,\cdots,n). \quad \text{(B-5)}$$

It can be easily seen that the first term on the right-hand side of Eq. (B-5) vanishes, and that the second and the third terms cancel each other out when we use the form of $\tilde{\phi}_1$ in Eq. (14) and that of $\phi_1^{(i)}$ in Eq. (B-4). As a result, the first non-vanishing term in Eq. (B-5) is of the second-order of the perturbation. Therefore, the value of the right-hand side of Eq. (B-3) is of the fourth-order of the perturbation and can be neglected as long as we consider the second-order energy.

The Crystal Structure of the Cupric Complex with Succinimide. II. Potassium Tetrakis(succinimidato)copper(II) Hexahydrate and Lithium Tetrakis(succinimidato)copper(II) Monohydrate

Tomitake TSUKIHARA, Yukiteru KATSUBE, Kumiko FUJIMORI, Kiyoshi KAWASHIMA, and Yoshiaki KAN-NAN

Faculty of Engineering, Tottori University, Koyama 1-1, Tottori, 680

(Received November 9, 1973)

As part of a program for the study of the crystal structure of copper(II)-complex with succinimide, the crystal structures of potassium tetrakis(succinimidato) copper(II) hexahydrate and lithium tetrakis(succinimidato) copper-(II) monohydrate have been determined by means of X-ray analysis. In the potassium-salt, the copper atom has a square planar coordination and the potassium ion has a trigonal prismatic environment formed by six oxygen atoms. In the lithium-salt, the copper atom has a flattened tetrahedral coordination, and each lithiun ion is tetrahedrally surrounded by four oxygen atoms. The conformational difference between the complex anion of the potassium-salt and that of the lithium-salt seems to result from the different sizes of the alkali-metal ions.

As part of a systematic study of the crystal structures of the copper(II)-complexes, crystal structure analyses of the $M_2(Cu(sucim)_4)nH_2O$ type, where M indicates an alkalimetal, have been planned to find the conformational features around the metals that might be responsible for the difference between the crystal structures of the complexes. The first investigation in this series was the crystal structure determination of $Cs_2(Cu(sucim)_4)2H_2O$.[1] In this paper, the crystal structures of $K_2(Cu(sucim)_4)6H_2O$ and $Li_2(Cu(sucim)_4)H_2O$ will be described.

Experimental and Structure Determination

*Potassium Tetrakis(succinimidato)copper(II) Hexahydrate.** Pink-colored crystals in the form of platelets were prepared by the method described by Tschugaeff.[2] Since the crystals effloresce easily in air, the crystals were sealed in glass capillaries for the X-ray work.

Preliminary Weissenberg and oscillation photographs showed the crystals to be triclinic; the crystal data are listed in Table 1.

For the 0kl–5kl layers about the *a* axis, intensity data were collected by the equi-inclination Weissenberg method with Cu$K\alpha$ radiation. A large crystal with the approximate dimensions of $0.6\times0.6\times0.2$ mm^3 was used for the collection of the data, because the crystal of a suitable size for the X-ray work was consumed within one layer's exposure. Therefore, the data collected were not of a high degree of accuracy. A total of 1515 reflections was obtained, and the intensities were estimated visually with a standard scale. The usual Lorentz and polarization corrections were applied, but no correction was made for absorption and extinction. Corrections for variation in spot-size on the high-layer-line photographs were made by the method presented by Phillips.[3]

Chemical units per unit cell:	1	4
D(calculated):	1.64 g/cm^3	1.59 g/cm^3
D(observed):	1.63 g/cm^3	1.57 g/cm^3

The space group was initially assumed to be $P\bar{1}$, implying a center of symmetry in the complex. The copper atom was placed at the origin of the unit cell, and approximate coordinates for the remaining atoms were obtained by Patterson synthesis and successive Fourier syntheses. The atomic positions and temperature factors were refined by a block-diagonal least-squares method. After several refinement cycles, the structure converged, with an *R*-value of 16%. The refinement with the *P*1 space group did not improve the *R* value and showed no tendency to destroy the center of symmetry. Thus, the space group was confirmed to be $P\bar{1}$.

All the atomic scattering factors were taken from the "International Tables for X-ray Crystallography."[4] Those of the copper and potassium atoms were corrected for anomalous dispersion, and anisotropic temperature factors were introduced for the copper and potassium atoms.

The final composite electron density and atomic parameters are shown in Fig. 1 and Table 2 respectively. The mean estimated standard deviations of the positional para-

meters are 0.02 Å for the carbon, nitrogen, and oxygen atoms and 0.006 Å for the potassium atom.

*Lithium Tetrakis(succinimidato)copper(II) Monohydrate.*** Blue-colored, needle-like crystals were prepared by the same procedure as was used for the potassium-salt. Since the crystals were hygroscopic, the crystals for the X-ray work were sealed in glass capillaries. The crystals were monoclinic, with a space group of $P2_1/a$; the cell dimensions are shown in Table 1.

The intensity data were collected for the crystal ($0.05\times 0.40\times 0.05$ mm^3) rotating about the c axis, allowing the observation of 1869 independent reflections ($l=0$—6). The procedure of the determination of the structure was similar to that used in the case of the potassium-salt. The position of the copper atom was deduced from Patterson synthesis; a Fourier synthesis based on the phases determined by the copper atom revealed all of the non-hydrogen atoms except the lithium ions. The positions of the lithium ions were found by a difference Fourier synthesis. The refinement was carried out by the block-diagonal least-squares method; the final R value was 13%. The final atomic parameters are shown in Table 3. The estimated standard deviations of the

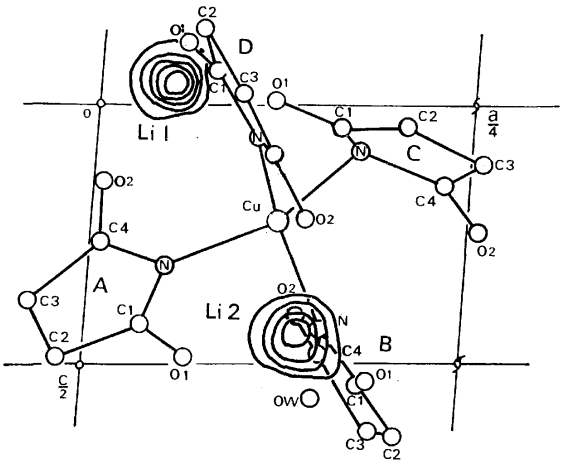

Fig. 2. The composite difference electron density map for $Li_2(Cu(sucim)_4)H_2O$. The contributions of the hydrogen atoms and lithium ions were excluded from the calculated structure factors. Two lithium ions are clearly shown in the map. The contours are drawn at intervals 0.05 e/Å^3 starting at 0.05 e/Å^3 for lithium ions, and there is no other peak higher than 1.2 e/Å^3.

positional parameters are 0.05 Å for the lithium ions, 0.02 Å for the carbon, nitrogen, and oxygen atoms and 0.003 Å for the copper atom.

Results and Discussion

Geometry of the Coordination around the Copper Atom. In the present series of complexes, each of the copper atoms is coordinated by four nitrogen atoms from four succinimides. The bond lengths and angles around the copper atoms for the potassium- and lithium-salts are shown in Fig. 3.

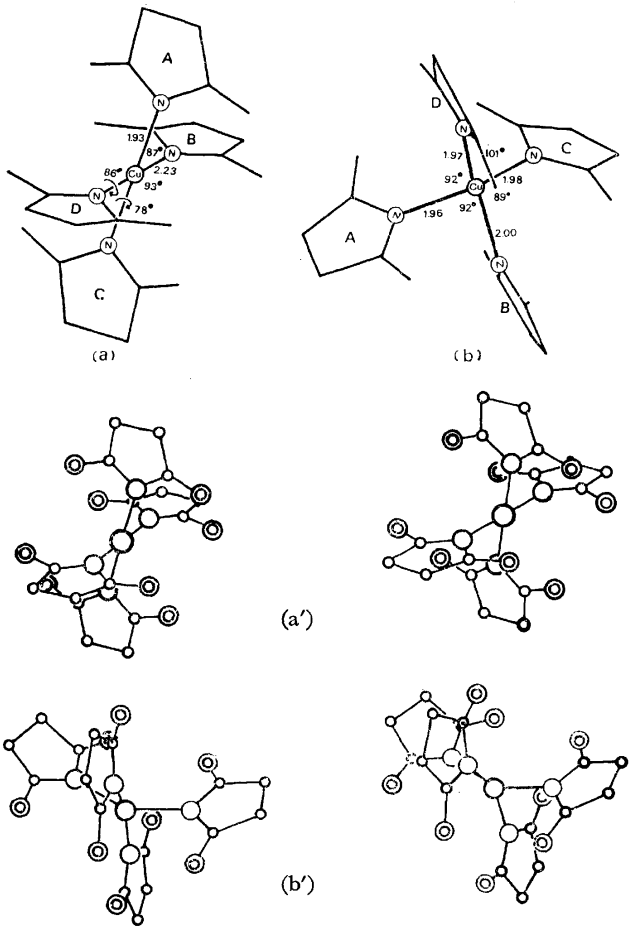

Fig. 3. The geometry around the copper atom.
(a) and (a'): Potassium-salt
(b) and (b'): Lithium-salt
(a') and (b') are the stereographic illustrations.

In the potassium-salt, the coordination around the copper atom is square planar and the complex anion is centrosymmetric. The coordination plane defined by the copper atom and four nitrogen atoms is, therefore, exactly planar. Although a distortion from an ideal square planar configuration may be evident in the different lengths of the Cu–N bonds and in the different angles of the N–Cu–N's, this can not be discussed in detail because of the low accuracy of the present analysis. Each plane of the succinimide residues is tilted by 82° to the coordination plane. Thus, the whole structure of the complex anion of the potassium-salt has a slightly distorted D_{4h} symmetry. This configuration for the anion agrees with that proposed spectroscopically by Yamada *et al.*[5]

In the lithium-salt, the coordination around the copper atom may be considered as either a distorted square planar or a distorted flattened tetrahedron. This configuration of the coordination resembles that of bis(*N*-ethyl-salicylaldiminato)copper(II) monohydrate[6] and that of 2,2'-biphenylbis(2-iminomethylenephenolato)copper(II).[7] The bond angles around the copper atoms in these complexes are listed in Table 4. Such a coordination polyhedron has generally been described as a tetrahedron distorted in the flattened form.

TABLE 4. BOND ANGLES AROUND THE COPPER ATOM

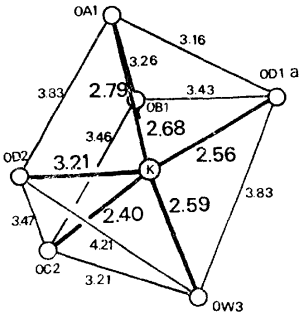
N(B)–Cu–N(D)	155	N–Cu–N'	157	
Average	152		155	152

* Crystal I, II, and III represent lithium tetrakis(succinimidato)copper(II), monohydrate, bis(*N*-ethylsalicylaldiminato)copper(II),[6] and 2,2'-biphenylbis(2-iminomethylenephenolato)copper(II),[7] respectively.

Environment of the Alkali-metal Ion. The distances around the alkali-metal ions are shown in Fig. 4. The mean distance from the alkali-metal ion to the oxygen atom in the individual complex is in fairly good agreement with the sum of their ionic radii: 3.11 Å for Cs–O, 2.71 Å for K–O, and 1.93 Å for Li–O respectively.

In the case of the potassium-salt, each of the K^+ ions is surrounded by six oxygen atoms at the corners of a distorted trigonal prism. One of these oxygen atoms belongs to the water molecule, while the remaining



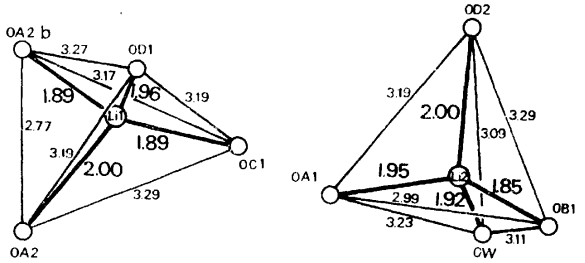


Fig. 4. The environment of the alkali-metal ion.

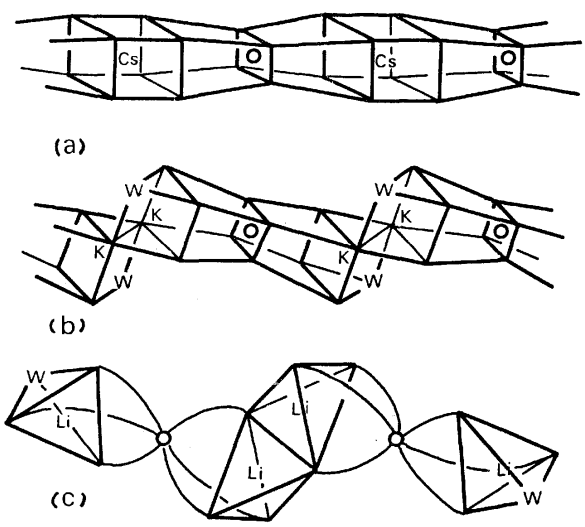

Fig. 5. The arrangements of coordination polyhedra around the alkali-metal ions in (a) cesium-salt, (b) potassium-salt and (c) lithium-salt. Circle and W represent the copper atom and the water oxygen atom, respectively.

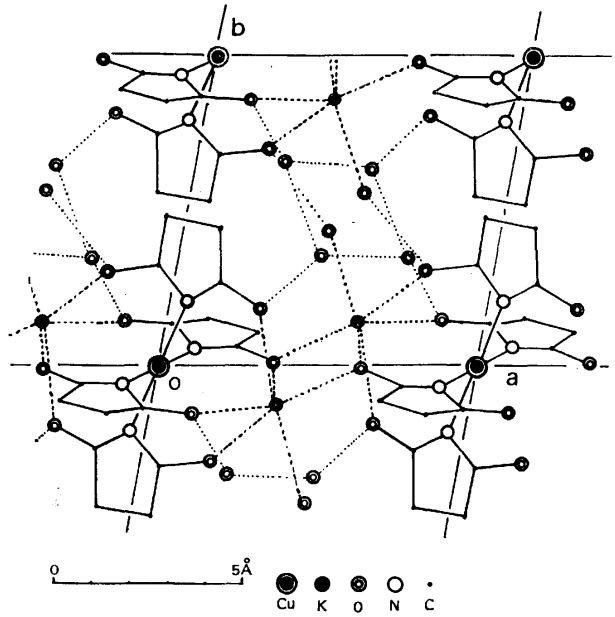

Fig. 6. The crystal structure of potassium-salt.

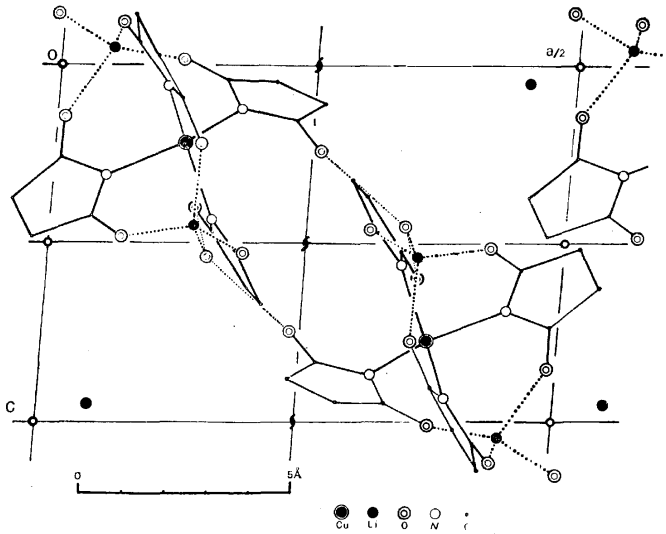

Fig. 7. The crystal structure of lithium-salt.

five are the carbonyl oxygen atoms. Of these five carbonyl oxygen atoms, the four lying on the corners of a rectangular face of the prism, OA1, OB1, OC2, and OD2, belong to the same complex anion. Two trigonal prisms related to each other by a center of symmetry share an edge. Thus, an endless chain having the –A–K·K– sequence, where A indicates the complex anion and where K·K denotes two polyhedra sharing an edge, is formed. The chain formed by electrostatic interactions between the K^+ ions and the oxygen atoms is schematically shown in Fig. 5. The crystal structure consists of these chains held together by hydrogen bonds involving the water molecules.

In the case of the lithium-salt, two independent Li^+ ions exist in the structure. Both lithium ions have tetrahedrally-distributed oxygen neighbors; $Li(1)^+$ is surrounded by four carbonyl oxygen atoms, while $Li(2)^+$ has three carbonyl oxygen atoms and one water oxygen atom as neighbors. Of the eight carbonyl oxygen atoms in the complex anion, three coordinate to $Li(1)^+$, another three coordinate to $Li(2)^+$, and the remaining two are free. Such an arrangement of the carbonyl oxygen atoms with respect to the Li^+ ions may impose a large distortion from the D_{4h} symmetry upon the structure of the complex anion. Two tetrahedra related to each other by a center of symmetry are condensed by sharing an edge. The compositions of Li–A–Li·Li–A–Li, which are formed by electrostatic interactions between the Li^+ ions and the oxygen atoms, are linked together to form an infinite chain by the hydrogen bonds between the water molecules and the carbonyl oxygen atoms which are free from the Li^+ ions.

The crystal structures and the hydrogen-bonding schemes are illustrated in Figs. 6 and 7.

Consequently, it appears that the size of the alkali-metal ion may govern the structure of the complex.

The authors wish to express their thanks to Dr. Tamaichi Ashida for permission to use his program and to Dr. Seiko Komorita for her valuable discussions and for kindly supplying the samples.

Isoelectric Point of Manganese Oxide

Tetsuo MORIMOTO and Shigeharu KITTAKA*

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700
**Department of Chemistry, Faculty of Science, Okayama College of Science, Ridaicho, Okayama 700*

(Received December 3, 1973)

The isoelectric point (IEP) of manganese oxide is measured on samples prepared by heating β-MnO_2 and amorphous manganese oxide, $MnO_{1.75}$, at temperatures from 200 to 1400 °C. The IEP values thus obtained are characteristic of each stage of the oxidation of manganese oxide; that is, <5.1 for MnO_2, 7.6—9.0 for α-Mn_2O_3, and 3.3—5.2 for Mn_3O_4. These values can be explained by the electrostatic interaction theory introduced by Parks, in which the CFSE correction is eliminated. It is also found that manganese ions with specific valencies are responsible for the electrification of the surfaces of manganese oxide.

In order to clarify the origin of the electrification of metal oxides in aqueous media, the present authors have measured the electrokinetic potential (ζ-potential) or isoelectric point (IEP) of TiO_2,[1,2] Al_2O_3, Cr_2O_3, and Fe_2O_3[3-5] in electrolyte solutions. The results obtained indicate that the electrification of these metal oxides is generally determined by the electrostatic interaction between a metal ion on the solid surface and the H^+ ion in the surface hydroxyl group bonded to the metal ion,[4] to which the crystal structure of the oxide and the valency of the metal ion concerned are decisively responsible. A number of papers[6-8] have been published concerning the study of the IEP of metal oxides, but a very few works have related IEP to the crystal structure of a metal oxide and the valency of the component metal ion, which changes step-by-step upon heat treatment.[4,9]

The heat treatment of manganese oxide gives three types, which differ in the valency of the manganese ion, *i.e.*, MnO_2, Mn_2O_3, and Mn_3O_4. Fuerstenau *et al.*[10] have studied the electrification of manganese oxide, but only that of MnO_2. The purpose of this study is to measure the IEP of three kinds of manganese oxides which differ in composition, and to investigate the origin of the electrification of the oxides.

Experimental

Materials. Two samples of manganese oxide were used in this study. One was β-MnO_2 (MI), which was prepared by the pyrolysis of $Mn(NO_3)_2$ by heating it at 160 °C for 500 hr in air. The other was amorphous manganese oxide (MII), which was precipitated by mixing a 1 mol/l $Mn(NO_3)_2$ solution with 3 mol/l ammonia water in the presence of H_2O_2. The two samples were treated at various temperatures from 200 to 1400 °C for 3 hr in air, and then washed with distilled water until the ionic impurities in the filtrate disappeared; this resulted in the complete hydration of the surfaces.

The crystal structure of the samples was analyzed by the X-ray diffraction method, and the thermal analysis was carried out by means of the TGA method, in which the temperature was raised at the rate of 20 °C/min.

Measurement of IEP. The IEP of the samples was obtained by measuring the ζ-potential in aqueous solutions of various pH values. The ζ-potential was measured at 25.0 °C by using the streaming potential method, the Helmholtz-Smoluchowski equation being used as has been described previously.[3] The pH value was varied with HCl and NaOH. In order to keep the thickness of the electrical double layer constant and in order to eliminate the effect of surface conductance on the ζ-potential measurement,[11,12] the ionic strength was adjusted at 10^{-3} mol/l by using a NaCl solution. The deionized water used for the experiments was further purified by double distillation from an alkaline permanganate solution; prior to the measurement N_2 was bubbled in to remove any dissolved carbon dioxide.

Results and Discussion

Figure 1 shows the TGA data of the samples. It may be seen from Fig. 1 that the decomposition of MI starts at 540 °C and finishes at 650 °C to form Mn_2O_3, and that the latter decomposes at 920 °C to produce Mn_3O_4. On the other hand, the first sharp decomposition of MII occurs between 420 and 560 °C, while the second one occurs in the same temperature range as that of MI. X-Ray analysis showed that the MI sample has the structure of β-MnO_2, whereas the MII sample is amorphous; it has a nonstoichiometric composition, $MnO_{1.75}$, at room temperature, as is found by calculating from the data in Fig. 1. Furthermore, it was found that both samples represent α-Mn_2O_3 from 600 to 900 °C and Mn_3O_4 over 1000 °C, while the crystallinity of the α-Mn_2O_3 and Mn_3O_4 prepared from MII is more excellent than that prepared from MI.

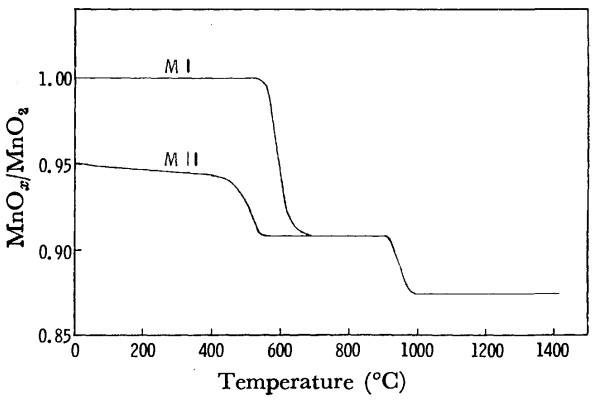

Fig. 1. TGA curve of manganese oxides.

The ζ-potential of MI is plotted against the pH value in Fig. 2. It may be seen clearly from Fig. 2 that the pH value of the zero point of charge, *i.e.*, IEP, changes remarkably with the pretreatment temperature of the samples. The IEP of MI and MII is plotted in Fig. 3 as a function of the temperature of pretreatment.

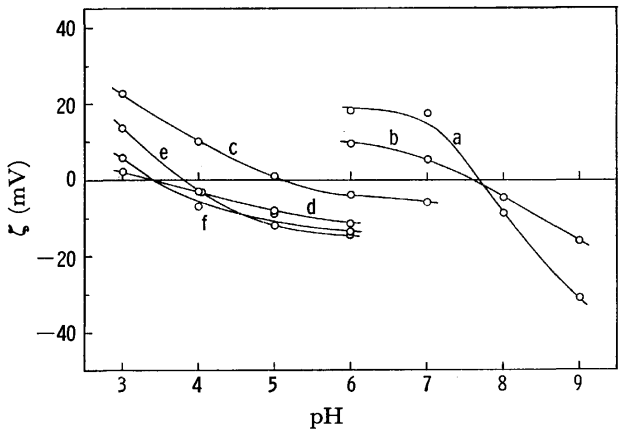

Fig. 2. ζ-potential of manganese oxide MI against pH, pretreated at a 500, b 800, c 900, d 1000, e 1200 and f 1400 °C.

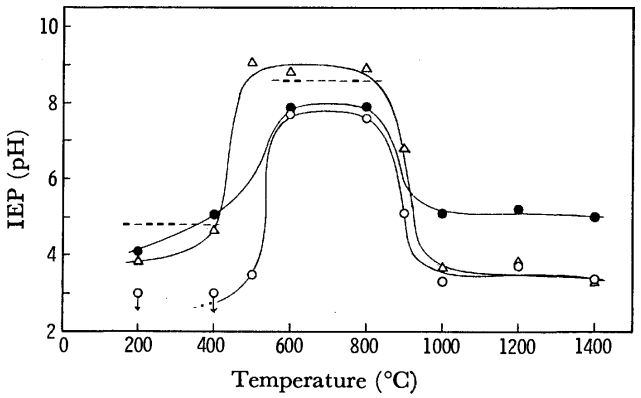

Fig. 3. IEP of manganese oxides against pretreatment temperature, ○ MI, ● crushed MI, and △ MII.

In this figure, the IEP of the samples which were obtained by crushing MI in an agate mortar is also added. Since the measurement of the ζ-potential of the samples pretreated below 400 °C (below 500 °C in the case of MI), however, was very difficult because of the high electric conductivity of the solids, the IEP in this temperature range was determined from the point where the sign of the streaming potential changed.

The comparison of the change in composition (Fig. 1) with the change in IEP (Fig. 3) makes it possible to infer that each oxidation state of manganese oxide has a characteristic value of IEP: that is, <5.1 for MnO_2, 7.6—9.0 for α-Mn_2O_3, and 3.3—5.2 for Mn_3O_4. Parks[6] has introduced a simi-empirical relation which describes the IEP of metal oxides can be expressed by this equation:

$$\text{IEP} = A - 11.5\left[\frac{Z}{R} + 0.0029a\right]. \quad (1)$$

Here, A is a constant which depends on the extent of surface hydration and the coordination number of surface metal ions, being 18.6 for fully-hydroxylated surfaces of metal oxides containing octahedrally-coordinated metal ions; Z is the valency of the metal ion. R is the distance between a surface metal ion and the H^+ ion in the surface hydroxyl group attached to the metal ion, that is, the sum of the radius of the metal ion and the diameter of the adjacent O^{2-} ion. a is the crystal-field stabilization energy for the hydration of metal ions, the second term in the bracket being the correction term for the coulombic interaction between a H^+ ion and the surface of a metal oxide. A preliminary calculation indicates that this correction is generally small in the present samples.

By introducing the crystallographic data into Eq. (1), IEP can be calculated to be 4.8 and 8.6 for β-MnO_2 and α-Mn_2O_3 respectively; they are represented as dotted lines in Fig. 3. Figure 3 shows that the observed and calculated values of IEP agree well with each other except for the data on uncrushed MI below 500 °C. It is interesting to note that IEP approaches more closely to the calculated value when the sample is crushed. This may be due to the fact that, on pyrolyzing and oxidizing the original samples at 160 °C in air, an excess of oxygens is bonded to surface metal ions, thus giving rise to a higher oxidation state of the metal ions.

As is well known, the structure of Mn_3O_4 is a spinel exhibiting the tetragonal form. The oxidation state of manganese ions and their coordination number to oxygen in Mn_3O_4, however, are subject to dispute; the formulas of $Mn^{2+}[Mn_2^{3+}]O_4$,[13] $Mn^{3+}[Mn^{2+}Mn^{3+}]O_4$,[14] and $Mn^{2+}[Mn^{2+}Mn^{4+}]O_4$[15] have been proposed, where the manganese ions in and outside the bracket are those of the coordination numbers of 6 and 4 respectively. The calculation of IEP for every type of these manganese ions according to Eq. (1) gives the values of 12.2, 9.6, and 5.8 for the octahedrally-coordinated Mn^{2+}, Mn^{3+} and Mn^{4+}, and 9.2 and 5.6 for the tetrahedrally-coordinated Mn^{2+} and Mn^{3+}, respectively. The observed value, 5.1, of IEP on the crushed MI approximates the calculated values, 5.6 and 5.8. This suggests that the octahedrally-coordinated Mn^{4+} and/or tetrahedrally-coordinated Mn^{3+} ions will determine the IEP of the samples. On the other hand, the IEP of uncrushed MI and MII are considerably smaller than these calculated values. This fact may be considered to depend on the characteristic features of the surfaces of Mn_3O_4 treated at elevated temperatures. If the Mn^{4+} ions tetrahedrally coordinated by oxygens are formed on the surfaces, then the calculated IEP will result in the value of 2.1. Thus, it may be possible to infer that the tetrahedrally-coordinated Mn^{4+} ions coexist along with tetrahedrally-coordinated Mn^{3+} and/or octahedrally-coordinated Mn^{4+} ions on the actual surface of Mn_3O_4.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. IX.[1] Polynitrobenzoic Acid Complexes with Aromatic Monoamines

Yoshio MATSUNAGA and Ryuzo OSAWA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 7, 1973)

When 2,4,6-trinitrobenzoic acid is combined with aromatic monoamines, true benzoates are mostly formed. However, not only a white true benzoate, but also a red 2: 1 complex of the CPT type, in which charge-transfer and proton-transfer interactions operate simultaneously between the component molecules, were obtained with aniline. In addition, the brown 2,4,5-trimethylaniline complex reported by Noelting and Sommerhoff was found to be of a similar nature. The phenomenon of complex isomerism was observed upon combination with *o*-chloroaniline; that is, the colorless salt isomerizes into an orange-colored charge-transfer complex at about 133 °C. Only the complexes with *p*-dimethylaminobenzaldehyde and *o*-nitroaniline, which have the lowest pK_a values among the amines examined, and those with the halogenated 2-naphthylamines are of the charge-transfer type. The 3,5-dinitrobenzoic acid complexes were also examined. Complexes of the CPT type with a 3: 2 composition were isolated with aniline and *p*-toluidine.

The combination of an aromatic amine and a polynitrophenol is known to form a true phenolate by acid-base interaction or a charge-transfer (CT) complex by electron donor-acceptor interaction. In addition, some interesting phenomena have been noted with the complexes of such bifunctional component molecules. Many years ago, Hertel demonstrated that the same components, if appropriately chosen, can form either phenolates or CT complexes, depending upon the ambient conditions.[2] This phenomenon was named "complex isomerism" by this author. Further pairs of complex isomers have been presented in a previous paper of the present series.[3] Secondly, our study of the vibrational and electronic spectra of the orange-colored 1-naphthylamine-picric acid (2: 1) complex revealed that a proton is transferred from the acid to the amine, and that the interaction between the picrate ion and the second amine molecule is capable of producing a CT absorption band.[4] For brevity, such a complex was denoted as a complex of the CPT type because of the simultaneous operation of CT and proton-transfer (PT) interactions between the component molecules. Many complexes of a similar nature, including the brick red *o*-toluidine–picric acid (1: 1), the reddish orange tryptophan picrate, and the orange-red *o*-toluidine-tetranitrobiphenyldiol (2: 1), have been prepared by us.[1,5-7]

Bifunctional component molecules are not limited to aromatic amines and polynitrophenol. The present work will be concerned with the behavior of polynitrobenzoic acids when subjected to complexation with aromatic monoamines. 2,4,6-Trinitrobenzoic acid, hereafter abbreviated as TNBA, was selected for this purpose, because not only its strength as an acid but also that as an electron acceptor are well comparable with those of picric acid.[8,9] The salts of TNBA with fourteen aromatic amines, including aniline, 2,4,5-trimethylaniline, *m*-nitroaniline, and naphthylamines, were prepared by Sudborough and his collaborators as early as the turn of the century.[10,11] They noted that all the salts become dark when heated and then melt, evolving a considerable quantity of gas and yielding a dark red oil. The melting points were observed to depend on the rate of heating. The red product was identified by Sudborough to be the corresponding *s*-trinitrobenzene (TNB) complex formed by the decarboxylation of TNBA.[12] Moreover, Noelting and Sommerhoff isolated a colorless salt by combining TNBA and 2,4,5 trimethylaniline in cold ethanol and a brown complex in warm methanol.[13] The nature of the latter was left unclarified. In addition, we studied the complexes of 3,5-dinitrobenzoic acid (DNBA) in the present investigation.

Experimental

Materials. The polynitrobenzoic acids, all the derivatives of aniline, and 1-naphthylamine used in this work were commercially obtained. The 1-chloro-2-naphthylamine was prepared by the procedure of Cleve,[14] and the 1-bromo- and 1,6-dibromo-2-naphthylamines, by those of Franzen and Eidis.[15] The complexes were precipitated by mixing the component compounds separately dissolved in ethanol.

Measurements. The vibrational spectra of the solid complexes were measured as hexachloro-1,3-butadiene mulls in the region from 2000 to 4000 cm^{-1} and as Nujol mineral oil mulls in the region from 1500 to 1800 cm^{-1} with a Jasco IR–G infrared spectrophotometer, and the electronic spectra of the powdered complexes sandwiched between two quartz plates in the visible region, with a Beckman DK-2A spectroreflectometer. The calorimetric curves were recorded on a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C, at a heating rate of 3 °C/min. The heats of transition were estimated by comparing the peak areas with that for the transition in hexamethylbenzene, which is known to take place at 110.6 °C with ΔH=0.422 kcal/mol.[16]

Results and Discussion

TNBA Complexes. The solid complexes with the following twenty-three amines (arranged in the order of decreasing pK_a values) were found to be colorless or pale yellow, in accordance with the work by Lloyd and Sudborough:[10] *N,N*-diethyl-*m*-toluidine (pK_a= 7.12), *N,N*-diethylaniline (6.61), *p*-anisidine (5.31),

* Present address: Bridgestone Tire Co., Kodaira, Tokyo.

p-phenetidine (5.20), *N*-butylaniline (5.12), *N*-ethylaniline (5.12), *p*-toluidine (5.10), 2,4,5-trimethylaniline (4.96), *m*-xylidine (4.89), *N*-methylaniline (4.84), *m*-toluidine (4.69), aniline (4.60), *o*-anisidine (4.52), *o*-toluidine (4.39), *m*-aminophenol (4.3), *m*-anisidine (4.20), *p*-chloroaniline (4.15), 1-naphthylamine (3.96), *m*-chloroaniline (3.46), *o*-chloroaniline (2.65), *o*-iodoaniline (2.60), *o*-bromoaniline (2.53), and *m*-nitroaniline (2.46). As no experimental pK_a value is available for 2,4,5-trimethylaniline,[17] the value predicted by the equation of Clark and Perrin is used above.[18] The large shift of the carbonyl-stretching vibrational band clearly indicates that the expected PT from TNBA to the amines is taking place in these complexes. While TNBA exhibits a band at about 1730 cm^{-1}, the salts have a band around 1630 cm^{-1} attributable to the COO^- group. Additional evidence for the PT is provided by the replacement of an NH_2 pattern by a NH_3^+ pattern when the amines are primary. Furthermore, an examination of the vibrational spectrum revealed that the red decomposition product is essentially the corresponding TNB complex, as was noted by Sudborough and also by Noelting and Sommerhoff.[12,13] As has been demonstrated with picrates and 2,4-dinitrophenolates,[19] the phenomenon of complex isomerization by melting may be expected to be observed with the complexes with some amines with relatively low pK_a values if there is no decarboxylation.

In addition to the colorless trinitrobenzoate, a red complex with a 2:1 mole ratio was isolated with aniline by employing an excess of the donor component. Calcd for $2C_6H_7N \cdot C_7H_3N_3O_8$: C, 51.46; H, 3.83; N, 15.79%. Found: C, 51.39; H, 3.84; N, 15.86%. The vibrational spectrum has a carbonyl-stretching band at about 1630 cm^{-1}, indicating the PT from the acid to the amine and both the NH_2 and NH_3^+ patterns in the region from 2300 to 3500 cm^{-1}. Consequently, it is certain that this complex consists of anilinium trinitrobenzoate and aniline. The diffuse reflectance spectrum given in Fig. 1 is almost identical with that of the aniline-TNB complex. The absorption appearing upon the incorporation of the second aniline molecule is undoubtedly to be ascribed to a CT interaction between the amine molecule and the trinitrobenzoate ion. Therefore, this is a complex of the CPT type as defined in our previous paper.[5] As the acceptor-strength of TNBA is comparable with that of TNB,[9] the effect of the dissociation of the carboxyl group appears to be negligible. This conclusion is in accordance with that for the case of picric acid.[4,20] The brown 2,4,5-trimethylaniline complex reported by Noelting and Sommerhoff was found to be of a 3:2 composition. Calcd for $3C_9H_{13}N \cdot 2C_7H_3N_3O_8$: C, 53.54; H, 4.93; N, 13.70%. Found: C, 54.08; H, 5.15; N, 14.22%. Here again, a close similarity in the diffuse reflectance spectrum was observed between this complex and the corresponding TNB complex (see Fig. 1). It is evident that this deeply colored complex is also of the CPT type. This conclusion is supported by the presence of the NH_2, NH_3^+, and COO^- patterns in the vibrational spectrum.

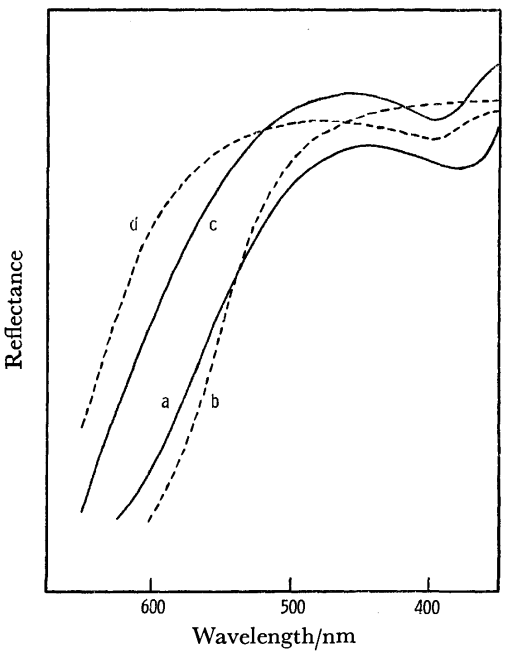

Fig. 1. Reflectance spectra of a) the aniline–TNBA (2:1) complex, b) the corresponding TNB complex, c) the 2,4,5-trimethylaniline–TNBA (3:2) complex, and d) the corresponding TNB complex.

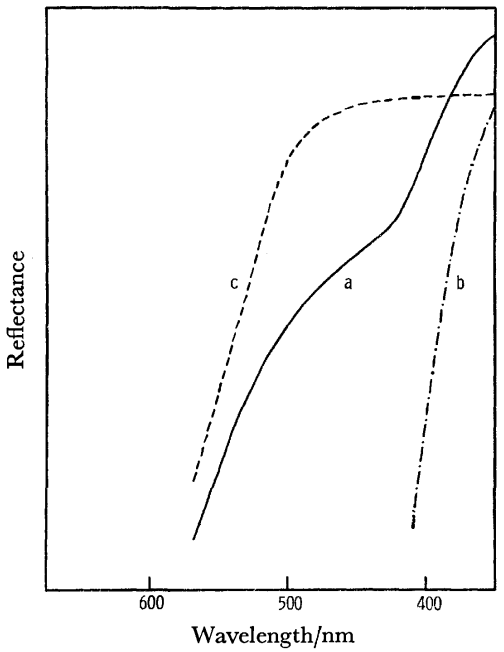

Fig. 2. Reflectance spectra of a) the orange form and b) the colorless form of the *o*-chloroaniline-TNBA complex and c) the corresponding TNB complex.

The most interesting result of the present work is the complex isomerism observed with the *o*-chloroanilinium salt. The colorless benzoate was found to turn orange at about 133 °C. Calcd for $C_6H_6NCl \cdot C_7H_3N_3O_8$: C, 40.57; H, 2.34; N, 14.56; Cl, 9.23%. Found: C, 40.41; H, 2.21; N, 14.58; Cl, 8.96%. The color change is due to the appearance of an absorption in the region from 410 to 600 nm; see Fig. 2. This location is in good agreement with that of the CT absorption in the corresponding TNB complex. The transition is accompanied by a drastic change in the

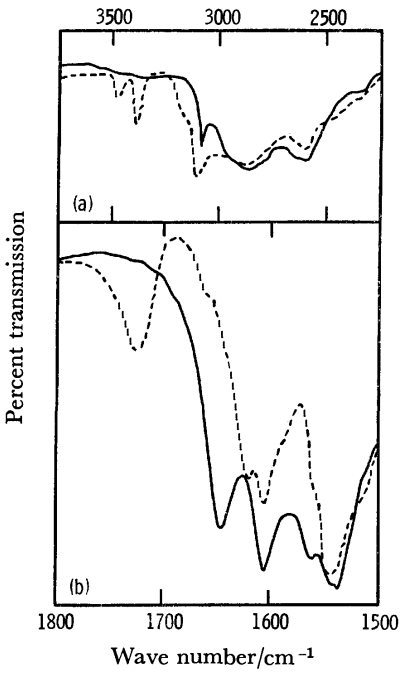

Fig. 3. Vibrational spectra of the colorless form (——) and the orange form (------) of the *o*-chloroaniline–TNBA complex.

vibrational spectrum. As is shown in Fig. 3, the appearance of an NH_2 pattern is noted above the transition temperature. Moreover, the carbonyl-stretching band located at 1650 cm^{-1} in the colorless form is replaced by the one located at 1730 cm^{-1} in the orange form. The X-ray diffraction patterns of these two forms are distinctly different from each other. The complex melts at about 145 °C. The narrow temperature difference between the transition point and the melting point did not allow us to carry out the above-mentioned measurements at high temperatures. Therefore, samples heated a little above the transition point with the differential scanning calorimeter and then cooled as quickly as possible were employed for the spectroscopic and X-ray examinations. These observations lead to the conclusion that the benzoate isomerizes into a CT complex at about 133 °C. The heat of this enantiotropic transition was estimated to be about 2.2 kcal/mol. It must be added that this value is markedly smaller than those observed with the transitions in Hertel's picric acid complexes; that is, 6—8 kcal/mol.[21] Previously it was noted that the chance of finding complex isomers is high in the salts derived from halogenated amines, especially *o*-haloanilines.[3] The newly-found pair fits into this group. As to the electron-acceptor components, it may be said that all the component compounds so far found have two nitro groups at the *ortho* positions related to the proton-donating group; namely, 2,6-dinitrophenol, picric acid and its alkyl derivatives, 3,3′,5,5′-tetranitrobiphenyl-4,4′-diol, and the present acid.[2,3,7]

The complexes with *p*-dimethylaminobenzaldehyde and *o*-nitroaniline, which have the lowest pK_a values among the amines examined (1.62 and −0.26 respectively) are deeply colored. Their vibrational spectra indicate the lack of PT; therefore, these two complexes may be supposed to be of the CT type. The pK_a value of the former amine is significantly higher than that of the acid, 0.65, suggesting that pK_a is not a good measure of the acid strength in these molecular solids or that the pK_a value of TNBA is a little too small. It must be noted that, in contrast to the case studied here, we have seen a good coincidence between the pK_a value of the acceptor component and the lower limit of the pK_a range when PT occurs in the complex formation of 2,4-dinitrophenol.[19] 1-Chloro-, 1-bromo- and 1,6-dibromo-2-naphthylamines are known to form true phenolates with picric acid which isomerize into CT complexes at the transition points.[2,22] Their TNBA complexes are as red as the TNB complexes are. Because of the deep coloration and the presence of the NH_2 and COOH patterns in the vibrational spectra, these three complexes are also considered to be of the CT type.

DNBA Complexes. Solid complexes were obtained with all the above-mentioned anilines except *m*- and *o*-nitroanilines. The fifteen anilines among the seventeen with pK_a values higher than 4.15 give colorless or pale yellow benzoates. The pK_a value of the last aniline in this group is, again, markedly higher than that of DNBA, that is, 2.82.[8] They easily lose the electron-donor component upon heating; therefore, we did not attempt to examine the possible complex isomerization by melting. However, the observation made by Ley and Grau of the diethylanilinium salt might be related to this phenomenon. This salt, with a melting point of 93 °C, was reported to turn a brownish red at 70 °C when heated under water.[23] The calorimetric measurements indicated that a transition without complex isomerization takes place at 108 °C in the pale-yellow *m*-hydroxyanilinium salt. Calcd for $C_6H_7NO \cdot C_7H_4N_2O_6$: C, 48.61; H, 3.45; N, 13.08%. Found: C, 49.75; H, 3.60; N, 13.03%. The enthalpy change is as small as 1.3 kcal/mol, reflecting the absence of complex isomerization.

p-Toluidine and aniline give deep orange-colored complexes of a 3: 2 composition. Calcd for $3C_7H_9N \cdot 2C_7H_4N_2O_6$: C, 56.39; H, 4.73; N, 13.15%. Found: C, 55.93; H, 4.72; N, 13.11%. Calcd for $3C_6H_7N \cdot 2C_7H_4N_2O_6$: C, 54.62; H, 4.15; N, 13.93%. Found: C, 54.49; H, 4.12; N, 13.98%. As may be expected from the high pK_a values of these amines, the spectroscopic examinations revealed that these two complexes are of the CPT type. Since we made no effort to prepare such complexes, their isolation may have been rather accidental and the formation of this type of complexes may not be limited to these two amines. The CT complex-forming ability of the 3,5-dinitrobenzoate ion has been known by the work of Menger and Bender on complexes in an aqueous solution with *N*-(indole-3-acryloyl)-imidazole and two more compounds, and also by the work of Colter and Grunwald on a complex in an aqueous solution with 1-naphthol.[24,25] However, no solid complex containing the anion as an electron-acceptor has been isolated. The five anilines the pK_a values of which are in the range from 3.46 to 1.62 form complexes of the CT type.

Dielectric Relaxation and Molecular Structure. XI. Dielectric Behavior of Various Polar Molecules in the Supercooled *o*-Terphenyl Solution

Masahiko NAKAMURA, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received December 7, 1973)

The dielectric constants and losses of dilute solutions of anthrone, xanthone, phenothiazine, 9-fluorenone, benzophenone, diphenylnitrosamine, 1,8-dinitronaphthalene, *p*-nitrotoluene and *m*-nitrophenol in *o*-terphenyl have been measured in the supercooled state in the frequency range 1—100 MHz and temperature range 15—30 °C. The results have been analyzed by Davidson-Cole's skewed-arc method to calculate the relaxation times, the distribution parameters, the activation enthalpies and entropies for the dielectric relaxation processes.

Davidson and Cole[1] found that glycerol and propylene glycol in the supercooled liquid state show the skewed-arc behavior and introduced the empirical equation

$$\varepsilon' - j\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{(1+j\omega\tau_0)^\beta} \quad (1)$$

where ε_0 and ε_∞ are the limiting low and high frequency dielectric constants, respectively, ω is the angular frequency, τ_0 the characteristic relaxation time and β the distribution parameter. When β is equal to unity, the locus becomes a Debye-type semicircle.

Recently Shears and Williams made dielectric measurements on various polar molecules in supercooled *o*-terphenyl solution.[2] The absorption curves were found to be unsymmetrical and broader than expected for any Debye relaxation process; large activation energies were obtained in agreement with the cooperative process.

The present study has been conducted since little information is available on the dielectric behavior of the supercooled state in this particular solvent. *o*-Terphenyl provides a medium having viscosity so high that the region of dielectric absorption is in the range 1—100 MHz at room temperature.

Experimental

Materials. Commercial chemicals were carefully purified by recrystallization before use. The melting and glass transition points of *o*-terphenyl are 58 and −29 °C, respectively. The measurements were carried out not in a glassy state, but in the state of so-called metastable equilibrium.[3] Crystallization in the solution was prevented either by examining visually or by checking its dielectric constant and loss.

Apparatus. Dielectric constants and losses were measured in the frequency range 1—100 MHz with a twin-T bridge of type DLB-1101D (Fujisoku Electric Co., Ltd.). This bridge consists essentially of a circuit for impedance measurement divised by Sinclair and Woods, the detailed description of which was given by S. Okamoto.[4] Temperature was kept constant within ±0.2 °C by thermistors.

Results and Discussion

Dielectric constants and losses are plotted against the logarithm of the frequency (*e.g.*, *cf.* Fig. 1 for anthrone in *o*-terphenyl). In all the solutions the dispersion and absorption of solute molecules were observed in the frequency range 1—100 MHz and temperature range 15—30 °C. Dielectric constants and losses are also plotted in a complex plane; normalized Davidson-Cole

TABLE 1. VALUES OF THE CHARACTERISTIC RELAXATION TIME (τ_0)

Substance	τ_0(ns) 15°C	20°C	25°C	30°C	τ (ps) (in benzene)
Anthrone	106	41.7	18.7	11.2	24.8(20°C)[5] 18.4(40°C)
Phenothiazine	115	45.0	21.0	11.4	
Xanthone	94.9	40.0	18.2	9.1	21.0(25°C)[6]
9-Fluorenone	80.4	37.1	15.3	7.6	19.9(20°C)[5] 14.9(40°C)
Diphenyl-nitrosamine	76.4	32.8	14.2	7.1	
1,8-Dinitronaphthalene		65.0	32.0	14.6	
p-Nitrotoluene	48.4	22.7	10.1	5.6	19 (22°C)[7]
Benzophenone	52.9	24.2	12.4		16.2(20°C)[8]
m-Nitrophenol	53.4	26.2	11.7	6.3	

diagrams are shown in Fig. 2. The values of ε_0 and ε_∞ are obtained by extrapolation at each temperature.

The characteristic relaxation times τ_0 obtained in this experiment are shown in Table 1 together with literature values in benzene. The decrease in the relaxation times in benzene with a rise of 20 °C is 6.4 ps for anthrone and 5.0 ps for 9-fluorenone. In the supercooled state the decrease for 15 °C becomes almost ten times for anthrone, 9-fluorenone and other compounds.

According to Eyring the relaxation time τ_0 is expressed in terms of thermodynamic parameters as follows.

$$\tau_0 = \frac{h}{kT}\exp\left(\frac{\Delta H^*}{RT}\right)\exp\left(-\frac{\Delta S^*}{R}\right). \qquad (2)$$

where ΔH^* is the activation enthalpy, ΔS^* the activation entropy and k, h, and R are the Boltzmann, Planck and gas constants, respectively. The activation enthalpy obtained from temperature dependence of τ_0 (Table 2) is much greater than that obtained in ordinary non-polar solvents; ΔH^*s for anthrone and 9-fluorenone in benzene are 8.8 and 8.4 kJ mol^{-1}, respectively.[5] We see that ΔS^* increases with ΔH^* so that an apparently linear relationship exists between these parameters.

$$\Delta S^*(\text{J deg}^{-1}\text{ mol}^{-1}) = 3.44\Delta H^*(\text{kJ mol}^{-1}) - 106 \qquad (3)$$

Equations similar to Eq. (3) have been obtained for

TABLE 2. VALUES OF THE DISTRIBUTION PARAMETER (β), THE ACTIVATION ENTHALPY (ΔH^*) AND ENTROPY (ΔS^*)

Substance	β	ΔH^* $\left(\frac{\text{kJ}}{\text{mol}}\right)$	ΔS^* $\left(\frac{\text{J}}{\text{deg mol}}\right)$

other dielectric relaxation processes,[9] *e.g.*, for polar polymers[10] and for nonrigid molecules in the polystyrene matrix.[11]

Normalized absorption curves, shown in Figs. 3 and 4, are unsymmetrical in shape and broader than the pure Debye curves. All the points measured at different temperatures are reasonably close to a single curve for each sample. The above feature differs from one for polar molecules dispersed in the polystyrene matrix, where a symmetrical distribution of relaxation times occurs;[11] it also differs from that for rigid molecules in Nujol[12,13] or decalin (normal[13]) and supercooled[14] liquids), where the absorption curves become broader with decreasing temperature.

The abosorption curves of anthrone, xanthone and phenothiazine have almost the same shape with nearly the same values of β (Fig. 3 and Table 2). This might arise from the similarity in the size and shape of these molecules. The absorption curve of benzophenone (▲ in Fig. 3) is, however, broader than that of its related molecules 9-fluorenone (● in Fig. 3) in the higher frequency side. Possibly an extra absorption

occurs in the higher frequency region on account of the intramolecular rotation of the phenyl groups of benzophenone.[15]

Figure 4 shows the normalized absorption curves of four remaining molecules whose size and shape are not similar. The curve for *m*-nitrophenol (▲ in Fig. 4) is far broader in the higher frequency side than curves of other molecules. The deviation might originate from the high frequency absorption due to rotation of the OH group.

Denny[16] made skewed-arc plots for several supercooled, branched hydrocarbon halides including isobutyl bromide which is known to have a single relaxation time in the normal liquid state.[17] In order to explain the unsymmetrical distribution of relaxation times of those nonassociated molecules, Glarum[18] proposed a defect diffusion model, in which the shape of the distribution function becomes very little dependent upon temperature (Figs. 3 and 4). High activation energies obtained indicate the difficulty of diffusion of defects through solvent molecules. The results of this experiment seem to support Glarum's mechanism.

One of us (M.N.) is indebted to Professor Mansel Davies, University of Wales, for his interest and encouragement.

Spectroscopic and Theoretical Studies on the Protonation to Xanthone Derivatives

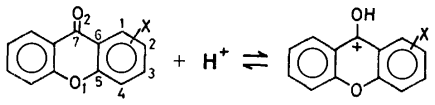
Kimiko MIZUTANI,* Kimiko MIYAZAKI, Kimiko ISHIGAKI, and Haruo HOSOYA**

Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo 112

(Received December 18, 1973)

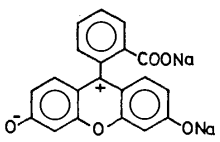
Ultraviolet absorption, fluorescence, and excitation spectra of xanthone and its hydroxyl and methoxyl derivatives were measured in sulfuric acid solutions of various acidities. The basicities (pK_a's) of these compounds were obtained from the spectral change. Variable-β type molecular orbital calculations of the π-systems were performed, assignment of the absorption spectra being made. It was confirmed that protonation occurs at the carbonyl oxygen atom. A method for obtaining the equilibrium constant without knowing the absolute intensity is proposed.

It has been established that in strong acidic media protonation occurs at the carbonyl oxygen atom of γ-pyrone and its derivatives.[1,2] As a dibenzo derivative of γ-pyrone, xanthone (or 9H-xanthen-9-one, **1**: X=H) is also expected to be protonated at the carbonyl oxygen atom forming hydroxyxanthylium ion (**2**: X=H).



1 **2**

Actually xanthone is known to be stable in concentrated sulfuric acid showing strong emission,[3] and the basicity of xanthone has been obtained from the change of the ultraviolet absorption spectra.[4-6] The basic and emissive characters of xanthone are expected to vary with the number and positions of the substituent such as a hydroxyl group, according to reports on the features of the substitution effect on the absorption and emission of xanthone derivatives.[3,5,7] These phenomena have close resemblance to those of the hydroxyl derivatives of anthraquinone forming the alizarin dye group where electron donating power of the hydroxyl group and the competitive intramolecular hydrogen bonding are the major factors determining basic and emissive characters. It should also be noted that the emissive character of xanthone is related to that of fluorescein (**3**).



3

We have studied in detail the acidity dependence of the electronic absorption and emission spectra and the basicities of mono-hydroxyl and methoxyl derivatives of xanthone (**1**: X=OH, OCH_3) and interpreted the results with the molecular orbital calculations of the π-electronic structures.

Experimental

Materials. Commercial G.R. grade of xanthone was purified by recrystallization from ethanol. 1-, 2-, 3-, and 4-methoxyxanthones and the corresponding hydroxyxanthones were synthesized after Ullmann and Zlokasoff[8] and purified by recrystallization from aqueous ethanol. Concentrated sulfuric acid of high special grade (Wako Pure Chemical Industries, Ltd.) was used without further purification.

Measurement. A Shimadzu multiconvertible spectrophotometer D40R was used to measure the ultraviolet and visible absorption spectra with stopcocked fused quartz 1 cm cells. A Hitachi MPF-2A fluorescence spectrophotometer was used for the excitation and fluorescence spectra. Fluorescence spectra were automatically corrected with Rhodamine B by use of the spectrum correction attachment. Absorption and emission spectra were measured in ethanol and in sulfuric acid of various acidities at room temperature. All the solutions were prepared just before the measurement, the concentration of the solute being about 10^{-4}—10^{-5} M. The acid concentrations were determied by titration with a standard aqueous solution of sodium hydroxide. The value of Hammett's acidity function were taken from the table by Jørgensen and Hartter.[9] The basicities (pK_a) of the xanthone derivatives were determined from the change of the ultraviolet absorption spectra by the iterative least squares calculation for the sigmoid curve of ε-H_0 plot.[10] Although the absolute intensity of excitation spectra was not obtained, we could obtain fairly accurate values of pK_a from the relative change of the excitation spectra at two different wavelengths. Details are given in the Appendix.

Results and Discussion

Ultraviolet Absorption Spectra. Ultraviolet absorption spectra of the neutral (**1**, in EtOH) and protonated (**2**, in conc. H_2SO_4) xanthone are shown in Fig. 1 and Table 1, the former spectrum being in accordance with the previous results.[7,11,12] The spectra of the hydroxyl and methoxyl derivatives are given in Figs. 2 and 3 and Table 1. The spectra of the hydroxyl and the corresponding methoxyl derivatives, except for the 1-derivatives are so similar that the spectra of 2-,

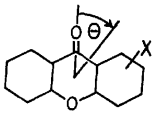
a) Direction of the transition moment.



3-, and 4-hydroxyxanthones have been omitted. The spectra of 1-hydroxy- and 1-methoxyxanthones are quite different from each other indicating an intramolecular hydrogen bonding in 1-hydroxyxanthone (**4**). The n→π^* bands of these compounds were not observed in the polar solvents used in this study.[12] The spectra of the neutral compounds are generally seen to shift to the red on protonation, *viz.*, the 340 nm band of xanthone is shifted to 400 nm. The electronic structures of forms **1** and **2** of the 1-, 2-, and 4-derivatives seem very similar to those of xanthone, while those of the 3-derivatives are modified by the electron flow from the substituent etherial lone pair electrons.[7] This anomaly is also reflected in the basicity.

a) See the footnote in Table 1a.

Fluorescence and Excitation Spectra. We did not measure the phosphorescence spectra of xanthones, since a number of studies have been reported.[12-14] Fluorescence spectra of xanthone in concentrated sulfuric acid is exemplified in Fig. 1 as the most typical of the compounds studied. That the conjugate acid **2** fluoresces more strongly than the neutral compound **1** reminds one of the structure of the fluorescent form **3** of fluorescein.

For a series of the protonated xanthone derivatives the values of the Stokes shift are scattered in the range 3500—7000 cm^{-1}, revealing a drastic change in the geometry of the compounds on protonation. However, no apparent correlation was observed between the values of the Stokes shift and the basicity of the parent compound.

·····: Fluorescence spectrum (corrected) of **1** ($\sim10^{-5}$ M) in conc. H_2SO_4. Emitted at 420 nm.

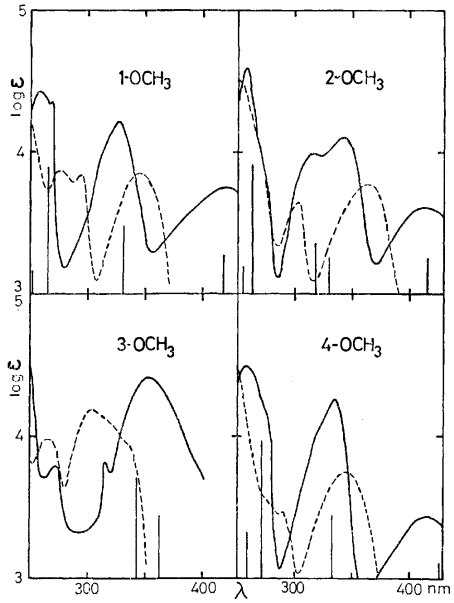

Fig. 2. Ultraviolet absorption spectra of methoxyxanthones in ethanol (----) and in concentrated sulfuric acid (——) solutions. The spectra of hydroxyxanthones are essentially the same as the corresponding methoxyl derivatives except for 1-substituted compounds (See Fig. 3). The calculated spectra of the protonated compounds are shown with solid bars.

Excitation spectrum of xanthone in concentrated sulfuric acid changes with the solute concentration as shown in Fig. 4. For the solutions with solute concentration lower than 10^{-5} M, 330 and 400 nm bands

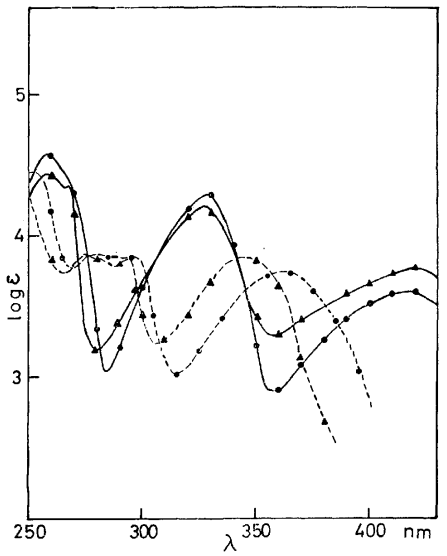

Fig. 3. Ultraviolet absorption spectra of 1-hydroxy- (●) and 1-methoxyxanthones (▲) in ethanol (----) and in concentrated sulfuric acid (——) solutions.

undoubtedly correspond to the absorption spectrum. As the solute concentration increases the relative intensities of these two bands become reversed, and reabsorption is gradually observed around 330 nm. As a result, solutions with concentration higher than 10^{-3} M give a quite different spectral shape. However, at lower concentrations no secondary change such as energy transfer seems to occur. We therefore adjusted the concentration below 10^{-4} M for the measurement of the excitation spectra for obtaining the basicities of the xanthone derivatives. The change of the excitation spectra of xanthone with the solvent acidity is shown in Fig. 5.

Table 2. Basicities and π-electron densities of xanthone derivatives

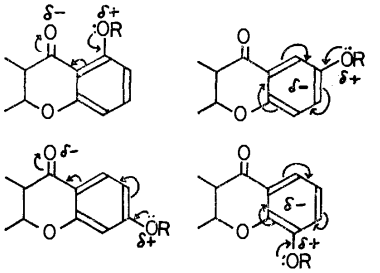
X	$-pK_a$		π-Electron density	
	Absorption	Excitation	Carbonyl O	Ethereal O
H	4.1	4.0	1.425	1.772
1-OH	4.1	4.3	1.455	1.769
1-OCH_3	2.2	2.2		
2-OH	3.9	3.8	1.428	1.773
2-OCH_3	3.7	3.7		
3-OH	3.0	2.6	1.434	1.771
3-OCH_3	2.8	2.5		
4-OH	4.2	4.2	1.425	1.777
4-OCH_3	4.2	4.4		

its eight derivatives were determined both from the absorption and excitation spectra (Table 2). The values for xanthone, −4.1 (absorption) and −4.0 (excitation), are in agreement with the reported values, −4.08,[4] −4.12,[5] and −4.2,[6] all from the ultraviolet absorption measurement, but no report can be found for the derivatives studied here. Comparing these values with those for benzophenone (−6.4), anthrone (−5.0), 4,4'-dimethoxybenzophenone (−4.4), and 4,4'-dihydroxybenzophenone (−4.2),[15] we find these data suggest that protonation occurs at the carbonyl oxygen atom of xanthone. The electron donating ethereal oxygen lone pair of xanthone acts as a bridge for the conjugation of the π-electron between the two benzene rings and also an electron supplier to the carbonyl oxygen atom, placing the basicity of xanthone as high as that of dihydroxybenzophenone. All the hydroxyl and methoxyl derivatives are no less basic than xanthone.

Except for the 1-substituted derivatives the basicities of hydroxyl and the corresponding methoxyl derivatives are almost the same. The basicities of the methoxyxanthones are in the following order:

$$1 > 3 > 2 > 0\ (=\text{xanthone}) > 4.$$

Note a gap between the 3- and 2-methoxyxanthones. This can be explained by the resonance theory as in the following scheme:



More quantitative correlation can be obtained from the molecular orbital calculation. In Table 2 the π-electron densities on the carbonyl and ethereal oxygen atoms of the xanthone derivatives are compared with the basicity data, which are correlated well with the π-electron densities on the carbonyl oxygen atom (Fig. 6) but not with the ethereal oxygen atom. Although a similar argument has been given by Efimov and Komarov for the basicities of xanthone and γ-pyrone derivatives, it is based on the Hückel molecular orbital.[16] It should be noted that for π-electron systems with many heteroatoms the Hückel method often gives unreasonable π-electron densities.[17]

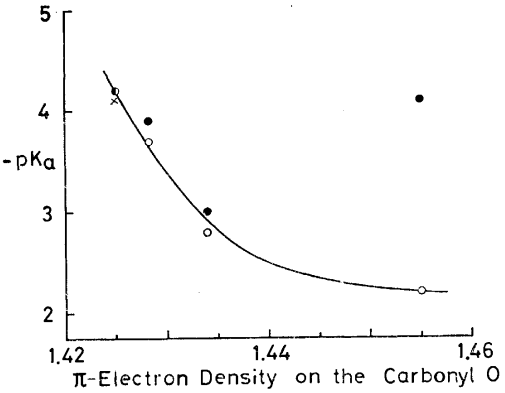


Fig. 6. Correlation between the basicities (pK_a's) and the π-electron densities on the carbonyl oxygen atom of xanthone derivatives
×: xanthone ●: hydroxyxanthone
○: methoxyxanthone
The pK_a values are taken from the UV absorption data.

On the other hand, as evident from **4** the excess π-electron on the carbonyl oxygen atom of 1-hydroxyxanthone is pulled away through the hydrogen bond, causing no net effect on the value of the basicity.

If no side-reaction intervenes in the excited states of fluorescent molecules the basicities can be obtained fairly accurately from the change of the excitation spectra.

Calculation of the π-Electronic Structures of Xanthone and Its Derivatives. In order to get theoretical support

for the mechanism of protonation to xanthone derivatives and to interpret the observed electronic spectra, the π-electronic structures of the ground and lower excited states of the neutral and protonated xanthone derivatives were calculated with the variable-β approximation proposed by Nishimoto and Forster,[21] in which the consistency of the bond order-bond length relation is attained automatically with the PPP type molecular orbital framework. No accurate geometry of a molecule is therefore necessary for the input data.[22] No distinction was taken between the hydroxyl and methoxyl derivatives. For the protonated xanthones the protonated carbonyl oxygen atom was treated simply as a hydroxyl oxygen atom. No parametrization was tried for the different electronegativities of positively charged carbon atoms. Extensive singly excited configuration interaction was carried out. The parameters and details of the calculation are after Nishimoto.[23]

Electronic Structures of Xanthone and Its Derivatives. The net π-electron charge densities and the calculated bond lengths of the two forms of xanthone (**1**,**2**: X=H) are shown in Fig. 7. In both cases the charge distribution over the central three atoms lying on the molecular axis (z-axis) is rather uneven, while electron is uniformly populated over the wing benzene moiety. For the hydroxyl and methoxyl derivatives, the π-electron densities on the carbonyl oxygen atom are found to be correlated well with their basicities (Table 2 and Fig. 6), but not the total π-electron energies of **1** and **2**.

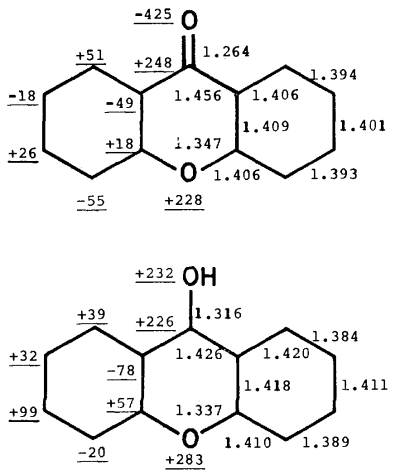

Fig. 7. The bond lengths and the net charge densities of the ground state of the neutral and protonated xanthones. The charge densities in the unit of 10^{-3} electron are underlined.

Assignment of the Electronic Spectrum of Xanthone. In order to discuss the assignment, the higher occupied and lower vacant π-molecular orbitals given in Table 3 should be considered. Both the HOMO and LUMO are symmetric (S) with respect to the plane passing through the molecular axis, and perpendicular to the molecular plane (yz-plane) to which the symmetry notations S and A will be referred unless otherwise stated. Assignment of the electronic spectra is given in Table 4. Pownall and Huber (abbreviated as PH) gave the assignment based on their phosphorescence excitation measurement.[12] There are a few discrepancies between their assignment and ours. Although σ-electron is not taken into this calculation we can expect that the lowest $^1n\rightarrow\pi^*$ transition (Band I according to PH) is roughly expressed as (n→9) and x-polarized, *i.e.*, perpendicularly to the molecular plane, as both the π-LUMO 9 and σ-HOMO n have S symmetry. That this band is observed by PH as z-polarized may be an outcome of possible vibrational perturbation. The most dominant contribution to the lowest $\pi\rightarrow\pi^*$

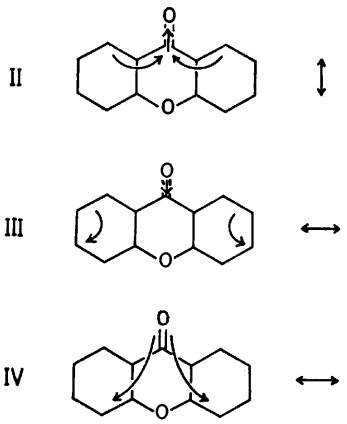
transition (Band II) is denoted by (8→9) and polarized along the molecular axis. Inspection of the wave functions indicates that this is a charge-transfer band, in which electron flows into the carbonyl oxygen atom from the ring moiety. The next higher band (Band III) is a mixture of several transitions with y-polarization, most of which are locally-excited in the ring moiety. In contrast to the tentative assignment by PH that Band IV is a z-polarized charge-transfer band, our calculation shows that it is a y-polarized *back*-charge-transfer band due to transition (8→10). The upper orbital 10 has A symmetry with no coefficient on the carbonyl group. The electron flow associated with the electronic transitions II, III, and IV in xanthone are shown in the diagram below, in which the two-headed arrow shows the direction of the transition moment.



The reliability of the variable-β calculation especially for the assignment of the electronic spectra of heteroatomic systems has been tested with a number of molecules.[21,24] As evident from Figs. 1 and 2 and Table 1 this is also the case for the xanthone derivatives. Agreement between calculation and observation is generally better for the protonated xanthone derivatives than the neutral compounds.

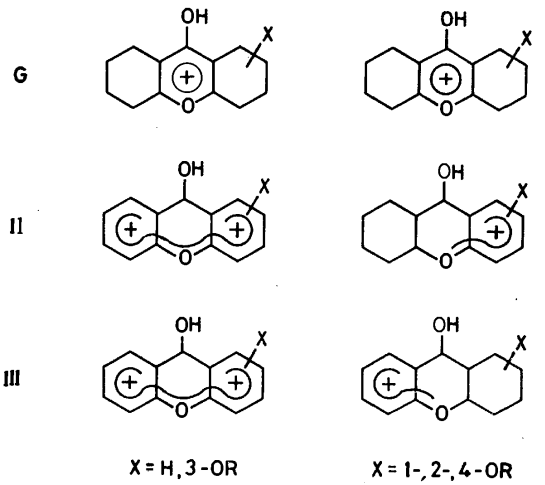


Fig. 8. Illustrative sketches of the charge densities of the ground and lower excited states of the protonated xanthone derivatives
G: Ground state II: Lowest $\pi\rightarrow\pi^*$ state
III: Second lowest $\pi\rightarrow\pi^*$ state

The 3-substituted derivatives show quite different spectral patterns, which are reproduced fairly well by the molecular orbital calculation. Charge densities of the ground and lower excited states of the protonated xanthone derivatives are given in Fig. 8. The 3-derivatives again behave quite differently from other derivatives, *viz.*, in xanthone and 3-derivatives the lowest two $\pi\rightarrow\pi^*$ excitations are delocalized all over the molecules, while in other derivatives the excitations are localized. Of the four derivatives of the protonated xanthone the 3-derivative has the lowest value of the total π-electron energy.

The authors are indebed to Dr. T. L. Kunii, the University of Tokyo, for allowing them to use the variable-β program on a Hitac 5020E computer at the Computer Centre, the University of Tokyo. Part of this study was supported by a grant from the Ministry of Education.

Appendix

Determination of the Equilibrium Constant without Knowing the Absolute Intensity. Let us assume that following acid-base equilibrium takes place.

$$B + H^+ = A, \tag{A1}$$

where B and A are, respectively, an organic base and the conjugate acid. If the analytical concentration of B is c, of wflich fraction x is protonated to form A, the dissociation constant K_a of the conjugate acid A is expressed as

$$K_a = \frac{c(1-x)h_0}{cx} = \frac{h_0(1-x)}{x}, \tag{A2}$$

where the acid concentration h_0 is related to Hammett's acidity function H_0 as

$$H_0 = -\log h_0.^{25} \tag{A3}$$

By definition the basicity of B or its pK_a value is expressed as

$$\begin{aligned} pK_a &= -\log K_a \\ &= H_0 + \log\frac{x}{1-x}, \end{aligned} \tag{A4}$$

A physical quantity Q for an equilibrated system is assumed to be additive of the components as in

$$Q = \alpha\{c(1-x)q_b + cxq_a\}, \tag{A5}$$

where q is the molar quantity of the component, such as molar extinction coefficient and the emission intensity per mole expected with a unit quantum yield, and α is a factor dependent on experimental conditions. Namely, factor α is the length of the cell in the case of electronic absorption measurement, while for emission spectra it is a function of the quantum yield, cell length, quenching mechanism, *etc.* and is usually left unknown.

Let us consider the latter case with unknown α. By choosing two different abscissae, or wavelengths, λ_1 and λ_2 (Fig. 9), we get

$$\begin{aligned} Q_1 &= \alpha\{c(1-x)q_{b1} + cxq_{a1}\} \\ Q_2 &= \alpha\{c(1-x)q_{b2} + cxq_{a2}\}. \end{aligned} \tag{A6}$$

For the ratio R, we get

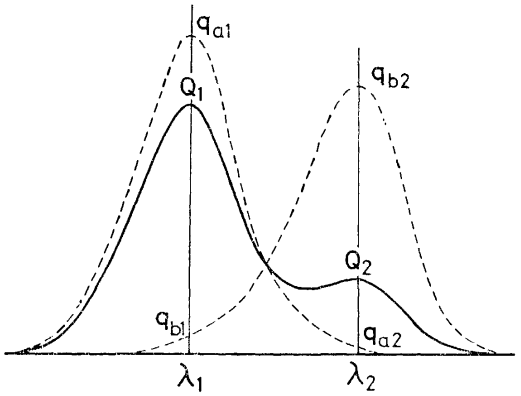

Fig. 9. Illustration for obtaining the equilibrium constant by measureing the absorbances at two different wavelengths
——: Observed spectrum
----: Spectrum of the component A
·····: Spectrum of the component B

$$R = \frac{Q_1}{Q_1+Q_2} = \frac{(1-x)q_{b1}+xq_{a1}}{(1-x)(q_{b1}+q_{b2})+x(q_{a1}+q_{a2})}$$
$$= \frac{q_{b1}+(q_{a1}-q_{b1})x}{(q_{b1}+q_{b2})+(q_{a1}+q_{a2}-q_{b1}-q_{b2})x}$$
$$= \frac{F+Gx}{D+Ex}, \qquad \text{(A7)}$$

which is a function of x (Eq. (A4)) and can be changed by varying the acidity H_0 of the solvent. By plotting R against H_0 we get a sigmoid curve whose limits are F/D and $(F+G)/(D+E)$ (Fig. 10).

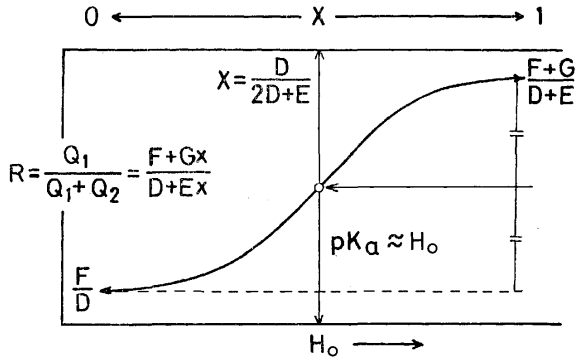

Fig. 10. Graphical method for obtaining the inflexion point of a sigmoid curve. Inflexion point is marked with ○.

Now let us find the inflexion point of this curve. By means of the relations[10]

$$\frac{dx}{dh_0} = \frac{(1-x)^2}{K_a} \qquad \text{(A8)}$$

$$\frac{dh_0}{dH_0} = -2.303h_0 \qquad \text{(A9)}$$

we get

$$\frac{dR}{dH_0} = -\frac{2.303h_0(1-x)^2(DG-EF)}{K_a(D+Ex)^2} \qquad \text{(A10)}$$

$$\frac{d^2R}{dH_0^2} = \frac{2.303^2h_0(1-x)^2(DG-EF)\{D-(2D+E)x\}}{K_a(D+Ex)^3} \qquad \text{(A11)}$$

By equating the identity (A11) to be zero, we get

$$x = \frac{D}{2D+E} = \frac{q_{b1}+q_{b2}}{(q_{b1}+q_{b2})+(q_{a1}+q_{a2})}, \qquad \text{(A12)}$$

with which the identity (A10) is not zero. Thus Eq. (A12) certifies the inflexion point. Substitution of Eq. (A12) into Eq. (A4) gives

$$pK_a = H_0 + \log\frac{q_{b1}+q_{b2}}{q_{a1}+q_{a2}}, \qquad \text{(A13)}$$

This means that if $q_{b1}+q_{b2}$ is nearly equal to $q_{a1}+q_{a2}$ the basicity pK_a is obtained as the H_0 value at the inflexion point of the curve $Q_1/(Q_1+Q_2)$ against H_0. Usually the quantities q's are unknown. However, if the maxima of Q for components A and B are of the same order of magnitude, the second term of the right hand side of Eq. (A13) would be negligible by choosing these peak wavelengths as λ_1 and λ_2 as in Fig. 9. This is shown in Table 2 for the case of xanthone derivatives, where the pK_a values estimated from the excitation spectra by using this method are very close to the values obtained from the ultraviolet absorption spectra.

When it is difficult to read the inflexion point of a sigmoid curve, the following additional relations are helpful. As evident from Eqs. (A10) and (A11), the slope of the curve R–H_0 is maximum at the inflexion point. It can easily be shown that the R value at the inflexion point is the arithmetic mean of the two asymptote readings

$$\left(F+G\frac{D}{2D+E}\right)\Big/\left(D+E\frac{D}{2D+E}\right) = \left(\frac{F}{D}+\frac{F+G}{D+E}\right)\Big/2. \qquad \text{(A14)}$$

The present method is not restricted to the case of an acid-base equilibrium (A1) and is also applicable to other types of equilibrium such as that of monomer-dimer

$$2A = A_2. \qquad \text{(A15)}$$

Analysis is straightforward.[26]

Studies of the π-π^* Absorption Bands of *p*-Quinones and *o*-Benzoquinone

Akira KUBOYAMA, Sanae MATSUZAKI, Hiroshi TAKAGI, and Hiroshi ARANO
National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151
(Received January 11, 1974)

The π—π^* absorption spectra of *p*-benzoquinone, α-naphthoquinone, anthraquinone, and their derivatives, mainly in *n*-heptane up to the vacuum UV region, were obtained. On the other hand, MO calculations of the π-electronic systems of these *p*-quinones and *o*-benzoquinone were carried out by means of the P-P-P method. The π—π^* absorption bands of these quinones could be favorably assigned on the basis of the calculated results.

As for the assignments of the $\pi \rightarrow \pi^*$ absorption bands of quinones in the ultraviolet (UV) region, many theoretical works[1-3] have been carried out. However, it is very desirable to clarify the absorption spectra in the vacuum ultraviolet (VUV) region in assigning the $\pi \rightarrow \pi^*$ absorption bands. The VUV absorption spectra of quinones have never been reported. In this work, the $\pi \rightarrow \pi^*$ absorption spectra of *p*-benzoquinone (*p*-BQ), α-naphthoquinone (α-NQ), anthraquinone(AQ), and their derivatives have been obtained up to the VUV region. On the other hand, MO calculations of the π-electronic systems of these *p*-quinones and *o*-benzoquinone have been carried out by means of the P–P–P method in order to determine the assignments of the $\pi \rightarrow \pi^*$ bands of these quinones.

Experimental

Measurements. The absorption spectra in the UV region were measured with a Cary 14 M recording spectrophotometer, and those in the VUV region, with a VUV-3 recording spectrophotometer of the Japan Spectroscopic Co., Ltd. The sample chamber and detector system of the latter apparatus have been modified as is shown in Fig. 1 after our previous work[4] on ketone vapors. Quartz cylindrical cells with 0.1, 0.5, and 1 mm paths were used; the design was similar to that used by Tsubomura *et al.*[5] *n*-Heptane and 1,1,1,3,3,3-hexafluoroisopropanol were used as solvents; they could be used up to 175 and 170 nm respectively with an 0.1 mm-path cell, but the former was mainly used. Daifloil (polymer of trifluorochloroethylene) was also used for *p*-benzoquinone in the UV region for the purpose of comparison.

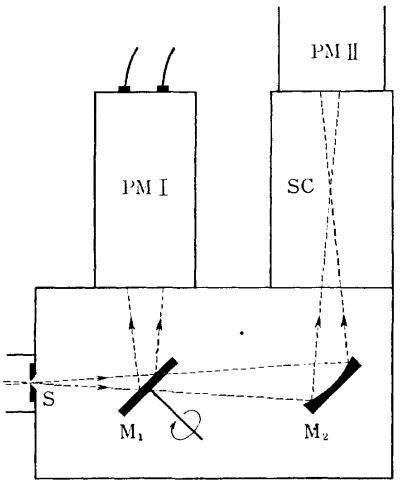

Fig. 1. The sample chamber and detector system
S: excit slit, M_1: plane rotating-sector mirror, M_2: concave mirror, SC: sample chamber, PMI and PMII: photomultiplyers (HTV R189).

Materials. *p*-BQ, 2,5-dimethyl-, and 2,5-dichloro-*p*-BQs, AQ, and 2-*t*-butyl-AQ (commercial products) were purified by sublimation. α-NQ (commercial products) was purified by vacuum sublimation at 30 °C. 2,5-Di-*t*-butyl-*p*-BQ (commercial products) was twice recrystallized from cyclo-

hexane. 2,3-Dimethyl-α-NQ was prepared according to the methods described in the literature[6] and, was purified by vacuum sublimation. The melting points of all these purified samples agreed with those reported in the literature. *n*-Heptane was treated with conc. sulfuric acid and purified by silica gel chromatography. 1,1,1,3,3,3-Hexafluoroisopropanol (Eastman Co.) and Daifloil (#1; mean molecular weight, 500; Daikin Kogyo Co.) were used without further purification.

Results. The absorption spectra obtained are shown in Figs. 2—5. In Fig. 3, the absorption bands of 2,5-di-*t*-butyl- and 2,5-dichloro-*p*-BQs near 305 and 325 nm respectively are not shown; that of the former is very similar to that of 2,5-dimethyl-*p*-BQ. The wavelength (λ_{max}), energies (E_{max}), and molar absorptivities (ε_{max}) of the absorption maxima in these spectra are shown in Table 1. Since the solubility of AQ in *n*-heptane was too poor for us to determine its concentration, the molar absorptivities of the absorption maxima of AQ in *n*-heptane were obtained by assuming that of the band near 320 nm to be 4800, considering its value (4800) in cyclohexane, obtained by Brockmann.[7]

Calculations

Method. As for the electronic integral values in the P-P-P method, various kinds of integral values were tentatively used, considering the results obtained in our previous calculation[1a] on the π-electronic system of *o*-BQ. Finally, it was proved that a good agreement between the calculated and the experimental results was generally obtained using the electronic integral values shown in Table 2. In this table, the suffix letters C and O denote the carbon and oxygen atoms respectively. U_C^* denotes the U_C of the carbonyl carbon atoms, while β_{CC}, β_{CC}^*, β_{CC}^{**}, and β_{CO} denote those of the conventional C–C single, double and benzene-ring bonds, and carbonyl C–O bond respectively. The values in brackets are those for α-NQ. The value of U_C is the same as that used in Hush and Pople's paper,[9] while that of $|U_O|$ seems to be too small in view of the valence-state ionization potential of the oxygen atom (17.25 eV).[10] As has been pointed out by Sidman,[2e] however, the U-term in Pople's SCF MO method[11] should be regarded as the valence-state orbital energy corrected for the fact that the atom is no longer isolated,

Table 2. Electronic integral values (eV)

(1) One-center core integrals	
U_C	−9.50
U_C^*	−10.00
U_O	−13.00
(2) Two-center core integrals	
β_{CC}	−2.00 (−1.80)
β_{CC}^*	−2.50 (−2.70)
β_{CC}^{**}	−2.30
β_{CO}	−2.50
(3) Electronic repulsion integrals	
Nishimoto-Mataga method[8]	

but is now a part of a molecule. From this point of view, the value of U_O may not be unreasonable. The value of U_C^* was taken in view of the π-electron densities being considerably smaller than those of other carbon atoms. In order to explain theoretically the effect of methyl-group substitution on the energy of the $\pi\rightarrow\pi^*$ bands of α-NQ, the calculation of 2,3-dimethyl-α-NQ was carried out taking the U_C value of the substituted carbon atoms as −9.00 eV, considering the inductive effect of the methyl group, but without considering its resonance effect. The values of β_{CC}, β_{CC}^*, and β_{CO}, except those for α-NQ, are the same as those of Case II in our previous work[1a] on *o*-BQ and close to those used by Edwards *et al.*[3d] in the calculations of conjugated carbonyl compounds. The values of β for carbon-carbon bonds are, except those for α-NQ, far less sensitive to the variation in C–C bond distance than those generally used.

In the calculations, all the singly-excited configurations were included except in the case of AQ, where the lowest forty configurations were included. The calculations were carried out with a FACOM 270-30 computer. The dimensions of the quinones assumed are shown in Fig. 6. Those of the three *p*-quinones were assumed according to the results of the X-ray analysis.[12-14] The lengths of all the bonds in the benzene rings in α-NQ and AQ were assumed to be 1.40 A. The value for *o*-BQ was assumed on the basis of the bond orders obtained in our previous work.[1a]

Fig. 6. Dimensions of the quinones (Å)
a: 120°, b: 121.5°, c: 117.5°, d: 118°, e: q118°, f: 117.5°

Results. The calculated excitation energies (E), oscillator strengths (f), and symmetry species[15] of the excited singlet states are shown, along with the observed results in *n*-heptane solutions, in Table 3. In this paper, the molecular planes are regarded as yz-planes, and the symmetry axes of *o*-BQ and α-NQ and the C–O bond axes of *p*-BQ and AQ are regarded as z-axes. The first column of this table indicates the numbering of the magnitude of E. In this table, the data on the higher excited states with small f-values have been omitted.

Discussion

o- *and* p-*Benzoquinones.* The absorption spectra of *o*-BQ in solutions obtained by Goldschmidt *et al.*[16] show that *o*-BQ has two $\pi\rightarrow\pi^*$ bands of a moderate intensity near 360 and 250 nm, and a strong $\pi\rightarrow\pi^*$ band near, 200 nm, or a little shorter than 200 nm.

The absorption spectra of *p*-BQ and its derivatives in Figs. 2 and 3 show that *p*-BQ has a weak $\pi\rightarrow\pi^*$ band[2f,17] near 280 nm and two strong $\pi\rightarrow\pi^*$ bands near 240 and 170 nm. It is noticeable that the absorption intensity of the band near 240 nm of *p*-BQ in 1,1,1,3,3,3-hexafluoroisopropanol and Daifloil is considerably stronger than that in *n*-heptane, and that the relative intensity of the absorption maxima of the bands near 250 and 175 nm is considerably different between 2,5-dimethyl- and 2,5-di-*t*-butyl-*p*-BQs.

In *o*- and *p*-BQs, the correspondences between the calculated and observed results are excellent, and the excited states of the $\pi\rightarrow\pi^*$ bands mentioned above could be favorably assigned, as is shown in Table 3. The theoretical and experimentally-determined[2b,18] assignments of the transitions of *p*-BQ in the UV region agree with each other. In our previous work[1a] on *o*-BQ, the assignment of the band near 250 nm was uncertain, but it could be reasonably determined in

TABLE 4. THE CHANGES OF THE CALCULATED $\pi\rightarrow\pi^*$ EXCITATION ENERGIES OF α-NQ WITH THE SUBSTITUTION OF TWO METHYL GROUPS TO ITS 2- AND 3-POSITIONS

No.	ΔE (eV)	No.	ΔE (eV)
1	+0.016	6	−0.098
2	−0.023	9	−0.013
3	−0.200	12	−0.029
4	+0.046	14	+0.082
5	+0.005	16	+0.023

this work. In *o*-BQ, two or three $\pi\rightarrow\pi^*$ bands of a moderate intensity may be expected to be found in the VUV region, judging from the calculated results shown in Table 3.

α-Naphthoquinone. As may be seen in Fig. 4, α-NQ has three distinct $\pi\rightarrow\pi^*$ bands—that is, a relatively weak band near 330 nm and two strong bands near 245 and 195 nm. Besides these three bands, α-NQ appears to have a $\pi\rightarrow\pi^*$ band of a moderate intensity between the two bands near 245 and 195 nm. Furthermore, comparing the absorption spectrum of 2,3-dimethyl-α-NQ with that of α-NQ in Fig. 4, it is clear that the band near 245 nm of α-NQ is composed of two bands the intensities of which are of comparable order, and that one of these two bands remarkably shifts toward longer wavelengths with the substitution of two methyl groups at the 2- and 3-positions of α-NQ. The changes in the calculated $\pi\rightarrow\pi^*$ excitation energies of α-NQ with this substitution are shown in Table 4.[19] As may be seen in Table 4, only the No. 3 state shows a large energy decrease with this substitution. Therefore, the No. 3 state may be assigned to the excited state of the band which largely shifts toward longer wavelengths with that substitution. On the other hand, the band near 330 nm is quite broad; this band may be composed of two $\pi\rightarrow\pi^*$ bands. Considering the above discussion, the excited states of the $\pi\rightarrow\pi^*$ bands of α-NQ can be reasonably assigned as is shown in Table 3. The assignments of the bands in the UV region agree with those made by Titz *et al.*[3e]

Anthraquinone. As may be seen in Fig. 5, AQ has five distinct $\pi\rightarrow\pi^*$ bands—that is, a relatively weak band near 320 nm, and four strong bands near 270, 250, 205, and 180 nm. As may be seen in Table 3, the correspondences between the calculated and observed results for these five bands are excellent, and the excited states of these $\pi\rightarrow\pi^*$ bands can be favorably assigned.[20] The assignments of the bands in the UV region agree with those by Nishimoto *et al.*[3a] and Titz *et al.*[3e] and are consistent with the experimental facts obtained by many authors.[21] As for the No. 30 state in Table 3, a $\pi\rightarrow\pi^*$ band corresponding to this state is expected to be found at the wavelength region shorter than 170 nm.

The authors are grateful to Dr. Fumihiko Hirota of Shizuoka University for his helpful advice in making the computer program and to Mr. Fumio Kobayashi and Mr. Teruo Kimura for their helpful co-operation in the experiments.

High-resolution Photoelectron Spectroscopy of Naphthacene Polycrystal by Means of Helium 21.22 eV Resonance Line

Kazuhiko SEKI, Yoshiya HARADA,* Koichi OHNO,* and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
**Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153*

(Received January 28, 1974)

The photoelectron spectrum of naphthacene polycrystal was obtained with a high-resolution photoelectron spectrometer using a helium 21.22 eV light source, and the vibrational fine structures were examined. The resolution, 21 meV FWHM for the argon $P_{3/2}$ peak, became much better than that obtained by means of a retarding-potential-type electron analyzer. Broad peaks with no distinct intramolecular vibrational structure were observed, and the origin of the peak width was discussed.

Recent progress in the molecular photoelectron spectroscopy of the polycyclic aromatic hydrocarbons[1-3] has made possible a direct comparison between the photoelectron spectra of these compounds in the gaseous and solid states. From the comparison, it has been made clear that the ionization in the solid state reflects that of one molecule very well.[4,5] Until the present time, however, almost all solid-state photoelectron spectroscopic studies of these compounds[6] have been carried out by rather low-resolution retarding-potential-type electron-energy analyzers, and the precise examination of the fine structures associated with the electronic transitions was very difficult.

Considering the narrow electronic valence-band width of the molecular crystals, one might expect to find the well-seperated intramolecular vibrational levels of the ionic states by means of photoelectron spectroscopy.

Recently Kiyono *et al.*[7] studied the energy states of naphthacene polycrystal with a high-resolution photoelectron spectrometer. They suggested the existence of some intramolecular vibrational structures, but the weak intensity of the signal prevented them from drawing any definite conclusion. On the other hand, some mechanisms have been proposed which lead to the broadening of the peaks. Zagrubskii and Vilesov[8] pointed out the possibility of a Franck-Condon quantum-mechanical spread. Further, Silinsh[9] and Sworakowski[10] suggested the dispersion of the ionization potential by the lattice vibrations in the neutral state.

In this paper, we wish to report our findings regarding the high-resolution photoelectron spectrum of naphthacene polycrystal obtained using the helium 21.22 eV line.

Experimental

The photoelectron spectrometer was an electrostatic 127° co-axial cylindrical-type one which has already been reported.[11] The ionization chamber of the instrument, however, was modified for the solid sample. Naphthacene was evaporated on a copper substrate and was inserted into the ionization chamber. The resolution of the electron spectrometer was 21 meV FWHM for the argon $P_{3/2}$ peak, but it was about one-third of this FWHM value at the first ionization peak of naphthacene, since the kinetic energy of the photoelectron was scanned by the voltage between the two deflector electrodes. The contact potential difference between the sample and the deflector electrodes was hard to estimate, so in calculating the ionization potentials it was assumed to be zero.

Results and Discussion

In Figs. 1a and 2a, the full and expanded spectra of the lower ionization potential region of naphthacene polycrystal are shown. In Figs. 1b and 2b, the molecular photoelectron spectra of the corresponding regions[1] are shown for comparison. In Table 1, the numerical values of the ionization potentials for the region of Fig. 2a are listed, along with the gaseous-state values and also other photoemission results.

Figures 1a and 2a show that the resolution is much better than that of the previous retarding potential method.[5] For example, the peaks at 8.77 and 10.72 eV appeared as shoulders in the retarding potential study. The position of the small shoulder at 8.3 eV was a little less reproducible than the other peaks, so the numerical value in Table 1 is given as 0.1 eV. A comparison with the other photoemission works in Table 1 shows that the agreement is very good; this finding suggests that the contact potential difference,

ignored in this work, is really very near to zero.

The work in the gaseous state shows[1)] that the first ionization peak contains only one electronic transition, so it is appropriate for the examination of fine structures. As is shown in Fig. 2b, there is an intramolecular vibrational structure of 1380 cm^{-1} (0.17 eV) in the gas spectrum, but, at least at this stage of resolution, there is no distinct corresponding structure in the first ionization peak in the solid state and the peak width (the overall FWHM of this band is 0.64 eV) is much larger than that of the gas spectrum (*cf.* Fig. 2a).

The fact that the 0–0 transition is very strong in the gaseous state suggests that no large deformation of the molecule occurs upon ionization; therefore, it is difficult to ascribe the large peak width in the solid state to intramolecular vibrations.

Some other mechanisms which lead to the broadening of the peaks have been proposed. If these effects are large enough, and if every intramolecular vibrational level is accompanied by them, the disappearance of the fine structures may be explained. Considering the interaction of the ion as a point charge with the nearest four molecules, Zagrubskii and Vilesov[8)] estimated the Franck-Condon quantum-mechanical spread due to the local lattice deformation for anthracene and obtained a value of 0.35 eV for the difference between the adiabatic and vertical transitions (*cf.* Fig. 3a, where this difference is $P_a - P_v$). However, they took the value for the total ion-dipole and dipole-dipole interactions and neglected the energy for the lattice deformation itself (ΔE in Fig. 3a). After correction for this, the value for anthracene is only 0.08 eV. We made similar calculations for naphthacene with a mean molecular polarizability of 32.4 $Å^3$ [12)] and with a force constant of 100 cm^{-1} for the lattice deformation; we thus obtained a value of 0.17 eV. With this value, and considering the roughness of the approximation, we are not able to decide at this stage whether this mechanism can explain the large peak width or not.

Further, Silinsh[9)] and Sworakowski[10)] suggested a dispersion of the polarization energy due to the lattice vibrations in the neutral state (P_{max} to P_{max} in Fig. 3b). The FWHM expected for this mechanism amounts to about 0.3 eV (assuming σ=0.1 eV for the gaussian distribution). It seems certain that this mechanism plays some role in the broadening of the peaks.

In both mechanisms, the first peak is expected to correspond to the vertical ionization from the equilibrium position for the lattice vibrations. The fact that the ionization energies estimated for this process (5.81 eV by Sworakowski[10)] and 5.83 eV by Batley *et al.*[13)]) agree well with the value for the first peak confirms this idea.

Other possible mechanisms contributing to the peak width are as follows: (1) a variation in the ionization potential between the bulk and the surface;[14)] (2) an energy loss of the photoelectrons on the way to the surface[15)] as a result of the excitations of the intra-

molecular vibrations of the other neutral molecules (an energy loss due to the phonons is less likely because of their small energy quantum), and (3) the lifetime broadening of the photoelectrons.[16] To determine the degrees of contribution from these factors, however, further comprehensive studies, including the improvement of the resolution, will be necessary.

The authors are very grateful to Drs. I. Harada, N. Ueno, and M. Kotani for their helpful discussions and to the Nishina Memorial Foundation for its financial support. They also wish to thank to Mr. Kiyoo Tsuji for modifying the photoelectron spectrometer.

Effect of Cesium Counterion on the ESR Spectrum of Tetracyanoethylene Anion Radicals

Masaaki OGASAWARA, Seizo INABA, Hiroshi YOSHIDA, and Koichiro HAYASHI*

Faculty of Engineering, Hokkaido University, Sapporo, 060

(Received August 1, 1973)

Evidence was obtained by ESR for the ion-pair formation between the tetracyanoethylene anion radical and the cesium counterion in tetrahydrofuran. The hyperfine lines of the ESR spectrum of cesium tetracyanoethylenide were exceptionally broad at high salt concentrations in tetrahydrofuran, while they were remarkably narrowed by the addition of a small amount of DMF or triglyme (cation-solvating agents) or by replacing the counterion with the tetra-*n*-butylammonium ion. This indicates that the broad linewidth is due to the unresolved hyperfine splitting of the cesium counterion. In addition, the concentration dependence of the ESR spectrum indicates that the line broadening is to be interpreted not only in terms of the Heisenberg spin exchange, but also in terms of the equilibrium between the ion-pair and the free ion. The cesium hyperfine coupling constant was estimated by simulating the line shape to be 40 m Gauss in the ion-pair state between the tetracyanoethylene anion radical and the cesium ion in the tetrahydrofuran solution.

Since the first observation of the electron spin resonance (ESR) spectrum of the tetracyanoethylene (TCNE) anion radical by Weissman *et al.* in 1960,[1] this anion radical has been known to be very stable in many solutions at room temperature and has been known to give a simple well-resolved ESR spectrum with a hyperfine structure due to the four equivalent ^{14}N nuclei. Several workers have studied the variety of metal tetracyanoethylenide systems by ESR, but have failed to observe any metal hyperfine splittings.[1-4] Furthermore, the electronic spectra of these systems were found to depend neither on the solvent nor on the metal cation.[5]

Recently, we studied the electron-transfer reaction of the TCNE anion in ethereal solvents and found that the observed kinetical behavior could be interpreted in terms of the electrostatic interactions between anions and counterions, and also that the line shape of the ESR spectrum of cesium tetracyanoethylenide became wide and distorted as the concentration of TCNE anion increased.[6] The previous investigation will be extended here to a study of the shape of the ESR spectrum of cesium tetracyanoethylenide in tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) in more detail. Our new evidence for the ion-pair formation of the TCNE anion will be reported in the present paper.

Experimental

Materials. The cesium tetracyanoethylenide (TCNE$^-$Cs$^+$) was synthesized as follows.[7] TCNE of a guaranteed reagent grade (Tokyo Kasei Kogyo Co., Ltd.) was purified by repeated sublimations *in vacuo*. Cesium iodide of a guaranteed reagent grade (Wako Pure Chemical Ind., Ltd.) was dried *in vacuo* at 100 °C for 24 hr. The TCNE and cesium iodide were dissolved into acetonitrile *in vacuo*, and the mixture was stirred by a magnetic stirrer for 48 hr at 0 °C. The solution was filtered *in vacuo* and condensed by evaporating the solvent. After the solution had then stood overnight, a reddish-brown solid, TCNE$^-$Cs$^+$, crystallized; this was washed with acetonitrile and dried. The crystalline TCNE$^-$Cs$^+$ was stable at room temperature in a glass ampoule for more than one year. The purity of the sample, as determined by elementary analysis, was approximately 92%.

The THF and DME were carefully purified and dried as has been described previously.[6] The trimethylene glycol dimethylether (triglyme) and *N,N*-dimethylformamide (DMF) were distilled over calcium hydride at reduced pressure. The tetra-*n*-butylammonium perchlorate (Bu_4NClO_4) was synthesized and purified as has been described previously.[6]

Sample Preparation and Measurements. The sample solution was prepared by dissolving crystalline TCNE$^-$Cs$^+$ into the respective solvent *in vacuo* and was sealed into a ESR sample tube made of Pyrex glass. Triglyme or DMF was added to the sample solution, if needed, through a break seal.

The concentration of TCNE$^-$Cs$^+$ was determined from the absorption maximum at 420 nm ($\varepsilon = 7100\ cm^{-1}\cdot l\cdot mol^{-1}$)[7] in the visible spectra.

All the ESR spectra were taken with a JES-NE-2X spectrometer equipped with 100 kHz filed modulation and a variable-temperature control unit.

Results and Discussion

Effect of Additives. The ESR spectrum of the TCNE anion consists of 11 lines with a separation of 1.65 Gauss, as has been reported by Weissman *et al.*[1] Most of the alkali metal (Li^+, Na^+, K^+) salts and tetra-*n*-butylammonium(Bu_4N^+) salt give ESR spectra consisting of sharp hyperfine lines, though their width increases slightly with an increase in the salt concentration. In contrast, it was found for cesium salt that the width of the hyperfine lines increased remarkably with an increase in the concentration. Figure 1 shows a representative spectrum with broad hyperfine lines at a high concentration of cesium salt. It was also found that the line shape deviated more and more

Fig. 1. ESR spectrum of 3.0×10^{-4} M TCNE$^-$Cs$^+$ in THF at 25 °C.

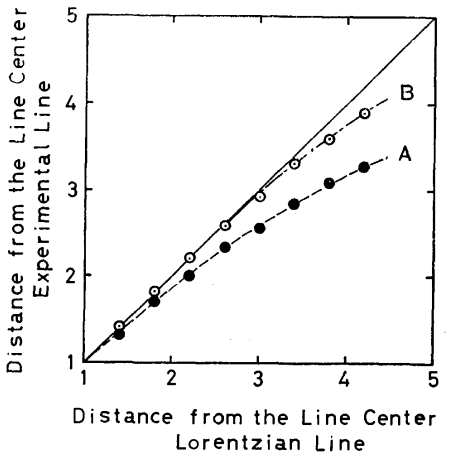

Fig. 2. Line shapes of the $\bar{M}=0$ lines in the first-derivative ESR spectra of TCNE$^-$Cs$^+$ at 25 °C. The distance in units of half the peak-to-peak width of the experimental line is plotted against the distance at which a Lorentzian line has the same relative amplitude: A, 4.2×10^{-4} M TCNE$^-$Cs$^+$ in THF; B, 4.6×10^{-4} M TCNE$^-$Cs$^+$ in THF–triglyme (2.8 mole%) mixture; solid line, a Lorentzian shape.

from a Lorentzian shape as the concentration increased. Figure 2(A) shows the deviation of the ESR spectral shape for the central hyperfine line observed at the 4.2×10^{-4} M TCNE$^-$, Cs$^+$ solution in THF from the ideal Lorentzian shape. The experimentally-observed first-derivative line shape is compared with the first-derivative line shape of a Lorentzian line having the same peak-to-peak amplitude and width as the experimental line. The distance in units of half the peak-to-peak width of the experimental line from the line center at several amplitudes is plotted against the corresponding value for the pure Lorentzian line. The solid line indicates the relation expected for a pure Lorentzian line shape. It is evident that the observed shape falls off at the tail much more rapidly than a Lorentzian shape. It has been reported that potassium tetracyanoethylenide gave a Lorentzian shape even at concentrations as high as 7×10^{-4} M.[4]

To study the effect of solvation on the ESR spectrum

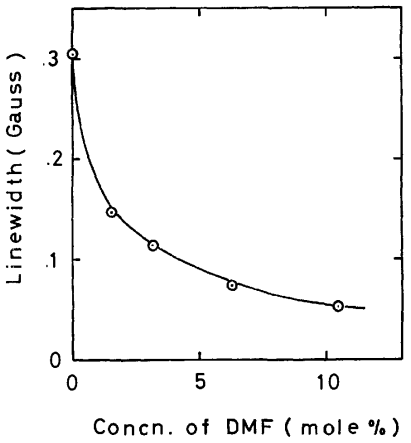

Fig. 3. Change of ESR linewidth ($\bar{M}=0$) of 3.0×10^{-4} M TCNE$^-$Cs$^+$ upon addition of DMF into THF solution at 25 °C.

of the TCNE$^-$Cs$^+$–THF system, DMF and triglyme were used as cation-solvating agents. Figure 3 shows the change in the ESR linewidth for the 3×10^{-4} M of TCNE$^-$ caused by the added DMF. The linewidth is considerably reduced by the presence of a small amount of DMF. With the increasing amount of DMF, the linewidth seems to decrease beyond the limit of measurement (—25 m Gauss). The linewidth is also reduced by the addition of triglyme. The results at several temperatures are shown in Fig. 4.

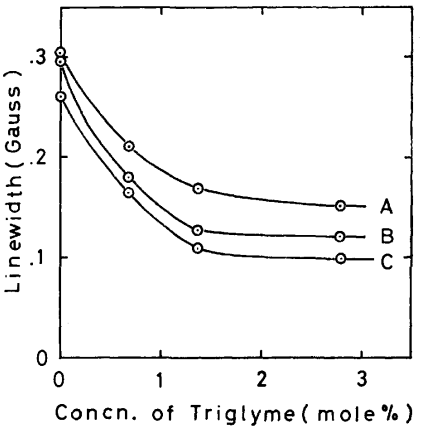

Fig. 4. Change of ESR linewidth ($\bar{M}=0$) of 3.0×10^{-4}M TCNE$^-$Cs$^+$ upon addition of triglyme into THF solution at various temperatures: A, 25 °C; B, 0 °C; C, −30 °C.

Because both additives are known to solvate preferentially the cesium ion,[8,9] the observed change of the linewidth may be interpreted by Process (1) or (2);

$$\text{TCNE}^-\text{Cs}^+ + n\text{DMF} \longrightarrow \text{TCNE}^-\text{Cs}^+(\text{DMF})_n \quad (1)$$

$$\text{TCNE}^-\text{Cs}^+ + n\text{Triglyme} \longrightarrow \text{TCNE}^-\text{Cs}^+(\text{Triglyme})_n \quad (2)$$

Here, TCNE$^-$Cs$^+$ and TCNE$^-$Cs$^+$(additive)$_n$ denote the ion-pair and the solvent-separated ion-pair respectively. Thus, the effect of cation-solvating agents strongly suggests that the abnormally broad ESR spectrum is to be attributed to unresolved cesium hyperfine splitting.

The linewidth tends to reach a plateau at high concentrations of triglyme (>2—3 mol%). The plateau value is thought to be the linewidth of the cesium-free TCNE anion at this radical concentration. On the other hand, there is no such trend for DMF, and the linewidth seems to decrease continuously. Because DMF is known to solvate not only cations but also anions, the narrower linewidth at high concentrations of DMF may be due to the coordination of DMF molecules to the TCNE anion.

Figure 5 shows the change in the linewidth of the 3.0×10^{-4} M TCNE$^-$Cs$^+$ sample caused by the addition of Bu_4NClO_4 salt. The linewidth is rapidly reduced at first and then gradually by the addition of Bu_4NClO_4. It is known that the alkali metal hyperfine splitting in the ESR spectrum of the alkali metal anthracenide–THF system disappears upon the addition of this salt, which has been interpreted in terms of the

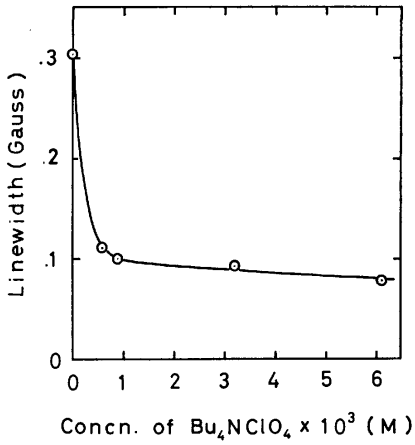

Fig. 5. Change of ESR linewidth ($\bar{M}=0$) of 3.0×10^{-4}M TCNE$^-$Cs$^+$ upon addition of tetra-*n*-butylammonium perchlorate into THF solution at 25 °C.

replacement of counterion.[10] The analogous replacement of the counterion is responsible, in this case, for the narrowing of the linewidth, as;

$$TCNE^-Cs^+ + Bu_4N^+ \longrightarrow TCNE^-Bu_4N^+ + Cs^+. \quad (3)$$

Concentration Dependence. Figure 6 shows the relation between the radical concentration and the ESR linewidth of TCNE$^-$Cs$^+$ in three different solvents; THF, DME, and THF containing 2.8 mol% of triglyme. In THF, the linewidth increases rapidly with an increase in the radical concentration up to 3×10^{-4} M and then the rate of increase is lowered. The linewidth in DME and the THF–triglyme mixture is dependent rather slightly on the radical concentration. Especially in the THF–triglyme mixture, only a small dependence was observed. The intercepts of these three curves at zero concentration were coincident with each other within the limits of experimental error.

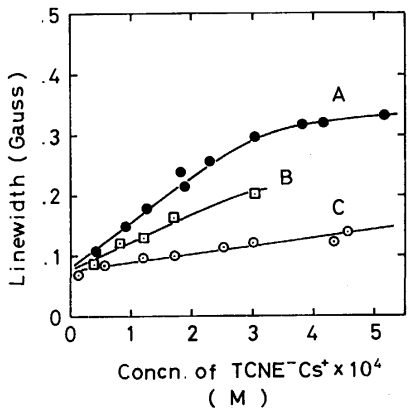

Fig. 6. Concentration dependence of ESR linewidth ($\bar{M}=0$) of TCNE$^-$Cs$^+$ in various solvents at 0 °C: A, THF; B, DME; C, THF-triglyme (2.8 mol%) mixture.

One of the possible mechanisms is the Heisenberg spin exchange between the anion radicals, which results in an increase in the linewidth with an increase in the concentration. It is well established that the effects of the Heisenberg spin exchange on the ESR spectra are identical with those of the diffusion-controlled or nearly diffusion-controlled chemical exchange.[4,11,12] In the slow exchange limit, the second-order rate constant of the spin exchange, k, is expressed for a Lorentzian line as:

$$k = \frac{\sqrt{3}}{2} f_{\bar{M}} |\gamma_e| \Delta H_{\bar{M}} / C, \quad (4)$$

where γ_e is the gyromagnetic ratio; $\Delta H_{\bar{M}}$ is the increase in linewidth due to the spin exchange; C, the concentration of paramagnetic entities in question, and $f_{\bar{M}}$, the statistical factor for the transition of the spectral index number, $\bar{M}$ ($f_0=1.306$ for the TCNE anion).[4] Assuming that the observed ESR broadening is attributable to the Heisenberg spin exchange, the second-order rate constant can be evaluated from Fig. 6 and Eq. (4). Table 1 summarizes the values calculated from the slopes of the lines in Fig. 6. Since the plots for the THF as solvent are not linear over the entire concentration range examined, the rate constant was evaluated from the slope of the line (A) in the low-concentration range (0—2×10^{-4} M).

Table 1. Spin-exchange rate constants k at 0 °C

Solvent	k($M^{-1}\cdot s^{-1}$) Experimental	Theoretical
THF	1.48×10^{10}	5.0×10^9
DME	8.9×10^9	4.9×10^9
THF–triglyme (2.8 mol%) mixture	2.7×10^9	5.0×10^9

Table 1 also includes the rate constants estimated from the simple Brownian diffusion model, in which the mean time, τ, between successive bimolecular encounters of radicals is represented by the following equation:[4]

$$\tau^{-1} = 4\pi d D \Pi \quad (5)$$

where Π refers the density of the radicals and where D is the diffusion coefficient in a Stokes-Einstein model:

$$D = kT/6\pi a\eta \quad (6)$$

determined by the molecular radius, a, the solvent viscosity, η, and the interaction distance for exchange, d (here it was assumed to be $2a$).[4] For the sake of simplicity, the effect of the charge was neglected in deriving Eq. (5). With the effect of the charge involved, the rate constant would be smaller than those given in Table 1. The viscosity of THF–triglyme was assumed to be the same as that of pure THF.

The k value derived from the observed linewidths in THF is much larger than that to be expected from the diffusion model. This leads to the recognition that the line broadening (Line A in Fig. 6) can not be explained solely by the spin-exchange mechanism. This fact, together with the effects of additives, may indicate that the strong dependence of the linewidth on the radical concentration in THF is, to a large extent, due to the ion-pair formation between the THF anion and the cesium ion. The equilibrium between the ion-pair and the free ion:

$$TCNE^-Cs^+ \rightleftarrows TCNE^- + Cs^+, \quad (7)$$

shifts to the left-hand side, and the fraction of the ion-

pair increases, when the radical concentration increases, resulting in a broadening of the ESR linewidth. The break of Line (A) at 3×10^{-4} M may be interpreted in terms of the complete ion-pair formation at this concentration.

As is shown in Fig. 6 and Table 1, the linewidth increases more slowly and the observed k is rather close to the expected k in DME than in THF. This is attributable to the high solvation of the cesium ion in DME,[13] which results in the formation of a solvent-separated ion-pair and/or increase in the free-ion fraction and, therefore, less effect of the cesium counterion on the ESR linewidth.

In the THF–triglyme mixture, the observed k is in agreement with the expected one. A more excellent agreement can be obtained if the effect of the charge and the increment in the viscosity arising from the addition of triglyme are taken into account. The activation energy evaluated from the Arrhenius plot of the observed k was found to be 3 kcal·mol^{-1}. This value is comparable with that of the diffusion-controlled chemical reaction in THF. Furthermore, the observed k agrees with that for the potassium tetracyanoethylenide–DME system reported by Freed *et al.*[4] In addition, the hyperfine lines were found to have a Lorentzian shape in this solvent within the limits of experimental error, as is shown in Fig. 2(B). These observations indicate that there is no broadening effect of the cesium ion in the THF–triglyme mixture and that the Heisenberg spin exchange solely determines the ESR linewidth in this system.

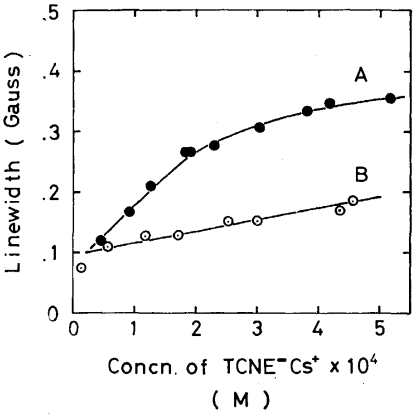

Fig. 7. Concentration dependence of ESR linewidth ($\bar{M}=0$) of TCNE$^-$Cs$^+$ in various solvents at 25 °C: A, THF; B, THF–triglyme (2.8 mol%) mixture.

Figure 7 shows the concentration dependence of the linewidth at 25 °C in THF and THF–triglyme. In comparison with the results obtained at 0 °C (Fig. 6), the break of the curve for the THF shifts toward a lower concentration. This can reasonably be interpreted in terms of the quilibrium (7). Because the dissociation reaction of the ion-pair is exothermic in a liquid, as has been suggested by Denison and Ramsay[14] and Szwarc *et al.*,[13,15] the equilibrium (7) will be shifted to the left-hand side by raising temperature. Therefore, the higher the temperature, the more readily is the ultimate formation of the ion-pair reached. Figure 7 shows the same slope for both THF and THF–triglyme, after the ultimate formation of ion-pair is reached in the former solvent. This suggests that only the Heisenberg spin exchange contributes to the ESR line-broadening in this concentration range in THF, as is the case over the entire concentration range in the THF–triglyme mixture.

Simulation of ESR Spectra. Although the behavior of the spectra indicated ion-pair formation in the TCNE$^-$Cs$^+$–THF system, as has been mentioned above, the hyperfine splitting due to the cesium ion was too small to be resolved experimentally.

Therefore, the hyperfine coupling constant was estimated by comparing the observed spectra with the simulated ones. The simulated spectra were synthesized by means of digital computer (Hokkaido University Computing Center) under the following assumptions: (1) the life-time of the cation-anion pair is long enough compared with the inverse of the cesium hyperfine splitting; (2) each of the 11 lines of the spectrum of the TCNE anion (see Fig. 1) consists of equally-spaced Lorentzian component lines due to $I=7/2$ for the cesium nuclei, and (3) the contribution from the natural abundance of ^{13}C can be ignored. Then, the first-derivative line shape was simulated for an observed line; the $\Delta H_{obs}/\Delta H_L$ ratio is numerically related to the $a_{Cs}/\Delta H_L$ ratio. Here, ΔH_{obs} is the observed peak-to-peak linewidth; ΔH_L, the peak-to-peak linewidth for the first-derivative of the component Lorentzian line, and a_{Cs}, the hyperfine coupling constant of the cesium ion. This treatment is essentially the same as that used for the ion-pair with a sodium counterion by Jones *et al.*[16] The ΔH_{obs} increases with the increasing $a_{Cs}/\Delta H_L$ ratio. When the value of $a_{Cs}/\Delta H_L$ reaches 0.8, the individual component lines begin to become resolved.

If the value of ΔH_L is known, a_{Cs} can be derived from the observed linewidth of the TCNE$^-$Cs$^+$–THF system (ΔH_{obs}) at concentrations high enough for all the anions to form ion-pairs with cesium ion. We presumed that the linewidth observed in the THF–triglyme mixture (Line B in Fig. 7) is identical with the ΔH_L in THF at the same concentration and temperature, because the anion is free from the counterion in the mixture solvent. Thus, the cesium hyperfine coupling constant, a_{Cs}, in THF at 25 °C is determined to be 40 m Gauss from the Line A in Fig. 7 at concentrations higher than 3×10^{-4} M.

Molecular Orbital Study on the H_2O-HCl System

Shuzo SHIBATA, Fumihiko HIROTA, and Yukio OTA
Department of Chemistry, Shizuoka University, Oya, Shizuoka 420
(Received December 14, 1973)

The hydrogen bonded system of H_2O–HCl was studied by the CNDO/2 method. Calculation of the potential energy for the system showed that the complex of H_2O–HCl is considerably stable. The equilibrium structure of the complex and its charge distribution were also investigated.

A number of studies by molecular orbital calculations on simple hydrogen bonded systems have been reported since Clementi carried out a detailed study on ammonium chloride.[1] One of us (S.S.) determined experimentally the molecular structure of NH_4Cl in gaseous phase.[2] Structure determination of the H_2O–HCl system was undertaken for studying simple hydrogen bonded systems. Electron diffraction study was also carried out on the system in gas state. The result confirmed the existence of the molecular complex of H_3OCl. A theoretical study was made in order to see whether the H_2O–HCl molecular complex is actually stable and, if so, to confirm its geometrical structure.

According to Murthy and Rao[3] who carried out many molecular orbital calculations on various hydrogen bonded systems showed that the CNDO/2 procedure[4] can yield satisfactory results for potential energies of hydrogen bonds. Kollman and Allen,[5] and Rao and Murthy[6] recently carried out calculations for the H_2O–HF and NH_3–HF systems, respectively. However, there have been no CNDO/2 studies on hydrogen bonds containing a chlorine atom. It is well-known that the CNDO/2 method is also applicable to the system in which d orbitals contribute.[7] Thus CNDO/2 calculation was carried out on the H_2O–HCl system.

Procedure

Most calculations were performed with the use of a spd set as a basis, and some of them with a sp set. The values of the parameters used in these calculations were the same as those given by Santry and Segal[7] except for the empirical parameter K which is defined by the following relation of the resonance integral:

$$\beta_{AB} = K(\beta_A + \beta_B)/2$$

Santry and Segal suggested the use of 0.75 for K. However, this seems to be somewhat ambiguous, and other values were also used.

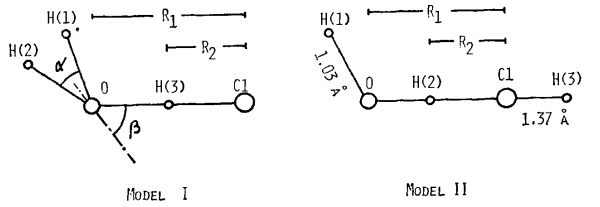

Fig. 1. Geometries of the H_2O–HCl system.
The numbering of hydrogen atoms and the notation of molecular parameters are given in the figure. The listed values of the molecular parameters were assumed in the CNDO/2 caculations.

With respect to geometries of the H_2O–HCl complex two structures, shown in Fig. 1, were taken into consideration. Both were inferred from the gas electron diffraction study. The O–Cl distance, denoted by R_1, and the H(3)–Cl distance (H(2)–Cl distance in model II), by R_2, were varied at intervals of 0.3 and 0.1 Å, respectively. In the neighbourhood of minimum of potential energy R_1 was varied at an interval of 0.1 Å. The angle H(1)OH(2), denoted by α, and the O–H distance were also varied. In the first stage of calculations α was assumed to be 105° from the experimental data for water[8] and the O–H distance was fixed as 1.05 Å obtained from the calculation where other parameters were kept in most probable values. In model I the angle between the H(1)OH(2) plane and the OH(3)Cl line, denoted by β, was also varied preserving the C_s symmetry of the complex. A planar structure was assumed for model II. In both models the hydrogen bonds of O–H–Cl were assumed to be linear. All the calculations were carried out with a FACOM 230-60 computor at Nagoya University Computing Center.

Results and Discussion

For model I, the potential energies of the system, shown in Fig. 2, were calculated as a function of R_1 with the fixed R_2. The calculations were carried out by using K=0.75, spd set, R(O–H)=1.05 Å and α=105°. A potential energy minimum was found at R_1=2.8 Å, independent of R_2. Calculations using the sp basis set also gave nearly the same equilibrium distances

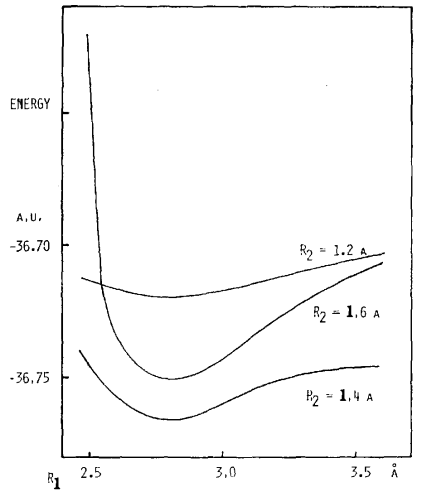

Fig. 2. The energy of the H_2O–HCl system (the model I) as a function of the O–Cl distance, R_1.

as those for the spd basis set though the total energies were considerably different. The distance of 2.8 Å seems to be reasonable in comparison with the O–Cl distance of 2.95 Å found experimentally in crystalline hydrogen chloride monohydrate H_2O–HCl.[9]

The potential curve shows no energy barrier for formation of the complex $H_2O \cdot HCl$. The dissociation energy of the complex was found to be 16 kcal/mol (Table 1). This value also seems to be reasonable in compaison with the calculated value of 10.7 kcal/mol for the H_2O–HF system.[3]

Table 1. Dissociation energies for the H_2O–HCl systems (kcal/mol)

K	Model I		Model II	
	spd	sp	spd	sp
0.75	16	19	8	−14
0.875	8		19	
1.0	5	6	40	−18

Fixed as R(O–H)=1.03 Å, α=104°.

Calculations were carried out varying β from 0 to 60°. The planar structure (β=0°) was found to be most stable. The energy difference between the planar structure and the structure with β=60° was estimated to be 4 kcal/mol. This is contrary to the expectation that the hydrogen bond would be formed toward the direction of the lone pair sp^3 hybrid orbitals of the oxygen atom. It would be understandable from the view point of dipole-dipole interaction.[10]

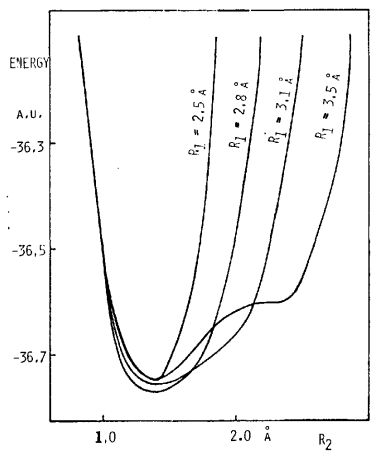

Fig. 3. The energy of the H_2O–HCl system (the model I) as a function of the H(3)–Cl distance.

Figure 3 shows potential energy calculated as a function of R_2 with the fixed R_1, using K=0.75 and spd set. The minimum of the potential energy was found at R_2=1.4 Å, nearly independent of R_1. The H(3)–Cl equilibrium distance of 1.4 Å is considerably greater than 1.27 Å found experimentally for free hydrogen chloride.[11] However, the HCl equilibrium distance calculated by the CNDO/2 method is 1.37 Å. Thus the net increment of H–Cl distance in the complex formation seems to be fairly small. On the other hand, the O–H(3) distance of 1.4 Å is much greater than the O–H(1) distance of 1.03 Å, which is the value calculated for water molecule by the CNDO/2 method. Thus the H_2O–HCl complex can be considered essentially as H_2O hydrogen bonded to HCl. It can be seen from Fig. 3 that transfer of the hydrogen atom of HCl to H_2O is very difficult.

When R_1 is smaller than 2.8 Å, there is no evidence for a double minimum potential. The potential is close to the NH_3–HF potential calculated by Rao and Murthy,[6] differing slightly from the NH_3–HCl potential calculated by Mazur and Ratajczak[12] by means of the Extended Hückel method. As R_1 becomes larger, the potential curve appears asymmetric around the minimum. For R_1=3.5 Å, which is unreasonably long, a new minimum was found around R_2=2.3 Å. In this configuration an ionic structure can be predominant because excess electronic charge on the chlorine atom is 0.67. The complex can thus be considered as hydronium chloride, $H_3O^+Cl^-$.

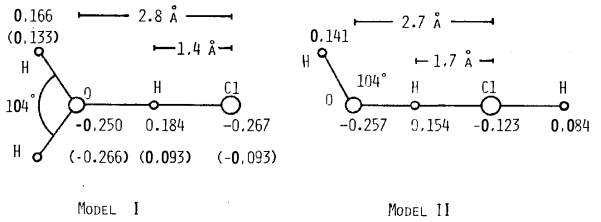

Fig. 4. The equilibrium structures and the atomic populations for the two models.

Figure 4 shows equilibrium structures and their charge distributions calculated by the use of K=0.75 and spd set. Numbers in parentheses are the charge distributions in free H_2O and HCl molecules. In the formation of the complex, H_2O donates electron to HCl, especially to the chlorine atom. However, the total amount of electrons donated to HCl is 0.08. The amount of charge transfer is almost the same as in the case of NH_3–HF system where it was estimated to be 0.05.[6] When the spd basis set was used with K=1 in the CNDO/2 calculations, the equilibrium structure and the charge distribution obtained were the same as those from K=0.75, but the dissociation energy of the complex decreased to about 5 kcal/mol.

For model II, the calculations were carried out by use of the spd basis set with K=0.75 in order to estimate the dissociation energy as well as the equilibrium structure. The dissociation energy was 8 kcal/mol (Table 1), which leads to the conclusion that model I is preferable to model II in agreement with the result for H_2O–HF system by Kollman and Allen.[5] On the other hand the use of the sp basis set showed that model II was unstable itself. From the calculation using the spd set with K=1, however, the dissociation energy was estimated to be 40 kcal/mol, which seems large as compared with the calculated value of 100 kcal/mol (experimental value of 37—58 kcal/mol) for the very strong hydrogen bonds such as HF_2^-.[13] This calculation also gives a large population in d_σ orbital of the chlorine atom, 0.2. This is caused mainly by a large overlap between d_σ orbital of the chlorine atom and 1s orbitals of the H(2) and H(3) atoms. The use of the

spd set with $K=1$ may not be correct since it gives rise to an excessive contribution of the d orbital. Santry and Segal found that good agreement of calculation with experiment is obtained for $K=0.75$.[7] These results lead us to prefer model I for the structure of the H_2O–HCl complex. However, a definite conclusion cannot be made since the stabilities of the two models are essentially dependent on the choice of the K value.

Conclusion

The CNDO/2 procedure gave the conclusion that the H_2O–HCl complex is stable in the planar structure with the equilibrium O–Cl distance of 2.8 Å. The complex can be considered to be H_2O hydrogen bonded to HCl than H_3O^+ bonded to Cl^-. The results, however, could not exclude the other structure of HOH–ClH with the O–Cl distance 2.7 Å.

An MO Calculation of 1,3-Dipolar Cycloaddition between Ethylene and Diazomethane

Tsutomu MINATO, Shinichi YAMABE, Satoshi INAGAKI, Hiroshi FUJIMOTO, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 1, 1974)

A semiempirical SCF MO calculation of the reaction between ethylene and diazomethane was carried out as an example of 1,3-dipolar cycloaddition. A calculation of the interaction energy and electron population by the use of the configuration interaction wave function showed that the formation of the two new bonds in this reaction is concerted but non-synchronous. This result is attributable to the extension of the highest occupied molecular orbital of diazomethane.

The molecular orbital (MO) approach can be used to interpret the chemical reactivity of organic molecules, both saturated[1] and unsaturated.[2] Most of the MO criteria for the chemical reactivity are based upon the use of various reactivity indices.[3] These indices agree fairly well with the experimental results. Therefore, the study of electronic effects appears to lead to the elucidation of the reaction mechanism. We will study 1,3-dipolar cycloaddition through calculations of the electron states of ethylene and diazomethane.

1,3-Dipolar cycloaddition is the union of a 1,3-dipole (a—b—c) with a multiple bond system (d—e), the so-called dipolarophile, to form a five-membered ring.[4,5] A 1,3-dipole a—b—c is described by a zwitterionic octet structure, *e.g.*:

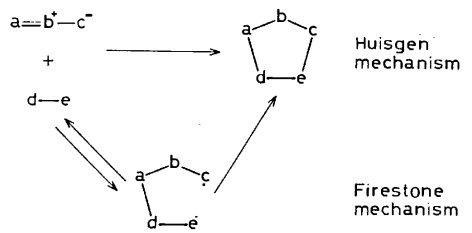
$$a \equiv b^+ - c^- \longleftrightarrow a^- = b^+ = c \quad (b=N)$$

$$a = b^+ - c^- \longleftrightarrow a^- - b^+ = c \quad (b=N\text{-}R,\ O)$$

Specific classes of molecular 1,3-dipoles include diazoalkanes ($R_2C{=}N^+{=}N^-$), nitrile oxides (Ar–C≡N^+–O^-), azides (Ar–N=N^+=N^-), nitrones (Ar–CH=N^+(Me)–O^-) and nitrile amines (Ar–C≡N^+–N^-–Ar).

The concept of this reaction was first suggested by Smith.[6] The generality of the reaction was recognized by Huisgen[4] in a splendid series of researches, during which many new reactions were predicted and discovered. The picture of the reaction mechanism which Huisgen's group drew was that of a single-step, concerted cycloaddition, in which the concerted formation of the two new bonds (*i.e.*, a—d and c—e) is not necessarily synchronous.[4]

Woodward-Hoffmann rules for the conservation of orbital symmetry[7] supply the theoretical basis and, taken with most of the experimental results,[4] provide support for Huisgen's earlier predictions.[8] That is, the rules reveal that 1,3-dipolar cycloaddition is symmetry-allowed for the ground state. Recently Firestone has argued in favour of a two-step mechanism involving biradical intermediates.[9]



The nature of orientation in the reaction (*i.e.*, unsymmetrical dipolarophiles can add to the unsymmetrical 1,3-dipole in two directions, (I) and (II)) has not been adequately interpreted and predicted.

(I) (II)

However, Houk qualitatively discussed the regioselectivity in 1,3-dipolar cycloaddition in terms of the extension of particular MO's, and his conclusion is consistent with the experimental results.[10,11] Furthermore, he and his co-workers[11] qualitatively discussed nonsynchroneity in the formation of two new bonds; this nonsynchroneity seems to play a part in the determination of the orientation of the concerted mechanism.[12]

Considering these circumstances, we will undertake a more detailed perturbational MO calculation of the nonsynchronous formation of new bonds in the course of the 1,3-dipolar cycloaddition reaction between olefin and diazoalkane.

Here olefin (dipolarophile) and diazoalkane (1,3-dipole) will be typified by ethylene and diazomethane for the sake of simplicity of calculation.

Method of Calculation

In this paper, the means of calculation is based upon one[13] of the isolated molecule approximations that Fukui *et al.* have developed. That is, the wave function (Ψ) of a chemically-interacting state in a reaction between ethylene and diazomethane is represented by means of the configuration interaction (CI) procedure;

$$\Psi = C_0\Psi_0 + \sum_{i=1}^{6}\sum_{l=9}^{14} C_{i\to l}\Psi_{i\to l} + \sum_{k=1}^{8}\sum_{j=7}^{12} C_{k\to j}\Psi_{k\to j} + \sum_{i=1}^{6}\sum_{j=7}^{12} C_{i\to j}\Psi_{i\to j} + \sum_{k=1}^{8}\sum_{l=9}^{14} C_{k\to l}\Psi_{k\to l} \qquad (1)$$

where Ψ_0 means the adiabatically-interacting state in which all valence electrons occupy the MO's of ethylene (i) and those of diazomethane (k), both doubly-occupied in their initially-isolated state. $\Psi_{i\to l}$ implies the charge-transferred state, with one electron in the i-th occupied MO of ethylene transferred into the l-th unoccupied one of diazomethane, while $\Psi_{k\to j}$ implies a back charge-

transferred state in which one electron in the k-th occupied MO of diazomethane jumps up into the j-th unoccupied one of ethylene. $\Psi_{i\to j}$ is a locally-excited state in which an electron in the i-th MO of ethylene is excited into the j-th MO of ethylene and $\Psi_{k\to l}$ indicates a locally-excited state in diazomethane as does $\Psi_{i\to j}$ in ethylene. These wave functions are constructed by means of Slater determinants, composed of the semiempirical LCAO SCF MO's,[14] including all valence electrons and overlap integrals. C_0, $C_{i\to l}$, $C_{k\to j}$, $C_{i\to j}$, and $C_{k\to l}$ in Eq. (1) are the CI coefficients obtained by solving the usual CI secular equation.

When the CI seqular equation is expanded in the approximate sense that the interaction is not too strong, the total stabilization energy (ΔW) due to the CI effect mentioned above can be partitioned into the following four terms: Coulombic (E_Q), exchange (E_K), delocalization (D), and polarization (π) terms.[13]

$$\Delta W = E_Q + E_K - D - \pi \qquad (2)$$

E_Q is the electrostatic interaction energy between ethylene and diazomethane. E_K is the exchange repulsion energy between two closed-shell molecules[15] resulting from the overlap between the occupied MO's of two molecules; it increases unfavorably as the reaction proceeds. D is the stabilization energy due to the mixing-in of the charge-transferred states ($\Psi_{i\to l}$ and $\Psi_{k\to j}$) with the adiabatically-interacting state (Ψ_0); it works to promote the reaction. The last term in Eq. (2), π, is also the stabilization energy due to the mixing-in of local excited states ($\Psi_{i\to j}$ and $\Psi_{k\to l}$). π is usually less important than the others on the right-hand side of Eq. (2).[15]

The electron density ($\rho(1|1)$) of the interacting state (Ψ) is given by:[16]

$$\rho(1|1) = 28\int \Psi^*(1, 2, \cdots, 28)\Psi(1, 2, \cdots, 28) \times d\varepsilon_1 d\tau_2 \cdots d\tau_{28} \qquad (3)$$

where the number "28" indicates the total valence electrons in the whole system, where $d\varepsilon_1$ is the integral over the spin coordinate of the 1 electron, and where $d\tau_i$ is the integral over both the spin and space coordinates of the i electron. Furthermore, $\rho(1|1)_{C_2H_4}+\rho(1|1)_{CH_2N_2}$ signifies the simple sum of the electron density of ethylene and that of diazomethane. Of course, $\rho(1|1)$ is different from $\rho(1|1)_{C_2H_4}+\rho(1|1)_{CH_2N_2}$.

Results and Discussion

The molecular geometry of ethylene and diazomethane which we have employed comes from Herzberg[17] without any deformation, because it seems that the interaction between ethylene and diazomethane is sufficiently weak at the early stage of the reaction. Figure 1 illustrates the geometry of the assumed reaction models. M in Fig. 1 represents the center of the linear C_3–N_4–N_5 line of diazomethane. Theta (θ) in Fig. 1 represents the angle between the C_3–N_4–N_5 line and the X-axis. The restrictions adopted in the selection of the geometry in Fig. 1 are as follows. The two molecular planes (*i.e.*, two Y–Z planes) to which ethylene and diazomethane respectively belong are parallel at $\theta=90°$. The distance between the planes is 2.7 Å. M moves horizontally along the C_3–N_4–N_5 line of diazomethane from a position just above the C_1 of ethylene to one above the C_2 of ethylene in order to determine the relative position of the two parallel molecules. Therefore, the geometry of the assumed reaction model is selected in terms of the position of M which gives the lowest total energy by the CNDO/2 method.[18] This geometry ($\theta=90°$) is defined as Model 1. Furthermore, diazomethane is rotated about M by $\pm5°$; we define the geometry at $\theta=85°$ as Model 2 and the geometry at $\theta=95°$ as Model 3.

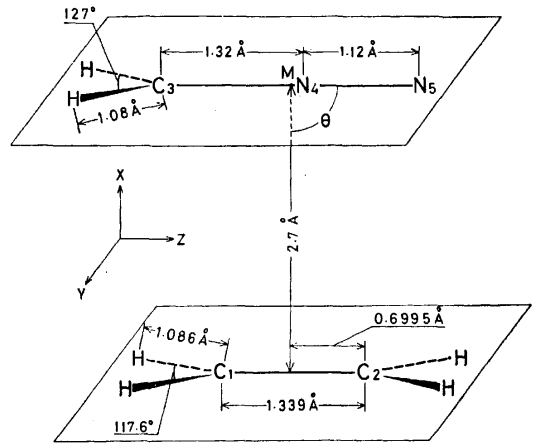


Fig. 1. Assummed interacting models between ethylene and diazomethane at the initial stage of the reaction. The former molecule holds D_{2h} symmetry and latter has C_{2v} one.

The MO energy levels of the ethylene and diazomethane obtained by the SCF procedure are given in Fig. 2.

First let us consider Model 1 at $\theta=90°$, in which

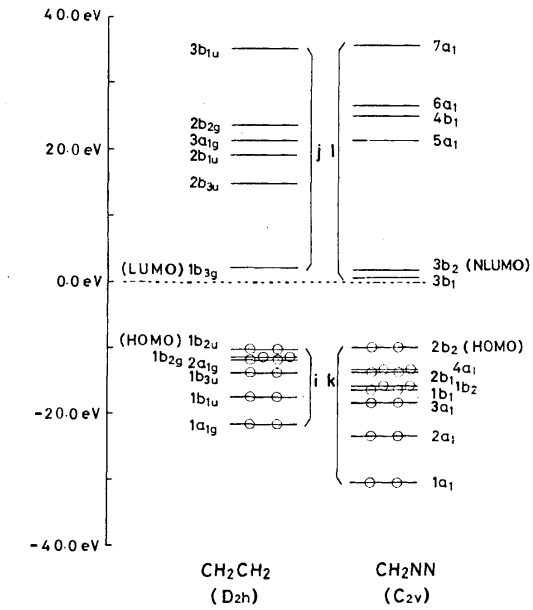

Fig. 2. Schematic presentation of MO levels of ethylene and diazomethane. NLUMO in this figure represents the next unoccupied MO of the lowest unoccupied MO.

two molecular planes are parallel. The interaction energy, ΔW, was calculated for Model 1; the results are given in Table 1. Table 1 shows that, in this reaction model, E_Q and π are small in value because the two reactants we use are *neutral* molecules. E_K and D are larger than the former two terms. E_K is found to hinder the progress of the reaction. On the other hand, D greatly stabilizes this reaction system, thus prompting the reaction.

Table 1. Interaction energies between diazomethane and ethylene

	Model 1	Model 2	Model 3
θ[a] (°)	90	85	95
E_K (eV)	2.769	2.588	3.260
E_Q (eV)	−0.015	−0.014	−0.015
D (eV)	1.325	1.141	1.958
π (eV)	0.040	0.044	0.053
ΔW (eV)	1.389	1.389	1.234

a) θ is shown in Fig. 1.

In order to seek for the CI configuration ($i \rightarrow l$ and $k \rightarrow j$ combinations) which is the most contributive to D, the calculated CI coefficients of Eq. (1) are given in Eq. (3). Here, the polarization effect is neglected because the effect is sufficiently small, as may be understood from the value of π in Table 1.

$$\Psi_{\text{Model 1}} = 0.883\Psi_0 + 0.342\Psi_{2b_2 \rightarrow 1b_{3g}} + 0.129\Psi_{2a_{1g} \rightarrow 3b_2} - 0.059\Psi_{2a_1 \rightarrow 1b_{3g}} - 0.034\Psi_{1b_{2u} \rightarrow 3b_2} \quad (3)$$

The terms with a CI coefficient whose absolute value is smaller than 0.03 are neglected. Equation (3) shows that the largest CI coefficient except C_0 (=0.883) that is contributive to D is that of the charge-transferred state from the highest occupied (HO) MO of diazomethane ($2b_2$) to the lowest unoccupied (LU) MO of ethylene ($1b_{3g}$). Therefore, there is no doubt that the charge-transfer interaction between the particular MO's, *i.e.*, the HOMO of diazomethane and the LUMO of ethylene, plays a remarkably important role in promoting the reaction.[2]

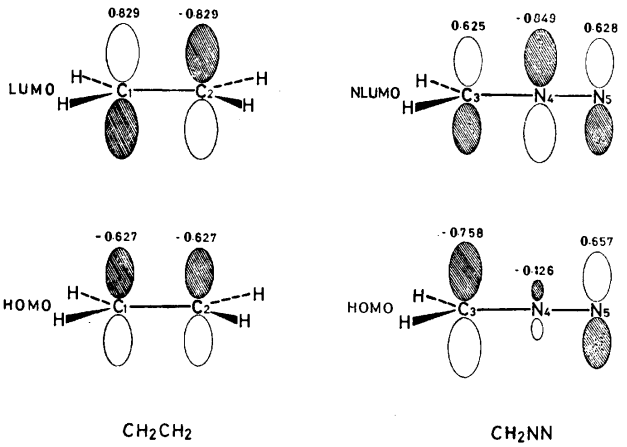

Fig. 3. The nodal property of the particular MO's in ethylene and diazomethane. The values in this figure are the AO coefficients.

The *frontier* MO's* nodal property of ethylene and diazomethane is given in Fig. 3. The values represent the atomic orbital (AO) coefficients of the *fronitier* MO's. Figure 3 shows that the AO coefficient of C_3 (−0.758) is larger than that of N_5 (0.657) in the HOMO of diazomethane.

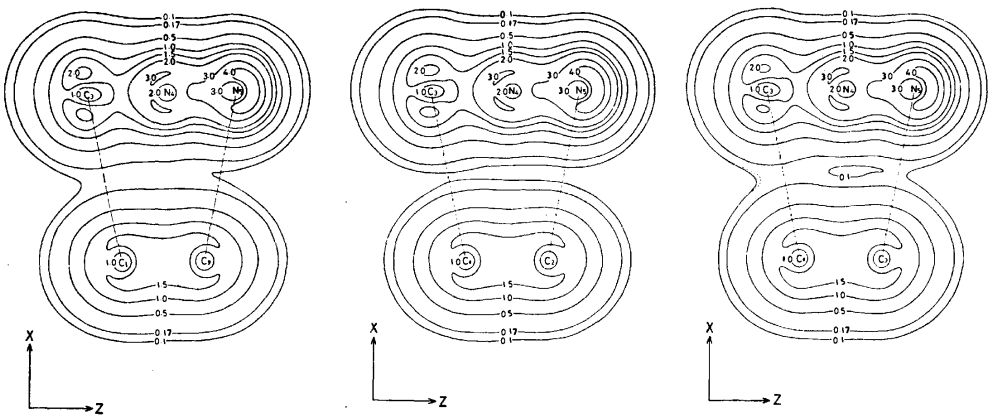
Here, the electron-density contour maps, which make it easy to understand the new bond formation and the old bond disappearance along the reaction course, are considered at the stage of the reaction shown in Fig. 1 by the use of the CI coefficients of Eq. (3). These contour maps are given in Fig. 4 with respect to Model 1. All the electron density lines are pictured on the X-Z plane of Y=0.0.

Figure 4(a) shows the simple sum of the electron density of ethylene and diazomethane, without any interaction between them. This electron density is defined as $\rho(1|1)_{C_2H_4} + \rho(1|1)_{CH_2N_2}$.

Figure 4(b) shows the electron density with only the adiabatic interaction included; this density is defined as $\rho(1|1)_{0,0}$. It may be noted by observing the 0.1 e/Å^3 density line that the electron density in the intermolecular region, especially that between C_1 of ethylene and C_3 of diazomethane, and that between C_2 of the former molecule and N_5 of the latter, decreases as a result of the inclusion of the electron-exchange interaction in Fig. 4(b), compared with that in Fig. 4(a). This reflects the fact that E_K works repulsively between the two molecules. This is essential to the interaction between two closed-shell systems, as in the case of two helium atoms.

Figure 4(c) shows the electron density with both adiabatic interaction and charge-transfer interaction; this density is defined as $\rho(1|1)$. The comparison of the 0.1 e/Å^3 density line in Fig. 4(c) with that in Fig. 4(a) shows that the electron density between C_1 of ethylene and C_3 of diazomethane, and that between C_2 of the former and N_5 of the latter, overcome the electron density decrease caused by the electron-exchange interaction, thus resulting in an increasing electron density in the reaction zone on account of the mixing-in of the charge-transferred state. We can see that the decrease in the intermolecular electron density between N_4 of diazomethane and ethylene in Fig. 4(b) by the exchange interaction is still preserved in Fig. 4(c). As the overlap between the diazomethane HOMO on N_4 and the ethylene LUMO is small, as Fig. 3 shows, the charge-transfer effect does not appear on N_4 and ethylene. This causes the bending of 1,3-dipole which was adopted in Huisgen's model.[4] Furthermore, Fig. 4(c) also gives us the information that the electron density between C_3 and N_4 of diazomethane decreases, shown, for instance, by the 1.5 e/Å^3 density line which indicates the weakening of the C_3–N_4 bond. The electron density between C_1 and C_2 of ethylene is calculated to decrease in Fig. 4(c), but the decrease is too small to be observed in the figure. Figure 4(c) demonstrates that the electron density increases in the neighborhood of C_1 and C_2 of

* The LUMO of diazomethane is not the *frontier* MO, because it ($3b_1$) can not overlap with the HOMO of ethylene ($1b_{2u}$).



(a) (b) (c)

Fig. 4. Total electron density (in e/Å^3) of Model 1.
(a): $\rho(1|1)_{C_2H_4}+\rho(1|1)_{CH_2N_2}$, (b): $\rho(1|1)_{0,0}$,(c): $\rho(1|1)$.
The dotted line is the 0.1 e/Å^3 density line of (a).

ethylene and decreases in the neighborhood of C_3 of diazomethane. This shows that the carbon of diazomethane is *nucleophilic*.[4c]

Figure 4 shows that the formation of two intermolecular new bonds, C_1–C_3 and C_2–N_5, and the weakening of the old bonds, C_3–N_4 in diazomethane and C_1–C_2 in ethylene, can be described approximately in terms of the mixing-in of the charge-transferred state with the adiabatically-interacting one. That is, at the early stage of this reaction the two bonds are formed by the charge-transfer interaction corresponding to D in the energy expression and the N_4 atom is repulsed from ethylene by the exchange interaction (E_K). The five-membered ring can, then, be pictured by this scheme. At the same time, the HOMO–LUMO interaction is most important, as is shown by the CI coefficients in Eq. (3).

The AO coefficient of C_3 is larger than that of N_5 in the HOMO of diazomethane, as is shown in Fig. 3. To see how this difference in the values influences the reactivity, we prepared Model 2 (θ=85°) and Model 3 (θ=95°).

The interaction energy of Model 2 and that of Model 3 are evaluated, in comparison with that of Model 1 in Table 1. Here the most preferable reaction path may be defined as the model that makes ΔW the smallest.[15] Therefore, the results in Table 1 show that Model 3 is the most reasonable among the three models considered here at the early stage of this reaction.

The wave functions with respect to Model 2 and Model 3 corresponding to Eq. (3) of Model 1 are given by Eqs. (4) and (5):

$$\begin{aligned}\Psi_{\text{Model 2}} = {} & 0.898\Psi_0 + 0.310\Psi_{2b_2\to 1b_{3g}} + 0.128\Psi_{2a_{1b}\to 3b_2} \\ & - 0.058\Psi_{2a_1\to 1b_{3g}} - 0.042\Psi_{1b_{2u}\to 3b_2} \\ & + 0.039\Psi_{1b_{2g}\to 3b_1} \qquad (4)\end{aligned}$$

$$\begin{aligned}\Psi_{\text{Model 3}} = {} & 0.843\Psi_0 + 0.411\Psi_{2b_2\to 1b_{3g}} + 0.130\Psi_{2a_{1g}\to 3b_2} \\ & - 0.059\Psi_{2a_1\to 1b_{3g}} - 0.056\Psi_{1b_{1u}\to 3b_2} \\ & - 0.033\Psi_{3a_1\to 1b_{3g}} \qquad (5)\end{aligned}$$

The absolute values of the CI coefficients smaller than 0.03 are neglected, as in Eq. (3). A comparison of Eqs. (4) and (5) indicates that the charge-transfer effect works most successfully in Model 3. When C_3 which has the largest AO coefficient of the HOMO of diazomethane, approaches C_1 of ethylene, the MO overlap between the HOMO of diazomethane and the LUMO of ethylene is extended. Therefore, Model 3 is favorable to the charge-transfer interaction.

Furthermore, the contour maps are depicted for Model 2 and Model 3. Figure 5 indicates the electron density of Model 2 in the X–Z cross section. Figure 5(a) shows the sum of the electron density of ethylene and diazomethane, corresponding to Fig. 4(a) of Model 1. Figure 5(b) shows the electron density with the adiabatic and the charge-transfer interactions, corresponding to Fig. 4(c) of Model 1. Model 2 is an unfavorable reaction path, as may be understood from the interaction energy in Table 1; a comparison of Fig. 5(a) with Fig. 5(b) gives the information that the electron-density increase in the intermolecular region of Model 2 as a result of the mixing-in of the charge-transferred state with Ψ_0 is similar in appearance to that of Model 1.

Figure 6 indicates the electron density of Model 3 in the X–Z cross section. Figure 6(a) shows the sum of the electron density of ethylene and diazomethane, corresponding to Fig. 4(a) of Model 1 and Fig. 5(a)

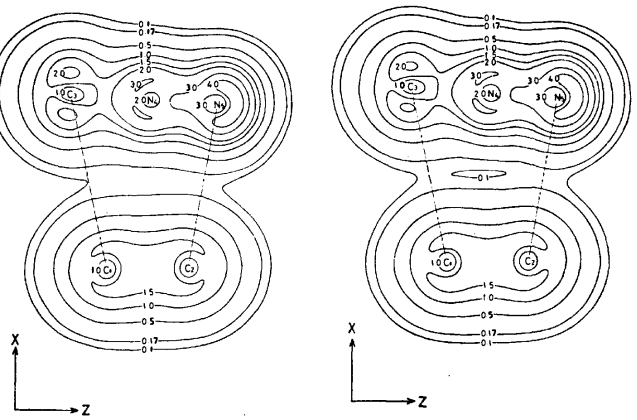


Fig. 5. Total electron density (in e/Å^3) of Model 2.
(a): $\rho(1|1)_{C_2H_4}+\rho(1|1)_{CH_2N_2}$, (b): $\rho(1|1)$.

of Model 2. Figure 6(b) shows the electron density with the adiabatic and the charge-transfer interactions, corresponding to Fig. 4(c) of Model 1 and Fig. 5(b) of Model 2. Model 3 is found, from the findings on interaction energy in Table 1, to be the most favorable reaction model. In this model, the electron density in the intermolecular region, especially C_1–C_3, shows a considerable increase as a result of a more effective mixing-in of the charge-transferred state with Ψ_0 than the others, as the comparison of the 0.17 e/Å^3 density line in Fig. 6(a) with that in Fig. 6(b) shows. Therefore, a concerted cycloaddition of diazomethane to ethylene may be expected to show an unequal progress of the bond formation, as Houk and his co-workers proposed.[11]

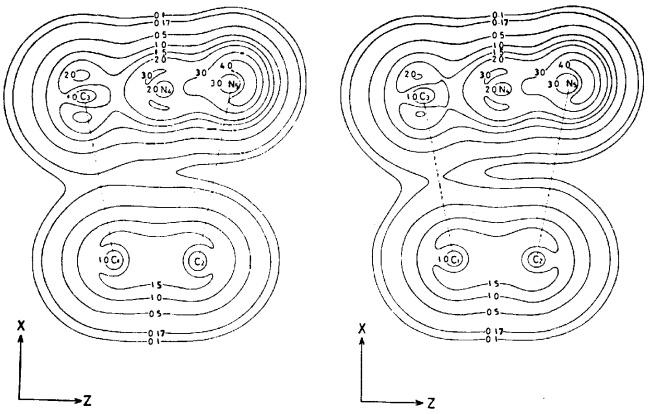

Fig. 6. Total electron density (in e/Å^3) of Model 3.
(a): $\rho(1|1)_{C_2H_4}+\rho(1|1)_{CH_2N_2}$, (b): $\rho(1|1)$.

This nonsynchroneity of the two new bond formations may be explained as follows. In ΔW, the largest stabilization comes from D; it is the charge-transfer interaction from the HOMO of diazomethane to the LUMO of ethylene that is the most contributive to D, as is shown by the comparison of the CI coefficients. Therefore, the reaction will take place along the path which maximizes the MO overlap between the HOMO and the LUMO. The HOMO of diazomethane has a larger extension on C_3 than on N_5. Therefore, it is favorable that the approach of C_3 to C_1 occurs first.

If steric complications are not considered it is reasonable to assume that, in an asymmetric dipolarophile, the largest HOMO-coefficient atom of diazomethane (*i.e.*, the carbon atom) unites with the largest LUMO-coefficient atom of the dipolarophile.[10,11,19]. Diels-Alder reactions between two dissymmetrical reagents are also most likely to be non-synchronous, as has been suggested by Woodward and Katz.[20] As Diels-Alder reactions have been shown to be under *frontier* control,[21] it seems reasonable to think that the first bond would link the largest HOMO-coefficient atom of diene and the largest LUMO-coefficient atom of dienophile.[12,22]

Conclusion

An approximate MO calculation of the 1,3-dipolar cycloaddition of diazomethane to ethylene has been carried out by a CI method. The results of the present calculation have proved nonsynchroneity in the formation of two new bonds. This result can be explained on the basis of the fact that the extension of the HOMO of diazomethane is different on different constituting atoms. Therefore, the extension of the HOMO is important in any consideration of the reaction path.

The authors wish to express their appreciation to the Data Processing Center of Kyoto University for a generous permission to use the FACOM 230-60 computer.

Magnetic Susceptibility of Magnesium 2,2'-Dipyridylide in its THF Adducts

Tatsuo HORIBA, Ken-ichi HARA,* Motomichi INOUE, and Masaji KUBO
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464
(Received February 20, 1974)

The magnetic susceptibility of magnesium 2,2'-dipyridylide has been determined in its THF (tetrahydrofuran) adducts in a temperature range of 1.6—20 K. The susceptibility of $Mg(dipy)_2 \cdot THF$ exhibits two maxima at about 3.9 and 9.5 K due to short range and long-range interactions, respectively. The observed susceptibility conforms to the alternating linear Heisenberg model above about 6 K. $Mg(dipy)_2 \cdot 3THF$ shows no definite maximum of magnetic susceptibility. The magnetic behavior of these complexes different from that of $Be(dipy)_2$ is attributable to the difference in the ionic character between Mg–N and Be–N bonds.

The magnetic susceptibility of beryllium 2,2'-dipyridylide, $Be(dipy)_2$, conforms to an equation for isolated binuclear clusters, indicating that antiferromagnetic interaction operates between two 2,2'-dipyridyl radical anions within a molecule.[1] The tetrahydrofuran adduct of magnesium 2,2'-dipyridylide, $Mg(dipy)_2 \cdot 3THF$, was found to show an effective magnetic moment of 2.73 B.M. at room temperature.[2] This value is nearly equal to $(2 \times 3)^{1/2}$ B.M. for a biradical having two independent unpaired electrons, indicating the presence of two dipyridyl ion radicals in a molecule. However, magnesium 2,2'-dipyridylide is suspected to show a magnetic property different from that of $Be(dipy)_2$ at low temperature, because beryllium and magnesium compounds differ from each other in bond nature. One may expect to obtain information about magnetic interaction by comparing the magnetic properties of the beryllium and magnesium complexes. Therefore, we have undertaken to determine the magnetic susceptibility of magnesium 2,2'-dipyridylide.

Experimental

Preparation of Materials. Excess metallic magnesium was mixed with a solution of 2,2'-dipyridyl in THF. On adding a small quantity of iodine to the solution, deep red crystalline precipitate separated. Recrystallization from THF yielded the crystals of $Mg(dipy)_2 \cdot 3THF$[2] (Calcd: Mg, 4.5%. Found: Mg, 4.4%). When the precipitate was recrystallized from benzene, deep red needle crystals were obtained. On heating in vacuum at about 90 °C, weight loss amounted to 19.2%. The liberated gas did not freeze even at dry-ice temperature, indicating that the crystals were those of a THF (mp, −108.5°) adduct, $Mg(dipy)_2 \cdot THF$, rather than a benzene adduct (Calcd: Mg, 5.9%; THF, 17.6%. Found: Mg, 5.6%; THF, 19.2%). As the compounds were very sensitive to atmospheric oxygen and moisture, they were preserved in an atmosphere of argon or helium.

Magnetic Measurement. The magnetic susceptibility was determined by means of a Hartshorn bridge operating at 90 Hz with a field strength equal to about 10 Oe. Iron(III) alum was employed as a standard. The molar susceptibility was corrected for diamagnetic contributions (10^{-6} emu/mol) from 2,2'-dipyridyl (−93) and THF (−55). The values were calculated on the basis of the observed susceptibility of pyridine and the Pascal constants.[3]

Electronic Spectra. Electronic spectra were recorded in solutions by means of a Model 323 recording spectrophotometer from Hitachi Ltd.

Results and Discussion

The magnetic susceptibility *versus* temperature curve of $Mg(dipy)_2 \cdot THF$ exhibits two maxima at about 3.9 and 9.5 K as shown in Fig. 1. The broad maximum

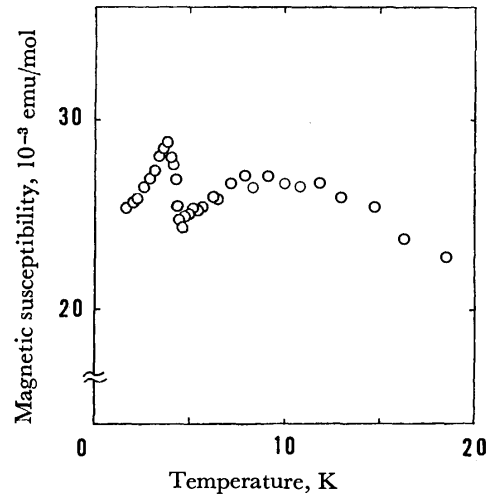

Fig. 1. Magnetic susceptibility of $Mg(dipy)_2 \cdot THF$.

at the higher temperature is undoubtedly due to a short-range magnetic interaction. An ESR study carried out on magnesium 2,2'-dipyridylide in a glassy 2-methyltetrahydrofuran matrix has indicated that each metal ion has a tetrahedral coordination comprising four nitrogen atoms from two dipyridyl ions.[4] From the result, the biradical molecules of $Mg(dipy)_2$ are expected to exist as units in the crystals of $Mg(dipy)_2 \cdot THF$. This suggests that the magnetic behavior due to a short-range interaction can be explained by the binuclear cluster model. However, the observed curve can be reproduced with difficulty by the theoretical formula for weakly coupled biradicals[5] as well as by isolated biradicals. For the coupled dimer model or the alternating linear Heisenberg model, the Hamiltonian is given by

$$\mathcal{H} = -2J\sum_{i=1}^{N/2}(\mathbf{S}_{2i-1}\cdot\mathbf{S}_{2i} + a\mathbf{S}_{2i}\cdot\mathbf{S}_{2i+1}) + g\beta\sum_{i=1}^{N}\mathbf{S}_i\cdot\mathbf{H}$$

* Present address: Central Research Laboratory, Fuji Electric Co., Ltd., Nagasaka, Yokosuka.

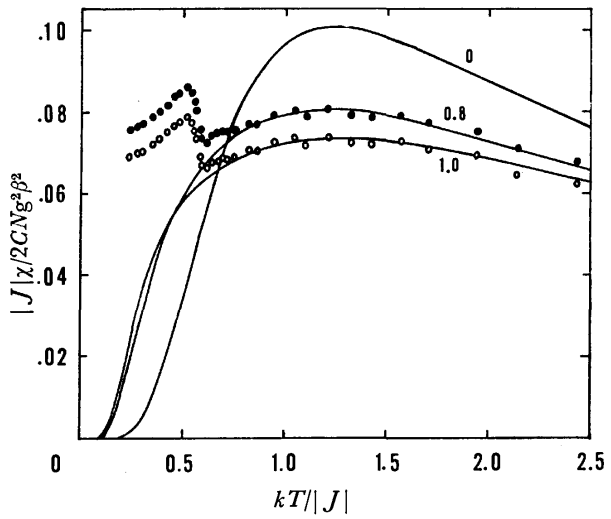

Fig. 2. Theoretical magnetic susceptibility of alternating linear chains with a=0—1 and the observed curves of Mg(dipy)$_2$·THF (○: $J/k=-7.6$ K, C=0.93; ●: $J/k=-7.6$ K, C=0.85).

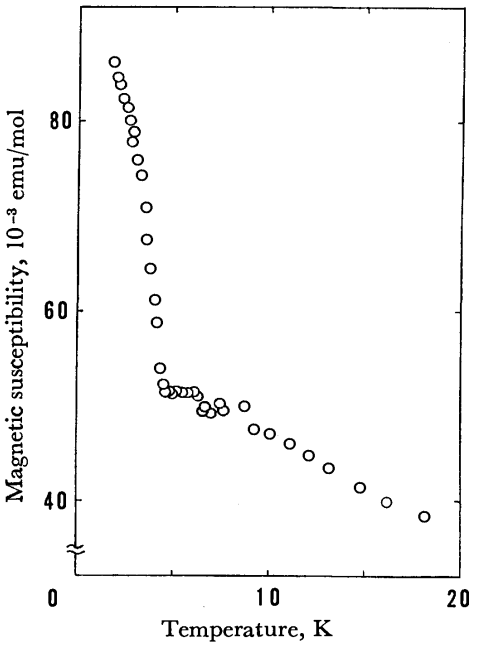

Fig. 3. Magnetic susceptibility of Mg(dipy)$_2$·3THF.

where apart from obvious notations, J denotes the exchange integral and a is the alternation parameter ($0\leq a\leq 1$). Duffy and Barr[6] have calculated the theoretical curve of $|J|\chi/Ng^2\beta^2$ *versus* $kT/|J|$ for various a values using the Hamiltonian with N=10. The result is applicable to the susceptibility of Mg(dipy)$_2$·THF, when $|J|\chi/Ng^2\beta^2$ is rewritten as $|J|\chi/2CNg^2\beta^2$ (C denotes the fractional radical concentration and g is reasonably assumed to be equal to 2.00 for organic radicals). As shown in Fig. 2, the theoretical curves with a=0.8 and 1.0 agree well with the observed data except for a region below about 6 K. The exchange integral was evaluated as $J/k=-7.6$ K. As described above, the curve for isolated binuclear clusters (a=0) does not reproduce the observed curve even in a region above the temperature of the maximum susceptibility.

The magnetic susceptibility exhibits another maximum at about 3.9 K. The appearance of the second peak in a susceptibility *versus* temperature curve has been observed for some metal complexes having one-dimensional lattices,[7,8] but no quantitative discussion has been given. Undoubtedly, the maximum at the lower temperature is due to a three-dimensional ordering existing below the temperature.

The magnetic behavior of Mg(dipy)$_2$·3THF resembles that of Mg(dipy)$_2$·THF to some extent, but no definite maxima were observed in the temperature range investigated (see Fig. 3). Below about 4.5 K, the susceptibility *versus* temperature curve shows a sharp increase and a gradual diminution of the slope with decreasing temperature, suggesting the appearance of a peak at still lower temperature. The almost constant susceptibility between 4.5 and 6 K is due to a short-range interaction. Although accurate analysis is difficult owing to the absence of any definite maximum, the susceptibility conforms to the alternating linear chain model rather than to the isolated binuclear cluster model.

From the result of an ESR study carried out on the magnesium salt in a glassy matrix,[4] the biradical molecules of Mg(dipy)$_2$ are expected to be present as crystal units. However, the observed value of the alternation parameter, a=0.8—1.0, shows that alternating linear chains rather than binuclear clusters should be regarded as magnetic units. The appearance of long-range ordering also suggests the presence of alternating linear magnetic chains interacting with one another. On the other hand, Be(dipy)$_2$ shows magnetic properties conforming to theoretical susceptibility for isolated binuclear clusters. The quite different magnetic properties are evidently due to the difference in crystal structure between the magnesium and beryllium compounds, because the electronic absorption spectrum of the magnesium salt in a diethyl ether solution bears a strong resemblance to those of the corresponding lithium and beryllium salts[1,9] (see Table 1). Beryllium occupies a unique position among group IIA elements and readily forms covalent bonds.[10] This favors the regular tetrahedral arrangement of Be–N bonds. Because Mg–N bonds are essentially ionic in the crystals of some magnesium salts, 2,2'-dipyridyl anions are presumably stacked face to face to form a one-dimensional array, which exists commonly in the crystals of

radical ion salts.[11,12] Even if a tetrahedral arrangement comprising Mg–N bonds exists in crystals, the tetrahedral coordination is suspected to be distorted to a great extent. Probably the distortion facilitates the presence of magnetic interaction between the biradicals. The magnitude of exchange interaction ($J/K=-7.6$ K) is smaller than those in $Be(dipy)_2$ (-11.6 K) and $Li(dipy)\cdot(C_2H_5)_2O$ (-80 K).[1,11] If interaction takes place through the sp^3 orbitals of the central metal in the beryllium complex, ferromagnetic interaction ($J>0$) must be dominant because the sp^3 orbitals are orthogonal to one another. This contradiction to the experimental results suggests the intervention of a more complicated mechanism. A charge-transfer mechanism proposed for Wurster's salts is applicable also to beryllium 2,2'-dipyridylide. When a charge-transfer state, $Be^0(dipy^0)_2$, interacts with the ground state, $Be^{2+}(dipy^-)_2$, to some extent, the singlet state in the degenerate ground state is stabilized, whereas the triplet state is unaffected. This mechanism leads to an antiferromagnetic interaction, which masks the ferromagnetic interaction through the sp^3 orbitals as experimental results indicate. In the magnesium salts also, only the singlet state of $Mg^{2+}(dipy^-)_2$ can interact with a charge-transfer state, $Mg^0(dipy^0)_2$ or $Mg^{2+}(dipy^0)(dipy^{2-})$. Evidently, the magnitude of exchange interaction depends on the ionization potential and the distance between radical ions.

Topochemical Studies. III. The Crystal and Molecular Structures of Crotonic Acid, $CH_3CH=CHCOOH$, and Crotonamide, $CH_3CH=CHCONH_2$

Shozo SHIMIZU, Shinji KEKKA,* Setsuo KASHINO, and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received March 25, 1974)

Crotonic acid crystallizes in the monoclinic space group C2/c, with $a=15.30(3)$, $b=4.06(1)$, $c=16.18(2)$ Å, $\beta=107.4(1)°$ and $Z=8$; crotonamide in the monoclinic space group $P2_1/a$, with $a=9.71(2)$, $b=6.90(2)$, $c=7.75(1)$ Å, $\beta=104.0(4)°$ and $Z=4$. The structures have been solved by the Patterson method and refined by the block-diagonal least-squares method. The final R values are 0.090 for 337 observed reflections for crotonic acid, and 0.088 for 525 observed ones for crotonamide. The configuration of the molecules of crotonic acid and crotonamide is approximately planar and of *trans*-type regarding the C=C bond. Every two centrosymmetrically related molecules form a dimer through hydrogen bonds of 2.645 Å (OH···O) for crotonic acid and 2.963 Å (NH···O) for crotonamide. In the crystals of crotonamide additional NH···O hydrogen bonds (2.862 Å) link the neighboring molecules related by the a-glide plane to form a sheet parallel to (001) plane. Distances between the C=C bonds of the nearest neighbors are 3.86 Å for crotonic acid and 3.62 and 3.88 Å for crotonamide.

In the first paper of this series[1] attention has been drawn to the crystal structure of aconitic acid as an unsaturated aliphatic acid in order to test the topochemical rule[2] and to examine the relationship between the molecular geometry and the hydrogen bond system.[3] The present paper is devoted to the examination of the degree of planarity of the molecules and the packing arrangement of the simplest α,β-unsaturated acid, crotonic acid, and its amide.

Experimental

Crotonic acid crystallized from aqueous solution as soft, colorless transparent plates elongated along the b axis and became gradually sublimate. The differential thermogram showed a weak *endo*-peak at 44 °C and the melting peak at 72 °C. Crontonamide crystallized from ethanol solution as twinned plates or as prisms elongated along the a axis. Crystals of crotonic acid were sealed in glass capillaries. Single crystals of crotonamide were obtained by cutting the twinned plates with razor. Equi-inclination Weissenberg photographs were taken by using Cu$K\alpha$ radiation, $\lambda=1.5418$ Å. Crystal data are summarized in Table 1. The space group for crotonic acid was deduced from the systematic absences to be Cc or C2/c, but the latter was assumed, and confirmed by subsequent refinement. The intensities were estimated visually, and corrected for the Lorentz and polarization factors and for spot shape.

TABLE 1. CRYSTAL DATA

	Crotonic acid	Crotonamide
Chemical formula	$CH_3CH=CHCOOH$	$CH_3CH=CHCONH_2$
Molecular weight	86.09	85.12
Melting point	72 °C	158 °C
Space group	Monoclinic, C2/c	Monoclinic, $P2_1/a$
Systematic absences	hkl for $h+k$ odd	$h0l$ for h odd
	$h0l$ for l odd	$0k0$ for k odd
Cell constants: a	15.30(3) Å	9.71(2) Å
b	4.06(1)	6.90(2)
c	16.18(2)	7.75(1)
β	107.4(1)°	104.0(4)°
Z	8	4
D_c	1.19 g/cm^3	1.12 g/cm^3
D_m	1.19	1.11
$F(000)$	368	184
μ for Cu$K\alpha$ ($\lambda=1.5418$ Å)	8.18 cm^{-1}	6.72 cm^{-1}
Dimension of crystals used	0.5×1.5×0.2 mm	0.3×0.1×0.1 mm
	0.7×0.5×0.2 mm	
Layers photographed	$h0l$ to $h2l$	$0kl$ to $7kl$
	$0kl$ to $7kl$	
Observed reflections	337	525

* Present address: Dainichi Seika Co., Ltd., Kawaguchi 332.

Structure Determination and Refinement

Crotonic Acid. Two-dimensional Patterson and Fourier maps projected along the b axis were used to obtain the trial structure. The y coordinates were estimated by tilting and shifting the planar molecular model against the b axis so that the calculated structure factors may suit to the observed ones. The trial structure gave an R value of 0.27. Three cycles of block-diagonal least-squares refinement of positional and isotropic thermal parameters reduced the R value to 0.15. The reflections $20\bar{4}$, $11\bar{3}$, and $11\bar{2}$, which were considered to suffer from extinction effect, were dropped off in subsequent refinements. Including the positions of hydrogen atoms obtained from a difference synthesis and the appropriate isotropic thermal parameters, further refinements were repeated with the weighting scheme:

$$w = (16.0/F_o)^2 \quad \text{for } |F_o| > 16.0$$

$$w = 1.0 \quad \text{for } 16.0 \geq |F_o| \geq 6.7$$

and

$$w = 0.5 \quad \text{for } 6.7 > |F_o| > 0.0.$$

The final R value was 0.090 for 337 observed reflections.

Crotonamide. The trial structure was obtained from the Patterson maps projected along the b and a axes, and corrected by the Fourier synthesis projected along the b axis. A three-dimensional Fourier map

gave the structure of the R value of 0.33. A diagonal least-squares refinement with isotropic thermal parameters reduced the R value to 0.178. A difference synthesis at this stage revealed all the seven hydrogen atoms. Excluding the reflections 012, 201, and 20$\bar{1}$, block-diagonal least-squares refinement with anisotropic thermal parameters for the non-hydrogen atoms and with isotropic ones for the hydrogen atoms was carried out by using the weighting scheme:

$$w = (4.0/F_o)^2 \quad \text{for } |F_o| > 4.0$$

$$w = 1.0 \quad \text{for } 4.0 \geq |F_o| \geq 2.2$$

and

$$w = 0.5 \quad \text{for } 2{\cdot}2 > |F_o| > 0.0.$$

The final R value was 0.088 for 525 observed reflections.

The computations were carried out on a HITAC 8800/8700 computer at the Computer Center of the University of Tokyo and on a NEAC 2200—500 computer at the Okayama University Computer Center. The main programs used were RSSFR-5, HBLS-4, RSDLS-3, RSDA-4, and RSBP-3 of the UNICS Program System.[4] The atomic scattering factors were taken from International Tables for X-ray Crystallography.[5]

C (4)	−0.004	C (4) −0.0006	C (4) −0.006	C (4) 0.003

Table 3; the final atomic parameters in Tables 4 and 5. Bond lengths and angles along with the numbering scheme for atoms are shown in Fig. 1 for crotonic acid, and in Fig. 2 for crotonamide.

Molecular Shape. The equations of best planes and the deviations of the atoms from each plane are listed in Table 6. Dihedral angle between the ethylenic and carboxylic planes of crotonic acid is only 1.0°, and that between the ethylenic and amide planes of crotonamide is 2.9°, which are rather smaller than the corresponding value (3.6°) found in *trans*-β-2-furylacrylamide.[6] Thus the configurations of both crotonic acid and crotonamide are nearly planar. The bond length C(2)=C(3) of crotonic acid is rather shorter. The difference between the bond lengths C(4)=O(1) and C(4)–O(2) in crotonic acid is very small as observed in β-methyl-*cis*-cinnamic acid and β-chloro-*cis*-cinnamic acid.[7] On the other hand, the C(4)=O and C(4)–N distances in crotonamide are very close to the values (1.225 and 1.349 Å, respectively) predicted from hybridization effect.[8] The C=O bonds of both carboxyl and amide groups adopt the *cis*-configuration with respect to the ethylenic C=C bonds. Some intramolecular contacts are shown in Figs. 1 and 2.

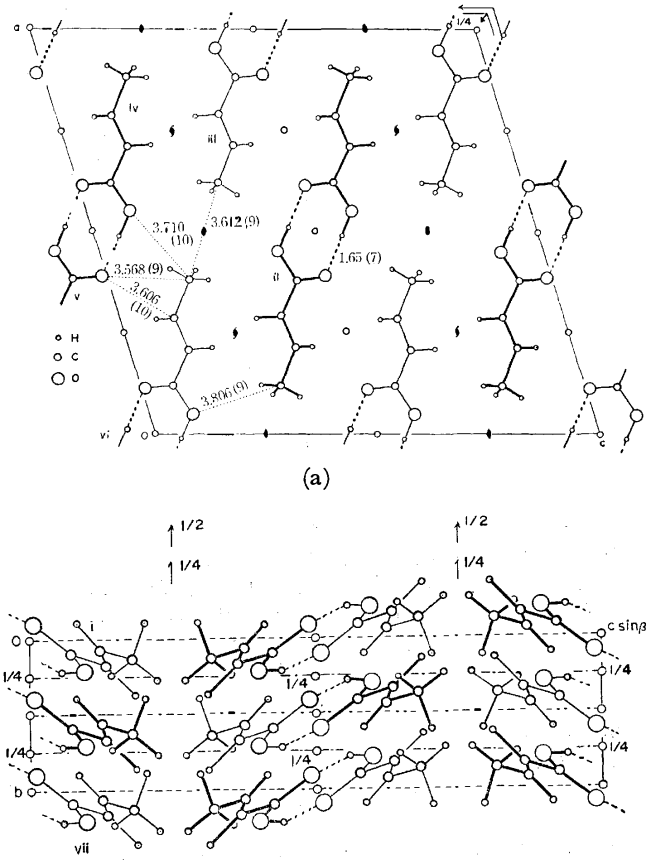

Fig. 3. Projections of the crystal structure of crotonic acid.
(a) Viewed along the b axis.
(b) Viewed along the a axis.
Broken lines show hydrogen bonds, and dotted lines intermolecular contacts.
Symmetry code: i $x/a, y/b, z/c$; ii $1/2-x/a, 1/2+y/b, 1/2-z/c$; iii $1-x/a, y/b, 1/2-z/c$; iv $1/2+x/a, 1/2+y/b, z/c$; v $1/2-x/a, 1/2-y/b, -z/c$; vi $-x/a, -y/b, -z/c$; vii $x/a, 1+y/b, z/c$.

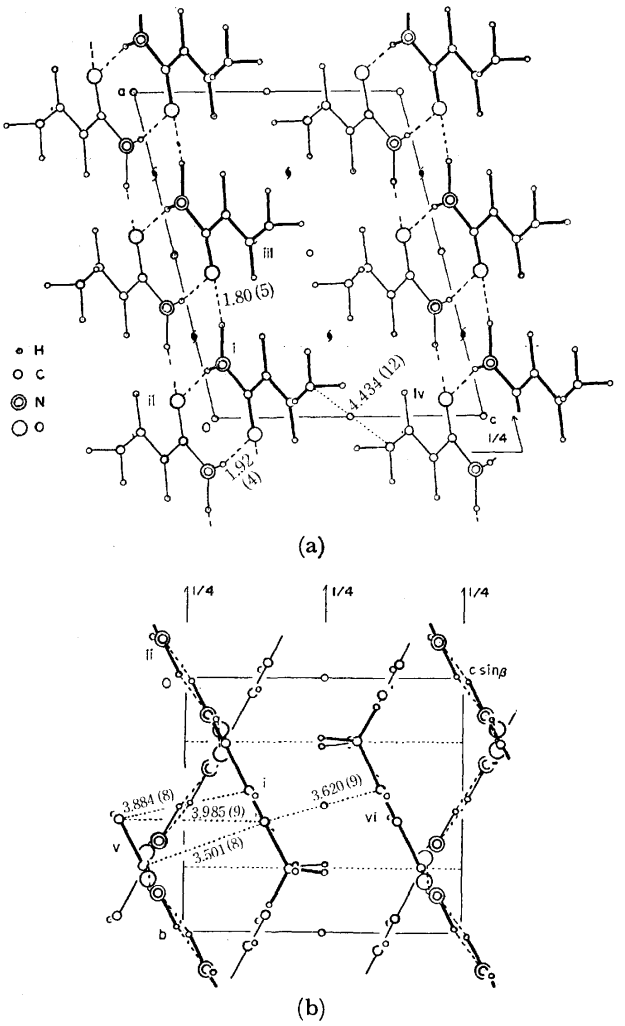

Fig. 4. Projections of the crystal structure of crotonamide.
(a) Viewed along the b axis.
(b) Viewed along the a axis.
Broken lines show hydrogen bonds, and dotted lines intermolecular contacts.
Symmetry code: i $x/a, y/b, z/c$; ii $-x/a, -y/b, -z/c$; iii $1/2+x/a, 1/2-y/b, z/c$; iv $-x/a, 2-y/b, 1-z/c$; v $-x/a, 1-y/b, -z/c$; vi $-x/a, 1-y/b, 1-z/c$.

A significant difference in the C=O bond lengths has been pointed out between the carboxyl (1.209 Å) and the amide (1.247 Å) groups in fumaramic acid,[9] but the situation has reversed in the case of crotonic acid and crotonamide.

Molecular Packing. Projections of the crystal structure of crotonic acid viewed along the b and a axes and some intermolecular contacts are shown in Fig. 3 and those of crotonamide in Fig. 4. Geometry of the hydrogen bonds is listed in Table 7. The crystal structure of crotonic acid consists of two identical stacks of centrosymmetrically hydrogen-bonded pairs of the molecules, which are held together by van der Waals interactions between the methyl groups at a distance of 3.61 Å to form infinite chains along the

TABLE 7. HYDROGEN-BOND DISTANCES (Å) AND ANGLES (°)
Symmetry code is given in Figs. 3 and 4.

[201] direction. The corresponding contact in α-tetronic acid[10] is 3.81 Å, and that in *p*-toluic acid[11] 3.50 Å. The hydrogen-bonded carboxyl groups are not fully coplanar, being offset 0.04 Å.

Crotonamide molecules related by a center of symmetry are linked by N–H···O hydrogen bonds to form pairs at (000) and (1/2, 1/2, 0), which are held together side by side through the a-glide plane by additional N–H···O hydrogen bonds. This packing mode belongs to the glide-plane packing type.[12] The intrapair amide groups are distinctly not planar, the separation between the two corresponding parallel planes being 0.23 Å. The inclination of the amide pair to the glide plane is 61.5° and the nearest methyl-methyl distance is 4.43 Å. The interpair angles C–N···O and C=O···N are 118.9 and 142.7°, respectively, which are close to those found in furylacrylamide.[6]

The structures of crotonic acid and crotonamide show short enough distances between ethylenic groups (C(3)···C(2^{vii}) 3.86 and C(3)···C(3^{v}) 3.88 Å, respectively) to dimerize or polymerize on irradiation with ultraviolet light, and the parallel alignment of double bonds considered as a pre-requisite for cycloaddition occurs in both compounds.

UV-Spectra of Fluorenyl Salts in the Binary Mixtures of DME and Benzene

Katsuhiko TAKAYA and Norio ISE

Department of Polymer Chemistry, Kyoto University, Kyoto 606

(Received March 28, 1974)

The temperature dependence of UV spectra of fluorenyl lithium and sodium was investigated in 30, 40, and 50 vol% dimethoxyethane (DME)–benzene mixtures. The lithium salt had two absorption peaks at 352 and 373 nm, and the sodium salt at 358 and 373 nm. The fraction of solvent-separated ion pairs for the sodium salt was much lower than that of the lithium salt, and the heat of conversion ($-\Delta H_i$) of contact-ion pairs to solvent-separated ion pairs was larger (9—11 kcal/mol) for the sodium salt than that (1—4 kcal/mol) for the lithium salt.

In our laboratory living anionic polymerizations of styrene with alkali metal gegenions were investigated in the binary mixtures of 1,2-dimethoxyethane (DME) and benzene[1-3] and in triglyme–benzene mixtures.[4] The reactivity of ion pairs in DME–benzene mixtures was higher[1-4] than that in other ethereal solvents in general.[5-9] The dissociation constants of polystyryl ion pairs in DME–benzene systems were not larger than those in other solvent systems. These tendencies suggest that the higher reactivity of the ion pair (even for the caesium salt) should be attributed to the contribution of the solvent-separated ion pairs. This is supported by the fact that lithium and sodium salts have a larger inter-charge distance a in the ion pair (6—10.5 and 9.3 Å, respectively),[2] calculated by the Fuoss equation,[10] than in THF (4.5 and 4.4 Å, respectively) and in MeTHF (3.3—3.4 Å) and in THP (3.5—3.7 Å)

$$K_d = \frac{3000}{4\pi Na^3} \cdot \exp\left(-\frac{e^2}{a\varepsilon kT}\right), \qquad (1)$$

where K_d, N, ε, and k are the dissociation constant of ion pair, the Avogadro number, the dielectric constant, and the Boltzmann constant, respectively.

It must, however, be taken into consideration in the present systems that the formation of the "cybotactic region" [11] of DME molecules or a different composition of the solvent in the vicinity of the ions and ion pairs from that in the bulk solvent system might be probable as one of the reasons for the larger a values.

It was also a question why the sodium ion pair was most reactive among the polystyryl salts in DME–benzene (50 vol%) mixture. To obtain information about the solvation of the ion pairs, we investigated UV spectra of lithium and sodium salts of fluorene as model compounds in the binary mixtures of DME and benzene between 0 and 25 °C. Smid *et al.* studied the UV spectra of the same salts in ethereal solvents.[12]

Experimental

Commercial fluorene was recrystallized several times using alcohol and dried under a high vacuum. DME, preliminarily dehydrated by metal sodium, were refluxed over CaH_2 for a week and distilled onto Na–K alloy. Then DME was subjected to deaeration-dehydration treatment on a vacuum line by cooling and degassing with stirring in the presence of Na–K alloy dispersion. Benzene, contacted with concentrated sulfuric acid for a few weeks, was fully washed with concentrated sulfuric acid, aqueous sodium hydroxide solution, and water to be neutral, then dehydrated with $CaCl_2$ and thereafter with CaH_2. This benzene was then treated in the same manner as DME.

The fluorenyl salts were prepared from solutions of the corresponding polystyryl salts in tetrahydrofuran (THF) under a high vacuum. The THF of the fluorenyl salt solution was substituted with DME–benzene mixtures.

The fluorenyl salt solutions directly prepared in the DME–benzene mixture by treating fluorene with sodium mirror did not show different spectra from those of the salts prepared from polystyryl salts. The salt solutions were stored in a freezer or in an ice-box.

Results and Discussion

In Fig. 1, the UV spectra of fluorenyl lithium in the binary mixture of DME and benzene (at DME contents of 30, 40, and 50 vol%) between 0 and 25 °C are given. The carbanions had absorption bands at 350 and 373 nm, and the absorption peak at 350 nm decreased and that at 373 nm increased when the temperature was lowered.

In Fig. 2, the UV spectra of fluorenyl sodium in the 30, 40, and 50 vol% DME–benzene mixtures between 0 and 25 °C are shown. Two peaks were observed and maxima were at 358 and 373 nm in addition to the absorptions in the visible regions.

In both salts, absorption peaks were the same as those observed in other solvent systems.[12] As new

peaks were not observed, the presence of higher aggregates in these salts than ion pairs remained unknown.[4]

The isosbestic points were observed for all cases and the relative heights of the two peaks were not affected by addition of highly dissociable tetraphenylboride as common ion salt. These facts indicate that the observed changes correspond to an equilibrium between contact ion pairs and solvent-separated ion pairs, which is sensitive to solvent, temperature, and gegenions. The peaks, which were predominant at high temperatures, are dependent on cations (*viz.* 350, and 358 nm for lithium and sodium salts, respectively, in the present system), but the peaks at 373 nm were independent of cations, as was shown by Smid *et al.*[12] The formation of the cybotactic region in the present system was suggested by the fact that the absorption peaks of the contact-ion pairs of lithium and sodium salts (F^-, M^+) were most bathochromically shifted in DME–benzene systems among the ethereal solvents and close to those in pure DME.

In Table 1, the fraction of solvent-separated ion pair $F^-//M^+$ was calculated according to Smid's method and is summarized together with other relevant data. The fraction of $F^-//M^+$ for both the lithium and sodium salts was larger than in other ethereal solvents with a similar polarity. Comparing the lithium and sodium ion pairs, the former is much richer in $F^-//Li^+$ than the latter. So the fraction of the solvent-separated ion pairs in the sodium salt of living polystyrene should be expected to be smaller than that of lithium salt, when we assume that the polystyryl anions have a structure

		0	4.07	358	373	0.17
	50	25	4.33	358	373	0.06
		0	4.67	358	373	0.21

relatively similar to fluorenyl anions. Therefore the difference of the ion-pair rate constant k_p' between the lithium and sodium salts in the DME–benzene systems should be attributed to the difference of the structure of the solvent-separated ion pairs of the both salts.

The equilibrium constant K between the two kinds of ion pairs should be written as

$$F^-, M^+ + n\cdot DME \overset{K}{\rightleftharpoons} F^-//M^+ \quad (2)$$

$$K = \frac{[F^-//M^+]}{[F^-, M^+]\cdot[DME]} \quad (3)$$

If the solvent is in a large excess, the ratio $[F^-//M^+]/[F^-, M^+](\equiv K_i)$ should be proportional to K. So the K_i value should be constant at a fixed temperature. The K_i values for the fluorenyl salts in the DME–benzene systems were calculated by the method by

Smid *et al.*[12,13] and are given in Table 2. From the slope of $\log K_i$ *vs.* $1/T$ plot, the $-\Delta H_i$ values were given as 1.3—3.8 kcal/mol and 9.2—11 kcal/mol for the lithium and sodium ion pairs, respectively. The ΔH_i and ΔS_i values in the present systems are summarized in Table 3, together with the results in other solvents.

TABLE 3. THERMODYNAMIC QUANTITIES OF THE CONVERSION OF F^-,M^+ TO $F^-//M^+$ IN VARIOUS SOLVENTS

	Li^+	THP (5.6)	6.6	28
	Li^+	MeTHF (6.2)	7.5	27

a) Taken from Ref. 12.

The $-\Delta H_i$ values should be determined by a competition between the Coulombic energy between electric charges in the ion pairs and the solvation energy; the former is endothermic and the latter exothermic. If we assume that the solvation energy for ion pairs of fluorenyl lithium and sodium is nearly the same, as seen from the fact that the absorption peaks of solvent-separated ion pairs are independent of solvent, gegenions and temperature, and if we assume that the degrees of solvation in solvent-separated ion pairs and those in free ions should differ from each other, the trends of

$-\Delta H_i$ in Table 3 will be understood as follows. The smaller $-\Delta H_i$ values for the lithium salt in DME–benzene systems is reasonable because Coulombic forces in the lithium contact ion pairs are stronger than in the sodium ion pairs. In this respect, the sodium salt of 4,5-dimethyl-phenanthrene anion[14] has larger $-\Delta H_i$ and $-\Delta S_i$ values than the lithium salt (namely, $-\Delta H_i=5.0$ and 12.6 kcal/mol and $-\Delta S_i=17.0$ and 51.6 e.u. for the lithium and sodium salts, respectively, in THF, and $-\Delta H_i=3.7$ and 19.1 kcal/mol and $-\Delta S_i=10.9$ and 61.2 e.u. for the lithium and sodium salts, respectively, in DME). When we compare these values for the lithium salt between the DME–benzene system and the THF system, the larger $-\Delta H_i$ value in the latter should be attributed to the lack of the external solvation towards contact-ion pairs. The fact that the increase of DME content decreased the $-\Delta H_i$ value might be due to solvation towards the contact-ion pairs.

Polarographic and Anodic Stripping Polarographic Studies of Aliphatic Polyamine Complexes of Several Metal Ions

Masahiro KOMATSU

National Industrial Research Institute of Kyushu, Tosu, Saga 841

(Received September 3, 1973)

The polarography of several aliphatic polyamine complexes of Pb(II), Zn(II), and Ni(II), and the anodic stripping polarography of polyamine complexes of Zn(II), Cd(II), Pb(II), and Cu(II) were studied. The aliphatic polyamines used were ethylenediamine(en), 1,3-propanediamine(1,3-pn), 1,2-propanediamine(1,2-pn), diethylenetriamine(den), and triethylenetetramine(trien). These lead(II) complexes gave a one-step reversible wave which was diffusion-controlled. The relation between the logarithm of the concentration of polyamine and the half-wave potential of the Pb(II) complex was straight, so that one species of complex ion was found to be predominant in the bulk of solution. The ionic species in the bulk of solution were found to be $Pb(en)_2^{2+}$, $Pb(1,3\text{-pn})_2^{2+}$, $Pb(1,2\text{-pn})_2^{2+}$, $Pb(den)_2^{2+}$, and $Pb(trien)^{2+}$. The stability constants of these complexes were calculated and were found to increase in the order of $Pb(1,3\text{-pn})_2^{2+} < Pb(en)_2^{2+} < Pb(1,2\text{-pn})_2^{2+} < Pb(den)_2^{2+} < Pb(trien)^{2+}$. The polarographic waves of Zn(II)-polyamine and Ni(II)-polyamine complexes were irreversible and diffusion-controlled, so the electrode reactions of these complexes were assumed using Matsuda-Ayabe's theory. All these polyamine complexes of Zn(II), Cd(II), Pb(II), and Cu(II) gave well-defined anodic stripping polarograms. 1,3-pn was the best complexing reagent among these polyamines, because it gave the best separation of the peaks of the anodic stripping polarograms of the four metal ions. Calibration curves were obtained from 0.01 to 0.10 ppm for Zn(II), Pb(II), and Cu(II), and from 0.001 to 0.010 ppm for Cd(II) in 0.4 M 1,3-pn and 0.2 M KCl media. The effects of acid and base on the anodic stripping polarograms were also studied.

It has been well known that aliphatic polyamines react with metal ions to give stable complexes in a fairly strongly alkaline medium.[1] The copper(II) and cadmium(II)-ethylenediamine(en), 1,2-propanediamine(1,2-pn), 1,3-propanediamine(1,3-pn), diethylenetriamine(den), and triethylenetetramine(trien) complexes were studied by means of a dropping mercury electrode.[2-4] Also, zinc(II) and nickel(II)-en complexes,[5] the lead(II)-trien complex[6] and the nickel(II)-1,2-pn complex[7] were studied by means of a dropping mercury electrode.

Anodic stripping polarography has been known to be a sensitive method for the analysis of the metal ions and various supporting electrolyte solutions have been used.[8] Moreover, the anodic stripping polarography of nickel(II), cobalt(II), manganese(II) has been studied in an aqueous solution of polyamine.[9] In a fairly strongly acidic solution (<pH 2), the hydrogen wave interferes with the determination of the zinc (II) ion, so it is interesting that anodic stripping polarography is carried out in an alkaline medium.

The present paper will report about the electrode reaction of lead(II), zinc(II), and nickel(II) in an aqueous solution of polyamine and about an application of these polyamine complexes to trace analysis by anodic stripping polarography.

Experimental

Materials. All the solutions of the amines, obtained from the Tokyo Kasei Co., Ltd, were standardized by 0.1 M HCl using a B.P.B. indicator. The lead(II) nitrate, zinc(II) nitrate and nickel(II) nitrate were standardized with 0.01 M EDTA. The potassium nitrate was once recrystallized and was used as a supporting electrolyte for polarography. Gelatine was used as a maximum suppressor for the zinc(II) and nickel(II) complexes. The potassium chloride was purified by extracting heavy metal ions with dithizone–chloroform system, after then having been recrystallized twice and heated at 300 °C in an electric furnace for 3 hr and it was used as the supporting electrolyte for anodic stripping polarography. The standard solution of the metal ions for anodic stripping polarography was prepared from metal chlorides. Water was deionized on a mixed-bed ion-exchange resin and was then distilled from an alkaline permanganate.

Apparatus. The polarograms were recorded with a Shimadzu polarograph, model RP-50. The initial potentials were measured with a Shimadzu potentiometer, model K-2. The span voltage was 1.0 V for lead(II), and 2.0 V for zinc-(II) and nickel(II). An H-type cell with a saturated calomel electrode was then used. The dropping mercury electrode (DME) used for lead(II) and zinc(II) had an m value of 2.47 mg/s and a drop time of 3.47 s at the mercury column height of 70 cm in a distilled water with an open circuit. The other DME used for nickel(II) had an m value of 1.75 mg/s and a drop time of 2.85 s at the mercury column height of 40 cm at the applied potential of −1.40 V *vs.* SCE. All the DC polarograms were recorded in a thermostat at 25.0± 0.1 °C.

The block diagram of anodic stripping polarograph is shown in Fig. 1. The potential-current curves were recorded with a X–Y recorder (D5–SN, Rikendenshi Co., Ltd.). The potential was driven by a sweep generator (Sanyo Denki Co., Ltd.). The scanning rate was 0.1 V/s. The initial voltage

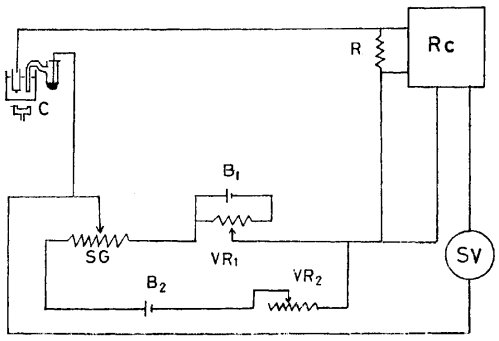

Fig. 1. Block diagram of anodic stripping polarograph. Rc, X-Y recorder; SV, standard voltage generator; C, electrolytic cell; B_1, B_2, battery; R, load resistor; SG, sweep generator; VR_1, VR_2, variable resistor

of the X–Y recorder was adjusted by a standard voltage generator (SV–12, Rikendenshi Co., Ltd.). The applied potential was controlled by B_1 and B_2. A balanced-head, stationary hanging mercury drop electrode(HMDE)[10] was used. The surface area of HMDE used was 0.028 cm^2. A saturated calomel electrode was used as the reference electrode. The cell assembly has been reported elsewhere.[11]

Procedure. The polarographic electrolyte solutions were prepared by placing a stock solution of metal(II) nitrate, potassium nitrate, polyamine and, lastly, a fresh solution of gelatine in a 25 ml flask. The anodic stripping polarographic electrolyte solutions were prepared by placing a stock solution of metal(II)-chloride, potassium chloride and polyamine in a 50 ml flask. Oxygen was removed from the electrolyte solutions by passing nitrogen gas through them for about 10—15 min, prior to the measurements of the DC polarogram and pre-electrolysis in anodic stripping polarography. The procedure of anodic stripping polarography was as follows. The electrolyte solution was stirred at 360 rpm during the pre-electrolysis with a magnetic stirrer by means of synchronous rotating motor. Following the pre-electrolysis for a certain time, the stirring was stopped for 30 s, then the potential was scanned into a positive direction in order to strip the deposited metal anodically from the mercury electrode. All the anodic stripping polarographic measurements were carried out at room temperature.

Results and Discussion

Polarography of Lead(II) Complexes. Typical DC polarogram of the lead(II)-polyamine complex is given in Fig. 2(a). The limiting current varied with the

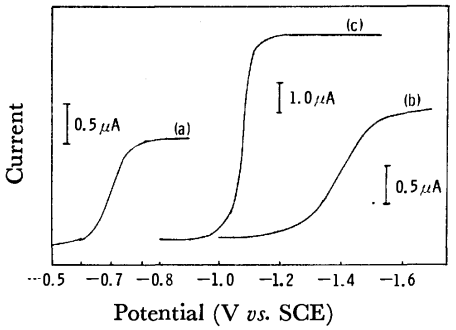

Fig. 2. Typical DC polarograms of Pb(II), Zn(II), and Ni(II) in the aqueous solution of aliphatic polyamine.
(a) 0.44 mM Pb(II) in 0.19 M ethylenediamine and 0.2 M KNO_3
(b) 0.44 mM Zn(II) in 0.10 M 1,2-propanediamine, 0.2 M KNO_3 and 0.01% gelatine
(c) 0.98 mM Ni(II) in 0.10 M 1,3-propanediamine, 0.2 M KNO_3 and 0.015% gelatine

mercury column height, while the $i_l/\sqrt{H_{corr}}$ value, where H_{corr} is the value corrected for the back pressure, was constant, this indicates that the electrode reactions were diffusion-controlled. The waves were analyzed by the log plot method from the current i at the potential of E of the dropping mercury electrode and the limiting current, i_l. The reciprocal slopes of the log plot of the lead(II) waves are given in Table 1 and these electrode reactions were reversible, two-electron reactions. The limiting current was gradually lowered with an increase in the concentration of the polyamine, because of the enhancement of the viscosity of the electrolyte solution.[5] In Fig. 3, the half-wave potentials are plotted against the logarithm of the various concentrations of the ligand. The resultant curves are straight, so only one ionic species is predominant in this concentration range.[12] The slope of $E_{1/2}$ *vs.* log C for en was 0.056 V, for 1,2-pn 0.057 V, for 1,3-pn 0.055 V and for den 0.056 V, indicating that two molecules of en, 1,2-pn, 1,3-pn or den were attached to lead(II) ion,[12] while for trien

a) [Pb(II)]: 0.22 mM

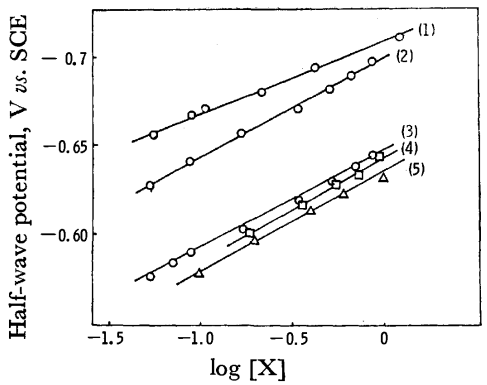

Fig. 3. Relation between $E_{1/2}$ of lead (II) complexes and log [X].
(1) trien; (2) den; (3) 1,2-pn; (4) en; (5) 1,3-pn

the slope was 0.034 V, indicating that one molecule of trien was attached. Because white precipitates were observed when 0.44 mM of Pb(II) was used in the case of the Pb(II)-1,3-pn system, 0.22 mM of Pb(II) was used. The limiting current of the Pb(II)-1,3-pn complex was linearly proportional to the concentration from 0 to 0.33 mM Pb(II) ion. The den complex is of interest because its maximum coordination number is three. The 1:2 complex for the den complex was observed in the case of copper-(II),[2] cadmium(II),[3] mercury(II),[13] and zinc(II)[14] complexes. The dissociation constants (k_d), which were calculated from Lingane's equation,[12] are given in Table 1. The stability constant of the trien complex was in good agreement with that obtained potentiometrically by Reiley and Schmid,[15] but slightly higher than that obtained by Lai and Chen,[6] probably because of the hydrolysis of the lead(II) ion. The stability constants increased in the order of: 1,3-pn complex<en complex<1,2-pn complex<den complex<trien complex; this tendency was identical with that of the copper(II)[2] and cadmium(II)[3] complexes. The stability constant of the complexes with a tri- or tetradentate ligand was larger than that of those with a bidentate ligand. Among these diamine complexes, the stability constant of the 1,2-pn complex was largest, probably because of its five-membered ring and one methyl group.

Polarography of Zinc(II) Complexes. The polarography of zinc(II)-1,2-pn, 1,3-pn, den, and trien complexes was studied in this work. A typical DC polarogram of Zn(II)-polyamine complex is given in Fig. 2(b). All the zinc(II)-polyamine complexes gave one-step waves. The currents varied with the mercury column height and the $i_l/\sqrt{H_{corr}}$ value was constant, indicating that the electrode reactions were entirely diffusion-controlled. The reciprocal slope of the log plot was 0.044 V for 1,2-pn, 0.049 V for 1,3-pn, 0.045 V for den and 0.050 V in trien concentration range from 0.006 to 0.030 M and 0.045 V in trien concentration range from 0.059 to 0.295 M for trien complex. These values demonstrated that these electrode reactions were irreversible reduction processes. When only the MX_N^{m+} complex, which is predominant in the bulk of the solution, dissociates very rapidly into the MX_p^{m+} complex in the vicinity of the electrode surface, when the MX_p^{m+} complex is reduced irreversibly at DME, and when its electrode reaction is diffusion-controlled, then Matsuda-Ayabe's equation for the irreversible half-wave potential of the complex ion[16] is expressed as:

$$(E_{1/2})_{irr} = 2.3\frac{RT}{\alpha nF}\left\{\log\frac{(k_f^\circ)_B}{\sqrt{D_N}} - (N-p)\log[X] + \frac{1}{2}\log\tau - 0.053\right\} \quad (1)$$

where [X] is the concentration of the polyamine, α is the transfer coefficient, τ is the dropping time of DME, $(k_f^\circ)_B$ is the forward (reduction) rate constant of the electron transfer process at the potential of the normal hydrogen electrode, and D_N is the diffusion coefficient of the complex ion MX_N^{m+} (all activities are assumed to be unity in above equation). The $(N-p)$ value can be obtained from the slope of the $(E_{1/2})_{irr}$ *vs.* log [X.] plot and the value of the reciprocal slope of log plot. The relation between $(E_{1/2})_{irr}$ and log [X] is given in Fig. 4. The slope obtained for 1,2-pn was 0.045 V, for 1,3-pn 0.054 V, for den 0.045 and for trien 0.050 V and 0.005 V. The calculated $(N-p)$ values for the zinc-(II)-polyamine complexes are given in Table 2(i). If

TABLE 2. THE CALCULATED VALUE OF $(N-p)$ OF Zn(II) AND Ni(II)-POLYAMINE COMPLEXES

i) Zn(II)-polyamine complexes	1, 2-pn	1, 3-pn	den	trien	
$(N-p)$	1.1	1.2	1.0	1.0[a]	0.01[b]

ii) Ni(II)-polyamine complexes	1, 3-pn	den		trien	
$(N-p)$	1.8	1.0[c]	0.0[d]	0.96[e]	0.0[f]

a) 0.006 M≦trien≦0.030 M. b) 0.059 M≦trien≦0.295 M. c) 0.003 M≦den≦0.035 M. d) 0.071 M≦den≦0.284 M. e) 0.003 M≦trien≦0.028 M. f) 0.042 M≦trien≦0.056 M.

the value of N is known, p may be assumed. The zinc(II)-polyamine complexes have been studied potentiometrically and the ionic species in the bulk of solution were known except for the zinc(II)-1,3-pn system.[17] $Zn(1,2\text{-pn})_3^{2+}$, $Zn(den)_2^{2+}$, and $Zn(trien)^{2+}$ were predominant in the aqueous solution of each polyamine. From the values of $(N-p)$ and the complexes in the bulk

of the solution, the following rapid dissociation-association reactions were assumed for the electrode reactions of the zinc(II)-polyamine complexes:
for the 1,2-pn complex:

$$Zn(1,2\text{-pn})_3^{2+} \rightleftarrows Zn(1,2\text{-pn})_2^{2+} + 1,2\text{-pn}$$

for the 1,3-pn complex:

$$Zn(1,3\text{-pn})_N^{2+} \rightleftarrows Zn(1,3\text{-pn})_{N-1}^{2+} + 1,3\text{-pn}$$

for the den complex:

$$Zn(den)_2^{2+} \rightleftarrows Zn(den)^{2+} + den$$

for the trien complex:

$$Zn(trien)^{2+} \rightleftarrows Zn^{2+} + trien$$
$$(0.006M \leqq trien \leqq 0.030M).$$

Above 0.059 M trien, $Zn(trien)^{2+}$ would participate in the electrode reaction.

Polarography of Nickel(II) Complexes. The polarography of nickel(II)-1,3-pn, den, and trien complexes were investigated in this work. The polarography of the nickel(II)-1,2-pn complex had been reported elsewhere.[8] A typical DC polarogram of the nickel(II)-polyamine complex is given in Fig. 2(c). All the nickel(II)-polyamine complexes investigated in this work gave a one-step wave. The $i_l/\sqrt{H_{corr}}$ value was also constant, indicating that the electrode reaction was entirely diffusion-controlled. Polarograms were recorded in the ranges of concentration of 1,3-pn from 0.018 to 1.03 M, of den from 0.003 to 0.284 M and of trien from 0.003 to 0.056 M. The half-wave potentials were shifted to more negative value with an increase in the concentration of polyamine as is shown in Fig. 5. However, the half-wave potentials of the den or

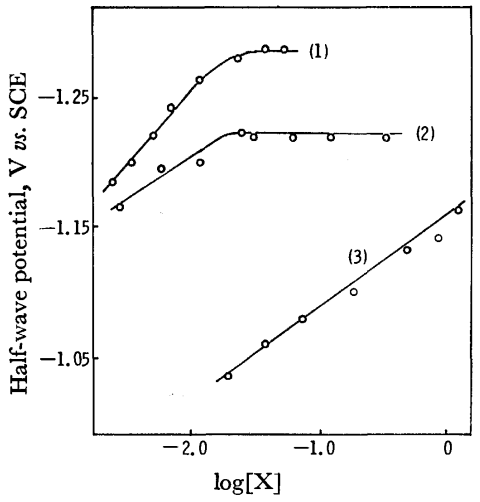

Fig. 5. Relation between $E_{1/2}$ of nickel(II) complexes and log[X].
(1) trien; (2) den; (3) 1,3-pn

trien complex were constant from 0.071 to 0.284 M den or from 0.042 to 0.056 M trien respectively. The reciprocal slope of the log plot was 0.038 V for the 1,3-pn complex, 0.056 V for the den complex in the concentration from 0.003 to 0.284 M den and 0.120 V for the trien complex in the concentration range of 0.003 to 0.056 M trien. These values demonstrated that these electrode reactions were irreversible electrode process and that Eq. (1) can be used to interpret the waves. The slope of $(E_{1/2})_{irr}$ *vs.* log [X] plot was 0.075 V for the 1,3-pn complex, 0.055 V in the ranae of 0.003—0.035 M of den and 0.00 V in the range of 0.071—0.288 M of den and 0.115 V in the range of 0.003—0.028 M trien, and 0.00 V in the range of 0.042—0.056 M trien. The ionic species of Ni(II)-polyamine complexes in thebulk ofsolution had been studied potentiometrically,[17] and $Ni(1,3\text{-pn})_3^{2+}$, $Ni(den)_3^{2+}$ and $Ni(trien)_2^{2+}$ were observed. The calculated $(N-p)$ values of Ni(II)-polyamine complexes are given in Table 2(ii). Thus, the following dissociation-association reactions were assum ed for the electrode reaction of Ni(II)-polyamine complexes:
for the 1,3-pn complex:

$$Ni(1,3\text{-pn})_3^{2+} \rightleftarrows Ni(1,3\text{-pn})^{2+} + 2(1,3\text{-pn})$$

for the den complex:

$$Ni(den)_2^{2+} \rightleftarrows Ni(den)^{2+} + den$$
$$(0.003M \leqq den \leqq 0.035M)$$

for the trien complex:

$$Ni(trien)_2^{2+} \rightleftarrows Ni(trien)^{2+} + trien$$
$$(0.003M \leqq trien \leqq 0.028M).$$

It is shown that the ionic states of these complexes which participate in the electrode reaction must form a 1: 1 complex at lower concentrations of these polyamines. Above 0.071 M den and 0.042 M trien, $Ni(den)_2^{2+}$ and $Ni(trien)_2^{2+}$ must directly participate in the electrode reaction.

Anodic Stripping Polarography. The present work and past works demonstrated that Cu(II), Pb(II), Cd(II), and Zn(II) formed stable complexes with en, 1,2-pn, 1,3-pn, den, and trien. As an application of these polyamine complexes to trace analysis, anodic stripping polarographic studies of these four metal ions were carried out in aqueous solutions of these polyamines. The peak potentials were measured in an aqueous solution of 0.05 M of each polyamine, they are shown in Fig. 6. 1,3-pn was found to be the best reagent among these polyamines, because it gave the best separation of the peaks of these metal ions. Typical anodic stripping polarograms of Zn(II), Cd(II), Pb-

(II), and Cu(II) in 0.4 M 1,3-pn are given in Fig. 7. The pre-electrolysis potential was −1.50 V *vs.* SCE for Zn(II), −1.10 V *vs.* SCE for Cd(II), −0.80 V *vs.* SCE for Pb(II) and −0.60 V *vs.* SCE for Cu(II). With choices of these pre-electrolysis potentials, interference by more cathodic waves could be omitted. Because the electrode reaction of Cu(II)-polyamine complex is a two-electron transfer process, its anodic stripping peak current could be sharper than that of Cu(II) in thiocyanate, NH_3, chloride or pyridine, in which a two-step wave of Cu(II) appears.[12] The calibration curves are given in Figs. 8 and 9. The wave height of these ions were linearly proportional to the concentration of the metal ions. The effects of acid and base on these anodic stripping polarograms

were also studied. 0.01—0.10 M NH_3 or 0.1—0.2 M hydrochloric acid was added to a mixture of Zn(II), Cd(II), Pb(II), and Cu(II), 0.4 M 1,3-pn and 0.2 M KCl, and then anodic stripping polarograms were recorded. The results are shown in Figs. 10 and 11. The wave heights of Cu(II), Pb(II), Cd(II), and Zn(II) were almost constant when NH_3 was added, but a slight increase in the wave heights of Zn(II) and Cd-(II) was observed with an increase of the concentration of hydrochloric acid. And also, by the addition of hydrochloric acid the peak potentials of Cu(II) and Pb(II) were shifted to so positive a potential that the peak height of Pb(II) and Cu(II) could not be exactly measured (Fig. 11). Accordingly, it is necessary to neutralize the acidic test solution by NH_3 prior to the determination.

The author is grateful to Professor S. Misumi of Kyushu University for his kind discussions and also to Dr. H. Kakiyama of the National Industrial Research Institute, Kyushu, for his continual encouragement.

The Solvent Extraction of the Copper-Pyrocatechol Violet Chelate with Tridodecylethylammonium Bromide

Yoshio SHIJO

Department of Industrial Chemistry, Faculty of Engineering, Univereity of Utsunomiya, Ishii-machi, Utsunomiya 321-31

(Received September 20, 1973)

The solvent extraction of the copper–Pyrocatechol Violet chelate with tridodecylethylammonium bromide (abbreviated TDEA) in benzene as an ion-association system has been investigated by the spectrophotometric method. The copper–PV–TDEA complex can be extracted into such aromatic hydrocarbons as benzene, toluene, and xylene, but not into such polar solvents as *n*-butanol, ethyl acetate, methylisobutylketone, and nitrobenzene. When a sample solution containing copper and PV, the pH of which has been adjusted to 7.5—8.5, is shaken with TDEA in benzene for 10 s, the maximum extraction of the ternary complex is obtained. The extractability of the complex from 50 ml of an aqueous solution into 10 ml of benzene is 98.3% under the optimum conditions. The absorbance and stability of the complex increase upon the addition of a small amount of ethanol to the extracted layer. Beer's law is obeyed up to 6.5 μg copper per 10 ml of benzene, and the molar absorptivity of the complex is 7.9×10^4 $cm^{-1}\cdot mol^{-1}\cdot l$ at 663 nm. The composition of the complex is confirmed to be Cu: PV: TDEA = 1: 2: 2 by the continuous variation method. A structure for the complex is proposed.

Pyrocatechol Violet (abbreviated as PV) forms water-soluble chelates with many metal ions and has been used as a metallochromic indicator or as a colorimetric reagent for several metal ions. The PV metal chelate anions react with quaternary ammonium salts as cetylpyridinium to form a water-soluble or a water-insoluble ion-association complex. The solvent extraction of the ion pair formed by the interaction of PV metal chelate anions with cations of 1,3-diphenylguanidinium, cetylpyridinium, *etc.* has been applied to the spectrophotometric determination of molybdenum(VI),[1] indium,[2] gallium,[3] and iron(III).[4] Recently, Přibil and Vesely[5] used a chloroform solution of Aliquat 336-S (methyltricaprylammonium chloride) in the solvent extraction of the Xylenol Orange metal cheletes. Because of its superior extraction efficiency, the oleophilic quaternary ammonium salt as Aliquat 336-S has been used for the extraction of many inorganic or organic anions[6-10] and also used as an ion exchanger for a liquid-membrane ion-selective electrode.[11,12] In this paper, the fundamental conditions for the solvent extraction of the copper–PV chelate anion with a benzene solution of tridodecylethylammonium bromide which has been synthesized in our laboratory and the composition of the ternary complex extracted into benzene are discussed in terms of the spectrophotometric method.

Experimental

Reagent. About a 2.5×10^{-3} M copper solution was prepared by dissolving a definite amount of cupric chloride in 1 M hydrochloric acid and by subsequent dilutions with deionized water. The resulting solution was standardized by EDTA titration. A working standard solution was prepared as needed by the dilution of the 2.5×10^{-3} M solution with deionized water to the desired concentration. A 5.0×10^{-4} M PV solution was prepared by dissolving the Dotite PV in deionized water without any further purification. The TDEA was prepared by the reaction[13] of tridodecylamine with ethylbromide in an alcoholic solution. The salt was recrystallized from petroleum benzine. A 6.0×10^{-4} M TDEA solution was prepared by dissolving the above TDEA in benzene.

All the other chemicals used were of a guaranteed reagent quality.

Apparatus. All the absorption spectra were obtained on a JASCO automatic recording spectrophotometer, model ORD-UV5. On the other hand, at a fixed wavelength measurements were made on a Hitachi manual spectrophotometer, model 101. Matched 1 cm absorption cells were used in all instances. The pH measurements were made with a Hitachi-Horiba model M-5 glass electrode pH meter.

Standard Procedure. Place up to 6.5 μg of copper in a 100 ml separatory funnel and add a definite amount of 0.2 M hydrochloric acid. Adjust the pH to 7.6 with a sodium acetate-sodium phosphate buffer solution. Add 4.0 ml of a 5.0×10^{-4} M PV solution and dilute to 50 ml with deionized water. Add 10 ml of 6.0×10^{-4} M TDEA in benzene and extract for 10 s with vigorous shaking. After the phases have separated, draw off the aqueous layer and centrifuge the extract for 5 min at 6000 rpm. Transfer 3.0 ml of the extract into a absorption cell and add 0.2 ml of ethanol. Measure the absorbance at 663 nm against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. The absorption spectra of the ternary complex extracted into benzene and the copper–PV chelate in an aqueous solution are given in Fig. 1, along with that of the reagent blank. The absorption curves of the ternary complex and the copper–PV chelate all have their maximum at 663 and 632 nm respectively. In the former, however, the absorbance is about three times greater than that of the latter. The bathochromic effect and the increase in the absorbance in the former are probably due to the combination with TDEA. By the addition of 0.2 ml of ethanol to 3.0 ml of the extract, the absorbance and stability of the ternary complex increase, but the absorbance of the reagent blank decreases. By the addition of ethanol into the initial organic phase, however, the extraction of the ternary complex is decreased extremely. PV is extracted into the organic layer under the conditions used in the standard procedure.

Effect of pH. The effect of the pH of the aqueous phase on the extraction was examined. The results are shown in Fig. 2. The maximum extraction of the

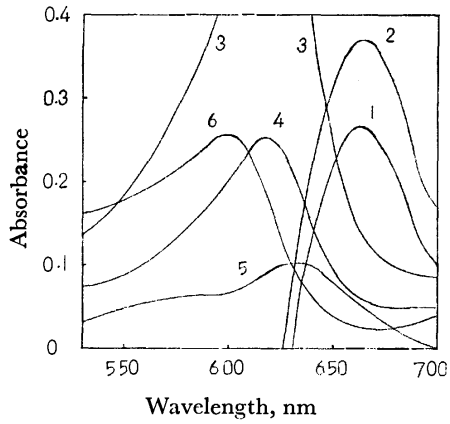

Fig. 1. Absorption spectra of the Cu-PV-TDEA complex in benzene and the Cu-PV chelate in aqueous solution.
pH: 7.6, Volume of aq. layer $V_w=50$ ml, $[acetate]_w=0.16$ M; Volume of org. layer $V_O=10$ ml, [secondary phosphate]$_w=0.08$ M

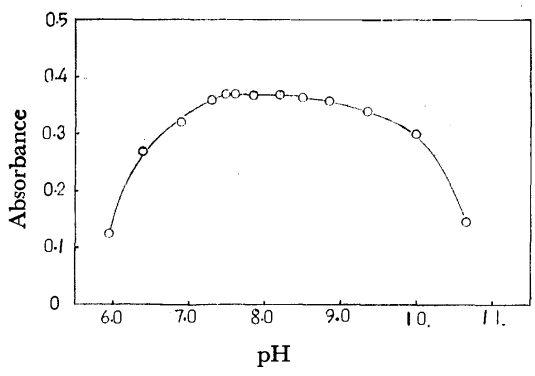

Fig. 2. Effect of pH on the extraction of the Cu-PV-TDEA complex.
pH: 7.6 $V_w=50$ ml, $V_O=10$ ml; Cu: 3.2 μg, $[PV]_w=4.0\times10^{-5}$ M, $[TDEA]_O=6.0\times10^{-4}$ M, $[ethanol]_O=6$ vol%, $[acetate]_w=0.16$ M, [secondary phosphate]$_w=$ 00.8 M.

ternary complex is reached at pH values from 7.5 to 8.5. This pH range is extended to lower pH values by increasing the concentration of TDEA in benzene. The absorbance of the reagent blank in the organic layer increases extremely with an increase in the pH value.

Organic Solvents. Several kinds of organic solvents were tested in order to achieve a quantitative extraction of copper. The ternary complex can be extracted into such aromatic hydrocarbons as benzene, toluene, and xylene, but not into such polar solvents as *n*-butanol, ethyl acetate, methylisobutylketone, and nitrobenzene. Benzene was chosen as the solvent which gave the highest absorbance.

The Effect of the PV Concentration. The effect of the PV concentration in the aqueous phase on the

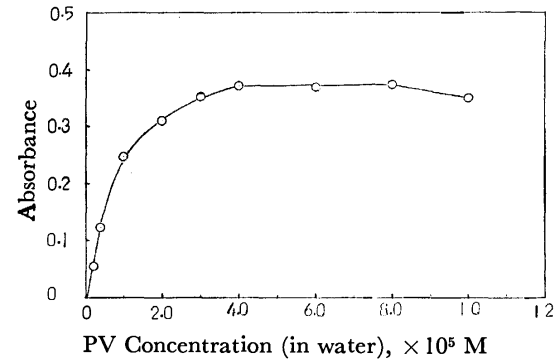

Fig. 3. Effect of the Pyrocatechol Violet concentration in aqueous phase on the extraction of the Cu-PV-TDEA complex.
pH: 7.6, $V_w=50$ ml, $V_O=10$ ml; Cu: 3μg, .2 $[TDEA]_O=6.0\times10^{-4}$ M, $[ethanol]_O=6$ vol%, $[acetate]_w=0.16$ M, [secondary phosphate]$_w=0.08$ M

extraction of the ternary complex was examined by varying the PV concentration, while other variables were held constant. The absorbance of the extract was constant when the PV in the initial aqueous phase was in the concentration range from 4.0×10^{-5} M to 8.0×10^{-5} M, as is shown in Fig. 3. The absorbance of the extract gradually decreased upon the further addition of PV. The absorbance of the reagent blank in the organic layer increased extremely with the increase in the PV concentration because the bulk of the PV was extracted into the organic layer. Therefore, the PV concentration was kept at 4.0×10^{-5} M.

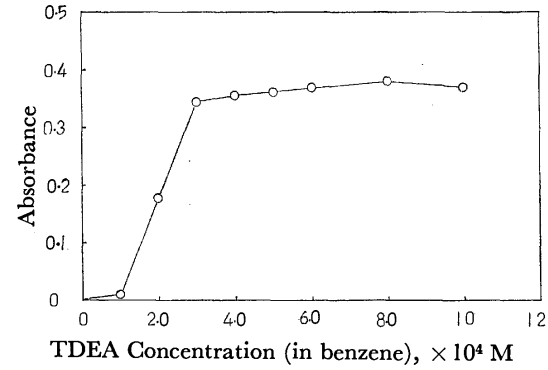

Fig. 4. Effect of tridodecylethylammonium bromide concentration in benzene on the extraction of the Cu-PV-TDEA complex.
pH: 7.6, $V_w=50$ ml, $V_O=10$ ml; Cu: 3.2 μg, $[PV]_w=4.0\times10^{-5}$ M, $[ethanol]_O=6$ vol%, $[acetate]_w=0.16$ M, [secondary phosphate]$_w=0.08$ M

The Effect of the TDEA Concentration. The effect of the concentration of TDEA in benzene on the extraction of the ternary complex was examined. The absorbance of the extract increased gently when the TDEA in benzene was in the concentration range from 3.0×10^{-4} M to 8.0×10^{-4} M, as is shown in Fig. 4. The absorbance of the reagent blank increased with the increase in the TDEA concentration in benzene. Therefore, the TDEA concentration was kept at 6.0×10^{-4} M.

The Effect of the Shaking Time. The shaking time

was varied from 5 s to 10 min. The absorbance of the extract was constant for the shaking times from 5 s to 30 s, but upon further shaking it gradually decreased. A shaking time of 10 s was, therefore, selected.

The Effect of the Ethanol. The effect of the addition of ethanol to the extract on the absorbance of the ternary complex was examined. The absorbance became highest when the ethanol concentration in the extract was about 6 vol%. The absorbance of the extract decreased upon the further addition of ethanol. The stability of the ternary complex and the reproducibility of the absorbance increased upon the addition of ethanol to the extract. The absorbance of the reagent blank, however, decreased upon the addition of ethanol.

Extractability, Distribution Ratio, and Molar Absorptivity. The extractability of the ternary complex under the optimum conditions was determined by a repetition of the extraction procedure on the same aqueous layer. When a 50 ml portion of the aqueous layer containing 6.4 μg of copper was shaken with 10 ml of benzene, 98.3% of copper was extracted by one extraction and almost completely by two. The distribution ratio and the molar absorptivity calculated by using the percentage extraction and the absorbance were 3.78×10^2 and 7.9×10^4 $cm^{-1}\cdot mol^{-1}\cdot l$ respectively.

Calibration Curve. A calibration curve for the determination of copper was made under the optimum conditions. A good linear relationship was obtained over the concentration range from 0 to 6.5 μg of copper per 10 ml of benzene.

The Effect of Diverse Ions. The effect of foreign ions on the determination of copper according to the standard procedure was also examined. Thorium, iron(III), cobalt, and nickel interfered at all the concentrations investigated. Up to about 10 μg of vanadium(V), aluminum, beryllium, manganese, zirconium, and uranium(VI) did not interfere with the determination of copper. Of the anions examined, chloride, sulfate, nitrate, and citrate did not interfere. However, thiosulfate and EDTA interfered seriously, giving negative errors.

1 Cu–PV–TDEA complex, $[Cu]_w+[PV]_w=2.5\times10^{-5}$ M, $[TDEA]_O=6.0\times10^{-4}$ M, $[ethanol]_O$=6 vol%
2 Cu–PV chelate, $[Cu]_w+[PV]_w=4.0\times10^{-5}$ M

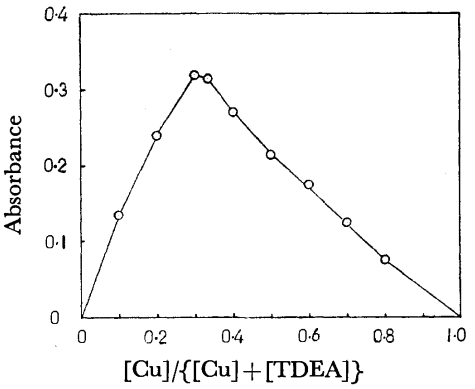

Fig. 6. Continuous variation method applied to the Cu–PV–TDEA complex.
pH: 7.6, $V_w=10$ ml, $V_O=10$ ml; $[Cu]_w+[TDEA]_O=5.0\times10^{-5}$ M, $[PV]_w=2.0\times10^{-4}$ M, $[ethanol]_O$=6 vol %, [asetate]$_w$=0.16 M, [secondary phosphate]$_w$=0.08M

The Composition and Structure of the Ternary Complex. Using the continuous variation method, the molar ratio of copper to PV was found to be 1:2, as is shown in Fig. 5. The molar ratio of copper to TDEA was also found to be 1:2, as is shown in Fig. 6. Thus, the composition of the ternary complex was estimated to be $Cu(PV)_2(TDEA)_2$. Recently, the structures of the ternary complexes of Sn–PV–cetyltrimethylammonium, Al–PV–cetyltrimethylammonium, and Mo–PV–diaklylmonomethylbenzylammonium were proposed by Bailey *et al.*,[14] Chester *et al.*,[15] and Kohara *et al.*[1] respectively. A similar structure, such as is shown in Fig. 7, may be possible for the ternary complex $Cu(PV)_2$-$(TDEA)_2$.

Conditions for the Formation of Fe_3O_4 by the Air Oxidation of $Fe(OH)_2$ Suspensions.

Masao KIYAMA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received September 25, 1973)

The optimum conditions were studied for the formation of Fe_3O_4 by the air oxidation of $Fe(OH)_2$. The suspensions obtained by mixing NaOH and $FeSO_4$ solutions in various values of $R(=2NaOH/FeSO_4)$ were subjected to oxidation with air at various temperatures. The oxidation products were then examined by X-ray powder diffraction, chemical analysis, electron microscopic observation, and BET surface-area determination. Fe_3O_4 is formed at higher temperatures than is FeOOH. The temperature of formation becomes low as R approaches 1.0. In neutral suspensions ($R<1$), Fe_3O_4 is formed *via* green rust II or a mixture of green rust II and $Fe(OH)_2$. By further oxidation, the Fe_3O_4 formed gradually changes to γ-Fe_2O_3. A mixture of α-FeOOH and either $NaFe_3(OH)_6(SO_4)_2$ or α-Fe_2O_3 is formed as the final oxidation product. In alkaline suspensions ($R>1$), Fe_3O_4 is formed directly. The morphology and ferrous-ion content of Fe_3O_4 powder change considerably with the presence of green rust II before the formation of Fe_3O_4. It is suggested that Fe_3O_4 is formed near the surface of the particles of $Fe(OH)_2$ and green rust II by the coprecipitation of ferrous ions with ferric hydroxo-complexes.

The formation of iron oxides and oxyhydroxides, such as α-Fe_2O_3, γ-Fe_2O_3, Fe_3O_4, α-FeOOH, β-FeOOH, γ-FeOOH, and δ-FeOOH, has thus far been achieved by means of wet methods, such as the hydrolysis and oxidation of iron salt solutions. α-FeOOH, β-FeOOH, and α-Fe_2O_3 have been obtained by the hydrolysis of ferric salts.[1-7] A mechanism of hydrolysis was suggested on the basis of the spectrophotometric and magnetic properties of the ferric complexes present in the solution prior to the formation of precipitates.[8]

δ-FeOOH is formed when $Fe(OH)_2$ is oxidized rapidly in an alkaline solution by the addition of hydrogen peroxide.[9,10] If oxidation is carried out slowly by passing air into a suspension obtained by mixing ferrous salt and alkaline solutions, α-FeOOH, γ-FeOOH or Fe_3O_4, or a mixture of them is obtained according to the pH, the temperature, and the kind of anion present.[11-15] Feitknecht proposed the following mechanism:[16] (1) γ-FeOOH, δ-FeOOH, and γ-Fe_2O_3 are formed by the surface oxidation of green rust, $Fe(OH)_2$, and Fe_3O_4 particles respectively. (2) The formation of α-FeOOH proceeds in a liquid phase of suspension. (3) The formation of Fe_3O_4 takes place by the surface oxidation of the green rust particles in a neutral suspension medium. The formation can also take place in a liquid phase of alkaline suspension. From crystallochemical considerations, Bernal *et al.* suggested that the reaction of solid phase proceeds topotaxially in the particles of intermediate oxidation products.[17]

These theories hold except for the formation of γ-FeOOH and Fe_3O_4. The presence of green rust is not indispensable for the formation of γ-FeOOH.[18-20] In this paper, the conditions and the mechanism of the formation of Fe_3O_4 will be given.

Experimental

Material. Chemical reagents of an analytical grade were used. The air for stirring and oxidation was bubbled through washing vessels containing a KOH solution to remove carbon oxides and dust. Distilled water into which nitrogen had been bubbled at the boiling point for 2 hr to remove any dissolved oxygen was used.

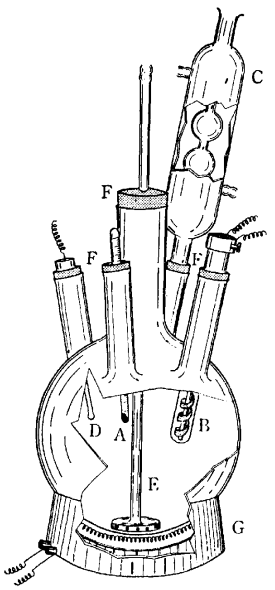

Fig. 1. The reaction vessel.
A: Thermometer, B: Temperature regulator, C: Reflux condenser, D: Electrode for self-recording pH meter, E: Glass tube, F: Rubber stopper, G: Electrical heater.

Apparatus. Figure 1 shows the reaction vessel specially constructed for the air-oxidation experiments. A spherical flask with a capacity of about 4 l is fitted with five inlet necks. A glass tube (E) with a flat end having eight holes (0.1 cm in diameter) at equal intervals is kept in contact with the bottom of the flask. The temperature regulator (B) consists of a spiral bimetal strip dipped in oil in a glass tube. Since the $Fe(OH)_2$ suspension in the flask is thoroughly stirred with air, a small portion (50—100 ml) taken out of the suspension can be considered to be an appropriate sample.

Procedure. The suspensions of $Fe(OH)_2$ were prepared by adding various amounts of a NaOH solution to 1 l of 0.72 M-$FeSO_4$ in each flask, the total volume of each suspension then being made 3 l with water. The suspensions in the flasks were quickly heated to the desired temperatures. Nitrogen was passed through the suspension from the eight holes at a rate of 1 l/min to prevent bumping and oxidation. When the suspension reached the desired temperature, compressed air was passed through in place of nitrogen. The

temperature was kept constant during the course of oxidation.

The oxidation conditions were confined as follows: a) The $R(=2NaOH/FeSO_4)$ molar ratio was kept at 0.1—4.0. b) Air was passed through at a rate of 200 l/hr. c) Oxidation was carried out at temperatures between 5 and 85 °C. The oxidation product was collected on filter paper, washed with water, and then dried at about 50 °C under reduced pressure.

Analysis of the Oxidation Product. The amounts of ferrous and ferric ions were determined by chemical analysis. The ferrous-ion content was determined by means of $KMnO_4$ titration after the sample had been dissolved in dilute H_2SO_4 by heating under a nitrogen atmosphere. The total iron content was determined by the gravimetry of the precipitate obtained from the solution prepared by the dissolution of the sample in a mixture of dilute HNO_3 and HCl solutions by heating.

The samples were examined by means of X-ray diffraction using FeKα radiation. By means of electron microscopic examination, it was found that FeOOH particles are needle-like, while Fe_3O_4 particles are spherical, cubic, and octahedral. The presence of a small amount of FeOOH was detected by electron-microscopic examination. For the sake of confirmation, the samples found by X-ray analysis to consist only of Fe_3O_4 were subjected to electron-microscopic examination. When $Fe(OH)_2$ and green rust remained in the suspension, the wet precipitate obtained by filtration was also subjected to those examinations. In order to prevent oxidation during X-ray analysis, the wet precipitate was sealed with cellophane tape.

The mean particle size of the samples was estimated from their surface area as measured by the BET method using nitrogen gas.

Results and Discussion

Formation of Fe_3O_4. Precipitates were formed when NaOH and $FeSO_4$ solutions were mixed: (a) When the amount of NaOH was insufficient ($R<1$), the resulting whitish suspension was neutral (pH 7—9). The precipitate was usually amorphous, but the precipitate in the suspension with $R<0.6$ changed to a crystalline precipitate of ferrous basic sulfate when subjected to aging in an inert gas.[21] (b) When excess NaOH ($R>1$) was added, the suspension became alkaline (pH>10) enough to give a white precipitate. The precipitate in (b) consisted of fine crystal particles of $Fe(OH)_2$, the size of which increased with the NaOH concentration.

The black ferromagnetic precipitate (Fe_3O_4) was formed by the oxidation of the suspension at higher temperatures than was the yellowish brown and non-ferromagnetic precipitate (FeOOH). The process of the Fe_3O_4 formation in (a) differs from that in (b). Electron-micrographs of the precipitates formed at 70 °C in the course of oxidation, corresponding to the R values of 0.5 and 2.0, are shown in Figs. 2(a) and (b) respectively. After 90 min, a whitish precipitate (Fig. 2(a(0)) was oxidized; thereafter it turned dark green. It consists of hexagonal particles (a(1.5)), the pH of the suspension being reduced from 7.2 to 6.5.* About 40% of the total iron ions were ferric ions in the

Number in parentheses indicates the time of oxidation in hr.

precipitate, and its X-ray diffraction data agreed with those of green rust II (hexagonal crystal unit cell, a 3.17 and c 10.7 Å).[17] The precipitate of Fe_3O_4 began to be formed at pH 6.5. After 4 hr, green rust II was transformed into Fe_3O_4 and a small amount of α-FeOOH, the former being spherical and the latter needle-like (Fig. 2(a(4.0)), the pH being suddenly reduced from 6 to 3.7. On the other hand, distinct octahedral and cubic particles of Fe_3O_4 were obtained directly from the alkaline suspension of $Fe(OH)_2$(b (0), (2), (5), and (20), Fig. 2). The appreciable difference in particle shape between the precipitates of $Fe(OH)_2$ and green rust II, and the precipitate of Fe_3O_4 indicates that the formation of Fe_3O_4 does not take place by the surface oxidation of the particles of $Fe(OH)_2$ and green rust II.

In the case where $R<0.6$, all the whitish precipitate turned to green rust II, irrespective of the oxidation temperature. The formation of Fe_3O_4 or FeOOH, or

* When the suspension was not stirred, its pH decreased to about 5.

their mixture took place at pH 6.0 ± 0.5. For the R values of 0.6—1.0, the formation of Fe_3O_4 or FeOOH, or their mixture took place at pH 7—9 due to the presence of colloidal $Fe(OH)_2$ besides green rust II. When these precipitates were completely oxidized, the pH suddenly dropped below 4.5. On the further oxidation of these suspensions at 70 °C or above, the Fe_3O_4 precipitate disappeared very gradually, and a mixture (nonferromagnetic) of α-FeOOH and either $NaFe_3(OH)_6(SO_4)_2$($R<0.6$) or α-Fe_2O_3($0.6<R<1$) was formed as the final oxidation product.

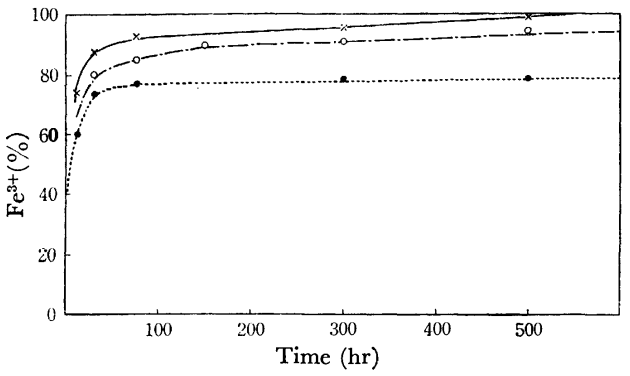

Fig. 3. Change in the ferric ion content of the suspension given in Table 1 with time. Temperature of oxidation: 40 ···●···, 70 ○---○ and 85 °C ×—×.

In order to study the formation and the decomposition of Fe_3O_4, the suspension with $R=1.0$ was oxidized at 40, 70, and 85 °C for a very long time. Table 1 shows the precipitates present in the suspension, together with the pH values at different times. The ferric-ion contents of the suspension are plotted against the time in Fig. 3. When the pH remained in the 7—9 range, the rate of oxidation was great because of the presence of $Fe(OH)_2$. When the precipitate of $Fe(OH)_2$ was completely oxidized to Fe_3O_4 or a mixture of Fe_3O_4 and α-FeOOH, the pH dropped below 4.5 and the changes in pH and ferric-ion content became very slow. By oxidation at 40 °C, a small amount of α-FeOOH is formed in addition to Fe_3O_4, the composition of the precipitate being nearly independent of the oxidation time. Fe_3O_4 is gradually oxidized to γ-Fe_2O_3 at 70 and 85 °C, since the surface oxidation of the Fe_3O_4 particles takes place topotaxially. The

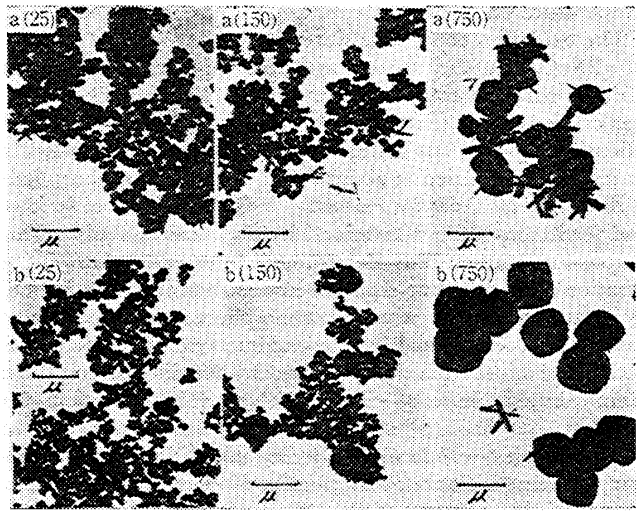

Fig. 4. Electron micrographs of the precipitates during the course of oxidation at 70 (a) and 85 °C (b). Number in parentheses indicates the time of oxidation in hr.

black color remained unchanged until the ferrous-ion content decreased to about 10% of the total iron ions. Electron-micrographs of the precipitates during the course of oxidation at 70 and 85 °C are given in Fig. 4. Electron microdiffraction showed that the X-, Y-, and I-shaped particles were all α-FeOOH. The spherical particles below 0.2 μm in size were of the spinel type (a solid solution of γ-Fe_2O_3 and Fe_3O_4), and the bigger ones, α-Fe_2O_3. This indicates that α-FeOOH and α-Fe_2O_3 are formed on the further oxidation of the particles (the solid solution) in an acidic solution. This might result from the hydrolysis of the ferric hydroxo-complexes formed by the dissolution of the precipitate of γ-Fe_2O_3, which is unstable in an acidic solution.

A kinetic study of the aerial oxidation of mixtures of $FeSO_4$ and NaOH solutions was made by Miyamoto.[22] He found that the oxidation of the suspensions proceeds in proportion to the time, irrespective of the R values. This could be explained by considering the fact that oxidation takes place in the liquid phase and not in the solid phase. In the present experiments, the ferric-ion content in the suspension increased in proportion to the oxidation time until 70% or more of the total precipitates of $Fe(OH)_2$ or green rust II had been transformed into Fe_3O_4 (or FeOOH). At a given temperature, the smaller the concentration of excess NaOH, the greater the acceleration of oxidation, in line with Miyamoto's result. The concentration of $FeSO_4$ in the neutral suspensions with $R<0.8$ slightly influenced the oxidation rate, which increased as R approached 1.0.

If the solid-phase reaction is predominant, the increase in the ferric-ion content in the suspension must be apporoximately represented by the parabolic law because the oxidation rate decreases with the increase in the thickness of the Fe_3O_4 layer on the particles of Fe $(OH)_2$ and green rust II. The fact that the oxidation of the suspension proceeds in proportion to the time indicates that the formation of Fe_3O_4 takes place in

liquid phases of alkaline and neutral suspensions. The suspension medium is saturated with respect to $Fe(OH)_2$ or green rust II. When air was bubbled into the suspension, the ferrous ions in the suspension medium react with the dissolved oxygen, thus giving rise to the formation of a ferric hydroxo-complex (polynuclear complex). When the suspension is well stirred by bubbling air, the ferrous ion consumed by oxidation is incessantly supplied by the dissolution of the precipitates of $Fe(OH)_2$ and green rust II in the suspension medium. If bubbling is carried out at a constant rate, the oxidation might proceed in proportion to the time since the rate of the dissolution of oxygen is constant. The rate of oxidation is determined by the rate of the dissolution of oxygen or the precipitates of $Fe(OH)_2$ and green rust II into the suspension medium.

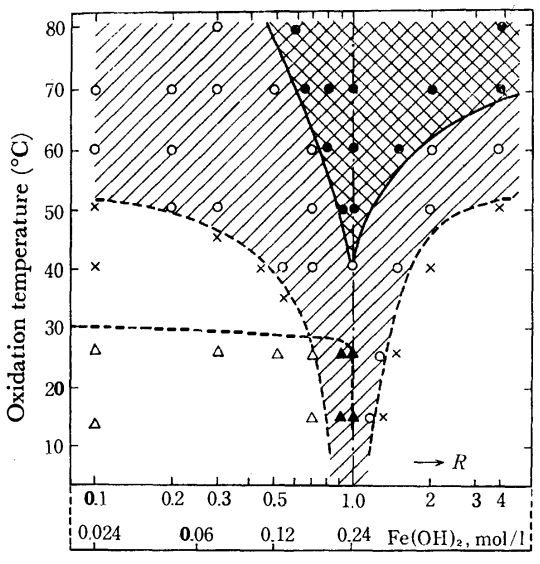

Fig. 5. Oxidation conditions for the formation of Fe_3O_4. ●: Fe_3O_4, ×: α-FeOOH, ○: A mixture of Fe_3O_4 and α-FeOOH, ▲: A mixture of Fe_3O_4, α-FeOOH and γ-FeOOH, △: A mixture of α-FeOOH and γ-FeOOH.

Conditions for the Formation of Fe_3O_4. Oxidation in the alkaline suspensions ($R>1$) was continued until the precipitate of $Fe(OH)_2$ completely disappeared, whereas oxidation in the neutral suspensions ($R<1$) was stopped as soon as the pH dropped below 4.5. The formation of precipitates is shown in Fig. 5 in terms of the temperature (ordinate) and the R value (abscissa). For the R values up to 1.0, the amount of ferrous precipitates such as $Fe(OH)_2$, formed by the addition of the NaOH solution to the $FeSO_4$ solution increases with the increase in R. The amount of ferrous precipitate in the starting suspension as calculated from the R value, is also indicated in terms of $Fe(OH)_2$ on the other abscissa. We see that the temperature at which Fe_3O_4 is formed is lowered as R approaches 1.0. Only Fe_3O_4 is formed in the upper triangular region, but FeOOH is also formed in the lower region. The influence of R on the Fe_3O_4 formation is almost symmetrical with respect to the line with $R=1.0$.

Either Fe_3O_4 or FeOOH, or their mixture, is formed in the suspension of the same value of R, depending on the oxidation temperature. Such a variety in the product formation may be due to the difference in the pH in the suspension. From the measurements of the hydrolysis constants of ferrous ions, it is generally considered that the $FeOH^-$ ion** is in equilibrium with the Fe^{2+} ion** in a neutral suspension medium or with $HFeO_2^-$ ion** in an alkaline suspension medium[23,24] and that the saturated solution of only $Fe(OH)_2$, in which most ferrous ions are present as $FeOH^+$ ions, has a pH value of 9.3 or 9.4.[25] Each particle of $Fe(OH)_2$ or green rust II in the suspension might be surrounded by a thick and dense layer of $FeOH^+$ ions. The R value most favorable for the formation of Fe_3O_4 was 1.0. The starting suspensions with the R of 1.0 had a pH of 9—10. The pH value in the layer of $FeOH^+$ ion can also be taken as 9—10.

The Fe_3O_4 particles are considered to be formed and to grow on (or in) the layer with pH 9—10 by the slow coprecipitation of $FeOH^+$ with ferric hydroxo-complexes formed by oxidation. Some of the particles of Fe_3O_4 might migrate outside the layer with pH 9—10 and be gradually oxidized to γ-Fe_2O_3. On the other hand, FeOOH may be formed outside the layer by the hydrolysis of the ferric hydroxo-complexes. Favorable conditions for the formation of Fe_3O_4 include an increase in the surface area and volume of the layer (roughly given by the product of the thickness and the total surface area of the particles of green rust II and $Fe(OH)_2$ in the suspension). The thickness of the layer might increase with the temperature, so that a temperature rise is favorable for the formation of Fe_3O_4.

Morphology and Ferrous-ion Content of the Fe_3O_4 Powders. Electron-micrographs of the Fe_3O_4 powders are given in Fig. 6. The particles of the Fe_3O_4 powders obtained in the neutral suspensions (A–D) are spherical and cubic (the needle-like particles are α-FeOOH); those in the alkaline suspensions (E and F) are cubic, octahedral, and orthorhombic. The mean particle size of the Fe_3O_4 powders obtained in the neutral suspensions,

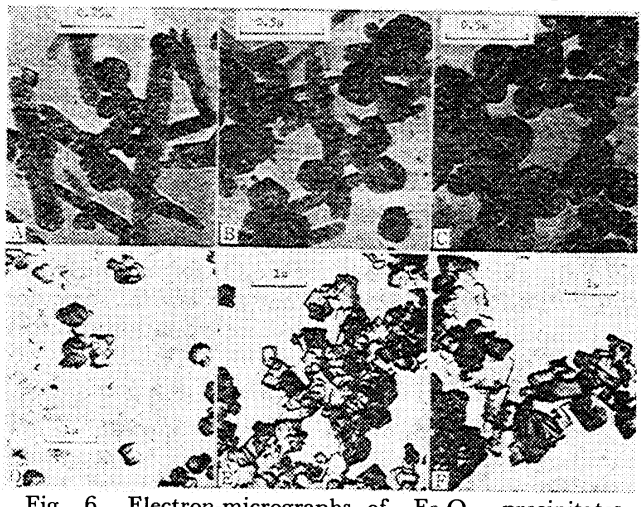

Fig. 6. Electron-micrographs of Fe_3O_4 precipitates formed by the oxidation of the suspensions at 70 °C with R values 0.1 (A), 0.3(B), 0.8(C), 1.0(D), 2.0(E) and 4.0(F). D, E and F were observed by the carbon replica method.

** H_2O ligands are omitted.

under the conditions where only Fe_3O_4 is formed, was found to be below 0.1 μm. The ferrous-ion content of the powders was less than 25% of the total iron ions, decreasing with the rise in the temperature and with the decrease in *R*. On the other hand, the mean particle size of the Fe_3O_4 powders in the alkaline suspensions was found to increase remarkably with the rise in the temperature and the *R* value, their ferrous-ion contents being about 30%. The absence of green rust II before the formation of Fe_3O_4 does not hinder the growth of Fe_3O_4 particles.

It is known that the rate of oxidation of Fe_3O_4 particles in an aqueous solution changes with the pH, the temperature, the particle size, *etc.* Oxidation may take place upon the dissolution of the ferrous ions in Fe_3O_4 particles into the aqueous solution or upon the adsorption of the oxygen atom on the Fe_3O_4 particles. In either case, the iron ions should diffuse toward the surface of Fe_3O_4 particles, thus causing oxidation. Since the oxidation of Fe_3O_4 particles takes place topotaxially, and since its rate depends on the surface area, the ferrous-ion content in each particle of Fe_3O_4 in the suspension is determined by its size. The fact that non-stoichiometric Fe_3O_4 (ferrous ion content$<$ 33.3%) was obtained in the present work might be a result of the particle-size distribution in the powder.

Additional Remarks on the Conditions for Fe_3O_4 Formation.

a): An air-flow rate greater or less than 100—400 l/hr was unfavorable for Fe_3O_4 formation. This indicates that the rate of movement of the particles of green rust II and $Fe(OH)_2$ in suspension affects the total surface area of the $FeOH^+$ layer with pH 9—10. When the flow rate is too small, the surface area of the layer with pH 9—10 diminishes as a result of a coagulation of the particles of $Fe(OH)_2$ and green rust II. When it is too great, the surface area of the layer with pH 9—10 diminishes as a result of the reduction of the thickness of the layer.

b): An increase in the concentrations of all ferrous ions in the starting suspension was favorable for Fe_3O_4 formation.

c): The use of $FeCl_2$, $FeBr_2$, or FeI_2 instead of $FeSO_4$ facilitated the formation of Fe_3O_4 or γ-FeOOH in the neutral suspension. The precipitate of Fe_3O_4 was formed *via* green rust I (not green rust II). The temperature for Fe_3O_4 formation could be lowered as compared with the case of $R<1$ in Fig. 5. For example, when suspensions with $R=0.5$ contained $FeCl_2$, $FeBr_2$, and FeI_2, the temperature for Fe_3O_4 formation fell to 25 °C. This might indicate that the crystal structure and composition of the intermediate oxidation product affect the thickness of the layer with pH 9—10.

d): When LiOH or KOH was used as a precipitant, the temperature for Fe_3O_4 formation ($R>1$, Fig. 5) became lower in the former and rose in the latter.

When a small amount of divalent metal ions (M^{2+}), such as Mg^{2+}, Mn^{2+}, and Co^{2+} ions, existed in the starting suspension, a ferromagnetic precipitate of $M_xFe_{3-x}O_4$ was obtained on slow oxidation. The conditions for $M_xFe_{3-x}O_4$ formation were similar to those for Fe_3O_4 formation, the amount of divalent metal ion in the precipitate depending on the pH.

The author is indebted to Professor Toshio Takada for drawing his attention to this problem and to Mr. Hisato Ihara and Mr. Toshikazu Akita for their assistance in the experiments.

The Reduction of [Ru(Hedta)(H_2O)] at the Mercury Electrode and Subsequent Reactions*

Kunio SHIMIZU, Tadashi MATSUBARA, and Gen P. SATÔ

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received November 9, 1973)

The reduction of [Ru(Hedta)(H_2O)] at the mercury electrode and the subsequent chemical reactions in buffer solutions were investigated by AC and DC polarography and by large-scale electrolysis. Two polarographic steps were observed; the more positive step is discussed in this paper. The step was a diffusion-controlled, one-electron reduction of ruthenium(III) to ruthenium(II). For $[H^+]=(10^{-3}—10^{-5})$ mol dm^{-3} the reduction was reversible, and it became less reversible if $[H^+]<10^{-5}$ mol dm^{-3}. Large-scale electrolysis in formate buffer solutions at the potential of the polarographic diffusion current plateau confirmed that the reduction is a one-electron process. In formate buffer, the reduced form of the complex is deactivated. Furthermore, in the presence of perchlorate ions the reduced form is reoxidized to the original form. The rate constant for the reoxidation reaction at 25.0 °C was $k_2=(1.38\pm0.26)\times10^{-3}$ mol^{-1} dm^3 s^{-1}. The activation parameters for the reoxidation reaction were $\Delta H^*=(94.1\pm17.6)\times10^3$ J mol^{-1} and $\Delta S^*=(19.0\pm6.3)$ J K^{-1} mol^{-1}.

Although electrochemical studies of ruthenium have been reported by several authors,[1-7] most of the work dealt with aqua or chloro complexes in aqueous solutions. In fact, the electrode processes of ruthenium complexes are not well understood.

All the known complexes of ruthenium(II) and ruthenium(III) take the low-spin d^6 and d^5 configurations respectively, which are considerably substitution-inert. Taube and co-workers[8-11] first studied redox reactions of ammine complexes of ruthenium(II) and ruthenium(III) in aqueous solutions and proposed that the electron transfer process between them proceeds *via* an outer-sphere mechanism. They reported also that ruthenium(II) complexes can be oxidixed by perchlorate ions, which are known to be relatively weak oxidizing agents. Recently the oxidation of ruthenium(II) aqua complexes by perchlorate ions[12] and substitution reactions on ruthenium(II) complexes[13-16] have been reported, and these data are in agreement with those reported by Taube. Recent progress in the study of redox reactions of ruthenium complexes has been reviewed by Ford[17] and Taube.[18]

In the present work, (hydrogenethylenediaminetetraacetato)aquaruthenium(III), which has been proved to take the low-spin d^5 configuration,[19] was investigated by means of polarography, and the effect of perchlorate ions on the reduced form of the complex was investigated by using a large-scale electrolytic method.

Experimental

Materials. (Hydrogenethylenediaminetetraacetato)-aquaruthenium(III)-3-water, [Ru(Hedta)(H_2O)]·3H_2O was prepared according to the procedure described by Mukaida.[19] The product was a dull-yellow powder and readily soluble in water (Found: C, 25.73; H, 3.29; N, 6.18%. Calcd: C, 25.97; H, 4.59; N, 6.06%). The IR spectrum of the product obtained agreed with that reported by Mukaida. Its purity as determined by alkalimetric titration was 99.96%. The alkalimetric titration curve showed two pH-jumps indicating the existence of two dissociable protons. The pK values** calculated from the pH-titration curve were 2.37 and 7.63. This pK_1 value was very similar to that of [Rh(Hedta)(H_2O)] (pK_1=2.32, pK_2=9.12),[20] but the aqua group was more acidic than in the rhodium complex. The corresponding equilibria are represented by;

$$[Ru(Hedta)(H_2O)] \overset{K_1}{\rightleftharpoons} [Ru(edta)(H_2O)]^- + H^+$$

$$[Ru(edta)(H_2O)^-] \overset{K_2}{\rightleftharpoons} [Ru(edta)(OH)]^{2-} + H^+$$

The near ultraviolet-visible absorption spectrum of the complex in 0.2 mol dm^{-3} formic acid–sodium formate solution (pH=2.80) showed one absorption band at 283 nm ($\varepsilon=2.75\times10^2$ m^2 mol^{-1}). The spectrum remained identical in 0.01 mol dm^{-3} (pH=1.88) and 1.0 mol dm^{-3} (pH=0.88) perchloric acid solutions as well.

Sodium perchlorate-1-water was prepared from perchloric acid and sodium carbonate, according to the procedure reported earlier.[21]

All the other reagents were of Guaranteed Reagent grade and used without further purification. Twice distilled water was used except for the synthesis of the complex.

Polarography. All the polarograms were recorded with a potentiostat type AC-DC polarograph constructed locally. For AC polarography, alternating voltage of 10 mV (rms) was superimposed, the frequency was 35 Hz unless otherwise stated. The characteristics of the dropping mercury electrode (DME) were as follows: $m=1.685$ mg s^{-1}, $t_d=4.89$ s under a mercury head of 60 cm (−0.4 V *vs.* SCE, acetate buffer, ionic strength=0.5 mol dm^{-3}, 25.0 °C).

A conventional beaker type cell was used for polarographic measurements. A spiral of platinum wire served as the counter electrode. A reference saturated calomel electrode (SCE) was connected to the cell solution through a series of two H-type salt bridges (saturated sodium nitrate) with filter paper plugs. Dissolved oxygen was expelled by passing nitrogen which had been passed through vanadium(II) sulfate solution and water.

The following supporting electrolytes were used for the polarographic measurements: sodium acetate – acetic acid buffer (pH$_c$***>3.5), sodium formate – formic acid buffer (2>pH$_c$>3.5), 0.02 mol dm^{-3} sodium perchlorate – 0.18 mol dm^{-3} perchloric acid (pH$_c$=0.72). The ionic strength of all the buffer solutions was adjusted to 0.2 mol dm^{-3} with sodium perchlorate. Each solution contained 0.002% gelatin as maximum suppressor.

* Partly presented at the 18th Meeting of the Polarographic Society of Japan, Tokyo, October, 1972.

** pK represents $-\log(K/\text{mol dm}^{-3})$.

*** pH$_c$ represents $-\log([H^+]/\text{mol dm}^{-3})$.

All the potentials reported in this paper refer to SCE. All measurements were performed at (25.0±0.1)°C unless otherwise stated.

Controlled-Potential Electrolysis. The electrolytic measurement was performed with a potentiostat type electrolyzer constructed locally. About 20 μmol of the complex dissolved in 10 cm^3 of supporting electrolyte solution was electrolyzed at −0.40 V under a nitrogen atmosphere in a glass cell having two side compartments. The side compartments were separated from the cell by agar plugs. The working electrode was a mercury pool at the bottom of the cell (surface area, about 7.1 cm^2). Another mercury pool in one of the side compartments served as the counter electrode, and an SCE was connected to the solution in the other side compartment. The solution was stirred during electrolysis with a stirrer made of polyformaldehyde resin rotating at 700 revolutions per minutes. The cell was equipped with a DME for recording polarograms in the course of electrolysis. The quantity of electricity was determined by integrating the recorded electrolytic current-time curve graphically. The electrolytic current was corrected for the residual current.

For all electrolytic measurements, a mixture of sodium formate – formic acid was used as buffer, sodium perchlorate being added when perchlorate ion effect was studied. The ionic strength of the solutions was adjusted to 0.5 mol dm^{-3} by adding sodium chloride.

Others. Alkalimetric titration of the complex was performed with an automatic titrator (Radiometer; Type ASU1a Auto Burette, TTC1c Titrator, SBR2c Titrigraph). An appropriate amount of the complex was titrated with a carbon-dioxide free sodium hydroxide solution standardized against potassium hydrogenphthalate.

All the pH_c values of the solutions were determined with a Radiometer pH Meter 25E, whose meter readings were calibrated against standard hydrochloric acid solutions, and the hydrogen ion concentrations of the solutions were directly calculated from their pH_c values.

Results

Polarography. Typical AC and DC polarograms of [Ru(Hedta)(H_2O)] are shown in Fig. 1. Two DC steps appeared at −0.2 and −1.0 V. A symmetrical AC wave appeared at the potential of the more positive (first) step; but no AC wave corresponding to the more negative (second) step was observed. The heights of both DC steps were nearly equal, but the second step appeared to be less steep than the first and was accompanied by a maximum, which could not be suppressed even in the presence of 0.02% gelatin. The maximum became larger at higher hydrogen ion concentration, and no distinct second step was observed in formic acid – sodium formate buffer solutions. It was impossible to infer the nature of the first reduction product from the analysis of the second step.

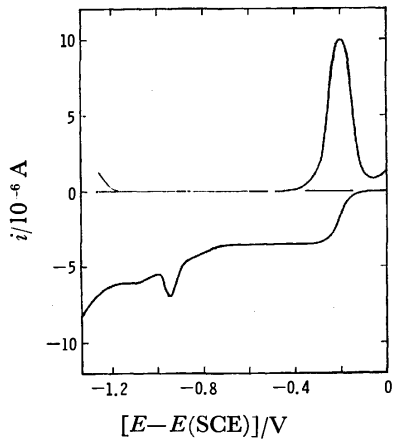

Fig. 1. AC (upper) and DC (lower) Polarograms of [Ru(Hedta)(H_2O)]. 1 mmol dm^{-3} [Ru(Hedta)-(H_2O)]; acetate buffer; 0.002% gelatin; pH_c=3.68; ionic strength=0.2 mol dm^{-3}.

The limiting current of the first step was directly proportional to both the concentration of the complex and the square root of the corrected head of mercury. No kinetic contribution was detected even at 40.0 °C. The half-wave potential was affected neither by the concentration of the complex nor the drop time.

The plot of $\log[i/(i_d-i)]$ against E, where i_d and i are the diffusion current and the current at potential E, respectively resulted in a straight line whose reciprocal slope was −62——63 mV at $pH_c<5$. At pH_c higher than 5, the reciprocal slope was larger and increased gradually over a long period of time (a few hours at 25.0 °C), presumably owing to slow hydrolysis of the complex. The half-wave potential became more negative at higher pH_c, and tended to reach a constant value at pH_c higher than 5 (Fig. 2). It was independent of free edta added to the solution up to 100 mmol dm^{-3} at pH_c=3.68.

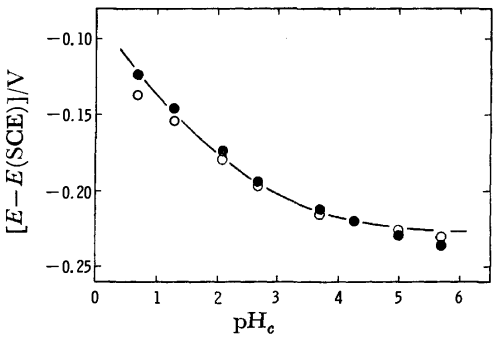

Fig. 2. pH_c-Dependence of half-wave potential and summit potential. 1 mmol dm^{-3} [Ru(Hedta)(H_2O)]; buffer solution; ionic strength=0.2 mol dm^{-3}; ●: $E_{1/2}$, ○: E_s, ——Calculation from Eq. (1b) using the best-fit set of K_O, K_R, and K'_R.

The polarographic diffusion coefficient of the complex (pH_c=3.68) calculated by using the Ilkovic equation modified by Koutecký[22] was 6.00×10^{-10} m^2 s^{-1}. This value is quite reasonable when compared with those of similar depolarizers obtained by the same method: (Cu(II)edta,[23] 5.47×10^{-10} m^2 s^{-1}; Tl(III)-edta,[24] 5.8×10^{-10} m^2 s^{-1}; H_4edta,[25] 5.01×10^{-10} m^2 s^{-1}).

The summit potential, E_s, of the corresponding AC wave coincided with $E_{1/2}$ within ±2 mV when the pH_c of the solution was higher than about 2. At a lower pH_c, E_s became more negative than $E_{1/2}$ (Fig. 2).

When $\log[(i_s/i)^{1/2}-(i_s-i)/i^{1/2}]$ (where i_s and i are the alternating currents at E_s and at E, respectively) was plotted against E, a pair of straight lines with reciprocal slopes of +125 and −106 mV was obtained (pH_c=3.68). The summit current was maximum at

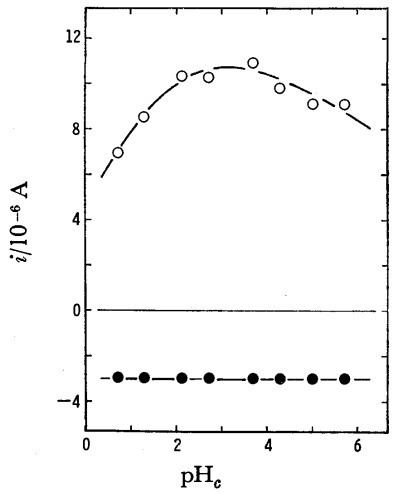

Fig. 3. pH_c-Dependence of i_d and i_s. 1 mmol dm^{-3} [Ru(Hedta)(H_2O)]; buffer solution; ionic strength= 0.2 mol dm^{-3}; ●: i_d; ○: i_s, ΔV=10 mV, f=35 Hz.

pH_c values between 3 and 4, decreasing at higher and lower pH_c (Fig. 3). The dependence of i_s on the frequency of the superimposed alternating voltage was examined at pH_c=0.72, 3.68, and 5.78 in the frequency range of 35—190 Hz, and i_s was found to be proportional to the square root of the frequency at pH_c= 3.68; in the other cases, the relation between i_s and the frequency was not linear.

Controlled-Potential Electrolysis. When the complex was partially reduced at the potential of the diffusion current plateau of the first step (−0.40 V), a redox polarographic step appeared at about −0.2 V. It was also noted that the reduced form of the complex was oxidized to the original form of the complex by passing air into the solution. The solution became slightly greenish when the electrolysis roceeded.

In the absence of perchlorate ions, the polarographic oxidation and reduction diffusion currents, i_d^a and i_d^c, recorded by suspending the electrolysis were plotted against the quantity of electricity consumed (Q) (Fig.

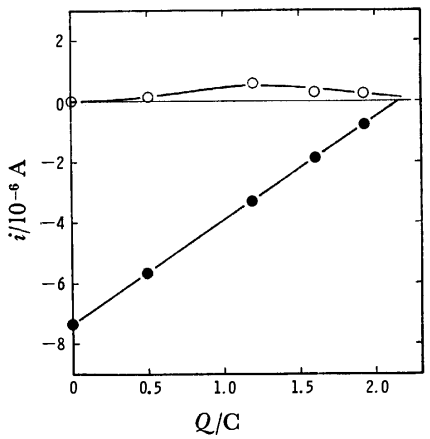

Fig. 4. Polarographic diffusion current against quantity of electricity consumed. Solution volume, 10 cm^3; 2.26 mmol dm^{-3} [Ru(Hedta)(H_2O)]; formate buffer; pH_c=4.34; ionic strength=0.5 mol dm^{-3}; 25 °C; ○: i_d^a, ●: i_d^c.

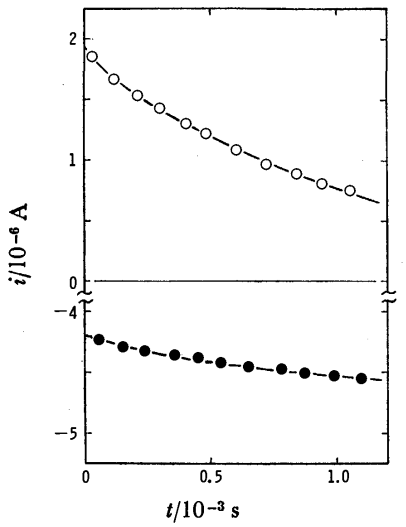

Fig. 5. Time-dependence of i_d^a and i_d^c. Formate buffer; 0.15 mol dm^{-3} $NaClO_4$; pH_c=4.35; ionic strength= 0.5 mol dm^{-3}; 25 °C; ○: i_d^a, ●: i_d^c.

4). The reduction diffusion current decreased in proportion to the advancement of the electrolysis. The slope obtained from the decrease in $|i_d^c|$ indicated that the reduction is a one-electron process. On the contraty, i_d^a remained small during the electrolysis instead of increasing proportionally. When the partially electrolyzed solution was allowed to stand, i_d^a decreased with a half-decay time of about 30 min while i_d^c remained constant.

In the solution containing perchlorate ions, the dependence of i_d^c on Q was not linear. When the electrolysis was suspended, i_d^a decreased faster than in the absence of perchlorate ions while $|i_d^c|$ increased (Fig. 5).

Discussion

Electrode Processes and Equilibria. In acid buffer solutions the first reduction step is DC-polarographically reversible, and its $E_{1/2}$ is independent of the concentration of $edta^{4-}$ in the solution. On the basis of these observations the pH-dependence of $E_{1/2}$ can be explained in terms of a set of acid-base equilibria (Fig. 6).

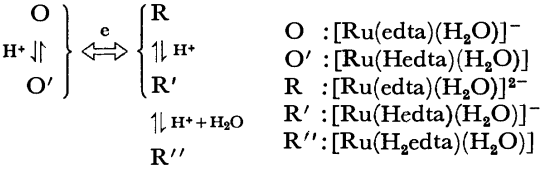

Fig. 6. Electrode process and acid-base equilibria.

Here $[Ru(edta)(OH)]^{2-}$ is ignored, because its concentration is negligible in acid solutions. Furthermore, any protonated species of the Ru(III) complex can be excluded by the fact that the electronic spectra of the complex in acid solutions were unchanged up to pH_c= 1. If each reaction is virtually in equilibrium in the course of the DC-polarographic reduction, the current-potential curve should follow Eqs. (1a) and (1b).

$$E = E_{1/2} - \frac{RT}{F} \ln \frac{i}{i_d - i} \quad (1a)$$

with

$$E_{1/2} = E_c + \frac{RT}{F} \ln \frac{([H^+]/c^\ominus)^2 + K_R[H^+]/c^\ominus + K_R K_R'}{([H^+]/c^\ominus) + K_O} \quad (1b)$$

where

$$K_O = [O][H^+]/[O']c^\ominus$$

$$K_R = [R][H^+]/[R']c^\ominus$$

$K_R' = [R'][H^+]/[R'']c^\ominus$ with $c^\ominus = 1$ mol dm^{-3}.

Among these constants $K_O = 4.29 \times 10^{-3}$ was determined by the titration of [Ru(Hedta)(H_2O)]. The others were calculated by applying the method of least squares to Eq. (1b). The best fit was obtained by the following set: $E_c = -0.078$ V, $K_R = 6.20 \times 10^{-4}$, and $K_R' = 2.53 \times 10^{-2}$. The agreement between the 'best' curve and the experimental data is excellent (Fig. 2).

The points in Fig. 2 lying along a single curve were obtained by using different buffer solutions. It follows that no anion is involved in the proton uptake of the reduced form. Although no direct evidence has yet been obtained for the protonated reduced form, the value of K_R' seems reasonable.

Polarographic Reversibility. The result of coulometry shows that the charge number of the reduction step is one. The log-plot of the DC step and the single redox step observed in the partially electrolyzed solutions show that the first step is reversible at $pH_c < 5$.

The AC reversibility was tested by analyzing the shape and height of the AC wave and the frequency dependence. The AC log-plot resulted in a pair of straight lines whose reciprocal slopes were in fair agreement with the reversible value of ± 118 mV.[26] For an AC-reversible wave the ratio of the summit AC current (i_s) to the diffusion current (i_d) is given by Eq. (2).

$$\frac{i_s}{i_d} = \frac{nF\Delta V(2\pi f)^{1/2}}{4RT(7/3\pi)^{1/2} t_d^{-1/2}(1+x)} \quad (2)$$

with

$$x = bD^{1/2}m^{1/3}t_d^{1/6}$$

Where ΔV and f are the amplitude and frequency of the superimposed AC voltage and t_d is the mean drop time in the potential region where i_s and i_d are measured; the constant b is 39.7 m^{-1} kg$^{1/3}$ given by Koutecký.[22] Inserting the necessary values into Eq. (2) one obtains $i_s/i_d = 3.34$. The corresponding experimental value at $pH_c = 3.68$ was 3.11; the agreement is reasonable. The summit current was proportional to $f^{1/2}$ up to $f = 190$ Hz as expected for a reversible case. All these data demonstrate that at $pH_c = 3$—5 the reduction process is reversible in both AC- and DC-polarographic senses.

However, at $pH_c > 5$ both AC and DC polarograms became more or less irreversible. This seems to suggest that the reduction of $[Ru(edta)(OH)]^{2-}$ is less reversible. At $pH_c < 2$, on the other hand, the DC step remained reversible, but the AC wave broadened and its height decreased. A study on the AC wave using a phase-selective AC polarograph indicated a reversible electron-transfer followed by a relatively slow chemical reaction.[27] The less reversible behavior of the AC wave may be explained by assuming that the proton dissociation of the reduced form, which involves the substitution of one of the ligating water molecules by the carboxyl group, is sluggish compared with the frequency of the superimposed AC voltage.

Chemical Reactions Subsequent to Electrode Reaction. As mentioned earlier, the reduction of the complex proceeds through a one-electron process. But the polarograms recorded in the course of the electrolysis showed an unusual behavior of the reduced form of the complex. The gradual decrease in i_d^a observed in the absence of perchlorate ions, when the partially electrolyzed solution was allowed to stand, shows the existence of at least one following chemical reaction by which the reduced form is consumed. We call this chemical reaction the deactivation reaction since the product is polarographically inactive as demonstrated by the fact that no polarographic step was observed when the solution was left to stand for a sufficient time after the completion of the electrolysis.

In the presence of perchlorate ions not only did i_d^a decrease but $|i_d^c|$ increased (Fig. 5). The faster decrease in i_d^a than that observed in the absence of perchlorate ions indicates the contribution of another chemical reaction in which the reduced form and perchlorate ions react. The increase in $|i_d^c|$ indicates the regeneration of the original form of the complex. These facts suggest that perchlorate ions reoxidize the reduced form to the original oxidized form. We call this reaction the reoxidation reaction. In the presence of perchlorate ions, the deactivation and reoxidation reactions occur simultaneously.

Kinetic Study of Chemical Reactions. The rate constants of both reactions can be determined by analyzing the time-dependence of i_d^a and i_d^c when the electrolysis is suspended.

The following reaction scheme is proposed:

$$\mathrm{Ox} \overset{e}{(\rightleftharpoons)} \mathrm{Red} \xrightarrow{k_3'[\mathrm{Red}]} \mathrm{Z}$$

$$\uparrow \quad\quad\quad\quad\quad\quad\quad\quad \downarrow$$

$$\underset{k_2'[\mathrm{Red}]}{\longleftarrow}$$

where Ox, Red, and Z represent the oxidized (equilibrium mixture of O and O'), reduced (equilibrium mixture of R, R', and R''), and deactivated forms of the complex, respectively, and [Red] is the concentration of Red. If the rate of decrease of [Red] is assumed to be first-order with respect to [Red], the time differentiation of [Red], when the electrolysis is suspended, is given by:

$$-\frac{d[\mathrm{Red}]}{dt} = (k_2' + k_3')[\mathrm{Red}] \quad (3)$$

where k_2' and k_3' are the apparent first-order rate constants for the respective reactions. Integrating Eq. (3) with the boundary condition, $[\mathrm{Red}] = [\mathrm{Red}]_0$ at $t = 0$, one obtains:

$$[\mathrm{Red}] = [\mathrm{Red}]_0 \exp\{-(k_2' + k_3')t\}. \quad (4)$$

Similarly, the time differentiation of the concentration of Ox under the same conditions is

$$\frac{d[\mathrm{Ox}]}{dt} = k_2'[\mathrm{Red}]. \quad (5)$$

The equation obtained by inserting Eq. (4) into Eq. (5) is integrated with the boundary condition, $[Ox]=[Ox]_0$ at $t=0$. Rearranging the resulting expression, we have

$$\frac{k_3}{k_2'+k_3'} = \frac{[Ox]-[Ox]_0}{[Red]-[Red]_0}. \quad (6)$$

By assuming equal diffusion coefficients for both Red and Ox, Eqs. (4) and (6) are expressed as follows:

$$\ln (i_d^a/i_{d,0}^a) = -(k_2'+k_3')t \quad (7)$$

$$\frac{i_d^c - i_{d,0}^c}{i_{d,0}^a - i_d^a} = \frac{k_2'}{k_2'+k_3'} \quad (8)$$

where $i_{b,0}^a$ and $i_{b,0}^a$ are the respective diffusion currents at $t=0$.

M represents mol cm^{-3}. a) The solution contains 0.1 mol dm^{-3} H_4edta.

Equations (7) and (8) were experimentally satisfied, and by solving them k_2' and k_3' were obtained as shown in Table 1. k_3' was found to be independent of perchlorate ion concentration. It seems that the deactivation process involves a reaction between Ru(II)edta species and formic acid similar to that reported in the case of the tetrachlororuthenate(II)–formic acid system.[28] Details on the kinetics of this reaction and identification of the reaction product will be reported separately.

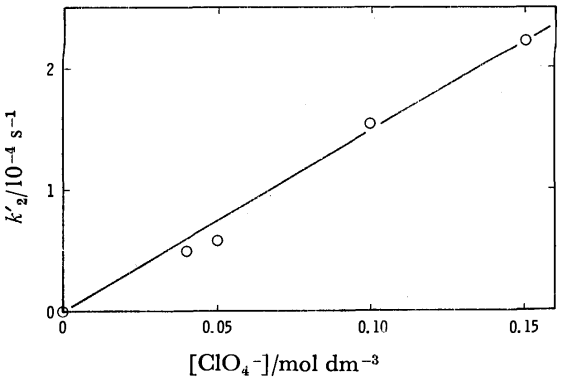

Fig. 7. Effect of perchlorate ion concentration on reoxidation rate. Formate buffer; ionic strength= 0.5 mol dm^{-3}; 25 °C.

The apparent rate constant of the reoxidation, k_2', was independent of the hydrogen ion concentration and formic acid concentration. When k_2' was plotted against perchlorate ion concentration a straight line was obtained (Fig. 7), from which the rate constant for the reoxidation, k_2 at 25.0 °C is estimated at the 90% confidence limit as follows:

$$k_2 = \frac{k_2'}{[ClO_4^-]} = (1.38\pm0.26)\times10^{-3}\ \text{mol}^{-1}\ \text{dm}^3\ \text{s}^{-1}$$

Linear Arrhenius plots are obtained for k_2. The activation parameters for the reoxidation process are calculated at the 90% confidence limit by applying the rate theory of Eyring with the assumption tnat the transmission coefficient and quotient of activity coefficients are unity. At 25.0 °C, ΔH^* and ΔS^* obtained are as follows:

$$\Delta H^* = (9.41\pm17.6)\times10^3\ \text{J mol}^{-1},$$

$$\Delta S^* = (19.0\pm6.3)\ \text{J K}^{-1}\ \text{mol}^{-1}.$$

The value of ΔH^*, which is very similar to those for other ruthenium(II) substitution reactions[13-15] but much larger than those for ruthenium(II)—ruthenium(III) electron transfer reactions,[11] seems to indicate that the rate determining step of the reoxidation reaction is the substitution of perchlorate ion on the reduced form of the complex. The most probable mechanism for the attack of perchlorate ion on the reduced form is similar to that proposed by Taube[9] in the case of hexaammineruthenium(II) ions.

The authors wish to thank to Dr. M. Mukaida of Sophia University, for his kind help in the synthesis of the complex. Thanks are due to Mr. T. Kimura of St. Paul University, for permission to use his computer program for the calculation of acid-base equilibrium constants. The authors also thank Sr. Jean Michalec for correcting the manuscript.

The Complexing of the Sodium Ion in Acetonitrile with Other Solvents. Investigation by the Use of a Cation-sensitive Glass Electrode

Kosuke Izutsu, Toshiaki Nomura, Toshio Nakamura,
Hidetoshi Kazama, and Shigeo Nakajima
Chemistry Department, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received November 16, 1973)

The complexing of the sodium ion in acetonitrile (AN) with such solvents as methanol, water, DMF, DMA, DMSO, HMPA, and pyridine has been studied potentiometrically by using a monovalent cation-sensitive glass electrode. The reference electrode of Ag-0.005 M $AgNO_3$(AN) and the salt bridge of 0.1 M Et_4NPi(AN) were used. Mono- and di-solvated ions were formed for methanol, water, and pyridine. For DMF, DMA, DMSO, and HMPA, tri-solvated species were also formed. The formation constants for the mono-solvated sodium ion were 0.7 for pyridine, 1 for methanol, 1.8 for water, 2.5 for DMF, 5 for DMA, 6 for DMSO, and 30 for HMPA.

The hydration constants of alkali metal ions and several monovalent anions in acetonitrile(AN) have been determined by Chantooni and Kolthoff.[1] This was done by measuring conductometrically the ionic solubility of a slightly soluble salt in AN in the presence of a known concentration of water.

In the present paper, we investigated the complexing of the sodium ion in AN with such solvents as methanol, water, dimethylformamide(DMF), dimethylacetoamide (DMA), dimethylsulfoxide(DMSO), hexamethylphosphoramide(HMPA), and pyridine by using a monovalent cation-sensitive glass electrode. The emf of the following cell was measured:

$$\underset{(A)}{Ag|0.005\ M\ AgNO_3(AN)}\|\underset{(B)}{0.1\ M\ Et_4NPi(AN)}\|\underset{(C)}{10^{-3}\ M\ NaClO_4+0.01\ M\ Et_4NClO_4(AN+D)}|Glass\ electrode$$

Cell I

where D denotes a solvent added to the AN solution in the compartment (C). The liquid junction potential between the salt bridge (B) and the solution in the compartment (C) was assumed to change only negligibly upon the addition of a solvent (D). The salt bridge of the 0.1 M tetraethylammonium picrate (Et_4NPi) in AN was used because Parker *et al.*[2,3] reported that the junction potential between this salt bridge and a 0.01 M $AgClO_4$ solution in other dipolar solvents is usually relatively small. The Nernstian response of the cation-sensitive glass electrode towards alkali-metal ions has been verified in several nonaqueous solvents.[4,5] We found, in the present study, that the glass electrode can also be used to measure the difference in the activity of the sodium ion in various solvents, provided that a suitable reference electrode system is employed.

In the mixture of AN and D, the following equilibrium is attained between sodium ions solvated only by AN (denoted by Na_s^+) and those which are solvated also by D (denoted by Na_{xD}^+, where x is the number of solvating D molecule(s)):

$$Na_s^+ + xD = Na_{xD}^+ \quad (1)$$

$$K_x = \frac{[Na_{xD}^+]}{[Na_s^+][D]^x} \quad (2)$$

where K_x is the corresponding formation constant. If we denote the activity of Na_s^+ in pure AN by $[Na_s^+]_{AN}$, and that in the mixture of AN and D by $[Na_s^+]_{AN-D}$, the following relations hold:

$$R \equiv \left\{\frac{[Na_s^+]_{AN}}{[Na_s^+]_{AN-D}} - 1\right\}/[D] = K_1 + K_2[D] + K_3[D]^2 + \cdots \quad (3)$$

and

$$(R-K_1)/[D] = K_2 + K_3[D] + \cdots \quad (4)$$

Here, the values of $[Na_s^+]_{AN}/[Na_s^+]_{AN-D}$ can be obtained from the potentials of the glass electrode in pure AN and an AN–D mixture as follows:

$$[Na_s^+]_{AN}/[Na_s^+]_{AN-D} = 10^{(E_{AN}-E_{AN-D})/59} \quad (5)$$

where E_{AN} and E_{AN-D} are in mV. By plotting the relations between R and [D] and between $(R-K_1)/[D]$ and [D], we can obtain the values of the formation constants of Reaction (1).

In the determination of formation constants, the following assumptions are made: (i) the solvent (D) in AN–D mixtures is monomeric, and the activity of D is equal to the analytical concentration; (ii) the activity of AN does not change upon the addition of D and is equal to unity; and (iii) the salt-effect activity coefficient of the sodium ion, calculated by the Debye-Hückel equation, is equal in pure AN and in AN–D mixtures. We also assume that the amount of the solvent(D) consumed by the solvation of the ions of an indifferent electrolyte is negligible. The last assumption seems to be justified when the indifferent electrolyte is 0.01 M Et_4NClO_4 if we consider that the hydration constant of perchlorate ion in AN has been reported to be 0.7.[1]

Apparatus and Reagents

Apparatus. The assembly of Cell I is shown in Fig. 1. In each experiment, the solution in the compartment (C) was initially composed of 50 ml of the AN solution which was 10^{-3} M in $NaClO_4$ and 0.01 M in Et_4NClO_4; from the solvent inlet, the solvent (D) was titrated with a microsyringe. The maximum volume of D added to the cell was 0.85 ml for water, 1.25 ml for methanol, 1.8 ml for HMPA, and 2.5 ml for DMF, DMA, DMSO, and pyridine. After each addition of solvent, the solution was stirred with a magnetic stirrer. The emf was measured with the expanded scale of a Hitachi-Horiba pH meter, model F-7ss, to ± 0.1 mV. The mono-

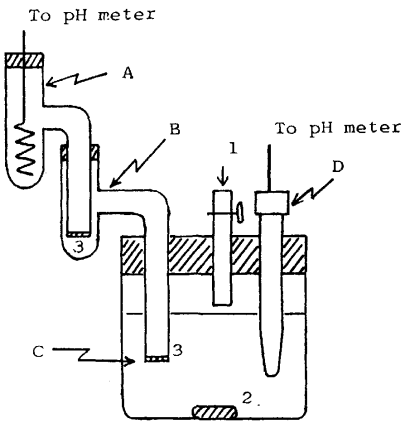

Fig. 1. Diagram of cell assembly.
A: reference electrode, B: salt bridge, C: cell for test solution, D: cation-sensitive glass electrode, 1: solvent inlet, 2: magnetic stirrer, and 3: fine porosity sintered glass. The cell is kept in a bath at 25±0.1 °C.

valent cation-sensitive glass electrode was a Beckman 39047. The reference electrode of Ag-0.005 M $AgNO_3$ in AN was connected to the solution in (C) through a salt bridge of 0.1 M Et_4NPi in AN. The reference electrode and the salt bridge were prepared every day before measurement in order to avoid mixing of solutions between compartments. When the reference electrode and the salt bridge were too fresh, however, the emf of the cell changed with the time. Therefore, the titration was carried out after the shift of emf had become less than 0.5 mV/hr. The emf of the cell of the initial AN solution was reproducible; it was 75±1 mV. Polarograms were measured with a three-electrode polarograph, Yanagimoto P8-PS. All the experiments were carried out at 25±0.1 °C.

Reagents. Unhydrated sodium perchlorate was dried before use at 130 °C under a vacuum. The tetraethylammonium picrate was prepared by the method of Coetzee and Padmanabhan.[6] The tetraethylammonium perchlorate was prepared and dried by the conventional method. Acetonitrile was purified by distilling it three times using an adiabatic vacuum fractional distillation column, first from P_2O_5, next from CaH_2, and finally without any addition.[7] The purified AN was used within a day after distillation. The pyridine was used after the purification of the spectrophotometric product by fractional crystallization. The other solvents were of an analytical reagent grade and were used without further purification.

Results

Response of the Glass Electrode to the Activity of Sodium Ion in Different Solvents. The slope of the response of the glass electrode to the concentration of the sodium ion in AN has been reported to be 56 mV in the presense of 0.1 M Bu_4NClO_4.[4] The glass electrode used in the present study showed a slope of 58 mV to the sodium ion between 10^{-4} and 10^{-2} M in AN–0.01 M Et_4NClO_4. If corrected for the change in the salt-effect activity coefficient, the response towards pa_{Na^+} is very near to the Nernstian slope of 59 mV.

For the present study, it is also necessary for the electrode to respond to the difference in the activity of the sodium ion between solvents of different species or compositions. This was verified by comparing the emfs of the following cell with the polarographic half-wave potentials of the sodium ion, which are considered to make a Nernstian response to the solvent effect on the activity of the sodium ion:

Ag|0.005 M $AgNO_3$(AN)‖0.1 M Et_4NPi(AN)‖
10^{-3} M $NaClO_4$ + 0.01 M Et_4NClO_4(D)|Glass electrode
(D denotes AN, MeOH, H_2O, DMF, and DMSO)
Cell II

The half-wave potentials were measured in a solution of 10^{-3} M $NaClO_4$+0.01 M Et_4NClO_4 by using a reference electrode and salt bridge similar to those in Cell II.

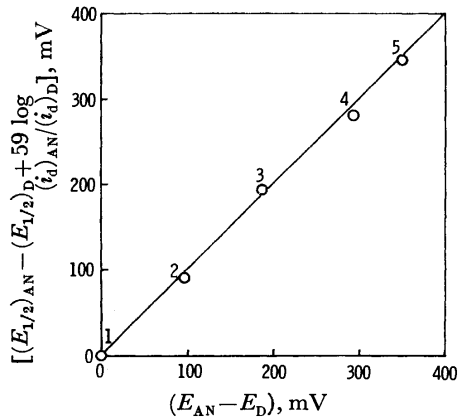

Fig. 2. Relations between the emf of Cell II and the half-wave potential of sodium ion in various solvents. Referred to the values in AN. Circle 1 is in AN, 2 in MeOH, 3 in H_2O, 4 in DMF, and 5 in DMSO.

The results in Fig. 2 show that the emf and the half-wave potential (corrected for the change in diffusion current) in each solvent, both referred to the values in AN, agree quite well, suggesting that the glass electrode can respond to the activity of the sodium ion in different solvents.

Complexing of the Sodium Ion in AN with Other Solvents. From the emf measurement of Cell I, the values of the formation constants of Reaction (1) were calculated by using the relations of Eqs. (3) to (5). The results are summarized in Table 1. Figures 3 to 6 show some

Table 1. Complex formation constants of sodium ion in AN with other solvents

Solvent	K_1	K_2	K_3
H_2O	1.8	1.8	
	1.8	1.8	
	1.8	1.9	
MeOH	$1._0$	0.4	
	$1._2$	0.4	
DMF	2.4	$2._1$	$1._1$
	2.5	$2._0$	$1._2$
DMA	5.3	10	$7._6$
	5.2	12	$5._2$
DMSO	5.8	10	$1._3\times10$
	6.2	12	$1._5\times10$
HMPA	28	$3._2\times10^2$	$1._4\times10^3$
	30	$3._1\times10^2$	$1._2\times10^3$

examples of R-[D] and $(R-K_1)/[D]$-[D] relations.

By the addition of water, mono- and di-hydrated sodium ions are formed, with K_1 and K_2 equal to 1.8 and 1.8 respectively. These values are in fairly good agreement with those of 2 and 3 respectively obtained by Chantooni and Kolthoff from the conductometric measurement of the solubility.[1] The solvation of methanol is weaker than hydration, and K_1 and K_2 are 1 and 0.4 respectively. The solvation becomes easier with the increase in the solvent basicity in the order: MeOH<H_2O<DMF<DMA~DMSO<HMPA. For DMF, DMA, DMSO, and HMPA, a complexing up to three solvent molecules is observed. It is interesting, however, that pyridine, which is strongly basic, solvates only weakly with a K_1 of approximately 0.7. The weak solvation of pyridine to the sodium ion is consistent with the results of the calorimetric investigation in acetone.[8]

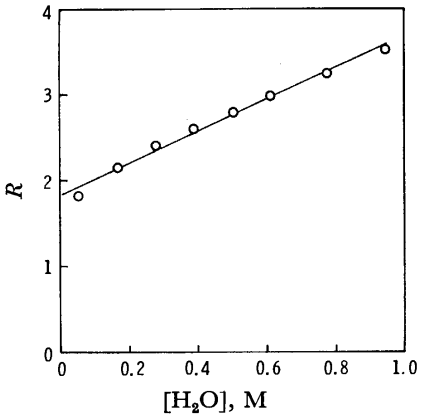

Fig. 4. R-[H_2O] relation.

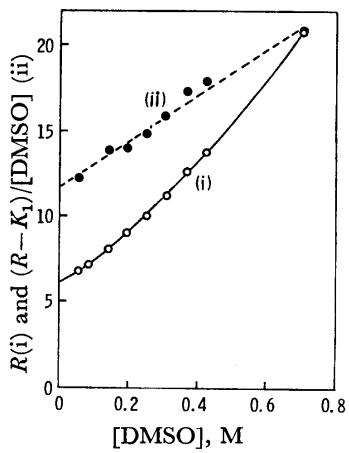

Fig. 5. R-[DMSO] (Curve i) and $(R-K_1)/[DMSO]$ -[DMSO] (Curve ii) relations.

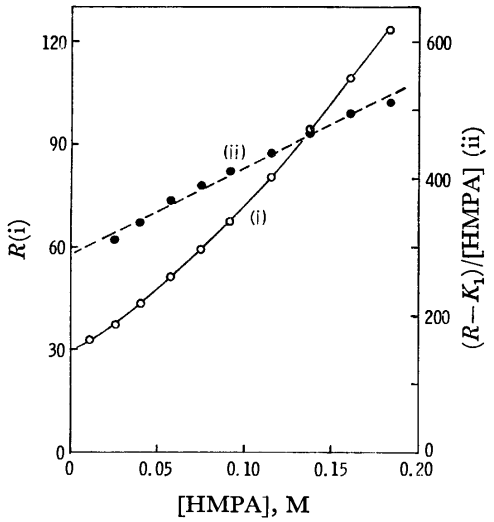

Fig. 6. R-[HMPA] (Curve i) and $(R-K_1)/[HMPA]$-[HMPA] (Curve ii) relations.

Discussion

From the results in Fig. 2, the glass electrode may be considered to respond with a Nernstian slope to the solvent effect on the activity of the sodium ion.

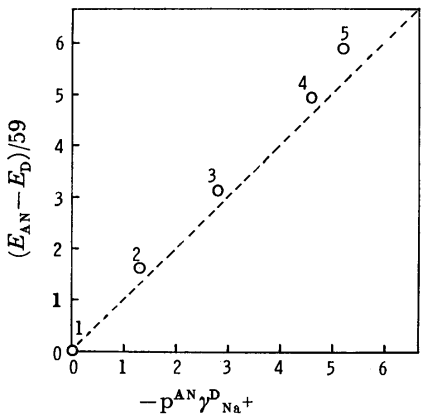

Fig. 7. Relations between the emf of Cell II and the solvent activity coefficient of sodium ion in various solvents. Referred to the values in AN. Circle 1 is in AN, 2 in MeOH, 3 in H_2O, 4 in DMF, and 5 in DMSO. E_{AN} and E_D are in mV.

Figure 7 shows the relation between the emfs of Cell II and the solvent activity coefficients of the sodium ion in several solvents, all referred to the values in AN. As the solvent activity coefficients, the values reported by Kolthoff and Chantooni ($p^{H_2O}\gamma^{MeOH}=1.5$, $p^{H_2O}\gamma^{AN}=2.8$, $p^{H_2O}\gamma^{DMF}=-1.8$, and $p^{H_2O}\gamma^{DMSO}=-2.4$)[9] were used. As is apparent from this figure, the values of $(E_{AN}-E_D)/59$ and $p^{AN}\gamma^{D}_{Na^+}$ for each solvent are in fairly good agreement. This may support the con-

sideration that the solvent activity coefficients quoted here are reasonable values and allow us to speculate that the junction potentials between the salt bridge and the solutions in these different solvents are relatively small, as has been reported by Cox *et al.*[3]

In the determination of formation constants, the junction potential between the salt bridge and the solution in (C) of Cell I was assumed to change only negligibly upon the addition of the solvent (D). According to Cox *et al.*,[3] the junction potential between the salt bridge of 0.1 M Et_4NPi(AN) and an aqueous 0.01 M $AgClO_4$ solution is approximately 10 mV (Fig. 1, Ref. (3)). If this is correct, the change in the junction potential in the present study, in which water up to *ca.* 1 M (1.7 v/v%) is added to the AN solution, is expected to be small (probably less than 1 mV) and it will tend to decrease the apparent value of $(E_{AN}-E_{AN-D})$. On the contrary, if a salt bridge of 0.1 M Et_4NPi in acetone is used instead of 0.1 M Et_4NPi in AN, the junction potential may be expected, according also to Cox *et al.*, to change to the opposite direction and to increase the apparent value of $(E_{AN}-E_{AN-D})$ (Fig. 1, Ref. (3)). The values of K_1 and K_2 for the hydration of the sodium ion, obtained by using a salt bridge of 0.1 M Et_4NPi in acetone, are 1.8 and 1.9

Table 2. Effect of salt bridge on hydration constants of sodium ion in AN

Salt bridge	K_1	K_2
0.1 M Et_4NPi in AN	1.8	1.8
	1.8	1.8
	1.8	1.9
0.1 M Et_4NPi in Acetone	1.7	2.0
	1.8	1.9
	1.8	1.9

(Table 2) respectively, in good agreement with the values of 1.8 and 1.8 respectively obtained with Cell I. This seems to support the assumption that the change in the junction potential by the addition of water is negligibly small. For the addition of methanol, however, the change in the junction potential may be somewhat larger than for water (Fig. 1, Ref. (3)). For other aprotic solvents, the change in the junction potential seems to be smaller than in the case of water.[3]

In the present study, the solution of the sodium ion usually contained 0.01 M Et_4NClO_4 as an indifferent electrolyte. According to the conductance measurement,[10] sodium ions in AN associate with perchlorate ions with an association constant of *ca.* 11. The hydration constants of the sodium ion in Table 3, determined in the presence of the indifferent electrolyte of 0, 0.01 and 0.1 M Et_4NClO_4 are, however, in good agreement with each other, suggesting that the effect of ion association is small in this case.

Table 3. Effect of concentration of indifferent electrolyte on hydration constants of sodium ion in AN

Concn. of Et_4NClO_4(M)	K_1	K_2
0	1.7	1.7
	1.8	1.8
	1.7	1.9
0.01	1.8	1.8
	1.8	1.8
	1.8	1.9
0.1	1.8	1.7
	1.8	1.8
	2.0	1.7

In addition to the factors considered above, the values of formation constants may also be affected by such factors as follows: (i) Some part of the solvent added may be self-associated, and the activity of the solvent may be less than the concentration. (ii) Both the activity of AN and the medium character may change upon the addition of other solvent. Because the effect of these factors increases with the increase in the amount of solvent added, the deviation of the values of K_2 and K_3 from the true values may be larger than the deviation of K_1. The values of K_1 in Table 1 seem to be reliable within $\pm 10\%$, except for the case of methanol, in which the reliability is somewhat less.

Due to the importance of solvation phenomena in the mechanism of various chemical reactions, the solvation of the sodium ion has recently been studied extensively by a variety of experimental techniques, among which infrared[11] and NMR[12] spectroscopies, conductometry[1] and calorimetry[8] are most significant. The present potentiometric method, however, seems to be superior to these techniques in the point that the activity of the sodium ion is directly measured.

The complexing of the lithium ion in AN with other solvents is now under investigation by using a similar method.

This work partly supported by a grant from the Ministry of Education of Japan.

Effect of Ethanol on the Outer-sphere Association of Λ- or Δ-Tris(ethylenediamine)cobalt(III) with *d*-Tartrate Ions in Aqueous Solutions

Hayami YONEDA, Katsuhiko MIYOSHI, Shingo SUZUKI, and Toshiaki TAURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received December 24, 1973)

The effect of ethanol on the outer-sphere association of Λ- or Δ-$[Coen_3]^{3+}$ ion (en=ethylenediamine) with *d*-tartrate ion was investigated in aqueous solutions containing 0, 1, 3, and 5 wt% of ethanol at 25 °C by measuring the change in optical density of the charge-transfer spectra at 265 nm. It was found that the association constant of Λ-$[Coen_3]^{3+}$ ion with *d*-tartrate ion $K_{A(\Lambda)}$ was a little larger than that of Δ-$[Coen_3]^{3+}$ ion $K_{A(\Delta)}$, and that the addition of ethanol increased both $K_{A(\Lambda)}$ and $K_{A(\Delta)}$ but decreased the ratio $K_{A(\Lambda)}/K_{A(\Delta)}$. The diminished discrimination between Λ- and Δ-$[Coen_3]^{3+}$ ions by *d*-tartrate ion was discussed in terms of the solubility of these diastereoisomers in aqueous ethanol and was attributed to the increased electrostatic interaction between the complex and *d*-tartrate ions arising from the decrease in the dielectric constant of the medium.

It is well-known that the racemic $[Coen_3]^{3+}$ ion is resolved from the fact that the Λ-form precipitates as Λ-$[Coen_3]X$*d*-tart (X=halide anion and *d*-tart=*d*-tartrate dianion), while the corresponding Δ-form remains gelatinous when evaporated in aqueous solution. The discrimination of Λ- from Δ-forms by *d*-tart ion is expected to take place also in solution, *viz.*, the differential outer-sphere association with *d*-tart ion is anticipated for Λ- and Δ-$[Coen_3]^{3+}$ ions. Addition of alcohol decreases solubility of many inorganic salts. This is the case with this system. Thus, it seems of interest to examine the effect of alcohol on the outer-sphere association of Λ- or Δ-$[Coen_3]^{3+}$ ion with *d*-tart ion in aqueous solution. The purpose of this investigation is to find optimum conditions for the discrimination between Λ- and Δ-forms. As the first step, the association constants were determined by spectrophotometry in aqueous ethanol.

Ogino and Saito[1] and Nordén[2] reported from the measurements of charge-transfer (CT) and the corresponding circular dichroism (CD) spectra that *d*-tart ion associates to a greater extent with Λ-$[Coen_3]^{3+}$ than with Δ-$[Coen_3]^{3+}$ ion in aqueous solution. They neglected the association of $[Coen_3]^{3+}$ ion with perchlorate ion added to adjust ionic strength constant, on the ground that the spectra are not altered by its addition. However, it is not plausible from both electrostatic[3] and experimental[4] viewpoints that $[Coen_3]^{3+}$ ion does not associate at all with ClO_4^- ion even in aqueous solution. Addition of alcohol is expected to promote ionic association of the complex cation not only with *d*-tart ion but also with ClO_4^- ion owing to the accompanying decrease in the dielectric constant of the medium. Therefore, measurements should be carried out on a system which contains no anions other than *d*-tart ion.[5]

Experimental

Materials. Λ-$[Coen_3](d\text{-tart})_{3/2}\cdot 6H_2O$(or $5.5H_2O$) was prepared by the double decomposition of Λ-$[Coen_3]Brd$-tart$\cdot 5H_2O$ with an equivalent amount of Ag_2*d*-tart. Found: C, 25.32; H, 6.99; N, 15.15%. Calcd for $C_{12}H_{42}N_6O_{15}Co$(or $C_{12}H_{41}N_6O_{14.5}Co$): C, 25.31(25.72); H, 7.43(7.37); N, 14.76 (15.00)%. Similar procedures gave Δ-$[Coen_3](d\text{-tart})_{3/2}\cdot 6H_2O$(or $6.5H_2O$) when Δ-$[Coen_3]Br_3\cdot 2H_2O$ was used in place of Λ-$[Coen_3]Brd$-tart$\cdot 5H_2O$. Found: C, 24.73; H, 7.18; N, 14.46%. Calcd for $C_{12}H_{42}N_6O_{15}Co$(or $C_{12}H_{43}N_6O_{15.5}Co$): C, 25.31(24.92); H, 7.43(7.49); N, 14.76(14.53)%. Since the number of molecules of the water of crystallization in these complex salts was not definite, the concentration of the stock solutions was determined spectrophotometrically by using the absorption band at 465 nm, the magnitude and the shape of which do not change on the addition of *d*-tart ion. Its molar extinction coefficients are listed in Table 1. Molar rotation at 589 nm was +620 and −380° for Λ- and Δ-form, respectively.[6] Their optical purity is thus satisfactory, taking the contribution from 3/2 *d*-tart ion (+126°) into consideration.

The starting materials Λ-$[Coen_3]Brd$-tart$\cdot 5H_2O$ and Δ-$[Coen_3]Br_3\cdot 2H_2O$ were prepared by the usual method,[7] their specific rotations being in good agreement with those given in the literature.[7] $[Coen_3](ClO_4)_3$ was prepared by the usual method[7] starting with $CoSO_4\cdot 7H_2O$ and $HClO_4$ in place of $CoCl_2\cdot 6H_2O$ and HCl, respectively. Found: C, 13.41; H, 4.53; N, 15.86%. Calcd for $C_6H_{24}O_{12}Cl_3Co$: C, 13.41; H, 4.50; N, 15.63%.

Ion-exchanged water was purified by distillation. Ethanol was refluxed over calcium oxide and then over magnesium ethoxide, and then fractionated. Mixed solvents were prepared by weight. KNa*d*-tartrate$\cdot 4H_2O$ of reagent grade was used without further purification.

Apparatus. A Shimadzu double beam spectrophotometer UV-200 with 1 cm quartz cells was used for the measurement of CT absorption spectra. Its cell compartment was kept at 25±0.2 °C with a Komatsu-Yamato Coolnics CTR-120.

Procedure. Sample solutions used for measurements were prepared with appropriate amounts of stock solutions of Λ- and Δ-$[Coen_3](d\text{-tart})_{3/2}$ (0.01 mol/l) and of KNa*d*-tart (0.05 mol/l). Reference solutions prepared from the stock solutions of $[Coen_3](ClO_4)_3$ (0.01 mol/l) had strictly the same total concentration of $[Coen_3]^{3+}$ ion as in the corresponding sample solutions so that the spectrophotometer could allow us to measure directly the absorption at 265 nm due to the ion-pair formation between Λ- or Δ-$[Coen_3]^{3+}$ and *d*-tart ions. The concentration of $[Coen_3]^{3+}$ ion was $(1.0—6.0)\times 10^{-3}$ mol/l and that of *d*-tart ion was $(1.0—1.2)\times 10^{-2}$ mol/l, giving the final ionic strength 0.033 taking the decrease by ion-pair formation into consideration. Since pH of the sample solutions was around 7, the formation of H*d*-tart$^-$ ion or H_2*d*-tart was negligible.

Solubility was measured at 25 °C by a conventional method in the mixed solvents with ethanol, the concentration of the saturated solutions being determined by spectrophotometry.

Results and Discussion

Let M^{3+} and A^{2-} denote $[Coen_3]^{3+}$ and *d*-$tart^{2-}$ ions, respectively. Then the outer-sphere association equilibrium is

$$M^{3+} + A^{2-} \rightleftarrows MA^{+}$$

if only the first step association is assumed. The outer-sphere association constant K_A is given by

$$K_A = [MA^+]/[M^{3+}][A^{2-}] = x/(C_M - x)(C_A - x) \quad (1)$$

where C_M and C_A refer to the total concentration of M^{3+} and A^{2-}, respectively, and x refers to the concentration of MA^+ at equilibrium. Since no other species than M^{3+} and M^+ present in solution contributes to the absorbance at the wavelength employed for the measurement (265 nm), the difference of the absorbance ΔD between a sample solution and its reference solution can be given by

$$\Delta D = x(\varepsilon_{MA} - \varepsilon_M) \quad (2)$$

if both sample and reference solutions have the same total concentration of M^{3+} and the cell length is 1 cm. ε denotes the molar extinction coefficient of the species indicated by the subscript. Combining Eqs. (1) and (2) we have

$$C_M(C_A - x)/\Delta D = (C_A - x)/(\varepsilon_{MA} - \varepsilon_M) + 1/K_A(\varepsilon_{MA} - \varepsilon_M) \quad (3)$$

which is valid at a constant ionic strength and constant temperature.

Firstly an appropriate value of K_A is assumed and x's obtained from Eq. (1) are substituted into Eq. (3). The plot of the quantity on the left-hand side of Eq. (3) *vs.* $(C_A - x)$ gives a refined association constant as (slope)/(intercept), which is again substituted into Eq. (1). The same procedures are continued until a constant K_A is attained. Calculation should be carried out with the data having the same final ionic strength I, which is given by

$$I = 3C_M + 3C_A - 6x.$$

Details of analysis have been given by Tanaka *et al.*[5]

Typical examples of the plot of ΔD *vs.* C_M are shown in Fig. 1, where for any value of C_M, the amount of A added to Λ-solution is equal to that to Δ-solution. Thus we see in Fig. 1 that ΔD of Λ-solution is larger than that of Δ-solution and that the addition of ethanol increases ΔD of both solutions but decreases the difference in ΔD between them. Figure 2 shows some of the final plots of Eq. (3) obtained along the line described above. The linearity in Fig. 2 supports the assumption that only the first step association occurs under these experimental conditions.

Derived parameters along with the values of ε_M (at 265 nm) are summarized in Table 1, where $K_{A(\Lambda)}$ and $K_{A(\Delta)}$ refer to the association constant of *d*-tart ion with Λ- and Δ-$[Coen_3]^{3+}$ ions, respectively, the final ionic strength being 0.033 in all cases. These para-

meters indicate that $K_{A(\Lambda)}$ is a little larger than $K_{A(\Delta)}$ and that the addition of a small amount of ethanol promotes ionic association. The promotion might be interpreted in terms of the decrease in the dielectric constant of the medium. It should be noted that $(\varepsilon_{MA}-\varepsilon_M)$ as well as ε_M increases with the increase of ethanol content, but the values for Λ-form are equal to those for Δ-form in every case investigated within experimental error. On the other hand, Ogino and Saito[1] obtained 366±15, 415±16, and 365±13[3] as the value of $(\varepsilon_{MA}-\varepsilon_M)$ for Λ-, Δ-, and racemic forms, respectively, in aqueous solutions at $I=0.1$ ($NaClO_4$).[2] ε_M (at 265 nm) we obtained in water differs somewhat from the value 158 reported by Ogino and Saito but agrees well with that by Nordén. Though the origins of the differences are not known, it is certain that the value of $(\varepsilon_{MA}-\varepsilon_M)$ for the racemate should lie between the corresponding values for Λ- and Δ-forms if they are different.

The ratio $K_{A(\Lambda)}/K_{A(\Delta)}$, a measure of the discrimination between Λ- and Δ-forms by *d*-tart ion in solution and defined to be a *discrimination factor*, is diminished on the addition of ethanol. Ogino and Saito,[1] and Nordén[2] reported 1.30 and 1.18, respectively, for the value of the factor in water, both of which are considerably larger than the value 1.11 we obtained. In order to compare our results with theirs in detail, our association constants in water were extrapolated to $I=0.1$ with the aid of the extended Debye-Hückel equation for activity coefficients with $a=5$ and 6 Å. The results are listed in Table 2 together with the values estimated by means of Fuoss[9] and Bjerrum[3] equations derived on the basis of pure electrostatics. We see that our association constant is about twice as large as theirs and that 6 Å[10] substituted as a into the theoretical equations reproduces our association constants satisfactorily. The interionic distance seems reasonable from molecular models though *d*-$tart^{2-}$ ion is not an ideal rigid-sphere with its charge uniformly distributed. Thus it may be concluded that the neglect of the association of $[Coen_3]^{3+}$ ion with ClO_4^- ion is responsible for the smaller K_A values obtained by Ogino and Saito, and Nordén and that outer-sphere association of *d*-tart ion with Λ- or Δ-$[Coen_3]^{3+}$ ion is described almost completely by pure electrostatic theories; the contribution from non-electrostatic interaction which is thought to discriminate Λ- from Δ-forms, is much smaller than that from the electrostatic one.

In order to explain the large discrimination factors obtained by Ogino and Saito, and Nordén, it is assumed that the electrostatic field of $[Coen_3]^{3+}$ ion is reduced by the ion-pair formation with ClO_4^- ion, and the electrostatic interaction between the complex ion and *d*-tart ion is weakened, *viz.*, non-electrostatic interaction is enhanced as compared with an electrostatic one when a large amount of $NaClO_4$ is added. Thus it follows that presence of some univalent anions such as ClO_4^- or Br^- ion in solution seems more effective in the discrimination between Λ- and Δ-forms by *d*-tart ion than the addition of alcohol which causes increase in the electrostatic interaction between Λ- or Δ-$[Coen_3]^{3+}$ and *d*-tart ions. In fact Br^- ion in crystalline Λ-$[Coen_3]$-Br*d*-tart·$5H_2O$ is attached closely to $[Coen_3]^{3+}$ ion from the direction of its three-fold axis and is considered to play an important role in the crystal formation.[11]

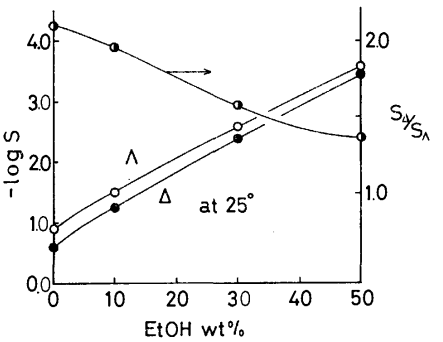

Fig. 3. Variation of solubilities of Λ- and Δ-$[Coen_3]$ (d-tart)$_{3/2}$ with the content of ethanol at 25 °C. Solubility ratio S_Δ/S_Λ (◑) corresponds to the right-hand scale. Open and closed circles for Λ- and Δ-forms, respectively.

The discrimination factor is very close to unity in solution and is therefore regarded at most as a part of the causes that precipitate only Λ-form as Λ-$[Coen_3]$-Br*d*-tart·$5H_2O$. In this connection, the effect of ethanol on the solubility of Λ- and Δ-$[Coen_3](d\text{-tart})_{3/2}$ was examined at 25 °C. The results are given in Fig. 3, where S denotes the concentration of the saturated solution in mol/l. The solubility difference between Λ- and Δ-forms decreases with the increase in ethanol content just like the discrimination factor in solution, but the solubility ratio S_Δ/S_Λ is considerably larger than the factor. Thus it might be concluded that the addition of alcohol is unfavourable to the discrimination of Λ- from Δ-forms by *d*-tart ion, since it only leads to increased electrostatic interaction between the complex and *d*-tart ions.

Potentiometric and Spectrophotometric Studies of Fluoride Complexes of Uranium(IV)

Hidetake KAKIHANA and Shin-ichi ISHIGURO

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received December 25, 1973)

The stability constants and the molar extinction coefficients of uranium(IV) fluoride complexes were determined in aqueous solutions containing 1 M $(Na^+ + H^+)Cl^-$ as a constant ionic medium at 25 °C. The emf data obtained by the use of a fluoride-ion-selective electrode were explained in terms of the formation of a series of mononuclear complexes, UF^{3+}, UF_2^{2+}, UF_3^+, and UF_4, with stability constants $\beta_1=(2.2\pm0.13)\times10^7$, $\beta_2=(1.33\pm0.05)\times10^{13}$, $\beta_3=(2.9\pm0.5)\times10^{17}$, and $\beta_4=(6\pm1)\times10^{21}$ respectively. Using these values for β's the spectra observed in the 350—700 nm region were analyzed by means of a computer in order to estimate the molar extinction coefficients of each uranium(IV) fluoride complex species.

The visible and ultraviolet spectra of uranium(IV) have thus far been investigated in crystal, gases, and aqueous solutions. Conway[1] measured the absorption spectra of UF, dissolved in a matrix of CaF_2 and assigned all the absorption peaks to the transition caused by two 5f electrons. Pappalardo and Jørgensen[2] studied the absorption spectra of uranium(IV) in the octahedral coordination. Satten *et al.*[3] calculated the energy parameters of $5f^2$ electrons in crystals.

The absorption spectra of aquated uranium(IV) ions in $HClO_4$[4] and $DClO_4$[5] solutions were reported. Spectrophotometric studies of uranium(IV) fluoride complexes were carried out by Stein *et al.*[6] in 1 M $HClO_4$ and 1 M H_2SO_4 solutions over the range of 300—1300 nm. They prepared complex salts $UFSO_4$-$(HSO_4)\cdot2H_2O$, $UF_2SO_4\cdot2H_2O$, and $(UF_3)_2SO_4\cdot4H_2O$ and discussed the infrared spectra and X-ray powder patterns. Baran and Tympl[7] measured the absorption spectra of the hydroxo and carbonato complexes of uranium(IV).

In solutions, the absorption spectra usually change in band shape and in position with the change in ligand concentration, because several species can coexist in a solution and because the mole fraction of each species varies with the ligand concentration.

A potentiometric titration is one of the most accurate methods for studying chemical equilibria in solution. Recently-developed fluoride-ion-selective electrodes are very useful for studying fluoride complexes in solution. Uranium(IV) fluoride complexes were studied by means of the fluoride-ion-selective electrodes by Norén[8] in a 4 M $HClO_4$ solution and by Grenthe and Varfeldt[9] in a mixture of 3.4 M $NaClO_4$ and 0.6 M $HClO_4$ and the formations of UF^{3+}, UF_2^{2+}, and UF_3^+ complexes have been reported. The electronic spectra of these species, however, have not yet been measured.

In the present study, the stability constants of uranium(IV) fluoride complexes were determined in a 1 M $(Na^+ + H^+)Cl^-$ solution by potentiometry with a fluoride-ion-selective electrode, and on the basis of these constants the spectrophotometric data were analyzed by means of a computer in order to estimate the molar extinction coefficients of each uranium(IV) fluoride complex species.

Experimental

Reagents. The uranium(IV) chloride used was prepared by the following method. The uranium metal was dissolved in dilute hydrochloric acid and then treated with nitric acid. The uranyl nitrate thus prepared was recrystallized twice from water and then converted to ammonium diuranate by the addition of ammonia. The ammonium diuranate precipitates were washed with water, dried under an infrared lamp, and decomposed to triuranium octoxide, U_3O_8, by heating at 900 °C for about 6 hr. The test solutions were prepared by the electrolytic reduction of UO_2Cl_2 solutions which had been prepared by dissolving U_3O_8 in hydrochloric acid.

The other chemicals used were of a reagent grade. Sodium fluoride was once recrystallized from water and dried in an electric furnace at 120 °C for 16 hr.

Apparatus. The test solutions containing fluoride ions were stored in polyethylene bottles. A fluoride-ion-selective electrode (Orion 94-09) was used for the determination of the free-fluoride-ion concentration. A specific-ion meter (Orion model 404) was employed to measure the potential of the fluoride-ion-selective electrode against a saturated calomel electrode used as reference.

The visible spectra were measured by means of an MPS 50L (Shimadzu Seisakusho Co. Ltd.) double-beam spectrophotometer, using a quartz cell 1.00 cm thick.

Measurements. In the solution used, the electrode exhibited Nernst behavior throughout the region of the free-fluoride-ion concentration of $10^{-4}\geq[F^-]\geq10^{-6}$ M. The constant ionic medium was kept at 1 M with sodium chloride. A back-titration technique starting at a high fluoride-ion concentration was employed in the present experiment in order to avoid the formation of precipitates during the titration and the corrosion of burets. A solution containing C_U M uranium(IV) and C_F M fluoride ions was titrated with a solution containing C_U M uranium(IV) ions to keep the total concentration of uranium(IV) constant (C_U) throughout the titration. The concentration of uranium(IV) was gravimetrically determined in the form of U_3O_8. Uranium-(IV) was gradually oxidized to uranium(VI) even in a solution under an atmosphere of nitrogen. To avoid errors caused by oxidation, the test solution was prepared immediately before each titration.

The test solutions for spectrophotometric measurements were prepared under the same ionic medium conditions as in the emf measurements.

Results and Discussion

Potentiometric Measurements. Formation curves at different total concentrations of uranium(IV) are shown in Fig. 1. The experimental results are discribed in terms of n_{exp}, the average number of fluoride ions

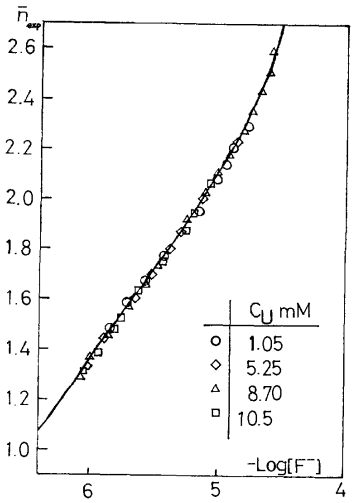

Fig. 1. Average number, $\bar{n}_{exp}$, of F⁻ bound per uranium(IV), as a function of $-\log [F^-]$. The curve was calculated using the constants obtained.

bound to the uranium(IV) ion, as a function of $-\log[F^-]$. Potentiometric measurements were carried out in the region where the fluoride-ion concentration was larger than 10^{-6} M, where the fluoride-ion-selective electrode exhibited Nernst behavior and a quick response to the change in the fluoride-ion concentration. Since the hydrogen fluoride complexes, HF and HF_2^-, are formed in an acidic solution ($[H^+] \gtrsim 0.1$ M),[10,11] $\bar{n}_{exp}$ was calculated by means of the equation:

$$\bar{n}_{exp} = (C_F - [F^-] - [HF] - 2[HF_2^-])/C_U = (C_F - f - K_{11}hf - 2K_{11}K_{12}hf^2)/C_U \quad (1)$$

where C_F, C_U, f, and h stands for the total fluoride, total uranium(IV), free-fluoride-ion, and free-hydrogen-ion concentrations respectively, and where K_{11} and K_{12} denote the step-by-step stability constants of these reactions:

$$H^+ + F^- = HF;\ K_{11} = [HF]/[H^+][F^-] \quad (2)$$

$$HF + F^- = HF_2^-;\ K_{12} = [HF_2^-]/[HF][F^-] \quad (2')$$

The values of K_{11} and K_{12} are given as 6.93×10^2 and 3.2 respectively.[10]

As is shown in Fig. 1, the formation curves are independent of the uranium(IV) concentration. This fact indicates the formation of a series of mononuclear complexes. The approximate values of the stability constants of the complexes were estimated by the graphical method as has been described by Rossotti and Rossotti.[12] The formation function:

$$\bar{n}_{exp} = \sum n\beta_n f^n / (1 + \sum \beta_n f^n) \quad (3)$$

can be rearranged as follows:

$$\sum_{i=0}^{n-1} \left(\frac{\bar{n} - i}{n - \bar{n}} \right) \beta_i f^{i-n} = \beta_n + \sum_{i=n+1}^{N} \left(\frac{i - \bar{n}}{n - \bar{n}} \right) \beta_i f^{i-n} \quad (4)$$

where β_n denotes the cumulative stability constant of this reaction:

$$U^{4+} + nF^- = UF_n^{4-n};\ \beta_n = [UF_n^{4-n}]/[U^{4+}][F^-]^n \quad (5)$$

The initial part of the plot of $\sum_{i=0}^{n-1} (\bar{n} - i)\beta_i f^{i-n}/(n - \bar{n})$ against $(i - \bar{n})f/(n + 1 - \bar{n})$ gives a straight line with an intercept of β_n and a slope of β_{n+1}. The procedure is continued until the plot of $\sum_{i=0}^{n-1} (\bar{n} - i)\beta_i f^{i-n}/(n - \bar{n})$ against $(i - \bar{n})f/(n + 1 - \bar{n})$ becomes horizontal. In our case, the procedure could be carried out until $n=4$, the plot was so spread that the formation of UF_5^- was not conclusive.

If we assume the formation of four complexes, UF^{3+}, UF_2^{2+}, UF_3^+, and UF_4, the mole balances for uranium(IV), fluoride, and hydrogen ions can be expressed by the following equations:

$$C_U = [U^{4+}] + [UF^{3+}] + [UF_2^{2+}] + [UF_3^+] + [UF_4] = u(1 + \sum_{n=1}^{4} \beta_n f^n) \quad (6)$$

$$C_F = [F^-] + [HF] + 2[HF_2^-] + [UF^{3+}] + 2[UF_2^{3+}] + 3[UF_3^+] + 4[UF_4] = f + K_{11}hf + 2K_{11}K_{12}hf^2 + u\sum_{n=1}^{4} n\beta_n f^n \quad (7)$$

$$C_H = [H^+] + [HF] + [HF_2^-] = h + K_{11}hf + K_{11}K_{12}hf^2 \quad (8)$$

where u represents the free-uranium(IV)-ion concentration. n_{calcd} is given by the following equation:

$$\bar{n}_{calcd} = \sum_{n=1}^{4} n\beta_n f^n / (1 + \sum_{n=1}^{4} \beta_n f^n) \quad (9)$$

Finally, the error-square sum, $U = \sum (1 - \bar{n}_{exp}/\bar{n}_{calcd})^2$ was minimized in order to obtain a set of the best-fit values of the stability constants by the least-squares method with the help of an electronic computer (HITAC 8500 and 8700). The formation curve was calculated using the four stability constants thus obtained. The calculated formation curve well explains the experimental points, as Fig. 1 shows. If only three complexes, UF^{3+}, UF_2^{2+}, and UF_3^+, were taken into consideration, the formation curve deviated from the experimental points at high $\bar{n}$ values ($\bar{n} \geq 2.2$). Since the calculation on the assumption of the formation of the UF_5^- complex in addition to the other four did not reduce the error-square sum remarkably, it may be concluded that there is very little mole fraction of the UF_5^- complex, if any, in this system. The final values of the stability constants obtained for the four uranium(IV) fluoride complexes, UF^{3+}, UF_2^{2+}, UF_3^+, and UF_4, are $\beta_1 = (2.2 \pm 0.13) \times 10^7$, $\beta_2 = (1.33 \pm 0.05) \times 10^{13}$, $\beta_3 = (2.9 \pm 0.5) \times 10^{17}$, and $\beta_4 = (6 \pm 1) \times 10^{21}$ respectively. They are listed in Table 1, together with the values reported in Ref. 8 and 9 and those obtained by solubility measurements by Savage and Browne.[13] As for β_2 and β_3, our results agreed well with Ref. 8, while for β_4 they agreed fairly well with Ref. 13. In Fig. 2, we show the distribution of the species of uranium(IV) fluoride complexes.

Mesmer and Baes[14] have studied a general correlation for the step-by-step stability constants of the fluoride complexes of a large number of metal ions and reported that the $\Delta \log K_n$ values can be well represented by:

$$\Delta \log K_n = -\alpha \Delta n \quad (10)$$

where K_n is the step-by-step stability constant ($=\beta_n/\beta_{n-1}$) and where n is the number of fluoride ions in the complex formed. They have concluded that the best-fitting value for α is 1.1. The $\Delta \log K_n$ values for uranium(IV) are plotted against n, together with those for other metals such as uranium(VI),[10] thorium(IV),[8,16,17] hafnium(IV),[18] and beryllium(II).[14] The

Uncertainties of the stability constants were estimated as 3σ where σ denotes the standared deviation. The results are described in terms of β_p^*, $\beta_p^*=\beta_p/K_{11}^p$, for comparison with other data. β_p^* is the over-all stability constants of the following reaction,

$$U^{4+}+pHF=UF_p^{4-p}+pH^+;\ \beta_p^*=[UF_p^{4-p}][H^+]^p/[U^{4+}][HF]^p$$

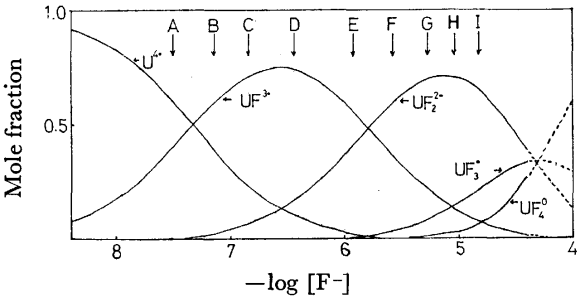

Fig. 2. The distribution of species of uranium(IV) fluoride complexes calculated using the stability constants obtained. Arrows (A-I) indicate compositions of species and free fluoride ion concentrations used for spectrophotometric measurements.

same α value of 1.1 is obtained for uranium(VI) and beryllium(II) fluoride complexes. A little larger value of 1.5 is found for the uranium(IV) and thorium(IV) fluoride complexes, with the exception of UF_4, the step-by-step stability constant of UF_4 being larger than would be expected from Eq. (10) on the assumption that $\alpha=1.5$. The plots for thorium(IV) fluoride complexes in different ionic media give the same slope.

Spectrophotometric Measurements. Without the fluoride ion, the spectra of the aquated uranium(IV) ion

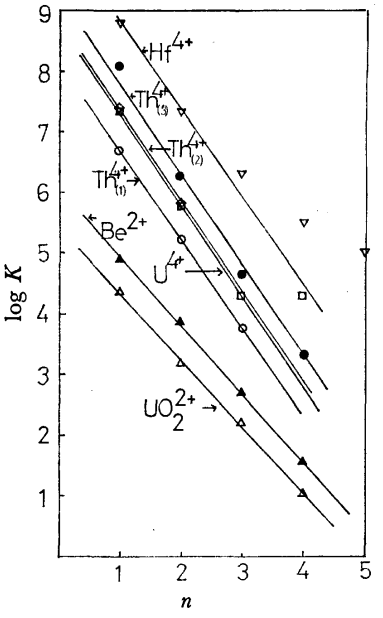

Fig. 3. The correlation of stepwise formation constants with n, the number of fluoride ion in the complex.

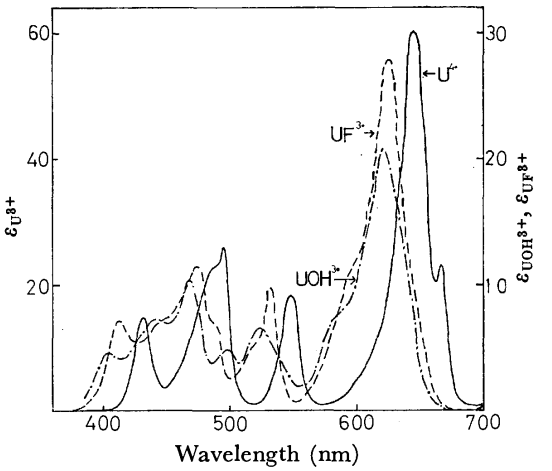

Fig. 4. The spectra of the aquated U^{4+} and UOH^{3+} ions and the calculated spectrum of UF^{3+}.

were measured in a 1 M HCl solution with various uranium(IV) concentrations in the 350—700 nm region, where the formation of chloro complexes of uranium(IV) is negligible.[15] The molar extinction coefficients of the aquated uranium(IV) ion in this region are shown in Fig. 4, together with those of UOH^{3+} as measured by Baran and Tympl.[7] The spectra of the uranium(IV) fluoride complexes were measured in the same ionic media as those used for the potentiometric titrations. The 9 fluoride-ion concentrations at which the spectra have been measured are marked with arrows (A-I) in Fig. 2.

Since four mononuclear complexes of uranium(IV) fluoride were found by the potentiometric measurements, the total absorbance, A, in solution can be expressed as follows:

$$\begin{aligned} A &= \varepsilon_0[U^{4+}] + \varepsilon_1[UF^{3+}] + \varepsilon_2[UF_2^{2+}] \\ &\quad + \varepsilon_3[UF_3^{+}] + \varepsilon_4[UF_4] \\ &= u\sum_{n=0}^{4}\varepsilon_n\beta_n f^n \end{aligned} \qquad (11)$$

where ε_n denotes the molar extinction coefficient of the relevant species and where β_0 is unity. Nine sets of data obtained by spectrophotometric measurements were used for the estimation of the molar extinction coefficients of the uranium(IV) fluoride complexes. The value of ε_0 at a given wavelength was adopted from the results in Fig. 4 (the spectrum of U^{4+}). In order to avoid errors in the calculation at a given uranium(IV) concentration, the total absorbance of the solution at the absorption maximum (600—650 nm)

was kept approximately constant (about 0.8) by varying the uranium(IV) concentration from 0.023 to 0.047 M. The values of ε's of the complexes can be calculated by solving Eqs. (6), (7), (8), and (11) at any point in the 350—700 nm region. The most suitable values of ε's were obtained by minimizing the error-square sum, $U=\Sigma(A_{calcd}-A_{exp})^2$, at given wavelength. The calculated molar extinction coefficients of the UF^{3+} complex are graphically shown in Fig. 4, while those of UF_2^{2+} and UF_3^+ are shown in Fig. 5. Using these values for ε_n, the total absorbance was calculated and compared with the observed absorbance. Some typical results of the comparison are shown in Fig. 6. This good agreement between the observed and calculated spectra may support the above-mentioned analysis and may make it possible to discuss ε_n a little further.

The spectrum of UOH^{3+}, as measured by differential spectroscopy by Baran and Tympl,[7] is depicted for comparison in Fig. 4. It may be seen from Fig. 4

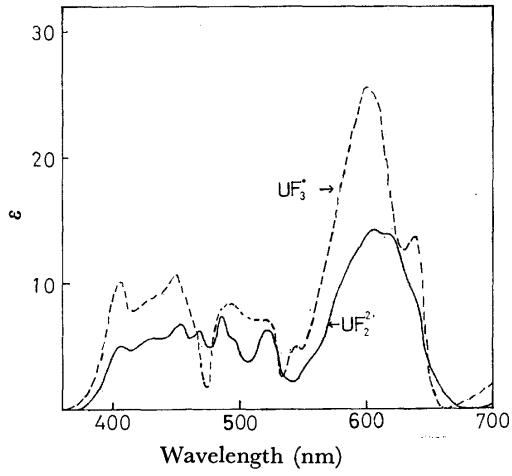

Fig. 5. The calculated spectra of UF_2^{2+} and UF_3^+.

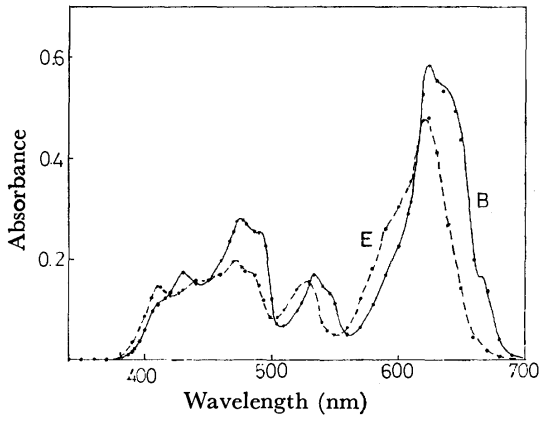

Fig. 6. Typical absorption spectra of uranium(IV) fluoride complexes. The calculated total absorbances are represented by dots. Solid and broken lines show measured absorption spectra of solutions with the following compositions of species.
(B) U^{4+}: 38.7%, UF^{3+}: 58.8%, UF_2^{3+}: 2.5% (indicated by arrow B in Fig. 2)
(E) U_4^+: 2%. UF^{3+}: 54.8%, UF_2^{2+}: 42%, UF_3^+: 1.2% (arrow E)

that, as a rule, the absorption peaks of the aquated U^{4+} ion shift to a wavelength shorter by 20—25 nm when a water molecule in the aquated U^{4+} ion is replaced with F^- or OH^- ions. Furthermore, the spectrum of UOH^{3+} has small absorption peaks at about 430 and 500 nm and a shoulder at 580 nm, while the spectrum of UF^{3+} has shoulders at about 430, 490, 520, and 595 nm. These small absorption peaks and shoulders of UOH^{3+} and UF^{3+} do not correspond to any peaks of the aquated U^{4+}. They may be supposed to be caused by changes in the ligand-field symmetry of UOH^{3+} and UF^{3+}. The hydroxyl ion may have a larger effect on the splitting of the degenerated states of $5f^2$ electrons in uranium(IV) than does the fluoride ion.

As for the spectrum of UF_2^{2+}, the peaks shift by about 10 nm to a wavelength shorter than those of UF^{3+}, and several additional peaks appear in the 400—500 nm region. The large absorption band at about 610 nm becomes weaker in intensity (about half of that of UF^{3+}) and broader in width.

Since the mole fraction of UF_3^+ is, at most, 35%, much less than those of UF^{3+} (75%) and UF_2^{2+} (70%), the calculated spectrum of UF_3^+ is uncertain compared with those of UF^{3+} and UF_2^{2+}. The absorption peaks of UF_3^+ also seem to shift to a shorter wavelength, but become stronger in intensity than those of UF_2^{2+}, even if uncertainities in calculation are considered.

The authors wish to thank Professor Hitoshi Ohtaki for his helpful advice and also Dr. Isao Okada for his discussions of the manuscript.

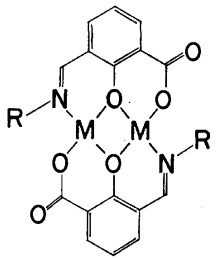
(Received April 1, 1974)

Copper(II) and nickel(II) complexes of H_2fsac-R have been synthesized, where H_2fsac-R denotes the Schiff bases prepared from 3-formylsalicylic acid and alkylamines (alkyl(R)=methyl, ethyl, hydroxyethyl, *n*-propyl, *n*-butyl, isobutyl, and *sec*-butyl). On the bases of elemental analyses, IR spectra, visible spectra and cryomagnetic measurements, it was found that the complexes have a binuclear structure connected by two phenolic oxygens; the complexes are abbreviated to M_2(fsac-R)$_2$. The nickel(II) complexes contain two, three or four molecules of coordinated water. The cryomagnetic data for Cu_2(fsac-R)$_2$ are interpreted in terms of the Bleaney-Bowers equation with large $-2J$ values (>700 cm^{-1}), indicating the presence of strong intramolecular antiferromagnetic spin-exchange interactions. The Ni_2(fsac-R)$_2\cdot nH_2O$ obey the Curie-Weiss law, the Weiss constants being estimated to -35——41 K.

In the previous paper of this series,[2] it was shown that 3-formylsalicylic acid forms binuclear copper(II) and nickel(II) complexes bridged by the phenolic oxygens. This report relates to the syntheses and characterization of the copper(II) and nickel(II) complexes of the Schiff bases derived from 3-formylsalicylic acid and alkylamines (R–NH_2). The Schiff bases are abbreviated to H_2fsac-R, in which R is methyl, ethyl, hydroxyethyl, *n*-propyl, *n*-butyl, isobutyl, or *sec*-butyl. Based on elemental analyses, IR spectra, visible spectra, and cryomagnetic data, the complexes seem to possess the binuclear structure shown in Fig. 1. The complexes are denoted by M_2(fsac-R)$_2$.



R=alkyl
M=Cu(II), Ni(II)

Fig. 1.

The copper(II) complexes are similar in structure to dihalogenobis(N-alkylsalicylaldimino)dicopper(II) complexes,[3-7] whose magnetic properties have been well elucidated. The exchange integrals of Cu_2(fsac-R)$_2$ were discussed in comparison with those of the above complexes.

Experimental

Syntheses. 3-Formylsalicylic acid was prepared after the method of Duff and Bills.[8] The synthetic methods of the complexes are nearly the same. A typical procedure is as follows. To an aqueous solution (30 ml) of sodium carbonate (106 mg) containing 3-formylsalicylic acid (154 mg) and ethylamine (70% aqueous solution, 75 mg), was added an aqueous solution (30 ml) of copper(II) acetate monohydrate (200 mg). The mixture was heated at 60 °C on a water-bath for a while to give blue prisms, which were collected and thoroughly washed with hot water. The nickel(II) complexes were obtained as yellowish green prisms using nickel(II) acetate tetrahydrate as a metal source. The analytical data are given in Table 1.

Table 1. Elemental analyses of complexes

Ni_2(fsac-*n*-Bt)$_2\cdot 4H_2O$	46.28	5.10	4.15	45.91	5.45	4.46

Measurements. Magnetic susceptibilities of the complexes were measured by the Faraday method from liquid nitrogen temperature to room temperature. The Pascal constants[9] were used for diamagnetic correction. The effective magnetic moments were determined by the equation, $\mu_{eff}=2.828\sqrt{(\chi_A-N\alpha)T}$, where the temperature-independent paramagnetism for nickel(II) ion is estimated at 193×10^{-6} e.s.u./mol.[10] The infrared spectra were measured with a Hitachi 215 grating infrared spectrophotometer in the region 4000—650 cm^{-1}. In some cases the hexachlorobutadiene-mull method was applied for the measurements in the region 4000—2000 cm^{-1}. Electronic spectra on solids and in pyridine solutions were obtained with a Hitachi EPS-3T spectrophotometer.

Results and Discussion

Copper(II) Complexes. Some IR bands, ligand field bands (powder and pyridine solution) and effective magnetic moments at room temperature are given in Table 2. The IR bands near 1640 and 1545 cm^{-1} were tentatively assigned to the azomethine and the

Table 2. Properties of $Cu_2(fsac\text{-}R)_2$ complexes

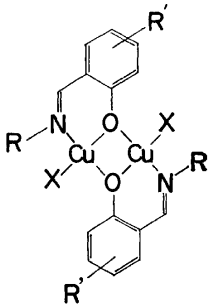
carboxylate groups respectively. The skeletal vibration near 1550 cm^{-1} is useful to distinguish the binuclear structure bridged by phenolic oxygen.[3,11] In the present complexes, however, this band could not be well recognized owing to the strong absorption of the carboxylate group. The reflectance spectra of the complexes show a d-d band in the region 15.4—14.9 kK, that is higher in energy than that (14.1 kK) for bis(3-formylsalicylato)dicopper(II)[2] (which is a $[CuO_4]$-chromophore). The spectral data are consistent with the binuclear structure of the $[CuO_3N]$-chromophore (Fig. 1), since most $[CuO_2N_2]$-chromophores containing bridging oxygen atoms exhibit a ligand field band in the region 15.4—18.5 kK.[12-15] The effective magnetic moments at room temperature are much lower than the spin-only value. From all of these facts, it is concluded that the complexes possess a binuclear structure given in Fig. 1. The oxygen of the hydroxyethyl substituent in $Cu_2(fsac\text{-}enOH)_2$ does not seem to coordinate to the copper(II) ion, since the O–H stretching vibration is found around 3400 cm^{-1}. This fact is in line with Tokii *et al.*'s finding[7] that dichlorobis(*N*-hydroxyethylsalicylaldimino)dicopper(II) has a binuclear structure as shown in Fig. 2 and the hydroxy group in the *N*-substituent is not concerned with coordination.



R=alkyl, aryl
R'=alkyl
X=Cl, Br

Fig. 2.

The ligand field band determined from pyridine solution spectrum of each complex is located to lower energy region than that from the corresponding powder spectrum. Since the shifts, however, are small (0.1—0.3 kK) and no splitting is found in each spectrum, the complexes seem to keep binuclear structure in pyridine, in which no coordination of pyridine to the metal is supposed. When the pyridine solution was concentrated, the pyridine-free complexes were recovered.

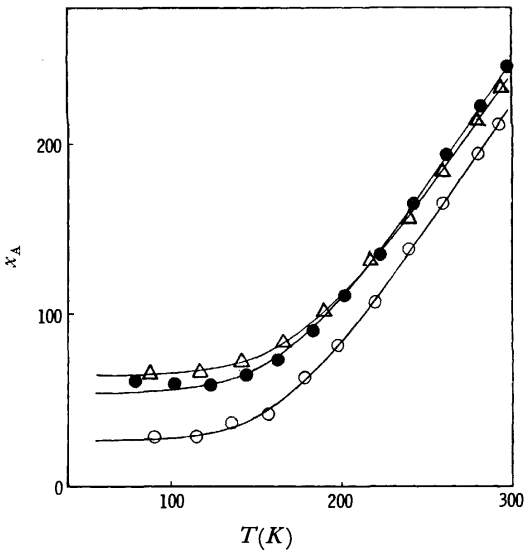


Fig. 3. Variation of molar susceptibility of $Cu_2(fsac\text{—}R)_2$ complexes; (●) R=Me, (○) R=Et, and (△) R=Pr.

The magnetic susceptibilities of the complexes were measured at various temperatures. The results were well interpreted on the basis of the Bleaney-Bowers equation,[16]

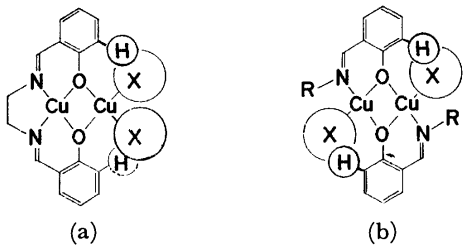
$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha,$$

where J is the exchange integral, k the Boltzmann constant, N the Avogadro number, β the Bohr magneton and g the Lange g-factor. The typical examples are shown in Fig. 3. The magnetic parameters, $-2J$, g and $N\alpha$, determined from the best fit of the data to the Bleaney-Bowers equation are given in Table 3. Judging from the $-2J$ values (which are energy separation between the singlet and triplet states) of the complexes presented here, it does not seem that the substituents attached to the imino-nitrogen exert any appreciable effect upon the spin-exchange interaction.

Table 3. Magnetic parameters of $Cu_2(fsac\text{-}R)_2$ complexes

	$-2J$ (cm^{-1})	g	$N\alpha\times10^6$ (e.s.u./mol)
$Cu_2(fsac\text{-}Me)_2$	720	2.20	55
$Cu_2(fsac\text{-}Et)_2$	715	2.20	27
$Cu_2(fsac\text{-}enOH)_2$	820	2.20	37
$Cu_2(fsac\text{-}Pr)_2$	725	2.20	55
$Cu_2(fsac\text{-}n\text{-}Bt)_2$	705	2.20	35
$Cu_2(fsac\text{-}i\text{-}Bt)_2$	735	2.17	65
$Cu_2(fsac\text{-}s\text{-}Bt)_2$	750	2.20	50

The magnetic properties of dihalogenobis(*N*-alkylsalicylaldimino(dicopper(II) complexes, which are similar to the present complexes, were explored by Kato *et al.*[6,7] and Harris *et al.*[3-5] The $-2J$ values of these complexes are in the range 194—580 cm^{-1}, depending upon the substituents attached to the aromatic ring and the



(a) (b)

Fig. 4.

imino-nitrogen. Therefore, it is evident that our complexes exhibit a very strong antiferromagnetic spin-exchange interaction compared to the dihalogenobis-(*N*-alkylsalicylaldimino)dicopper(II) complexes.

The difference in magnetic properties between the present complexes and dihalogenobis(*N*-alkylsalicylaldimino)dicopper(II) complexes can be explained in terms of the geometries of the complexes. It was demonstrated from X-ray investigation[17] that the coplanarity of two tetragonal planes of the copper(II) ion in dichloro [*N*, *N'*-ethylenebis (salicylaldimino) copper (II)]-copper(II) is considerably distorted owing to the steric repulsions between the chloro group and the hydrogen attached to the 3-position of the salicylaldehyde moiety (Fig. 4a). From the same steric requirement (Fig. 4b), it is also expected that the $\overset{X}{N}\!>\!Cu\!<\!\overset{O}{O}\!>\!Cu\!<\!\overset{N}{X}$ plane in dihalogenobis(*N*-alkylsalicylaldimino)dicopper(II) complexes is distorted. In fact Sinn *et al.*[18] have recently studied the structures of dichlorobis(*N*-methylsalicylaldimino) dicopper (II), dichlorobis (*N*-ethylsalicylaldimino)dicopper(II) and dibromobis(*N*-ethylsalicylaldimino)dicopper(II) and found that the dihedral angles between the planes formed by Cu_2O_2 and $Cu_2N_2Cl_2$ are appreciably large (39.3° for R=methyl and X=chloro, 33.1° for R=ethyl and X=chloro, and 35.7° for R=ethyl and X=bromo). On the other hand, such a steric hindrance is not anticipated for the present complexes, since the carboxyl group attached to 3-position is involved in coordination to the copper(II) ion. Accordingly our complexes seem to have a nearly coplanar structure in regard to the $\overset{N}{O}\!>\!Cu\!<\!\overset{O}{O}\!>\!Cu\!<\!\overset{O}{N}$ plane. In this case the overlapping of $d_\pi(Cu)$-$p_\pi(O)$-$d_\pi(Cu)$ orbitals is sufficiently large, thereby strengthening the spin-exchange interaction. An importance of π-superexchange pathway in spin-exchange interaction for binuclear copper(II) complexes has been reported.[13,19] The present result is in line with the previous findings[20-22] that the more coplanar the tetragonal planes of the copper(II) ions is, the larger the magnetic exchange interaction between the copper-(II) ions becomes.

Nickel(II) Complexes. The nickel(II) complexes forms yellowish green prisms containing two, three or four water molecules. Some IR bands, d-d bands (powder and pyridine solution) and effective magnetic moments at room temperature and near liquid nitrogen temperature are given in Table 4. The IR bands near 1635 and 1565 cm^{-1} may be attributed to the azomethine and the carboxylate groups respectively. The broad band around 3300 cm^{-1} is assigned to the O–H vibration of coordinated water. The reflectance spectra of the complexes show two bands in visible region: 8.7—8.9 and 15.4—15.7 kK. This fact clearly indicates that the nickel(II) ion has a nearly octahedral geometry, although the complexes have only two or three molecules of water except Ni_2(fsac-*n*-Bt)$_2$·$4H_2O$. The solution spectrum of each complex in pyridine shows the first d-d band (which corresponds to 10 Dq) in the region 9.5—9.6 kK, which is higher by 0.7—0.9 kK than that from the corresponding powder spectrum. This fact implies that in pyridine solution the complexes are coordinated with solvents in apical positions.

The magnetic moments at room temperature are comparable to the values for common octahedral nickel-(II) complexes. On the other hand, the values near liquid nitrogen temperature are lower than the spin-only value, 2.83 B.M. These facts imply an antiferromagnetic spin-exchange interaction between nickel-

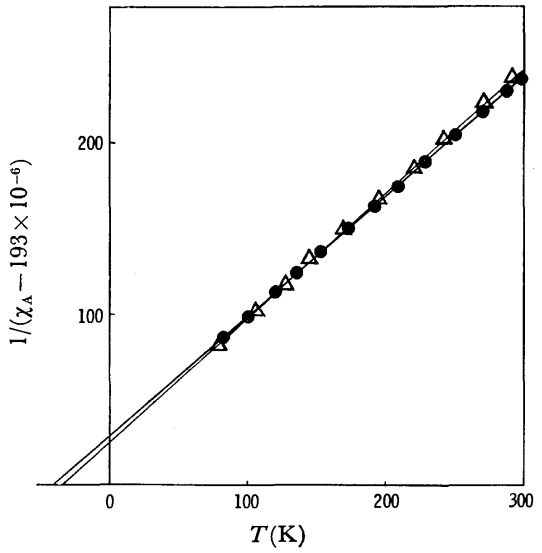


Fig. 5. Plots of inverse susceptibilities of (●) Ni_2(fsac—Et)$_2$·$3H_2O$ and (△) Ni_2(fsac–enOH)$_2$·$2H_2O$ per a nickel atom as a function of temperature.

(II) ions. To elucidate the magnetic behaviors of the complexes, the magnetic susceptibilities were measured as a function of temperature. The results were well interpreted on the basis of the Curie-Weiss law, $\chi_A = C/(T-\theta)$. The representatives of the $1/(\chi_A - 193 \times 10^{-6})$ *versus* T plots are shown in Fig. 5. The Weiss constants obtained are −35 K for R=methyl, −41 K for R=ethyl, −35 K for R=hydroxyethyl, and −40 K for R=*n*-butyl.

There are a few binuclear nickel(II) complexes, in which two nickel(II) ions are connected by the phenolic oxygens.[2,23,24] These complexes show demagnetization by the spin-coupling *via* the phenolic oxygen bridges; the Weiss constants are estimated at −50—−125 °C. In general, the Weiss constants of the mononuclear nickel(II) complexes are small, say a few degrees at best. Therefore, judging from the magnitude of the Weiss constants it may be concluded that the demagnetization in $Ni_2(fsac\text{-}R)_2 \cdot nH_2O$ is caused by the intramolecular spin-exchange interaction through the oxygen bridges.

The authors are grateful to the Ministry of Education for a Scientific Research Grant-in-aid.

Diels-Alder Reactions of 5,5,5-Trichloro-3-penten-2-one and Related Compounds[1]

Sadao Tsuboi, Yasuhiro Ishiguro, and Akira Takeda

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received August 8, 1973)

The Diels-Alder reaction of 5,5,5-trichloro-3-penten-2-one (**1a**) with cyclopentadiene afforded *exo*-2-acetyl-*endo*-3-trichloromethylbicyclo[2.2.1]hept-5-ene (**2a**) stereoselectively. The stereochemistry of the reactions of cyclopentadiene with several γ-chlorinated α,β-unsaturated ketones was examined. The *endo*-directive abilities decreased in the following order: $CCl_3 > CCl_2CH_3$, $CHCl_2$, $CCl(CH_3)_2 > CH(CH_3)_2 > CH_3$. Compound **1a** reacted with butadiene and furan to give 4-acetyl-5-trichloromethylcyclohexene (**3**) and 4-(2-furyl)-5,5,5-trichloropentan-2-one (**7**) respectively.

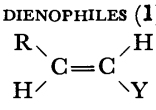
We have recently published several works on the allylic rearrangement of 5,5,5-trichloro-3-penten-2-one (**1a**)[2,3] and on the reaction of **1a** with nucleophiles.[4] To expand the knowledge of its chemical properties, especially its dienophilic reactivity, we have now carried out the reaction of the compound **1a** and related compounds with such dienes as cyclopentadiene, butadiene, and furan.

A great number of examples have manifested a wide applicability of the well-known rule[5] of *endo* addition in the Diels-Alder reaction. However, many examples have also disclosed deviations from the *endo* rule.[6-8] Williamson and Hsu have reported that pentachlorocyclopentadiene with many dienophiles gives bicycloheptene Diels-Alder adducts in which the predominant isomer has the chlorine atom on the bridge *anti* to the double bond.[9] Recently, McBee *et al.* have reported that fluorine substituents dominate the stereochemical course of the Diels-Alder reactions.[10]

Results and Discussion

A list of dienophiles prepared for this study is given in Table 1. The methyl ketone **1d** was prepared by the reaction of triethylphosphonoacetone with 2-chloro-2-methylpropanal in the presence of sodium hydride. Compound **1i** was prepared by the condensation of chloral with 4-methyl-2-pentanone. Other α,β-unsaturated ketones were prepared by the methods described in the literature. All the dienophiles listed here were assigned to the *trans* configuration on the basis of the large coupling constants (J=14—17 Hz) observed of olefin protons and the infrared absorption at *ca.* 970 cm^{-1}.

Table 1. Preparation and properties of dienophiles (**1**)



Compd.	R	Y	Yield %	Bp, °C/mmHg (Mp, °C)	Ref.
1a	CCl_3	$COCH_3$	80	95—100/20	a
1b	$CHCl_2$	$COCH_3$	65	91—92/17	b
1c	CCl_2CH_3	$COCH_3$	52	77—80/6	b
1d	$CCl(CH_3)_2$	$COCH_3$	55	53—55/4	g
1e	$CH(CH_3)_2$	$COCH_3$	13	59—61/25	c
1f	CH_3	$COCH_3$	41	119—125	d

When the trichloromethyl compound **1a** (*trans*) was allowed to react with cyclopentadiene at 90—100 °C for 40 hr, a cycloaddition product (**2a**) was formed in a high yield. The yield was quantitative when the reaction was conducted for 3 day, even at room temperature. The elemental analysis and mass spectral data clearly indicated the formation of the 1 : 1 adduct of **1a** and cyclopentadiene (see Table 3). The infrared spectrum of **2a** showed a strong band at 1724 cm^{-1} due to an isolated carbonyl group and a weak band at 1583 cm^{-1} due to a norbornene ring double bond. In the NMR spectrum of **2a**, which is shown in Fig. 1, the signals at 2.32 ppm (clean singlet, 3H) and at 4.01 ppm (q, 1H, J=3.4 and 5.5 Hz) are attributable to acetyl protons and a C_3-methine proton[11] respectively. The signals of two olefin protons appeared at 6.28 ppm (t, 2H, J=1.3 Hz). It is reasonable to conclude that the adduct **2a** has an *exo*-2-acetyl-*endo*-3-trichloromethyl structure, because signals of olefin protons in *endo*-2-acetylbicyclo[2.2.1]hept-5-ene tend to appear as two multiplets, with the result that the resonance due to the C_6-olefin proton is shifted to a higher field than that of the *exo*-acetyl isomer.[12] The

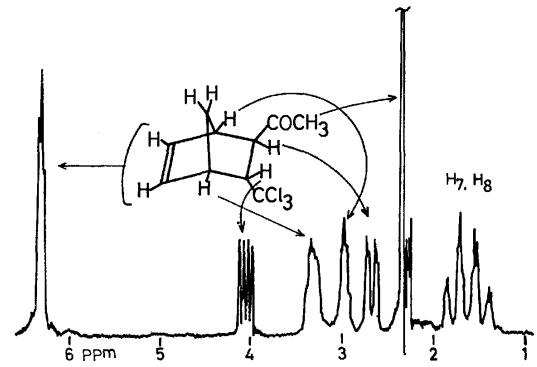

Fig. 1. NMR spectrum of *exo*-2-acetyl-*endo*-3-trichloromethylbicyclo[2.2.1]hept-5-ene (**2a**) in $CDCl_3$.

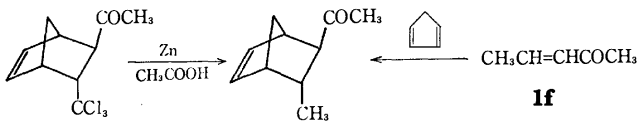
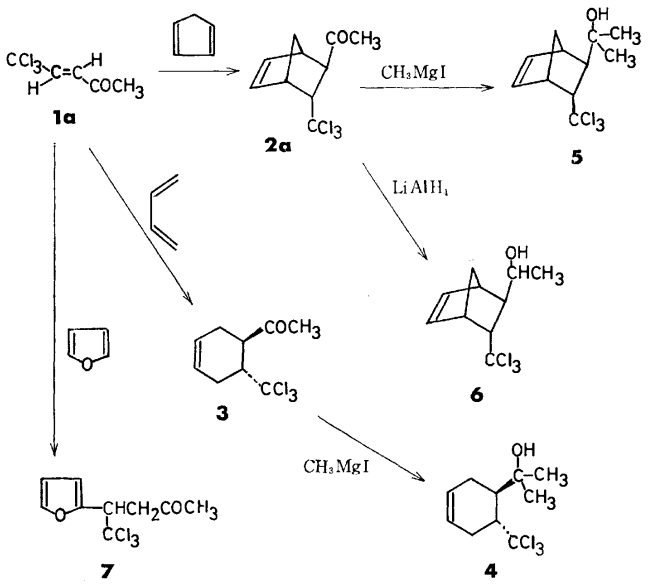
endo structure of **2a** was further substantiated by the fact that it was reduced with zinc in acetic acid, giving *exo*-2-acetyl-*endo*-3-methylbicyclo[2.2.1]hept-5-ene (*endo* **2f**), one of the two isomers derived from the reaction of 3-penten-2-one (**1f**) with cyclopentadiene, whose structure has been unambiguously established. The NMR spectrum ($COCH_3$, 2.20 ppm; CH_3, 0.93 ppm) of the compound **2f** which we obtained was identical with that of the authentic sample of the *endo* **2f** prepared independently by Kobuke's procedure.[8]



2a *endo*-**2f** **1f**

The yields, *endo* percentages, and physical properties of the adducts of cyclopentadiene with ketones listed in Table 1 are summarized in Table 2. Their elemental analyses and the spectral data are tabulated in Table 3. The configurational determination of the Diels-Alder adducts was accomplished by analyzing the NMR spectrum. The NMR spectra of trichloromethyl compounds, **2a**, **2g**, and **2i**, which were free from an *exo* component, showed clear patterns of chemical shifts and coupling constants. Those of other compounds containing both *endo* and *exo* components showed more complicated patterns. The C_3-protons of compounds **2a**, **2c**, **2g**, and **2i** showed a sharp quartet with a small width of the peak at half-height (*ca.* 0.75 Hz),[13] indicating that these protons are in the *exo* configuration. If they were in the *endo* configuration, a long-range coupling between the C_3-proton and the bridge proton would be expected to work over the coplanar W in the order of 1—2 Hz.[9] The signals of the C_2-protons of the adducts **2** usually appeared at 2.5—3 ppm. The methyl protons of the *exo*-acetyl isomers appeared as a singlet at a lower field than those of the *endo*-acetyl isomers.[14] The configurations of compounds **2b**, **2d**, **2e**, and **2f** were determined on the basis of the signals due to acetyl and olefin protons, while that of **2h** was determined by comparing its NMR spectrum with that of **2f**, especially on the basis of the signals due to olefin and methyl protons.

From the data given in Table 2, it is apparent that chlorine substituents exert the principal influence on the stereochemical course of the Diels-Alder reaction.[15] It should be noted as remarkable that the dienophiles **1a**, **1g**, and **1i**, each possessing a trichloromethyl group, afforded *endo* products exclusively. When we compare the *endo* percentages of **2a**, **2g**, and **2i** with each other, and also those of **2f** and **2h** with each other, it is understandable that the group Y is of minor importance in predicting the stereochemical course of the reaction of the dienophiles **1** with cyclopentadiene. Thus, the *endo*-directive abilities of substituents in the Diels-Alder reactions of a series of γ-chlorinated α,β-unsaturated ketones with cyclopentadiene may be regarded as decreasing in this order: $CCl_3 > CCl_2CH_3$, $CHCl_2$,



Scheme 1.

a) *Endo* and *exo* materials from **2f** were separated by glpc and each component was analyzed. NMR spectra were identical with those of authentic samples.[8] b) Compound **2g** was measured by a Nujol method. All the others were measured in neat. c) Measured in $CDCl_3$. d) This compound was too volatile to be analyzed.

$CCl(CH_3)_2$>$CH(CH_3)_2$>CH_3.

Compound **1a** further gave the Diels-Alder adduct **3** with butadiene, as is shown in Scheme 1. The adduct **3** was converted to 4-(1-hydroxy-1-methylethyl)-5-trichloromethylcyclohexene (**4**) in a 50% yield by the action of methylmagnesium iodide. On the other hand, the Grignard reaction of the adduct **2a** afforded 2-(1-hydroxy-1-methylethyl)-3-trichloromethylbicyclo[2.2.1]hept-5-ene (**5**) in only a 5% yield, probably because of the steric restriction of the norbornene skeleton. The reduction of **2a** with lithium aluminum hydride gave the corresponding carbinol **6** in a 38% yield. When the dienophile **1a** was allowed to react with furan, a substitution-addition product **7** was obtained in a low yield.[16] The structural assignments of these compounds were accomplished by the aid of the IR, NMR, and Mass spectra and by elemental analyses (see Experimental).

Experimental

The melting points and boiling points are uncorrected. The elemental analyses were carried out by Mr. Eiichiro Amano. The analytical determinations by glpc were performed on a Hitachi K-53 model gas chromatograph fitted with 10% Apiezon Grease L on Chromosorb W (3 mm o.d.×1 m). The preparative isolations by glpc were performed on 10% Apiezon Grease L on Chromosorb W (3 mm o.d.×2.25 m). The mass spectra were measured on a Hitachi RMS-4 model mass spectrometer with an ionization energy of 70 eV. We are indebted to Mr. Heizan Kawamoto and Miss Hiromi Ootani for the NMR (60 MHz) measurement.

Compounds **1a**, **1b**, and **1g** were prepared by the procedures described in the literature. Compound **1f** was prepared by the method of Claisen[17] by dehydrating 4-hydroxypentan-2-one: bp 119—125 °C; IR (cm^{-1}, liquid) 1675 (C=O) and 1635 (C=C). Ethylideneacetophenone (**1h**) was prepared by the method of Kohler from crotonyl chloride and benzene[18]: bp 140—145 °C/30 mmHg; IR (cm^{-1}, liquid) 1670 (C=O), 1628 (C=C), 1603, 1585 (benzene C=C). Cyclopentadiene was generated from its dimer by a standard procedure[19] just prior to use.

*5-Chloro-5-methyl-3-hexen-2-one (**1d**).* To a mixed solution of 1.9 g (0.04 mol) of sodium hydride (52% in mineral oil) in 40 ml of dry tetrahydrofuran (THF) was added 7.8 g (0.04 mol) of diethylphosphonoacetone at 30—35 °C with stirring. Freshly-distilled 2-chloro-2-methylpropanal (4.3g, 0.04 mol) was then added at 20—25 °C, and the mixture was stirred for 15 min at 45 °C. After 50 ml of water had then been added, the organic layer was extracted with ether. The ethereal layer was washed with water and dried over $MgSO_4$. After the removal of the solvent, the residue was distilled to give 3.1 g (55%) of **1d**: bp 53—55 °C/4 mmHg; IR (cm^{-1}, liquid) 1695 (cisoid C=O), 1670 (transoid C=O), 1625 (C=C); NMR ($CDCl_3$) δ 1.73 (s, 6H, $CCl(CH_3)_2$), 2.28 (s, 3H, $COCH_3$), 6.21 and 6.92 (2d, 2H, J=17 Hz, -CH=CH-).

Found: C, 57.10; H, 7.70. Calcd for $C_7H_{11}ClO$: C, 57.34; H, 7.56.

*6-Methyl-1,1,1-trichloro-2-hepten-4-one (**1i**).* A mixture of chloral hydrate (82 g, 0.5 mol), 4-methyl-2-pentanone (60 g, 0.6 mol), acetic anhydride (50 g, 0.5 mol), glacial acetic acid (30 g, 0.5 mol), and sodium acetate (2.0 g, 0.024 mol) was refluxed for 24 hr. After the removal of the solvent, the residue was dissolved in ether and the ether solution was treated with charcoal. After most of the ether had been removed, the precipitate was collected and recrystallized from ether to give 51.4 g (42%) of 2-hydroxy-6-methyl-1,1,1-trichloroheptan-4-one:[20] mp 86—87 °C; IR (cm^{-1}, nujol) 3400 (OH), 1710 (C=O), 820, 793; NMR ($CDCl_3$) δ 0.97 (d, 6H, J=6 Hz, $-CH(C\underline{H}_3)_2$), 2.23 (m, 1H, $-C\underline{H}(CH_3)_2$), 2.27 (d, 2H, J=12 Hz, $C\underline{H}_2CH(CH_3)_2$), 3.00 (m, 2H, $-CH(OH)C\underline{H}_2-$), 3.60 (broad s, 1H, OH), and 4.69 (dd, 1H, J=4 and 7 Hz, $>C\underline{H}(OH)$).

Found: C, 38.75; H, 5.30. Calcd for $C_8H_{13}Cl_3O_2$: C, 38.82; H, 5.29.

To 320 ml of conc. H_2SO_4 was added 51 g (0.21 mol) of 2-hydroxy-6-methyl-1,1,1-trichloroheptan-4-one at −5—0 °C with stirring. After the mixture had been stirred for 4 hr at room temperature, it was poured onto crashed ice. The organic layer was extracted with ether, and the ethereal layer was washed with water and then dried over $MgSO_4$. After the evaporation of the solvent, the residue was distilled to yield 40.4 g (83%) of **1i**: bp 96—97 °C/6 mmHg; IR (cm^{-1}, liquid) 1705 (cisoid C=O), 1678 (transoid C=O), 1632 (C=C); NMR ($CDCl_3$) δ 0.98 (d, 6H, J=6 Hz, $2CH_3$), 1.80—2.70 (m, 1H, $-C\underline{H}(CH_3)_2$), 2.50 (d, 2H, J=5 Hz, $-C\underline{H}_2CH(CH_3)_2$), 6.51 (d, 1H, J=17 Hz, $-CH=C\underline{H}CO$), 7.01 (d, 1H, J=17 Hz, $CCl_3C\underline{H}=CH-$).

Found: C, 41.85; H, 4.78. Calcd for $C_8H_{11}Cl_3O$: C, 41.87; H, 4.83.

Diels-Alder Additions. Most of the reactions were conducted in autoclaves or ampoules. A solution of two mols of diene and one mol of dienophile in benzene ([c]=*ca.* 10 mol/l) was heated at 90—100 °C for 40 hr,[21] under an atmosphere of nitrogen. After the solvent had then been evaporated, the residue was distilled to give nearly pure Diels-Alder adducts. The crystallized materials were collected and purified by recrystallization from petroleum ether (bp 45—50 °C). If necessary, the microanalyses and spectral measurements were performed on samples collected by glpc or tlc.

exo-*2-Acetyl*-endo-*3-methylbicyclo[2.2.1]hept-5-ene (endo **2f**).* To a solution of 5.1 g (0.02 mol) of **2a** in 10 ml of acetic acid was added, in several portions, 5.2 g (0.08 mol) of zinc powder at 0—5 °C. The mixture was then stirred at 5 °C for 30 min. Zinc chloride and the resinous material were filtered off, and the filtrate was extracted with ether. The ethereal layer was washed with water and dried over $MgSO_4$. The removal of the solvent left 1.9 g of a brown oil which, on distillation, gave 0.7 g of a clean oil: bp 67—69 °C/7 mmHg. The glpc analysis (column temp., 110 °C; carrier gas, N_2, 0.5 kg/cm^2, 40 ml/min) of this oil showed two peaks. The peaks, retention times (min), and peak areas were as follows: 1, 7.3, 57%; 2, 8.0, 43%.

The component 1 collected by preparative glpc was identified as the *endo* **2f** by comparison of the NMR spectrum and retention time with that of the *endo* isomer isolated from the Diels-Alder adducts (see Table 2) of 3-penten-2-one (**1f**) with cyclopentadiene: yield, 13%: IR (cm^{-1}, liquid) 1700 (C=O), 1570 (C=C); NMR ($CDCl_3$)[8] δ 0.93 (d, 3H, J=7 Hz, *endo*-CH_3), 2.20 (s, 3H, *exo*-$COCH_3$), 6.02—6.35 (m, 2H, olefin protons); Mass *m/e* (rel. intensity) 150 (M^+, 20), 135 (M^+-CH_3, 31), 126 (66), 117 (M^+-COCH_3, 26), 107 (71), 105 (56), 92 (56), 91 (79), 85 (100), 79 (75).

The structure of the component 2 collected by preparative glpc was not resolved: IR (cm^{-1}, liquid) 1710, 1635, 1360, 1160, 910, 740; NMR ($CDCl_3$) δ 0.80—1.35 (m, 1H), 2.15 (s, 3H, $COCH_3$), 2.0—3.6 (m, 5H), 4.85—5.22 (m, 2H), 5.68 (s, 2H), 5.52—6.15 (m, 1H); Mass *m/e* (rel. intensity) 150 (2), 135 (10), 117 (38), 93 (56), 92 (100), 91 (86), 79 (58), 77 (60), 66 (58).

4-Acetyl-5-trichloromethylcyclohexene (*3*) was prepared by the Diels-Alder reaction of **1a** with butadiene: yield, 77%; bp 114—117 °C/3 mmHg; IR (cm^{-1}, liquid) 1718 (C=O), 1670 (C=C); NMR ($CDCl_3$) δ 1.88—3.96 (m, 4H, H_3 and H_6), 2.30 (s, 3H, $COCH_3$), 3.17 (q, 1H, $>C\underline{H}COCH_3$), 3.41 (q, 1H, $CHCCl_3$), 5.79 (t, 2H, -CH=CH-); Mass *m/e* (rel. intensity) 240 (0.6, M^+), 204 (4, M^+-HCl), 169 (39), 162 (39), 127 (100), 123 (58), 105 (44), 91 (87), 79 (90).

Found: C, 44.42; H, 4.23. Calcd for $C_9H_{11}Cl_3O$: C, 44.75; H, 4.59.

*4-(1-Hydroxy-1-methylethyl)-5-trichloromethylcyclohexene (**4**).* The ethereal solution of methyl magnesium iodide was prepared from magnesium (0.61 g, 0.025 mol), methyl iodide (4.3 g, 0.030 mol), and ether (20 ml) in the usual manner. To this solution was added a solution of 3.0 g (0.015 mol) of **3** in 20 ml of dry ether at −10—−5 °C. After the complete addition, the mixture was stirred for 30 min at room temperature. It was then acidified with 10% HCl at −5 °C, and the organic layer was extracted with ether. The extract was washed with saturated sodium chloride solution and dried

over $MgSO_4$. The subsequent removal of the solvent gave 2.8 g of a brown oil. The tlc analysis[22] of this oil showed two spots at R_f values of 0.42 and 0.52 in the ratio of 3: 1. The spot of **3** appeared at R_f 0.52. The component with the R_f value of 0.42 separated by preparative tlc was identified as **4**: yield, 50%; IR (cm^{-1}, liquid) 3500 (OH), 1677 (C=C); NMR ($CDCl_3$) δ 1.26 (s, 3H, CH_3), 1.34 (s, 3H, CH_3), 1.68 (s, 1H, OH), 2.20—2.80 (m, 5H, H_3, H_4 and H_6), 3.14—3.40 (m, 1H, >CHCCl$_3$), 5.78 (broad s, 2H, -CH=CH-).

Found: C, 46.43; H, 5.82. Calcd for $C_{10}H_{15}Cl_3O$: C, 46.63; H, 5.87.

2-(1-Hydroxy-1-methylethyl)-3-trichloromethylbicyclo[2, 2, 1]hept-5-ene (5). The adduct **2a** (2.5 g, 0.01 mol) was allowed to react with methyl magnesium iodide (methyl iodide, 0.018 mol; magnesium, 0.015 mol) in ether. When the mixture was treated as usual, 1.98 g of a clean oil was obtained. The tlc analysis[22] of this oil showed two spots at R_f values of 0.37 and 0.51 in the ratio of 1: 4. The spot of **2a** appeared at R_f 0.51. The component with the R_f value of 0.37 was separated by preparative tlc and was identified as **5**: yield 5%; IR (cm^{-1}, liquid) 3530 (OH), 1571 (C=C); NMR ($CDCl_3$) δ 1.12—1.77 (m, 2H, $2H_7$), 1.33 and 1.42 (2s, 6, -C(C$\underline{H}_3$)$_2$), 1.77—2.10 (m, 1H, H_2), 1.87 (s, 1H, OH), 2.90 (m, 1H, H_1), 3.40 (m, 2H, H_3 and H_4), 6.20 (m, 2H, -CH=CH-).

OH

Found: C, 49.28; H, 5.57. Calcd for $C_{11}H_{15}Cl_3O$: C, 49.01; H, 5.56.

2-(1-Hydroxyethyl)-3-trichloromethylbicyclo[2.2.1]hept-5-ene (6). To a mixture of 30 ml of dry ether and 0.75 g (0.02 mol) of lithium aluminum hydride was added dropwise a solution of 10.1 g (0.04 mol) of **2a** in 30 ml of dry ether at reflux temperature. After the complete addition, the mixture was refluxed for a further 30 min. To the mixture was added 10 ml of ice–water, and it was acidified with 10% H_2SO_4. The organic layer was extracted with ether. The extract was washed with water and dried over $MgSO_4$. The subsequent removal of the solvent left a residue which, on distillation, gave 3.8 g (38%) of **6**: bp 124 °C/0.25 mmHg; IR (cm^{-1}, liquid) 3375 (OH), 1572 (C=C); NMR ($CDCl_3$) δ 1.28 and 1.34 (2d, 3H, J=7 Hz, -CH(OH)C$\underline{H}_3$), 1.40—1.60 (m, 2H, $2H_7$), 1.79—1.95 (m, 1H, H_2), 2.01 (s, 1H, OH), 2.82—3.55 (m, 3H, H_1, H_3, and H_4), 3.91—4.73 (m, 1H, >C$\underline{H}$(OH)), 6.23 (m, 2H, -CH=CH-).

Found: C, 47.26; H, 5.26. Calcd for $C_{10}H_{13}Cl_3O$: C, 47.00; H, 5.13.

4-(2-Furyl)-5,5,5-trichloropentan-2-one (7). A mixed solution of **1a** (5.6 g, 0.3 mol) and furan (4.1 g, 0.06 mol) in benzene (20 ml) was heated for 40 hr at 80 °C under an atmosphere of nitrogen. The solvent and excess furan were then removed *in vacuo*; the residue, on distillation, gave 0.9 g (11%) of **7**: bp 111 °C/4 mmHg; IR (cm^{-1}, liquid) 1730 (C=O), 1506 (furan C=C); NMR ($CDCl_4$) δ 2.14 (s, 3H, $COCH_3$), 3.34 (d, 2H, J=7 Hz, $-CH_2-$), 4.49 (t, 1H, J= 7 Hz, >CH), 6.37 (m, 2H, furan H_3 and H_4), 7.37 (m, 1H, furan H_5); MS *m/e* (rel. intensity) 218 (49, M^+-HCl), 183 (40), 162 (10), 149 (37), 141 (27), 137 (11), 81 (10), 43 (100).

Found: C, 42.43; H, 4.02. Calcd for $C_9H_9Cl_3O_2$: C, 42.30; H, 3.55.

The Synthesis of 1,3-Thiazines by the Reaction of Non-isolable β-Imino(dithiocarboxylic) Acids with Aldehydes

Tetsuko MIYAUCHI, Yutaka KADOKURA, Naoaki FUKADA, and Tatsuo TAKESHIMA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba-shi 280

(Received November 5, 1973)

1,3-Thiazines, (**1**)—(**6**), were synthesized, in yields ranging from 2.9 to 43%, by the reaction of aldehyde with the intermediate β-iminodithiocarboxylic acids which are formed by the reaction of ketones with carbon disulfide in the presence of ammonia.

We have previously reported that a series of 1,3-thiazines were synthesized by means of the reaction of 2-iminocyclopentanedithiocarboxylic acid with carbonyl compounds.[1] This method, however, requires an isolated β-iminodithiocarboxylic acid as the starting material, and the preparation of the free acid is possible in only a few limited cases; thus, the scope of this method is restricted. Though there are many *N*-substituted β-iminodithiocarboxylic acids, they do not undergo the present reaction.

Only a few specific ketones, such as cyclopentanones and 4,5-dihydro-3-methyl-1-phenyl-1*H*-pyrazol-5-one, afforded the corresponding β-iminodithiocarboxylic acid when reacted with carbon disulfide in the presence of ammonia.[2-4] Other ketones, such as methyl ethyl ketone, cyclohexanone, cycloheptanone, and cyclooctanone, immediately give 1,3-thiazines, which are considered to be formed from the intermediate β-iminodithiocarboxylic acids by a reaction with the material ketones present.[5] All attempts to isolate the intermediate acids from the reaction products were unsuccessful. An attempt at the synthesis of the iminodithiocarboxylic acids from the corresponding β-ketodithiocarboxylic acids also failed.

The present investigation was undertaken in order to extend the method of preparing the 1,3-thiazines by making use of the supposed intermediate iminodithiocarboxylic acids mentioned above. Thus, a mixture of two kinds of carbonyl compounds, and carbon disulfide were allowed to react in the presence of ammonia to give the cross-reaction products. Cyclohexanone, 4-methylcyclohexanone, cycloheptanone, and cyclooctanone were chosen as the sources of the intermediate. Vanillin and salicylaldehyde were used as the other parts of the reactant because they gave easily crystallizable products. The yields of the present reaction ranged from 2.9 to 43%.

The limitation of the present reaction is that the use of two kinds of carbonyl compounds, both which have α-hydrogen atom, is unfavorable, because four kinds of 1,3-thiazines may be formed including the cross-reaction products.

Scheme

The products which were obtained here were identified on the basis of IR and UV spectra, and elemental analyses (see Experimental section). The spectra were similar to that of 4(1*H*)-thiono-5,6,7,8-tetrahydro-4*H*-3,1-cyclohexathiazine-2-spirocyclohexane.[5]

Experimental

2-(p-Hydroxy-m-methoxyphenyl)-4(1H)-thiono-5,6,7,8-tetrahydro-4H-3,1-cyclohexathiazine (1). A mixture of carbon disulfide (15.2 g, 0.20 mol) and cyclohexanone (1.5 g, 0.015 mol) was added to a solution of vanillin (3 g, 0.02 mol) in 28% aqueous ammonia (140 ml), and then the mixture was shaken at room temperature for 4 hr. The solid product was collected, washed with water, ether and ethanol, and dried (yield, *ca.* 2 g; 43%). Recrystallization from pyridine–ethanol gave yellow crystals; mp 222—224 °C (slow heating) and 240—242 °C (rapid heating). IR (KBr): 3290 (m, s NH), 3080 (m, br OH and aromatic CH), 1600 (m, aromatic C=C), and 1515 (s, br conj. C=C) cm^{-1}. UV: λ_{max}^{EtOH} 234 (log ε 4.19), 280 (3.37), 341 (3.79), 406 (4.26) nm.

Found: C, 58.73; H, 5.55; N, 4.71; S, 20.60%; mol wt (Mass), 307. Calcd for $C_{15}H_{17}NO_2S_2$: C, 58.63; H, 5.58; N, 4.56; S, 20.82%; mol wt, 307.3.

2-(o-Hydroxyphenyl)-4(1H)-thiono-5,6,7,8-tetrahydro-4H-3,1-cyclohexathiazine (2). A mixture of carbon disulfide (5 g, 0.066 mol) and cyclohexanone (3 g, 0.031 mol) was added to a solution of salicylaldehyde (5 g, 0.041 mol) in 28% aqueous ammonia (50 ml), and then the mixture was worked up as has been described for **1**. The crude product was washed with water and acetic acid, and dried (yield, *ca.* 3 g; 35%). Recrystallization from methanol gave orange crystals; mp 222—224 °C (slow heating) and 240—242 °C (rapid heating). IR (KBr): 3290 (s, NH), 3140 (s, br OH and aromatic CH), 1610 (w, NH), 1600 (s, aromatic C=C), 1500 (*vs.* conj. C=C) cm^{-1}. UV: λ_{max}^{EtOH} 275 (log ε 3.42), 343 (3.74), 406 (4.24) nm.

Found: C, 60.63; H, 5.43; N, 5.03; S, 22.99%; mol wt (Mass), 277. Calcd for $C_{14}H_{15}NOS_2$: C, 60.64; H, 5.45; N, 5.05; S, 23.08%; mol wt, 277.3.

2-(p-Hydroxy-m-methoxyphenyl)-6-methyl-4(1H)-thiono-5,6,7,8-tetrahydro-4H-3,1-cyclohexathiazine (3). A mixture of 4-methylcyclohexanone (1 g, 0.009 mol), carbon disulfide (2 g, 0.026 mol), vanillin (1.5 g, 0.01 mol), and 28% aqueous ammonia (15 ml) was shaken at room temperature for 5 hr and then kept overnight in an ice box. The solid product was collected, washed with ethanol, and dried (yield, 0.48 g; 17%). Recrystallization from pyridine–water gave yellow crystals; mp 247—248 °C (in a sealed tube, slow heating) and

263—265 °C (decomp.) (in a sealed tube, rapid heating). IR (KBr): 3270 (s, br NH), 3200 (br, sh OH), 3040 (sh aromatic CH), 1615 (w, NH), 1605 (m, aromatic C=C), 1520 (s, br conj. C=C) cm^{-1}. UV: λ_{max}^{EtOH} 235 (log ε 4.15), 285 (3.29), 338 (3.74), 350 (3.79), 406 (4.26) nm.

Found: C, 59.99; H, 5.98; N, 4.49; S, 19.74%; mol wt (Mass), 321. Calcd for $C_{16}H_{19}NO_2S_2$: C, 59.80; H, 5.96; N, 4.36; S, 19.92%; mol wt, 321.3.

2-(o-Hydroxyphenyl)-6-methyl-4(1H)-thiono-5,6,7,8-tetrahydro-4H-3,1-cyclohexathiazine (4). A mixture of 4-methylcyclohexanone (10 g, 0.089 mol), carbon disulfide (20 g, 0.26 mol), salicylaldehyde (15 g, 0.12 mol), and 28% aqueous ammonia (100 ml) was worked up as has been described for **1.** The reaction mixture was then shaken with some ether and filtered. The filtrate was evaporated under reduced pressure, and to this chloroform was added. The solid product was collected and recrystallized from ethanol to give yellow crystals (yield, 0.75 g; 2.9%); mp 222—223 °C (decomp.) (slow heating) and 238—240 °C (decomp.) (rapid heating). IR (KBr): 3270 (s, NH), 3100 (s, br OH and aromatic CH), 1605 (w, NH), 1595 (s aromatic C=C), 1500 (*vs.* conj. C=C) cm^{-1}. UV: λ_{max}^{EtOH} 343 (log ε 3.78), 405 (4.24) nm.

Found: C, 61.71; H, 5.67; N, 4.94; S, 21.93%; mol wt (Mass), 291. Calcd for $C_{15}H_{17}NOS_2$: C, 61.85; H, 5.88; N, 4.81; S, 21.97%; mol wt, 291.3.

2-(p-Hydroxy-m-methoxyphenyl)-4(1H)-thiono-5,6,7,8-tetrahydro-4H-3,1-cycloheptathiazine (5). A mixture of cycloheptanone (1 g, 0.009 mol), carbon disulfide (2 g, 0.026 mol), vanillin (1.5 g, 0.01 mol), and 28% aqueous ammonia (20 ml) was worked up as has been described for **1.** Recrystallization from pyridine–methanol gave yellow crystals (yield, 0.57 g; 19%); mp 225—226 °C (decomp.) (slow heating) and 241—243 °C (rapid heating). IR (KBr): 3240 (s, NH), 3090 (m, br OH and aromatic CH), 1610 (w, NH), 1595 (s, aromatic C=C), 1510 (s, br conj. C=C) cm^{-1}. UV: λ_{max}^{EtOH} 233 (log ε 4.22), 282 (3.62), 336 (3.77), 404 (4.22) nm.

Found: C, 59.82; H, 5.84; N, 4.67; S, 19.63%; mol wt (Mass), 321. Calcd for $C_{16}H_{19}NO_2S_2$: C, 59.80; H, 5.96; N, 4.36; S, 19.92%; mol wt, 321.3.

2-(p-Hydroxy-m-methoxyphenyl)-4(1H)-thiono-5,6,7,8,9,10-hexahydro-4H-3,1-cyclooctathiazine (6). A mixture of cyclooctanone (1 g, 0.008 mol), carbon disulfide (2.5 g, 0.33 mol), vanillin (1.5 g, 0.01 mol), and 28% aqueous ammonia (20 ml) was worked up as has been described for **1.** The solid product was collected and recrystallized from ethanol–ether (yield, 0.65 g; 26%) and then from acetone–ethanol to give yellow crystals; mp *ca.* 135 °C. IR (KBr): 3270 (s, NH), 3140 (m, sh OH), 3040 (w, aromatic CH), 1600 (m, aromatic C=C), 1510 (*vs.* conj. C=C) cm^{-1}. UV: λ_{max}^{EtOH} 235 (sh) (log ε 4.15), 290 (3.53), 340 (3.77), 412 (4.23) nm.

Found: C, 60.80; H, 6.51; N, 3.90; S, 18.92%; mol wt (Mass), 335. Calcd for $C_{17}H_{21}NO_2S_2$: C, 60.88; H, 6.31; N, 4.18; S, 19.09%; mol wt, 335.4.

The Iodination of Benzene with Iodine in the Thallium(III) Trifluoroacetate-Trifluoroacetic Acid System

Nobuo ISHIKAWA and Akira SEKIYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 20, 1973)

Molecular iodine in the system of thallium(III) trifluoroacetate-trifluoroacetic acid has been found to possess a high potency for aromatic iodination. Under controlled conditions, benzene and also mesitylene were step-by-step mono-, di-, and triiodinated, whereupon whole iodine was consumed for the iodination by the oxidation process of the thallium(III) salt. In the course of the iodination of benzene, an intermediate has been revealed to consist of thalliated benzenes, which were transformed into iodinated benzenes by the electrophilic attack of iodine.

Recently, Taylor *et al.*[1,2] reported a new aromatic iodination process, one which involves thalliation with thallium(III) trifluoroacetate to aryl thallium(III) ditrifluoroacetate, followed by iodination with potassium iodide to aryl iodide. On the other hand, the iodination with molecular iodine in the presence of thallium(III) trifluoroacetate in carbon tetrachloride was additionally described in their experimental section,[2] which attracted our attention for practical purposes. This iodination, however, was not investigated in the mechanistic aspect.

In this paper we will describe our finding that molecular iodine in the system consisting of thallium(III) trifluoroacetate and trifluoroacetic acid possesses a high potency for direct aromatic iodination.

Results and Discussion

A preliminary test for the aromatic iodination with molecular iodine was carried out in order to examine the effect of metal trifluoroacetate on the iodination of benzene. Several metal trifluoroacetates, such as Fe(III),[3] Cu(II),[3] Ag(I), Hg(II), and Tl(III) salts, were prepared, and the iodination was carried out in the presence of these metal salts in a large excess of benzene at its refluxing temperature. The results are summarized in Table 1. As can be seen, Tl(III), Ag(I), and Hg(II) salts showed a considerable effect in the reaction, while the other salts were almost inert. Among these three salts, particularly thallium(III) trifluoroacetate exhibited a noticeable result. The yield in this case was 83% for a two-molar-equivalent formation from a one-molar equivalent of iodine,

Table 1. Effect of metal trifluoroacetates on the iodination of benzene

$$C_6H_6 \xrightarrow[M(CF_3CO_2)_n\text{-}C_6H_6]{I_2^{a)}} C_6H_5I$$

M(n)	Fe(III)	Cu(II)	Ag(I)	Hg(II)	Tl(III)
Yield[b] (%)	trace	trace	48	48	83
Solubility[c] of $M(CF_3CO_2)_n$	p.s.	p.s.	s.	s.	p.s.

a) A mixture of I_2 (2.5 mmol), $M(CF_3CO_2)_n$ (3.75 m mol) and benzene (10 ml) was refluxed for 2.5 hr. b) Yield is based on the formation of 2 mol of iodobenzene from 1 mol of iodine, and determined by glc using nitrobenzene as an internal standard. c) s., soluble; p.s., partly soluble.

Table 2. Solvent effect on the iodination of benzene[a)]

Solvent	Reaction temp. (°C)	Yield[b] (%) of iodobenzene
MeCN	80	13
$CHCl_3$	63	34
CCl_4	76	87
DMF	85	0
Dioxane	85	0
MeOH	65	3
CF_3CO_2H	68	100

a) A mixture of C_6H_6 (5.5 mmol), I_2 (2.5 mmol), and $Tl(CF_3CO_2)_3$ (2.75 mmol) in solvent (8 ml) was heated for 2.5 hr. b) Similar to the b) of Table 1.

suggesting that an oxidation-reduction process is involved.

On the basis of these results, further study was centered on the behavior of thallium(III) trifluoroacetate toward the iodination. Experiments with this thallium salt in various solvents were carried out, generally at the refluxing temperature of the solvents used. The results are summarized in Table 2. As can be seen, trifluoroacetic acid, carbon tetrachloride and benzene showed marked effects on the iodination. The effect of trifluoroacetic acid was most remarkable, affording an almost quantitative yield of iodobenzene even at room temperature (30 °C) in a 15 min reaction period. The formation of thallium(I) salt equivalent to the reacted thallium(III) trifluoroacetate was confirmed as thallium(I) chromate by the quantitative analysis of the reaction mixture. Therefore, the reaction can be represented by the following overall equation:

$$Tl(CF_3CO_2)_3 + I_2 + 2C_6H_6 \longrightarrow Tl(CF_3CO_2) + 2C_6H_5I + 2CF_3CO_2H \quad (1)$$

The effectiveness of the iodination in trifluoroacetic acid in the presence of thallium(III) trifluoroacetate was further realized for the polyiodination of benzene. The di-, tri-, and tetraiodinations of benzene were performed step-by-step with appropriate amounts of iodine and thallium(III) trifluoroacetate, as is shown in Table 3. 1,4-Diiodobenzene, 1,2,4-triiodobenzene, and 1,2,4,5-tetraiodobenzene were obtained in fair yields by this method. Despite the high efficiency of this method for iodination, though, the insolubility of the polyiodobenzenes in the reaction medium appears

Table 3. Iodination of benzene and mesitylene[a)]

Substrate	Molar ratio Sub : I_2 : $Tl(TFA)_3$	Solv.	Temp. (°C)	Time (hr)	Product	Yield (%)

a) A mixture of benzene or mesitylene (3 mmol), I_2 and $Tl(CF_3CO_2)_3$ in solvent (8 ml) was allowed to react. b) Yield is determined by glc using nitrobenzene as an internal standard. c) Yield is based on the product actually isolated.

to resist further penta- or hexa-iodination. The use of carbon tetrachloride instead of trifluoroacetic acid as a solvent failed in the diiodination of benzene. By the same procedure as has been described for benzene, mesitylene was iodinated step-by-step to give mono-, di-, and triiodomesitylene in good yields (Table 3).

In view of the above iodination results, iodine in the system of thallium(III) trifluoroacetate-trifluoroacetic acid has been revealed to be a powerful iodinating agent. The effect of trifluoroacetic acid was recognized from the fact that iodine in thallium(III) acetate-acetic acid did not work even for the monoiodination of benzene.

It is obvious that the overall reaction (1) for the iodination of benzene involves successive iodination with iodine formed through the oxidation of I^- with Tl^{3+} [Eq. (3)] after the initial iodination [Eq. (2)]. The iodine formed in Eq. (3) retraces the same path over again:

$$C_6H_6 + I_2 \xrightarrow{Tl(CF_3CO_2)_3} C_6H_5I + HI \quad (2)$$

$$2HI + Tl(CF_3CO_2)_3 \longrightarrow Tl(CF_3CO_2) + I_2 + 2CF_3CO_2H \quad (3)$$

The formation of less than a half molar equivalent of iodobenzene in the use of silver(I) and mercury(II) trifluoroacetates seems to be due to the inertness of these salts for the oxidation of I^- to iodine.

A problem is how Reaction (2) proceeds mechanistically under these conditions. The aromatic thallation has been reported by Taylor *et al.*[4)] to proceed smoothly in trifluoroacetic acid by the use of thallium(III) trifluoroacetate.

$$C_6H_6 + Tl(CF_3CO_2)_3 \longrightarrow C_6H_5Tl(CF_3CO_2)_2 + CF_3CO_2H \quad (4)$$

The rapidity of this reaction is enough to consider phenyl thallium bis-trifluoroacetate as an intermediate for the iodination. In order to confirm this consideration, phenyl thallium bis-trifluoroacetate was allowed to react with one half and with one molar equivalent of iodine in trifluoroacetic acid under the conditions used for the above-mentioned iodination. The reaction proceeded with sufficient rapidity to give mainly iodobenzene in the former case and mainly 1,4-diiodobenzene in the latter, in yields of 78 and 86% respectively. These reactions can be written as follows:

$$C_6H_5Tl(CF_3CO_2)_2 + \frac{1}{2}I_2 \longrightarrow C_6H_5I + \frac{1}{2}Tl(CF_3CO_2) + \frac{1}{2}Tl(CF_3CO_2)_3 \quad (5)$$

$$C_6H_5Tl(CF_3CO_2)_2 + I_2 \longrightarrow C_6H_4I_2(p\text{-}) + Tl(CF_3CO_2) + CF_3CO_2H \quad (6)$$

A possible pathway of Reaction (5) can be represented by the following equations:

$$C_6H_5Tl(CF_3CO_2)_2 + I_2 \longrightarrow C_6H_5I + TlI(CF_3CO_2)_2 \quad (7)$$

$$TlI(CF_3CO_2)_2 + CF_3CO_2H \longrightarrow Tl(CF_3CO_2)_3 + HI \quad (8)$$

$$HI + \frac{1}{2}Tl(CF_3CO_2)_3 \longrightarrow \frac{1}{2}Tl(CF_3CO_2) + \frac{1}{2}I_2 + CF_3CO_2H \quad (9)$$

The reaction is presumed to be initiated by Eq. (7), which is regarded as an electrophilic substitution attacked by iodine, thus affording iodobenzene. The succeeding stages, (8) and (9), involve oxidation of I^- to iodine by the action of Tl^{3+}. By the summation of Eqs. (7), (8), and (9), an overall Eq. (5) is given. In Reaction (5) it is supposed that the iodobenzene and thallium(III) trifluoroacetate formed react further in an equimolar ratio to form thalliated iodobenzene ($C_6H_5I + Tl(CF_3CO_2)_3 \rightarrow IC_6H_4Tl(CF_3CO_2)_2 + CF_3CO_2H$). Actually, when iodobenzene was refluxed with an equimolar amount of thallium(III) trifluoroacetate in trifluoroacetic acid for 2.5 hr, a loss of about two-thirds the iodobenzene was observed by glc.

This is consistent with the above finding that Reaction (5) gave only a moderate yield of iodobenzene. Also,

Reaction (6) must have proceeded through the *para*-thalliated iodobenzene.

It may be concluded that the iodination of benzene [Eq. (1)] in the system of thallium(III) trifluoroacetate–trifluoroacetic acid proceeds by the pathway of (4), (7), (8), and (9), which are summed up by Eq. (1). It should be emphasized that the iodination reaction described here involves two important stages; one is the electrophilic substitution of phenyl thallium di-trifluoroacetate with iodine, and the other is the oxidation of the resultant iodide anion to iodine with thallium(III) salt. This mechanism is quite different from that of the iodination of aryl thallium di-trifluoroacetate with potassium iodide reported by Taylor *et al.*[2] They speculated that the reaction proceeds *via* aryl thallium diiodide:

$$ArTl(CF_3CO_2)_2 + 2KI \longrightarrow [ArTlI_2] \longrightarrow ArI + 2CF_3CO_2K + TlI.$$

Experimental

Metal Trifluoroacetates. The Tl(III),[2,4] Hg(II),[5] and Ag(I) trifluoroacetates[6] were prepared according to the methods of the literature. The Fe(III) and Cu(II) trifluoroacetates were prepared as follows.

Into a solution of $Fe(CF_3CO_2)_2$, which had been prepared by the addition of iron powder to an aqueous trifluoroacetic acid solution (more than 3 molar equivalents), 30% H_2O_2 was added; the resulting solution of the Fe(III) salt was then concentrated to dryness.

Copper(I) oxide freshly prepared from $CuSO_4 \cdot 5H_2O$ and NaOH was dissolved in aqueous trifluoroacetic acid, and the resulting solution was concentrated to dryness to give $Cu(CF_3CO_2)_2$.

These metal trifluoroacetates were used after having been thoroughly dried over P_2O_5 *in vacuo*.

Iodination Procedure. The iodinations shown in Table 1, Table 2, and Table 3 were carried out as follows.

To the solvent (in Table 1 benzene itself was used) placed in a flask, metal trifluoroacetate and iodine were added. The mixture was immediately refluxed or warmed at the fixed temperature. Ag(I) and Hg(II) trifluoroacetates were easily soluble in benzene, but the other Fe(III), Cu(II) and Tl(III) salts were only partly soluble. In the run with Ag(I) trifluoroacetate, AgI was precipitated as the reaction proceeded (Table 1). In the iodinations in several solvents (Table 2), acetonitrile, DMF, methanol, and trifluoroacetic acid gave a homogeneous reaction solution, but chloroform and carbon tetrachloride were able to dissolve Tl(III) trifluoroacetate to only a limited extent. When 1,4-di-, 1,2,4-tri- or 1,2,4,5-tetraiodobenzene, and mono-, di- or triiodomesitylene were formed (Table 3), these products were deposited during the reaction because of their low solubility. In the polyiodination of benzene in trifluoroacetic acid, a mixture of tri- and tetraiodobenzene made a mass such as was formed in the reaction mixture. Therefore, in these cases the reaction required a longer period. In general, monoiodobenzene was quantitatively analyzed from the reaction mixture by glc, using a column of silicone DC 550 and with nitrobenzene as the internal standard.

All the iodinated benzenes except iodobenzene were isolated by the following procedure. After the evaporation of trifluoroacetic acid from the reaction mixture, the residue (in the case of tri- and tetraiodobenzene) or its benzene solution (in the case of 1,4-diiodobenzene) was washed with 10% nitric acid and then with aqueous sodium bisulfite to remove the metal trifluoroacetate and unreacted iodine. The crystals obtained as 1,4-diiodobenzene by the evaporation of benzene were almost pure, colorless crystals: mp 128 °C (lit,[7] mp 128—129 °C). Its IR spectrum was consistent with that of an authentic specimen. The 1,2,4-tri and 1,2,4,5-tetraiodobenzene were obtained as a mixture, which was separated by alumina-column chromatography. The 1,2,4-triiodobenzene was obtained by elution with *n*-hexane, and then 1,2,4,5-tetraiodobenzene was eluted with benzene. 1,2,4-Triiodobenzene: colorless crystals, mp 91 °C (lit,[7] mp 90—91 °C). 1,2,4,5-Tetraiodobenzene: colorless crystals, mp 250—251 °C (lit,[7] mp 252—253 °C). Their IR spectra were consistent with those of authentic specimens.

The monoiodomesitylene was obtained in the same manner as has been described for 1,4-diiodobenzene. Monoiodomesitylene: colorless crystals, mp 31—32 °C (lit,[8] mp 32—34 °C). Most of the di- and tri-iodomesitylenes were deposited from the reaction mixture; filtration gave almost pure crystals. Diiodomesitylene: colorless crystals mp 80—81 °C (lit,[8] mp 81—82 °C). Triiodomesitylene: colorless crystals, mp 206 °C (lit,[8] mp 206—208 °C).

Reaction of Phenyl Thallium bis-Trifluoroacetate with Iodine in Trifluoroacetic Acid. To a solution of 1.27 g (0.0025 mol) of phenyl thallium bis-trifluoroacetate in 8 ml of trifluoroacetic acid, 0.32 g (0.0012 mol) of iodine was added, after which the mixture was refluxed for 1 hr. The brown color of the iodine disappeared about 10 min after the beginning of refluxing. When the reaction mixture was cooled, crystals came out; these were collected (0.04 g) and identified with 1,4-diiodobenzene. The reaction mixture was carefully concentrated, and after the resulting residue has been washed with 10% nitric acid it was dissolved in benzene. The benzene solution was subjected to glc, using nitrobenzene as the internal standard. The yield of iodobenzene was 78%. Using 0.64 g (0.0025 mol) of iodine, the reaction was carried out in the way described above; 1,4-diiodobenzene was thus obtained in an 86% yield, while the formation of only a trace of monoiodobenzene was detected by glc.

The Oxyphenylation of Cyclic Olefins Conjugated to the Benzene Ring by Means of Palladium Chloride[1]

Hiroshi HORINO, Mannosuke ARAI, and Naoto INOUE
College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received November 28, 1973)

The reaction of 1,2-dihydronaphthalene, indene, and acenaphthylene with phenylpalladium chloride prepared *in situ* from phenylmercuric chloride and lithium chloropalladate in aqueous acetone afforded 2-phenyltetrarol, 2-phenylindanol, and 2-phenylacenaphthenol respectively, accompanying by the corresponding phenylated olefins. Acetoxyphenylation products were also obtained in the reactions in acetic acid. The configurations of these oxyphenylated compounds were determined to be *trans*.

Recently, extensive studies of the arylation of olefins using palladium complexes have been reported.[2-5] Heck reported that the reaction of olefins with the reactive organopalladium compounds prepared *in situ* from organomercurials and palladium salts gave the substituted olefins.[3] The Heck reaction is a representative example of the addition of a reactive carbon-palladium-σ-complex to olefins. In addition, the reaction has the valuable characteristic that the arylation takes place at the carbon atom bonded to the mercury of the organomercurials. When this reaction was applied to the cyclic olefin conjugated to the benzene ring in a protic solvent, a new reaction was found in which an aryl group and an anion part of the solvents were added simultaneously to the olefins.[1]

In spite of many studies of the Heck reaction,[3,4] no report describing such a kind of product has appeared. In this paper, we will report the oxyphenylation of 1,2-dihydronaphthalene, indene, and acenaphthylene in various protic solvents.

Results and Discussion

The reaction of 1,2-dihydronaphthalene (I) with phenylmercuric chloride and lithium chloropalladate in aqueous acetone (1: 1) at room temperature gave an unexpected oxygenated compound, $C_{16}H_{16}O$ (IIIa) (mp 76—77 °C), in a 60% yield, accompanied by 2-phenyl-3,4-dihydronaphthalene (II).[6] The IR spectrum of IIIa showed an absorption band at 3300 cm^{-1} (OH) and 1020 cm^{-1} (C–O), with a characteristic signal of a doublet (1H, J=9 Hz) at 4.65 ppm in its NMR spectrum. The structure of IIIa was confirmed to be *trans*-2-phenyltetrarol by a mixed-melting-point test with an authentic sample.[7] The experiment in a mixture of dioxane and water (1: 1) gave also IIIa in a 52% yield.

In the reaction of I with phenylpalladium chloride in methanol or ethanol, methyl (IIIb) or ethyl ether (IIIc) of 2-phenyltetrarol was obtained in a 45 to 50% yield. However, the yield of isopropyl ether

TABLE 1. RESULTS OF OXYPHENYLATION IN VARIOUS SOLVENTS

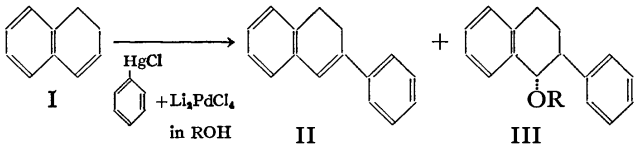
XI	PhHgCl	Acetic acid (Sodium acetate 4 mol.eq.)	XII (28) XIIIb (13)

(IIId) was relatively low and no alkoxy derivative was found in the reaction in *t*-butanol, while the yeild of the substitution product, II, increased with the size of the alkoxy group. The major product of the reaction in acetic acid was II, and the oxyphenylation product, IIIe, was obtained in only a 14% yield.

When the reaction was carried out in the presence of 4 molar equivalents of sodium acetate to palladium chloride, the formation of IIIe was the main reaction.

The structures of these oxyphenylated products were determined by their elemental analyses and by means of their IR and NMR spectra.

These results are shown in Table 1.



a; R=H
b; R=CH_3
c; R=CH_2CH_3
d; R=$CH(CH_3)_2$
e; R=$COCH_3$

trans-2-Phenyltetrarol and its acetate, synthesized according to the method of Hanaya,[7] were identical with the oxyphenylation products, IIIa and IIIe respectively. The treatment of IIIa with sodium hydride and subsequently with methyl iodide afforded IIIb.

The NMR data of the oxyphenylated products are shown in Table 2.

The coupling constants of hydrogen attached to carbinol carbon in the NMR spectra are found in the range of 7 to 9 Hz: this shows that the *trans* configuration is between the phenyl group and the hydroxy one.

In the reaction of I with *p*-cumyl- and *β*-naphthylmercuric chloride in aqueous acetone, the respective corresponding alcohols (V) and (VII) were obtained, accompanied by the arylated olefins, (IV) and (VI).

These structures were proved by their elemental analyses and by the spectral data shown in Table 2.

trans-2-Phenylindanol (Xa) and *trans*-2-phenylacenaphthenol (XIIIa) were obtained by the reaction of indene (VIII) and acenaphthylene (XI) respectively, with phenylpalladium chloride in aqueous acetone. The oxyphenylation products of VIII or XI in an acetic acid solution of sodium acetate were found to be *trans*-2-phenylindanol acetate (Xb) and *trans*-2-phenylacenaphthenol acetate (XIIIb). These structures were confirmed by the following experiments.

The application of hydroboration to 2-phenylindene (IX)[8] and 1-phenylacenaphthylene (XII)[9] gave the corresponding *trans* alcohols, which were identical with the oxyphenylation products, Xa and XIIIa.

These substances were then acetylated to Xb and XIIIb with acetic anhydride and pyridine.

According to the reaction mechanism proposed by Heck,[3] hydrochloric acid and mercuric chloride are produced in the reaction of olefins with phenylmercuric chloride and lithium chloropalladate.

Thus, the catalytic action of these acids might bring about an addition reaction of water to the arylated olefins.

The treatment of II (or IX) with hydrochloric acid

(two molar equivalents of II) or mercuric chloride (equimolecular) in an aqueous acetone mixture (1: 1) resulted in the recovery of II (or IX).

The same results were observed in the case of methanol.

The presence of sodium acetate in the reaction mixture of I or VIII with phenylpalladium chloride caused an increase in the acetoxy- and hydroxyphenylation products at the expense of the arylated olefin, as is shown in Table 1. Therefore, it is clear that the oxyphenylation products were not derived from the arylated olefins.

The function of sodium acetate is probably not only to neutralize hydrochloric acid, but also to raise the nucleophilic attack of acetic acid on the reactive intermediate. Taking into account the fact mentioned above, the same reaction intermediate as that of the Heck reaction may be assumed to give the oxyphenylation product as well as the arylated olefin:

$$ArHgCl + PdCl_2 \longrightarrow ArPdCl + HgCl_2$$

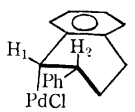
$$ArPdCl + \underset{}{\overset{H}{\diagdown}}C{=}C\underset{}{\overset{}{\diagup}} \longrightarrow$$

$$\longrightarrow \underset{}{\overset{Ar}{\diagdown}}C{=}C\underset{}{\overset{}{\diagup}} + HPdCl \quad \text{(Heck reaction)}$$

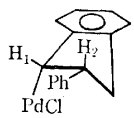
$$Ar\text{-}\overset{H}{\overset{|}{C}}\text{-}\overset{|}{C}\text{-}PdCl \xrightarrow{ROH} Ar\text{-}\overset{H}{\overset{|}{C}}\text{-}\overset{|}{C}\text{-}OR + HPdCl \quad \text{(Oxyphenylation)}$$

Heck suggested a step-by-step and stereospecific reaction mechanism including a *cis*-elimination of the hydridopalladium species.[3]

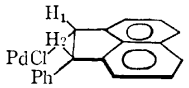
When this reaction mechanism is applied to the cyclic olefins, I, VIII, and XI, the organopalladium intermediates may be represented by the following formulae, (XIVa), (XIVb), and (XIVc) respectively.



XIVa



XIVb



XIVc

The *trans*-configurations of benzylic hydrogen, H_2, and the palladium atom in XIVa, XIVb, and XIVc make the *cis*-elimination of hydridopalladium chloride difficult. Thus, the reaction intermediates with long lives are subjected to nucleophilic replacement by protic solvents. The *trans*-configuration between the phenyl group and the acetoxy, alkoxy, or hydroxy group means that the solvent anion attacks the carbon atom bearing a palladium atom from the back side of the metal. The reaction mechanism proposed above is consistent with the results of the acetoxypalladation studies of cyclohexene by Henry,[10] in which the nucleophilic attack of the acetate ion on palladium occurred from outside the co-ordination sphere in an S_N2 fashion.

In conclusion, the oxyphenylation has presented an useful method for synthesizing *trans*-2-phenylcycloalkanols from benzocycloalkenes. The extension of the reaction to acyclic olefins, *e.g.*, methylstyrenes, is now under investigation.

Experimental

All the melting points are uncorrected. The IR and NMR spectra were measured with a Hitachi 215 grating infrared spectrometer by the KBr disk method, and with Varian A-60D (60 MHz) in carbon tetrachloride, using TMS as the internal standard.

Materials. The following compounds were synthesized by the method described in the literature: phenylmercuric chloride,[11] *p*-cumylmercuric chloride,[3] *β*-naphthylmercuric chloride,[12] and 1,2-dihydronaphthalene.[13] Indene and acenaphthylene of a commercial grade were used.

Reaction of I with Phenylmercuric Chloride and Lithium Chloropalladate in a Mixture of Acetone and Water (1: 1). To a solution of palladium chloride (356 mg, 2 mmol) and lithium chloride (168 mg, 4 mmol) in a mixture of acetone and water (1: 1) (20 ml), I (290 mg, 2.2 mmol) and then phenylmercuric chloride (626 mg, 2 mmol) were added, after which the mixture was stirred for 6 hr at room temperature. The mixture was then added to 100 ml of a saturated solution of sodium chloride, and the resulting oil was extracted with benzene.

The benzene layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure to give a yellow oily residue (430 mg). The residue was chromatographed on silica gel. Elution with *n*-hexane and a mixture of benzene and *n*-hexane (1: 1) gave colorless crystals (II) (51 mg, 13%, mp 58—60 °C) and a yellow oil (IIIa) (269 mg, 60%) respectively. The latter was crystallized from *n*-hexane; mp 76—77 °C. Neither showed any depression in a mixed-melting-point test with 2-phenyl-3,4-dihydronaphthalene[6] and *trans*-2-phenyltetrarol.[7]

In a similar way, the following experiments in various solvents were carried out. The yields and spectrographic data of the oxyphenylation products are shown in Table 1 and Table 2.

In Methanol; *trans*-2-Phenyltetrarol methyl ether IIIb; colorless oil; bp 133—136 °C/1 mmHg.

Found: C, 85.86; H, 7.50%. Calcd for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

In Ethanol; *trans*-2-Phenyltetrarol ethyl ether IIIc; colorless oil; bp 142—144 °C/3 mmHg.

Found: C, 85.16; H, 8.38%. Calcd for $C_{18}H_{20}O$: C, 85.67; H, 7.99%.

In 2-Propanol; *trans*-2-Phenyltetrarol isopropyl ether IIId; colorless crystals; mp 59—60 °C; recrystallized from *n*-hexane.

Found: C, 84.94; H, 8.46%. Calcd for $C_{19}H_{22}O$: C, 85.67; H, 7.99%.

In an Acetic Acid Solution of Sodium Acetate; To an acetic acid solution of palladium chloride (356 mg, 2 mmol) and lithium chloride (168 mg, 4 mmol), I (290 mg, 2.2 mmol), sodium acetate (656 mg, 8 mmol), and phenylmercuric chloride (626 mg, 2 mmol) were added successively. The mixture was then stirred for 7 hr at room temperature, and the reaction mixture was treated as has been described above.

trans-2-Phenyltetrarol acetate IIIe: colorless crystals; recrystallized from ethanol; mp 113—114 °C.

Found: C, 81.15; H, 6.83%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

This substance showed no depression in a mixed-melting-point with an authentic sample.[7]

The following procedure was carried out in the same way as in the reaction of I with phenylmercuric chloride and lithium

chloropalladate except for the use of *p*-cumylmercuric chloride and *β*-naphthylmercuric chloride instead of phenylmercuric chloride.

Reaction of I with p-*Cumylmercuric Chloride and Lithium Chloropalladate in a Mixture of Acetone and Water (1: 1).* 2-Isopropylphenyl-3,4-dihydronaphthalene IV; mp 68 °C.

Found: C, 92.26; H, 7.74%. Calcd for $C_{19}H_{20}$: C, 91.88; H, 8.12%.

trans-2-Isopropylphenyltetrarol V; mp 116 °C.

Found: C, 85.70; H, 8.64%. Calcd for $C_{19}H_{22}O$: C, 85.67; H, 8.33%.

Reaction of I with β-Naphthylmercuric Chloride and Lithium Chloropalladate in a Mixture of Dioxane and Water (1: 1). 2-*β*-Naphthyl-3,4-dihydronaphthalene VI; mp 150—151 °C; recrystallized from ethanol.

Found: C, 93.71; H, 6.29%. Calcd for $C_{20}H_{16}$: C, 93.67; H, 6.34%.

trans-2-*β*-Naphthyltetrarol VII; mp 118—119 °C: recrystallized from *n*-hexane.

Found: C, 87.46; H, 6.73%. Calcd for $C_{20}H_{18}O$: C, 87.56; H, 6.61%.

Analogous procedures were undertaken in the reaction of indene VIII with phenylmercuric chloride and lithium chloropalladate in a mixture of acetone and water (1: 1) and also in an acetic acid solution of sodium acetate.

2-Phenylindene IX;[9] mp 164—165 °C; recrystallized from benzene.

Found: C, 94.01; H, 6.44%. Calcd for $C_{15}H_{12}$: C, 93.71; H, 6.29%.

trans-2-Phenylindanol Xa; mp 82—83 °C; recrystallized from *n*-hexane.

Found: C, 85.49; H, 6.55%. Calcd for $C_{15}H_{14}O$: C, 85.68, H, 6.71%.

trans-2-Phenylindanol acetate Xb; bp 163—165 °C/1 mmHg;

Found: C, 80.00; H, 6.31%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.83%.

Reaction of Acenaphthylene (XI) with Phenylmercuric Chloride and Lithium Chloropalladate in a Mixture of Acetone and Water (1: 1). In a similar manner, the reaction of XI (457 mg 3.3 mmol) with phenylmercuric chloride (940 mg, 3 mmol) in a solution of lithium chloropalladate (130 mg, 3 mmol) was carried out to give yellow crystals (XIIIa) (354 mg, mp 97—98 °C) which were later recrystallized from a mixture of benzene and *n*-hexane. The crystals were found to be identical with the *trans*-2-phenylacenaphthenol synthesized as will be described below by a comparison of their IR spectra and by a mixed-melting-point test.

Synthesis of trans-*2-Phenylacenaphthenol from 1-Phenylacenaphthylene.* 1-Phenylacenaphthylene (684 mg) was dissolved in a solution of sodium borohydride (324 mg) in dried tetrahydrofuran (30 ml).

To the solution boron trifluoride etherate (1.2 ml) was added, drop by drop, at 23 °C for 20 min. After the reaction mixture had then been stirred for 1 hr, water (1 ml) was added to decompose the excess diborane. To the solution was added 3 M sodium hydroxide (1.5 ml) and then 30% hydrogen peroxide (1.5 ml), drop by drop, at 40 °C. After the solution had been stirred for 1 hr, it was poured into water and extracted with ether. The ether extract was concentrated, and the residual paste (820 mg) was chromatographed on a silica gel column. Elution with benzene gave *trans*-2-phenylacenaphthenol as colorless crystals (298 mg); mp 99—100 °C; recrystallized from a mixture of benzene and *n*-hexane.

Found: C, 87.43; H, 5.74%. Calcd for $C_{18}H_{14}O$; C, 87.77; H, 5.73%.

Besides, elution with a mixture of benzene and *n*-hexane (1: 10) gave a recovery of 1-phenylacenaphthylene (XII) (338 mg).

The authors wish to express their thanks to the Kawaken Fine Chemical Co., Ltd., for its gift of palladium chloride.

Pyridoxal Model Compounds. I. The Regioselective Formylation of Methoxy-substituted Aromatic Compounds[1]

Masaaki IWATA and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received December 8, 1973)

9-Substituted 2-methoxyanthracenes (IVa—d) and -triptycenes (Va, b), and 3-substituted anisoles (VIa, b) were formylated by the use of the Vilsmeier-Haack method (Method A) and the metallation method using *n*-butyllithium (Method B). By the Method A, IVa—c, Vs', and VIs' were regioselectively formylated at C-1, C-3, and C-6 respectively, without exception, while by the Method B IVa—c, Va, VIa, and VIb were regioselectively formylated at C-3, C-3, C-2, and C-6 respectively, and Vb gave C-1 and C-3 formylated derivatives in the ratio of 10 to 1 respectively. Possible transition states concerning the occurrence of the regioselectivity were proposed and discussed.

Pyridoxal catalyzes many reactions of amino acids,[2] and the study of the reaction mechanism has shown that the *ortho*-positioning of the formyl and the hydroxy groups on the pyridine ring is essential to the activity.[3] In practice, it has been demonstrated that salicylaldehyde derivatives with a similar interrelation of these two functional groups to pyridoxal indicate a pyridoxal-like activity for amino acids.[4] On the basis of this advanced knowledge, we designed synthetic schemes to obtain new model compounds of pyridoxal functioning, as expected, as an "asymmetric inversion catalyst".[5] In the present paper we wish to report the first example of the regioselective formylation at *ortho*-positions of these methoxy-substituted aromatic compounds: 9-substituted 2-methoxyanthracenes (IVa—c), 9-substituted 2-methoxytriptycenes (Va, b), and 3-substituted anisoles (VIa, b).

Since, to our knowledge, there is a dearth of systematical investigations concerning the regioselective introduction of a formyl group into methoxy-substituted aromatic compounds, our interest was focused on the elucidation of the reactivity of these compounds for Vilsmeier-Haack reagents and *n*-butyllithium.

Results and Discussion

Synthesis of Starting Materials. The 2-methoxyanthracenes (IVa—d) were prepared in four steps from the reaction of phthalic anhydride with anisole. The reduction of *o*-(*p*-methoxybenzoyl)benzoic acid (I) with zinc–ammonia gave *o*-(*p*-methoxybenzyl)benzoic acid (II) quantitatively. In this step, the Clemmensen reduction (zinc–hydrochloric acid) of (I) yielded II and 3-(*p*-methoxyphenyl)phthalide (IIa) in a ratio of about 2 to 1 respectively.[6] The Wolff-Kishner reduction (hydrazine–*n*-butanol–potassium hydroxide) of (I) afforded only 3-(*p*-methoxyphenyl)-6-oxo-1H-phthalazine (IIb). The dehydrative cyclization of II with concd. sulfuric acid gave 2-methoxy-9-anthrone (III) in a good yield; it was then treated with the corresponding Grignard reagents to give IVa—c. To exemplify and compare the results with those of the literature,[7] 2-methoxyanthracene (IVd) was prepared by the reduction of III with sodium borohydride. 2-Methoxytriptycenes (Va, b) were synthesized by the addition of IVa and IVd respectively to benzyne.

VIa R=$-OCH_3$
VIb R=*tert*-C_4H_9

Regioselective Formylation. Formylation was carried out by the use of two methods: the Vilsmeier-Haack method (Method A)[8] and the metallation method using *n*-butyllithium–*N*-methylformanilide (Method B).[9] The results obtained are shown in Table 1.

Table 1. The regioselective formylation of methoxy-substituted aromatic compounds. Yields and the formylated positions

Compound	Method A		Method B	
	Formylated position	Yield(%)	Formylated position	Yield(%)
IVa	1	98	3	71
IVb	1	50	3	64
IVc	1	48	3	63
IVd[a]	1, 3	40, 23[b]	—	—
Va	3	79	3	58
Vb	3	82	1, 3	41, 4[c]
VIa	6[d]	62[d]	2[e]	75[e]
VIb	6	95	6	17

a) In the lit.[7] 1 and 3 formylated products have been obtained in almost equal amounts in about 70% total yield. b) 40% for 1 and 23% for 3. c) 41% for 1 and 4% for 3. d) By use of dimethylformamide and phosphorus oxychloride,[10] the same C-6 formylated product has been regioselectively obtained in 85% yield. e) By metallation with phenyllithium and subsequent formylation with *N*-methylformanilide in abs. ether at r.t.,[11] the same C-2 formylated product has been regioselectively obtained in 55% yield.

The data listed in Table 1 indicate (a) that the formylation according to Method A is strictly regioselective for all types of compounds and that the formylated position is independent of the substituent group in each case and (b) that the formylation according to Method B is less selective and that the regioselectivity is dependent on the substituent group except for the case of anthracenes.

The Determination of the Structures of Formylated Compounds. The structures of the formylated compounds were determined by the use of IR, UV, NMR, and elemental analyses. The lanthanide-induced NMR spectra were especially effective for the determination of the introduced position of the formyl group.

The NMR Spectral Data. The lanthanide-induced spectra with the aid of tris(dipivalomethanato)europium(III), $Eu(DPM)_3$, were measured for all the formylated anthracenes and triptycenes. From the spectra, the following findings were obtained: (a) the metal ion of the shift reagent associated more tightly with the aldehyde oxygen atom than with the methoxy group: (b) the formyl proton of the C-3 position experiences greater shift than that of the C-1 position by about 10 factors, and (c) the effect of the interaction between the shift reagent and the neighboring protons of the formyl group is transferred more effectively through the bond than the space. Detailed analyses of the induced spectra are in progress; the results will be published in the forthcoming paper.

On the basis of these findings the chemical shifts and the coupling constants of the main protons of the formylated compounds in the original NMR spectra were assigned as is shown in Tables 2 and 3. In the C-1 formylated 9-arylanthracenes, the aldehydic protons appears in a higher field than that of the other aldehydic protons by *ca.* 1.3 ppm (Table 2). The shift may be due to the anisotropic effect of the ring current of the peri-aryl substituent and to the steric effect of the peri-substituent affecting the non-coplanarity of the formyl group and the aromatic ring. The C-1 aromatic proton of the C-3 formylated anthracenes may experience a similar ring current anisotropy of the 9-aryl group and reveals a chemical shift at a higher field. In the NMR data of triptycenes (Table 3), the formyl protons showed the normal chemical shifts. However, in the C-1 formylated triptycene the C-9 methine proton was deshielded by the anisotropic effect of the adjacent formyl group and showed a chemical shift at a field lower by 1.97 ppm than that of the C-3 formylated triptycene. In Table 4, the chemical shifts and the coupling constants of the formylated anisoles are collected. One of the aromatic protons at the *meta*-position of the formyl group showed spin-spin coupling with the formyl proton when one of the *ortho*-positions of the formyl group was not substituted.[12]

The UV Spectral Data. The structural features of the formylated compounds were well reflected on the UV spectra. The UV spectral data of some of the anthracene derivatives are summarized in Table 5. In the table the original ^1B_b band, the longitudinally-polarized transition, at 255—259 nm splits into two electronic transitions of nearly equal intensities when the C-3 position is formylated. One appears on the shorter-wavelength side, and the other, on the side longer than the original band. The spacings of these bands are almost constant; in the C-3 formylated compound of IVd, 266.5—244.2=22.3 nm, and in that of IVa, 277—256=21 nm. Therefore, it is apparent that these two ^1B_b bands are due to the longitudinal polarization in the directions of both the methoxy and the formyl groups. The vibrational structures of the transversely-polarized ^1L_a bands on the side with wave-

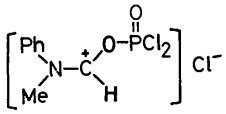
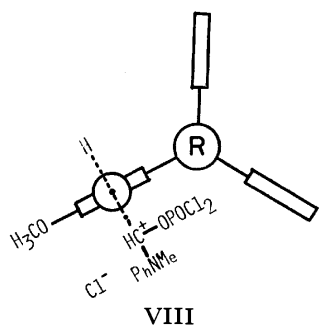
lengths longer than 314 nm disappeared when the C-1 or C-3 positions of IVd and the C-3 position of IVa were formylated. However, in the C-1 formylated derivative of IVa the vibrational characteristics remained considerably clear, although the bands showed slightly bathochromic shifts. This may be assumed to be due to the non-coplanarity of the formyl group and the anthracene ring affected by the steric overlap of the formyl group with the aryl group at the peri-position and the methoxy group at C-2; this reliable assumption coincides with the results of the analysis of the NMR spectral data.

Possible Transition States of Formylation. By many authors[13] since Vilsmeier,[8] several reaction mechanisms have been proposed for the Vilsmeier-Haack reaction. Of these proposals, it seems most reasonable to adopt the mechanism suggested by Bosshard and Zollinger,[14] where the following reactive intermediate (VII) of the formylating reagents attacks the most electron-rich



VII

position of the substrate molecule. However, it should be noted that VII is bulky around the positive charge and that, thus, VII would select the reaction point of the substrate with respect not only to the electronic density but also to the steric environment if there is not much difference in electronic density. Practically, from the results shown in Table 1, it seems clear that, in methoxyanthracenes (IVa—d), the regioselectivity of formylation by Method A is due only to the difference in electronic density,[15] and that in methoxytriptycenes (Va, b) and methoxybenzenes (VIa, b) the steric factors govern the reaction predominantly. Typically, for example, in methoxytriptycenes involving a C_s point group the transition state of formylation attacking the C-1 position could be shown by a tetrahedral intermediate like VIII. In this model it is apparent that the attack of the formylating active species (VII) on the C-1 position may be prevented because of the steric interaction of VII with the bridged benzene rings and the C-9 substituent. Therefore, the C-3 position will be regioselectively formylated in methoxytriptycenes. In a similar manner, it may be



VIII

Fig. 1. A transition state model of formylation of methoxytriptycenes. VIII is projected from the front side of the R-axis and C-9 carbon is on the plane. The rectangle shows the hydrogen-abbreviated benzene ring.

suggested that the results of formylation in anisoles can be explained by the steric interaction of VII and the substituent, and that the C-6 position is regioselectively formylated.

In formylation by the metallation method (Method B), it was empirically observed that no types of aromatic compounds were formylated by the addition of *N*-methylformanilide without the formation of the dark green or blue colored complex of the substrate with *n*-butyllithium. Thus, the driving force of formylation by Method B seems to be the formation of the lithium complex, doubtless a radical anion. Although, unfortunately, the reactivity of the radical anions is not yet known in detail,[16] the results found by Method B may be explained on the basis of the following assumptions: (a) the electronic distribution of the substrate is quite different from that of the substrate-lithium complex, and (b) the unstable lithium complex and the transition state of formylation have nearly the same energy content, and thus their interconversion will involve only a small reorganization of the molecular structure, in agreement with the Hammond's postulation.[17] In methoxyanthracenes the fact that the C-3 position is regioselectively formylated without exception may be understood on the basis of the (a) assumption; that is, the C-3 position may be nucleophilically more active than the C-1 position in the complex state. The experimental results that the dependency of formylation on the substituents was shown in triptycenes and anisoles seem to give evidence of the least gap of the energy content being between two reactive positions in the complex, as is indicated in the cases of Vb and VIa. Also, the results in Va and VIb seem alternatively to demonstrate that the substituent effects on formylation may be due to mainly the steric effect. Therefore, it could be concluded that, in the case of Method A, the reaction selectivity may be determined by the steric interaction of the formylating reagents with the substrate in the transition state and the electronic density, while in Method B the perturbation of the electronic distribution of the substrate in the complex state may cause the regioselectivity of the formylated positions.

Experimental

The instruments for spectral measurements were a Shimadzu IR-27 (IR) apparatus, a Hitachi 124 spectrophotometer (UV), and a Varian HA-100D (NMR) apparatus. Merck Art. 7734 was used for the preparative separation of products on a silica gel column by elution chromatography, and Wakogel B-5 UA, for thin-layer chromatography. The *m*-methoxyanisole (VIa) was commercially available, and the *m-tert*-butylanisole (VIb) was obtained by the methylation of the corresponding phenol (commercially available) with dimethyl sulfate in a good yield. The melting points are uncorrected.

o-(p-Methoxybenzoyl)benzoic Acid (I). To a mixture of phthalic anhydride (148 g, 1 mol) and anisole (250 ml) in 250 ml of carbon disulfide we added 140 g of aluminium chloride under vigorous stirring at room temperature. After all the anhydride disappeared to form a viscous dark red solution, the solution was hydrolyzed with ice water, and the solvents were removed by steam distillation. From the cooled residual solution, a grey solid was precipitated. After most of the supernatant solution had been decanted, *ca.* 1000 ml of chloroform was poured into the flask to dissolve the solid and the organic layer was separated. The solvent was then evaporated to give almost pure (I) (204—250 g; 80—97%). For analytical use, a part of the solid was recrystallized from acetic acid; colorless plates; mp 122—123.5 °C. Found: C, 70.30; H, 4.65%. Calcd for $C_{15}H_{12}O_4$: C, 70.30; H, 4.72%. IR (KBr disk): ν_{max} 1664 (–CO–) and 1689 (–COOH) cm^{-1}.

o-(p-Methoxybenzyl)benzoic Acid (II). In a three-necked flask, 64 g (0.25 mol) of (I), 600 ml of 20% ammonia, and 60 ml of 20% ammonia containing 5 g of cupric sulfate were successively added, after which the mixture was heated until gentle reflux. Then 150 g of zinc powder was added in limited amounts. After having been stirred at 95—100 °C for 24 hr, the mixture was cooled and filtered to give a transparent solution which was acidified by the addition of *ca.* 1500 ml of 10% hydrochloric acid. The white precipitate was collected and dried to give II (50.6—57.6 g; 84—95%). For analytical use, a part of the solid was recrystallized from 50% aqueous ethanol; colorless fine crystals; mp 117—118 °C. Found: C, 74.29; H, 5.75%. Calcd for $C_{15}H_{14}O_3$: C, 74.36; H, 5.83%. IR (KBr disk): ν_{max} 1680 (–COOH) and 1250 (=C–O–C) cm^{-1}.

2-Methoxy-9-anthrone (III). Fine powdered II (57.6 g, 0.238 mol) was dissolved in 250 ml of ice-cold concd. sulfuric acid, after which the mixture was stirred at 0—5 °C for 2 hr. Then the solution was poured into *ca.* 2000 ml of ice water to give III (35.8 g; 67%) as a yellow solid. The solid was purified by elution chromatography with THF; fine yellow needles; mp 96—97.5 °C. IR (KBr disk): ν_{max} 1648 (–CO–) and 1296 (=C–O–C) cm^{-1}. The purified III was used for the subsequent reactions.

Synthesis of 9-Substituted 2-Methoxyanthracenes by the Grignard Reaction. General Procedure. The compounds from IVa—IVc were synthesized by the following procedure. Into 0.02 mol of turnings-magnesium in 30 ml of dry THF, 0.02 mol of the corresponding aryl or alkyl bromide was vigorously stirred under a nitrogen atmosphere at room temperature. To the resulting Grignard reagent 0.01 mol of III in 20 ml of THF was added drop by drop at the temperature of ice water. After the completion of the reaction, followed by tlc, the reaction mixture was hydrolyzed with ice water containing ammonium chloride, acidified with *ca.* 6M HCl, and stirred until all the corresponding 9-substituted 2-methoxy-9-anthranol had been dehydrated to the corresponding 9-substituted 2-methoxyanthracene. The mixture was extracted with ethyl acetate, and the organic layer was separated and dried with anhydrous Na_2SO_4. After the removal of the solvents under reduced pressure, the residue was chromatographed on a silica gel column with benzene to give the corresponding pure 9-substituted 2-methoxyanthracenes.

9-(2-p-Cymenyl)-2-methoxyanthracene (IVa). Obtained in a 76% yield; a yellow green viscous liquid. Found: C, 88.09; H, 7.10%. Calcd for $C_{25}H_{24}O$: C, 88.19; H, 7.11%. NMR (CCl_4): δ 1.27 (6H, d, J=7.0 Hz, $-CH(C\underline{H}_3)_2$), 1.83 (3H, s, $Ar-C\underline{H}_3$), 3.86 (1H, qui, J=7.0 Hz, $-C\underline{H}(CH_3)_2$), 7.03 (1H, quar, J=2.7, 9.0 Hz, C_3–H), and 7.82 (1H, d, J=9.0 Hz, C_4–H) ppm. IR (neat): ν_{max} 1632, 1468, 1268, 1230, and 1210 cm^{-1}. UV data are shown in Table 5.

9-Phenyl-2-methoxyanthracene (IVb). Yield, 96%; pale yellow plates; mp 100—102 °C. Found: C, 88.71; H, 5.62%. Calcd for $C_{21}H_{16}O$: C, 88.70; H, 5.67%. NMR (CCl_4): δ 3.63 (3H, s, $-OCH_3$), 6.71 (1H, d, J=2.7 Hz, C_1–H), 7.04 (1H, quar, J=2.7, 9.0 Hz, C_3–H), 7.80 (1H, d, J=9.0 Hz, C_4–H), and 8.27 (1H, s, C_{10}–H) ppm. UV (ethanol): λ_{max} (log ε) 258.2 (5.10), 318 (3.41), 333.8 (3.67), 351.5 (3.78), 376.5 (3.76), and 396 (3.76) nm. IR (KBr disk): ν_{max} 1628 and 1225 cm^{-1}.

9-Methyl-2-methoxyanthracene (IVc). Yield, in 64%; light yellow needles; mp 147—149 °C. Found: C, 86.25; H, 6.18%. Calcd for $C_{16}H_{14}O$: C, 86.45; H, 6.35%. NMR (CCl_4): δ 2.97 (3H, s, Ar–CH_3), 3.95 (3H, s, –OCH_3), 7.70 (1H, quar, J=2.7, 9.0 Hz, C_3–H), 7.79 (1H, d, J=9.0 Hz, C_4–H), 7.26 (1H, d, J=2.7 Hz, C_1–H), and 8.13 (1H, s, C_{10}–H) ppm. UV (ethanol): λ_{max} (log ε) 259 (5.16), 319 (3.36), 334 (3.61), 352 (3.71), 377 (3.72), and 397 (3.71) nm. IR (KBr disk): ν_{max} 1630, 1469, 1213, and 735 cm^{-1}.

2-Methoxyanthracene (IVd). III (1.5 g, 0.067 mol) was reduced with 0.265 g (0.07 mol) of sodium borohydride in ethanol and hydrolyzed with ice water containing methanol and *ca.* 6 M HCl. The precipitate was collected by filtration, and the solid was dehydrated in benzene by then addition of concd. sulfuric acid with vigorous stirring overnight. The supernatant solution was then separated, and the solvent was removed under reduced pressure. The residue was chromatographed on a silica gel column with benzene to give IVd (1.20 g, 86%) as a pale yellow solid; mp 163—165 °C. Found: C, 86.66; H, 5.85%. Calcd for $C_{15}H_{12}O$: C, 86.51; H, 5.81%. NMR ($CDCl_3$): δ 3.76 (3H, s, –OCH_3), 7.04 (1H, quar, J=2.4, 9.0 Hz, C_3–H), 7.85 (1H, d, J=9.0 Hz, C_4–H), 8.21 (1H, s, C_9–H), and 8.29 (1H, s, C_{10}–H) ppm. IR (KBr disk): ν_{max} 1640, 1465, 1214 (=C–O–C), and 875 $cm.^{-1}$ The UV data are shown in Table 5.

Synthesis of 9-(2-p-Cymenyl)-2-methoxytriptycene (Va) and 2-Methoxytriptycene (Vb). The preparation of benzyne and its addition to anthracenes were carried out by the same method as has been described previously.[18] Then the products were isolated by elution-column chromatography with cyclohexane–benzene (1 : 9 v/v). Va was obtained in a 27% yield as a yellow viscous liquid. Found: C, 89.39; H, 7.04%. Calcd for $C_{31}H_{28}O$: C, 89.38; H, 6.78%. UV (cyclohexane): λ_{max} (log ε): 226 (4.42), 244 (s) (4.01), 255 (s) (3.74), 261 (3.60), 269.5 (3.57), 277 (3.60) and 289.5 (3.49) nm. IR (neat): ν_{max} 1460, 1280, and 1230 $cm.^{-1}$ NMR (CCl_4): δ 1.39 (6H, d, J=7.5 Hz, –$CH(CH_3)_2$), 1.77 (3H, s, Ar–CH_3), 3.59 (3H, s, –OCH_3), 5.19 (1H, s, C_{10}–H), 6.36 (1H, quar, J=2.5, 8.0 Hz, C_3–H), and 7.17 (1H, d, J=8.0 Hz, C_4–H) ppm. Vb was obtained in a 33% yield as pale yellow crystals from petroleum ether; mp 173—174 °C. Found: C, 88.75; H, 5.50%. Calcd for $C_{21}H_{16}O$: C, 88.70; H, 5.67%. UV (cyclohexane): λ_{max} (log ε) 224.5 (4.19), 273 (3.62), 280 (3.75), and 291 (3.62) nm. NMR (CCl_4): δ 3.65 (3H, s, –OCH_3), 5.23 (2H, s, C_9–H and C_{10}–H), 7.12 (1H, d, J=2.0 Hz, C_1–H), 6.37 (1H, quar, J=2.0, 8.0 Hz, C_3–H) ppm.

General Procedure of Formylation. The formylation of the compounds from IV to VI was carried out by two kinds of procedure. One was the Vilsmeier-Haack method using *N*-methylformanilide (MFA) and phosphorus oxychloride (Method A); the other was the metallation method using *n*-butyllithium and MFA (Method B).

Method. A. To a solution of a methoxyaromatic compound (1 mmol) in MFA (2.6 mmol), we added phosphorus oxychloride (3.7 mmol) drop by drop after which the mixture was heated at 70—80 °C for 2 hr. After the mixture had been treated with sodium acetate–ice water, it was extracted with benzene or chloroform. After the removal of the solvents, the residue was chromatographed on a silica gel column with benzene–ethyl acetate to give the products.

Method B. A solution of a methoxyaromatic compound (1 mmol) in THF was added to a solution of *n*-butyllithium (1.5—2.5 mmol) in hexane (*ca.* 20%) under a nitrogen atmosphere, and then MFA (1.5—2.5 mmol) was added. The mixture was stirred at room temperature or in an ice-bath for 1.5—2 hr. After the usual work-up, the products were isolated by silica-gel column chromatography with benzene or chloroform.

Formylation of IVa by Method A. Yield of 9-(2-*p*-cymenyl)-1-formyl-2-methoxyanthracene, 98%; dark brown shell ligaments; mp 110—112 °C. Found: C, 84.73; H, 6.61%. Calcd for $C_{26}H_{24}O_2$: C, 84.75; H, 6.57%. The NMR and UV data are shown in Tables 2 and 5 respectively. IR (KBr disk): ν_{max} 1690 (–CO–) and 1250 (=C–O–C) cm^{-1}.

Formylation of IVb by Method A. Yield of 1-formyl-2-methoxy-9-phenylanthracene, 50%; mp 131.5—132.5 °C. The NMR data are shown in Table 2.

Formylation of IVc by Method A. Yield of 1-formyl-2-methoxy-9-methylanthracene, 48%; yellow crystals; mp 177.5—179 °C. Found: C, 81.55; H, 5.58%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%. UV (cyclohexane): λ_{max} (log ε) 256 (4.67), 319 (s) (3.56), 350 (3.45), 368 (3.59), and 421 (3.52) nm. IR (KBr disk): ν_{max} 1650 (–CO–) and 1250 (=C–O–C) cm^{-1}.

Formylation of IVd by Method A. Yield of 1-formyl- and 3-formyl-2-methoxyanthracenes, 40 and 23% respectively.

The 1-formyl derivative; pale yellow needles; mp 185—186 °C (lit.[7] 192—194.5 °C). Found: C, 81.62; H, 5.18%. Calcd for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%. IR (KBr disk); ν_{max} 1650 (–CO–) and 1250 (=C–O–C) cm^{-1}. The NMR and UV data are shown in Tables 2 and 5 respectively.

The 3-formyl derivative; pale yellow needles; mp 113—114 °C (lit.[7] 116—117 °C). Found: C, 81.41; H, 5.00%. IR (KBr disk): ν_{max} 1668 (–CO–), 1265, and 1215 (=C–O–C) cm^{-1}. The NMR and UV data are shown in Tables 2 and 5 respectively.

Formylation of Va by Method A. Yield of 9-(2-*p*-cymenyl)-3-formyl-2-methoxytriptycene, 79%; yellow red crystals; mp 93.2—94.5 °C. Found: C, 86.65; H, 6.39%. Calcd for $C_{32}H_{28}O_2$: C, 86.45; H, 6.35%. UV (cyclohexane): λ_{max} (log ε) 226 (4.51), 248.5 (s) (4.20), 254 (4.05), 261 (4.00), 266 (3.78), 278 (3.96), 278 (s) (3.94), and 333 (3.81) nm. IR (KBr disk): ν_{max} 1680 (–CO–), 1260, and 1230 (=C–O–C) cm^{-1}. The NMR data are shown in Table 3.

Formylation of Vb by Method A. Yield of 3-formyl-2-methoxytriptycene, 82%; pale yellow crystals from cyclohexane-ethanol; mp 242.5—243 °C. Found: C, 84.58; H, 4.87%. Calcd for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16%. UV (cyclohexane): λ_{max} (log ε) 234 (4.60), 256 (3.91), 263.5 (3.97), 272.5 (4.02), 275 (s) (4.00), 323 (3.85), and 331 (3.85) nm. IR (KBr disk): ν_{max} 1670 (–CO–) and 1250 (=C–O–C) cm^{-1}. The NMR data are shown in Table 3.

Formylation of VIa by Method A. Yield of 4-methoxy-*o*-anisaldehyde, 62%; pale yellow crystals; mp 70.5—71.5 °C. Found: C, 65.27; H, 5.77%. Calcd for $C_9H_{10}O_3$: C, 65.05; H, 6.07%. IR (KBr disk): ν_{max} 1674 (–CO–), 1265, and 1220 (=C–O–C) cm^{-1}. The NMR data are shown in Table 4.

Formylation of VIb by Method A. Yield of 4-*tert*-butyl-*o*-anisaldehyde, 95%; colorless liquid. Found: C, 74.83; H, 8.38%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%. IR (neat): ν_{max} 1684 (–CO–) and 1230 (=C–O–C) cm^{-1}. The NMR data are shown in Table 4.

Formylation of IVa by Method B. Yield of 9-(2-*p*-cymenyl)-3-formyl-2-methoxyanthracene, 71%; brown red needles; mp 118—119 °C. Found: C, 84.64; H, 6.26%. Calcd for $C_{26}H_{22}O_2$: C, 84.75; H, 6.57%, IR (KBr disk): ν_{max} 1695 (–CO–), 1231, and 1210 (=C–O–C) cm^{-1}. The NMR and UV data are shown in Tables 2 and 5 respectively.

Formylation of IVb by Method B. Yield of 3-formyl-2-methoxy-9-phenylanthracene, 64%; yellow needles; mp 160.4—162.6 °C. IR (KBr disk): ν_{max} 1680 (–CO–), 1225, and 1215 (=C–O–C) cm^{-1}. The NMR data are shown in Table 2.

Formylation of IVc by Method B. Yield of 3-formyl-2-methoxy-9-methylanthracene, 63%; yellow needles; mp 150.4

—152.4 °C. The NMR data are shown in Table 2.

Formylation of IVd by Method B. A trace of 1-formyl-2-methoxyanthracene was detected on tlc. However, its isolation was not attempted.

Formylation of Va by Method B. This yielded the same product as was detected by Method A in a 58% yield. Its behavior on tlc, EA, NMR, UV, and IR data were consistent with 9-(2-*p*-cymenyl)-3-formyl-2-methoxytriptycene.

Formylation of Vb by Method B. Yields of 1-formyl and 3-formyl-2-methoxytriptycenes, 41 and 4% respectively.

The 1-formyl isomer; fine crystals from cyclohexane; mp 210.5—212 °C. Found: C, 84.68; H, 5.07%. Calcd for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16%. UV (cyclohexane): λ_{max} (log ε) 223 (4.24), 236.7 (4.16), 257 (s) (3.97), 269.7 (3.82), 277.5 (3.86), and 333.5 (3.68) nm. IR (KBr disk): ν_{max} 1675 (–CO–), 1266, and 1237 (=C–O–C) cm^{-1}. The NMR data are shown in Table 3.

Formylation of VIa by Method B. Yield of 6-methoxy-*o*-anisaldehyde, 75%; needles; mp 98—99 °C (lit.[11] mp 98—99 °C). Found: C, 65.04; H, 5.99%. Calcd for $C_9H_{10}O_3$: C, 65.05; H, 6.07%. IR (KBr disk): ν_{max} 1675 (–CO–) and 1250 (=C–O–C) cm^{-1}. The NMR data are shown in Table 4.

Formylation of VIb by Method B. This yielded the same product as was isolated by formylation with Method A in a 17% yield. Its behavior on tlc, IR, and NMR were coincident with 4-*tert*-butyl-*o*-anisaldehyde.

This study was supported in part by a Grant for Life Science from this Institute.

The authors wish to thank the following: Mr. Jun Uzawa and Mrs. Tamiko Chijimatsu for their NMR spectral measurements; the staff of the Organic Microanalytical Laboratory in this Institute for their elemental analyses, and Assistant Professor Kazutoshi Yamada, Chiba University, for his computer calculations and helpful discussions.

The Reaction of Alcohols with Hexamethylphosphoric Triamide[1]

Seiji ARIMATSU, Ryohei YAMAGUCHI, and Mituyosi KAWANISI*)

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received December 17, 1973)

The thermal treatment of 4-homoadamantanol and bicyclo[3.3.1]nonanols with hexamethylphosphoric triamide (HMPT) gave the corresponding olefins in moderate yields. The application of this dehydration method to a system in which olefin formation was regarded as difficult or impossible stereochemically led to various types of reactions, *i.e.*, reduction, substitution, and phosphorodiamidation. Upon being heated in HMPT, 2-adamantanol afforded 2-adamantyl tetramethylphosphorodiamidate, whereas 1-adamantanol was transformed into adamantane *via* 1-adamantyl tetramethylphosphorodiamidate. In the case of allylic or benzylic alcohols, dimethylamino-substituted compounds were obtained. The reduction of the amount of HMPT promoted the formation of an ether, while dibenzhydryl ether was produced exclusively from benzhydrol. The mechanism of these reaction is discussed.

Recently Hexamethylphosphoric triamide (HMPT) has been widely used as a reaction medium because of its excellent properties as a dipolar aprotic solvent.[2] More recently it was found that HMPT behaved as a reagent for dehydrohalogenation,[3a] dehydration,[3b-d] and various types of reactions in organic synthesis.[3e-m]

In line with the interest in the behavior of HMPT as a reagent, we attempted to apply Monson's method[3b-d] for the dehydration of alcohols to bicyclo[3.3.1]-nonane and homoadamantane systems; the corresponding olefins were thus obtained in a moderate yield. However, when this method was extended to a system in which the olefin formation was regarded as difficult judging from the Bredt rule,[4] divergent types of reactions were observed. Among these reactions, in view of the fact that dimethylamino-substituted compounds were obtained from allylic or benzylic alcohols, we investigated the reaction of benzylic alcohols with HMPT in more detail.

This paper will describe the results obtained in the reaction of HMPT (a) with some alicyclic alcohols, and (b) with benzyl alcohols, including (b-1) the effect of the reaction temperature, (b-2) the formation of an ether, and (b-3) the detection of benzylpentamethylphosphoric triamide.

Finally, (c) some mechanistic aspects will be considered particularly, with particular attention being paid to the reaction of benzyl alcohols.

Results and Discussion

The Reaction of Alicyclic Alcohols with HMPT. As shown in Table 1, the dehydration of alcohols took place readily and gave the corresponding olefins in moderate yields. Among these, it should be noted that 4-homoadamantanol is converted to 4-homoadamantene in an excellent yield; this provides the most convenient method yet for the preparation of this cage olefin.[5]

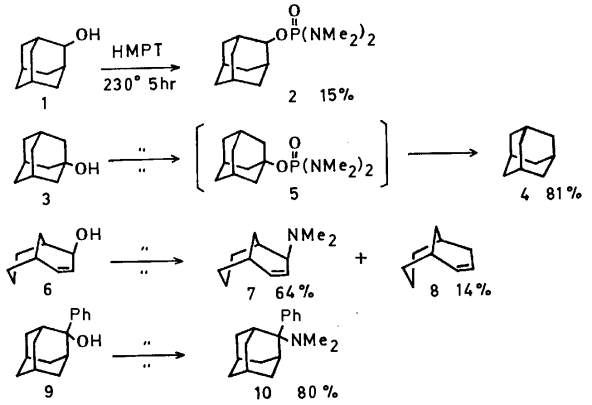
When 2-adamantanol (**1**) was treated with HMPT, 2-adamantyl tetramethylphosphorodiamidate (**2**) could be isolated in a 15% yield, as is shown in Scheme 1.[6] On the other hand, 1-adamantanol (**3**) afforded only the reduction product, adamantane (**4**). When the reaction of **3** with HMPT was followed by glc, combined with MS, however, it was found that 1-adamantyl tetramethylphosphorodiamidate (**5**) was an intermediate leading to the final product, **4**. Compared with the MS spectrum of **2**, that of **5** indicates the base peak at *m/e* 135, corresponding to the adamantyl cation, whereas that of **2** indicates the base peak at *m/e* 151, corresponding to the adamantyloxy cation. This may reflect the more facile formation of adamantane (**4**) from **5** than from **2**.

Table 1. DEHYDRATION OF ALCOHOLS IN HMPT

Alcohol	Olefin	Yied (%)
4-Homoadamantanol	4-Homoadamantene	91
exo-Bicyclo[3.3.1]nonan-2-ol	Bicyclo[3.3.1]non-2-ene	43
endo-Bicyclo[3.3.1]nonan-2-ol	Bicyclo[3.3.1]non-2-ene	28
Bicyclo[3.3.1]nonane-2,6-diol[a]	Bicyclo[3.3.1]nona-2,6-diene	35

a) Epimeric mixture; *endo, endo*-, and *endo, exo*-diols.

A similar reaction of *exo*-bicyclo[3.3.1]non-3-en-2-ol (**6**) gave 2-*exo*-dimethylaminobicyclo[3.3.1]non-3-ene (**7**), together with a reduction product, bicyclo[3.3.1]-non-2-ene (**8**). The *exo*-configuration of the dimethylamino group at the 2 position of **7** was established by NMR, which indicated a narrow half-band width of 5.0 Hz assignable to the methine proton at the 2 position.[7] Furthermore, 2-phenyl-2-adamantanol (**9**) gave 2-phenyl-2-dimethylaminoadamantane (**10**) in an 80% yield.



Scheme 1.

The Reaction of Benzyl Alcohols with HMPT. The fact that dimethylamino-substituted compounds were obtained from allylic or benzylic alcohols such as **6** and **9** prompted us to investigate the reaction of benzyl alcohols with HMPT. The results obtained are listed in Table 2.

Table 2. Reaction of benzyl alcohols with HMPT

Alcohol	Product	Yield (%)
Benzyl alcohol	Benzyldimethylamine	10
	Dibenzylmethylamine	40
Benzhydrol	Diphenylmethane	8
	Benzhydryldimethylamine	56
Triphenylmethanol	Triphenylmethane	44

Monson and Priest have already reported that benzyl alcohols were converted to the corresponding dimethylamino derivatives.[3f] However, we could obtain some additional results—that is, the formation of dibenzylmethylamine and two reduction products, diphenylmethane and triphenylmethane.

The Effect of the Reaction Temperature: The reaction of benzyl alcohols with HMPT seems to be highly sensitive to the reaction temperature employed. As is shown in Table 3, dibenzylmethylamine was produced over 215 °C, whereas benzyldimethylamine was a sole product at 200 °C. In the case of benzhydrol, a temperature dependency could be also observed, as is shown Table 4, but it was extremely small as compared with the result in the case of benzyl alcohol. Triphenylmethanol gave only triphenylmethane in the temperature range of 200—230 °C. The formation of reduction products seems to be dependent upon the steric effects; that is, although toluene escaped from detection in the case of benzyl alcohol, the yield of the reduction products increased as the number of phenyl group increased.

Table 3. Reaction of benzyl alcohol with HMPT

Reaction time hr	Reaction temp. °C	Product distribution (%)[a]	
		$PhCH_2NMe_2$	$(PhCH_2)_2NMe$
1	200	100	—
1	215	85	15
1	230	59	41
5	230	25	75

a) Determined by glc analysis. The yield was almost quantitative except in the case of last run, which is shown in Table 2.

Table 4. Reaction of benzhydrol with HMPT

Reaction time hr	Reaction temp. °C	Product distribution (%)[a]	
		Ph_2CH_2	Ph_2CHNMe_2
1	200	6	94
1	215	7	93
1	230	9	91
5	230	11	89

a) Determined by glc analysis. The yield was almost quantitative except in the case of last run, which is shown in Table 2.

The Formation of an Ether: When a series of experiments was performed on the reaction of benzyl alcohol with varying amounts of HMPT, a novel type of reaction was discovered—namely, the formation of an ether.[8] These data, summarized in Table 5, show that, in the presence of smaller amounts of HMPT, the production of the ether is favored. HMPT was fully consumed when 3 mol of benzyl alcohol was treated with 1 mol of HMPT at 230—240 °C. Since the ratio of benzyldimethylamine (**11**) and dibenzylmethylamine (**12**) was almost unchanged in varying amounts of HMPT, HMPT might be indifferent to the formation of **11** and **12** from the presumed intermediate, benzyl tetramethylphosphorodiamidate (**13**).[3f]

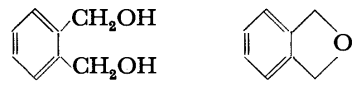
Table 5. Reaction of benzyl alcohol with varying amounts of HMPT

Molar ratio of benzyl alcohol and HMPT	Product distribution (%)[a]		
	$PhCH_2NMe_2$	$(PhCH_2)_2NMe$	$(PhCH_2)_2O$
1 : 1	56	39	5
1 : 2/3	55	38	7
1 : 1/3	50	35	15

a) Determined by glc analysis. The yield was almost quantitative.

When 3 mol of benzhydrol was treated with 1 mol of HMPT, dibenzhydryl ether (**14**) was obtained as the sole product in a 71% yield after recrystallization from ethanol.

These results further prompted us to investigate the reaction of phthalyl alcohol (**15**) with HMPT, which was supposed to give rise to intramolecular ether-formation affording phthalan (**16**) (Eq. (1)). Actually, although the yield was far from satisfactory, **16** was obtained in an 8% yield from a mixture of equimolar amounts of **15** and HMPT.



15 **16** (1)

Detection of Benzylpentamethylphosphoric Triamide: When a solution of benzyl alcohol and HMPT was refluxed for 5 hr, a small amount of a new product was detected; this product identified as benzylpentamethylphosphoric triamide (**17**) from the spectroscopic data (see Experimental section). It is highly probable that this compound was formed by the amine-exchange reaction of the benzyldimethylamine produced with HMPT.

Mechanistic Investigations. Intermediacy of Alkyl Tetramethylphosphorodiamidate in the Reaction of Alcohols with HMPT: Concerning the mechanism of the reaction of alcohols with HMPT, Monson and Priest suggested, without rigorous proof, that the initial step of the reaction was the formation of alkyl tetramethylphosphorodiamidate (**18**) (Eq. (2)).[3d]

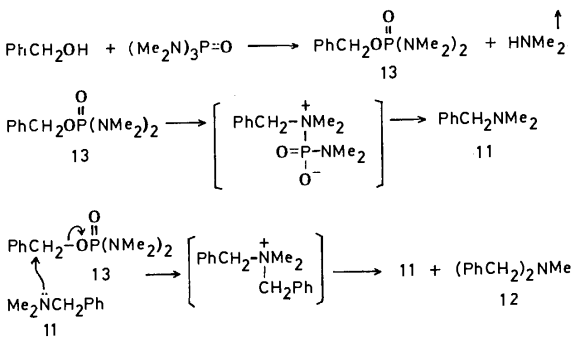
$$ROH + (Me_2N)_3P{=}O \longrightarrow ROP(NMe_2)_2 + HNMe_2\uparrow \quad (2)$$

18

As is shown in Scheme 1, this presumed intermediate was actually isolated by using an adamantanol.

Also, with regard to the mechanism of the reaction of benzyl alcohols with HMPT, Monson and Priest suggested that the benzyl tetramethylphosphorodiamidates initially produced rearranged to benzyldimethylamine (**11**).[3f] In order to establish this mechanism, we prepared benzyl tetramethylphosphorodiamidate (**13**) from sodium benzylate and tetramethylphosphorodiamidic chloride in ether, and thermally treated **13** *without* solvents. The treatment of **13** at 230—240 °C for 1 hr gave **11** and dibenzylmethylamine (**12**) in the same ratio as in the reaction of benzyl alcohol with HMPT. This implies that **13** is actually an intermediateto the two final products, **11** and **12**. According to the Monson mechanism, it is understandable that **11** was produced by the rearrangement of the **13** intermediate. However, it is still not clear how **12** was obtained from **13**. Since Monson did not obtain **12**, we are left with the intriguing question of how **12** was formed from **13**.

The Formation of Dibenzylmethylamine by the Reaction of Benzyl Tetramethylphosphorodiamidate and Benzyldimethylamine: One explanation of the formation of **12** is that the benzyldimethylamine produced (**11**) attacks the benzylic carbon atom of the still-surviving benzyl tetramethylphosphorodiamidate (**13**), which is an intermolecular analogy of the rearrangement of the **13** intermediate (Scheme 2).



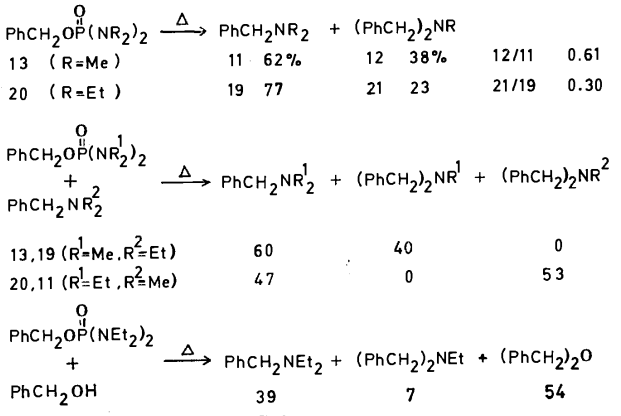
Scheme 2.

In order to test this hypothesis, we investigated the crossed reactions between benzyl tetramethylphosphorodiamidate (**13**) and benzyldiethylamine (**19**)[9] as well as those between benzyl tetraethylphosphorodiamidate (**20**) and benzyl dimethylamine (**11**).[10] It was preliminarily observed that **20** was also thermally converted to benzyldiethylamine (**19**) and dibenzylethylamine (**21**), but the ratio of **21**/**19** was smaller than that of **12**/**11**. In the former case, no crossed reaction was observed, but in the latter case, the crossed reaction did take place and dibenzylmethylamine (**12**) was obtained (Scheme 3).

These observations imply that the rate of the attack of **19** must be slower than that of **11** for steric reasons and also well explain the fact that dibenzhydrylmethylamine is not obtained in the case of benzhydrol.

From these results we concluded that **12** was derived from the nucleophilic substitution reaction of **13** by **11** as is shown in Scheme 2.

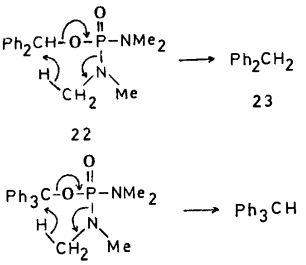
Additionally, when an equimolar mixture of **20** and



Scheme 3.

benzyl alcohol was treated at 230—240 °C for 1 hr, dibenzyl ether was obtained at the expense of **20**, together with **19** and **21**. (Scheme 3) Therefore, it is highly probable that the ether-formation proceeds by the nucleophilic substitution reaction of **18** by the still-remaining alcohol.

Mechanism Concerning the Formation of the Reduction Products: As for the formation of the reduction products, such as diphenylmethane and triphenylmethane, we tentatively propose the mechanism depicted in Scheme 4.



Scheme 4.

When the intramolecular rearrangement occurs, hydrogen from the methyl group attached to nitrogen transfers to the benzylic carbon atom. An attempt to prepare benzhydryl tetramethylphosphorodiamidate (**22**) did not succeed, but instead of **22**, we directly obtained diphenylmethane (**23**) and benzhydryldimethylamine (**24**) in refluxing ether, though the ratio of **23** and **24** was *ca.* 1 : 1, different from the results of the reaction of benzhydrol with HMPT. This explanation can also be extended to the formation of adamantane and bicyclo[3.3.1]non-2-ene from their precurcors. However, these observations can not be explicitly explained at present, and an intermolecular pathway cannot be ruled out.

Experimental

All the temperature are uncorrected. The IR spectra were obtained on a Shimadzu IR-27 spectrophotometer. The mass spectra were taken by using a Hitachi RMS-4 mass spectrometer. The NMR spectra were obtained on a EM-360 spectrometer, TMS being chosen as the internal standard. The microanalyses were performed by Mrs. Kiyoko Fujimoto.

Hexamethylphosphoric Triamide (HMPT). Commercially-available HMPT was refluxed for 5 hr under N_2 with calcium

hydride and then distilled; bp 110—115 °C/15 mmHg.

Starting Materials. The following compounds were prepared according to the reported methods: 4-homoadamantanol,[5] *exo*-bicyclo[3.3.1]nonan-2-ol,[11] *endo*-bicyclo[3.3.1]-nonan-2-ol,[11] bicyclo[3.3.1]nonane-2,6-diol,[12] 1-adamantanol,[13] 2-adamantanol,[14] *exo*-bicyclo[3.3.1]non-3-en-2-ol,[11] benzhydrol,[15] triphenylmethanol,[16] and phthalyl alcohol.[17]

Preparation of 2-Phenyl-2-adamantanol. The Grignard reagent prepared from bromobenzene (9.7 g; 0.062 mol) and magnesium (1.5 g; 0.062 atom) in ether (35 ml) was treated with adamantanone (4.5 g; 0.03 mol) in ether (55 ml) and then hydrolyzed with 20% H_2SO_4. The ether layer was separated, combined with an ether extract of the aqueous layer, and dried over Na_2SO_4. The subsequent evaporation of the solvent yielded 4.2 g (63%) of 2-phenyl-2-adamantanol: mp 89.5—90.5 °C, mass spectrum: *m/e* 228 (M^+), NMR ($CDCl_3$): δ 7.1—7.45 (m, 5H), IR (Nujol mull): 3220, 1601, 1008, 697 cm^{-1}. Found: C, 84.38; H, 8.53%. Calcd for $C_{16}H_{20}O$: C, 84.16; H, 8.83%.

General Procedure for Dehydration of Alcohols by HMPT. The substrate (0.01 mol) was dissolved in HMPT (10 ml) and heated at 230—240 °C under N_2 for 5 hr. The reaction mixture was then poured onto water and extracted five times with petroleum ether (bp 40—50 °C). The extract was washed two times with brine and dried over Na_2SO_4. The subsequent evaporation of the solvent gave crude materials. Since 4-homoadamantene[5] and bicyclo[3.3.1]non-2-ene[11] sublimed during the reaction, they could be obtained in pure form from the sublimates. Bicyclo[3.3.1]nona-2,6-diene was purified by distillation; bp 60—65 °C/20 mmHg (lit,[18] 51—51.5 °C/15 mmHg).

Thermal Reaction of Alcohols with HMPT. The treatment was essentially the same as was been described above. The reaction mixture was poured onto water and extracted five times with benzene. The extract was washed two times with brine and dried (Na_2SO_4). After the evaporation of the solvent, a crude material was obtained; this material was purified by a combination of column chromatography and preparative glc.

2-Adamantyl Tetramethylphosphorodiamidata (2): Mp 51.5—53 °C (from *n*-hexane), mass spectrum: *m/e* 286 (M^+), 151 (100%), 135, NMR (CCl_4): δ 2.59 (d, J_{PH} 9.0 Hz, 12H), 4.19—4.60 (b, 1H), IR (Nujol mull): 1290, 1195, 999, 988, 750 cm^{-1}. Found: C, 58.70; H, 9.62; N, 9.59%. Calcd for $C_{14}H_{27}N_2O_2P$: C, 58,72; H, 9.50; N, 9.78%.

2-exo-Dimethylaminobicyclo[3.3.1]non-3-ene (7): Mass spectrum: *m/e* 165 (M^+), NMR (CCl_4): δ 2.20 (s, 6H), 2.68 (m, 1H, $W_{1/2}$ 5.0 Hz), 5.87 (m, 2H), IR (liquid film): 1180, 1040, 1000, 720 cm^{-1}. Found: C, 80.21; H, 11.46; N, 8.73%. Calcd for $C_{11}H_{19}N$: C, 79.94; H, 11.59; N, 8.48%.

2-Phenyl-2-dimethylaminoadamantane (10): Mp 109.5—111 °C, mass spectrum: *m/e* 255 (M^+), NMR ($CDCl_3$): δ 1.36—1.79 (m, 10H), 1.82 (s, 6H), 2.17—2.42 (b, 1H), 2.40—2.78 (b, 3H), 7.02—7.26 (m, 5H), IR (Nujol mull): 1491, 755, 703 cm^{-1}. Found: C, 84.65; H, 10.11; N, 5.55%. Calcd for $C_{12}H_{25}N$: C, 84.65; H, 9.87; N, 5.48%.

Reaction of Benzyl Alcohols with HMPT. The procedure was the same as that described above. The products were identified by comparison with the reported spectral data (Sadtler Standard Spectra, The Aldrich Library of IR Spectra).

Formation of Dibenzhydryl Ether (14) by the Reaction of Benzhydrol with HMPT: A mixture of 1.84 g (0.01 mol) of benzhydrol and 0.6 g (0.003 mol) of HMPT was heated at 230—240 °C for 1 hr under N_2. The usual work-up and recrystallization from ethanol gave 1.25 g (71%) of dibenzhydryl ether (**14**): mp 107—108 °C (lit,[19] 109 °C), mass spectrum: no parent, *m/e* 167 (100%), NMR (CCl_4): δ 5.33 (s, 2H), 7.30 (m, 20H), IR (Nujol mull): 1050 cm^{-1}.

Formation of Phthalan (16) by the Reaction of Phthalyl Alcohol (15) with HMPT: A mixture of 1.38 g (0.01 mol) of phthalyl alcohol and 1.79 g (0.01 mol) of HMPT was heated for 1 hr according to the procedure described above. Column Chromatography (Al_2O_3, *n*-hexane: benzene=4: 1) of the crude material afforded 0.1 g (8%) of phthalan (**16**):[20] mass spectrum: *m/e* 120 (M^+), 91 (100%), NMR (CCl_4): δ 5.0 (s, 4H), 7.13 (s, 4H), IR (liquid film): 3030, 1040, 900, 740 cm^{-1}.

Isolation of Benzylpentamethylphosphoric Triamide (17) in the Reaction of Benzyl Alcohol with HMPT: The procedure was as has been described above except that the reaction time was 5 hr. The benzene extract was evaporated; subsequent column chromatography of the residue afforded 3% of benzylpentamethylphosphoric triamide, together with benzyldimethylamine and dibenzylmethylamine. **17**: mass spectrum: *m/e* 255 (M^+), 211, 120 (100%), NMR (CCl_4): δ 2.47 (d, J_{PH} 7.8 Hz, 3H), 2.62 (d, J_{PH} 10.2 Hz, 12H), 4.15 (d, J_{PH} 9.0 Hz, 2H), 7.2—7.4 (m, 5H), IR (liquid film): 1600, 1500, 1300, 1200, 980, 775, 740, 700 cm^{-1}.

Preparation of Benzyl Tetramethylphosphorodiamidate (13). To 2.16 g (0.02 mol) of benzyl alcohol dissolved in 40 ml of anhydrous ether, we added 0.48 g (0.02 mol) of sodium hydride. The mixture was stirred and refluxed for 2 hr. To the suspention of sodium benzylate in ether we then slowly added tetramethylphosphorodiamidic chloride.[21] The mixture was stirred and refluxed overnight. The precipitates were removed by filtration, and the organic layer was washed two times with brine and dried (Na_2SO_4). The subsequent evaporation of the solvent, followed by distillation at 140—145 °C/5 mmHg, yielded 3.8 g (79%) of benzyl tetramethylphosphorodiamidate (**13**)[22]: mass spectrum: *m/e* 242 (M^+), 151 (40%), 91 (100%), NMR (CCl_4): δ 2.53 (d, J_{PH} 9.6 Hz, 12H), 4.85 (d, J_{PH} 9.6 Hz, 2H), 7.30 (s, 5H), IR (liquid film): 1305, 1200, 990, 750, 700 cm^{-1}.

Preparation of Benzyl Tetraethylphosphorodiamidate (20). The procedure described above was followed, but we used tetraethylphosphorodiamidic chloride[23] instead of tetramethylphosphorodiamidic chloride. Thus, 2.8 g (94%) of the pure material was obtained after decolorizing with active carbon. **20**: mass spectrum: *m/e* 298 (M^+, feeble), 91 (100%), NMR (CCl_4): δ 1.06 (t, 12H), 3.02 (d of quartet, J_{PH} 12.6 Hz, 8H), 4.87 (d, J_{PH} 7.8 Hz, 2H), 7.30 (s, 5H), IR (liquid film): 1235, 1010 cm^{-1}. Found: C, 60.54; H, 9.38; N, 9.38%. Calcd for $C_{15}H_{27}N_2O_2P$: C, 60.37; H, 9.12; N, 9.38%.

Thermolysis of 13 and 20. The substrate (0.002 mol) was heated for 1 hr at 230—240 °C under N_2. During the period of the reaction, an insoluble oily layer appeared; upon cooling, it solidified to a gummy, crystalline mass. This phenomenon was also observed upon the reaction of benzyl alcohol with HMPT. This compound was identical with bisdimethylammonium dihydrogen pyrophosphate, $(Me_2NH_2)_2H_2P_2O_7$, which Monson and Priest have reported on.[3f] The upper layer was immediately subjected to glc analysis; the products shown in Scheme 3 were observed in the specified ratio.

Thermal Reaction between 13 and 19, as well as between 20 and 11. Benzyldimethylamine (**11**)[10] and benzyldiethylamine (**19**)[9] were prepared according to the reported methods. Each equimolar mixture of the substrates was treated by the procedure described above. The reaction mixture was immediately subjected to glc analysis. The relative ratios are shown in Scheme 3.

The authors wish to thank Professor Hitosi Nozaki

for his valuable advice and continuous encouragement, and also Mr. Koichi Kimoto for his skillful technical assistance and discussions.

Asymmetric Hydroformylation of Styrene. The Effects of the Reaction Conditions on the Stereoselectivity

Masato TANAKA, Yoshihisa WATANABE, Take-aki MITSUDO, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 26, 1973)

The effects of the reaction conditions on the asymmetric hydroformylation of styrene with rhodium catalysts have been studied. The $[\alpha]_D$ value and the configuration of the product, hydratropaaldehyde, were much affected by the phosphine/rhodium ratios, the reaction temperatures (20—110 °C), and the partial pressures of carbon monoxide and hydrogen (10—100 atm). The results were mainly explained in terms of the structures of the catalysts and the skeletal isomerization of acyl complexes. The predominant species of the catalysts and the participation of a π-benzyl-type intermediate were also discussed.

Recently, catalytic asymmetric syntheses with chiral phosphine transition-metal complexes have attracted much interest, and several papers on the asymmetric hydroformylation of olefins with chiral phosphine rhodium complexes have been published.[1-4] However, there has been no example of an investigation of the effects of the reaction conditions on the asymmetric hydroformylation. The hydroformylation reaction is believed to proceed *via* the π-olefin, alkyl, and acyl complexes:

$$\rangle{=}\langle + \text{H-M(CO)}_{3-n}\text{L}_n \longrightarrow \rangle\underset{|}{\text{C}}\text{-M(CO)}_{3-n}\text{L}_n \quad (1)$$

$$\rangle\underset{|}{\text{C}}\text{-M(CO)}_{3-n}\text{L}_n \longrightarrow \text{R-M(CO)}_{3-n}\text{L}_n \quad (2)$$

$$\text{R-M(CO)}_{3-n}\text{L}_n + \text{CO} \longrightarrow \text{R-}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{-M(CO)}_{3-n}\text{L}_n \quad (3)$$

$$\text{R-}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{-M(CO)}_{3-n}\text{L}_n + \text{H}_2 \longrightarrow \text{RCHO} + \text{H-M(CO)}_{3-n}\text{L}_n \quad (4)$$

where L is carbon monoxide or a phosphorus ligand and M is cobalt or rhodium. Great effects on the reaction rate and the distribution of the products (the straight/branched ratio) are brought about by changing the reaction conditions, the structure of the active species and the reaction mechanisms have been discussed on the basis of these results.[5]

In this paper, the authors will describe the effects of the reaction conditions (the reaction temperatures, the phosphine/rhodium ratios, and the partial pressures of carbon monoxide and hydrogen) on the asymmetric hydroformylation of styrene with chiral phosphine rhodium complexes.

Experimental

Benzene was refluxed over lithium aluminum hydride, distilled under argon, and stored over calcium hydride. Styrene was distilled at a reduced pressure of argon and was stored with *p-tert*-butylcatechol as a radical inhibitor in a refrigerator. Neomenthyldiphenylphosphine[6] and (*R*)-benzylmethylphenylphosphine[7] were prepared according to the methods of the literature.

The glpc analysis was carried out on a Shimadzu model GC-3B apparatus equipped with a stainless steel column (3 mm$^{\phi}$ × 3 m) packed with diethylene glycol adipate polyester on chromosorb. The optical rotations were measured neat on a JASCO model DIP-180 automatic polarimeter.

Reaction Procedure. An autoclave (100 ml) made of stainless steel (SUS-32) and equipped with a magnetic stirrer was used. Ten ml of benzene, 10 ml of styrene, 3.1 mg of μ,μ'-dichlorotetracarbonyldirhodium, and a desired amount of a chiral phosphine were placed into the autoclave under a slow stream of argon. After the autoclave has been purged with 20 atm of hydrogen several times, hydrogen and carbon monoxide were introduced at certain pressures, after which the mixture was heated up to the desired temperature. The reaction temperature was regulated automatically within a variation of ±1 °C. After having been agitated for a certain time, the autoclave was discharged and an aliquot of the reaction mixture was analyzed by gas chromatography. The optically-active hydratropaaldehyde produced was isolated by the distillation of the reaction mixture, and then the optical rotation was measured.

Reduction of Hydratropaaldehyde. The configuration and the maximum rotation of hydratropaaldehyde are unknown. Therefore, the aldehyde was transformed into 2-phenyl-1-propanol, whose configuration and maximum rotation are known. To a suspension of lithium aluminum hydride (2.19 g) in ether (120 ml), an ether solution (20 ml) of hydratropaaldehyde (5.4 g, $[\alpha]_D$ +1.28°) was added, drop by drop, at 0 °C, and then the mixture was refluxed for 2 hr. The resultant solution was hydrolyzed with 3 M H_2SO_4 (60 ml), and the aqueous layer was extracted three times with 30 ml portions of ether. The combined organic layer was washed with water, dried over magnesium sulfate, and distilled to give 4.7 g of 2-phenyl-1-propanol; bp 63.0—64.2 °C/0.6 mmHg, $[\alpha]_D$ −0.120° (neat). As the maximum rotation of (*S*)-2-phenyl-1-propanol is $[\alpha]_D$ −15.16° (neat),[8] that of (*S*)-hydratropaaldehyde is estimated to be $[\alpha]_D$ +160° (neat) if the reduction of the aldehyde proceeds without racemization. However, since such a racemization has been noted,[2] the authors will use not the "optical yield" but the $[\alpha]_D$ value in this text.

Results and Discussion

The effects of the reaction conditions (the reaction temperatures, the partial pressures of hydrogen and carbon monoxide, and the phosphine/rhodium ratios) on the $[\alpha]_D$ value of the product were examined; some typical results are summarized in Tables 1 and 2. Under the conditions used, styrene was converted into hydratropaaldehyde and hydrocinnamaldehyde. The former was always the main product, and no other by-products were detected by gas chromatography.

a) Styrene: 10 ml, benzene (solvent): 10 ml, $[Rh(CO)_2Cl]_2$: 3.1 mg, initial partial pressure of carbon monoxide and hydrogen: 70 atm, respectively. b) Phosphine/rhodium ratio. c) Total yield of hydratropaaldehyde and hydrocinnamaldehyde based on the amount of styrene used. d) 100×Hydratropaaldehyde/(hydratropaaldehyde+hydrocinnamaldehyde).

effects of the phosphine/rhodium ratio on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde were examined under the conditions, initial partial pressure of hydrogen and carbon monoxide of 70 atm and at 75 °C. Two kinds of chiral phosphines were used: (*R*)-benzylmethylphenylphosphine and neomenthyldiphenylphosphine (nmdpp). The former has an asymmetric center on phosphorus, while the latter has three asymmetric centers on the alkyl group. The results are illustrated in Figs. 1 and 2.

In the case of (*R*)-benzylmethylphenylphosphine, when the phosphine/rhodium ratio was 1 the stereochemical control was not so effective, so the $[\alpha]_D$ value was nearly zero. However, an increase in the ratio resulted in a larger stereoselectivity, and the $[\alpha]_D$ value amounted to +50.8° at the 2: 1 ratio. Then it approached asymptotically to a limit with an increase in the ratio (4: 1 and 8: 1). These results suggest an equilibrium among active species which is affected by both the phosphine/rhodium ratio and the partial pressure of carbon monoxide, which will be discussed later:

$$HRh(CO)_3 \underset{CO,\,-P^*}{\overset{P^*,\,-CO}{\rightleftarrows}} HRh(CO)_2P^* \underset{CO,\,-P^*}{\overset{P^*,\,-CO}{\rightleftarrows}} HRh(CO)P_2^* \quad (5)$$

where P* is a chiral phosphine. $HRh(CO)_3$ may be predominant at the 1: 1 ratio, and in principle, the

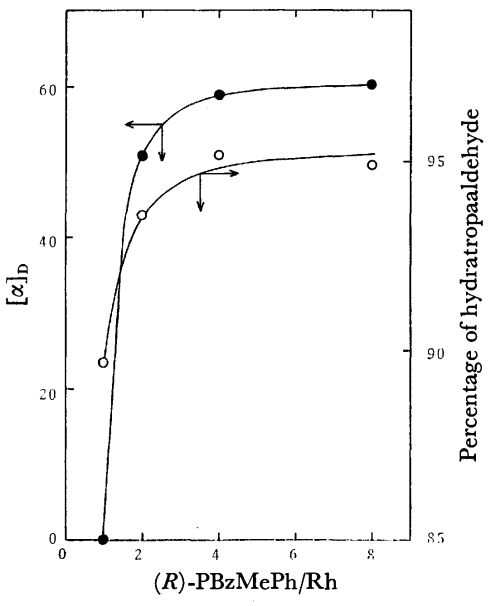

Fig. 1. Effects of (*R*)-benzylmethylphenylphosphine/rhodium ratios on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. ($P_{CO}=P_{H_2}=70$ atm, 75 °C)

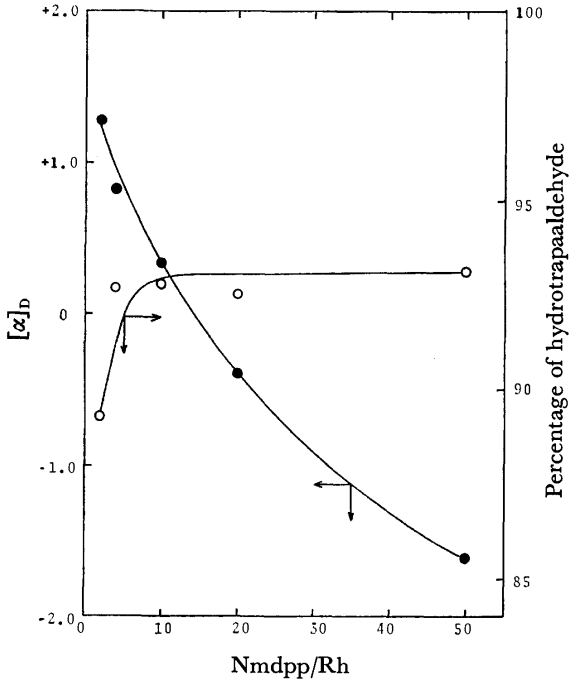

Fig. 2. Effects of neomenthyldiphenylphosphine/rhodium ratios on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. ($P_{CO}=P_{H_2}=70$ atm, 75 °C)

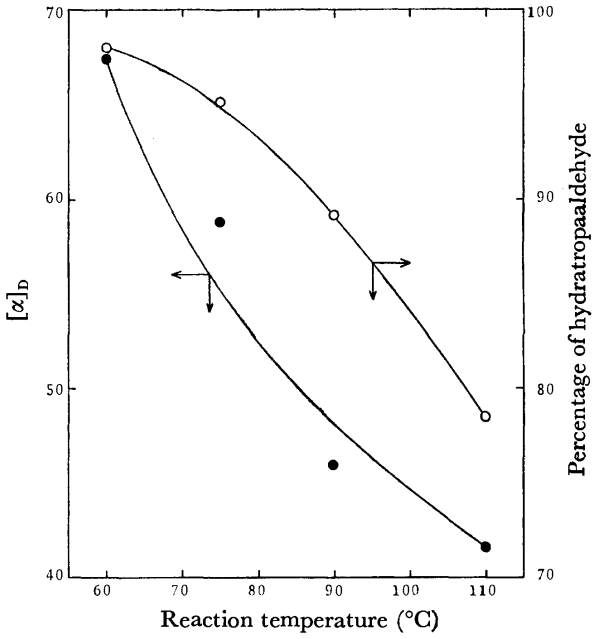

Fig. 3. Effects of reaction temperatures on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. ($P_{CO}=P_{H_2}=70$ atm, (*R*)-benzylmethylphenylphosphine /rhodium=4)

hydroformylation proceeds without any asymmetric induction. Therefore $HRh(CO)_2P^*$ may be the dominant species at larger ratios, and it may be alternated with $HRh(CO)P_2^*$ when the ratio becomes much larger. With catalytic activities, there may be no drastic differences among the species, judging from the results shown in Table 1. Therefore, it can be concluded that Equilibrium (5) is responsible for the relationship between the phosphine/rhodium ratio and the $[\alpha]_D$ value.[9]

As Fig. 2 shows, when nmdpp was used the effect on the $[\alpha]_D$ value was very different from that in the case of (*R*)-benzylmethylphenylphosphine. Thus, the $[\alpha]_D$ value decreased monotonously from $+1.28°$ to $-1.61°$ when the phosphine/rhodium ratio increased gradually from 2: 1 to 50: 1. The configuration of hydratropaaldehyde was reversed from *S* to *R* at a ratio around 14: 1. These results clearly suggest the participation of the equilibrium mentioned above. It seems reasonable that, when the phosphine/rhodium ratio is smaller, $HRh(CO)_2P^*$, which may be responsible for the formation of *S*-aldehyde, is predominant, and that $HRh(CO)P_2^*$, responsible for the formation of *R*-aldehyde, may take the place of $HRh(CO)_2P^*$ at larger ratios.

The difference in the behavior of the $[\alpha]_D$ value between these two phosphines may be attributed to the differences in their structures and coordination abilities.

On the other hand, the percentage of hydratropaaldehyde was slightly increased with an increase in the ratio both in the case of (*R*)-benzylmethylphenylphosphine and in that of nmdpp.

The Effect of the Reaction Temperature. The relationships between the reaction temperature and the $[\alpha]_D$ value, and the percentage of hydratropaaldehyde

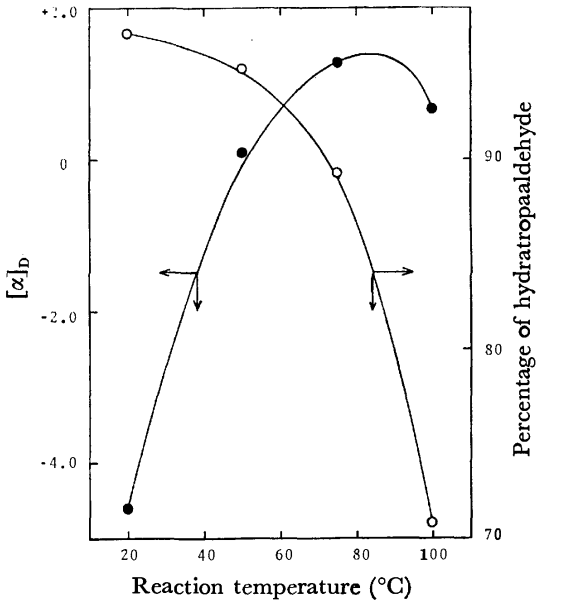

Fig. 4. Effects of reaction temperatures on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. ($P_{CO}=P_{H_2}=70$ atm, neomenthyldiphenylphosphine/ rhodium=2)

respectively, were examined under the conditions of a phosphine/rhodium ratio of 4: 1 for (*R*)-benzylmethylphenylphosphine, or one of 2: 1 for nmdpp, and with initial partial pressures of carbon monoxide and hydrogen of 70 atm. The results are illustrated in Figs. 3 and 4.

As Fig. 3 shows, when (*R*)-benzylmethylphenylphosphine was used as a chiral ligand, the $[\alpha]_D$ value of hydratropaaldehyde increased almost proportionally with a decrease in the reaction temperature. The $[\alpha]_D$

value reached +67° at 60 °C.* In considering the effect of the reaction temperature on the $[\alpha]_D$ value, two factors may be mainly taken into account: the reaction rate and the stability of the conformations of the reaction intermediates. Lowering the reaction temperature made the overall reaction slow down (see Tables 1 and 2). Though the real mechanism of the asymmetric induction is not clear, the reactions involving the diastereomeric key intermediate, which decides the configuration of the product, may also become slower, and so the stereoselection may be effective. About the second factor, the conformation and configuration of catalytically-active species and reaction intermediates may be more stable at lower temperatures. This means that the chiral environment at the reaction site is fixed and that the epimerization of the intermediates (the racemization of the alkyl or acyl group of the intermediates) does not occur easily. This factor, therefore, may result in a high $[\alpha]_D$ value.

In the case of nmdpp, a different type of relationship was observed. When the reaction temperature was lowered from 100 to 75 °C, the $[\alpha]_D$ value increased by a factor of about 2. This dependency is analogous to that in the case of (*R*)-benzylmethylphenylphosphine. However, the $[\alpha]_D$ value decreased when the temperature lowered further (50 and 20 °C). Thus, it was +1.28° at 75 °C, nearly zero at 50 °C, and −4.61° at 20 °C with a change in the configuration of hydratropaaldehyde from *S* to *R*. These facts clearly imply that the mode of the stereochemical control is delicately altered by changing the reaction temperature. The phosphine coordinated to rhodium can rotate around the coordination bond axis, and several metastable conformations of the catalytically-active species are possible. Therefore, the unexpected phenomenon may be attributed to this type of conformational alternation in the catalyst molecule. This conformational factor may be rather important with nmdpp, for neomenthyl group has three asymmetric carbons. On the other hand, as has been described above, the phosphine/rhodium ratio affects the $[\alpha]_D$ value and the configuration; these results have been discussed from the standpoint of the number of the phosphine coordinated to rhodium. The effect of the reaction temperature can be partly explained on the basis of this consideration. Lowering the reaction temperature has the same effect on the $[\alpha]_D$ value as the increase in the phosphine/rhodium ratio. Therefore, it is likely that the number of the phosphine on the rhodium is larger at lower temperatures. The unexpected phenomenon of the effect of the reaction temperature may also be attributed to this factor.

As is shown in both Figs. 3 and 4, the percentage of hydratropaaldehyde gradually decreases as the reaction temperature becomes higher. Previous work[10] in this laboratory has demonstrated that α-phenylpropionyltetracarbonylcobalt, which is formed by the reaction of hydridotetracarbonylcobalt with styrene under a carbon monoxide atmosphere, easily undergoes a skeletal isomerization to give the β-isomer, and that this type of isomerization is accelerated by elevating the reaction temperature. Under the conditions of the asymmetric hydroformylation;

$$PhCH(CH_3)CORh(CO)_{3-n}P_n^* \longrightarrow PhCH_2CH_2CORh(CO)_{3-n}P_n^* \quad (6)$$

an analogous isomerization seems to occur; therefore the percentage of hydratropaaldehyde decreases with an increase in the reaction temperature.

The Effect of the Partial Pressure of Carbon Monoxide. The effects of the partial pressures of carbon monoxide on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde were examined by the use of (*R*)-benzylmethylphenylphosphine under the following

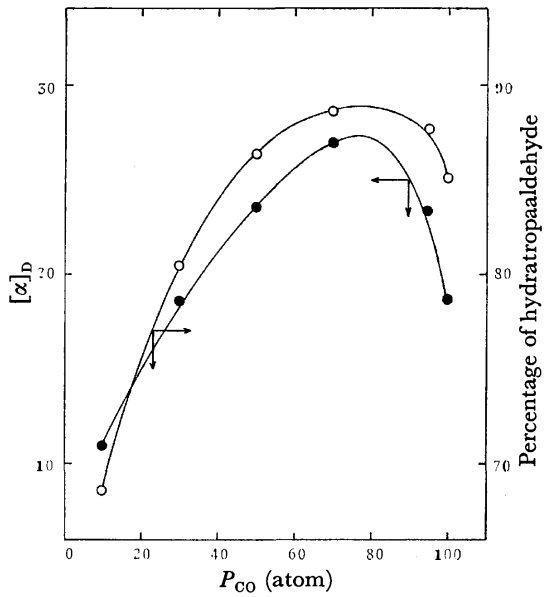

Fig. 5. Effects of partial pressures of carbon monoxide on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. (P_{H_2}=50 atm, 110 °C, (*R*)-benzylmethylphenylphosphine/rhodium=2)

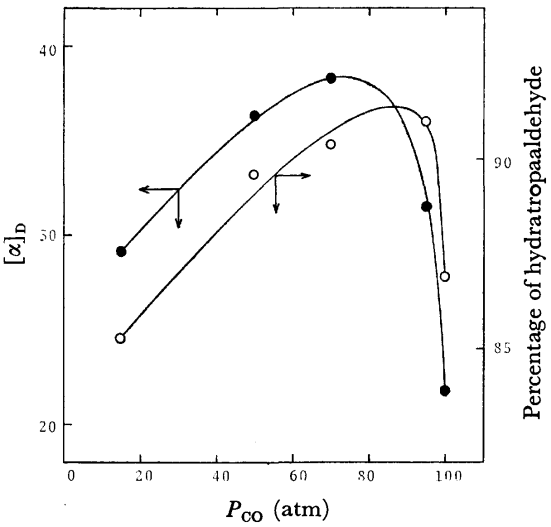

Fig. 6. Effects of partial pressures of carbon monoxide on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. (P_{H_2}=50 atm, 110 °C, (*R*)-benzylmethylphenylphosphine/rhodium=3)

* Taking the optical purity of the phosphine (76.6%) into consideration, this optical rotation indicates a 52% optical yield.

conditions; 110 °C, an initial partial pressure of hydrogen of 50 atm, and a phosphine/rhodium ratio of 2: 1 or 3: 1. The results are illustrated in Figs. 5 and 6.

As Figs. 5 and 6 show, the $[\alpha]_D$ value and the percentage of hydratropaaldehyde at first increased monotonously to a maximum, and then decreased with an increase in the partial pressure of carbon monoxide, when the other reaction conditions were fixed. These relations may be partly explained by the equilibrium of the active species. As the partial pressure of carbon monoxide increases, the Equilibrium (5) is shifted to the left; this shift brings about a decrease in the $[\alpha]_D$ value and the percentage of hydratropaaldehyde, as has been described in connection with the effect of the phosphine/rhodium ratio. The tendency of the right-hand half of the curves in Figs. 5 and 6 to decrease may be attributed to this factor. However, the left-hand half can not be explained clearly.

In contrast with the results shown in Figs. 5 and 6, the change in the partial pressure of carbon monoxide did not result in any appreciable effect at the phosphine/rhodium ratio 4: 1 (see Exps. No. 4 and 9 in Table 1). The (5) equilibrium seems to lie very far to the right at larger ratios; therefore, the equilibrium is not profoundly affected by changing the partial pressure of carbon monoxide in the range examined.

The Effect of the Partial Pressure of Hydrogen. The effects of the initial partial pressure of hydrogen were also examined; the results are shown in Figs. 7 and 8. As Figs. 7 and 8 show, the $[\alpha]_D$ value and the percentage of hydratropaaldehyde increased monotonously as the partial pressure increased, when the phosphine/rhodium ratio, the partial pressure of carbon monoxide, and the temperature were fixed at 2: 1 or 3: 1, 50 atm, and 110 °C respectively.

As has been described above, the effect of the partial pressure of carbon monoxide was much larger at a phosphine/rhodium ratio of 3: 1 or 2: 1 than that at

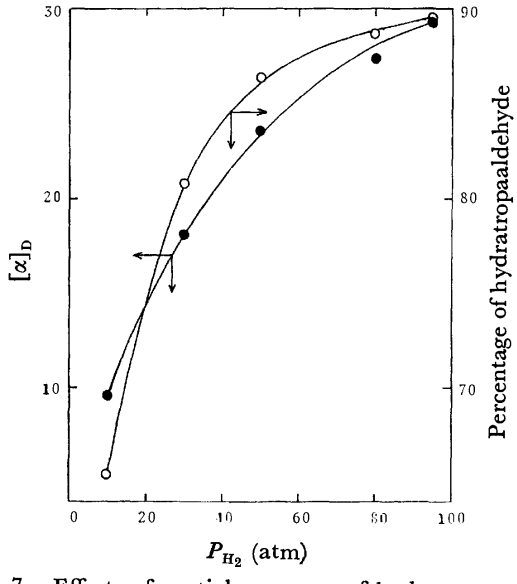

Fig. 7. Effects of partial pressures of hydrogen on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. (P_{CO}=50 atm, 110 °C, (*R*)-benzylmethylphenylphosphine/rhodium=2)

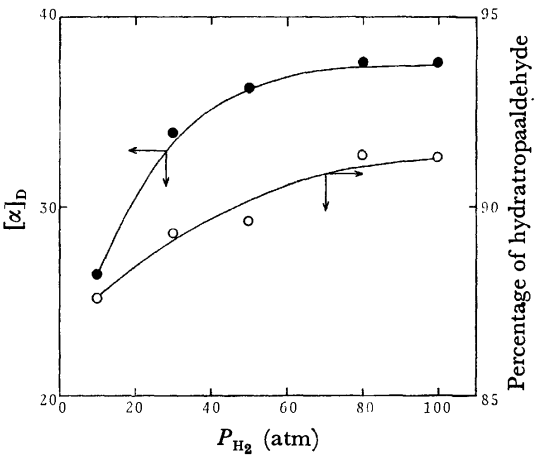

Fig. 8. Effects of partial pressures of hydrogen on the $[\alpha]_D$ value and the percentage of hydratropaaldehyde. (P_{CO}=50 atm, 110 °C, (*R*)-benzylmethylphenylphosphine/rhodium=3)

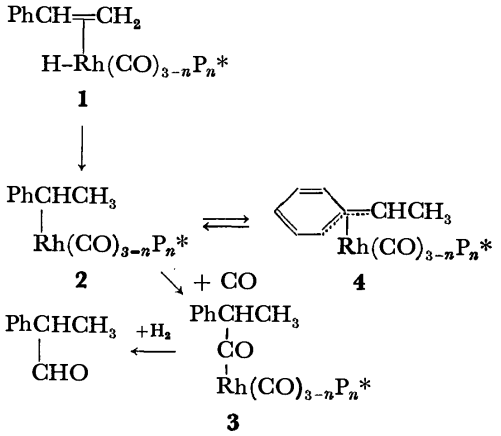
the 4: 1 ratio. This observation is also applicable to the present case. At the 4: 1 ratio, no significant effect of the partial pressure of hydrogen was observed (see Exps. No. 4 and 17 in Table 1).

General Discussion. As has been mentioned above, the $[\alpha]_D$ value and the percentage of hydratropaaldehyde show a fairly good parallelism in Figs. 5—8. This parallelism seems to indicate that the $[\alpha]_D$ value is also dependent on the route through which the hydratropaaldehyde is formed. According to the generally-accepted mechanism of hydroformylation, hydratropaaldehyde is thought to be formed *via* a styrene–rhodium π-complex (**1**), an α-phenethyl–rhodium complex (**2**), and an α-phenylpropionyl–rhodium complex (**3**) as intermediates. However, styrene shows behavior different from that of simple olefins in hydroformylation. With simple 1-olefins, the formylation mainly occurs on a terminal carbon to give a straight-chain aldehyde as a major product.[5] On the other hand, with styrene the inner carbon is predominantly formylated to give hydratropaaldehyde, a branched-chain aldehyde. Furthermore, with simple olefins an incremental addition of phosphine causes an increase in the percentage of the straight-chain aldehyde and a decrease in that of the branched-chain one, while with styrene an increase in the phosphine/rhodium ratio brings about an increase in the percentage of hydra-



tropaaldehyde. These facts show that styrene has a marked tendency to be formylated on the inner carbon. From these considerations, an alternative route which contains a π-benzyl-type complex (**4**) as an intermediate may reasonably be suggested. This is supported by the fact that a π-benzyl-rhodium complex is formed in the reaction of benzyl chloride and Rh(I) complexes ($RhClL(PPh_3)_2$, L; CO or PPh_3).[11] This hypothesis of a participation of the π-benzyl-type complex is not only consistent with the fact that styrene is mainly formylated on the inner carbon, but is also reasonable in view of the stereoselectivity. Thus, in the asymmetric hydroformylation of olefins such as styrene derivatives, simple olefins, and unsaturated ethers, the stereoselectivity is highest in styrene, while that of the other olefins is far lower.[12] The π-benzyl-type complex of styrene will construct a rigid conformation of the diastereomeric intermediate to make the asymmetric induction more effective. This is probably the reason why styrene shows a larger stereoselectivity than the other olefins examined in the asymmetric hydroformylation.

The Novel Synthesis of L-Hydroxyproline from D-Glutamic Acid

Chikahiko EGUCHI and Akio KAKUTA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received December 27, 1973)

L-Hydroxyproline (**1**) and D-*allo*-hydroxyproline (**2**) were synthesized from D-glutamic acid (**3**) using the asymmetric center of **3** as that at C_4 of 4-hydroxyproline. When the aqueous solution of **1** or **2** was heated at 200 °C for 2 hr, a solution in the equilibrium state, containing 55% of **1** and 45% of **2**, was obtained. From this mixture, **1** was obtained by fractional crystallization.

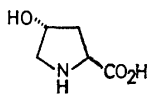
Since 4-hydroxyproline was first synthesized in 1905 by Leuchs,[1] several synthetic routes have been studied by many researchers.[2-7] In these routes, comparable amounts of racemic diastereomers, *i.e.*, DL-hydroxyproline (DL-Hyp) and DL-*allo*-hydroxyproline (DL-*a*Hyp), have been formed. Therefore, difficult procedures, that is, the fractionation of DL-Hyp and DL-*a*Hyp and the optical resolution of DL-Hyp, were unavoidable, if one was to obtain L-hydroxyproline (**1**) from these racemic diastereomers.[8-9]

This paper will deal with a new synthesis of (4*R*)-4-hydroxyproline, *i.e.*, **1** and D-*allo*-hydroxyproline (**2**), from D-glutamic acid (**3**) using the asymmetric center of **3** as that at C_4 of 4-hydroxyproline, and with a new method of the interconversion between **1** and **2**. By these methods, **1** can be easily obtained without optical resolution, as will be described below.

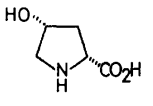
Results and Discussion

Synthesis of L-*Hydroxyproline and* D-allo-*Hydroxyproline.*

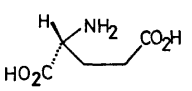
(*R*)-γ-Butyrolactone-γ-carboxylic acid (**4**) was prepared from **3** in an 85% yield by a reaction with nitrous acid in an aqueous solution. This reaction is known to proceed with a full retention of the configuration due to the participation of the neighboring carboxylate group.[10,11] The treatment of **4** with thionyl chloride afforded (*R*)-γ-butyrolactone-γ-carboxylic acid chloride (**5**) in a 96% yield. This reaction is considered to proceed with a full retention of its configuration by analogy with the conversion of *N*-trifluoroacetyl-L-proline to *N*-trifluoroacetyl-L-prolyl chloride.[12]



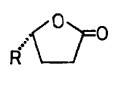
1



2



3



4 R=CO_2H **5** R=COCl
6 R=CH_2OH **7** R=CH_2Cl

Formulae.

(*R*)-γ-Hydroxymethyl-γ-butyrolactone (**6**) was prepared from **5** in a 77% yield by reduction with sodium borohydride in dry diglyme. A small amount of 1,2,5-trihydroxypentane was also formed in this reduction. However, it was easily removed by silica gel chromatography.

In the case of sodium borohydride reduction, it is occasionally troublesome to decompose the reaction products and to remove the resulting boric acid.[13] However, in the present case, when methanol was poured into the reaction mixture we could easily decompose the reaction products and convert the boric acid into volatile trimethyl borate. The reduction mechanism of acid chloride with sodium borohydride has not been exactly reported, however, the reaction-equation seems to be as follows, by analogy with the reduction with lithium borohydride:[14]

$$4\,RCOCl + 2\,NaBH_4 \longrightarrow NaCl + BCl_3 + NaB(OCH_2R)_4 \quad (1)$$

$$BCl_3 + CH_3OH \longrightarrow B(OCH_3)_3 + 3\,HCl \quad (2)$$

$$NaB(OCH_2R)_4 + 3\,CH_3OH + HCl \longrightarrow NaCl + B(OCH_3)_3 + 4\,RCH_2OH \quad (3)$$

Fickett, Govner, and Leres reported that the optically-active alcohol, 2-chloropropanol, was obtained, with a retention of its configuration, from the optically-active acid chloride, 2-chloropropionyl chloride, by reduction with litium aluminium hydride.[15] By analogy with this reaction and by a comparision between the specific rotation of **6** and that of its (*S*)-isomer, which was synthesized by Koga, Taniguchi, and Yamada from (*S*)-γ-butyrolactone-γ-carboxylic acid methyl ester,[16] this reduction step may be considered to proceed with a full retention of configuration.

(*R*)-γ-Chloromethyl-γ-butyrolactone (**7**) was prepared from **6** in a 93% yield by reaction with thionyl chloride in the presence of pyridine. In this reaction, the configuration is considered to be retained.

At the next step, the halogenation of the α-position of **7** was examined. The α-position of the lactone or the ester is known to be hardly halogenated without the cleavage of the ester group.[17,18] However, in the present case the halogenation must be carried out without opening the lactone ring if we are to retain the configuration of the γ-position. A mixture of **7** and sulfuryl chloride was heated in a sealed glass tube. α-Monochloro-compounds (**8**), α,α-dichloro-compound (**9**), α,β-dichloro-compound (**10**) and polychloro-substituted protoanemonins (**11**) were formed. The gas-liquid chromatographic analyses (glc) showed two α-monochloro-compounds, *i.e.*, one with a shorter retention time (**8a**) and the other with a longer retention time (**8b**); their stereochemistries were deduced from the products of their amination, as will be discussed later. **11** was a mixture of tetra-, tri-, and dichloro-substituted protoanemonins. The component ratios of these products were determined by means of the ratios of their peak-areas in glc. A part of the results are shown in

a) Molar ratio. b) Trace amount. c) Undetectable. d) Gaseous chlorine was bubbled into **7**.

Table 1. Hardly any reaction took place under 100 °C, and above 130 °C the amount of **11** rapidly increased. The amount of sulfuryl chloride required was more than twice the molar equivalent of **7**.

When **7** was chlorinated by gaseous chlorine, the same products (**8**—**11**) were formed, as is shown in Table 1. However, in this case **11** was more easily formed than in the case of the chlorination with sulfuryl chloride.

When **7** was heated for 15—25 hr with three—five times molar sulfulyl chloride at 110—120 °C, the total amount of α-chloro-compounds (**8a**, **8b**, and **9**) was the largest, as is shown in Table 1. However it was impossible to prepare only α-monochloro-compounds. Therefore, the selective conversion of **9** to **8** was examined. The chlorination products were hydrogenated in acetic acid under atmospheric pressure in the presence of sodium acetate and 5% Pd–C. The rate of the dehalogenation of **9** to **8a** and **8b** was much faster than that of **8** to **7**. Therefore, the reaction rate was followed by glc, and then the hydrogenation was stopped at the time when **9** was almost completely converted to **8** without the dehalogenation of **8**. The hydrogenated mixture generally contained 40—45% of **8a**, 30—40% of **8b**, and 2—3% of **9**.

These mixtures were aminated with conc. ammonium hydroxide and hydrolyzed with 3 M hydrochloric acid or 1 M sodium hydroxide. The Hyp and *a*Hyp thus produced were treated by means of an ion-exchange column (acid form) and decolorizing resin and were estimated by means of an automatic amino-acid analyzer. The results are shown in Table 2. The chlorination of **7** with sulfuryl chloride, followed by hydrogenation, amination, and hydrolysis, gave Hyp and *a*Hyp in a 46% overall yield.

The optical purities of these amino acids were determined by Manning and Moore's method,[19] with some modifications. Thus, four dipeptides, *i.e.*, L-leucyl-L-hydroxyproline, L-leucyl-D-hydroxyproline, L-leucyl-L-*allo*-hydroxyproline and L-leucyl-D-*allo*-hydroxyproline, were prepared from the amino acid mixture by reaction with *N*-carboxy-L-leucine anhydride. Then, the optical purity of Hyp was determined from the amounts of L-leucyl-L-hydroxyproline and L-leucyl-D-hydroxyproline. On the other hand, for the determination of the optical purity of *a*Hyp, the amino acid mixture was

Table 2. Amination of (γ*R*)-α-chloro-γ-chloromethyl-γ-butyrolactone (**8a** and **8b**)

Expt. No.	[8b]/[8a] [a]	Reaction conditions[b] Amination	Hydrolysis	4-Hydroxyprolines Yield[c] (%)	[1]/[2] [d]	Content of enantiomer, % D-Hyp[e]	L-*a*Hyp[f]
1	39/61	A	C	38	41/59	4.7	3.1
2	46/54	A	C	46	46/54	4.1	2.9
3	45/55	A	C	46	44/56	4.2	2.5
4	45/55	B	C	45	55/45	4.6	3.6
5	41/59	A	C	12	39/61		
6	41/59	A	D	10	40/60		

a) Molar ratio of **8b** to **8a** in the starting material of amination. b) A; at room temperature for 2 day in conc. ammonium hydroxide. B: at 100—110°C for 7.5 hr in conc. ammonium hydroxide. C; reflux for 2 hr in 3 M hydrochloric acid. D; reflux for 0.5 hr in 1 M sodium hydroxide. c) The yield is based on **7** by chlorination with sulfuryl chloride followed by hydrogenation, amination and hydrolysis in Expt. No. 1—4. In Expt. No. 5 and 6, that is based on **7** by chlorination with gaseous chlorine, amination, and hydrolysis. d) Molar ratio of **1** to **2** in the formed 4-hydroxyproline. e) [D-Hyp]/([D-Hyp]+[L-Hyp]). f) [L-*a*Hyp]/([L-*a*Hyp]+[D-*a*Hyp]).

reacted with *N*-carboxy-L-valine anhydride instead of *N*-carboxy-L-leucine anhydride, and the L-valyl-L-*allo*-hydroxyproline and L-valyl-D-*allo*-hydroxyproline thus formed were estimated by means of the automatic amino-acid analyzer. The Hyp was composed of about 4% of the D-isomer and about 96% of the L-isomer, while the *a*Hyp was composed of about 3% of the L-isomer and about 97% of the D-isomer, as is shown in Table 2.

By recrystallization from water–ethanol, **1** and **2** were obtained in a 40% yield based on **7** (*i.e.*, in a 23% yield based on **3**). In this mixture, D-hydroxyproline and L-*allo*-hydroxyproline were not found by the above-mentioned method used to determine the optical purity.

When the amination was carried out at room temperature, as is shown in Table 2, the molar ratio of **1** to **2** was in fair agreement with that of **8b** to **8a**. On the other hand, α-amino acid is known to be formed at room temperature from α-chlorocarboxylic acid with a full inversion of the configuration.[20] Therefore, it could unambiguously be deduced that **1** and **2** were formed from **8b** and **8a** respectively. Thus, **8a** must be (α*S*,γ*R*)-α-chloro-γ-chloromethyl-γ-butyrolactone and **8b** must be (α*R*,γ*R*)-α-chloro-γ-chloromethyl-γ-butyrolactone.

Interconversion between L-*Hydroxyproline and* D-allo-*Hydroxyproline and Isolation of* L-*Hydroxyproline.* To obtain **1** from the mixture of **1** and **2**, novel methods of interconversion and fractination were examined. Until now, the interconversion between **1** and **2** has been made by two methods: (A) by heating an aqueous solution of the amino acid in the presence of excess barium hydroxide at 200 °C for several hours[21] and (B) by treating the amino acid with an excess of acetic anhydride in refluxing glacial acetic acid.[22] The reaction mixtures at the equilibrium state contained about 50% of **1** in Method (A) and about 25% of **1** in Method (B).

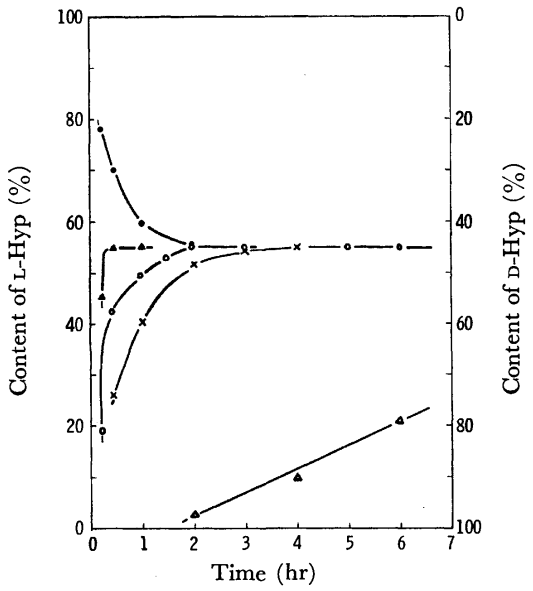

Fig. 1. Interconversion between L-hydroxyproline (**1**) and D-*allo*-hydroxyproline (**2**) in an aqueous solution: (△), **2** (starting material), 150 °C (reaction temperature); (×), **2**, 180 °C; (○), **2**, 200 °C; (▲), **2**, 220 °C; (●), **1**, 200 °C.

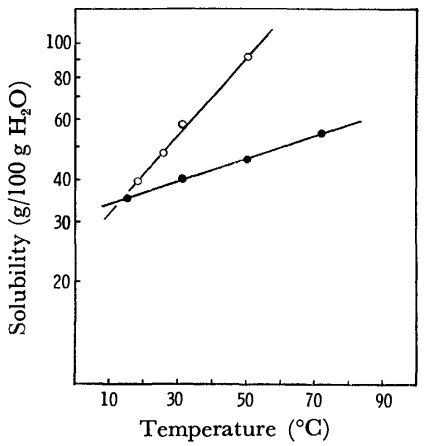

Fig. 2. Solubilities of L-hydroxyproline (●) and D-*allo*-hydroxyproline (○).

An aqueous solution of **1** or **2** was heated at 150, 180, 200, and 220 °C, and the contents of **1** and **2** in the solution were estimated using the optical rotation or an automatic amino-acid analyzer. The results are shown in Fig. 1. When the aqueous solution of **1** or **2** was heated at 200 °C for 2 hr, a solution at the equilibrium state, which contained 55% of **1** and 45% of **2**, was easily obtained.

The solubilities of **1** and **2** in water were also examined. The results are shown in Fig. 2. The temperature dependence of the solubility is apparently different between **1** and **2**. The solubility of **1** in water was constant regardless of the presence of **2**. Therefore, 9.00 g of a mixture of 55% of **1** and 45% of **2** gave 0.85 g of optically-pure **1** by fractional crystallization from 10 ml of water at 30 °C. Thus, the conversion of the mixture of **1** and **2** to **1** was carried out by a combination of interconversion and fractional crystallization in water. Also, by a method previously reported by the present authors, *i.e.*, the method through cyclic dipeptides, these mixtures could be easily converted to **1**.[23]

Experimental

The melting points are uncorrected. The IR spectra were recorded on a JASCO IR-S spectrometer. The NMR spectra were measured with a Varian T-60 or XL-100 spectrometer, using TMS as the internal standard. The mass spectra were obtained using a Hitachi RMU-6E spectrometer. The optical rotations were measured with a JASCO DIP-SL automatic polarimeter. The 4-hydroxyprolines were analyzed using a Hitachi KLA-3B automatic amino-acid analyzer (column size, 50×0.9 cm; resin, Hitachi Type 2612; column flow rate, 60 ml/hr; buffer, citrate (0.2 M) pH 3.25; temperature, 55 °C).

*Identification of the Chlorination Products of (*R*)-γ-Chloromethyl-γ-butyrolactone (***7***).* The reaction mixture was fractionated using a Shimadzu Gas Chromatograph GC-4A equipped with TCD and a glass column (5 ft×1/4 in. with 10% PEG-6000 on Chromosorb W (HMDS), 60—80 mesh; column temperature, 145 °C; flow rate of helium gas, 35 ml/min). The component ratios were determined by using a Hewlet Packard 402 High Efficiency Gas Chromatogram equipped with FID

and a glass column (4 ft×1/4 in. with 20% PEG-4000 on Chromosorb W (HMDS), 80—100 mesh; column temperature, 160 °C; flow rate of helium gas, 30 ml/min); the retention times (r.t.) will be shown below.

*(αS, γR)-α-Chloro-γ-chloromethyl-γ-butyrolactone (**8a**)*: r.t., 11.6 min; Mass spectrum *m/e* 119 (M–CH_2Cl, $C_4H_4O_2Cl$), 88, 83, 75 (C_3H_4Cl), 63 (C_2H_4Cl), 62 (C_2H_3Cl), 49 (CH_2Cl); IR (liquid film) 1960, 1795 (C=O), 1175, 1035 and 924 cm^{-1}.

*(αR, γR)-α-Chloro-γ-chloromethyl-γ-butyrolactone (**8b**)*: r.t., 15.6 min. The mass spectrum was identical with that of **8a**.

*(R)-α,α-Dichloro-γ-chloromethyl-γ-butyrolactone (**9**)*: r.t., 8.4 min; Mass spectrum *m/e* 153 (M–CH_2Cl, $C_4H_3O_2Cl_2$), 125, 109 (C_3H_3Cl), 96 ($C_2H_2Cl_2$), 61 (C_2H_2Cl), 49 (CH_2Cl); IR (liquid film) 2970, 1810 (C=O), 1179, 1034 and 963 cm^{-1}; NMR (in $CDCl_3$) $ClCH_dH_e$–$C_\gamma H_c$–$C_\beta H_bH_a$– δ_a 3.26, δ_b 2.97, 4.95, δ_d 3.79, δ_d 3.86, J_{ab}=14.6 Hz, J_{ac}=5.5 Hz, J_{bc}=9.3 Hz, J_{de}=12.3 Hz, J_{dc}=4.9 Hz, J_{ec}=4.6 Hz. The assignment of this five-spin system was confirmed by computor simulation.

*(γR)-α,β-Dichloro-γ-chloromethyl-γ-butyrolactone (**10**)*: r.t., 9.8 min. The mass spectrum was almost identical with that of **9**; however, they differed in the relative strengths of their peaks.

*Polychloro-substituted Protoanemonins (**11**)*: r.t., 1.8—2.8 min; Mass spectrum *m/e* 268 ($C_5HO_2Cl_5$), 233 ($C_5HO_2Cl_4$), 222 ($C_5O_2Cl_4$), 198 ($C_5HO_2Cl_3$), 185 ($C_4O_2Cl_3$), 151 ($C_4HO_2Cl_2$), 123. In NMR spectrum, the signals appeared between δ 6.13 and 7.70.

Determination of the Optical Purity of 4-Hydroxyproline by Ion-exchange Chromatography. allo-*Hydroxyproline*: The borate buffer (0.45 M, 500 ml) was prepared by dissolving boric acid (13.9 g) in 497 ml of boiled, distilled water and then by adding 50% sodium hydroxide to bring the solution to pH 10.2 at 25 °C. In 15 ml of this borate buffer, 20 mg (0.152 mmol) of an amino acid mixture of hydroxyproline and *allo*-hydroxyproline was dissolved, and then a small amount of silicone grease was added to minimize foaming. To the vigorously-stirred solution we then rapidly added, at 0—2 °C, a solution of *N*-carboxy-L-valine anhydride (26 mg, 0.18 mmol) in dioxane (1.0 ml). After this mixture has been vigorously stirred for 3 min, 3 ml of 2 M hydrochloric acid was added rapidly to stop the reaction. The solution was filled up to 25 ml with a citrate buffer (0.2 M, pH 2.2), and the contents of L-valyl-L-*allo*-hydroxyproline and L-valyl-D-*allo*-hydroxyproline in the solution were estimated by comparison with authentic mixtures using a Hitachi KLA-5 automatic amino-acid analyzer (column size, 50×0.9 cm; resin, Hitachi Type 2613; column flow rate, 60 ml/hr; buffer, citrate (0.2 M), pH 3.25; temperature, 55 °C).

The elution times were 142 min for L-valyl-D-hydroxyproline and L-valine, 170 min for L-valyl-D-*allo*-hydroxyproline, 190 min for L-valyl-L-hydroxyproline, and 207 min for L-valyl-L-*allo*-hydroxyproline. The detectable amount of L-*allo*-hydroxyproline in the amino acid mixture was checked by using an authentic mixture. A 0.5% amount of L-*allo*-hydroxyproline in *allo*-hydroxyproline was detectable; however, any amount less than 0.5% of L-isomer was not detectable.

Hydroxyproline: Using *N*-carboxy-L-leucine anhydride (29 mg, 0.18 mmol), the contents of L- and D-hydroxyprolines in a mixture of hydroxyproline and *allo*-hydroxyproline were estimated in a manner similar to that described in the part of *allo*-hydroxyproline. The elution times were 155 min for L-leucyl-D-hydroxyproline, 220 min for L-leucyl-L-hydroxyproline, and 254 min for L-leucyl-L-*allo*-hydroxyproline, L-leucyl-D-*allo*-hydroxyproline, and L-leucine. Any amount less than 0.5% of D-hydroxyproline was not detectable.

*(R)-γ-Butyrolactone-γ-carboxylic Acid (**4**)*. From D-glutamic acid ($[\alpha]_D^{27}$ −31.6° (*c* 10.2, 2 M HCl)), **4** was obtained in an 85% yield by the method of Austin and Howard:[24] bp 165.5—167.5 °C/0.30 mmHg; mp 73.5—74.0 °C (recrystallization from ethyl acetate–benzene–petroleum ether); $[\alpha]_D^{20}$ −15.9° (*c* 1.10, ethanol), +7.29° (*c* 1.03, water), −14.3° (*c* 1.19, methanol). Lit,[11] bp 150—155 °C/0.2 mmHg, mp 71—72 °C, $[\alpha]_D^{20}$ −2.8° (*c* 5.8, water), +10.6° (*c* 5.0, methanol) for (*S*)-isomer.

*(R)-γ-Butyrolactone-γ-carboxylic Acid Chloride (**5**)*. A mixture of **4** (55.7 g, 0.429 mol) and thionyl chloride (102.0 g, 0.857 mol) was refluxed for 2 hr and then allowed to stand at room temperature overnight. After the removal of the excess thionyl chloride, the residue was distilled under reduced pressure to give 61.1 g (0.413 mol) of **5** in a 96% yield: bp 117.1 °C/4.5 mmHg; $[\alpha]_D^{30}$ +0.196° (*c* 4.34, dioxane), −44.5° (*c* 3.70, benzene); IR (liquid film) 2970, 1805—1780, 1458, 1490, 1355, 1138, 1060, and 910 cm^{-1}; NMR (in $CDCl_3$) δ 2.7 (4H, m, $-CH_2-CH_2-$) and 5.3 (1H, m, C_γ–H); Mass spectrum *m/e* 85 (M–COCl, $C_4H_5O_2$), 57, 36, 29. Found: C, 40.65; H, 3.49; Cl, 23.59%. Calcd for $C_5H_5O_3Cl$: C, 40.42; H, 3.39; Cl, 23.87%. Lit,[25] bp 136—137 °C/12 mmHg for the racemic form.

*(R)-γ-Hydroxymethyl-γ-butyrolactone (**6**)*. A solution of **5** (24.8 g, 0.168 mol) in dry diglyme (50 ml) was added at 0—5 °C to a solution of sodium borohydride (4.12 g, 0.109 mol) in dry diglyme (175 ml). The mixture was then stirred for 30 min at room temperature. To the mixture, methanol (70 ml) was added. After the filtration of sodium chloride, the filtrate was concentrated under reduced pressure. The resulting syrup was placed on a silica gel column containing 100 ml of WAKO GEL C-200 and eluted with 2.5% ethanol in chloroform. **6** was eluted faster than 1,2,5-trihydroxypentane, so the two products were easily separated. After the removal of the solvent from the elute containing **6**, the residue was distilled under reduced pressure to give 14.7 g (0.127 mol) of **6** in a 76% yield: bp 101.0—102.0 °C/0.048 mmHg; $[\alpha]_D^{30}$ −53.5° (*c* 3.17 chloroform), −33.5° (*c* 3.12, ethanol); IR (liquid film) 3400, 1765, 1350, 1185, 1060, 935, and 803 cm^{-1}; NMR (in $CDCl_3$) δ 1.95—2.75 (4H, $-CH_2-CH_2-$), 3.80 (2H, $-CH_2OH$) and 4.63 (1H, C_γ–H); Mass spectrum *m/e* 116 (M^+), 85 (M–CH_2OH), 57, 31 (CH_2OH). Found: C, 51.90; H, 6.67%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.94%. Lit,[16] $[\alpha]_D^{28}$ +31.1° (ethanol) for the (*S*)-isomer.

*(R)-γ-Chloromethyl-γ-butyrolactone (**7**)*. Thionyl chloride (26.9 g, 0.226 mol) was added to a mixture of **6** (23.2 g, 0.200 mol) and dry pyridine (17.6 g, 0.222 mol) at 40—50 °C. The mixture was stirred for 1 hr at 60 °C. To the mixture, chloroform (200 ml) was then added. The resulting chloroform solution was washed with water (50 ml) (three times), saturated sodium bicarbonate (20 ml), and water (50 ml), dried with anhydrous sodium sulfate, and decolorized with active charcoal. After the removal of the chloroform, the residue was distilled under reduced pressure to give 25.0 g (0.187 mol) of **7** in a 94% yield; bp 94.0—94.2 °C/2.0 mmHg; $[\alpha]_D^{27}$ −12.9° (*c* 3.03, chloroform), −33.2° (*c* 3.51, ethanol); IR (liquid film) 2965, 1775, 1169, 1040, 915, and 738 cm^{-1}; NMR (in $CDCl_3$) δ 1.95—2.77 (4H, $-CH_2-CH_2-$), 3.70 (2H, CH_2Cl), 4.76 (1H, C_γ–H); Mass spectrum *m/e* 134 (M^+, 2%), 85 (M–CH_2Cl, 100%), 57, 55, 29. Found: C, 44.85; H, 5.17; Cl, 26.65%. Calcd for $C_5H_7O_2Cl$: C, 44.63; H, 5.24; Cl, 26.35%.

L-*Hydroxyproline (**1**) and* D-allo-*Hydroxyproline (**2**)*. A mixture of **7** (1.98 g, 14.8 mmol) and sulfuryl chloride (6.04 g, 44.7 mmol) was heated at 112 °C for 25 hr in a glass tube.

After the removal of the excess sulfuryl chloride from the mixture under reduced pressure, chloroform (50 ml) was added to the residue. The resulting chloroform solution was washed with water (10 ml), saturated sodium bicarbonate (10 ml), and water (10 ml), and dried with anhydrous sodium sulfate. The removal of the chloroform gave 3.39 g of a syrup. The results of glc analysis showed that the sryup contained 24% of **8a**, 10% of **8b**, 38% of **9**, a trace amount of **10**, 10% of **11**, and 18% of unchanged **7**.

This syrup was dissolved in 30 ml of acetic acid and hydrogenated in the presence of sodium acetate (1.0 g) and 5% Pd–C (250 mg) at atmospheric pressure. The conversion of **9** to **8a** and **8b** was followed by glc. When 230 ml of hydrogen gas had been absorbed, the reaction was stopped. After the filtration of the catalyst and the sodium acetate, the filtrate was concentrated under reduced pressure. Toluene (10 ml) was added to the residue. The toluene solution was evaporated to remove acetic acid under reduced pressure. The syrup (2.88 g) thus obtained was found by glc to contain 43% of **8a**, 37% of **8b**, 2% of **9**, 4% of **10**, 9% of **11**, and 5% of **7**.

This syrup was dissolved in 30 ml of conc. ammonium hydroxide, and the solution was stirred for 2 days at room temperature. The excess of ammonium hydroxide was evaporated under reduced pressure, 90 ml of 3 M hydrochloric acid was added, and the solution was refluxed for 2 hr. The solution was then evaporated under reduced pressure. The residue was dissolved in water (30 ml), and the aqueous solution was placed in an ion-exchange column containing 100 ml of IR-120 resin (acid form). The resin was washed with water, and the absorbed amino acids were eluted with 0.2 M ammonium hydroxide. The elute was concentrated under reduced pressure and decolorized by the use of decolorizing resin (Hokuetsu Tanso Co.'s HS decolorizing resin). By analysis using the automatic amino-acid analyzer, the solution was found to contain 0.409 g (31.2 mmol) of hydroxyproline, 0.478 g (36.5 mmol) of *allo*-hydroxyproline, and trace amounts of unidentified ninhydrin positive substances. The optical purity of the 4-hydroxyproline thus obtained was determined by the above-mentioned method. The hydroxyproline was composed of 95.9% of the L-isomer and 4.1% of the D-isomer, while the *allo*-hydroxyproline was composed of 97.1% of the D-isomer and 2.9% of the L-isomer.

The solution was evaporated to dryness under reduced pressure. The residue was recrystallized from water–ethanol to give 0.784 g (5.98 mmol) of a mixture composed of 44.8% of **1** and 55.2% of **2** in a 40% yield based on **7**: mp 239 °C (decomp.); $[\alpha]_D^{31}$ $-1.72\pm0.25°$ (*c* 2.03, water). Found: C, 45.71; H, 7.02; N, 10.89%. Calcd for $C_5H_9O_3N$: C, 45.79; H, 6.91; N, 10.68%. In the mixture thus obtained, D-hydroxyproline and L-*allo*-hydroxyproline were not found by the above-mentioned method used to determine the optical purity.

Interconversion between L-*Hydroxyproline (1) and* D-allo-*Hydroxyproline (2).* A solution of **2** (0.500 g, 3.82 mmol) in water (5 ml) was sealed in a glass tube and heated for 2 hr at 200 °C. The tube was then cooled and opened, and the solution was filled up to 50 ml. The specific rotations, $[\alpha]_D^{30}$ (*c* 1.00, water), of the solution and authentic **1** and **2** were -16.0, -76.0, and $+58.6°$ respectively. Therefore, the solution contained 55.4% of **1** and 44.6% of **2**. The analytical results obtained by means of the automatic amino-acid analyzer showed that the solution was composed of 56.2% of **1** and 43.8% of **2**. The experiments were similarly carried out while varying the heating time. The following results were obtained: 19.1% of **1** at 15 min, 42.4% of **1** at 30 min, 49.5% of **1** at 1 hr, 52.1% of **1** at 1.5 hr, 55.4% of **1** at 2 hr, 55.8% of **1** at 3 hr, 54.9% of **1** at 5 hr, and 55.5% of **1** at 6 hr. The experiments were similarly done at 150, 180, 200, and 220 °C by using **1** or **2** as the starting material.

Solubility of L-*Hydroxyproline (1) or* D-allo-*Hydroxyproline (2) in Water.* A suspension of **2** (10 g) in water (10 ml) was stirred at 32.0 ± 0.1 °C overnight. The supernatant solution (1.585 g) was then taken up and dried at 80 °C until the weight became constant. The rsidue weighed 0.580 g. Therefore, the solubility of **2** in water at 32 °C was determined to be 57.7 g/100 g-water. The solubilities of **1** or **2** in water were similarly determined at different temperatures.

The authors wish to express their thanks to Professor Naoki Inamoto of the University of Tokyo for his valuable suggestions and to Dr. Takehiko Ichikawa for his many helpful discussions.

The One-electron Reduction of Carbonium Ions. VI. The Trapping of the Cycloheptatrienyl Radical with 2-Methyl-2-nitrosopropane in the Course of the Zinc Reduction of the Tropylium Ion*

Kunio OKAMOTO and Koichi KOMATSU

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received January 5, 1974)

The zinc reduction of the tropylium ion was carried out in the presence of 2-methyl-2-nitrosopropane (a radical scavenger) in H_2O–THF (7: 3 by volume) at room temperature. In the reaction mixture with a short reaction time (5 min), *t*-butyl tropyl nitroxide (II) (a radical-trapping product) was identified by the ESR analysis. α-Phenyl-*N*-*t*-butylnitrone (I), which was isolated from the reaction mixture during a prolonged reaction time (30 min), was proved to be derived from the nitroxide II through the hydrogen abstraction by *t*-butyl nitroxide, which was itself formed from 2-methyl-2-nitrosopropane *in situ* in the acidic reaction mixture in the presence of zinc powder. The hydrogenation (on Pd/C) of the product mixture for a short reaction time (1 min) gave *N*-*t*-butyl-*N*-cycloheptylhydroxylamine and bicycloheptyl. On the basis of these observations, it is concluded that the primary product of the zinc reduction of the tropylium ion must be the tropyl radical.

The formation of bitropyl by the zinc reduction of the tropylium ion was first found by Doering and Knox.[1] They suggested an initial "one-electron" reduction, resulting in the formation of the tropyl (cycloheptatrienyl) radical, and a subsequent radical coupling. Since this mechanism seems certainly to be the most probable one, we have been considering the same mechanism in our series of studies of the reduction of substituted tropylium ions.[2] However, there has been no clear and direct evidence for the intervention of the tropyl radical in the course of the bitropyl formation. Thus, in order to confirm the validity of this mechanism, we have applied the "spin-trapping" technique[3] using *t*-nitrosobutane (2-methyl-2-nitrosopropane) to the zinc reduction of the tropylium ion.

Results and Discussion

The tropylium ion was allowed to react with an excess of zinc powder in the presence of 8 molar equivalents of *t*-nitrosobutane in H_2O–THF (7: 3 by volume) at room temperature for 30 min. The reaction products were then separated by elution chromatography to give bitropyl, α-phenyl-*N*-*t*-butylnitrone (I), and a comparable amount of *N*-*t*-butylhydroxylamine. The product distributions for the shorter reaction times were also examined to give the results summarized in Table 1.

The yields of bitropyl are almost invariable (50± 5%), whereas those of the nitrone I and *N*-*t*-butylhydroxylamine definitely increase with a prolonged reaction time. On the other hand, an analysis of the aqueous layer by means of ultraviolet spectroscopy revealed that the tropylium ion was completely consumed within one minute.

These results seem to indicate that the zinc reduction, which initially gives a primary product (presumably the tropyl radical), is rapidly completed and that about a half of the primary product so formed is trapped by *t*-nitrosobutane to give a transient product (II), which subsequently rearranges to the nitrone I[4] (see Scheme 1).

Table 1. The product distribution for the zinc reduction of the tropylium ion in the presence of *t*-nitrosobutane[a]

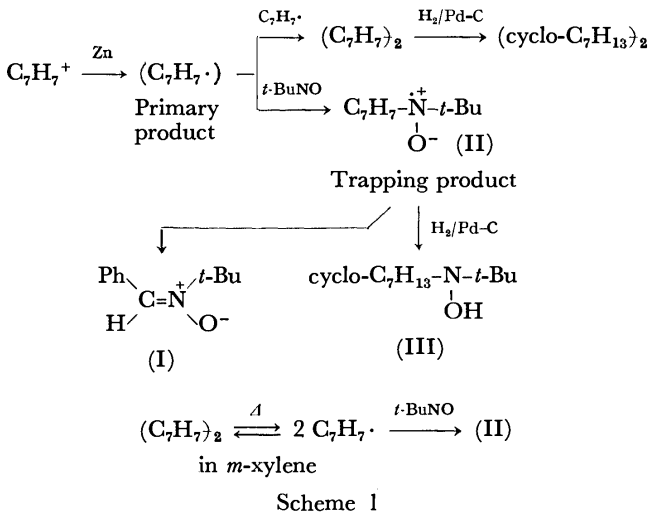
Reaction time, min	Temp. °C	Yield, %		
		Bitropyl	Nitrone I	Hydroxylamine[b]
1	24.0	50.4	4.4	~0
2	31.0	54.3	8.6	~0
15	31.0	45.5	32.0	~10.7
30	31.0	47.1	42.6	~21.0

a) [Tropylium fluoroborate] = 1.91×10^{-2} M; [Zn] = 5.0 atom equivalent with respect to the tropylium ion; [*t*-BuNO] = 0.153 M; Solvent = H_2O–THF (7: 3 by volume).
b) *N*-*t*-Butylhydroxylamine; the yield is calculated with reference to the tropylium ion. The real yield of this compound is supposed to be greater; see Ref. 15 in the Experimental.

The attempt to isolate this transient product was unsuccessful because of its instability and volatility. However, the reaction mixture with a short reaction time (5 min), after the usual work-up and vacuum distillation, gave a red oil which, after an immediate dissolution in benzene, exhibited an ESR spectrum composed of an equivalent triplet of the doublet; this radical was assigned to be *t*-butyl tropyl nitroxide (II) (a_N = 14.6 G, a_H = 2.2 G), the trapping product. The identical ESR spectrum was observed in the reaction of *t*-nitrosobutane with the tropyl radical, which was itself produced by the thermal dissociation of bitropyl[5] in *m*-xylene at 60 °C (see Experimental). Furthermore, when the product mixture with a short reaction time (1 min) was catalytically hydrogenated on palladium-carbon, *N*-*t*-butyl-*N*-cycloheptylhydroxylamine (III), which was supposedly derived from the trapping product (the nitroxide II), was isolated (9% yield), along with bicycloheptyl, which was produced by the hydrogenation of bitropyl. These results are illustrated in Scheme 1.

The control experiments to examine the course of the

* Presented at the 24th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1971.

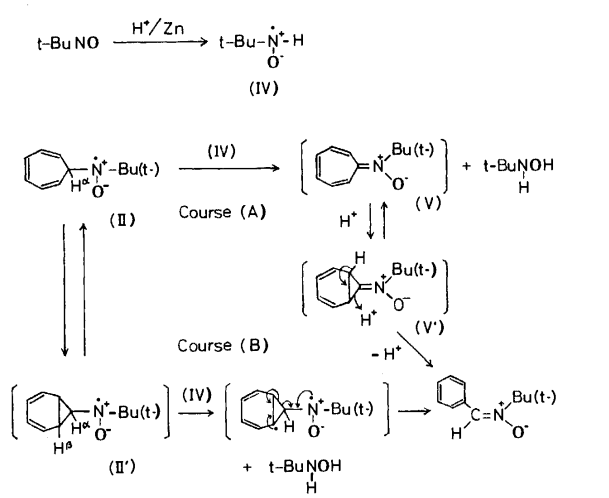


Scheme 1

formation of I indicated that the coexistence of three components, *i.e.*, *t*-nitrosobutane, zinc, and proton,[6] is a necessary condition in order to transform II into I. That is, the three reactions were continued for 30 min each after the immediate removal of the *t*-nitrosobutane (by bubbling off with air), zinc powder (by filtration), and proton[6] (by neutralization with NaOH) from the reaction mixtures with a short reaction time (1 min); no more than a trace amount of the nitrone I was detected in any of the reaction mixtures, whereas bitropyl was always found as the major product.

In another control experiment, the interaction of *t*-nitrosobutane with zinc in an aqueous tetrahydrofuran solution, acidified by the addition of acetic acid,[6] was found to give *t*-butyl nitroxide (IV), which was identified by means of its ESR spectrum (an equivalent triplet of doublet; $a_N = 13.9$ G, $a_H = 12.9$ G[7]). In addition, a nitroxide radical is known to be able to abstract a hydrogen atom.[8]

Consequently, it is most probable that, in the mixture with a prolonged reaction time, the nitroxide IV is produced *in situ* and that it immediately abstracts a hydrogen atom from the nitroxide II or its valence tautomer, II', to give *N*-*t*-butylhydroxylamine. This is illustrated in Scheme 2.



Scheme 2.

In Course (A), the nitrone V would be produced by the abstraction of α-hydrogen of the nitroxide II, and would subsequently be converted into the nitrone I through a norcaradiene-type intermediate, V', under acidic conditions in the reaction mixture or in the course of isolation, *e.g.*, during elution chromatography on silica gel.

As for Course (B), it is supposed that the cycloheptatriene-norcaradiene equilibrium lies to the norcaradiene side (II') when the electron-withdrawing nature of the partially polarized N–O bond in the nitroxide II is taken into consideration.[9] The subsequent β-hydrogen abstraction from the norcaradienyl system (II') to give the benzal system (I) seems plausible by analogy with the ionic rearrangements of a similar type found in the literature.[1,10] Thus, the preferred course (A or B) of the formation of the nitrone I from the nitroxide II has not yet been completely clarified.

However, on the basis of the ESR spectrum of the nitroxide II and of the isolation of the nitrone I and also the hydroxylamine III from the reaction mixture, it may be concluded that the primary product of the zinc reduction of the tropylium ion must be the tropyl radical.

Experimental[11]

Materials. Tropylium fluoroborate and *t*-nitrosobutane were prepared according to the methods of Conrow[12] and of Emmons[13] respectively. The zinc powder was of a reagent-grade quality. THF was distilled over 2,6-di-*t*-butyl-*p*-cresol; bp 66.0—66.2 °C.

Zinc Reduction of the Tropylium Ion in the Presence of t-*Nitrosobutane.* The Procedures for a representative run with the reaction time of 30 min will now be described. To a stirred solution of 0.750 g (4.20 mmol) of tropylium fluoroborate and 2.95 g (33.9 mmol) of *t*-nitrosobutane in 220 ml of H_2O–THF (7: 3 by volume), we added 1.38 g (21.0 mg-atom) of zinc powder under an atmosphere of nitrogen. After a 30 min reaction at 31 °C in the dark, the excessive zinc powder was filtered off. The filtrate was then worked up in the usual way to give 0.667 g of a partially-solidified red oil, which was then chromatographed over 25 g of silica gel (Nakarai, No. II-A, 100—200 mesh). Elution with *n*-hexane–benzene (4: 1 by volume) afforded 0.180 g (0.989 mmol) of bitropyl as white crystals, with an infrared spectrum identical with that of the authentic sample; 47.1% yield. The fractions eluted with benzene–ether (3: 2 by volume) gave 0.317 g (1.79 mmol) of the nitrone I as white crystals; its identity was established by means of the infrared and ultraviolet spectra and by a mixed mp; 42.6% yield; mp 73.0—74.5 °C (lit,[14] mp 75—76 °C). On the other hand, fractions eluted with ethanol and the ethereal extracts of the aqueous layer, which had been made alkaline, gave 0.0870 g[15] (0.978 mmol) of *N*-*t*-butylhydroxylamine as pale yellow crystals, which exhibited an infrared spectrum identical with that of the authentic sample; 2.9% yield based on *t*-nitrosobutane; 23.3% of the tropylium ion used.

In another run on half the scale of the above-mentioned reaction, after a reaction time of 5 min and the usual work-up, the reaction mixture was distilled under a vacuum to give 0.0184 g of a brownish-red oil; bp 70—85 °C (bath temperature)/0.4 mmHg. The distillate was immediately dissolved in benzene and sealed in a Pyrex tube (outer diameter, 4 mm) under a vacuum. An ESR spectrum was taken on

the sample to give the results described in the text.

Hydrogenation of the Crude Product Mixture. In the same way as has been described above, 1.00 g (5.60 mmol) of tropylium fluoroborate was reduced with 1.83 g (28.0 mg-atom) of zinc powder in the presence of 3.90 g (44.8 mmol) of *t*-nitrosobutane in 292 ml of H_2O–THF (7: 3 by volume) at room temperature. After 1 min, the reaction mixture was worked up and concentrated *in vacuo* to *ca.* 10 ml, which was subsequently hydrogenated over 0.8 g of palladium carbon (Nakarai, 5%) in dry THF to give 0.519 g of a yellowish oil. From this oil we isolated 0.315 g (1.62 mmol) of bicycloheptyl (58% yield; NMR, τ_{CCl_4} 7.9 (br, m, 2H, methine), 8.5 (br, s, 24H, methylene); $\nu_{max}^{CCl_4}$ 1450 (sh), 1460, 2870, 2940 cm^{-1}) and 0.088 g (0.51 mmol) of *N*-*t*-butyl-*N*-cycloheptylhydroxylamine (9.2% yield; NMR, τ_{CCl_4} 6.3 (br, s, 1H, methine), 7.1 (br, s, 1H, OH), 8.5 (br, s, 21H, methylene, methyl); $\nu_{max}^{CCl_4}$ 1025, 1120, 1215, 1350, 1380, 1450 (sh), 1460, 2870, 2930, 3420, 3630 cm^{-1}), by the use of preparative thin-layer chromatography over silica gel (Merck, Kieselgel PF_{254}), with benzene–ether (2: 1) as the eluent.

Found: C, 71.53; H, 12.30%. Calcd for $C_{11}H_{23}NO$: C, 71.30; H, 12.51%.

Reaction of t-*Nitrosobutane with Zinc in an Acidic Solution. ESR Measurements.* Into a Pyrex tube (outer diameter, 10 mm) with a capillary side tube (outer diameter, 1 mm) for ESR measurement, we charged 0.020 g (0.23 mmol) of *t*-nitrosobutane and 0.10 g (1.5 mg-atom) of zinc powder. The tube was then connected to a vacuum line, and 1.6 ml of a solution of acetic acid (0.04 M) in H_2O–THF (1: 1 by volume) was transferred into the tube with vacuum distillation. After sealing off the tube under a vacuum, the mixture was shaken at room temperature in the dark and an ESR spectrum of the supernatant solution was immediately recorded to give the results described in the text.

Thermal Dissociation of Bitropyl in the Presence of t-*Nitrosobutane. ESR Measurements.* Into a Pyrex tube (outer diameter, 5 mm) for ESR measurement, we charged 0.015 g (0.17 mmol) of *t*-nitrosubutane and 0.090 g (0.50 mmol) of bitropyl, which had been purified by sublimation (50 °C/1 mmHg). The tube was then connected to a vacuum line, and 0.5 ml of dry *m*-xylene was added by vacuum distillation. After being sealed off under a vacuum, the tube was shaken well in the dark and introduced into the ESR cavity, which had been kept at 60 °C with JEOL variable-temperature equipment, JES-UCT-2X. After 10 min, signals composed of an equivalent triplet of a doublet (a_N=14.5 G, a_H=2.2 G) began to appear in the ESR spectrum and kept increasing in intensity.

3) *cf.* E. G. Janzen, *Accounts Chem. Res.*, **4**, 31 (1971).

4) A control experiment indicated that the tropylium ion itself reacts slowly with *t*-nitrosubutane to yield a small amount (1.6%) of the nitrone I after 30 min at room temperature. However, 68.5% of the tropylium ion was recovered unchanged in this case. An ionic mechanism may be supposed to be operating.

5) Bitropyl is reported to yield the tropyl radical by homolytic thermal dissociation (G. Vincow, H. J. Dauben, Jr., F. R. Hunter, and W. V. Volland, *J. Amer. Chem. Soc.*, **91**, 2823 (1969)). Thus, it is most probable that the tropyl radical is trapped by *t*-nitrosobutane to give *t*-butyl tropyl nitroxide (II).

6) The acidity of an aqueous solution of the tropylium ion is reported to be almost equal to that of an aqueous solution of acetic acid (W. von E. Doering and L. H. Knox, *J. Amer. Chem. Soc.*, **76**, 3203 (1954)).

7) The lit. ESR: a_N=13.4 G, a_H=12.5 G (in methanol), a_N=13.8 G, a_H=13.8 G (in water); the ratio of a_N to a_H is strongly dependent on the solvent polarity (Th. A. J. W. Wajer, A. Mackor, and Th. J. de Boer, *Tetrahedron*, **25**, 175 (1969)).

Oxidation by Iron(III) Complexes. VIII. The Reactions of Iron(III) Chloride with Toluene and Substituted Toluenes[1]

Hiroo Inoue, Megumu Izumi, and Eiji Imoto
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received January 21, 1974)

The thermal and photochemical reactions of toluene with anhydrous iron(III) chloride in the solid state result in nuclear chlorination. In a homogeneous system, a side-chain reaction occurs under irradiation with light, although no product is obtained in the thermal reaction. The addition of water to the iron(III) chloride–toluene system in the range of the molar ratio of 1—5 changes the course of the photochemical reaction; in the water/iron(III) chloride molar ratios of 1—1.7, 3, and 4—5, the main products are the diphenylmethane-type compound, *o*- or *p*-chlorotoluene (*o*>*p*), and benzyl chloride respectively. Pyridine as a ligand acts to give benzyl chloride selectively. The Mössbauer data of the $FeCl_3/nH_2O$ solid show that the arrangement of the Cl^- ion around the Fe(III) ion changes upon the addition of water. The thermal and photochemical reactions of *p*-methoxytoluene with anhydrous iron(III) chloride give 2,2′-dimethoxy-4,4′-dimethylbiphenyl by oxidative aryl coupling. Water inhibits the aryl coupling reaction.

Previously we investigated the photo-oxidative cleavage of the carbon-carbon bond of 1,2-glycols[2] and the carbon-carbon coupling of the active methylene group of alkyl aryl ketones in the presence of iron(III) chloride.[3] As part of a series of studies of oxidation by iron(III) salts, we will here investigate the oxidation of toluenes by iron(III) chloride.

Anhydrous iron(III) chloride reacts with alkylbenzenes to bring about nuclear chlorination, the formation of diphenylmethane-type hydrocarbons, and polymerization.[4,5] Furthermore, the reaction of toluene and iron(III) chloride-lithium chloride in acetic acid under ultraviolet irradiation gives benzyl chloride and iron(II) chloride.[6] In this paper, we will describe the role of a ligand environment around the Fe(III) ion in controlling various competing reactions and the effect of the substituent at the *p*-position of toluene upon the reaction pathway. Some of the results of this investigation have been reported in a previous communication.[7]

Results and Discussion

Reaction of Toluene with Iron(III) Chloride. Thermal Reaction: When a homogeneous solution of iron(III) chloride in toluene was heated at 70 °C, no product was detected by glc. In a heterogeneous system, however, the isomeric chlorotoluenes (I) (*o*: (*m*+*p*)=13: 87) were produced in a satisfactory yield, along with iron(II) chloride (Table 1). The isomer distribution reflects the electrophilic property of the chlorination species.

$$C_6H_5CH_3 \xrightarrow[\Delta]{(FeCl_3)_m} ClC_6H_4CH_3$$
I

Photo-reaction: The irradiation of a homogeneous solution of iron(III) chloride in toluene yielded 98% phenyltolylmethanes (II) with an isomer ratio of *o*: *p*= 46: 54, plus a small amount of bibenzyl. When the iron(III) chloride was dispersed in toluene, I was produced along with II. The isomer distribution coincided with that in the thermal reaction. Although the amount of I produced under irradiation with light increased with the increase in the amount of iron(III) chloride dispersed, the amount of II came to be nearly constant independently of the dispersion amount; it depended on that of the iron(III) chloride dissolved in the toluene, as is shown in Fig. 1. Thus, anhydrous iron(III) chloride in the solid state undergoes nuclear chlorination. Iron(III) chloride has been reported to exist as a dimer (III) in non-polar solvents.[8] On the other hand, the iron(III) chloride in the solid state has a $FeCl_6$ octahedral structure (IV) as a structural unit, as will be described later. Thus, the structure of the iron(III) chloride in the reaction system affects the reaction course of either the nuclear chlorination or the side-chain reaction.

Effect of Water. Water was added to an anhydrous iron(III) chloride–toluene system consisting of 1.4 mmol of iron(III) chloride in 10 ml of toluene (Table 1).

At the water/iron(III) chloride molar ratio (n) of 1.7, the thermal reaction gave I and II in low yields of 6 and 10% respectively (70 hr). At molar ratios higher than 3, no product was detected by glc. In the photoreaction, however, I, II, and benzyl chloride (V) were obtained in higher yields. Furthermore, the yields changed depending on the value of n (Table 1). At n=1—1.7, the reaction yielded II along with the small amount of I. This phenomenon was similar to the results of the thermal toluene–copper(II) bromide reaction.[9] However, the course of the reaction again altered in the direction of nuclear chlorination with the predominance of the o-position (o: (p+m)=67: 33) upon the further addition of water. In addition, V was obtained. The maximum selectivity for nuclear chlorination was observed at n=3. When n became larger than 3, the yields of I and II decreased and that of V increased. The maximum yield of V was observed at n=4—5. Thus, water significantly changes the course of the photochemical reaction of toluene with iron(III) chloride.

$$C_6H_5CH_3 \xrightarrow[h\nu]{FeCl_3/(4-5)H_2O} C_6H_5CH_2Cl$$
V

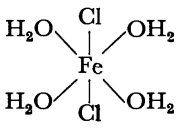
Table 1. The reaction of toluene with iron(III) chloride[a]

Additive	Molar ratio Additive/$FeCl_3$	Therm. or $h\nu$	Yield of product, %[b] I(o/p+m)	II(o/p)[e]	V
None[c]	0	70 °C	60(13/87)	0	0
None[d]	0	$h\nu$	44(13/87)	51(46/54)	0
H_2O	1.7	70 °C	6	10	0
H_2O	1.7	$h\nu$	12(65/35)	52(46/54)	0
H_2O	3	70 °C	0	0	0
H_2O	3	$h\nu$	54(67/33)	10(48/52)	28
H_2O	4—5	$h\nu$	0	8	91
C_5H_5N	5	$h\nu$	0	0	100

a) Reaction time: 70 hr. Amount of $FeCl_3$: 1.4—1.6 mmol in 10 ml of toluene. b) The yields of I, II, and V were calculated from 2 × (number of moles of the products/that of $FeCl_3$) × 100. c) Yield of $FeCl_2$: 77%. d) Yield of $FeCl_2$: 96%. e) The isomer distribution of phenyltolylmethanes which were prepared by the reaction of toluene with benzyl chloride in the presence of iron(III) chloride was o/p=43/57.

Effect of Pyridine. When the pyridine/iron(III) chloride molar ratio was higher than 1, the thermal reaction (70 °C, 70 hr) yielded I in a yield lower than 10% and the photochemical reaction gave (V) selectively; thus, the yield of V was 100% in the molar ratio of 5 (Table 1). II was not obtained at all in the thermal and photochemical reactions. This finding was similar to that in the case of water.

Mössbauer Data. The Mössbauer spectra were measured at room temperature for the iron(III) chloride solid containing water at n=1.7, 3, and 6. The results are compared in Table 2. All the samples are characterized by approximately the same isomer shift (0.38—0.44 mm/s). Thus, the electron density at the Fe nucleus appears to be about the same. However, the quadrupole splitting (Q.S.) changes with the amount of water. Anhydrous iron(III) chloride exhibits a single narrow resonance line, Q.S.=0. This means that the anhydrous salt has a $FeCl_6$ octahedra (IV) as a structural unit.[10] In $FeCl_3/6H_2O$, we found Q.S.= 0.83 mm/s, which was the same as was found by Nozik and Kaplan.[10] An X-ray diffraction study[11] shows that the structural unit in the crystal is the octahedral complex $Fe(H_2O)_4Cl_2$, with the Cl^- ions being coaxial (VI). On the other hand, in $FeCl_3/3H_2O$ we found Q.S.=0.36 mm/s. This indicates that the arrangement of the Cl^- ion and H_2O surrounding the central Fe(III) ion differs from the case of $FeCl_3/6H_2O$. The $FeCl_3/1.7H_2O$ solid exhibits a broad resonance line, thus indicating that the arrangement of the Cl^- ions is disturbed by water.



VI

Table 2. Mössbauer data of the $FeCl_3/nH_2O$ solid

$FeCl_3/nH_2O$	Isomer shift mm/s	Q.S. mm/s
$FeCl_3$	0.44	0
$FeCl_3/1.7H_2O$	0.44	—
$FeCl_3/3H_2O$	0.38	0.36
$FeCl_3/6H_2O$	0.45	0.83

Reaction Pathway. When the $FeCl_3/nH_2O$ solid is irradiated with light, the Cl· ion is oxidized by the excited Fe(III) ion, thus leading to the formation of Cl·(VII). The reactivity of the Cl· thus formed is

$$(FeCl_3\text{-}nH_2O)_m \xrightarrow{h\nu} (Cl\cdot FeCl_2\text{-}nH_2O)(FeCl_3\text{-}nH_2O)_{m-1}$$
VII

affected by the ligand environment around the Fe(III) ion and affords either nuclear chlorination or hydrogen abstraction from the methyl group leading to the benzyl radical. That is, the iron(III) chloride solid (n=0) with the structure of Fe–Cl···Fe undergoes nuclear chlorination. When the iron(III) chloride solid contains water, the reaction proceeds *via* the formation of the benzyl radical, followed by the Friedel-Crafts reaction giving II in the case of n=1—1.7, or by ligand-transfer oxidation[12] giving V in the case of n=4—5. In the case of n=3, however, the reaction pathway is uncertain. The formation of I (o>p) may mean that the ligand-transfer oxidation of the benzyl radical occurs at the o- or p-position. However, the reason why the reaction pathway changes with the arrangement of the Cl^- ion and water around the Fe(III) ion is not yet clear.

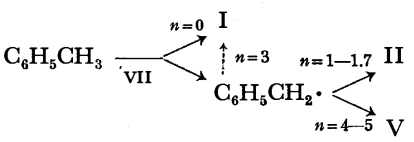


Table 3. The reactions of the substituted toluenes with iron(III) chloride[a]

p-Substituent	Additive	*n*	Therm. or *hν*	Yield of product,[b] %					Polymer mg
				N–Cl	S–Cl	$-CH_2-$	N–N	$FeCl_2$

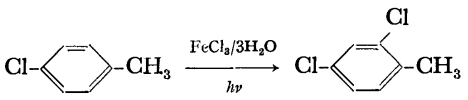
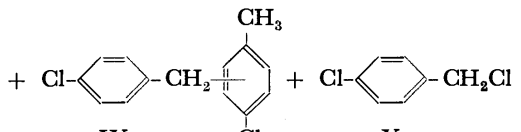
CH_3O	H_2O	3	*hν*	—	—	35	0	53	40

a) Amount of $FeCl_3$: 1.4—1.7 mmol in 10 ml of toluene. Reaction time: 40 hr for *p*-chlorotoluene and 20 hr for *p*-methoxytoluene. b) N–Cl, S–Cl, $-CH_2-$, and N–N: nuclear chlorination, side-chain chlorination, formation of diphenylmethanes, and aryl coupling, respectively. c) This run was made at ten times scale (86 hr).

Reactions of the p-*Substituted Toluenes with Iron(III) Chloride. Chloro Group*: The thermal and photochemical reactions of *p*-chlorotoluene with dispersed iron(III) chloride resulted in nuclear chlorination and a side-chain reaction, although the total yields of the products became lower than that of iron(II) chloride, as Table 3 shows. The other products could not be detected by means of glc. In the thermal reaction, the yield of the nuclear chlorination product, 2,4-dichlorotoluene (VIII), became lower than that in the case of toluene, but the mixture (IX) of 2,4′-dichloro-5-methyldiphenylmethane and 3,4′-dichloro-6-methyldiphenylmethane was produced in addition to the (VIII). In the photo-reaction, the yield of (IX) became higher than that of (VIII). When the $FeCl_3/3H_2O$ solid was used, *p*-chlorobenzyl chloride (X) was produced in addition to (VIII) and (IX). Among these products, the yield of (VIII) became higher in spite of deactivation by the chloro group at the *p*-position. These results were similar to those in the case of toluene.

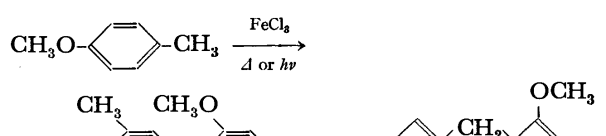


VIII



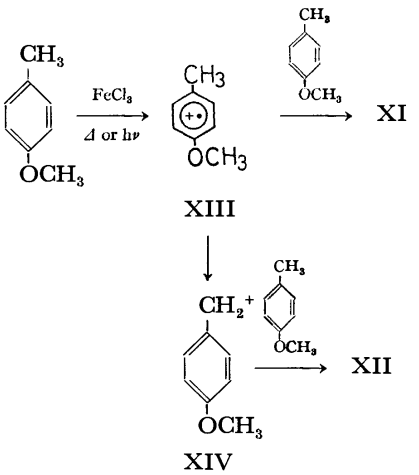
IX Cl X

Methoxy Group: A solution of iron(III) chloride in *p*-methoxytoluene, containing partially-insoluble iron(III) chloride, was heated at 70 °C for 20 hr. As Table 3 shows, 2,2′-dimethoxy-4,4′-dimethyldiphenyl (XI) was thus produced in a 19% yield by the coupling of two benzene nuclei, accompanied by the formation of 2,4′-dimethoxy-5-methyldiphenylmethane (XII) in a 13% yield. The other aryl coupling products were not obtained. In the reaction, iron(III) chloride was converted to iron(II) chloride. As another product, *p*-cresol was detected by means of glc, although the amount produced was very small. The total yields of the products became lower than that of iron(II) chloride because of the formation of a polymeric material. The yield of (XI) increased under irradiation with light; (XI) and (XII) were obtained in 41 and 21% yields respectively, while in the dark the yields of (XI) and (XII) were 5—6 and 2% respectively. The formation of (XI) and *p*-cresol indicates that the reaction proceeded *via* the cation radical (XIII) of *p*-methoxytoluene, which is formed by the oxidation of *p*-methoxytoluene by iron(III) chloride, followed by the reaction of (XIII) with *p*-methoxytoluene. The formation of the cation radical as an intermediate has been considered to occur in the oxidative coupling of methyl-substituted benzenoid compounds by lead tetra-acetate,[13] the radical-initiated oxidation of anisol,[14] the metal-catalyzed cyclodimerisation of aromatic enamines,[15] and the reaction of methylated benzil and bibenzyl derivatives with tris-(*p*-bromophenyl)ammonium hexachloroantimonate.[16]



XI XII

On the other hand, the facts that the diphenylmethane-type compound is produced in the homogeneous, thermal reaction and that the reaction occurs at the *o*-position of the methoxy group of *p*-methoxytoluene suggest that the *p*-methoxybenzyl cation (XIV) is formed from XIII and then reacts with *p*-methoxytoluene to give XII. When water was added to the iron(III) chloride-*p*-methoxytoluene system at $n=3$ and the solution was irradiated with light, XII was pro-



duced selectively in a 35% yield, along with a small amount of *p*-cresol. Thus, the aryl coupling was inhibited by water. The amount of the polymeric material produced became smaller.

Experimental

Materials. Anhydrous iron(III) chloride was prepared by the sublimation of commercial iron(III) chloride under the reduced pressure of 1 mmHg at 300 °C. The purity of the iron(III) chloride used was 99—99.8%; it was measured by the methods described in a previous paper.[3]

Toluene and Iron(III) Chloride, General Procedure. Thermal Reaction: The homogeneous solution was prepared by dissolving 0.3 mmol of iron(III) chloride in 10 ml of toluene. In the heterogeneous system, 1.4—1.6 mmol of iron(III) chloride was dispersed under stirring in 10 ml of toluene. The solution was placed in a tube (2 cm × 15 cm) and heated at 70 °C under a nitrogen atmosphere for a desired time. After the resulting reaction mixture had been filtered off to separate the iron(II) chloride, the filtrate was submitted to glc analysis. The products, *o*-, *m*-, and *p*-(I), which were obtained in the heterogeneous system were identified by a comparison of their retention times in glc with those of authentic specimens, and their amounts were determined by means of glc. The grey precipitate was repeatedly washed with benzene, dried, and submitted to the quantitative analysis of the Fe(II) ion.

Photo-reaction: The homogeneous or heterogeneous solution which was prepared above was placed in a Pyrex tube and irradiated with a Pyrex-covered 100 W high-pressure mercury lamp at a distance of 6 cm under a nitrogen atmosphere at room temperature for a desired time. During the reaction, the solution was stirred vigorously. After the reaction mixture had then been filtered off to separate the iron(II) chloride, the amount of I was determined by the glc analysis of the filtrate. II was isolated by glc as a mixture of the *o*- and *p*-isomers and bibenzyl. The NMR spectrum (CCl_4) of II showed signals at δ 2.15 (s, 3H, CH_3), 3.85 (s, 2H, CH_2), and 6.9—7.3 (m, 9H, aromatic protons) for the *o*-isomer, at δ 2.22 (s, 3H, CH_3), 3.90 (s, 2H, CH_2), and 6.9—7.3 (m, 9H, aromatic protons) for the *p*-isomer, and at δ 2.83 (s, 4H, CH_2) and 7.06 (s, 10H, aromatic protons) for bibenzyl. The isomer distribution was calculated from the relative heights of the integrated spectrum. The grey precipitate was iron(II) chloride and did not contain any polymeric material at all. Similar procedures were used for the experiments investigating the effect of the amount of the dispersed iron(III) chloride on the reaction.

Iron(III) Chloride–Water or Pyridine System. Various amounts of water or pyridine were added to 10 ml of toluene containing 1.4 mmol of iron(III) chloride. The solution was then heated or irradiated under conditions similar to those in the case of anhydrous iron(III) chloride. The amounts of I, II, and V thus produced were determined by means of glc.

p-*Chlorotoluene and Iron(III) Chloride.* *(a)*: Anhydrous iron(III) chloride (14.5 mmol) was dispersed in 100 ml of *p*-chlorotoluene, and the solution was irradiated with light for 86 hr under conditions similar to those in the case of toluene. The grey solid (1.71 g) then filtered out had 10.2 mmol of iron(II) chloride. A part of the filtrate was submitted to glc analysis. The products, VIII and IX, were identified by a comparison of their retention times in glc with those of authentic specimens, and their amounts were determined by means of glc. The authentic specimen of IX was prepared by the reaction of X and *p*-chlorotoluene in the presence of iron(III) chloride. Furthermore, IX was isolated by glc as a mixture of 2,4′-dichloro-5-methyldiphenylmethane and 3,4′-dichloro-6-methyldiphenylmethane. The NMR (CCl_4) of (IX) showed signals at δ 2.22 and 2.11 (s, 3H, CH_3), 3.95 and 3.81 (s, 2H, CH_2), and 6.8—7.4 (m, 7H, aromatic protons). The other part of the filtrate was submitted to chromatography on alumina (elution with carbon tetrachloride and then methanol). The elution with methanol gave a brown polymeric material (71 mg).

(b): Anhydrous iron(III) chloride (1.4 mmol) was dispersed in 10 ml of *p*-chlorotoluene, and the solution was heated at 70 °C under a nitrogen atmosphere for 40 hr. The grey solid (198 mg) filtered out had 0.73 mmol of iron(II) chloride. The amounts of VIII, IX, and the polymeric material were determined by a method similar to that used in the case of the photo-reaction (a).

(c): A mixture of anhydrous iron(III) chloride (1.4 mmol) and water (4.3 mmol) was allowed to react with 10 ml of *p*-chlorotoluene under irradiation with light for 40 hr. The identification and the determination of VIII, IX, and X were carried out by methods similar to those used in the cases of (a) and (b).

p-*Methoxytoluene and Iron(III) Chloride.* *(a)*: Anhydrous iron(III) chloride (1.4 mmol) was added to 10 ml of *p*-methoxytoluene, and the solution was irradiated with light for 20 hr under conditions similar to those used in the case of toluene. A red-brown solid (154 mg) was then filtered off, washed twice times with 3-ml portions of benzene, and dried. The solid contained 0.9 mmol of iron(II) chloride. The mixture of the filtrate and the benzene solution was freed off the solvent at 74 °C/25 mmHg. The residue was submitted to chromatography on alumina. Elution with benzene, carbon tetrachloride, and then methanol gave XI, XII, and a brown, oily material containing *p*-cresol respectively. The amounts of XI and XII were determined by means of glc (Table 3). XI, mp 59.5—60 °C (lit,[17] mp 61 °C), exhibited NMR (CCl_4) signals at δ 2.26 (s, 6H, CH_3), 3.62 (s, 6H, OCH_3), and 6.5—7.1 (m, 6H, aromatic protons). Mass spectrum *m/e*; 242 (parent peak).

Found: C, 79.30; H, 7.35%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

XII, mp 72—73.5 °C (lit,[17] 74 °C), exhibited NMR (CCl_4) signals at δ 2.18 (s, 3H, CH_3), 3.65 and 3.68 (s, 6H, OCH_3), 3.76 (s, 2H, CH_2), and 6.4—7.1 (m, 7H, aromatic protons). Mass spectrum *m/e*; 242 (parent peak).

Found: C, 79.20; H, 7.30%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

A similar procedure was used for the photo-reaction in the iron(III) chloride–water system.

(b): Anhydrous iron(III) chloride (1.44 mmol) was allowed to react with *p*-methoxytoluene (10 ml) under a nitrogen atmosphere at 70 °C for 20 hr. The products, XI, XII, *p*-cresol, a red-brown oily material, and iron(II) chloride, were isolated or detected by methods similar to those used in the case of (a).

Mössbauer Spectra. Anhydrous iron(III) chloride was evaporated on aluminium foil supports with spacing of less than 1 mm. The cell was covered by a polyethylene film to prevent the salt from absorbing atmospheric water. An appropriate amount of water was then dropped on the iron(III) chloride film. Gamma rays emitted by the ^{57}Co-in-copper source impinged upon the absorber sample at room temperature. Velocity calibrations were made using the well-known spectrum of natural iron metal as the standard.

Analyses. The quantitative analyses of iron(III) chloride and iron(II) chloride were carried out by the methods

described in the literature.[18] The amounts of the products were determined by means of glc using a 3 mm × 1 m column of 30% high-vacuum silicone grease or 3% Apieson grease L on Celite 545.

The authors are grateful to Dr. Akihiro Tomita, University of Osaka Prefecture, for measuring the Mössbauer spectra.

Carbonylation of Alcohols, Olefins, and Saturated Hydrocarbons by CO in the Ag(I)-H_2SO_4 System

Yoshie SOUMA and Hiroshi SANO

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received July 26, 1973)

In the presence of an Ag carbonyl-ion catalyst, prepared *in situ* from the Ag compound and carbon monoxide in H_2SO_4, olefins or alcohols reacted with carbon monoxide at room temperature and atmospheric pressure to produce exclusively tertiary carboxylic acids in high yields. The amount of Ag compound sufficient for carrying out the reaction is *ca.* 0.2 mol/l. The optimum reaction temperature is 0—40 °C. The reaction proceeds practically at above a 90% H_2SO_4 concentration. Saturated hydrocarbons, containing a tertiary hydrogen, also reacted with carbon monoxide in the presence of alcohols or olefins as carbonium ion precursors, thus producing tertiary carboxylic acids.

In our previous papers, we have reported the carbonylation reactions of olefins,[1] alcohols,[2] and saturated hydrocarbons[3] by the catalysis of the Cu(I) carbonyl ion[4] to produce tertiary carboxylic acids in high yields at room temperature and atmospheric pressure. The present investigation will deal with the use of the Ag compound as a catalyst for the same reaction.

Results

Olefins or alcohols react with carbon monoxide in the presence of the Ag carbonyl ion catalyst in a concd H_2SO_4 solution at room temperature and atmospheric pressure to produce tertiary carboxylic acids exclusively, because olefins or alcohols are protonated and rearrange to the most stable tertiary carbonium ion prior to the carbonylation. The results are shown in Table 1.

Table 1. Carbonylation of olefin or alcohol[a]

Substrates	Temp. (°C)	Time (min)	Products R_1	R_2	Yield (%)
1-Hexene	30	40	*n*-C_3H_7	CH_3	80
			C_2H_5	C_2H_5	16

					trans 33

a) In all cases, 8 mmol of Ag_2O, 40 ml of 98% H_2SO_4, and 20 mmol of olefins or alcohols were used. The pressure of carbon monoxide was 1 atm.

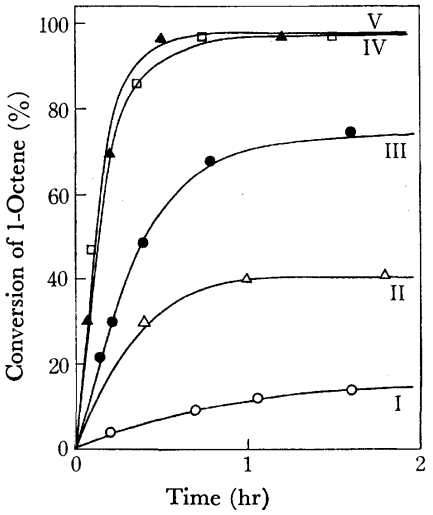

Fig. 1. The catalytic effect of Ag_2O.
1-Octene 5 mmol and 98% H_2SO_4 10 ml were used at 30 °C.
I: Ag_2O 0 mmol, II: Ag_2O 0.1 mmol, III: Ag_2O 1 mmol, IV: Ag_2O 2 mmol, V: Ag_2O 4 mmol.

The effect of the amount of Ag compound is illustrated in Fig. 1. Without Ag_2O, the rate of reaction is very slow and the yield of carboxylic acid is less than 15%. When Ag_2O is added in concd H_2SO_4, the rate of reaction and the yield increase considerably. The amount of Ag_2O sufficient for carrying out carbonylation is *ca.* 0.2 mol/l. In concd. H_2SO_4, the polymerization reaction proceeds in competition with the carbonylation reaction of olefin. When the amount of Ag_2O is not enough, the CO concentration enriched by Ag^+ in the solution is not sufficient for its reaction with the carbonium ion. Therefore, polymerization predominates over carbonylation.

Saturated hydrocarbons bearing tertiary hydrogen also react with carbon monoxide in the presence of olefins or alcohols, which form carbonium ions and which can abstract hydride from branched hydrocarbons. The results are shown in Table 2. The added olefins or alcohols in the reaction mixture also yield tertiary carboxylic acid.

As shown in Table 3, the effect of the H_2SO_4 concentration upon the carbonylation is parallel to its

Table 2. The carbonylation of saturated hydrocarbon in the presence of olefin or alcohol[a)]

Substrates	Olefin or alcohol	Reaction time (min)	Products	Yield (%)
Methylcyclohexane	1-Hexene	40	Methylcyclohexanecarboxylic acid	45
			tert-C_7 acids	33
Methylcyclohexane	1-Hexanol	90	Methylcyclohexanecarboxylic acid	42
			tert-C_7 acids	31
Methylcyclohexane	1-Octene	60	Methylcyclohexanecarboxylic acid	72
			tert-C_9 acids	23
1,4-Dimethylcyclohexane	1-Octene	60	1,4-Dimethylcyclohexanecarboxylic acid (*cis*: *trans*=1: 1)	60
			tert-C_9 acids	30
Methylcyclopentane	1-Octanol	120	Methylcyclopentanecarboxylic acid	60
			tert-C_9 acids	27
n-Octane	1-Hexanol	90	*tert*-C_9 acids	0
			tert-C_7 acids	75

a) In all cases, 1.856 g of Ag_2O, 40 ml of 98% H_2SO_4, 20 mmol of saturated hydrocarbons, and 20 mmol of olefins (or alcohols) were used. The reaction temperature was approximately 30 °C. The CO pressure was 1 atm. The components of *tert*-C_7 acids and *tert*-C_9 acids were the same as in Table 1.

effect upon the formation of the unstable Ag carbonyl ion, $Ag(CO)_n^+$, in the H_2SO_4 solution. As was shown in our previous paper, Ag^+ does not absorb carbon monoxide in H_2SO_4 of less than an 80% concentration.

Table 3. The effect of the H_2SO_4 concentration upon the carbonylation[a)]

Concn of H_2SO_4 (wt%)	$Ag(CO)^+/Ag^+$ mol ratio	Conversion of 1-octene, %	Reaction time (min)
100	0.14	97	20[b)]
95	0.07	90	25[b)]
90	0.04	80	90[c)]
85	0.01	17	150[c)]
80	0	0	—

a) 0.928 g of Ag_2O, 1.57 ml of 1-octene, and 20 ml of H_2SO_4 were used at 30°C. The 1-octene was added drop by drop in order to prevent polymerization. b) In concd H_2SO_4, 1-octene reacted with CO immediately after the addition of 1-octene. c) The reaction rate became slower when the concentration of H_2SO_4 was less than 90%.

It seems that Ag compounds form the unstable Ag carbonyl ion by absorbing carbon monoxide in concd H_2SO_4, as in the case of the Cu(I) carbonyl ion:[5)]

$$Ag^+ + nCO \overset{H_2SO_4}{\rightleftharpoons} Ag(CO)_n^+ \quad n=1\sim2$$

The $Ag(CO)_n^+$ is very unstable, and in the presence of such CO acceptors as carbonium ions, CO is liberated from $Ag(CO)_n^+$ and combines with the carbonium ion immediately. That Ag^+ seems to act as a CO carrier to keep a high CO concentration in solution.

Among the compounds, Ag_2O, Ag_2SO_4, and $AgClO_4$ are effective in this reaction. On the other hand, AgCl, AgBr, AgI, and AgCN do not show any catalytic activity. The presence of the halogen atom and CN^- may be supposed to prevent the formation of silver carbonyl ions.

The influence of the reaction temperature was also studied. The results are shown in Table 4.

1-Hexanol reacts with carbon monoxide at 0—30 °C and gives tertiary C_7 carboxylic acids in high yields. The rate of reaction becomes rapid with an increase in the temperature. A linear relationship between $\log k$ and $1/T$ was observed. However, the total yield of carboxylic acids and the proportion of tertiary C_7 carboxylic acid decrease with the increase in the temperature. The explanation of this is that the formation of unstable silver carbonyl ion decreases and the polymerization predominates over carbonylation. In addition, the β scission of carbonium ions begins to proceed with the increase in the temperature. In the reaction of 1-hexene or cyclohexene, the influence of the temperature is almost the same as that in the case of 1-hexanol. However, the rate of reaction is very rapid

Table 4. The influence of the temperature on the reaction of 1-hexanol[a)]

Reaction temp., °C	The total yield of carboxylic acids, %	The component of carboxylic acids				Rate constant $k\times10_5\,s^{-1}$ [b)]	$\frac{Ag(CO)^+}{Ag}$
		t-C_5	*t*-C_6	*t*-C_7	higher acids		
0	99	0	0	100	0	2.78	0.37
10	99	0	0	100	0	4.63	0.30
30	99	0	1	99	0	18.50	0.14
40	83	7	10	77	6	56.0	0.08
55	32	57	25	15	3	—[c)]	0.02

a) 1-Hexanol (10 mmol), Ag_2O (4 mmol), and 98% H_2SO_4 (20 ml) were used. b) The first-order rate constant was calculated from $-d[ROH]/dt=k[ROH]$. c) The rate constant could not be measured because the rate of reaction was too rapid and because the reaction proceeded immediately after the addition of 1-hexanol.

and depends on the rate of the addition of the reactant. The reactant must be added drop by drop to prevent polymerization.

Experimental

Preparation of the Ag Carbonyl Catalyst Solution. In a 300 ml three-necked flask, equipped with a thermometer and a CO gas buret, we placed 1.856 g of Ag_2O and 40 ml of 98% H_2SO_4. The apparatus was evacuated by means of a vacuum pump to remove the air, and then carbon monoxide was introduced from the gas buret. When the mixture was stirred, CO was absorbed by the Ag^+ solution in 10 min.

Carbonylation of Olefins, Alcohols, and Saturated Hydrocarbons. From a syringe, 20 mmol portion of olefins (or alcohols or equimolar mixtures of saturated hydrocarbons and alkylcation sources) was added, drop by drop, to the Ag carbonyl catalyst solution. The carbon monoxide was soon absorbed. After the reaction, the reaction mixture was poured over ice water, and the products were extracted by benzene. The yield of tertiary carboxylic acid was determined by the titration of the benzene extract with a 1/10 M NaOH ethanol solution, and also by gas chromatography by adding a known amount of the internal standard. Glpc analysis was performed using a 3 m FFAP column (10% on Chromosorb WAW).

All the identifications were carried out using authentic samples which had been obtained and characterized by the carbonylation of olefins, alcohols, or saturated hydrocarbons using a Cu(I) carbonyl catalyst.[1-3] The ratios of each isomer of *tert*-C_9 acids and *tert*-C_{11} acids were determined by ^{13}C NMR according to the method described in a previous paper.[2]

The author would like to thank Mr. Nobuyoshi Ookura for his valuable assistance.

Reaction of 2-Benzoylamino-2-methylpropionamidine and 2-Benzoylaminoacetamidine with Bifunctional Compounds

Hiroaki UCHIDA, Akiko CHINONE, and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received November 29, 1973)

The reaction of 2-benzoylamino-2-methylpropionamidine (III) with 1,3-bifunctional compounds was investigated in connection with studies on 2-benzoylaminoacetamidine (I). In case of the reaction of III an appreciable amount of 5,5-dimethyl-2-phenylimidazolin-4-imide (VIII) was formed, the yield of 2-(1-benzoylamino-1-methylethyl)-4,6-dimethylpyrimidine (VI) being low. On the other hand, III reacted with ethyl acetoacetate to give 2-(1-benzoylamino-1-methylethyl)-4-hydroxy-6-methylpyrimidine (IX) in about 50% yield besides VIII. Both III and I were made to react with ethoxymethyleneacetylacetone to yield 5-acetyl-2-(1-benzoylamino-1-methylethyl)-4-methylpyrimidine (X) and 5-acetyl-2-(*N*-benzoylaminomethyl)-4-methylpyrimidine (XI), respectively. Reaction of I with ethoxymethylenemalononitrile gave 4-amino-2-(*N*-benzoylaminomethyl)-5-cyanopyrimidine (XII), but did not proceed with benzoin, malondialdehyde, tetraethoxypropane or phenacyl bromide.

In a previous paper[1] the reactions of 2-benzoylaminoacetamidine (I)[2] and 2-benzyloxycarbonylaminoacetamidine (II)[2] with various 1,3-bifunctional compounds were described. It was pointed out that both I and II react with acetylacetone to produce 2-amino-3-benzoylamino- and 2-amino-3-benzyloxycarbonylamino-4,6-dimethylpyridine, respectively, erroneously reported by Goldberg and Kelly[3] to be pyrimidine derivatives. Reaction of I with ethyl acetoacetate gave 2-(*N*-benzoylaminomethyl)-4-hydroxy-6-methylpyrimidine. However, in every case, concurrent formation of a considerable amount of acylaminoacetamide was observed. The formation of pyridine derivatives is ascribed to the reactive α-methylene group of amidines and depends on the function of 1,3-bifunctional compounds. An amidine which has no α-hydrogen might therefore produce a pyrimidine derivative exclusively. We have investigated the reaction of 2-benzoylamino-2-methylpropionamidine (III) with acetylacetone and ethyl acetoacetate in the presence of alkali.

Amidine (I and III) hydrochlorides were prepared from the nitriles *via* the imidate hydrochlorides following the usual procedure. Shirai and Kurashige[4] reported that the reaction of 2-(*N*-acetyl-*N*-methylamino)-2-methylpropionitrile (IV) with hydrogen chloride and ethanol afforded the corresponding imidate hydrochloride and imidazolone hydrochloride, and ammonolysis of the imidate hydrochloride afforded imidazolinimide hydrochloride instead of the corresponding amidine hydrochloride.

As regards the imidate hydrochloride or amidine hydrochloride we prepared, contaminants in III hydrochloride were trace amounts of ammonium chloride and 2-benzoylamino-2-methylpropionamide (V), formation of imidazolone or imidazolinimide[4] not being observed. Purification of crude III hydrochloride was effected by fractional precipitation by adding ether to the alcoholic solution of the crude product.

Reaction of III with acetylacetone was carried out under various conditions, as shown in Table 1. It can be seen that attempts to improve the yield of 2-(1-benzoylamino-1-methylethyl)-4,6-dimethylpyrimidine (VI) were unsuccessful under all the conditions. The empirical formula of the main product was $C_{11}H_{13}N_3$ which did not change on heating in water. The compound did not seem to change under alkaline conditions where III and acetylacetone undergo reaction, but turned to 5,5-dimethyl-2-phenyl-4-imidazolone (VII) quantitatively on being left to stand with 10% hydrochloric acid at room temperature. Compound $C_{11}H_{13}N_3$ was warmed with acetic anhydride to give a monoacetylated compound. These results and the spectral data identified the product as 5,5-dimethyl-2-phenylimidazolin-4-imide (VIII).

Reaction of III and acetylacetone in ethanol formed VI in relatively high yield in the presence of weak alkali, and in water moderate temperature seemed to be required. Compound V was obtained in trace amount in Expt. 1—3, in several percent yield in Expt. 4—6, and in 17% yield in Expt. 7. Compound VII was obtained in 7% yield in Expt. 7. This might be caused by hydrolysis of VIII, or by cyclization of V

TABLE 1. REACTION OF III[a] WITH ACETYLACETONE

Expt. No.	Solvent	Reaction		Alkali	Molar ratio of III·HCl: alkali	Yield of	
		temp. (°C)	time			VI(%)	VIII(%)
1	C_2H_5OH	reflux	7.5 hr	K_2CO_3	1:1	17	72
2	C_2H_5OH	reflux	7.5 hr	C_2H_5ONa	1:0.2[b]	2	75
3	C_2H_5OH	r.t.	3 day	C_2H_5ONa	1:0.3[b]	5	90
4	H_2O	r.t.	5 day	K_2CO_3	1:1.1	5	26
5	H_2O	r.t.	5 day	NaOH	1:2.2	—	55
6	H_2O	55—60	2 hr	K_2CO_3	1:1.1	17	43
7	H_2O	reflux	1 hr	K_2CO_3	1:1.1	—	56

a) Used in the form of hydrochloride with exception of Reactions 2 and 3. b) Ratio of free III: alkali.

in the presence of alkali as reported by Mohr.[5]

Conversion of III hydrochloride itself was examined under nearly the same conditions as in the reaction with acetylacetone. Under reflux for 5.5 hr in ethanol with an equimolecular amount of potassium carbonate, 82% of III hydrochloride was recovered unchanged and a small quantity of amide V was obtained. Refluxing for 4.5 hr with two molar quantities of sodium ethoxide in ethanol gave VIII quantitatively.

Reaction of III and ethyl acetoacetate gave 2-(1-benzoylamino-1-methylethyl)-4-hydroxy-6-methylpyrimidine (IX), which showed a ring carbonyl band at 1682 cm^{-1} and no hydroxyl group absorption, suggesting it to have the keto form in solid state.

The above results show that competitive reactions occurred between intramolecular cyclization of III to VIII and pyrimidine ring formation from III with acetylacetone or ethyl acetoacetate. An attempt to react III with ethoxymethyleneacetylacetone, which is considered to be highly reactive and favorable for pyrimidine ring formation, gave 5-acetyl-2-(1-benzoylamino-1-methylethyl)-4-methylpyrimidine (X) in a satisfactory yield. The reaction with ethoxymethyleneacetylacetone I was also tried, and 5-acetyl-2-(*N*-benzoylaminomethyl)-4-methylpyrimidine (XI) was obtained. In this case α-methylene group of I did not participate in the reaction and no pyridine compound was formed. The reaction of I with ethoxymethylenemalononitrile resulted in the formation of 4-amino-2-(*N*-benzoylaminomethyl)-5-cyanopyrimidine (XII) which was identified by an alternative synthesis from ethyl 2-benzoylaminoacetimidate and aminomethylenemalononitrile. However, reactions of I with benzoin, malondialdehyde, tetraethoxypropane, and phenacyl bromide resulted in the formation of 2-benzoylaminoacetamide.

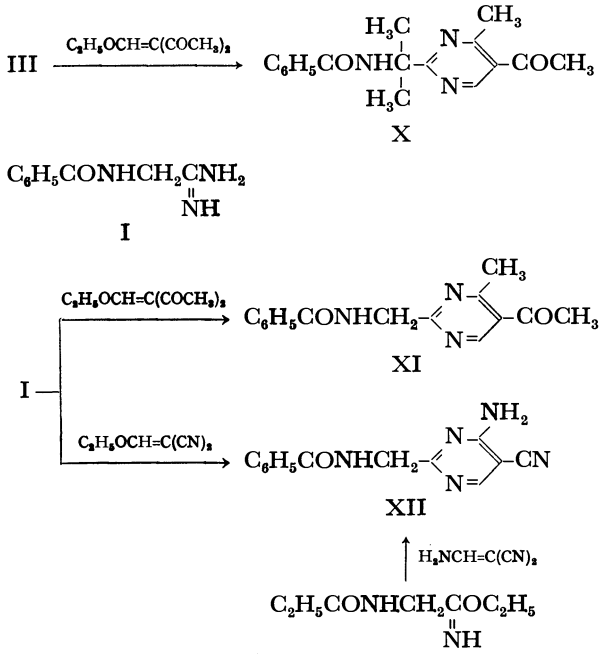

Chart 2

Experimental

All melting points were uncorrected. The NMR spectra were recorded at 60 MHz using tetramethylsilane as an internal standard.

2-Benzoylamino-2-methylpropionamidine(III) Hydrochloride. Hydrogen chloride was introduced to a suspension of 9.4 g (50 mmol) of 2-(*N*-benzoylamino)-2-methylpropionitrile[6] in a mixed solvent of chloroform (55 ml) and benzene (90 ml) containing 2.5 g of ethanol under cooling with ice-salt with occasional shaking, until the nitrile dissolved completely. On being left to stand in a refrigerator a viscous oily product separated which, after removal of the solvent by decantation, was crystallized by the addition of dry ether (150 ml). The resulting crystals were 12.4 g of crude ethyl 2-benzoylamino-2-methylpropionimidate hydrochloride, very hygroscopic, mp 200—202 °C. Found: N, 11.80%. Calcd for $C_{13}H_{19}O_2N_2Cl$: N, 10.35%.

To a solution of ammonia in ethanol (60 ml, 15% by wt) was added the imidate hydrochloride obtained above and the mixture was stirred for 1 hr under cooling with ice. The resulting solution, after being allowed to stand at room temperature for 1 day, was concentrated until crystals began to separate out. Dry petroleum ether (150 ml) was added to the residue, and 10.6 g of crude III hydrochloride was obtained, mp 212—214 °C. Recrystallization from acetonitrile gave colorless needles of III hydrochloride, mp 222—223.5 °C. Found: C, 54.50; H, 6.62; N, 17.68%. Calcd for $C_{11}H_{16}ON_3Cl$: C, 54.66; H, 6.67; N, 17.38%. IR (KBr) cm^{-1}: 3600—2800, 1645, 1536. NMR (DMSO-d_6) τ: 1.09 (s, 4H), 1.31 (s, 1H), 1.83—2.83 (m, 5H), 8.36 (s, 6H).

Crude III hydrochloride (5 g) was dissolved in 70 ml of ethanol, and a small amount of ammonium chloride was precipitated by the addition of 20 ml of dry ether. Additional 125 ml of dry ether gave 4.3 g of colorless needles of III hydrochloride, mp 221—223 °C. The filtrate was concentrated after III hydrochloride had been collected by filtration, and the residue was recrystallized from ethyl acetate to give 0.4 g of colorless needles of V, mp 205—206 °C. Found: C, 63.82; H, 6.89; N, 13.29%. Calcd for $C_{11}H_{14}O_2N_2$: C, 64.06; H, 6.84; N, 13.58%. IR (KBr) cm^{-1}: 3410, 3310, 3225, 3180, 1660, 1640, 1610, 1535. NMR (DMSO-d_6) τ: 1.83 (s, 1H), 1.97—2.69 (m, 5H), 2.97 (bs, 2H), 8.49 (s, 6H).

2-(1-Benzoylamino-1-methylethyl)-4,6-dimethylpyrimidine (VI).

a) Reaction of III with Acetylacetone in Ethanol (Expt. 1, Table 1): To a solution of 1.3 g (13 mmol) of acetylacetone in 30 ml of ethanol was added 2.4 g (10 mmol) of III hydrochloride and 1.5 g (11 mmol) of potassium carbonate, and the mixture was refluxed for 7.5 hr with stirring. The reaction mixture was filtered and the filtrate was concentrated to give crystalline residue. Recrystallization from methanol gave colorless prisms of VIII, mp 246 °C, 0.89 g. Found: C, 70.33; H, 6.88; N, 22.39%. Calcd for $C_{11}H_{13}N_3$: C, 70.56; H, 7.00; N, 22.44%. IR (KBr) cm^{-1}: 3325, 1675, 1603, 1550, 1320, 1290, 703. NMR (DMSO-d_6) τ: 1.65—2.83 (m, 5H), 2.28 (bs, 2H), 8.70 (s, 6H).

The filtrate, after VIII had been collected, was concentrated and the residue was subjected to column chromatography on silica gel. Crystals eluted with methylene chloride were recrystallized from acetonitrile to give colorless prisms of VI, mp 170—171 °C, 0.46 g (17%). Found: C, 71.63; H, 7.10; N, 15.78%. Calcd for $C_{16}H_{19}ON_3$: C, 71.34; H, 7.11; N, 15.60%. IR (KBr) cm^{-1}: 3350, 1664, 1600, 1530, 710. NMR (DMSO-d_6) τ: 1.32 (s, 1H), 2.02—2.63 (m, 5H), 2.86 (s, 1H), 7.58 (s, 6H), 8.27 (s, 6H).

With methylene chloride and ethyl acetate, 0.46 g of VIII was eluted, the total yield being 1.35 g (72%).

b) Reaction of III with Acetylacetone in Water (Expt. 6, Table 1): A solution of 1.5 g (15 mmol) of acetylacetone, 2.4 g (10 mmol) of III hydrochloride, and 1.5 g (11 mmol) of potassium carbonate in 20 ml of water was warmed to 55—60 °C for 2 hr. Crystals, a part of which began to separate out on being warmed for 30 min, were collected by filtration and recrystallized from acetonitrile to give colorless prisms of VI, mp 170—171 °C, 0.45 g (17%). Spectral data were identical with those obtained in the preceding experiment.

The filtrate of the reaction mixture was concentrated, and the residue was subjected to column chromatography on silica gel. Crystals eluted with methylene chloride were recrystallized from ethyl acetate to give colorless prisms of VII, mp 202—204 °C (lit,[7] mp 202 °C), 0.04 g (2%). Found: C, 70.04; H, 6.52; N, 14.94%. Calcd for $C_{11}H_{12}ON_2$: C, 70.18; H, 6.43; N, 14.88%. IR (KBr) cm^{-1}: 3425, 1740, 1713, 1620, 1606, 1550, 702. NMR (DMSO-d_6) τ: 1.46 (s, 1H), 1.69—2.72 (m, 5H), 8.70 (s, 6H).

Continued elution with methylene chloride gave 0.08 g (4%) of V, mp 205—206 °C (ethyl acetate).

With methylene chloride and ethyl acetate, 0.80 g (43%) of VIII was eluted, mp 248—249 °C (ethyl acetate).

2-(1-Benzoylamino-1-methylethyl)-4-hydroxy-6-methylpyrimidine (IX). *a) Reaction of III with Ethyl Acetoacetate in the Presence of Sodium Ethoxide*: An ethanol solution of sodium ethoxide prepared from 0.46 g (20 mmol) of sodium and 20 ml of ethanol was added to a solution of 2.4 g (10 mmol) of III hydrochloride in 30 ml of ethanol under ice cooling, and the precipitated sodium chloride was removed by filtration. To the filtrate was added 1.3 g (10 mmol) of ethyl acetoacetate. The mixture was warmed at 60 °C for 5 hr, and then concentrated. The residue was dissolved in 30 ml of water and neutralized with acetic acid to give a white precipitate. Recrystallization from *n*-butanol gave white powder of IX, mp 276—278 °C, 1.25 g (46%). Found: C, 66.29; H, 6.33; N, 15.22%. Calcd for $C_{15}H_{17}O_2N_5$: C, 66.49; H, 6.32; N, 15.49%. IR (KBr) cm^{-1}: 3230, 1682, 1633, 1600, 1550. NMR (DMSO-d_6) τ: 1.57 (s, 1H), 1.92—2.58 (m, 5H), 3.95 (s, 1H), 7.23 (s, 1H), 7.77 (s, 3H), 8.37 (s, 6H).

The aqueous filtrate, after IX had been separated, was concentrated and the residue was subjected to column chromatography on silica gel. Elution with ethyl acetate gave 0.04 g (2%) of V, mp 207—208 °C (ethyl acetate), and 0.62 g (33%) of VIII, mp 246—248 °C (ethyl acetate).

b) Reaction of III with Ethyl Acetoacetate in the Presence of Sodium Hydroxide: To a solution of III in 40 ml of ethanol, prepared from 2.4 g (10 mmol) of III hydrochloride and 0.23 g (10 mmol) of sodium by the same procedure as in the preceding experiment, was added 1.3 g (10 mmol) of ethyl acetoacetate. The reaction mixture was transferred to an evaporating dish and evaporated to dryness in a desiccator over sulfuric acid. The residue was added to a mixture of 5 ml of 20% aqueous sodium hydroxide and 25 ml of ethanol, and then stirred at room temperature for 1 day. The mixture was concentrated, and the work up as described in the preceding experiment gave white powder of IX, mp 277—278 °C (*n*-butanol), 1.4 g (52%). Spectral data were identical with those of IX obtained in *a*).

The aqueous filtrate after separating IX was concentrated and then subjected to column chromatography on silica gel. The elution with ethyl acetate gave 0.15 g (8%) of VII, mp 201—202 °C (ligroin), and 0.49 g (26%) of VIII, mp 247—248 °C (ethyl acetate).

5,5-Dimethyl-2-phenylimidazoline-4-acetimide. In 10 ml of acetic anhydride, 0.94 g (5 mmol) of VIII was heated at 80 °C for 30 min. The reaction mixture was concentrated and the residue was recrystallized from ethyl acetate to give colorless prisms of 5,5-dimethyl-2-phenylimidazoline-4-acetimide, mp 159 °C, 0.92 g (80%). Found: C, 68.40; H, 6.71; N, 18.45%. Calcd for $C_{13}H_{15}ON_3$: C, 68.10; H, 6.59; N, 18.33%. IR (KBr) cm^{-1}: 3235, 3160, 1690, 1530, 1280. NMR (DMSO-d_6) τ: −0.93 (s, 1H), 1.67—2.73 (s, 5H), 7.50 (s, 3H), 8.54 (s, 6H).

5-Acetyl-2-(1-benzoylamino-1-methylethyl)-4-methylpyrimidine (X). To an ethanol solution of III, prepared from 0.10 g (4.4 mmol) of sodium in 10 ml of ethanol and 1.10 g (4.6 mmol) of III hydrochloride in 15 ml of ethanol, was added 0.78 g (5 mmol) of ethoxymethyleneacetylacetone.[7] The mixture was allowed to stand at room temperature for 13 hr, heated to 80 °C for 1 hr and then concentrated. The residual crystals were recrystallized from ethyl acetate to give colorless needles of X, mp 155—156 °C, 0.83 g (64%). Found: C, 68.92; H, 6.48; N, 14.26%. Calcd for $C_{17}H_{19}O_2N_3$: C, 68.66; H, 6.44; N, 14.13%. IR (KBr) cm^{-1}: 3300, 1688, 1633, 1602, 1532. NMR (DMSO-d_6) τ: 0.63 (s, 1H), 1.10 (s, 1H), 1.73—2.50 (m, 5H), 7.16 (s, 6H), 8.06 (s, 6H).

Crystals insoluble in hot ethyl acetate were recrystallized from ethanol to give colorless needles of unchanged III hydrochloride, mp 225—227 °C, 0.3 g (12%). Spectral data were identical with those of authentic III hydrochloride.

5-Acetyl-2-(N-benzoylaminomethyl)-4-methylpyrimidine (XI). To an ethanol solution of I, prepared from 0.35 g (15 mmol) of sodium in 20 ml of ethanol and 3.2 g (15 mmol) of I hydrochloride in 20 ml of ethanol, was added 2.4 g (15.4 mmol) of ethoxymethyleneacetylacetone. Crystals, once precipitated in large quantities after 5 min stirring, were dissolved completely after 1 hr at room temperature. The mixture, after being allowed to stand at room temperature for 18 hr, was heated at 80 °C for 1 hr and then concentrated. Recrystallization of the residue from benzene gave colorless prisms of XI, mp 110—111 °C, 3.1 g (77%). Found: C, 66.99; H, 5.68; N, 15.72%. Calcd for $C_{15}H_{15}O_2N_3$: C, 66.90; H, 5.61; N, 15.61%. IR (KBr) cm^{-1}: 3410, 1688, 1650, 1600, 1536. NMR (DMSO-d_6) τ: 0.80 (s, 1H), 0.90 (s, 1H), 1.87—2.63 (m, 5H), 5.28 (d, 2H), 7.36 (s, 6H).

4-Amino-2-(N-benzoylaminomethyl)-5-cyanopyrimidine (XII). *a) Reaction of I with Ethoxymethylenemalononitrile*: To an ethanol solution of I, prepared from 0.15 g (6.5 mmol) of sodium in 20 ml of ethanol and 1.1 g (5 mmol) of I hydro-

chloride, was added 0.6 g (5 mmol) of ethoxymethylenemalononitrile[8] at 0 °C. The mixture was stirred at 0 °C for 1 hr and at 30 °C for an additional 1 hr. Crystals separated out were collected and recrystallized from ethanol to give colorless needles of XII, mp 208—209 °C, 0.7 g (56%). Found: C, 61.56; H, 4.43; N, 27.58%. Calcd for $C_{13}H_{11}ON_5$: C, 61.65; H, 4.38; N, 27.66%. IR (KBr) cm^{-1}: 3375, 3325, 3200, 2220, 1670, 1650. NMR (DMSO-d_6) τ: 1.13 (s, 1H), 1.14 (s, 2H), 1.88—2.62 (m, 6H), 5.53 (d, 2H).

b) Reaction of Ethyl Benzoylaminoacetimidate with Aminomethylenemalononitrile: An ethanol solution of sodium ethoxide, prepared from 0.23 g (10 mmol) of sodium and 20 ml of ethanol, was added to a solution of 2.4 g (10 mmol) of ethyl benzoylaminoacetimidate hydrochloride[3] in 30 ml of ethanol under ice cooling and the precipitated sodium chloride was removed by filtration. To the filtrate was added 0.9 g (10 mmol) of aminomethylenemalononitrile.[9] The mixture was warmed at 50 °C for 3 hr, and then concentrated. The oily residue was subjected to column chromatography on alumina. Crystals eluted with ethanol were recrystallized from ethanol to give XII, mp 208—209 °C, 0.25 g (10%). Spectral data were identical with those of XII obtained in the preceding experiment.

Photoinduced Reactions. LXXVII. On the Applicability of Excited Acetone to Induce Photoaromatization of Dihydroheteroaromatics[1]

Teruo MATSUURA and Yoshikatsu ITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received February 4, 1974)

Photoaromatization of various dihydroheteroaromatics and some carbocyclic dihydroaromatics with excited acetone was examined. Among the tested compounds, indoline, 2,3-dihydro-2-methylbenzofuran, and 9,10-dihydroanthracene were found to be photoaromatized. 2-Thiazolines, 2-oxazolines, 2-isoxazolines, 9,10-dihydrophenanthrene, 2,3-dihydro-5,6-dimethylpyrazine, 3,4-dihydro-1-methylisoquinoline, and 6-methyl-3(2*H*)-pyridazinone did not undergo photoaromatization, but recovered unchanged or underwent their own photochemical reactions.

In a previous paper,[2] we have reported that excited states of acetone could be used to dehydrogenate imidazolines to imidazoles. Our attention, then, was focused to see whether this photoaromatization could be extended to other dihydroaromatics. The present paper shows that it is not always the case but various types of reactions take place, although the photoaromatization occurs in some cases. Interpretation of the results with the Hückel molecular orbital (HMO) energy was attempted with some success.

An acetone solution of various dihydroheteroaromatics (AH_2), including a few carbocyclic dihydroaromatics, was irradiated with light mainly at 2537 Å and the products were separated by chromatographic methods. The results are summarized in Table 1, which also includes the results obtained with 2-imidazolines (No. 3—5)[2] for comparison. Various types of reactions occurred and they can be classified into the following six categories. A hydroaromatic radical (·AH), which is produced by hydrogen abstraction with excited acetone from AH_2, may undergo four types of processes; (i) dehydrogenation to an aromatic compound (A), (ii) coupling with the acetone ketyl radical (iii) dimerization, and (iv) regeneration of AH_2 by hydrogen transfer from the acetone ketyl radical. Process (iv) has been proved to occur in part in the case of imidazolines.[2] Other processes will involve the excited states (AH_2*) of the substrate itself; namely, (v) deactivation to AH_2 and (vi) its own photochemical reaction leading to products.

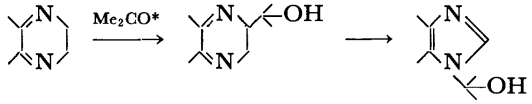
$$AH_2 + Me_2CO^* \longrightarrow \cdot AH + Me_2\dot{C}OH$$

$$A \xleftarrow{\text{(i) } -H\cdot} \cdot AH \xrightarrow{\text{(ii) } Me_2\dot{C}OH} Me_2C(OH)\text{-}AH$$

$$\cdot AH \xrightarrow{\text{(iii) } \cdot AH} (AH)_2 \qquad \cdot AH \xrightarrow{\text{(iv) } Me_2\dot{C}OH} AH_2 + Me_2CO$$

$$AH_2 \underset{\text{(v)}}{\overset{h\nu \text{ or } Me_2CO^*}{\rightleftharpoons}} AH_2^* \xrightarrow{\text{(vi)}} \text{Products}$$

Only indoline (No. 1), 2,3-dihydro-2-methylbenzofuran (No.2), and 9,10-dihydroanthracene (No.11) gave the corresponding aromatized product or its further photolysis product, *e.g.* dianthracene from dihydroanthracene.[11] The intermediary formation of radical ·AH is demonstrated in the latter two cases giving a cross-coupling product and a dimer, respectively. While 2-methyl-2-thiazoline (No. 6) and 3,5-diphenyl-2-isoxazoline (No. 10) gave *N*-vinylthioacetamide[5] and 4,5-diphenyl-3-oxazoline,[7] respectively, other compounds (No. 7, 9, 12, 14, and 15) were unreactive under the conditions except 2-methyl-2-oxazoline (No. 8) which gave a complex mixture of products. The photochemical isomerization of 2,3-dihydro-5,6-dimethylpyrazine (No. 13) to 1,4,5-trimethylimidazole has already been reported.[12] Since the transformation of this imidazole to the imidazole-acetone adduct, 1-(2-hydroxy-2-methylpropyl)-4,5-dimethylimidazole, did not occur under the similar photolytic conditions, it is assumed that the adduct is formed by a similar photoisomerization of the dihydropyrazine-acetone adduct [t pe (ii) product] as depicted below.



Although the present data are insufficient to make a proper prediction about the reaction courses which dihydroaromatic compounds will follow, we have attempted to interpret the results, particularly on photoaromatization, in terms of HMO π-electron energy (Table 1). We previously showed[2] that $\Delta E_{\pi 2}$ value, which implies the stabilization energy of π-electron for the aromatization step (·AH→A), has a more important meaning to the photodehydrogenation of imidazolines to imidazoles than $\Delta E_{\pi 1}$ value which might contribute to lowering the activation energy of the hydrogen abstraction step (AH_2→·AH). This argument may be valid in the case of the five-membered dihydroheteroaromatics. Thus, indoline (No. 1) having a higher $\Delta E_{\pi 2}$ value than those of imidazolines is easily photoaromatized and 2,3-dihydro-2-methylbenzofuran (No. 2) having a somewhat low $\Delta E_{\pi 2}$ value undergoes slow photoaromatization. 2-Methyl-2-thiazoline (No. 6), and 2-phenyl-2-oxazoline (No. 9) having a low $\Delta E_{\pi 2}$ value suffered no photoaromatization. These results are not interpreted in terms of the $\Delta E_{\pi 1}$ value. Attempts to interpret the data for the six-membered hydroaromatics in terms of either $\Delta E_{\pi 1}$ or $\Delta E_{\pi 2}$ value proved unsuccessful.

Experimental

All the melting points are uncorrected. NMR spectra were taken on an NEVA T-60 spectrometer with tetramethylsilane

a) Based on the initial amount of the starting material. b) A[i], HA-C(OH)Me_2[ii], $(HA)_2$[iii], and others[vi]. c) See ref. 2) for the method of calculation. E_π: total π-electron energy of the aromatic system ($E_{\pi A}$), ·AH ($E_{\pi\cdot AH}$), or AH_2 ($E_{\pi AH_2}$). $\Delta E_{\pi 1}=E_{\pi\cdot AH}-E_{\pi AH_2}$. $\Delta E_{\pi 2}=E_{\pi A}-E_{\pi\cdot AH}$. d) Intermediates having the radical center at 3 position for indoline, 2 for 2,3-dihydro-2-methylbenzofuran, 4 for 2-methyl-2-thiazoline, 4 for 2-phenyl-2-phenyl-2-oxazoline, 3 for 3,4-dihydro-1-methylisoquinoline, and 5 for 4,5-dihydro-6-methyl-3(2*H*)-pyridazinone were assumed as ·AH on the basis of their larger π-delocalization energy than those having the radical center at another position. e) The starting material decomposed during column chromatography on silica gel. f) Essentially no reaction occurred judging from NMR, IR, and tlc analyses of the photolysate. g) It gave a complex mixture which contained no 2-methyl-2-oxazole.

as the internal standard. IR spectra were measured on a JASCO IRS spectrophotometer. Mass spectra were determined on a HITACHI RMS-4 spectrometer. Vapor phase chromatography (vpc) was carried out with a Shimadzu GC-2C. Unless otherwise specified, column chromatography (cc) was carried out with Mallinckrodt silica gel (100 mesh) and thin layer chromatography (tlc) with Merck Kieselgel GF_{254}.

Materials. The starting materials were commercially available or prepared according to the methods of literatures cited in Table 1.

Irradiation. A given amount (Table 1) of the substrate was dissolved in 220 ml of acetone and the solution was irradiated internally with a 10-W low-pressure mercury lamp (Vycor housing) under bubbling nitrogen with external cooling with tap water. After evaporation of the solvent under reduced pressure, the residue was submitted to separation in the following way.

Isolation and Characterization of Photoproducts. Indole was isolated by vpc (Silicone DC 550, 40—60 mesh; helium, 1.1 kg/cm² gauge; 140 °C), mp 48.5—51 °C (lit,[13] mp 52 °C), which was identical with an authentic sample (IR). Yield of indole was determined by vpc using diphenyl as the internal standard.

The crude photolysate obtained from 2,3-dihydro-2-methylbenzofuran was chromatographed on 70 g of silica gel. Elution with 300 ml of petroleum ether gave 90 mg of 2-methylbenzofuran. The IR spectrum was identical with the Sadlter Standard Spectrum of this compound. Further elution with 1.3 l of petroleum ether afforded 680 mg of the starting material (tlc and IR). After elution of 440 mg of unidentified products, 380 mg of 2,3-dihydro-3-(α-hydroxyisopropyl)-2-methylbenzofuran was eluted with 1.1 l of benzene–chloroform (1 : 1) which was further purified by preparative tlc (benzene–chloroform, 5 : 1), and distilled to give a colorless oil; bp 75—80 °C (bath temp.)/2 mmHg; ν_{max}^{neat} 3470, 1595, 1240, 1135, 750 cm^{-1}; λ_{max}^{EtOH} 289 nm (ε 3600), 283 nm (4300); τ^{CDCl_3} 2.60—3.34 (4H, m, aromatic H), 5.18 (1H, d-q, J=3 Hz, J'=7 Hz, –CH–O), 7.02 (1H, slightly diffused d, J=3 Hz, –CH–CH–O), 7.83 (1H, broad s, disappeared on deuteration, OH), 8.63 (3H, d, J=7 Hz, CH_3–CH–), 8.78 (6H, d, J=1.5 Hz, $(CH_3)_2$–C–); *m/e* (rel. int.) 192 (M^+, 11), 134 ($M^+-(CH_3)_2CO$, 100), 133 ($M^+-(CH_3)_2COH$, 83), 119 (134—CH_3, 79), 105 (73), 91 (58), 59 (70).

Found: C, 74.77; H, 8.42%. Calcd for $C_{12}H_{16}O_2$: C, C, 74.97; H, 8.39%. Further elution with more polar solvents (chloroform and acetone) gave 1.20 g of a mixture of unidentified products.

During the photolysis of 9,10-dihydroanthracene, dianthracene (450 mg) precipitated as colorless crystals which were identical with an authentic sample[11] (IR). After removal of dianthracene and the solvent, the residue was chromatographed on 90 g of silica gel. Elution with 1.1 l of petroleum ether yielded 590 mg of the recovered starting material (tlc and IR). Further elution with 2.4 l of the same solvent gave 470 mg of 9,10,9′,10′-tetrahydrodianthranyl, mp273—274°C (lit,[14] mp 256—257 °C), which was identical with an authentic sample[14] (IR, NMR). Further elution with more polar solvents (benzene and chloroform) gave 1.57 g of a mixture of unidentified products.

The photolysate from 2,3-dihydro-5,6-dimethylpyrazine was found by NMR analysis to consist of mainly three components, the starting material, 1,4,5-trimethylimidazole, and 1-(2-methylpropyl)-4,5-dimethylimidazole, in the ratio of 0.8 : 2.6 : 1.6. The product mixture was chromatographed on 80 g of neutral alumina (Merck). Elution with 1 l of benzene–chloroform (2 : 1) gave 90 mg of a mixture of unidentified products. Further elution with 2.2 l of the same solvent afforded 870 mg of crude 1,4,5-trimethylimidazole, which was purified by preparative tlc (Aluminiumoxid GF_{254} Type E, Merck; chloroform–acetone, 2 : 1). Picrate, mp 216—217.5 °C (lit,[12] mp 219—220 °C). The NMR and IR spectra were consistent with those reported.[12] Further elution with 1.8 l of benzene–chloroform (1 : 2) and 1 l of chloroform yielded 610 mg of 1-(2-hydroxy-2-methylpropyl)-4,5-dimethylimidazole, which was purified by preparative tlc as mentioned above. A colorless viscous oil crystallized on standing; mp 90.5—92.5 °C; ν_{max}^{neat} 3150, 1500, 1220, 1180, 915, 725 cm^{-1}; λ_{max}^{EtOH} 226 nm (ε 5600); *m/e* (rel. int.) 168 (M^+, 100), 110 ($M^+-(CH_3)_2CO$, 93), 109 ($M^+-(CH_3)_2CHO$, 89), 95 (110—CH_3, 76), 59 (67); τ^{CDCl_3} 2.64 (1H, s, –CH=), 4.86 (1H, s, disappeared on deuteration, OH), 6.28 (2H, s, $-CH_2-$), 7.90 (6H, s, =C–CH_3), 8.80 (6H, s, $(CH_3)_2$–C–).

Found: C, 64.00; H, 9.66; N, 16.77%. Calcd for $C_9H_{16}N_2O$: C, 64.25; H, 9.59; N, 16.65%.

Further elution with more polar solvents (ethanol) gave 370 mg of a mixture of unidentified products. The starting dihydropyrazine decomposed during chromatography and could not be recovered.

Règles Concernant la Stéréochimie de L' Hydrogénation Catalytique

Eric BROWN et Michel RAGAULT

Laboratoire de Synthèse Organique, Faculté des Sciences, Centre Universitaire, Route de Laval, 72000, Le Mans, France

(Reçu, 4, Mai 1973)

The rule of maximum compactness is put forward as a guide for establishing the stereochemistry of catalytic hydrogenation in many cases. This rule complements the well-known Auwers-Skita rule.

La réaction globale d'hydrogénation catalytique:

$$R + H_2 \xrightarrow{Cat} P$$

est généralement la résultante des processus élémentaires I à V ci-après:[1-3]

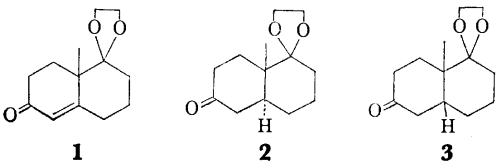
$Cat + H_2 \rightleftharpoons Cat\cdot HH$	(I)	Adsorption de H_2
$Cat\cdot HH + R \rightleftharpoons Cat\cdot HHR$	(II)	Adsorption de R
$Cat\cdot HHR \rightleftharpoons Cat\cdot H\cdot(HR)$	(III)	Hydrogénation de R
$Cat\cdot H\cdot(HR) \rightleftharpoons Cat\cdot P$	(IV)	Hydrogénation de R
$Cat\cdot P \rightleftharpoons Cat + P$	(V)	Désorption de P

Bien que l'on puisse souvent prévoir plusieurs composés hydrogénés P stéréoisomères (4 au maximum), l'expérience montre que l'hydrogénation catalytique est une réaction d'une grande stéréospécificité et que l'on obtient dans de nombreux cas un produit P unique résultant d'une addition *cis* d'hydrogène. Cette observation a conduit à admettre que le réactif R s'adsorbe sur le catalyseur par la face la plus dégagée et que, dans l'étape suivante, deux atomes d'hydrogène adsorbés viennent attaquer la molécule R par cette même face, conduisant ainsi à un composé *cis* dihydrogéné. Cette règle de l'encombrement catalytique d'Auwers-Skita,[4-8] si elle a le mérite de la simplicité, souffre malheureusement dans la pratique de nombreuses limitations, ainsi que nous l'illustrerons par la suite.

Pour interpréter et expliquer la stéréochimie des produits P obtenus par hydrogénation catalytique, les théories d'Auwers, Skita[4-6] et de leurs successeurs[1-3,7,8] considèrent uniquement les étapes d'adsorption (I) et (II) et de réduction (III) et (IV), sans se préoccuper des facteurs qui influent sur l'étape (V) de désorption du produit final P. Un tel point de vue est sans doute trop restrictif, ainsi que nous allons tenter de le montrer maintenant.

Nous pouvons admettre, avec Langmuir,[9] que dans Cat·HHR, le solvant utilisé, l'hydrogène et le réactif R sont fixés par physisorption (liaisons de van der Waals) et chimisorption, en formant une couche monomoléculaire à la surface du catalyseur. Les processus de sorption II et de désorption V sont certainement lents et imposent leur vitesse à la réaction globale d'hydrogénation. La désorption du produit P sera facilitée si ce dernier occupe sur le catalyseur une surface plus réduite que l'ensemble initial (R+2H), car ainsi les interactions de van der Waals avec les autres molécules adsorbées seront plus faibles qu'au départ. De plus, P aura d'autant moins d'affinité pour le catalyseur qu'il sera moins plan et que ses groupements fonctionnels polaires ou insaturés seront moins accessibles, par suite de la diminution corrélative du nombre des liaisons (de van der Waals, essentiellement) entre P, le catalyseur et les autres molécules adsorbées. Ainsi donc, plus P sera "recroquevillé" sur lui-même et plus ses groupements fonctionnels seront "masqués", plus le processus V de désorption, et par conséquent la réaction globale d'hydrogénation seront rapides. Ces arguments conduisent à énoncer la règle suivante qui modère la règle d'Auwers-Skita trop souvent mise en défaut: "Lorsque l'hydrogénation catalytique (effectuée en milieu neutre) d'un composé polycyclique insaturé est susceptible de conduire à plusieurs isomères saturés, il se forme de préférence l'isomère dans lequel les groupements fonctionnels polaires ou riches en électrons (π) sont le plus masqués et par conséquent le moins aptes à former des complexes avec le catalyseur et les molécules adsorbées sur ce dernier". Dans la plupart des cas habituels, cette règle pourra s'énoncer plus simplement de la façon suivante ("Règle de la compacité maximum"): "L'hydrogénation catalytique en milieu neutre d'un composé polycyclique insaturé conduit de préférence à l'isomère saturé le plus compact et le plus *gauche* compatible avec les exigences thermodynamiques". Exprimée sous cette forme, la règle précédente permet de comprendre pourquoi l'hydrogénation catalytique des doubles liaisons carbone-carbone conduit presque toujours aux composés hydrogénés *cis*, que la double liaison initiale soit en position intra- ou juxtanucléaire. Cependant, si la molécule R de départ est très volumineuse, l'hydrogénation ne modifiera que peu la compacité et on doit s'attendre à obtenir l'isomère d'hydrogénation le plus stable.

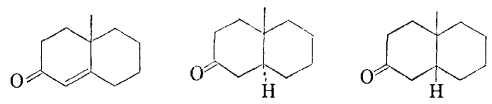
Les quelques exemples suivants nous paraissent significatifs et de nature à illustrer ce qui précède. La règle d'Auwers-Skita prévoit la formation de la cétone thermodynamique *trans* 2, par hydrogénation catalytique



1 **2** **3**

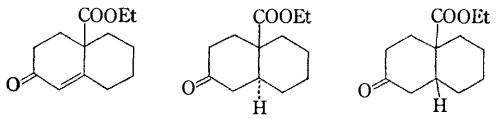
de la cétone éthylénique 1, du fait d'une arrivée *trans* (supposée) de l'hydrogène par rapport au méthyle angulaire. En réalité, nous avons obtenu presque exclusivement la cétone saturée *cis* **3**, laquelle est nettement plus compacte que son isomère *trans* **2**.[10]

De même, l'hydrogénation catalytique de la méthyl octalone-2 **4** devrait conduire à la cétone saturée *trans* **5**, toujours selon la règle d'Auwers-Skita. En fait, là encore, on obtient essentiellement la cétone *cis* **6**, qui est plus compacte.[11]



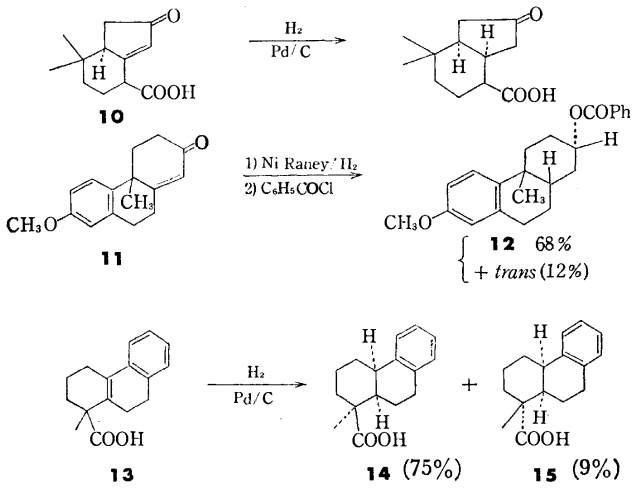
4 **5** **6**

L'hydrogénation catalytique suit un autre cours si le méthyle angulaire de l'octalone **4** est remplacé par un groupement fonctionnel polaire. Ainsi, l'ester **7** fournit par hydrogénation le composé *trans* **8**,[12] dans lequel la fonction ester est plus masquée que dans l'isomère *cis* **9** correspondant.



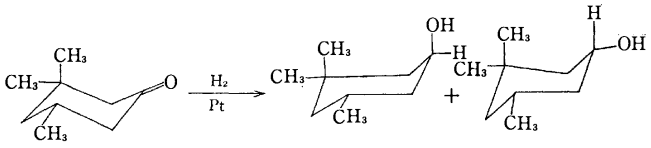
7 **8** **9**

Dans les exemples suivants, nous constatons que l'hydrogénation catalytique de l'indénone **10**,[13] de la phénanthrone **11**[14] et de l'hexahydrophénanthrène **13**[15] suivent bien la règle de la compacité maximum. Ainsi, l'hydrogénation du composé **11** conduit à une phénanthrone **12** à jonction *cis* alors que la règle d'Auwers-Skita laisserait prévoir un composé à jonction *trans*.



Le composé **13**, quant à lui, est susceptible de fournir par hydrogénation catalytique deux composés à jonction *cis* **14** et **15**. En fait, Ghatak et ses collaborateurs ont obtenu essentiellement l'isomère **14** dans lequel le groupement CO_2H occupe la position *endo*. L'examen des modèles moléculaires nous a montré que dans le composé **14**, le groupement CO_2H peut former des liaisons hydrogène avec le cycle aromatique, ce qui a pour effet de rendre ce composé plus compact que ses trois autres isomères possibles, et en particulier que son isomère **15**.

Pour en terminer avec cet exposé, nous allons donner un exemple qui a été souvent cité avant nous dans divers ouvrages[16-18] pour illustrer la règle d'Auwers-Skita:



L'hydrogénation sur platine de la cyclohexanone **16** fournit principalement l'alcool axial **17**. Si la formation de **17** suit bien la règle d'Auwers-Skita, il est manifeste qu'elle suit également la règle de la compacité maximum car **17** est plus compact que son isomère équatorial **18**.

Nous tenons à remercier les professeurs D. H. R. Barton, P. F. Casals et J. M. Conia pour les conseils qu'ils nous ont donnés à l'occasion de ce travail.

Stéréochimie des Perhydrobenz(*e*) Indénones-2

Eric BROWN et Michel RAGAULT

Laboratoire de Synthèse Organique, Faculté des Sciences, Centre Universitaire, Route de Laval, 72000, Le Mans, France

(Reçu, 4, Mai 1973)

The stereochemistry is given of various perhydrobenz(e) inden-2-ones, which have been synthesized as potential intermediates for C-nor-D-homo-steroids.

Nous avons décrit récemment[1] les synthèses des perhydrobenz(e)indénones-2 **4**, **5** et **6** en deux étapes à partir de la γ-dicétone **1**. La *trans-anti-trans* perhydrobenz(e) indénone-2 **6** devrait, selon nous, se révéler un intermédiaire utile dans la synthèse totale des C-nor D-homostéroïdes.

Nous allons exposer ci-après les arguments qui militent en faveur des structures **2**, **3**, **4**, **5** et **6** proposées pour les cinq benz(e) indénones-2 que nous avons préparées (schéma 1).

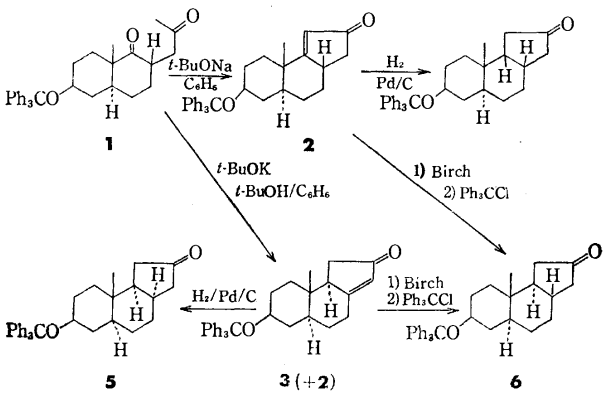

Schéma 1.

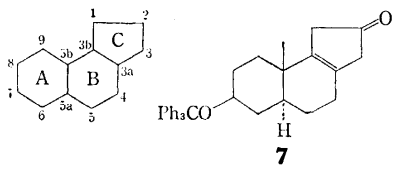
La cétone normale **2** est obtenue par crotonisation intramoléculaire de **1** par le *t*-butylate de sodium dans le benzène. Dans ce milieu alcalin et aprotique, la cétone déconjuguée **7** a peu de chances de se former et par conséquent, il n'y a aucune raison pour que la double liaison initialement en position 1,3b migre en position 3,3a.[2]



L'examen de modèles moléculaires montre que le cycle B a la forme chaise dans la structure **2** (qui possède un hydrogène 3a-β), tandis que dans l'isomère 3a-α correspondant, le cycle B adopterait la forme bateau moins stable. Dans les conditions de la crotonisation de **1**, l'hydrogène en 3a du composé **2** est épimérisable pour des raisons de vinylogie, et on doit donc obtenir finalement le produit thermodynamique, c'est-à-dire le composé **2** lui-même, à l'exclusion de son isomère 3a-α.

La crotonisation intramoléculaire de **1**, réalisée en milieu alcalin protique (*t*-butylate de potassium dans le mélange *t*-butanol/benzène), a fourni un mélange de cétones conjuguées **2** et **3** (d'après l'I.R. et la R.M.N.).

La formation de **3** passe nécessairement par l'intermédiaire de la cétone éthylénique déconjuguée **7**, laquelle résulte du mécanisme représenté sur le schéma 2.

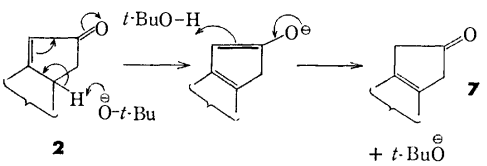


Schéma 2.

Après examen de modèles moléculaires, et en se livrant aux mêmes considérations que pour la cétone **2**, on doit conclure que l'hydrogène en 3b de la cétone **3** occupe la position α, ainsi que nous l'avons d'ailleurs représenté.

On peut prévoir que le méthyle angulaire en position 5b des benz(e)indénones-2 précédentes subira de la part du système cyclopenténone un effet de blindage d'autant plus prononcé que l'axe de la liaison $C_{(9b)}$-CH_3 fera un angle plus faible avec le plan du cycle considéré.[3-5] Dans ces conditions, les structures **2** et **3** proposées sont en accord avec les spectres de R.M.N. des composés correspondants. En ce qui concerne le composé **2**, où la cyclopenténone est relativement éloignée du méthyle angulaire, ce dernier résonne à δ 1.04 ppm (R.M.N. 100 MHz, avec $CDCl_3$ comme solvant). Par contre, dans l'isomère **3**, le cyclopentane est très proche du méthyle et exerce sur ce dernier un effet de blindage anormalement marqué, puisqu'on observe dans ce cas un $\delta(CH_3)\approx 0.56$ ppm (Fig. 1).

La stéréochimie des cétones saturées **4**, **5** et **6** pose des problèmes plus délicats. A priori, on aurait pu croire, en se fiant à la règle de l'encombrement catalytique d'Auwers-Skita que la molécule **2** s'adsorberait

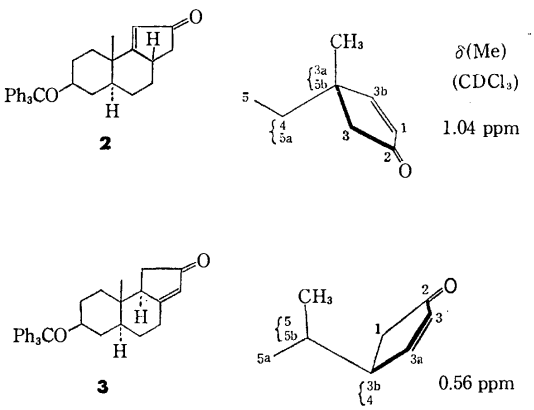

Fig. 1.

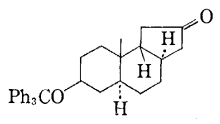
sur le catalyseur par la face dégagée, opposée au méthyle angulaire, et que, par conséquent, les deux atomes d'hydrogène viendraient s'additionner sur la double liaison en *trans* par rapport au groupement méthyle. S'il en était ainsi, on aurait normalement dû obtenir la cétone *trans-anti-trans* **6**, laquelle, étant la plus plane des quatre isomères possibles d'après l'examen des modèles, doit être également la cétone réduite la plus stable (car il y a espacement maximum des substituants et des hydrogènes des cycles). Nous aurions donc dû obtenir la même cétone **6**, à la fois par hydrogénation catalytique et par réduction de BIRCH du composé **2**, étant donné que les réductions chimiques conduisent généralement au produit thermodynamique. En fait, par réduction de BIRCH, nous avons obtenu une cétone saturée différente de celle résultant de l'hydrogénation catalytique de **2**, et par conséquent la structure 3a, 3b *cis* **4** a été attribuée au composé d'hydrogénation de **2**. De même, nous attribuons la structure compacte *trans-anti-cis* **5** au composé résultant de l'hydrogénation catalytique de la cétone éthylénique **3** isomère de **2**.

Par réduction de BIRCH (Li/NH_3 liquide), les cétones insaturées isomères **2** et **3** conduisent toutes les deux à un même composé (mêmes points de fusion, spectres I.R. superposables), auquel nous avons attribué la structure *trans-anti-trans* **6**. La structure *trans-anti-trans* de **6** est démontrée par le fait que ce composé est le seul qui puisse être obtenu par réduction à la fois de **2** et de **3**.[6] Nour pouvons également affirmer sans grand risque que le produit obtenu est le plus stable des benz(e)indénones-2 possibles, car il est obtenu par réduction chimique de deux cyclopenténones isomères. Ainsi que nous l'avons déjà dit précédemment, l'examen des modèles montre que la cétone *trans-anti-trans* **6** est la plus plane des quatre perhydrobenz(e)indénones-2 possibles et pour cette raison, ce doit être la plus stable thermodynamiquement. Le quatrième isomère, la cétone *trans-syn-trans* **8**, paraît peu probable car elle implique que le cycle B adopte la forme bateau peu stable.



8

Les structures **4**, **5** et **6** avancées pour les cétones saturées sont confirmées par leurs spectres de R.M.N. Sur la Fig. 2, nous avons représenté en perspective les cycles B et C des structures **4**, **5** et **6**, ainsi que les déplacements chimiques δ (ppm) des signaux observés pour les méthyles angulaires correspondants. Si on admet comme exactes les structures précédentes, on constate que la cyclopentanone exerce sur le méthyle angulaire un effet de blindage en R.M.N. d'autant plus marqué que le plan du cycle fait un angle plus faible avec l'axe de la liaison C_{5b}–CH_3, ce qui est conforme aux résultats indiqués dans la littérature[3-5] (Fig. 2).

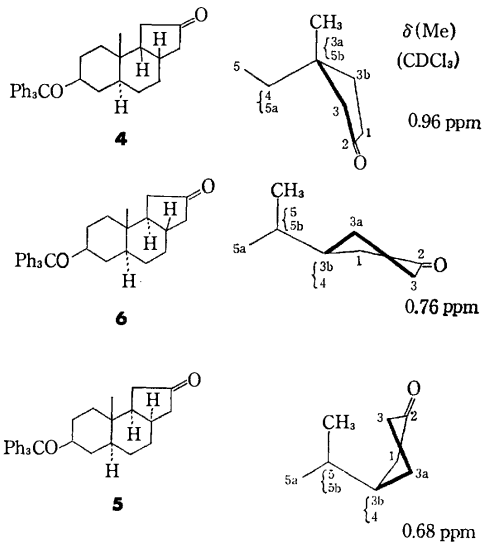


Fig. 2.

Il convient de noter que la cétone **6** est pour nous la plus digne d'intérêt, car elle présente la structure *trans-anti-trans* du système tricyclique A, B, C des C-nor D-homostéroïdes d'origine naturelle.[1] Etant donné qu'une telle molécule est pratiquement plane, elle constitue l'analogue d'un stéroïde, et par conséquent son méthyle angulaire doit avoir un déplacement chimique voisin de ceux des méthyles angulaires situés à la jonction des cycles A, B des stéroïdes normaux. En effect, l'examen des tables[7] montre que le méthyle angulaire à la jonction des cycles A, B des stéroïdes résonne à δ 0.8 ppm, valeur qui est par conséquent très voisine de la valeur δ=0.76 ppm observée pour le déplacement chimique du méthyle angulaire de la *trans-anti-trans* benz(e)indénone-2 **6**.

Nous tenons à remercier les professeurs D. H. R. Barton, P. F. Casals et J. M. Conia pour les conseils qu'ils nous ont donnés à l'occasion de ce travail.

Inositol Derivatives. 7. Azidolysis of Disulfonates of *myo*-Inositol and 1,2-*O*-Cyclohexylidene Derivative[1]

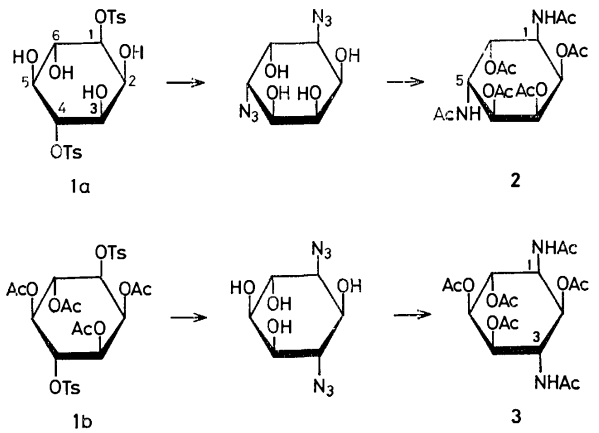
Tetsuo SUAMI, Seiichiro OGAWA, Shuichi OKI, and Haruo SATO

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received November 30, 1973)

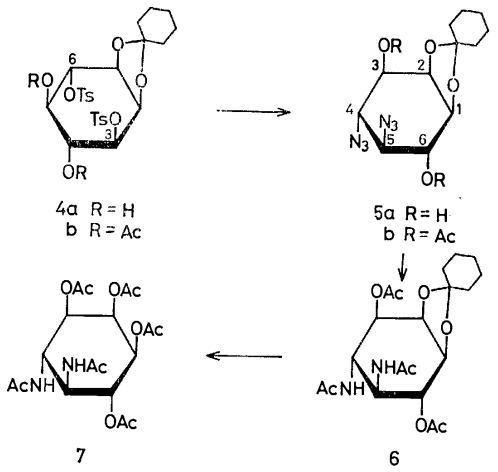
Reactions of azide ion with three disulfonates (1,4-, 1,5-, and 1,6-) of *myo*-inositol and its 1,2-*O*-cyclohexylidene derivative were studied. The structures of the new azido compounds thus obtained were established by PMR spectroscopy and reaction sequences. The reaction mechanisms of the neighboring-group participation reactions were discussed. Hydrogenation of the azido compounds followed by acetylation afforded the corresponding six inosadiamines as their hexaacetates: three known (*allo*-1,5, *muco*-1,3, and *myo*-4,5) and three hitherto unknown inosadiamines (*allo*-1,4, *muco*-1,2, and *chiro*-2,4).

Azido-deoxy- and diazido-dideoxy-inositols are useful intermediates for the synthesis of inosamines and inosadiamines or certain kinds of nucleoside analogs having pseudo sugar moieties. Investigations have been carried out on nucleophilic displacement reactions by azide ion with readily accessible sulfonate derivatives of inositols.[2] In the present paper, we wish to report on the azidolysis of three ditosylates of *myo*-inositol and its 1,2-*O*-cyclohexylidene derivative. The structures of the new azido compounds were established by PMR spectroscopy of their acetyl derivatives, and also by their transformation into known aminocyclitols. The reaction mechanisms in azidolysis were discussed.



Scheme 1

1,4-Ditosylates. Treatment of 1,4-di-*O*-tosyl-*myo*-inositol (**1a**)[3] with an excess amount of sodium azide in refluxing aqueous 2-methoxyethanol for 20 hr, followed by conventional acetylation, afforded an azido derivative as a syrup. The crude azido compound was catalytically hydrogenated and subsequently acetylated to give hexaacetyl *allo*-inosadiamine-1,5 (**2**)[4] in 58% yield. On the other hand, when 1,4-di-*O*-tosyl-*myo*-inositol tetraacetate (**1b**)[3] was treated with sodium azide under the same conditions, hexaacetyl *muco*-inosadiamine-1,3 (**3**)[4] was obtained exclusively in 44% yield. In the former reaction (**1a**→**2**), displacement of the sulfonyloxy group at C-4 takes place initially by participation of the hydroxyl group at C-5 forming an intermediary 4,5-epoxide. The epoxide ring is opened by azide ion preferentially in a *trans*-diaxial manner. Another sulfonyloxy group at C-1 is replaced by the participation of the hydroxyl group at C-6 to give a 1,6-epoxide, which is attacked by the nucleophile in the manner described above. In the latter reaction (**1b**→**3**), the initial formation of a 1,6- or 3,4-acetoxonium ion, and its *trans*-diaxial opening by the azide ion results in the formation of compound **3**.



Scheme 2

In order to remove participation of the acetoxy group at C-3 in the replacement reaction of the sulfonyloxy group at C-4 in **1b**, two hydroxyl groups of **1a** at C-2 and C-3 were blocked by a nonparticipating cyclohexylidene group to give 1,2-*O*-cyclohexylidene-3,6-di-*O*-tosyl-*myo*-inositol (**4a**).[3] Compound **4a** and its diacetate (**4b**)[3] were subjected to azidolysis under the same conditions to give an azido compound (**5a**) as the sole crystalline product in fairly good yield. Acetylation of **5a** gave the diacetate (**5b**). Catalytic reduction of **5a**, followed by acetylation, afforded tetraacetyl *O*-cyclohexylidene-inosadiamine (**6**). Mild hydrolysis of **6** in aqueous acetic acid followed by acetylation gave hexaacetyl *myo*-inosadiamine-4,5 (**7**).[4] Compound **6** was thus assigned to 4,5-diacetamido-3,6-di-*O*-acetyl-1,2-*O*-cyclohexylidene-4,5-dideoxy-*myo*-inositol and **5a** to 4,5-diazido-1,2-*O*-cyclohexylidene-4,5-dideoxy-*myo*-inositol. The structure of **5b** was further confirmed by its PMR spectrum which allowed an interpretation by a first-order method with nicely resolved signals. The narrow doublets at τ 5.87 and 5.50 were respectively assigned to the protons at C-1

TABLE 1. CHEMICAL SHIFTS OF ACETYL METHYL PROTONS OF HEXAACETYL INOSADIAMINES[a)]

Compound	Configuration	Solvent	Chemical shifts
2	*allo*-1,5	C	8.06 (3)

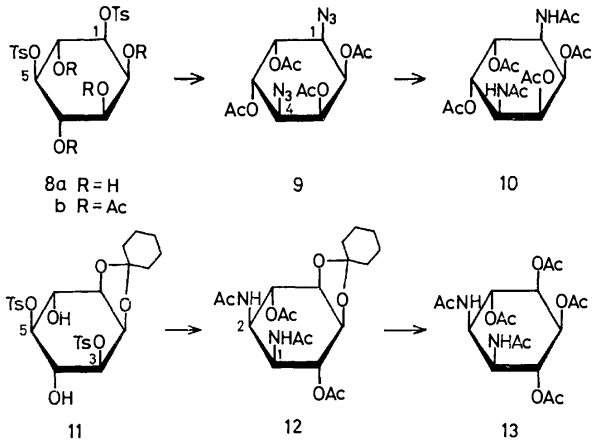
a) Measured at 60 MHz. Chemical shifts are expressed in terms of τ-values. Values in parentheses show number of protons. Abbreviations: C, $CDCl_3$; D, DMSO-d_6. The chemical shifts and pattern of the signals of known compounds (**2**, **3**, and **7**) are in good agreement with those reported by Nakajima *et al.*[4)]

and C-2 carrying the blocking group. The protons were shown to be coupled neither with H-4 (τ 6.72) nor with H-5 (τ 6.10).[5)]

In both reactions with **4a** and **4b**, the azidolysis involves the formation of an intermediary epoxide and acetoxonium ion, respectively, by participation of the neighboring group and its opening by an azide ion which is appreciably affected by the adjacent cyclohexylidene group in terms of steric and polar effects. Thus it is deduced that the opening of the 5,6-epoxide initially formed occurs in a *trans*-diaxial manner and the 3,4-epoxide is subsequently opened in a *trans*-diequatorial manner.



Scheme 3

1,5-Ditosylates. Treatment of 1,5-di-*O*-tosyl-*myo*-inositol (**8a**)[3)] and its acetyl derivative (**8b**)[3)] with sodium azide under similar conditions, followed by acetylation, gave diazidodideoxyinositol tetraacetate (**9**) as the sole crystalline product in 13 and 39% yields, respectively. Besides product **9**, two other unidentified minor products were detectable on tlc. Catalytic reduction of **9**, followed by acetylation, afforded hitherto unknown hexaacetyl inosadiamine (**10**). The PMR spectrum of **10** revealed three singlets of equal intensity in the vicinity of τ 8, ascribed to two acetamido, two acetoxy, and two acetoxy groups.[6)] From the pattern of the signals and their chemical shifts, it was deduced to be the time-averaged spectrum derived from a rapid interconversion between two equivalent conformations. The PMR spectrum of **9**, however, showed a wide double doublet (J=3 and 11 Hz) and a narrow triplet (J=3 Hz) at τ 6.00 and 5.56, respectively, which do not couple with each other and are ascribable to the protons on the carbon atoms carrying the azido groups.[5)]

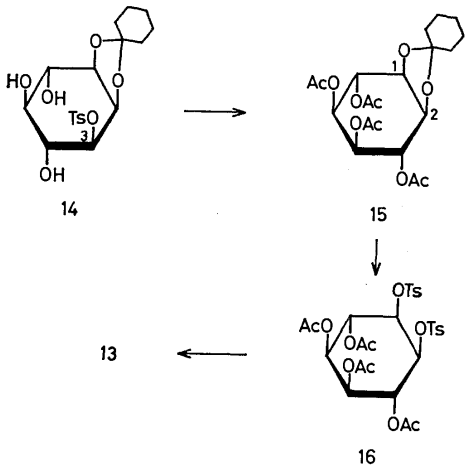
a) Chemical shifts are given in terms of τ-values. Values given for coupling constants (Hz) are of first-order. Abbreviations: t (triplet); dd (double doublet). b) Values in parentheses show number of protons.

A narrow triplet (τ 4.34) should be due to an equatorial proton on the carbon atom attached by the acetoxy group. Besides the expectation from analogous reaction mechanism, the results indicate that **9** should possess either *allo*-1,4- or *neo*-1,5-configuration. Since the former configuration satisfied the behavior of **10** in PMR spectroscopy, **9** was assigned to 1,4-diazido-1,4-dideoxy-*allo*-inositol tetraacetate and **10** to hexaacetyl *allo*-inosadiamine-1,4. Mechanistically, participation of the hydroxyl or the acetoxy group on C-4 to C-5 occurs initially to give rise to a 4,5-cyclic intermediate.

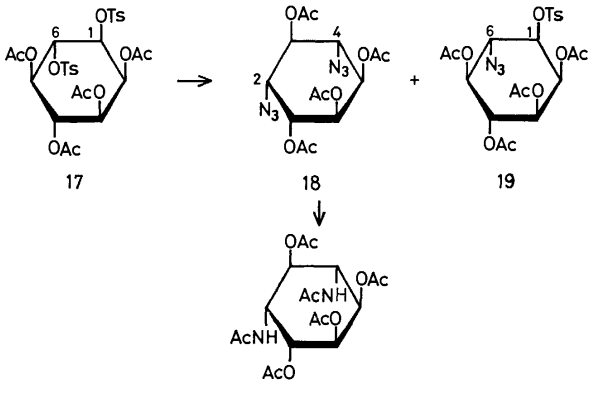
On the other hand, two hydroxyl groups at C-2 and C-3 of **8a** were blocked by a cyclohexylidene group to give compound **11**.[3] Azidolysis of **11** under similar conditions and subsequent acylation afforded tetraacetyl *O*-cyclohexylidene-inosadiamine (**12**) in 34% yield, which was converted into hitherto unknown inosadiamine (**13**). The PMR spectrum of **12** revealed four acetyl methyl protons as two singlets of equal intensities at τ 8.00 and 7.86, which were ascribed to two equivalent acetamido and acetoxy groups, respectively. The configuration of **12** is thus limited to *muco*-1,2 and *allo*-1,4. The PMR spectrum of **13** showed three singlets (1 : 1 : 1) due to six acetyl methyl protons, also supporting the above assignments.



Scheme 4

For the sake of confirmation, an alternative synthesis of **13** was successfully attempted as follows. 1,2-*O*-Cyclohexylidene-3-*O*-tosyl-*myo*-inositol (**14**)[3] was heated in aqueous 2-methoxyethanol with sodium carbonate and subsequently acetylated to give 1,2-*O*-cyclohexylidene-*muco*-inositol tetraacetate (**15**) in 65% yield. By removing the cyclohexylidene group in aqueous acetic acid, **15** was converted into *muco*-inositol tetraacetate, which was treated with tosyl chloride in pyridine to give 1,2-di-*O*-tosyl-*muco*-inositol tetraacetate (**16**). Azidolysis of **16** in the usual way followed by reduction and acetylation afforded **13** in 30% yield.

Consequently, the structure of **13** was established as hexaacetyl *muco*-inosadiamine-1,2. In the case of **11**, the nucleophilic substitution of the intermediate epoxides is also affected by the cyclohexylidene group located in *trans* orientation to them resulting in the initial *trans*-diequatorial opening of the 5,6-epoxide[7] followed by subsequent *trans*-diaxial opening of the 3,4-epoxide.



Scheme 5

1,6-Ditosylates. Treatment of 1,6-di-*O*-tosyl-*myo*-inositol tetraacetate (**17**)[3] with sodium azide by the usual method gave two major products, which were separated by fractional crystallization from ethanol into diazido compound (**18**) and monoazido compound (**19**) in 44 and 18% yields, respectively. Catalytic reduction of **18** and subsequent acetylation afforded a new hexaacetyl inosadiamine (**20**) in 42% yield. By analogy with the preceding results, the reaction involves the initial formation of the 5,6-acetoxonium ion, followed by its preferential diaxial opening with azide ion. However, in a favorable conformation of the intermediate, an attack of azide ion at C-5 would be somewhat interrupted by the adjacent *trans*-acetoxy group in pseudo equatorial orientation, which is probably reflected to a formation of **18** and **19** with a ratio of 2.4: 1. Another tosyloxy group at C-1 in **18** is replaced by the nucleophile in a direct S_N2 manner. **18** is therefore tentatively assigned to 2,4-diazido-2,4-dideoxy-*chiro*-inositol tetraacetate and **19** to 6-azido-6-deoxy-1-*O*-tosyl-*myo*-inositol tetraacetate.

The PMR spectrum of **18** (Table 1) shows a triplet (τ 6.13) and a double doublet (τ 6.22) which do not couple with each other, indicating the presence of the azido groups at C-2 and C-4. The chemical shifts of acetyl methyl protons of **20** also support its *chiro*-2,4 configuration. In the PMR spectrum of **19** (Table 1), the triplet (τ 6.05) due to a proton on the carbon atom bearing the azido group is coupled with H-1 double doublet (τ 5.43), supporting the above assignment.

In the case of **19**, the displacement of tosyloxy group at C-1 is significantly retarded by the existence of the neighboring azido group in *trans* orientation.

For the sake of comparison, 2,3-*O*-cyclohexylidene derivatives of the 1,6-ditosylates (**21a** and **21b**)[3] were subjected to azidolysis. Azidolysis of **21a** and **21b** proceeded in a quite different way to give 1,4-anhydro-5,6-*O*-cyclohexylidene-3-*O*-tosyl-*chiro*-inositol (**22**)[7] in 73 and 65% yields, respectively. This shows that the attack of the hydroxyl group (at C-6) on C-3 is preferential, the conformation being brought closer to that of boat form.[8]

Experimental

Unless otherwise stated, melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. The melting points marked with asteriks were determined in a liquid bath and are uncorrected. IR spectra were measured on a JASCO IR-E spectrophotometer in KBr disks. PMR spectra were obtained on a Varian Associates A-60D (60 MHz) spectrometer at a concentration *ca.* 10% in deuteriochloroform ($CDCl_3$) or dimethylsulfoxide-d_6 (DMSO-d_6), with tetramethylsilane as an internal standard. Chemical shifts are given in terms of τ-values, signals being denoted by s (singlet), d (doublet), t (triplet), dd (double doublet), or m (complex multiplet). Values given for coupling constants are of first-order. All the solutions were concentrated by a rotary evaporator at 40—50 °C under reduced pressure, and a trace of residual pyridine was removed by coevaporation with toluene. Catalytic hydrogenation was carried out with a Parr shaker apparatus in the presence of Raney nickel T-4[9] catalyst in the initial hydrogen pressure of 3.5 kg/cm² at room temperature. Tlc was performed on silica gel (Wakogel B-10, Wako Pure Chemical Industries, Ltd.) using a mixture of 2-butanone and toluene. The spots were indicated by heating above 150 °C after spraying with 30% sulfuric acid.

Hexaacetyl allo-*Inosadiamine-1,5 (2).* A mixture of 1,4-di-*O*-tosyl-*myo*-inositol (**1a**)[3] (3.0 g), sodium azide (3.0 g), and 90% aqueous 2-methoxyethanol (100 ml) was refluxed for 20 hr. The mixture was then evaporated to dryness and the residue was treated with acetic anhydride (10 ml) and pyridine (10 ml) overnight at room temperature. The insoluble material was removed by filtration and the filtrate was evaporated to dryness. The residue was extracted with hot ethyl acetate (50 ml) and the extract was purified by passing through a short alumina column. The solution was evaporated to give a syrup, which was, without further purification, hydrogenated in an ethanol solution (20 ml) for 15 hr. The catalyst was filtered off and the filtrate was concentrated to give an oily product, which was acetylated in the usual way to give crystals (1.56 g, 58%) of **2**, mp 202—204 °C. Recrystallization from ethanol–ether afforded an analytically pure sample, mp 204.5—205.5 °C (lit,[4] 203—204 °C). Found: C, 50.21; H, 6.08; N, 6.43%.

Hexaacetyl muco-*Inosadiamine-1,3 (3).* A mixture of 1,4-di-*O*-tosyl-*myo*-inositol tetraacetate (**1b**)[3] (2.5 g), sodium azide (2.5 g), and 90% aqueous 2-methoxyethanol (100 ml) was refluxed for 16 hr. The reaction mixture was then treated as in the preparation of **2**. The crude crystals were recrystallized from ethyl acetate to afford pure crystals (0.72 g, 44%) of **3**, mp 229—231 °C (lit,[4] 227—228 °C). Found: C, 49.81; H, 6.01; N, 6.35%.

*4,5-Diazido-1,2-*O*-cyclohexylidene-4,5-dideoxy-*myo*-inositol (5a).*

a): A mixture of 1,2-*O*-cyclohexylidene-3,6-di-*O*-tosyl-*myo*-inositol (**4a**)[3] (1.4 g), sodium azide (1.4 g), and 90% aqueous 2-methoxyethanol (30 ml) was refluxed for 20 hr. The reaction mixture was evaporated to dryness and the residue was extracted with hot ethyl acetate (60 ml). The extract was passed through a short alumina column and was then concentrated to give a syrup, which was crystallized from ethanol to afford colorless plates (0.46 g, 60%) of **5a**, mp 70—90 °C. Recrystallization twice from ethanol gave an analytical sample, mp 102—105 °C (after melting and resolidifying at 68—83 °C).

Found: C, 47.35; H, 6.86; N, 23.49%. Calcd for $C_{12}H_{18}N_6O_4$: C, 46.44; H, 5.85; N, 27.08%. Calcd for $C_{12}H_{18}N_6O_4 \cdot C_2H_5OH$: C, 47.18; H, 6.79; N, 23.58%.

The crystals lose ethanol by drying *in vacuo* over phosphorus pentoxide at 80—90 °C overnight.

Found: C, 46.49; H, 5.78; N, 26.91%.

b): 1,2-*O*-Cyclohexylidene-3,6-di-*O*-tosyl-*myo*-inositol diacetate (**4b**)[3] (2.0 g) was allowed to react with sodium azide (2.0 g) in refluxing 90% aqueous 2-methoxyethanol (60 ml) for 19 hr followed by a similar treatment to that described above to yield crystals (0.42 g, 43%) of **5a**, mp 70—90 °C.

Compound **5a** (69 mg) was treated with acetic anhydride (0.5 ml) in pyridine (0.5 ml) for 30 min at 80 °C. The mixture was then poured into ice and water giving crystals (69 mg, 78%) of the diacetate (**5b**), mp 149—150.5 °C. Recrystallization from ethanol afforded a pure sample. needles, mp 150—151 °C.

Found: C, 49.03; H, 5.76; N, 20.90%. Calcd for $C_{16}H_{22}N_6O_6$: C, 48.72; H, 5.62; N, 21.31%.

*4,5-Diacetamido-3,6-di-*O*-acetyl-1,2-*O*-cyclohexylidene-4,5-dideoxy-*myo*-inositol (6).* The crude crystals of **5a** derived from **4a** (1.5 g) was hydrogenated in an ethanol solution (10 ml) overnight. The product was treated with acetic anhydride (2 ml) and pyridine (3 ml) overnight at room temperature to give a crystalline product, which was crystallized from ethanol affording crystals (0.45 g, 43%) of **6**, mp* 249—250.5 °C. An analytical sample was obtained by recrystallization from chloroform–ethanol, needles, mp* 249—250 °C. PMR ($CDCl_3$): τ 8.08, 8.06, 7.91, 7.86 (3-proton s, OAc), 4.78 (dd, $J_{1,6}=7.5$ Hz, $J_{5,6}=11$ Hz, H-6), 4.70 (dd, $J_{2,3}=4$ Hz, $J_{3,4}=10$ Hz, H-3).

Found: C, 56.39; H, 6.93; N, 6.51%. Calcd for $C_{20}H_{30}N_2O_8$: C, 56.32; H, 7.09; N, 6.57%.

Hexaacetyl myo-*Inosadiamine-4,5 (7).* Compound **6** (0.20 g) was refluxed with 80% aqueous acetic acid (10 ml) for 2 hr and the mixture was evaporated to dryness. The residue was treated with acetic anhydride (0.5 ml) and pyridine (1 ml) overnight at room temperature. The product was crystallized from chloroform–ethanol to afford pure needles (0.18 g, 84%) of **7**, mp* 303—303.5 °C (lit[4], 294—295 °C). Found: C, 50.04; H, 6.03; N, 6.37%. In the PMR spectrum of **7** in $CDCl_3$, the chemical shifts of signals due to the acetyl groups (Table 1) were in good agreement with those of an authentic sample.[4]

*1,4-Diazido-1,4-dideoxy-*allo-*inositol Tetraacetate (9).*

a): A mixture of 1,5-di-*O*-tosyl-*myo*-inositol (**8a**)[3] (2.0 g), sodium azide (2.0 g), and 90% aqueous 2-methoxyethanol (80 ml) was refluxed for 14 hr. The reaction mixture was treated as in the preparation of **5a** to yield a syrupy compound. Tlc (1:5 2-butanone–toluene) indicated the formation of three components having close R_f values. The syrup was dissolved in ethanol–ligroin and the solution was allowed to stand in a refrigerator for a week giving crystals (0.22 g, 13%) of **9**, mp 145—150 °C. Recrystallization from ethanol gave an analytical sample, mp 151—152 °C.

Found: C, 42.32; H, 4.54; N, 20.94%. Calcd for $C_{14}H_{18}N_6O_8$: C, 42.21; H, 4.55; N, 21.10%.

The mother liquor of **9** was concentrated to give a syrup. which was hydrogenated in an ethanol solution (20 ml) overnight. The product was acetylated in the usual way to afford a syrupy product, which was without further purification de-*O*-acetylated by treatment with a catalytic amount of sodium methoxide in a methanol solution. The product was crystallized from ethanol to give white powder (0.13 g) of di-*N*-acetyl inosadiamine. A 52 mg portion of this compound was acetylated in the usual way to give crystals of hexaacetyl *allo*-inosadiamine-1,4 (**10**), mp* 247.5—248 °C. The yield of **10** was 10% based on **8a**.

Found: C, 50.15; H, 6.05; N, 6.30%. Calcd for $C_{18}H_{26}N_2O_{10}$: C, 50.23; H, 6.09; N, 6.51%.

b): A mixture of 1,5-di-*O*-tosyl-*myo*-inositol tetraacetate (**8b**)[3] (1.0 g), sodium azide (1.0 g) and 90% aqueous 2-methoxyethanol (40 ml) was refluxed for 17 hr. The reaction mixture was then treated as in the preparation of *a)* to give crystals (0.24 g, 39%) of **9**, mp 147—150 °C. The product was identified with the compound obtained before by comparison of IR spectra.

Hexaacetyl allo-*Inosadiamins-1,4 (10).* Compound **9** (154 mg) was hydrogenated in an ethanol solution (15 ml) overnight. The product was acetylated in the usual way to give crystals after crystallization from ethanol–ether: yield 52 mg (31%), mp* 247.5—248 °C. It was shown to be identical with the compound obtained before by comparison of IR spectra.

1,2-Diacetamido-3,6-di-O-*acetyl-4,5*-O-*cyclohexylidene-1,2-dideoxy*-muco-*inositol (12).* A mixture of 1,2-*O*-cyclohexylidene-3,5-di-*O*-tosyl-*myo*-inositol (**11**)[3] (1.0 g), sodium azide (1.0 g), and 90% aqueous 2-methoxyethanol (20 ml) was refluxed for 17 hr. The reaction mixture was then treated as in the preparation of **5a** to give an oily azido compound. Tlc (1: 5 2-butanone-toluene) showed the formation of one major component along with a trace of one minor component. The crude compound was directly hydrogenated and then acetylated in the usual manner to give crystals, which were recrystallized from ethanol to afford thin needles (0.25 g, 34%) of **12**, mp* 182—185 °C. An analytical sample was obtained by recrystallization from ethanol; mp* 186—187 °C. PMR ($CDCl_3$): τ 8.00 (3-proton s, NHAc), 7.87 (6-proton s, OAc), 5.64 (2-proton broad d, J=4 Hz, H-4 and H-5), 5.45 (2-proton broad d, H-1 and H-2), 4.73 (2-proton m, H-3 and H-6), 3.50 (2-proton d, J=8 Hz, NHAc).

Found: C, 55.94; H, 6.97; N, 6.35%. Calcd for $C_{20}H_{30}N_2O_8$: C, 56.32; H, 7.09; N, 6.57%.

Hexaacetyl muco-*Inosadiamine-1,2 (13).* Compound **12** (0.10 g) was refluxed with 80% aqueous acetic acid (5 ml) for 1 hr, and then acetylated in the usual way to give crystals (62 mg, 57%) of **13**, mp 90—120 °C. Recrystallization from ethanol–ether afforded an analytical sample, needles, which melted* at 220—221.5 °C sharply after melting at 90—120 °C and then resolidifying at 150—155 °C.

Found: C, 50.18; H, 6.36; N, 6.37%. Calcd for $C_{18}H_{26}N_2O_{10}$: C, 50.23; H, 6.09; N, 6.51%.

1,2-O-Cyclohexylidene-muco-*inositol Tetraacetate (15).* A mixture of 1,2-*O*-cyclohexylidene-3-*O*-tosyl-*myo*-inositol (**14**)[3] (0.50 g), potassium carbonate (0.50 g), and 80% aqueous 2-methoxyethanol was refluxed for 4.5 hr. The reaction mixture was evaporated to dryness and the residue was treated with acetic anhydride (10 ml) and pyridine (10 ml) overnight at room temperature. The insoluble material was filtered off and the filtrate was evaporated to give a syrup, which was crystallized from ethanol to afford plates (0.34 g, 65%) of **15**, mp 130—131 °C. Recrystallization from ethanol–petroleum ether afforded an analytical sample, mp 134—134.5 °C PMR ($CDCl_3$): τ 7.93, 7.89 (6-proton s, OAc), 5.75 (2-proton m, H-1 and H-2), 4.77 (2-proton m, H-4 and H-5). The two multiplets are consistent with the A_2 portion of the A_2X_2 system.

Found: C, 56.42; H, 6.54%. Calcd for $C_{20}H_{28}O_{10}$: C, 56.07; H, 6.59%.

1,2-Di-O-*tosyl*-muco-*inositol Tetraacetate (16).* A mixture of **15** (1.5 g) and 30% aqueous acetic acid (20 ml) was heated for 3 hr at 75 °C. The reaction mixture was then evaporated to give a partly crystalline compound, from which **15** (0.12 g) was recovered. The resulting syrup was concentrated to dryness and treated with tosyl chloride (3.5 g) in pyridine (20 ml) overnight at room temperature. The mixture was poured into ice water and the resulting crystals were collected by filtration. Recrystallization from ethanol afforded pure crystals (1.15 g, 56%) of **16**, mp 160 °C. PMR ($CDCl_3$): τ 7.99, 7.97 (6-proton s, OAc), 7.53 (6-proton s, OTs), 5.16 (2-proton m, H-1 and H-2), 4.73 (2-proton m, H-4 and H-5). The two multiplets are consistent with the A_2 portion of the A_2X_2 system.

Found: C, 51.38; H, 5.16; S, 9.64%. Calcd for $C_{28}H_{32}O_{14}S_2$: C, 51.21; H, 4.91; S, 9.76%.

Preparation of 13 from 16. A mixture of **16** (0.51 g), sodium azide (0.55 g), and 90% aqueous 2-methoxyethanol (30 ml) was refluxed for 20 hr. The reaction mixture was evaporated to dryness and the residue was dried by coevaporation with toluene. The solid residue was treated with acetic anhydride (10 ml) and pyridine (10 ml) overnight at room temperature. The insoluble material was removed by filtration and the filtrate was evaporated. The syrupy residue was purified with a short alumina column with chloroform as an eluent. The product was then hydrogenated and subsequently acetylated in the usual manner to give crystals, which were recrystallized from ethanol–ether to afford needles (97 mg, 30%) of **13**, mp* 213—216 °C. It was identified with the compound obtained before by comparison of IR spectra.

2,4-Diazido-2,4-dideoxy-chiro-*inositol Tetraacetate (18) and 6-Azido-6-deoxy-1*-O-*tosyl*-myo-*inositol Tetraacetate (19).* A mixture of 1,6-di-*O*-tosyl-*myo*-inositol tetraacetate (**17**)[3] (4.0 g), sodium azide (4.0 g), and 90% aqueous 2-methoxyethanol (150 ml) was refluxed for 12 hr. The reaction mixture was then treated as in the preparation of **9** to yield an oily azido compound which was found to consist of two major components. They were fractionally crystallized from ethanol to afford almost pure crystals (1.25 g, 47.8%) of **18** and pure prisms (0.695 g, 22.7%) of **19**. Recrystallization from ethanol gave needles (1.16 g, 44.4%) of **18**, mp 147—148 °C.

Found: C, 42.15; H, 4.57; N, 21.32%. Calcd for $C_{14}H_{18}N_6O_8$: C, 42.21; H, 4.55; N, 21.10%.

Recrystallization from chloroform-ethanol gave prisms (0.633 g, 18.3%) of **19**, mp 163.5—164.5 °C.

Found: C, 47.99; H, 4.83; N, 7.81; S, 6.31%. Calcd for $C_{21}H_{25}N_3O_{11}S$: C, 47.82; H, 4.78; N, 7.97; S, 6.08%.

Hexaacetyl chiro-*Inosadiamine-2,4 (20).* Compound **18** (0.22 g) was hydrogenated in an ethanol solution (20 ml) overnight. The product was acetylated in the usual way and the product was crystallized from ethanol–ether to afford prisms (0.10 g, 42%) of **20**, mp 253—256 °C. Recrystallization from ethanol–ether gave large prisms after long storage in a refrigerator; mp 160—170 °C.

Found: C, 48.31; H, 6.34; N, 6.33%. Calcd for $C_{18}H_{26}N_2O_{10}\cdot H_2O$: C, 48.21; H, 6.29; N, 6.25%.

1,4-Anhydro-5,6-O-cyclohexylidene-2-O-*tosyl*-chiro-*inositol (22).* A mixture of 5,6-di-*O*-acetyl-1,2-*O*-cyclohexylidene-3,4-di-*O*-tosyl-*myo*-inositol (**21b**)[3] (1.1 g), sodium azide (1.1 g), and 90% aqueous 2-methoxyethanol (20 ml) was refluxed for 15 hr. The reaction mixture was evaporated to dryness and the residue was extracted with hot ethyl acetate. The extracts were evaporated to give crystals which were recrystallized from ethanol to afford crystals (0.47 g, 65%) of **22**, mp 114.5—116 °C. The product was identified with an authentic IR spectrum.

The authors wish to thank Prof. Sumio Umezawa for his kind advice. They are grateful to Mr. Saburo Nakada for elementary analyses and to Mr. Hayashi Uchino for the preparation of compound **13** from **14**. The work was carried out with financial support from the Ministry of Education.

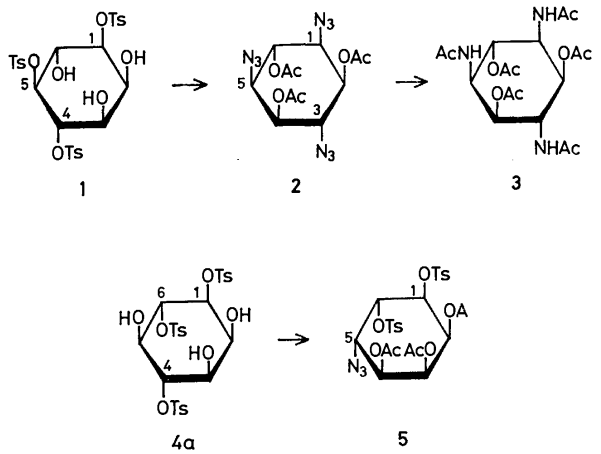
Inositol Derivatives. 8. Azidolysis of Tri- and Tetra-sulfonates of *myo*-Inositol[1]

Tetsuo SUAMI, Seiichiro OGAWA, Shuichi OKI, and Hideo KUNITOMO
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223
(Received November 30, 1973)

Reactions of the azide ion with four trisulfonates (1,4,5-, 1,4,6-, 1,5,6-, and 4,5,6-) and one tetrasulfonate (1,4,5,6-) of *myo*-inositol were studied. The structures of the new azido compounds were established by PMR spectroscopy and reaction sequences. The mechanism of neighboring-group participation reactions were discussed.

In continuation of the preceding work,[2] studies have been made on the azidolysis of four tritosylates (1,4,5,-1,4,6-, 1,5,6-, and 4,5,6-) of *myo*-inositol and some of their 2,3-*O*-cyclohexylidene derivatives, together with 1,4,5,6-tetra-*O*-tosyl-*myo*-inositol.

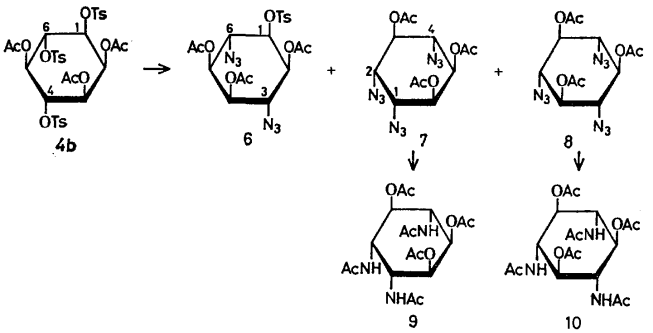
1,4,5-Tritosylate. Refluxing of 1,4,5-tri-*O*-tosyl-*myo*-inositol (**1**)[3] with sodium azide in 90% aqueous 2-methoxyethanol for 22 hr, followed by acetylation, exclusively gave crystalline triazidotrideoxyinositol triacetate (**2**) in 42% yield. Hydrogenation of **2** and subsequent acetylation gave the corresponding hexaacetyl inosatriamine (**3**) in 54% yield. Compound **2** was assigned to 1,3,5-triazido-1,3,5-trideoxy-*muco*-inositol triacetate on the basis of elemental analysis and IR and well-defined PMR spectra. In the PMR spectrum in deuteriochloroform ($CDCl_3$) (Table 1), the H-3 wide triplet (τ 5.80) shifted downfield remarkably as compared with two-proton double doublet (τ 6.02) due to two equivalent equatorial protons on C-1 and C-5, attributable to the deshielding effect of two *syn*-axial azido groups on C-1 and C-5.[4] The PMR spectrum of **3** in dimethylsulfoxide-d_6 (DMSO-d_6) also supported its *muco*-1,3,5 configuration. Thus, the acetyl methyl protons appearing as four singlets (2:1:1:2) at τ 8.18, 8.07, 8.04, and 7.87, could be ascribed to two equatorial and one axial acetamido, and one equatorial and two axial acetoxy groups, respectively.[5] The H-6 wide triplet (J=10 Hz) appeared in a lower field (τ 4.75) due to deshielding effect of two *syn*-axial acetoxy groups on C-2 and C-4.[4] It is interesting to note that, in the favored conformation of **2**, the two substituents located in *syn*-axial orientation appear to be not the acetoxy but the azido groups, in contrast with that of **3**, whose substituents on the same carbons were of *syn*-equatorial orientation.



Scheme 1

It is reasonable to deduce that the azidolysis proceeds *via* neighboring-group participation reaction initiated by the intramolecular attack of the 3-hydroxyl group to C-4 leading to the intermediate 3,4-epoxide. From the structure of **2**, it is feasible that the intermediate epoxides formed successively are opened by azide ion in *trans*-diaxial manner.

1,4,6-Tritosylates. On treatment with sodium azide under similar conditions to those for **1**, 1,4,6-tri-*O*-tosyl-*myo*-inositol (**4a**)[3] yielded, after subsequent acetylation, the monoazido compound (**5**) as the sole crystalline product in 6% yield. The structure of **5** was deduced to be 5-azido-5-deoxy-1,6-di-*O*-tosyl-*allo*-inositol triacetate on the basis of its PMR spectrum, which exhibited the H-5 signal as a double doublet (J=3 and 10 Hz) at τ 5.86.[6] Mechanistically, the 5-hydroxyl group is likely to form the 4,5-epoxide which is opened diaxially by azide ion.



Scheme 2

On the other hand, when the triacetate (**4b**)[3] was treated with sodium azide under identical conditions, three azido compounds were formed, which were successively separated by fractional crystallization from ethanol and methanol to give one diazido compound (**6**) (34%), and two triazido compounds (**7** (9%) and **8** (2%)). Syrupy **8**, which was later obtained in a crystalline form, was further characterized by converting it into known hexaacetyl *scyllo*-inosatriamine-1,3,5 (**10**).[7] The structure of **8** was then established to be 1,3,5-triazido-1,3,5-trideoxy-*scyllo*-inositol triacetate.[8] From the data of analysis and IR and PMR spectra **6** and **7** were assigned to 3,6-diazido-3,6-dideoxy-1-*O*-tosyl-*muco*-inositol triacetate and 1,2,4-triazido-1,2,4-trideoxy-*chiro*-inositol triacetate,[9] respec-

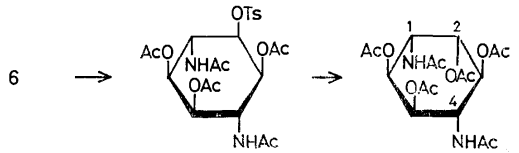
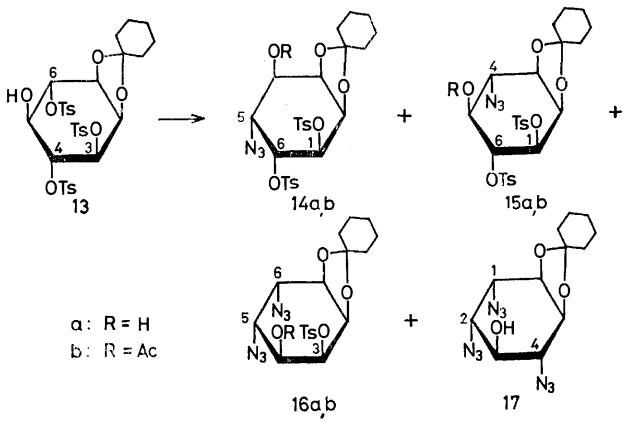
a) Chemical shifts are given in terms of τ-values. Values given for coupling constants (Hz) are of firts order. Abbreviations: s (singlet); d (doublet); t (triplet); dd (double doublet); m (complex multiplet). b) Values in parenthesis show number of protons.

tively. The PMR spectrum of **6** exhibited the H-3 signal as a narrow triplet and H-6 signal as a wide triplet at τ 5.88 and 5.85, respectively. The downfield shift of H-6 axial proton as compared with H-3 equatorial proton might be attributed to the deshielding effect of two *syn*-axial acetoxy groups on C-2 and C-4.[4)] The structure of **6** was finally confirmed by transforming it into known hexaacetyl *chiro*-inosadiamine-1,4 (**12**)[10)] in the following way. On reduction and



Scheme 3

subsequent acetylation, **6** gave 3,6-diacetamido-3,6-dideoxy-1-*O*-tosyl-*muco*-inositol triacetate (**11**). Without further purification, this was refluxed with sodium acetate in 90% aqueous 2-methoxyethanol followed by acetylation to afford **12** in 61% yield with an inversion of the configuration at C-1. The PMR spectral data of **7** established the axial orientation for H-3, H-4, and H-5, and the equatorial orientation for H-6. The PMR spectrum of hexaacetyl inosatriamine (**9**) derived from **7** showed the acetyl methyl protons as four singlet (2:1:2:1) at τ 8.21, 8.10, 8.06, and 7.85, which were assigned to two equatorial and one axial acetamido, and two equatorial and one axial acetoxy groups, respectively.[5)] These chemical shifts were found to be very similar to those of **12**. Consequently, the configuration of **7** was proved to be *chiro*-1,3,4. From these results, the azidolysis reactions of **4a** and **4b** should involve quite different mechanisms. In the case of **4b**, the initial formation of the intermediate 3,4- or/and 5,6-cyclic acetoxonium ion might be proposed.



Scheme 4

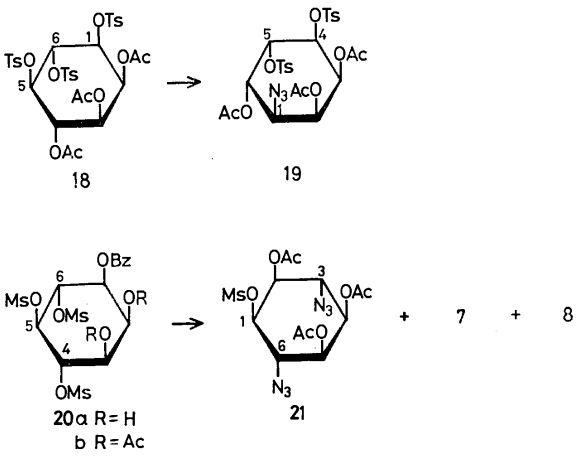
1,2-*O*-Cyclohexylidene-3,4,6-tri-*O*-tosyl-*myo*-inositol (**13**)[3)] was subjected to a similar azidolysis. In compound **13**, the neighboring-group participation of the 3-hydroxyl group to C-4 as would be expected in the azidolysis of **5** was not possible, since the two hydroxyl groups at C-2 and C-3 were blocked by *O*-cyclohexylidene group. The reaction was monitored by tlc. After 3 hr, **13** disappeared completely and the formation of two major components (**14a** and **15a**) was detected. **15a**, a slightly faster-moving component, was then disappeared slowly and the third component **16a** was formed. By a prolonged treatment, **16a** was converted almost completely into the more faster-moving component (**17**), while **14a** remained unchanged during the course of the reaction. Thus, when **13** was allowed to react with sodium azide on being refluxed in 90% aqueous 2-methoxyethanol for 3 hr, monoazido compounds (**14a** and **15a**) and a diazido compound (**16a**) were obtained in 26, 28, and 7% yields, respectively, after separation by fractional crystallization from ethanol or ethyl acetate. When the reaction time

was extended to 22 hr, compound **14a**, **16a**, and a triazido compound (**17**) were isolated in 26, 1.4, and 13% yields, respectively, after fractionation by a silica gel chromatography. Since **13** yielded the 4,5-epoxide selectively on treatment with sodium methoxide,[11] the intermediary-formation of the same epoxide might be postulated as in the azidolysis of **13**. The monoazido compounds are therefore formed through nucleophilic cleavage of the 4,5-epoxide by azide ion. The 5-azido compound seems to be less reactive for further substitution as compared with the 4-azido compound, because of lack of the participating group. Compounds **14a** and **15a** were thus reasonably assigned to 5-azido-2,3-*O*-cyclohexylidene-5-deoxy-1,6-di-*O*-tosyl-*allo*-inositol and 4-azido-2,3-*O*-cyclohexylidene-4-deoxy-1,6-di-*O*-tosyl-*myo*-inositol, respectively. Compound **15a** would readily undergo nucleophilic substitution *via* the intermediate 5,6-epoxide to give 5,6-diazido-1,2-*O*-cyclohexylidene-5,6-dideoxy-3-*O*-tosyl-*allo*-inositol (**16a**) as a predominant product, which was further transformed into a triazido compound (**17**), 1,2,4-triazido-5,6-*O*-cyclohexylidene-1,2,4-trideoxy-*chiro*-inositol. The structure of **17** was confirmed by its conversion into **7** by hydrolysis with 80% aqueous acetic acid followed by acetylation.

The tentatively assigned structures of **14a**, **15a**, and **16a** were supported by the PMR spectra of their corresponding acetyl derivatives (**14b**, **15b**, and **16b**). The PMR spectrum of **14b** showed a double doublet (J=3.5 and 9.5 Hz) at τ 5.78, which was ascribed to the proton attached to the carbon atom carrying the azido group. In the spectrum of **15b**, H-4 signal appeared as a multiplet, which was coupled with the adjacent signal due to H-3 proton. The PMR spectrum of **16b** exhibited three narrow multiplets at τ 6.00, 4.98, and 4.68 in the ratio 1 : 1 : 1, ascribable to three pairs of protons being vicinally located: H-5 and H-6, H-1 and H-2, and H-3 and H-4, respectively.

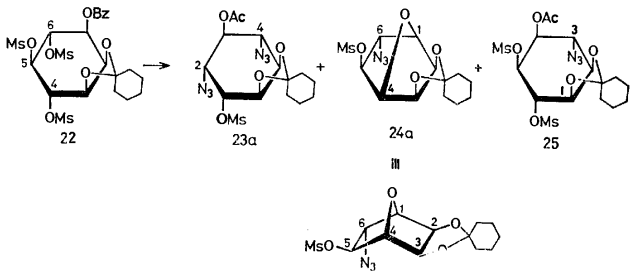
Hydrolysis of **14a** followed by acetylation gave **5** in 55% yield, supporting the proposed structure of **5**.

1,5,6-Tritosylate. Treatment of 1,5,6-tri-*O*-tosyl-*myo*-inositol triacetate (**18**)[3] with sodium azide under the usual conditions, followed by acetylation, gave predominantly the monoazido compound (**19**) in 26% yield. Tlc showed the formation of a trace of the more faster-moving component, probably the diazido compound, in addition to **19**. The structure of **19** was assigned to 1-azido-1-deoxy-4,5-di-*O*-tosyl-*allo*-inositol triacetate on the basis of its PMR spectrum. The two double doublets (τ 5.90 and 4.34) showed splittings of 3.5 and 10.5 Hz, coupled with each other. Thus they were ascribed to H-1 and H-6 protons, respectively. Compound **19** should be formed by diaxial scission of the intermediate 4,5-epoxide with azide ion.



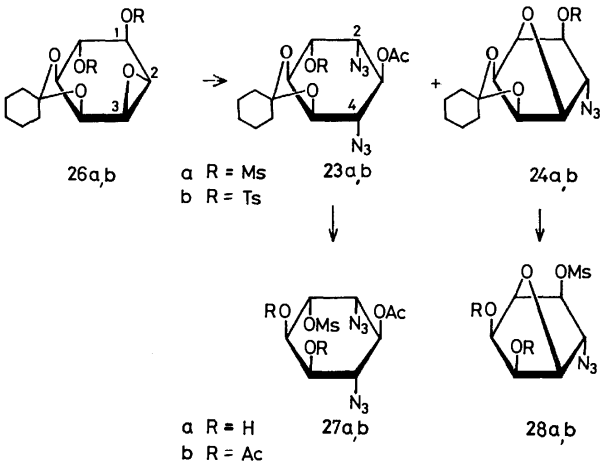
Scheme 5

4,5,6-Trisulfonates. 1-*O*-Benzoyl-4,5,6-tri-*O*-mesyl-*myo*-inositol (**20**)[12] was subjected to azidation. The products were fractionated by silica gel column chromatography to afford the monoazido compound (**21**), **7** and **8** in 31, 14, and 9.5% yields, respectively. The PMR spectrum of **21** (Table 1) was very close to that of **6**. Thus its structure was assigned to the corresponding 3,6-diazido-3,6-dideoxy-1-*O*-mesyl-*muco*-inositol. If the reaction is initiated by the participation of 1-benzoyloxy or 3-hydroxyl group to C-6 or C-4, the diaxial opening of the cyclic intermediates with azide ion should proceed preferentially to yield **21** as the predominant product along with the minor **8**. Compound **7** should have arisen from **21** by further direct S_N2 substitution of 1-mesyloxy group with azide ion. For the sake of confirmation, **21** was treated with sodium azide under the same conditions, but **7** was found to be only slightly formed by tlc. It was thus necessary to deduce an alternative reaction mechanism. We reported that the direct S_N2 displacement reaction of 5-tosyloxy function with chloride ion occurred readily in the tosylation of 1,2-*O*-cyclohexylidene-*myo*-inositol and its related compound.[12] By analogy with this, the initial substitution of the 5-mesyloxy group might be also feasible, and would account for the formation of **7** as well as **8** in relatively good yields.



Scheme 6

The azidolysis of the 2,3-*O*-cyclohexylidene derivative (**22**)[12] was carried out. Following the reaction by tlc, the formation of two major components was shown, together with two minor components which gradually disappeared with prolonged treatment. After 45 hr, the products were fractionated with a silica gel column to afford the diazido compound (**23a**) (8%), and monoazido compounds (**24a** (9%) and **25** (1.5%)). Since the reaction might proceed *via* the cyclic intermediate, 1,6-benzoxonium ion, azidolysis of an epoxide with a similar configuration was studied. Epoxides, 2,3-anhydro-4,5-*O*-cyclohexylidene-1,6-di-*O*-mesyl-*epi*-inositol (**26a**)[12] and -1,6-di-*O*-tosyl-*epi*-inositol (**26b**)[11] were subjected to azidolysis. Compounds **23a**,**b** and **24a**,**b** were obtained as expected from **26a**,**b** in comparatively good yields.



Scheme 7

Removal of the cyclohexylidene group of **23a** led to dihydroxyl compound (**27a**) which gave triacetate (**27b**). Similarly, **24a** was converted into dihydroxyl compound (**28a**) and diacetate (**28b**). On the basis of elemental analysis and IR and PMR spectra, **23a** and **24a** were assigned to 3-*O*-acetyl-2,4-diazido-5,6-*O*-cyclohexylidene-2,4-dideoxy-1-*O*-mesyl-*chiro*-inositol and 1,4-anhydro-6-azido-2,3-*O*-cyclohexylidene-6-deoxy-5-*O*-mesyl-*epi*-inositol, respectively. In the PMR spectrum of **27b**, a pattern of the signals due to the ring protons was shown to be essentially similar to that of 2,4-diazido-2,4-dideoxy-*chiro*-inositol tetraacetate,[2] supporting the proposed structure.

In the first step of the azidolysis, it is mechanistically reasonable to conclude that the 2,3-epoxide ring is opened by azide ion to give rise to 2- and 3-azido compounds, both of which are lacking in the participating groups for nucleophilic substitution of the sulfonyloxy group in a vicinal position. Thus in the case of the latter, substitution of the sulfonyloxy group at C-1 would proceed in direct S_N2 fashion to give **23a**. In the case of the former, a direct S_N2 attack on C-1 is considerably interrupted by steric and electronic effects due to the adjacent azido group, but the hydroxyl group at C-3 can attack the rear-side of C-6 intramolecularly in a boat-like conformation, resulting in the transannular epoxide (**24a**).[2,13]

The PMR spectral data of **24a** and its derivatives (Table 2) were consistent with the assigned structures. The C-2 and C-3 protons appeared at τ 5.31 and 5.67, respectively, as the AB quartet. The downfield shift of the former might be accounted for by assuming the proximity effect[14] and/or a strong magnetic field, excerted by the 6-*endo* azido group. No detectable coupling could be observed between the bridge head proton H-1 or H-4 and H-2 *endo* or H-3 *endo* protons, supporting the bicyclic structure. The coupling constants measured from **24a**, **24b**, and **28** were in good accord with those of bicyclo[2.2.1]heptane system.[15]

Table 2. PMR data of derivatives of 1,4-anhydro-*epi*-inositol in $CDCl_3$ at 60 MHz[a]

	24a	**24b**	**28b**

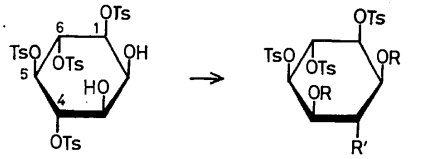

Scheme 8

1,4,5,6-Tetratosylate. Reaction of 1,4,5,6-tetra-*O*-tosyl-*myo*-inositol (**29**)[3] with sodium azide in the usual way gave the monoazido compound (**30a**) selectively in 62% yield, which was converted into the diacetate (**30b**). By a similar reaction with sodium acetate followed by acetylation, **29** yielded the triacetyl compound (**30c**) in 63% yield. The reactions seem to proceed *via* the intermediate 3,4-epoxide, followed by nucleophilic attack in diaxial manner. Exclusive products would possess *muco*-configuration. The PMR spectra of **30b** and **30c** supported the assigned structures. In **30b**, the acetyl methyl protons appeared as a single peak at τ 8.09, indicating a symmetrical structure. In **30c**, three acetoxy groups occurred as two singlets (2: 1) at τ 8.18 and 8.02, satisfying *muco*-configuration. The structures of **30a** and **30c** could thus be established as 3-azido-3-deoxy-1,5,6-tri-*O*-tosyl-*muco*-inositol and 2,3,4-tri-*O*-tosyl-*muco*-inositol triacetate, respectively.

Experimental

Unless otherwise noted, melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. IR spectra were measured on a JASCO IR-E spectrophotometer in KBr disks. PMR spectra were obtained on a Varian Associates A-60D (60 MHz) spectrometer at a concentration of approximately 10% $CDCl_3$ or DMSO-d_6, with tetramethylsilane as an internal standard. Chemical shifts are given in terms of τ-values, signals being denoted by s (singlet), d (doublet), dd (double doublet), t (triplet), or m (complex multiplet). Values given for coupling constants are of first-order. All the solutions were concentrated with a rotary evaporator at 40—50 °C under reduced pressure, a trace of residual pyridine being removed by coevaporation with toluene. Catalytic hydrogenations were carried out with a Parr shaker apparatus in the presence of Raney nickel T-4[16] catalyst in the initial hydrogen pressure of 3.5 kg/cm^2 at room temperature. Tlc was performed on silica gel

(Wakogel B-10, Wako Pure Chemica lIndustries, Ltd.) using a mixture of 2-butanone and toluene. The spots were indicated by heating above 150 °C after spraying with 30% sufuric acid.

1,3,5-Triazido-1,3,5-trideoxy-muco-*inositol Triacetate (2).* A mixture of 1,4,5-tri-*O*-tosyl-*myo*-inositol (**1**)[3] (1.50 g), sodium azide (1.50 g), and 90% aqueous 2-methoxyethanol (75 ml) was refluxed for 22 hr. The reaction mixture was then evaporated to dryness and the residue was treated with acetic anhydride (10 ml) and pyridine (10 ml) overnight at room temperature. An insoluble material was removed by filtration and the filtrate was evaporated to yield an oil which was purified by passing through a short alumina column with chloroform as an eluent. The solution was concentrated and the product was crystallized from ether to afford crystals (0.37 g, 42%) of **2**. Recrystallization from ethanol–ether afforded an analytical sample (0.33 g, 37%), mp 92—93 °C.

Found: C, 37.81; H, 3.95; N, 33.19%. Calcd for $C_{12}H_{15}N_9O_6$: C, 37.79; H, 3.97; N, 33.07%.

Hexaacetyl muco-*Inosatriamine-1,3,5 (3).* A solution of **2** (100 mg) in ethanol (10 ml) was hydrogenated for 6 hr. The catalyst was filtered off and the filtrate was evaporated to dryness. The residue was treated with acetic anhydride (1.5 ml) and pyridine (2 ml) overnight at room temperature. The reaction mixture was evaporated to give a crystalline residue which was recrystallized from ethanol–ether to give tiny needles (60 mg, 54%) of **3**, mp 259—260 °C (decomp.).

Found: C, 50.49; H, 6.42; N, 9.99%. Calcd for $C_{18}H_{27}N_3O_9$: C, 50.34; H, 6.34; N, 9.79%.

*5-Azido-5-deoxy-1,6-di-*O*-tosyl*-allo-*inositol Triacetate (5).* A mixture of 1,4,6-tri-*O*-tosyl-*myo*-inositol (**4a**)[3] (2.0 g), sodium azide (2.0 g), and 90% aqueous 2-methoxyethanol (50 ml) was refluxed for 22 hr. The mixture was evaporated to dryness and the residue was acetylated in the usual manner. Tlc showed the formation of one major component and two minor components. The products were extracted with chloroform and the extracts were evaporated to give an oil which was crystallized from ethanol to give needles (0.14 g, 6.3%) of **5**, mp 157—158 °C. Recrystallization from ethanol afforded a pure sample, mp 158—160 °C. PMR ($CDCl_3$): τ 8.13, 7.92, 7.90 (3-proton s, OAc), 7.50 (3-proton s, $OSO_2C_6H_4C\underline{H}_3$).

Found: C, 48.97; H, 4.70; N, 6.31; S, 9.98%. Calcd for $C_{26}H_{29}N_3O_{12}S_2$: C, 48.82; H, 4.57; N, 6.57; S, 10.02%.

*Azidolysis of 1,4,6-tri-*O*-tosyl*-myo-*inositol Triacetate (4b).*[3] A mixture of **4b** (3.25 g), sodium azide (3.85 g), and 90% aqueous 2-methoxyethanol (100 ml) was refluxed for 16 hr. The reaction mixture was then treated in a similar way to that for **1** to give a crystalline mixture (1.04 g), mp 121—134 °C. Tlc (1: 4 2-butanone–toluene) indicated the formation of two major components. Fractional crystallization from ethanol gave two crystals: 3,6-diazido-3,6-dideoxy-1-*O*-tosyl-*muco*-inositol triacetate (**6**), yield 0.73 g (33.8%), mp 134—135 °C, and 1,2,4-triazido-1,2,4-trideoxy-*chiro*-inositol triacetate (**7**), yield 0.122 g (8.7%), mp 112—113 °C. Analytical samples of **6** and **7** were obtained by recrystallization from ethanol and dried *in vacuo* over phosphorus pentoxide overnight at room temperature.

6: Found: C, 45.09; H, 4.51; N, 16.35; S, 6.00%. Calcd for $C_{19}H_{22}N_6O_9S$: C, 44.70; H, 4.34; N, 16.46; S, 6.28%.

7: Found: C, 38.05; H, 3.96; N, 33.30%. Calcd for $C_{12}H_{15}N_9O_6$: C, 37.80; H, 3.97; N, 33.06%.

Evaporation of the mother liquor gave a syrup which was shown by tlc to consist of a faster-moving major component together with traces of **6** and **7**. The syrupy crude 1,3,5-triazido-1,3,5-trideoxy-*scyllo*-inositol triacetate (**8**) was, without further purification, hydrogenated in an ethanol solution (10 ml) for 5.5 hr. The product was treated with acetic anhydride (5 ml) and pyridine (5 ml) overnight at room temperature, and the mixture was then evaporated to give an oil, which crystallized upon addition of methanol to give plates (40 mg, 2.2%) of hexaacetyl *scyllo*-inosatriamine-1,3,5 (**10**), which did not melt below 330 °C, but sublimed at 305 °C turning brown at 310 °C (lit,[7] mp 310—315 °C). The compound was identified with an authentic sample[7] by comparison of IR spectra.

Hexaacetyl chiro-*Inosatriamine-1,2,4 (9).* A solution of **7** (0.20 g) in ethanol (30 ml) was hydrogenated for 20 hr. After the catalys had been removed by filtration, the solution was evaporated and the residue was acetylated in the usual way to give crystalline product. Recrystallization from ethanol afforded crystals (136 mg, 60.4%) of **9**, mp 167—168 °C. Recrystallization from ethanol gave an analytical sample as needles, mp 166—169 °C.

Found: C, 48.51; H, 6.25; N, 9.33%. Calcd for $C_{18}H_{27}N_3O_9\cdot H_2O$: C, 48.31; H, 6.51; N, 9.39%.

Preparation of Hexaacetyl chiro-*Inosadiamine-1,4 (12) from 6.* Compound **6** (0.91 g) was hydrogenated in an ethanol solution (150 ml) for 16 hr. The product was acetylated in the usual manner to give syrupy 1-*O*-tosyl-*muco*-inosadiamine-3,6 triacetate (**11**). Without further purification, **11** was treated with anhydrous sodium acetate (0.80 g) in refluxing 90% aqueous 2-methoxyethanol (45 ml) for 45 hr, and the reaction mixture was then evaporated to dryness and subsequently acetylated to give a crystalline compound, which was crystallized from chloroform to afford crystals (0.47 g, 61%) of **12**, mp 126—131 °C (lit,[10] 127—129 °C). This compound was identified with an authentic sample by comparison of their IR and PMR (DMSO-d_6) spectra.

*Azidolysis of 1,2-*O*-Cyclohexylidene-3,4,6-tri-*O*-tosyl*-myo-*inositol (13).*[3] *a)*: A mixture of **13** (6.0 g), sodium azide (6.0 g), and 90% aqueous 2-methoxyethanol (90 ml) was refluxed, and the progress of the reaction was followed by tlc (1: 4 2-butanone–toluene). After 3 hr, **13** disappeared completely in the reaction mixture. It was then evaporated to dryness and the residue was extracted with hot ethyl acetate (3×50 ml). The extract was concentrated to give a crystalline mixture, whose tlc showed the formation of major three components along with a trace of a faster-moving component. Crystallization from ethyl acetate gave crystals (1.29 g, 26%) of 5-azido-5-deoxy-2,3-*O*-cyclohexylidene-1,6-di-*O*-tosyl-*allo*-inositol (**14a**), mp 165—169 °C. The crystals were shown by IR spectrum to contain ethyl acetate. Recrystallization twice from ethanol gave an analytical sample, mp 163.5—164 °C.

Found: C, 52.77; H, 5.52; N, 7.08; S, 10.37%. Calcd for $C_{26}H_{31}N_3O_9S_2$: C, 52.60; H, 5.26; N, 7.08; S, 10.80%.

Compound **14a** (0.33 g) was treated with acetic anhydride (2 ml) and pyridine (3 ml) overnight at room temperature. The reaction mixture was evaporated with toluene to give a syrup which was crystallized from ethanol–ether to afford crystals (0.33 g, 94%) of the acetate (**14b**), mp 163.5—165.5 °C. Recrystallization from ethanol–chloroform gave an analytical sample, mp 150—151 °C. PMR ($CDCl_3$): τ 7.86 (3-proton s, OAc), 7.52 (6-proton s, $OSO_2C_6H_4C\underline{H}_3$).

Found: C, 52.70; H, 5.22; N, 6.47; S, 10.08%. Calcd for $C_{28}H_{33}N_3O_{10}S_2$: C, 52.90; H, 5.23; N, 6.61; S, 10.09%.

The mother liquor of **14a** was concentrated to a small volume and allowed to stand at room temperature yielding thin needles, which were recrystallized from ethanol to afford tiny needles (1.37 g, 27.8%) of 4-azido-4-deoxy-2,3-*O*-cyclohexylidene-1,6-di-*O*-tosyl-*myo*-inositol (**15a**), mp 173—175 °C, after melting and resolidifying at 165—167 °C.

Found: C, 52.90; H, 5.17; N, 7.05; S, 11.10%. Calcd

for $C_{26}H_{31}N_3O_9S_2$: C, 52.60; H, 5.26; N, 7.08; S, 10.80%.

Compound **15a** (0.36 g) was acetylated as described above to give crystals, which were recrystallized from chloroform–ethanol to afford crystals (0.37 g, 95%) of the acetate (**15b**), mp 156.5—158.5 °C. PMR ($CDCl_3$): τ 7.94 (3-proton s, OAc), 7.55 (6-proton s, $OSO_2C_6H_4C\underline{H}_3$), 5.71 (dd, $J_{1,2}$= 3.5 Hz, $J_{2,3}$=5 Hz, H-2).

Found: C, 53.14; H, 5.44; N, 6.43; S, 10.14%. Calcd for $C_{2,}H_{33}N_3O_{10}S_2$: C, 52.90; H, 5.23; N, 6.61; S, 10.09%.

The mother liquor of **15a**, kept at room temperature for a long time, yielded crystals which were recrystallized from ethanol to afford pure crystals (0.26 g, 6.9%) of 5,6-diazido-1,2-*O*-cyclohexylidene-5,6-dideoxy-3-*O*-tosyl-*allo*-inositol(**16a**), mp 142—143.5 °C.

Found: C, 49.18; H, 5.20; N, 17.97; S, 7.15%. Calcd for $C_{19}H_{24}N_6O_6S$: C, 49.12; H, 5.21; N, 18.10; S, 6.90%.

Acetylation of **16a** gave a homogeneous syrupy acetate (**16b**), which did not crystallize in spite of several attempts.

b): A mixture of **13** (10.0 g), sodium azide (10.0 g), and 90% aqueous 2-methoxyethanol (200 ml) was refluxed for 22 hr, when, tlc showed the formation of a faster-moving component, together with **14a** and **16a**. The reaction mixture was evaporated to dryness and the residue was extracted with ethyl acetate (3×100 ml). The extracts were purified by passing through a short alumina column and then concentrated to a syrup, which was crystallized from ethyl acetate to give crystals (1.76 g, 21.4%) of **14a**, mp 145—148 °C. The mother liquor was evaporated to give a syrup which was chromatographed on a silica gel column (90 g) with 1:6 2-butanone–toluene as an eluent. The three fractions were separated in accord with the results of tlc.

Fraction 1 gave a syrup which slowly crystallized upon trituration with ligroin, affording needles (0.61 g, 13.2%) of 1,2,4-triazido-5,6-*O*-cyclohexylidene-1,2,4-trideoxy-*chiro*-inositol (**17a**), mp 95—97 °C.

Found: C, 42.55; H, 5.01; N, 37.53%. Calcd for $C_{12}H_{17}N_9O_3$: C, 42.98; H, 5.11; N, 37.60%.

Fraction 2 gave crystals (0.089 g, 1.4%) of **16a**, mp 140—142 °C, after crystallization from ethanol.

Fraction 3 gave crystals (0.372 g) of **14a**, mp 142—145 °C, after crystallization from ethanol. The total yield of **14a** was then 26%.

Acetylation of **17a** gave a homogeneous syrupy acetate (**17b**) which did not crystallize in spite of several attempts.

Treatment of **17a** (0.30 g) with refluxing 80% aqueous acetic acid (10 ml) for 1.5 hr, followed by acetylation, gave crystals (0.26 g, 65%) of **7**, mp 111.5—112.5 °C. The compound was identified with a sample obtained from **4b**.

Compound **14a** (0.28 g) was successively hydrolyzed and acetylated as described above to give crystals (0.17 g, 55%) of **5**, mp 157—159 °C, after recrystallization from chloroform–ethanol. The compound was identified with a sample obtained from **4a**.

*1-Azido-1-deoxy-4,5-di-*O*-tosyl-*allo*-inositol Triacetate (19).* A mixture of 1,5,6-tri-*O*-tosyl-*myo*-inositol triacetate (**18**)[3] (0.50 g), sodium azide (0.50 g), and 90% aqueous 2-methoxyethanol (15 ml) was refluxed for 6 hr. The reaction mixture was then treated in a similar way to that for **4b** to give crystals (0.11 g, 26.4%) of **19**, mp 179.5—180.5 °C. Recrystallization from chloroform–ethanol, mp 182—183 °C.

Found: C, 49.22; H, 4.76; N, 6.34; S, 10.11%. Calcd for $C_{26}H_{29}N_3O_{12}S_2$: C, 48.82; H, 4.57; N, 6.57; S, 10.03%.

*1-*O*-Benzoyl-4,5,6-tri-*O*-mesyl-*myo*-inositol (20a).* 1-*O*-Benzoyl-2,3-*O*-cyclohexylidene-4,5,6-tri-*O*-mesyl-*myo*-inositol (**22**)[12] (3.0 g) was treated with refluxing 80% aqueous acetic acid (60 ml) for 3 hr. On being cooled to room temperature, the resulting crystals were collected by filtration: yield 1.98 g (77%), mp 215—221 °C. An additional crop (0.31 g, total yield 89%) was obtained by evaporation of the water layer. An analytical sample melted at 228—230 °C.

Found: C, 36.99; H, 4.46; S, 18.51%. Calcd for $C_{16}H_{23}O_{13}S_3$: C, 37.10; H, 4.27; S, 18.21%.

Acetylation of **20a** (1.5 g) in the usual manner gave the diacetate (**20b**): yield 1.74 g (99%), mp 209—212 °C. Recrystallization from chloroform–ethanol afforded an analytical sample, mp 214—216 °C.

Found: C, 39.80; H, 4.51; S, 15.94%. Calcd for $C_{20}H_{27}O_{15}S_3$: C, 39.74; H, 4.31; S, 16.21%.

Azidolysis of 20a. A mixture of **20a** (2.0 g), sodium azide (1.25 g), and 90% aqueous 2-methoxyethanol (75 ml) was refluxed for 28 hr. The reaction mixture was then treated in a similar way to that for **4b** to give a syrupy mixture of azido acetates. Tlc showed the formation of three major components. The mixture was chromatographed on a silica gel column (80 g) with 1:6 2-butanone–toluene as an eluent. The three fractions were separated in accord with the results of tlc.

Fraction 1 gave needles (0.14 g, 9.5%) of **8**, mp 127—132 °C, after crystallization from methanol.

Found: C, 37.80; H, 3.97; N, 33.06%. Calcd for $C_{12}H_{15}N_9O_6$: C, 37.69; H, 3.93; N, 32.85%.

Fraction 2 gave needles (0.20 g, 13.6%) of **7**, mp 109—111 °C, after crystallization from ethanol.

Fraction 3 gave crystals (0.51 g, 30.5%) of 3,6-diazido-3,6-dideoxy-1-*O*-mesyl-*muco*-inositol triacetate (**21**), mp 111—113 °C, after crystallization from chloroform–methanol.

Found: C, 35.95; H, 4.18; N, 19.35; S, 7.38%. Calcd for $C_{13}H_{18}N_6O_9S$: C, 36.14; H, 4.15; N, 19.32; S, 7.11%.

*Azidolysis of 1-*O*-Benzoyl-2,3-*O*-cyclohexylidene-4,5,6-tri-*O*-mesyl-*myo*-inositol (22).* A mixture of **22** (2.0 g), sodium azide (0.90 g), and 90% aqueous 2-methoxyethanol (70 ml) was refluxed for 45 hr. The reaction mixture was then treated in a similar way to that for **13**, and the resulting product was acetylated in the usual way to give a syrup which was purified by being passed through a short alumina column with chloroform. The solution was concentrated to afford a small amount of crystals (92 mg) of 3-*O*-acetyl-2,4-diazido-5,6-*O*-cyclohexylidene-2,4-dideoxy-1-*O*-mesyl-*chiro*-inositol (**23a**), mp 127—129 °C. The mother liquor was evaporated to give a syrup which was chromatographed on a silica gel column (100 g) with 1:9 2-butanone–toluene as an eluent. The three fractions were separated in accord with the results of tlc.

Fraction 1 gave crystals (35 mg, total yield 7.7%) of **23a**, mp 128—129 °C, after crystallization from ethanol–ether.

Found: C, 42.00; H, 5.18; N, 19.72; S, 7.36%. Calcd for $C_{15}H_{22}N_6O_7S$: C, 41.86; H, 5.15; N, 19.52; S, 7.45%.

Fraction 2 gave crystals (116 mg, 8.7%) of 1,4-anhydro-6-azido-2,3-*O*-cyclohexylidene-6-deoxy-5-*O*-mesyl-*epi*-inositol (**24a**), mp 127—128.5 °C, after crystallization from ethanol–ether. An analytical sample melted at 130—132 °C.

Found: C, 45.56; H, 5.50; N, 12.24; S, 9.06%. Calcd for $C_{13}H_{19}N_3O_6S$: C, 45.21; H, 5.55; N, 12.17; S, 9.28%.

Fraction 3 gave crystals (27 mg, 1.5%), mp 190—191 °C. The structure was deduced to be 2-*O*-acetyl-3-azido-4,5-*O*-cyclohexylidene-3-deoxy-1,6-di-*O*-mesyl-*muco*-inositol (**25**). PMR (DMSO-d_6): τ 7.80 (3-proton s, OAc), 6.83, 6.74 (3-proton s, OMs).

Found: C, 39.92; H, 5.01; N, 8.40; S, 13.13%. Calcd or $C_{12}H_{25}N_3O_{10}S_2$: C, 39.75; H, 5.21; N, 8.69; S, 13.26%.

*Azidolysis of 2,3-Anhydro-4,5-*O*-cyclohexylidene-1,6-di-*O*-mesyl-epi-inositol (26a).*[12] *a)*: A mixture of **26a** (1.0 g), sodium azide (0.66 g), ammonium chloride (0.27 g), and 90% aqueous 2-methoxyethanol (50 ml) was refluxed for

24 hr. The reaction mixture was then treated in a similar way to that for **13**. The syrupy azido compounds thus obtained were crystallized from ethanol–ether to give crystals (246 mg, 28.3%) of **24a**, mp 127—128.5 °C. The mother liquor was evaporated to dryness and the residue was acetylated in the usual way to give a syrup which was crystallized from ethanol–ether to afford crystals (360 mg, 33.3%) of **23a**, mp 128—129 °C.

b): Under the same conditions except for the absence of ammonium chloride, **26a** (1.0 g) afforded **23a** (230 mg, 21.3%), mp 128—129 °C, and **24a** (303 mg, 34.9%), mp 127—128.5 °C.

Azidolysis of 2,3-Anhydro-4,5-O-cyclohexylidenle-1,6-di-O-tosyl-epi-inositol (26b).[11] Compound **26b** (1.0 g) was refluxed with sodium azide (0.59 g) and ammonium chloride (0.24 g) in 2-methoxyethanol (30 ml) for 22 hr. The reaction mixture was treated in a similar way to that for **13** to give crystals (373 mg, 39.7%) of 1,4-anhydro-6-azido-2,3-*O*-cyclohexylidene-6-deoxy-5-*O*-tosyl-*epi*-inositol (**24b**), mp 115—123 °C. Recrystallization from ethanol gave an analytical sample, mp 126—127 °C.

Found: C, 54.24; H, 5.44; N, 9.62; S, 7.87%. Calcd for $C_{19}H_{23}N_3O_6S$: C, 54.15; H, 5.50; N, 9.97; S, 7.61%.

The mother liquor was concentrated and acetylated in the usual way to give a syrup. Tlc indicated the formation of one major component in addition to **24b**, which was probably diazido compound (**23b**) corresponding to **23a**. The syrup did not crystallize.

*3-O-Acetyl-2,4-diazido-2,4-dideoxy-1-O-mesyl-*chiro*-inositol (27a).* Compound **23a** (854 mg) was treated with refluxing 80% aqueous acetic acid (20 ml) for 1.5 hr, and then the reaction mixture was evaporated to dryness. The residual syrup crystallized spontaneously to give crystals (538 mg, 77.4%) of **27a**, mp 101—104 °C. Recrystallization from ethanol gave an analytical sample, mp 102—104 °C.

Found: C, 31.10; H, 4.12; N, 24.01; S, 8.86%. Calcd for $C_9H_{14}N_6O_7S$: C, 30.86; H, 4.03; N, 23.99; S, 9.15%.

Compound **27a** (100 mg) was acetylated in the usual way to give crystals (92 mg, 74%) of 2,4-diazido-2,4-dideoxy-1-*O*-mesyl-*chiro*-inositol triacetate (**27b**), mp 114—116 °C. Recrystallization from chloroform–ethanol gave an analytical sample, mp 115.5—117 °C.

Found: C, 35.90; H, 4.17; N, 19.48; S, 7.27%. Calcd for $C_{13}H_{18}N_6O_9S$: C, 35.95; H, 4.18; N, 19.35; S, 7.38%.

*1,4-Anhydro-6-azido-6-deoxy-5-O-mesyl-*epi*-inositol (28a).* Compound **24a** (0.50 g) was refluxed with 80% aqueous acetic acid (15 ml) for 1.5 hr. After cooling, the resulting crystals were collected by filtration: yield 162 mg (42%), mp 177.5—178 °C. Another crop of crystals was obtained by evaporation of the filtrate: yield 103 mg. The total yield of **28a** was 69%. An analytical sample was obtained by recrystallization from ethanol, mp 177—178 °C.

Found: C, 31.71; H, 4.13; N, 15.92; S, 12.11%. Calcd for $C_7H_{11}N_3O_6S$: C, 31.70; H, 4.18; N, 15.84; S, 12.09%.

Compound **28a** (67 mg) was acetylated in the usual way to give crystals (83 mg, 95%) of the diacetate (**28b**), mp 141—142 °C, after crystallization from ethanol. An analytical sample was obtained by recrystallization from chloroform–ethanol, mp 158.5—159 °C.

Found: C, 37.67; H, 4.27; N, 12.02; S, 8.93%. Calcd for $C_{11}H_{15}N_3O_8S$: C, 37.82; H, 4.33; N, 12.03; S, 9.18%.

*3-Azido-3-deoxy-1,5,6-tri-O-tosyl-*muco*-inositol (30a).* A mixture of 1,4,5,6-tetra-*O*-tosyl-*myo*-inositol (**29**)[3] (2.0 g), sodium azide (2.0 g), and 90% aqueous 2-methoxyethanol (50 ml) was refluxed for 15 hr. The reaction mixture was evaporated and the residue was extracted with 2-butanone (2×20 ml). The extract was passed through an alumina column and then evaporated to give crystals (0.98 g, 62%) of **30a**, mp 162—163.5 °C. Recrystallization from ethanol afforded an analytical sample, mp 168.5—169.5 °C.

Found: C, 49.02; H, 4.61; N, 6.16; S, 14.50%. Calcd for $C_{27}H_{29}N_3O_{11}S_3$: C, 48.57; H, 4.38; N, 6.29; S, 14.41%.

Compound **30a** (0.33 g) was acetylated in the usual way to give crystals which were recrystallized from chloroform–ethanol to afford plates (0.32 g, 84%) of the diacetate (**30b**), mp 172.5—173 °C.

Found: C, 49.89; H, 4.67; N, 5.48; S, 12.50%. Calcd for $C_{31}H_{33}N_3O_{13}S_3$: C, 49.52; H, 4.42; N, 5.59; S, 12.80%.

*2,3,4-Tri-O-tosyl-*muco*-inositol Triacetate (30c).* A mixture of **29** (2.0 g), anhydrous sodium acetate (2.0 g), and 90% aqueous 2-methoxyethanol (50 ml) was refluxed for 19 hr. The reaction mixture was treated in a similar way to that for **4b**, and the product was crystallized from ethyl acetate–ether to give crystals (1.2 g, 63%) of **30c**, mp 162.5—163.5 °C.

Found: C, 51.81; H, 4.87; S, 12.29%. Calcd for $C_{33}H_{36}O_{15}S_3$: C, 51.55; H, 4.72; S, 12.51%.

The authors wish to thank Prof. Sumio Umezawa for his kind advice. They are grateful to Mr. Saburo Nakada for elementary analyses and to Mr. Takatoshi Tanaka for assistance in the preparative experiments. The work was carried out with financial support from the Ministry of Education.

Chemiluminescence of Succinylfluorescein and Related Compounds. I. Emitting Species Produced by the Reaction of Succinylfluorescein with Oxygen in Aprotic Solvents

Isao KAMIYA and Keizo AOKI

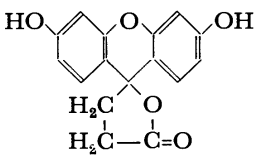
Department of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 24, 1973)

In the course of our studies of the chemiluminescence of xanthene dyes, we found the violet chemiluminescence emission (CL-emission) resulting from the reaction of succinylfluorescein with oxygen in an aerated alkaline aqueous system of a high concentration of an aprotic solvent (DMSO or DMF), an especially intense emission occurring in aerated dry DMSO or DMF with *tert*-BuOK as base. The CL-emission comprised two emission components: an intense violet emission (a peak, at 410 nm) whose spectral distribution was similar to that of the fluorescence band which appeared during the course of the reaction, and a weak greenish-yellow emission similar to the fluorescence of the dye. By isolating and identifying the violet-fluorescent reaction product with an authentic sample, and by comparing the CL-emission with the fluorescence emission of the isolated product, it was concluded that the violet CL-emission may be attributed to the formation of an excited dianion of 3,6-dihydroxyxanthone. The reaction path leading to the dioxetane intermediate which will be produced by the elimination of a proton from the C atom at the β-position of the dye, followed by the oxygenation *via* the caged radical pair, was discussed as a likely mechanism for the formation of the excited dianion.

In the previous paper,[1] the blue spectral component of the chemiluminescence (with a peak at 480 nm) observed in the reaction of such an xanthene dye as eosin Y with hydrogen peroxide in an alkaline solution was found to correspond to the fluorescence emission (FL-emission) of a blue-fluorescent product isolated from the reaction mixture; we concluded that the blue-fluorescent species is the primary excited product in the chemiluminescent reaction. Further study by means of a kinetic analysis of the blue-fluorescent product provided additional support for that conclusion.[2] However, the quantity of the isolated product was too small for it to be weighed or identified, so a question as to the identification of the product remained unanswered.

From the findings that several xanthene dyes other than eosin Y, uranin, eosin R, erythrosin B, 2',7'-dichlorofluorescein, rhodamine B, and even rhodamine S, which is not phthalyl, exhibited a similar blue emission with a production of an analogous blue-fluorescent species, we presupposed that the excited product might be a xanthone compound since excited species generated in many chemiluminescent systems have been reported to be carbonyl compounds,[3] thus we expected that a similar blue emission would arise from the oxidation of succinylfluorescein (**1**).



(**1**)

When succinylfluorescein was oxidized with hydrogen peroxide in an alkaline solution, however, a violet emission appeared with a peak at 410 nm in addition to a (weak) greenish-yellow emission. The violet emission was also found to appear from the oxidation of the dye with oxygen in an aerated alkaline aqueous system of a high concentration of such aprotic solvents as dimethylsulfoxide (DMSO) and *N'*,*N'*-dimethylformamide (DMF). Especially, an intense emission appeared in aerated dry DMSO (or DMF), with potassium *tert*-buthoxide (*tert*-BuOK) as the base. This paper will describe the chemiluminescent reaction of succinylfluorescein with oxygen in detail.

Experimental

Preparation of Succinylfluorescein (SF).[4] A 20 g portion of zinc chloride powder was added to a mixture of 11.01 g of resorcinol and 5.00 g of succinic anhydride, and then the mixture was heated to 180 °C for 4 hr. The reaction product was extracted with 4% hot hydrochloric acid, and the hot extract was filtered as quickly as possible. The product which precipitated on cooling was purified by repeated recrystallizations from 4% hydrochloric acid. Thin-layer chromatography showed only one spot, indicating the purity of the SF thus prepared.

Preparation of an Authentic Sample of 3,6-Dihydroxyxanthone.[5] After fluorescein had been chlorinated with phosphorous pentachloride, the produced fluorescein chloride was hydrolyzed by heating it in a concentrated aqueous sodium hydroxide solution to give 2,4,2',4'-tetrahydroxybenzophenone. With the dehydration of the benzophenone on heating, 3,6-dihydroxyxanthone was obtained. The purity of the prepared sample was confirmed by the thin-layer chromatographic method.

The Chemiluminescent Systems. Two systems were employed to investigate the chemiluminescence emission (CL-emission) of SF with oxygen.

DMSO (or DMF)–$NaOH_{aq}$ System: After 10—20 mg of the prepared SF had been dissolved in 10 ml of a mixture of DMSO (or DMF) and $NaOH_{aq}$, a portion of the reaction mixture (about 3 ml) was quickly transferred into a quartz cell ($10\times10\times45$ mm) which had been placed in a thermostat with circulating water at a constant temperature (40 °C). The volume ratio of DMSO to $NaOH_{aq}$ and the concentration of $NaOH_{aq}$ for the system employed are noted in the experimental results.

DMSO (or DMF)–tert-*BuOK System*: 6 mg of SF and 60 mg of *tert*-BuOK were dissolved in 10 ml of DMSO (or DMF) and 10 ml of *tert*-buthanol (*tert*-BuOH) respectively (the concentrations of SF and *tert*-BuOK were about $2.1\times$

10^{-3} and 5.3×10^{-2} M respectively), and when necessary, the two solutions were diluted with these solvents. The luminescent reaction was initiated by vigorously stirring 0.5 ml of the *tert*-BuOK solution (in *tert*-BuOH) into 2 ml of an aerated SF solution in DMSO (or DMF) in a quartz cell ($10\times10\times45$ mm) which had been placed in a thermostat.

The measurements of the intensity *versus* the reaction time and the spectrum of the CL-emission, and the absorption spectra of reaction mixture and the isolated product were carried out by a method essentially identical with those described in the previous paper.[1]

Results

The CL-Emission Spectrum of SF in Aerated-$NaOH_{aq}$ System. The CL-emission spectra of SF with oxygen in the system of DMSO–2 M $NaOH_{aq}$ (3: 1 v/v), measured at different reaction times, are shown in Fig. 1,

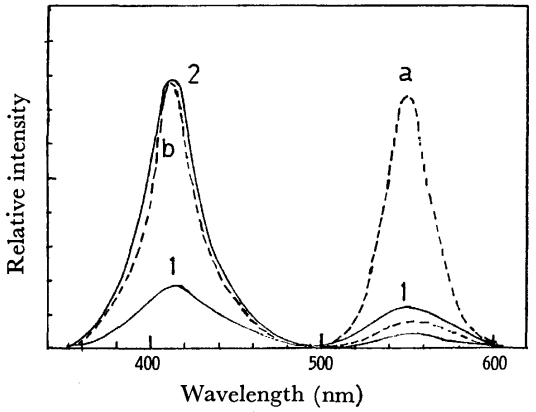


Fig. 1. CL-emission spectra of SF with oxygen measured at different reaction times; 1: after 1 min, 2: after 10 min, and FL-emission spectra of the reaction system measured at initial stage (a), and final stage (b) (DMSO–2 M $NaOH_{aq}$ system).

together with the fluorescence spectra (FL-emission) measured at the initial and final stages of the reaction. The results indicate that the CL-emission comprises two emission components: a weak greenish-yellow emission whose spectral distribution is similar to that of the fluorescence of SF (a peak at 555 nm), and an intense violet emission similar to the fluorescence band which appears during the course of the reaction (a peak at 410 nm). The intensity of the greenish-yellow emission at 555 nm showed a rapid decay, whereas that of the violet emission at 410 nm initially rose to a maximum and then showed a slight decay, followed by a long-lived steady glow, as is illustrated in Fig. 2.

The following two findings are noticeable. When nitrogen was bubbled into the luminescing system to remove the oxygen, the emission disappeared. Such xanthene dyes as uranin, eosin Y, erythrosin B, 2′,7′-dichlorofluorescein, rhodamine B and rhodamine S, which chemiluminesce as a blue emission upon oxidation with hydrogen peroxide, neither decomposed nor chemiluminesced with oxygen under comparable conditions.

The Effect of Solvent on the Chemiluminescence Emission. In DMSO–$NaOH_{aq}$ systems (0.25 M NaOH), the CL-emission appears only when the solution contains more

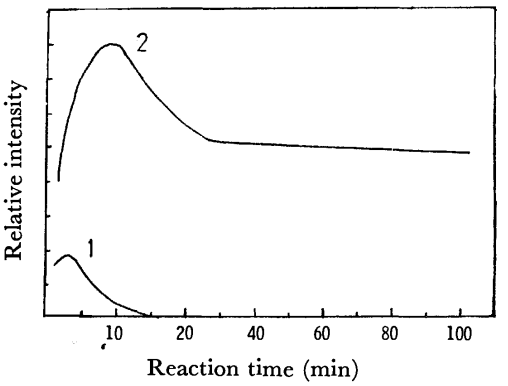

Fig. 2. Changes in the intensities of two components of CL-emission of SF in DMSO–2 M $NaOH_{aq}$ system, 1: violet emission component, 2: greenish-yellow component.

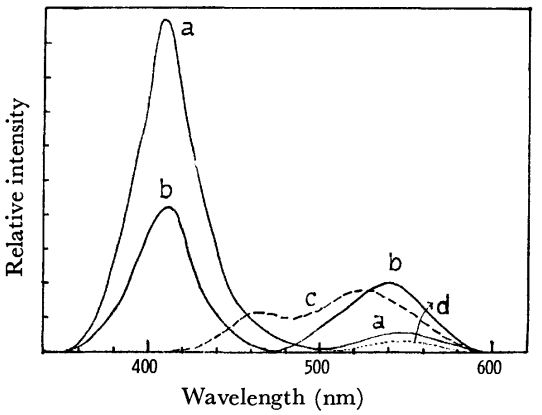

Fig. 3. CL-emission spectra of SF measured in DMSO– (a), DMF– (b), dioxane– (c), ethanol– (d), and methanol–2 M $NaOH_{aq}$ (3: 1 v/v) system (d).

than 50% DMSO in volume, and the higher the concentration of DMSO, the more intense the light which appears. Figure 3 shows the CL-emission spectra in DMSO–, DMF–, dioxane–, methanol–, and ethanol–2M $NaOH_{aq}$ (3: 1 v/v) systems. The spectrum in DMF is similar, but that in dioxane is dissimilar to the CL-emission spectrum in DMSO, and only a greenish-yellow emission appears in such protic solvents as methanol and ethanol. No emission could be observed in the acetone–, *tert*-BuOH–, and acetonitrile–2M $NaOH_{aq}$ (3: 1 v/v) systems, probably because the high concentration of these solvents prevents the dissolution of sodium hydroxide.

The Requisite Molar-ratio of Sodium Hydroxide to Succinylfluorescein for the Generation of the CL-Emission. Table 1 shows the relative intensities of CL-emissions measured when 10 and 20 mg of SF were dissolved in 10 ml of mixtures of DMSO and $NaOH_{aq}$ of different concentrations (3: 1 v/v). The results indicate that no appreciable emission appears when the molar-ratio of NaOH to SF is less than 3. The same requisite molar-ratio of NaOH to SF was found in DMF–$NaOH_{aq}$ systems.

The Effect of Adding Oxidizing Agent on the CL-Emission. When 0.5 ml of a 0.05 M aqueous solution of potassium ferricyanate was added to the luminescing DMSO–2M

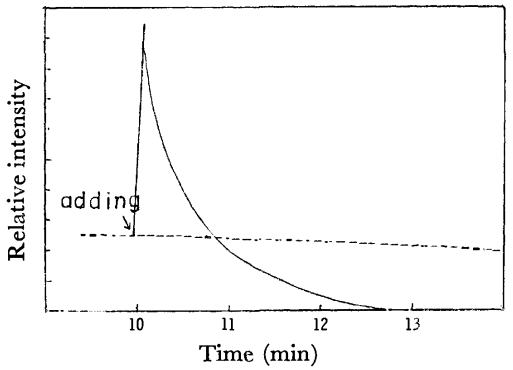

Fig. 4. Effect of adding $K_3Fe(CN)_{6aq}$ on the CL-emission intensity *versus* time; broken line shows intensity *versus* time when oxidizing agent was absent, and full line shows that after adding the agent (40 °C).

$NaOH_{aq}$ (3: 1 v/v) system, the intensity of the emission rapidly increased, then it vanished with a fast decay. A typical example of the effect of adding an oxidizing agent is illustrated in Fig. 4, where the dotted line shows an intensity *versus* reaction time curve measured when the oxidizing agent was absent, while the solid line shows the curve obtained after the agent was added. A similar effect was observed by adding aqueous solutions of bromine and potassium permanganate to the system. No emission, however, appeared when these agents were added to a deaerated system or to a system where the molar-ratio of NaOH to SF was less than three.

The Isolation and Identification of the Violet-fluorescent Product. During the course of the luminescent reaction in a DMSO–2M $NaOH_{aq}$ (3: 1 v/v) system, the absorption peak at 510 nm decreased; simultaneously a new absorption peak appeared at 370 nm, as is shown as the solid line curve in Fig. 5. The change in the absorption spectrum seems to be attributable to the decomposition of SF and the formation of a species. In an aerated aqueous solution of sodium hydroxide (containing no aprotic solvent), the absorption spectrum also changed, as is shown by the dotted line in Fig. 5. From the results, we can expect that the same reaction product may be formed in the two systems since the new absorption peak appeared at the same wavelength (370 nm). This was confirmed by the findings that

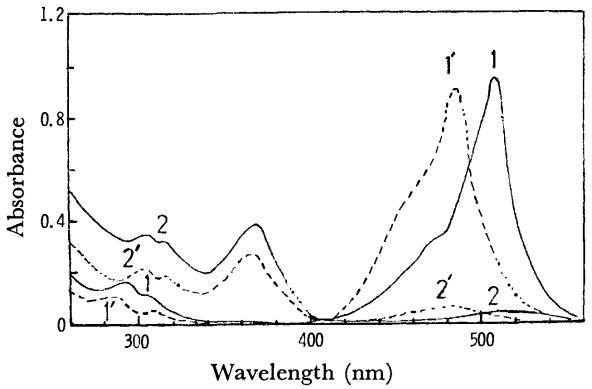

Fig. 5. Absorption spectra of reaction mixture in DMSO–2 M $NaOH_{aq}$ system (1: initial stage, 2: final stage) and those in 1/4 M $NaOH_{aq}$ system (1′: initial stage, 2′: final stage).

thin-layer chromatography (Silica gel G, $CHCl_3$–CH_3COOH, 1: 1) showed the same spot at R_f 0.14 (ascending method) and that paper chromatography (Toyo Filter Paper No. 50, 20% aqueous ethanol–5% aqueous ammonia, 1: 1) showed the same spot at R_f 0.30 (the descending method) for the products in the two systems. A large amount of the (violet-fluorescent) product could be prepared by the following method. Four grams of SF and 10 g of sodium hydroxide were dissolved in 300 ml of aerated water, and then the reaction mixture was kept at 40 °C with stirring in an open flask for three days. The residual reaction mixture was acidified with hydrochloric acid, and the precipitated crude brownish product was filtered off and adsorbed on a column of Mallinckrodt Silicic Acid (100 mesh). The column was eluted with ether; then, after the removal of the solvent, white needles were obtained. Recrystallization from 20% aqueous ethanol gave 50 mg of a pure product, which did not melt below 300 °C. The analytical data of the product are listed in Table 2. These data support the idea that the product is 3,6-dihydroxyxanthone. The product was further identified by its position on thin-layer chromatography (R_f 0.14,

TABLE 2. ANALYTICAL DATA FOR THE REACTION PRODUCT

Elemental analysis				
	Found (%)	Calcd for $C_{13}H_8O$(%)	Mass (M^+)	NMR (δ, ppm)
C	68.29	68.42	228	8.07 (d, J=9.0 Hz)
H	3.74	3.53		6.94 (dd, J=1.5, 9.0 Hz)
				6.88 (s)

(The NMR spectrum was taken in DMSO-d_6 with a JEOL MH-100 type spectrometer at 100 MHz using TMS as an internal standard.)

the ascending method) as well as by its position on paper chromatography (R_f 0.30, the descending method) compared with those of an authentic sample. The absorption and fluorescence spectra of the product in different media are illustrated in Figs. 6 and 7 respectively. These spectra also match those of the authentic sample.

Emission Characteristic in the DMSO (or DMF)–tert-BuOK System. The intensity of the CL-emission of SF in an aerated dry DMSO (or DMF)–*tert*-BuOK system was about 150 times greater than that in a DMSO–2M $NaOH_{aq}$ (3: 1 v/v) system. The spectra of the CL-emissions measured in the DMSO–, DMF–, and acetonitrile–*tert*-BuOK systems are illustrated in Fig. 8. The observed intense peak at 410 nm indicates that the CL-emission in the systems can be attributed to the formation of the excited dianion of 3,6-dihydroxyxanthone.

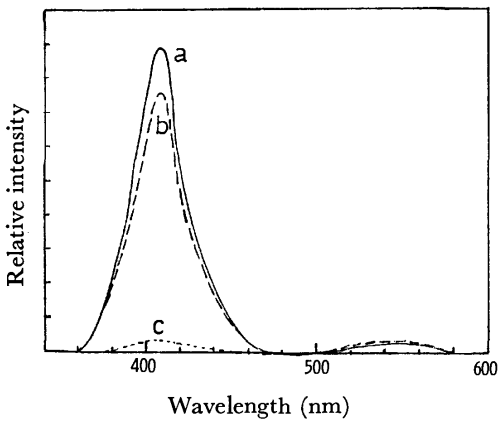

Fig. 8. CL-emission spectra of SF in DMSO– (a), DMF– (b), acetonitrile–*tert*-BuOK system (c)

The dependence of the molar-ratio of *tert*-BuOK to SF on the generation of the CL-emission in a DMSO–*tert*-BuOK system was investigated. The results, which are summarized in Table 3, indicate that no appreciable emission is generated when the molar-ratio of *tert*-BuOK to SF is less than 3.

TABLE 3. DEPENDENCE OF MOLAR-RATIO OF *tert*-BuOK TO SF (ρ) ON THE GENERATION OF CL-EMISSION IN AERATED DRY DMSO-*tert*-BuOK SYSTEM

[SF] (M)	[*tert*-BuOK] (M)							
	1.6×10^{-2}		2.6×10^{-3}		1.2×10^{-3}		6×10^{-4}	
	ρ	emission	ρ	emission	ρ	emission	ρ	emission
1.68×10^{-3}	6.8	G	1.57	N	—	—	—	—
8.4	12.6	G	3.15	G	1.43	N	—	—
5.6	18.9	G	4.7	G	2.14	N	—	—
4.2	25.2	G	6.3	G	2.86	N	1.43	N
2.1	50.4	G	12.6	G	5.7	G	2.86	N
1.05	100	G	25.2	G	11.4	G	5.7	U
5.25	—	—	50.4	G	22.8	G	11.4	G

(G: generated, N: did not generate, U: undefined)

The absorption spectrum of SF in an aerated DMSO solution showed no appreciable peak in the visible region. By adding a *tert*-BuOK solution (in *tert*-BuOH), a strong absorption at about 525 nm appeared, probably because of the structural change in the dye. (In a deaerated system, the absorption at 525 nm was found to be not so strong that oxygen would participate in the reaction which leads to the structural change.) During the course of the reaction, the spectrum changed as is shown in Fig. 9. It is of interest to find that a new absorption peak at 370 nm increases gradually and that the isobestic point appears at 364 nm. It seems reasonable to speculate that the main product is 3,6-dihydroxyxanthone, so the intense emission can be observed in a DMSO–*tert*-BuOK system. Figure 10 shows the intensity of the CL-emission and the change in the absorbance at 525 nm *versus* the reaction

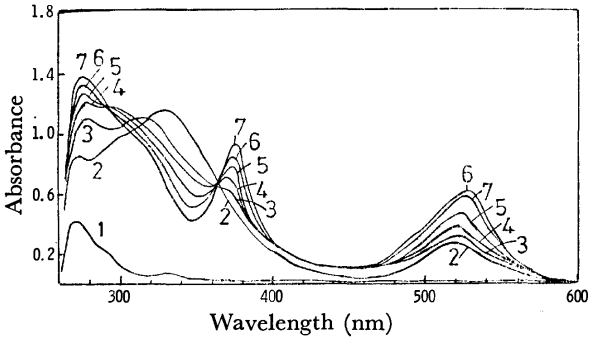

Fig. 9. Change of absorption spectrum of reaction mixture in DMSO–*tert*-BuOK–SF system ([*tert*-BuOK] $=2.6\times10^{-3}$ M, [SF]$=5.25\times10^{-5}$ M); 1: before adding *tert*-BuOK, 2→7: after adding *tert*-BuOK.

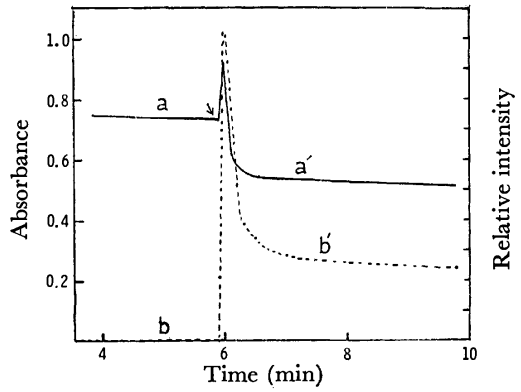

Fig. 10. Changes in the absorbance of reaction system at 525 nm (——a) and CL-emission intensity at 410 nm (----b) when adding 0.05 ml of a 6.6×10^{-3} M solution of *tert*-BuOK in *tert*-BuOH in 2 ml of a 6.8×10^{-5} M solution of SF in DMSO ($\rho=2.3$; *tert*-BuOK deficient system), and those (——a' and ----b') after adding 0.5 ml of the *tert*-BuOK solution ($\rho=23$; *tert*-BuOK sufficient system).

time measured when 0.05 ml of a 6.6×10^{-3} M solution of *tert*-BuOK was added to 2 ml of a 6.8×10^{-5} M solution of SF (the molar-ratio of *tert*-BuOK to SF is 2.3; it is a *tert*-BuOK deficient system) and also those measured when 0.5 ml of a *tert*-BuOK solution was added again to the system to make a *tert*-BuOK sufficient system (the molar-ratio is 23). The absorbance at 525 nm was found to increase to a maximum without any emission in the *tert*-BuOK deficient system (the peak at 370 nm did not appear in the system), whereas the absorbance decreased with emission in the *tert*-BuOK sufficient system.

The characteristics of the emission intensity *versus* the reaction time, which is strongly dependent upon the molar-ratio of *tert*-BuOK to SF, are so complicated that no kinetic analysis of the emission intensity could be made in the present study.

When such protic solvents as water, methanol, and ethanol were added drop by drop (each drop was about 0.02 ml) to the luminescing system (2.5 ml), a decrease in the intensity was found upon each addition. On the other hand, when a 0.05 M solution of benzoyl peroxide in DMSO was added, drop by drop, to the system, a bright flash appeared, with a lowering of the

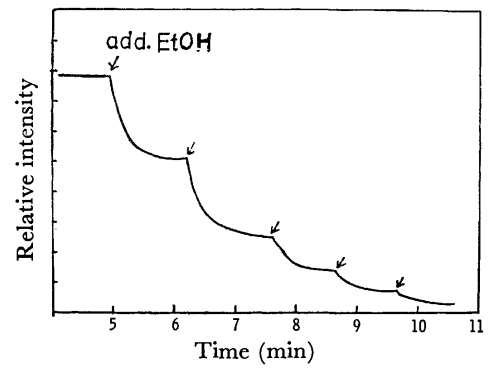

Fig. 11. Effect of adding H_2O or EtOH on the CL-emission intensity versus time in DMSO–*tert*-BuOK–SF system.

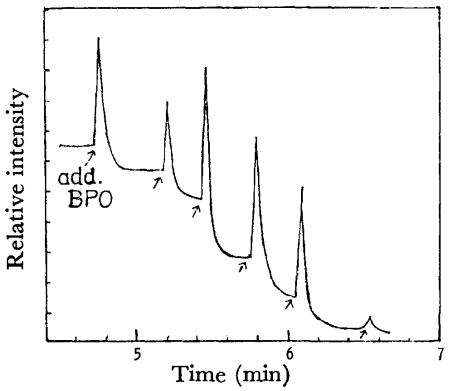

Fig. 12. Effect of adding benzoyl peroxide on the CL-emission intensity *versus* time in DMSO-*tert*-BuOK-SF system.

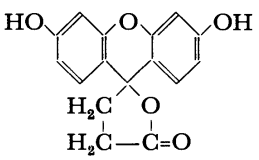
intensity of the steady glow, at each addition. Typical examples of the effects of adding a protic solvent and oxidizing agent are illustrated in Figs. 11 and 12 respectively. Neither an appreciable lowering of the intensity nor a flash was observed when a drop of DMSO was added to the luminescent system.

Discussion

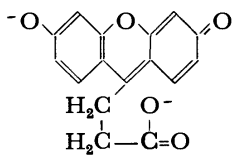
The appearance of a strong absorption peak at 525 nm upon the addition of NaOH or *tert*-BuOK to an aerated solution of SF may be attributed to the following structural change in SF:



(1)

Lactone form of a neutral molecule of SF in DMSO

↓ 2 *tert*-BuOK or 2 NaOH and O_2



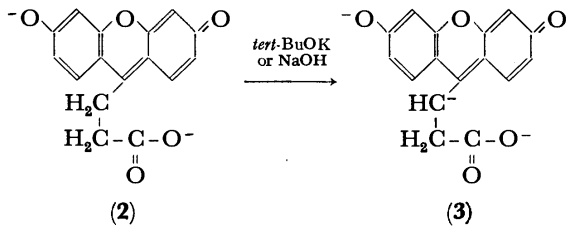
(2)

Quinoid form anion of SF in an aerated alkaline solution

A further reaction of SF with *tert*-BuOK will be necessary to initiate the luminescent reaction, because no appreciable emission appeared when the molar-ratio of *tert*-BuOK to SF was less than 3.

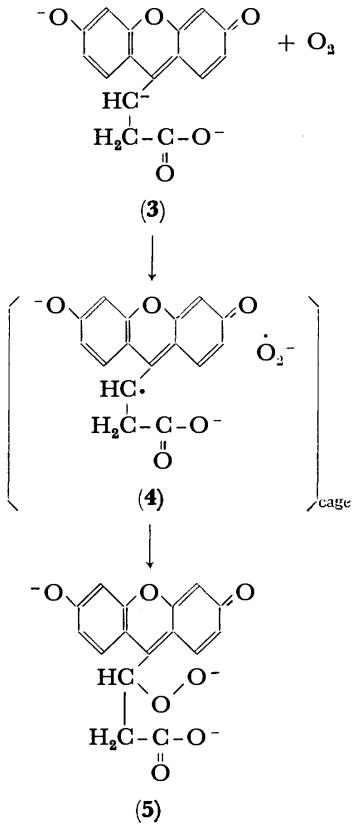
It has been reported that *tert*-BuOK prevents the reaction of DMSO with *tert*-BuOK under the experimental conditions employed here.[6]

A reasonable step may be the following elimination of a proton from the C atom at the β-position:



(2) (3)

Therefore, one possible mechanism for the reaction of **3** with oxygen may be the following oxygenation *via* a caged radical pair, **4**:[7]

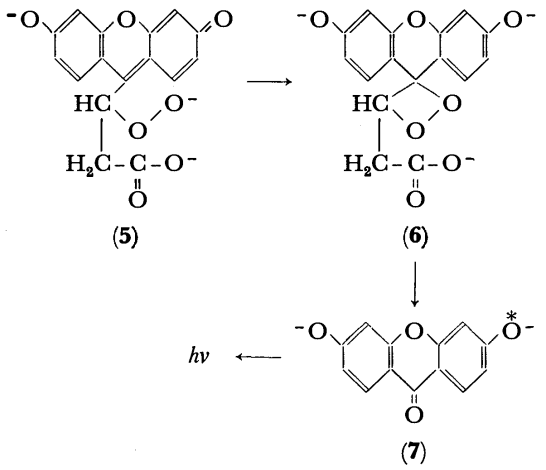


(3) (4) (5)

The experimental finding that the CL-emission rapidly increased upon the addition of an oxidizing agent will support this scheme.

The experimental results also indicate that the CL-emission is attributable to the formation of the excited dianion of 3,6-dihydroxyxanthone (**7**); thus, the reaction path leading to the dioxetane intermediate, **6**, may be the most probable mechanism for the formation of **7**, as has been proposed by many investigators.[8]

A finding similar to our finding that no appreciable emission arises in a protic solvent system has also been reported in the chemiluminescent reaction of photinus-ruciferin with oxygen;[9] also, a sharp rize in the intensity at the initial stage followed by a slight decay and then



(5) (6) (7)

a long-lived steady glow, has been demonstrated for the CL-emission of 3,3′-tetrahydro-1,1′-biisoquinolinium iodide with oxygen.[10]

The authors wish to express their thanks to Professor Teruo Matsuura of the Faculty of Engineering, Kyoto University, for his useful discussion, to Mr. Tatsuyuki Yamakawa for his measurements of the intensity and the spectrum of the reaction system, to Miss Kyoko Toya for the elemental analysis, and to Mr. Kozo Matsumoto of Nagoya University and Dr. Nobutaka Suzuki of Mie University for their measurements of the MS and NMR spectra and for their helpful discussions.

This work was supported in part by a Scientific Research Grant of the Ministry of Education.

The Reaction of 3-(ω-Ethoxycarbonylacetyl)-2*H*-cyclohepta[*b*]-furan-2-one with Active Methylene Compounds

Tetsuo NOZOE,* Kahei TAKASE,** Tomoo NAKAZAWA,*** Satoko SUGITA,**** and Motoyasu SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki-aza-Aoba, Sendai 980

(Received December 27, 1973)

The reaction of 3-(ω-ethoxycarbonylacetyl)-2*H*-cyclohepta[*b*]furan-2-one (**4**) with malononitrile and with cyanoacetamide, in the presence of sodium ethoxide, gave 4-hydroxyazuleno[2,1-*b*]pyrid-2(1*H*)-one derivatives, (**5**) and (**9**) respectively, in good yields. On the other hand, the reaction of **4** with ethyl cyanoacetate gave 3-cyano-2-ethoxycarbonylmethylazulene-1-carboxylic acid (**12**). The structures of these products were determined on the basis of the spectral data and some chemical evidences.

It is known[1] that the reaction of 2-chloro- or 2-methoxytropones with active methylene compounds, such as malononitrile, ethyl cyanoacetate, and diethyl malonate, is a useful method for synthesizing azulene derivatives, especially those with various functional groups at the 1-, 2-, and 3-positions. In addition, it has been found[2] that 2*H*-cyclohepta[*b*]furan-2-one derivatives were the reaction intermediates in this azulene-formation reaction and that their reactions with active methylene compounds also gave azulene derivatives. Of these, the reaction of 3-acetyl-2*H*-cyclohepta-[*b*]furan-2-one (**1**) with malononitrile or cyanoacetamide gave a 1-acetyl-2-aminoazulene derivative (**2a**) or (**2b**), whereas that with ethyl cyanoacetate gave a 2-methylazulene derivative (**3**) as the major product, together with a minor amount of an 1-acetyl-2-aminoazulene derivative (**2c**).[2b] On the application of such types of reactions to 3-(ω-ethoxycarbonylacetyl)-2*H*-cyclohepta[*b*]furan-2-one (**4**),[3] we have now found that azuleno[2,1-*b*]pyridine derivatives were easily synthesized; the results will be reported in this paper.

Results and Discussion

The reaction of **4** with malononitrile took place easily, in the presence of sodium ethoxide, at room temperature; an azulenic compound (**5**), $C_{14}H_8O_2N_2$, was formed in a good yield. Compound **5** is only slightly soluble in organic solvents, but it is easily soluble in aqueous alkali. The infrared spectrum of **5** in KBr exhibits absorptions at 3300—2500 (associated enolic OH), 2203 (C≡N), and 1634 and 1626 cm^{-1} (C=O). The ultraviolet absorption curve is similar to that of ethyl 2(1*H*)-oxoazuleno[2,1-*b*]pyridine-3-carboxylate,[4] as is shown in Fig. 1. The mass spectrum reveals a molecular ion peak at *m/e* 236. On the basis of these spectral data and some chemical evidence to be described below, as well as a consideration of the reaction mechanism to be described later, the structure of **5** is assumed to be 10-cyano-4-hydroxyazuleno-[2,1-*b*]pyrid-2(1*H*)-one (**5a**). As is confirmed apparently by its spectral data, **5** exists in the 2(1*H*)-pyridone form, **5a**, but not in the 2-hydroxypyridine form, **5b**. However, **5** gave both types of diacetyl derivatives, that is, *O,N*- (**6a**) and *O,O'*-diacetyl derivatives (**6b**), derived from **5a** and **5b** respectively. Thus, when heated with acetic anhydride at 130 °C, **5** gave **6a**. Its infrared spectrum exhibits absorptions at 1637 (*N*-acetyl) and 1783 cm^{-1} (*O*-acetyl), and its ultraviolet absorption curve is similar to that of **5** (Fig. 1). On the other hand, the acetylation of **5** with acetic anhydride in pyridine gave **6b**. Its infrared spectrum exhibits an absorption at 1773 cm^{-1} (*O*-acetyl), and its ultraviolet absorption curve is similar to that of ethyl 2-methoxyazuleno[2,1-*b*]pyridine-3-carboxylate[4] (Fig. 2). On methylation with diazomethane or with dimethyl sulfate, **5** gave only an azuleno[2,1-*b*]pyridone-type *O,N*-

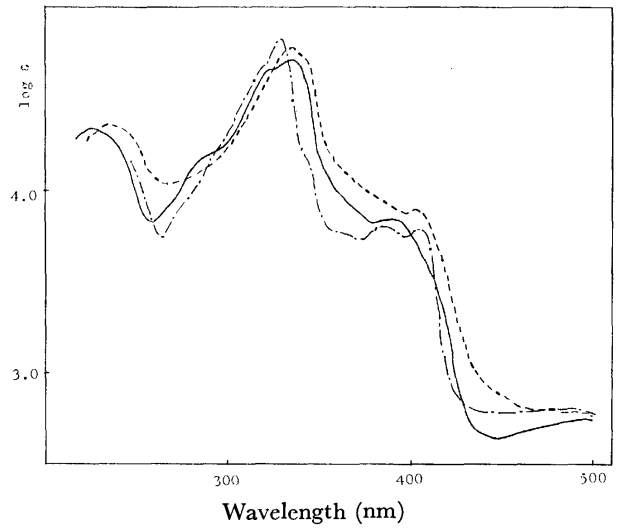

Fig. 1. The UV spectra of **5** (——), **6a** (----) and **10** (-·-·-) in methanol

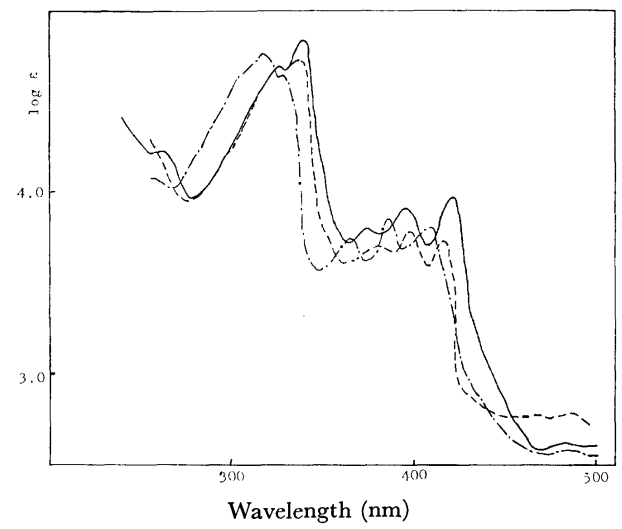

Fig. 2. The UV spectra of **6b** (——), **8** (----) and **11** (-·-·-) in methanol.

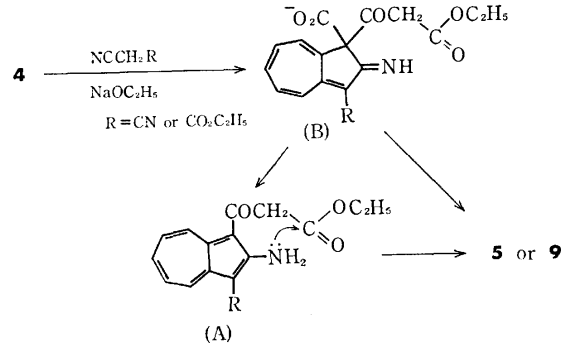
dimethyl derivative (**7**), derived from **5a**. The infrared spectrum of **7** exhibits absorptions at 2208 (C≡N) and 1656 cm^{-1} (C=O). The ultraviolet absorption curve of **7** is similar to that of **5**. On the other hand, the treatment of **5** with phosphorus oxychloride afforded an azuleno[2,1-*b*]pyridine-type dichloro compound (**8**). Its ultraviolet absorption curve is similar to that of **6b** (Fig. 2).

The reaction of **4** with cyanoacetamide, in the presence of sodium ethoxide, gave an azulenic compound (**9**) in a good yield. The same compound was also obtained from **5** when the latter was heated in 100% phosphoric acid at 100 °C. The infrared spectrum of **9** exhibits absorptions at 3300—2500 (associated enolic OH), and 1658, 1631, and 1621 cm^{-1} (C=O), but no absorption corresponding to the cyano group. The ultraviolet absorption curve is similar to that of **5**. The mass spectrum reveals a molecular ion peak at *m/e* 254. From these findings, **9** is assigned the structure of 10-carbamoyl-4-hydroxyazuleno[2,1-*b*]pyrid-2-(1*H*)-one. When **9** was heated in 100% phosphoric acid at 130 °C, decarbamoylation took place, with the formation of 4-hydroxyazuleno[2,1-*b*]pyrid-2(1*H*)-one (**10**). The same compound, **10**, was also obtained from **5** upon heating with 100% phosphoric acid at 130 °C. The infrared spectrum of **10** exhibits absorptions at 3300—2500 (associated enolic OH) and 1618 cm^{-1} (C=O). The ultraviolet absorption curve is similar to that of **5** (Fig. 1). These spectral data have substantiated the structure of **10**. Compound **10** gave an *N*-acetyl derivative on acetylation with acetic anhydride–pyridine. Further, the treatment of **10** with phosphorus oxychloride gave 2,4-dichloroazuleno[2,1-*b*]pyridine (**11**). Its ultraviolet absorption curve is similar to that of **8** (Fig. 2).

In the reaction of **4** with ethyl cyanoacetate, an azulenic compound (**12**) was obtained in a good yield. The infrared spectrum exhibits absorptions at 3300—2500, 1656 and 920 (COOH), 2212 (C≡N), and 1742 cm^{-1} (ester C=O). The methylation of **12** with diazomethane afforded an ester (**13**), while the alkaline hydrolysis of **12**, followed by the methylation of the resulting dicarboxylic acid (**14**) with diazomethane, yielded a dimethyl ester (**15**). Further, on heating in pyridine **14** gave 3-cyano-2-methylazulene-1-carboxylic acid (**16**).[2b] On the basis of these spectral data and chemical evidence, **12** was assigned the structure of 3-cyano-2-ethoxycarbonylmethylazulene-1-carboxylic acid.

When **12** or **14** was heated with acids, such as 75% sulfuric, 85% phosphoric, or concentrated hydrobromic acid, at about 100 °C, cyclization took place, with the formation of an imide (**17**). Its infrared spectrum exhibits absorptions at 3215 (NH), 1686 and 1678 cm^{-1} (C=O), but no absorption corresponding to the cyano group. Its NMR spectrum reveals a two-proton singlet at 4.31 ppm associated with the methylene protons. The mass spectrum reveals a molecular ion peak at *m/e* 211. These spectral data have substantiated the structure of **17**. The acetylation of **17** with acetic anhydride in pyridine gave an *N*-acetyl derivative, whereas that with acetic anhydride in the presence of concentrated sulfuric acid gave an *O*-acetyl derivative.

As has been described above, it has been found that the reaction of **4** with malononitrile or cyanoacetamide yielded directly the azuleno[2,1-*b*]pyrid-2(1*H*)-one derivative, **5** or **9** respectively. On the other hand, it has been found that the reaction of **4** with ethyl cyanoacetate yielded the azulene derivative, **12**, but no azuleno[2,1-*b*]pyrid-2(1*H*)-one derivative. The forma-



tion of **5** or **9** is presumed to be as follows. It had been found that, in the reaction of 3-acetyl-2*H*-cyclohepta[*b*]furan-2-one, **1**, with malononitrile or cyanoacetamide, the 1-acetyl-2-aminoazulene derivative, **2a** or **2b**, was formed *via* a dihydroazulene-type intermediate.[2b] Similarly, in the reaction of **4** with malononitrile or cyanoacetamide, an 2-amino-1-(ω-ethoxycarbonylacetyl)azulene derivative (A) should be formed at first *via* a dihydroazulene-type intermediate (B). In this case, however, cyclization between the amino and ester groups, which are present in a position favorable to lactam-formation, should occur subsequently to yield the azuleno[2,1-*b*]pyrid-2(1*H*)-one derivative, **5** or **9**. A similar cyclization should also be possible between the imino and ester groups in the intermediate (B), accompanying decarboxylation, to yield **5** or **9**. In the reaction of **4** with ethyl cyanoacetate, the azulene, **12**, is presumed to be formed through the same reaction mechanism as in the formation of 2-methylazulene derivative, **3**, in the reaction of **1** with ethyl cyanoacetate.[2b]

Experimental

All the melting points are uncorrected. The infrared spectra were taken on a Shimadzu IR-27 infracord. The ultraviolet spectra were run on a Hitachi EPS-3 spectrophotometer. The NMR spectra were determined with a Varian A-60 spectrometer. The mass spectral analyses were done on a Hitachi RMU-60 mass spectrometer.

10-Cyano-4-hydroxyazuleno[2,1-b]pyrid-2(1H)-one (5). To a solution of 1.30 g of **4** and 460 mg of malononitrile in 25 ml of anhydrous ethanol, 7.5 ml of a 1M sodium ethoxide solution was added, after which the mixture was stirred for 8 hr at room temperature. The reaction mixture was then diluted with water and acidified with 6M hydrochloric acid. The crystals thereby formed were recrystallized from dimethylformamide to give 1.23 g of **5** as reddish-violet needles; mp 354—360 °C (decomp.); UV (MeOH): λ_{max} 228 nm (log ε 4.35), 325 (4.68), 337 (4.69), 392 (3.86), and 500 (2.75).

Found: C, 71.38; H, 3.70; N, 12.04%. Calcd for $C_{14}H_8O_2N_2$: C, 71.18; H, 3.41; N, 11.86%.

1-Acetyl-4-acetoxy-10-cyanoazuleno[2,1-b]pyrid-2(1H)-one (6a). A mixture of 100 mg of **5** and 1 ml of pyridine was heated at 130 °C for 2 hr. After cooling, the addition of water to the reaction mixture yielded 90 mg of crystals. Recrystallization from dimethylformamide afforded **6a** as violet microcrystals; mp over 300 °C; IR (KBr): 2212 (C≡N), 1783, and 1637 cm^{-1} (C=O); UV (dioxane): λ_{max} 329 nm (log ε 4.75), 343 (4.85), 405 (3.94), 510 (2.16), and 554 (2.23); mass spectrum *m/e* 320 (M^+).

Found: C, 67.46; H, 3.84; N, 8.61%. Calcd for $C_{18}H_{12}O_4N_2$: C, 67.50; H, 3.78; N, 8.75%.

2,4-Diacetoxy-10-cyanoazuleno[2,1-b]pyridine (6b). A mixture of 100 mg of **5**, 0.5 ml of pyridine, and 0.5 ml of acetic anhydride was warmed in a water-bath for 1 hr. After cooling, the addition of water yielded 110 mg of crystals. Recrystallization from dimethylformamide afforded **6b** as violet micro-crystals; mp 234 °C (decomp.); IR (KBr): 2208 (C≡N) and 1773 cm^{-1} (C=O); UV (dioxane): λ_{max} 315 nm (log ε 4.66), 328 (4.74), 370 (3.71), 391 (3.82), 415 (3.84), 510 (2.45), and 543 (2.41).

Found: C, 67.66; H, 3.96; N, 8.85%. Calcd for $C_{18}H_{12}O_4N_2$: C, 67.50; H, 3.78; N, 8.75%.

10-Cyano-4-methoxy-1-methylazuleno[2,1-b]pyrid-2(1H)-one (7). a) To a solution of 100 mg of **5** in a mixture of 5 ml of ether and 1 ml of methanol, 3 ml of an ethereal solution of diazomethane was added, after which the mixture was stirred for 2 hr under ice-cooling and then allowed to stand overnight in a refrigerator. The crystals thereby formed were recrystallized from dimethylformamide, thus affording 80 mg of **7** as brownish-violet micro-crystals; mp 280—281 °C; IR (KBr): 2208 (C≡N) and 1656 cm^{-1} (C=O); UV (dioxane): λ_{max} 297 nm (log ε 4.09), 330 (4.71), 345 (4.78), and 525 (2.79); mass spectrum *m/e* 264 (M^+).

Found: C, 72.55; H, 4.76; N, 10.45%. Calcd for $C_{16}H_{12}O_2N_2$: C, 72.71; H, 4.58; N, 10.60%.

b) To a solution of 100 mg of **5** dissolved in a mixture of 2 ml of 6M potassium hydroxide solution and 15 ml of water, 1 ml of dimethyl sulfate and 2 ml of 6 M potassium hydroxide solution were added, after which the mixture was stirred for 9 hr at room temperature and then allowed to stand overnight. The reaction mixture was acidified with 6 M hydrochloric acid, and the crystals thereby formed were recrystallized from dimethylformamide to afford 90 mg of **7** as brownish-violet micro-crystals; mp 280—281 °C.

2,4-Dichloro-10-cyanoazuleno[2,1-b]pyrid-2(1H)-one (8). A mixture of 150 mg of **5** and 3 ml of phosphorus oxychloride was heated under reflux. The reaction mixture was poured into ice water, and the crystals thereby formed were recrystallized from dimethylformamide, thus giving 120 mg of **8** as violet plates; mp 295 °C; IR (KBr): 2217 cm^{-1} (C≡N); UV (dioxane): λ_{max} 320 nm (log ε 4.70), 332 (4.85), 355 (4.22), 368 (3.81), 380 (3.81), 390 (4.16), 414 (4.00), 476 (2.62), 496 (2.63), 510 (2.66), 528 (2.67), and 546 (2.65); mass spectrum *m/e* 272 (100%, M^+), 274 (65%, M^++2), and 276 (10.5%, M^++4).

Found: C, 61.03; H, 2.18; N, 10.01%. Calcd for $C_{14}H_6N_2Cl_2$: C, 61.56; H, 2.22; N, 10.26%.

10-Carbamoyl-4-hydroxyazuleno[2,1-b]pyrid-2(1H)-one (9). a) To a solution of 160 mg of **4** and 65 mg of cyanoacetamide in 10 ml of anhydrous ethanol, a 2 ml portion of a 1 M sodium ethoxide solution was added, after which the mixture was stirred for 10 hr at room temperature. The reaction mixture was then diluted with water and acidified with 6 M hydrochloric acid. The crystals thereby formed were recrystallized from dimethyl sulfoxide, thus giving 120 mg of **9** as brownish-violet prisms; mp 322—324 °C (decomp.); UV (DMF): λ_{max} 325 nm (log ε 4.51), 340 (4.46), 410 (2.79), and 520 (2.74).

Found: C, 65.81; H, 4.21; N, 11.31%. Calcd for $C_{14}H_{10}O_3N_2$: C, 66.13; H, 3.96; N, 11.02%.

b) A mixture of 100 mg of **5** and 2 ml of 100% phosphoric acid was heated at 230 °C for 1 hr. Then, a similar treatment gave 90 mg of **9** as brownish-violet prisms; mp 322—324 °C (decomp.). The treatment of **5** with conc. sulfuric acid in a similar manner gave the same product.

4-Hydroxyazuleno[2,1-b]pyrid-2(1H)-one (10). A mixture of 100 mg of **5** and 2 ml of 100% phosphoric acid was heated at 130 °C for 3 hr. The reaction mixture was then cooled to room temperature and diluted with water. The crystals thereby formed were recrystallized from dimethylformamide, thus giving 80 mg of **10** as violet microcrystals; mp over 290 °C; UV (dioxane): λ_{max} 322 nm (log ε 4.75), 336 (4.76), 358 (4.08), 400 (3.78), 500 (2.60), and 540 (2.60); mass spectrum *m/e* 211 (M^+).

Found: C, 74.10; H, 4.50; N, 6.39%. Calcd for $C_{13}H_9O_2N$: C, 73.92; H, 4.30; N, 6.63%.

The treatment of 100 mg of **9** in a manner similar to that described above also gave 84 mg of **10**; mp over 290 °C.

N-Acetyl Derivative: Violet crystals from dimethylformamide; mp over 290 °C; IR (KBr): 1647 and 1613 cm^{-1};

UV (MeOH): λ_{max} 218 nm (log ε 4.32), 282 (4.21), 344 (4.81), 330 sh (4.70), 316 sh (4.35), and 410 (3.94).

Found: C, 69.08; H, 4.91; N, 5.52%. Calcd for $C_{15}H_{11}O_3N \cdot 1/2H_2O$: C, 68.69; H, 4.61; N, 5.34%.

2,4-Dichloroazuleno[2,1-b]pyridine (11). A mixture of 150 mg of **10** and 3 ml of phosphorus oxychloride was heated under reflux for 2 hr and then poured into ice water. The crystals thereby formed were dissolved in chloroform and chromatographed on a silica gel column. The evaporation of the solvent from the effluent left green crystals. Recrystallization from benzene afforded 60 mg of **11** as green needles; mp 163—164 °C; UV (dioxane): λ_{max} 307 nm (log ε 4.68), 317 (4.75), 327 (4.64), 364 (4.75), 384 (3.86), 410 (3.57), 480 (2.23), 427 (2.46), 466 (2.54), and 616 (2.42); NMR (DMSO-d_6): δ ppm 7.2—7.8 (5H, m), 8.5 (1H, s), and 9.5 (1H, s); mass spectrum *m/e* 247 (100%, M+), 249 (64.7%, M+2), and 251 (10.6%, M+4).

Found: C, 62.65; H, 2.85; N, 5.35%. Calcd for $C_{13}H_7NCl_2$: C, 62.93; H, 2.84; N, 5.65%.

3-Cyano-2-ethoxycarbonylmethylazulene-1-carboxylic Acid (12). To a solution of 520 mg of **4** and 280 mg of ethyl cyanoacetate in 30 ml of anhydrous ethanol, a 4 ml portion of a 1 M sodium ethoxide solution was added, after which the mixture was stirred for 10 hr at room temperature. After standing overnight, the mixture was diluted with water and acidified with 6 M hydrochloric acid. The crystals thereby formed were recrystallized from dioxane, thus affording 480 mg of **12** as red prisms; mp 187—188 °C; UV (MeOH): λ_{max} 233 nm (log ε 4.61), 254 sh (4.22), 262 (4.27), 292 (4.64), 303 (4.75), 340 (3.84), 370 (3.83), and 503 (2.76).

Found: C, 67.37; H, 4.68; N, 4.66%. Calcd for $C_{16}H_{13}O_4N$: C, 67.84; H, 4.63; N, 4.95%.

Methyl 4-Cyano-2-ethoxycarbonylmethylazulene-1-carboxylate (13). To a suspension of 100 mg of **12** in a mixture of 10 ml of ether and 2 ml of methanol, 2 ml of an ethereal solution of diazomethane was added, after which the mixture was stirred for 2 hr under ice-cooling. The solvent was then evaporated, and the residue was dissolved in benzene and passed through an alumina column. The evaporation of the solvent gave 100 mg of **13** as red prisms; mp 128—129 °C; IR (KBr): 2217 (C≡N), 1742, and 1692 cm^{-1} (C=O); UV (MeOH): λ_{max} 234 nm (log ε 4.54), 265 (4.33), 293 (4.61), 304 (4.71), 340 (3.79), 370 (3.81), and 503 (2.73); NMR ($CDCl_3$): δ ppm 1.8 (3H, t, J=7.5 Hz), 4.0 (3H, s), 4.25 (2H, q, J=7.5 Hz), 4.41 (2H, s), 7.6—8.1 (3H, m), 7.75 (1H, m), and 9.73 (1H, m).

Found: C, 68.43; H, 5.01; N, 4.63%. Calcd for $C_{17}H_{15}O_4N$: C, 68.67; H, 5.08; N, 4.71%.

4-Cyano-2-carboxymethylazulene-1-carboxylic Acid (14). A solution of 220 mg of **12** dissolved in a mixture of 3 ml of ethanol and 3 ml of 1 M potassium hydroxide solution was heated under reflux for 2 hr. The reaction mixture was then diluted with water and acidified with 6 M hydrochloric acid, thus affording 185 mg of crude **14**. Recrystallization from ethanol afforded red prisms; mp 208—209 °C; IR (KBr): 3300—2500, 1701, 1653 (COOH), and 2217 cm^{-1} (C≡N); UV (MeOH): λ_{max} 234 nm (log ε 4.54), 264 (4.25), 294 (4.58), 305 (4.04), 341 (3.77), 370 (3.78), and 508 (2.74).

Found: C, 65.90; H, 3.76; N, 5.32%. Calcd for $C_{14}H_9O_4N$: C, 65.88; H, 3.55; N, 5.49%.

Methyl 4-Cyano-2-methoxycarbonylmethylazulene-1-carboxylate (15). To a suspension of 130 mg of **14** in a mixture of 3 ml of ether and 3 ml of methanol, 10 ml of an ethereal solution of diazomethane was added, after which the mixture was stirred for 2 hr under ice-cooling. The subsequent evaporation of the solvent left a crystalline material, which was dissolved in benzene and passed through a short column of alumina. The evaporation of the solvent from the effluent gave 110 mg of **15** as red needles; mp 138—139 °C; IR (KBr): 2212 (C≡N), 1736, and 1686 cm^{-1} (C=O); UV (MeOH): λ_{max} 234 nm (log ε 4.57), 264 (4.35), 293 sh (4.60), 304 (4.72), 340 (3.86), 369 (3.87), and 503 (2.92); NMR ($CDCl_3$): δ ppm 3.75 (3H, s), 3.98 (3H, s), 4.41 (2H, s), 7.6—8.1 (3H, m), 8.75 (1H, m), and 9.73 (1H, m).

Found: C, 67.84; H, 4.97; N, 4.73%. Calcd for $C_{16}H_{13}O_4N$: C, 67.84; H, 4.63; N, 4.95%.

3-Cyano-2-methylazulene-1-carboxylic Acid (16). A mixture of 100 mg of **14** and 1.5 ml of pyridine was heated at 130 °C for 2 hr. The reaction mixture was then diluted with water and acidified with 6 M hydrochloric acid, thus affording 76 mg of crude **16**; mp 272—273 °C. Recrystallization from dimethylformamide gave orange red needles; mp 273 °C. This was identified with an authentic sample[2b] by a mixed-melting-point determination and by an infrared spectral comparison.

1,2,3,4-Tetrahydroazuleno[1,2-c]pyridine-2,4-dione (17). A mixture of 100 mg of **12** and 2 ml of conc. sulfuric acid was heated at 100 °C for 30 min. The reaction mixture was then allowed to cool and poured into ice water, thus giving 65 mg of **17** as violet crystals; mp 226—230 °C. Recrystallization from dimethylformamide afforded violet columns; 232 °C (decomp.); UV (dioxane): λ_{max} 296 nm (log ε 4.71), 308 (4.82), 359 (3.79), 367 (3.77), 377 (4.02), 490 sh (2.57), 520 (2.68), 550 (2.60), and 600 (2.13); NMR (DMSO-d_6): δ ppm 4.31 (2H, s), 6.98 (1H, S s), 7.4—8.1 (3H, m), 8.67 (1H, m), 9.58 (1H, m), and 10.8 (1H, bs).

Found: C, 73.73; H, 4.57; N, 6.56%. Calcd for $C_{13}H_9O_2N$: C, 73.92; H, 4.30; N, 6.63%.

The treatment of 100 mg of **12** with conc. hydrobromic (3 ml) or 85% phosphoric acid (2 ml) in a manner similar to that described above also gave **17** (mp 232 °C) in yields of 65 mg and 65 mg respectively.

N-*Acetyl Derivative*: Violet columns (from dimethylformamide); mp 275 °C (decomp.); IR (KBr): 1634 cm^{-1} (C=O); UV (dioxane): λ_{max} 310 nm (log ε 4.65), 338 (4.90), 360 (4.59), 400 (4.46), 528 (2.76), 548 (2.82), and 594 (2.44); mass spectrum *m/e* 253 (M+).

Found: C, 71.40; H, 4.73; N, 5.74%. Calcd for $C_{15}H_{11}O_3N$: C, 71.14; H, 4.37; N, 5.53%.

O-*Acetyl Derivative*: Violet needles (from ethanol); mp 168—170 °C; IR (KBr): 1786 and 1626 cm^{-1} (C=O); UV (dioxane): λ_{max} 296 nm (log ε 4.62), 307 (4.73), 329 (4.15), 360 (4.01), 378 (4.01), 522 (2.97), 556 (2.90), and 604 (2.61); mass spectrum *m/e* 253 (1.5%, M+) and 211 (100%).

Found: C, 71.38; H, 4.62; N, 5.80%. Calcd for $C_{15}H_{11}O_3N$: C, 71.14; H, 4.37; N, 5.53%.

A Base-induced Elimination Reaction of Phenylsulfonylacetates. I. General Aspect and Stereochemistry

Akira SERA, Hiroshi MANO, and Kazuhiro MARUYAMA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 27, 1973)

Esters of phenylsulfonylacetic acid were found to undergo a base-induced β-elimination reaction with *t*-butoxide in *t*-butyl alcohol. The intervention of a carbanion as an intermediate of the elimination was proposed. The stereochemistry of the elimination was examined by the use of *erythro*- and *threo*-2-deuterio-1,2-diphenylethyl phenylsulfonylacetates. From the deuterium content in a product, *i.e.*, *trans*-stilbene, the elimination was found to occur predominantly in a *syn* fashion.

The pyrolytic elimination reaction of acetates has been investigated extensively, and it is well known that almost all of the reactions proceed through a cyclic six-membered transition state.[1] However, little is known about the base-induced β-elimination reaction of the acetates in solution.[2,3] Curtin and Kellom[3] observed that 1,2-diphenylethyl acetate predominantly undergoes a *syn* elimination with potassium amide in liquid ammonia to give stilbene. With *t*-butoxide in *t*-butyl alcohol, however, no elimination was observed. In a previous paper,[4] we reported that 1,2-diphenylethyl phenylsulfonylacetate produces *trans*-stilbene and methyl phenyl sulfone upon treatment with *t*-butoxide in *t*-butyl alcohol.[5] Experiments with a deuterium-labeled diastereoisomeric pair of the ester suggested that the stereochemistry of the reaction was a *syn* elimination. The present paper will be concerned with a more detailed investigation of the mechanism of this and related base-induced *syn* elimination reactions.

Results and Discussion

In order to shed light on the mechanism of elimination reactions of phenylsulfonylacetates, we first employed 2-phenylethyl phenylsulfonylacetate (**1a**). This ester did not react when heated in diphenyl ether (259 °C). Thus, we anticipated that no thermal elimination operated below this temperature. On the other hand, it was found that the ester gives methyl phenyl sulfone on treatment with potassium *t*-butoxide in *t*-butyl alcohol (reflux) or on treatment with sodium methoxide in diphenyl ether (reflux). Because the presence of a styrene-forming elimination reaction with bases had been suggested, kinetic studies of the base-induced elimination reactions were performed for *para*-substituted 2-phenylethyl phenylsulfonylacetates (**1a**—**d**) using potassium *t*-butoxide in absolute *t*-butyl alcohol. The rates of the olefin-forming elimination reactions from **1** were followed spectrophotometrically by means of the characteristic absorption of the styrenes produced. An excess of the base was required to bring

about the elimination reaction of **1** effectively. The pseudo-first-order rate constants and the other thermodynamic data for the eliminations from **1a—d** are given in Table 1. In the reaction of **1a** with an excess amount of potassium *t*-butoxide in *t*-butyl alcohol, the reaction mixture was quenched by hydrochloric acid-*d* at an appropriate stage of the reaction, and the recovered starting material was submitted to NMR examination. The NMR spectra of the recovered **1a** showed that the methylene hydrogen atoms positioned α to the sulfonyl group were considerably displaced by deuterium atoms.[4] This observation suggests that a large portion of **1** must be converted into its conjugate base (carbanion) under the above conditions. Numerous examples illustrating the base-induced hydrogen exchange of methylene hydrogens positioned α to a sulfonyl group have been reported, and they have been explained on the basis of the formation of a carbanion stabilized by a strongly electron-withdrawing inductive effect of the sulfonyl group and a 3d-orbital resonance

with the adjacent sulfur atom.[6]

Since 2-phenylethyl 2-methyl-2-(phenylsulfonyl)propanoate (**2**) has no methylene hydrogens positioned α to the sulfonyl group, it is unlikely to anticipate **2** to

$$PhSO_2-\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{C}}-COOCH_2CH_2Ph$$

2

give a carbanion similar to that of **1**. Accordingly, the reaction of **2** with potassium *t*-butoxide in absolute *t*-butyl alcohol was examined. The rate data and the activation parameters for the elimination reaction from **2** are also given in Table 1. As is shown in Table 1, the rate constant for the elimination from **2** is smaller than that for the elimination from **1a**. The values of the activation enthalpy and entropy for the elimination from **2** are quite different from those for the eliminations from **1a—d**. These results imply that the reaction mechanism of the elimination from **2** differs from that of **1**. It should be emphasized that a rapid formation of the carbanion occurs in the reaction of **1**, but not in the reaction of **2**. Judging from the facts described above, it is likely that the carbanion plays an important role in the olefin-forming elimination reaction of **1**. The carbanionic center thus formed in **1** should considerably lower the leaving ability of the leaving group ($ArSO_2CH_2COO^-$), thus decreases the rate of the E2 reaction of **1**. However, this is not the case. An alternative possibility is that the carbanionic center acts intramolecularly as an attacking base against β-hydrogen to promote the elimination; that is, an intramolecular carbanionic elimination takes place in the present case. A carbanionic mechanism has frequently been supposed to account for the *syn* eliminations in the systems where the favored *anti* co-planarity can not be readily attained.[7] However, the role of the carbanionic center in the present reaction is apparently distinct from those described in the literature.[7] It seems to act as a base to abstract β-hydrogen through a six-membered cyclic transition state. If so, the elimination should proceed in a *syn* fashion. Consequently, the stereochemistry of the elimination reaction was examined. The substrates used were two deuterium-labeled diastereoisomers of 1,2-diphenylethyl phenylsulfonylacetate (**3**)—that is, *dl-erythro-* and *dl-threo-*2-deuterio-1,2-diphenylethyl phenylsulfonylacetates (**4e** and **4t**).

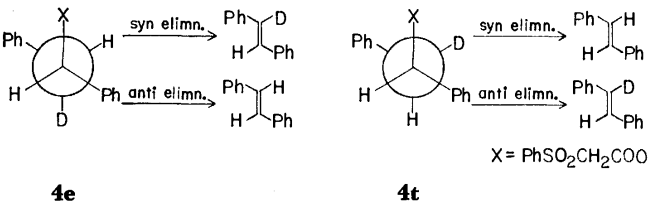
The products resulting from the reaction of **3** or **4** with potassium *t*-butoxide in absolute *t*-butyl alcohol were found by gas chromatography to be *trans*-stilbene, 1,2-diphenylethanol, and methyl phenyl sulfone. No *cis*-stilbene was detected; that is, this elimination is stereoselective. Under the conditions employed, no isomerization from **4e** to **4t** or the reverse occurred, as checked by NMR. Both *trans*-stilbene and 1,2-diphenylethanol were quite stable under the conditions employed, as checked by gas chromatography. Furthermore, **4e** or **4t** recovered from the reaction mixture was found to retain its deuterium atom, as checked by NMR and mass spectrometries; that is, no D–H exchange was present. Also, no hydrogen exchange of *trans*-stilbene was observed with potassium *t*-butoxide in *t*-butyl alcohol-*O-d*. These observations clearly show that the stereochemistry of the elimination can be elucidated by examining the deuterium content of *trans*-stilbene obtained from **4e** and **4t**.



4e **4t**

Scheme 1.

From a consideration of a stereo-model of **4**, the most favorable conformations are those depicted in Scheme 1. If the elimination occurred in a *syn* fashion, **4e** should give *trans*-stilbene-α-*d*, while if it occurred in an *anti* fashion, **4e** should give *trans*-stilbene with no deuterium. On the other hand, **4t** should give *trans*-stilbene with no deuterium in a *syn* elimination, while in an *anti* elimination **4t** should give *trans*-stilbene-α-*d*. The deuterium contents of *trans*-stilbene obtained from the reactions of **4e** and **4t** with potassium *t*-butoxide in *t*-butyl alcohol were determined by mass spectrometry. The results are shown in Table 2. It is quite clear

Table 2. Deuterium contents of *trans*-stilbene obtained from *erythro-* and *threo*-2-deuterio-1,2-diphenylethyl phenylsulfonylacetates (**4e** and **4t**) with *t*-butoxide in *t*-butyl alcohol[a]

[*t*-BuOK] (M)	Deuterium content of *trans*-stilbene[c]

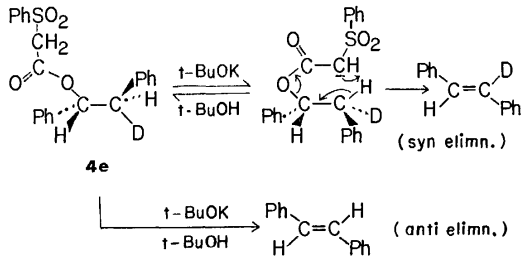
a) Reaction temperature was 90.0 °C. b) Initial concentration was [substrate] = 5.00×10^{-3}M. c) Deviations listed are standard deviations.

that the stereochemically-favored course of the elimination from **4** is *syn*, but the predominance of *syn* elimination is not overwhelming. It seems that a dual mechanism is operating in these eliminations—a predominant *syn* elimination accompanied by a concomitant *anti* elimination. The deuterium content of *trans*-stilbene obtained from the elimination of **4e** is almost independent of the concentration of the base, while that obtained from **4t** increases with an increase in the concentration of the base.

From these results, it can be concluded that the carbanion, the conjugate base of the substrate, is



Scheme 2.

rapidly formed as an intermediate which successively undergoes the *syn* unimolecular elimination reaction through a six-membered cyclic transition state (Ei), as is depicted in Scheme 2. An *anti* elimination also occurs concomitantly with a *syn* elimination. A possible alternative may be a *syn* E2 mechanism. However, it is unlikely that a *syn* concerted bimolecular elimination occurs predominantly in the present case.[8]

Previously, Curtin and Kellom[3] treated *erythro*- and *threo*-2-deuterio-1,2-diphenylethyl acetates with potassium amide in liquid ammonia and explained their results in terms of the *syn* elimination mechanism. They proposed the cyclic mechanism, which had been rejected by Hauser, Shivers, and Skell[2] because an excess amide ion was required to convert 2-phenylethyl acetate into styrene. Our observations are compatible with Curtin's cyclic intramolecular mechanism for the *syn* elimination.[3] That the presence of the excess base is necessary to bring about the reaction effectively indicates that the excess base is required to displace the equilibrium toward carbanion formation.[4] As is shown in Scheme 2, in the *syn* elimination from **4e** to give *trans*-stilbene-α-*d* the β-proton should be abstracted by a base, the carbanionic center in **4e**. On the other hand, in the corresponding *anti* elimination from **4e** the β-deuteron should be abstracted by an external base, *t*-butoxide. The reverse operates in the elimination reaction from **4t**. Thus, the kinetic isotope effect may be thought to be responsible for the apparently higher *syn* path: *anti* path ratio for **4e** than for **4t** (Table 2). An increase in the fraction of a bimolecular elimination, which results from an increase in the base concentration, should be more significant in the reaction of **4t** than in that of **4e**, because the value of the primary kinetic isotope effect (k_H/k_D) for the *anti* elimination reaction of **4** must be appreciably higher than unity. Table 2 indicates that this is the case. Especially, a change in the base concentration from 0.1 to 0.3 M gives rise to a considerable increase in the fraction of *anti* elimination from **4t**; whereas the corresponding increase is not so significant in the case of **4e**. However, a leveling effect upon the change in deuterium content is observed with a further increase in the base concentration. This effect suggests a possibility of the contribution of ion pairs. A study of the effect of ion pairs will be presented elsewhere.

The *syn* elimination mechanism described above resembles the so-called α',β-elimination mechanism. Both reactions include the preliminary abstraction of hydrogen in the leaving groups, and both proceed through cyclic transition states. However, the α',β-elimination is mainly a reaction of an 'onium salt with an organometallic compound[9] and necessarily includes an ylide intermediate, which leads inevitably to a five-membered transition state; this is in contrast with the elimination from phenylsulfonylacetates with alkoxides described in the present paper.

Experimental

All the melting points are uncorrected. The NMR spectra were taken on a JEOL JNM-PS-100 spectrometer, using tetramethylsilane as the internal standard, and the UV spectra on a Shimadzu UV-200 double-beam spectrophotometer. The gas chromatographic analyses were performed by means of a JEOL JGC-20K (f.i.d.) gas chromatograph. The mass spectra were recorded on a Hitachi RMS-4 mass spectrometer connected with a Hitachi K-53 gas chromatograph.

Materials. All the carboxylic esters were prepared in the usual way from the corresponding acid chlorides and the alcohols. These alcohols and carboxylic acids were prepared using methods reported in the literature.

*2-Phenylethyl Phenylsulfonylacetate (**1a**).* Recrystallized from ethanol; mp 81.0—81.5 °C; NMR ($CDCl_3$) δ 2.78 (t, 2H), 4.06 (s, 2H), 4.21 (t, 2H), and 7.01—7.90 (m, 10H). Found: C, 62.99; H, 5.34%. Calcd for $C_{16}H_{16}O_4S$: C, 63.14; H, 5.30%.

*2-(p-Tolyl)ethyl Phenylsulfonylacetate (**1b**).* Recrystallized from ethanol; mp 76.0—76.5 °C; NMR ($CDCl_3$) δ 2.25 (s, 3H), 2.73 (t, 2H), 4.05 (s, 2H), 4.18 (t, 2H), 7.01 (s, 4H), and 6.91—7.91 (m, 5H). Found: C, 64.20; H, 5.69%. Calcd for $C_{17}H_{18}O_4S$: C, 64.13; H, 5.70%.

*2-(p-Chlorophenyl)ethyl Phenylsulfonylacetate (**1c**).* Recrystallized from ethanol; mp 56 °C; NMR ($CDCl_3$) δ 2.76 (t, 2H), 4.08 (s, 2H), 4.20 (t, 2H), 7.03 (d, 2H), 7.16 (d, 2H), and 7.36—7.89 (m, 5H). Found: C, 56.77; H, 4.45%. Calcd for $C_{16}H_{15}ClO_4S$: C, 56.72; H, 4.46%.

*2-Phenylethyl p-Tolylsulfonylacetate (**1d**).* Recrystallized from ethanol; mp 63.5—64.0 °C; NMR ($CDCl_3$) δ 2.39 (s, 3H), 2.80 (t, 2H), 4.04 (s, 2H), 4.22 (t, 2H), 7.03—7.32 (m, 7H), and 7.74 (d, 2H). Found: C, 64.37; H, 5.66; S, 10.19%. Calcd for $C_{17}H_{18}O_4S$: C, 64.13; H, 5.70; S, 10.07%.

*2-Phenylethyl 2-Methyl-2-(phenylsulfonyl)propanoate (**2**).* Purified by column chromatography on silica gel, with chloroform as the eluent. Viscous sirup; n_D^{25} 1.5510; NMR (CCl_4) δ 1.48 (s, 6H), 2.75 (t, 2H), 4.14 (t, 2H), and 6.97—7.76 (m, 10H). Found: C, 64.92; H, 6.07%. Calcd for $C_{18}H_{20}O_4S$: C, 65.04; H, 6.06%.

*1,2-Diphenylethyl Phenylsulfonylacetate (**3**).* Recrystallized from ethanol; mp 97.0—97.5 °C; NMR ($CDCl_3$) δ 3.10 (seven lines, 2H), 4.05 (s, 2H), 5.90 (t, 1H), and 6.99—7.79 (m, 15H). Found: C, 69.28; H, 5.32%. Calcd for $C_{22}H_{20}O_4S$: C, 69.45; H, 5.30%.

dl-erythro-*2-Deuterio-1,2-diphenylethanol.* This alcohol was prepared from *trans*-stilbene oxide by treatment with lithium aluminum deuteride, and was then recrystallized from hexane; mp 66—67 °C (lit,[3] 64.4—65.4 °C); NMR ($CDCl_3$) δ 2.43 (s, 1H), 2.77 (d, J=8 Hz, 1H), 4.51 (d, J=8 Hz, 1H), and 6.80—7.04 (m, 10H).

dl-threo-*2-Deuterio-1,2-diphenylethanol.* This alcohol was prepared from *cis*-stilbene oxide by treatment with lithium aluminum deuteride, and was then recrystallized from hexane; mp 66—67 °C (lit,[3] 64.4—65.4 °C); NMR ($CDCl_3$) δ 2.53 (s, 1H), 2.85 (d, J=5 Hz, 1H), 4.68 (d, J=5 Hz, 1H), and 7.00—7.28 (m, 10H).

dl-erythro-*2-Deuterio-1,2-diphenylethyl Phenylsulfonylacetate (**4e**).* Recrystallized from ethanol; mp 97.0—97.5 °C;

NMR ($CDCl_3$) δ 3.13 (d, J=8 Hz, 1H), 4.03 (s, 2H), 5.83. (d, J=8 Hz, 1H), and 6.94—7.74 (m, 15H).

dl-threo-*2-Deuterio-1,2-diphenylethyl Phenylsulfonylacetate (4t)* Recrystallized from ethanol; mp 97.0—97.5 °C; NMR ($CDCl_3$) δ 2.98 (d, J=6.5 Hz, 1H), 4.03 (s, 2H), 5.87 (d, J=6.5 Hz, 1H), and 6.97—7.80 (m, 15H).

Solvent and Base. *t*-Butyl alcohol was distilled twice from clean metallic sodium under anhydrous conditions. Potassium metal was cut clean of all oxides and rinsed in purified *t*-butyl alcohol. The metal was immediately transferred into an appropriate amount of anhydrous *t*-butyl alcohol and allowed to dissolve under anhydrous conditions.

Kinetic Measurements. The reactions of **1a—d** and **2** with potassium *t*-butoxide in *t*-butyl alcohol were carried out in a 20 ml flask. The initial concentration of the substrate was 5.00×10^{-3} M, while that of the base was 1.00 M. Runs were carried out in a thermostatted bath. The temperature was controlled within $\pm$0.05 °C. At appropriate intervals of time, 2 ml aliquots were withdrawn from the flask and quenched in ethanol—water (1: 1 by volume) in a 25 ml volumetric flask. The volumetric flask was filled to the mark with the ethanol—water mixture and shaken. The concentration of olefin in this solution was measured spectrophotometrically. The pseudo-first-order rate constants were obtained from the measured absorbances at the absorption maximum of styrene or substituted styrenes. Each rate constant was calculated by following the reaction till 10—15% completion; after that time a concomitant alcohol-forming reaction caused it to give complex kinetics. The molar extinction coefficients in ethanol—water (1: 1 by volume) are as follows: styrene, λ_{max} 248 nm (ε, 1.42×10^4); *p*-methylstyrene, λ_{max} 252 nm (ε, 1.66×10^4); and *p*-chlorostyrene, λ_{max} 253 nm (ε, 1.84×10^4).

Product Analysis. To a 20ml solution of potassium *t*-butoxide in absolute *t*-butyl alcohol, we added 0.100 mmol of the substrate. After having been maintained at 90.0 °C for 1 hr, the mixture was poured into water and extracted with ether. The ethereal solution was washed with water, dried, and analyzed by gas chromatography using a 2 m column of 2% PEG 20 M on Celite 545 (60—80 mesh) at 200 °C. The reaction products detected were *trans*-stilbene and 1,2-diphenylethanol.

Deuterium Analysis. To a 20 ml solution of potassium *t*-butoxide in absolute *t*-butyl alcohol, we added 0.100 mmol of the substrate (**4e** or **4t**). The mixture in a sealed ampoule was maintained at 90.0 °C for 1 hr and then treated in a manner similar to that above. The deuterium content of *trans*-stilbene was determined by mass spectrometry using a mass spectrometer connected with a gas chromatograph. The ionizing energy used for the analyses was 70 eV. The deuterium content was evaluated from the intensities of the corresponding mass peaks, corrected for the natural abundances of isotopes. The calculation method was based on the assumptions that hydrogen randomization precedes the formation of M^+–H· species from the stilbene molecular ion and that the value of the deuterium isotope effect (k_H/k_D) on fragmentation is unity.[10]

Control Experiments. When *cis*-stilbene was treated with potassium *t*-butoxide in *t*-butyl alcohol at 90.0 °C for 1.5 hr, it showed no detectable isomerization to *trans*-stilbene as checked by gas chromatography.

trans-Stilbene and 1,2-diphenylethanol were treated with potassium *t*-butoxide as has been described above. No detectable change was observed, as checked by gas chromatography.

The NMR spectrum of *trans*-stilbene treated with potassium *t*-butoxide in *t*-butyl alcohol-*O*-*d* as described above showed no H–D exchange. *t*-Butyl alcohol-*O*-*d* was prepared from potassium *t*-butoxide and deuterium oxide using a modification of a method described in the literature.[11] The isotopic purity of this alcohol was checked by NMR before use.

The starting ester (**4e** or **4t**) recovered from the reaction mixture showed neither interconversion into the corresponding epimer nor H–D exchange, as checked by NMR and mass spectrometries.

We wish to express our appreciation to Dr. Tamio Ueno, Kyoto University, and the staff of Hitachi, Ltd., for their valuable comments and co-operation in the mass spectrometry.

A Base-induced Elimination Reaction of Phenylsulfonylacetates. II. Effects of the Base and the Solvent on the Stereochemistry of Elimination

Hiroshi MANO, Akira SERA, and Kazuhiro MARUYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 27, 1973)

The base-induced elimination reaction[1] of 1,2-diphenylethyl phenylsulfonylacetate was investigated in a variety of base–solvent systems. A stronger base was found to facilitate *syn* elimination. The addition of crown ether caused a remarkable change in the stereochemistry of elimination from *syn* to *anti*. In aprotic solvents, an overwhelming *syn* elimination was observed.

In the preceding paper we reported that 1,2-diphenylethyl phenylsulfonylacetate (**1**) undergoes β-elimination with potassium *t*-butoxide in *t*-butyl alcohol, predominantly through a *syn* pathway.[1] An intervention of a carbanion intermediate was described, and a cyclic transition state for the *syn* elimination was proposed. It was also suggested that an ion pair or an ion aggregate more or less controlled the stereochemistry of elimination.

Pedersen[2] has shown that cyclic polyethers containing from five to ten oxygen atoms can form stable complexes with a potassium ion as well as with other cations. Recently, the cyclic polyethers have been used in studies of bimolecular elimination reactions exhibiting *syn–anti* dichotomy, and a pronounced effect of base ion-pairing and association on the stereochemistry of β-eliminations has been observed.[3-5] The present paper will deal with the effect of base association on the stereochemistry of the base-induced carbanionic elimination from 1,2-diphenylethyl phenylsulfonylacetate. Dicyclohexyl-18-crown-6 ether (**3**) was employed as a mechanistic probe.

Results and Discussion

The stereochemistry of elimination from 1,2-diphenylethyl phenylsulfonylacetate ($PhSO_2CH_2COOCHPh\text{-}CH_2Ph$, **1**) was examined under a variety of conditions. Four base–solvent systems, KOH–aq.EtOH, MeOK–MeOH, EtOK–EtOH, and *t*-BuOK–*t*-BuOH, were employed, as well as systems of *t*-BuOK in THF and DMF. The substrates examined in the present investigation were *dl-erythro-* and *dl-threo*-2-deuterio-1,2-diphenylethyl phenylsulfonylacetates (**2e** and **2t**). The reaction products from **1** and **2** were *trans*-stilbene, 1,2-diphenylethanol, and methyl phenyl sulfone. The deuterium content of *trans*-stilbene was examined in order to find out the stereochemical course of elimination. If the elimination were to occur in a *syn* fashion, **2e** should give *trans*-stilbene-α-*d* and **2t** should give *trans*-stilbene with no deuterium, while if it were to occur in an *anti* fashion, **2e** should give *trans*-stilbene with no deuterium and **2t** should give *trans*-stilbene-α-*d*.[1] Table 1 shows the results. The yield of *trans*-stilbene is also shown.

In protic solvents (water, methanol, ethanol, and *t*-butyl alcohol), the deuterium content of *trans*-stilbene produced from **2e** increases with the following order of base–solvent systems. KOH–aq.EtOH, MeOK–MeOH, EtOK–EtOH, *t*-BuOK–*t*-BuOH, while that produced from **2t** decreases with the same order; that is, the stereochemical course of the elimination reaction from **2** with potassium *t*-butoxide in *t*-butyl alcohol is more *syn*-favored. Since *t*-butoxide is stronger as a base, it seems to be more effective to form a carbanion positioned α to the sulfonyl group of the substrate. The fact that the *syn* elimination reaction is caused by this carbanion was pointed out in the preceding paper.[1] These observations imply that the *syn* elimination from **2** is facilitated by the use of a stronger base, *t*-butoxide, in a solvent of a low dielectric constant, *t*-butyl alcohol. In addition, an ion pairing or ion aggregation of the base must be operating in the present base–solvent system, because it was necessary to employ a rather high base concentration in order to bring about the reaction effectively. It was suggested by Závada and Svoboda[6] that both the dissociated and ion-paired bases take part in the elimination reactions of cycloalkyl tosylates simultaneously; the former prefers an *anti* elimination, and the latter, a *syn*. Very recently, evidence has been presented to indicate that the base association is one of the essential requisites for *syn* elimination by using a macrocyclic polyether.[3-5] Macrocyclic polyethers (crown ethers) are known to co-ordinate with alkali metal cations; hence, they convert contact ion pairs into separated ions.[7,8] Accordingly, the effect of dicyclohexyl-18-crown-6 ether (**3**) was investigated.

The results shown in Table 1 clearly indicate that the

a) Reaction temperature was 90.0 °C (1 hr). b) Initial concentration was [substrate]$=5.00\times10^{-3}$M. c) Deviations listed are standard deviations. d) Overall yield of *trans*-stilbene. e) EtOH–H_2O; 80:20 by volume. f) Taken from Ref. 1. g) Concentration of crown ether **3** was 0.50 M. h) Concentration of crown ether **3** was 1.00 M.

addition of an equimolar amount of the crown ether, **3**, to the reaction mixture effected a remarkable change in the stereochemical course of the elimination. The deuterium contents of *trans*-stilbene produced show that the elimination reaction proceeds, for the most part, in an *anti* fashion in the presence of **3**. Roitman and Cram[8] studied the effect of crown ether on the rates and the stereochemical course of a potassium *t*-butoxide-catalyzed carbanion-generating reaction in *t*-butyl alcohol. They showed that the presence of crown ether dramatically increased the rates of both isotopic exchange and racemization. The occupation of the co-ordination sites of the potassium ion by crown ether was thought to be responsible for the restricted availability of these sites to both the leaving and entering groups in the reaction. Thus, the possibility of the association of a carbanion with the potassium ion complexed with crown ether was suggested.

A similar concept can account well for the present preferential *anti* elimination observed in the presence of **3** (Table 1). In *t*-butyl alcohol, the potassium ion was thought to associate with the carbanionic center of the substrate. In the presence of crown ether, the added ether must occupy a part of the co-ordination sites of the potassium ion. In the present case, however, the complexed potassium ion is supposed to be still held in the neighborhood of the carbanionic center of the substrate; hence, the carbanion may be prevented from taking the favored position for the intramolecular abstraction of the β-proton at the front face. Undoubtedly, the low dielectric nature of *t*-butyl alcohol plays an important role in the ion pairing between the carbanion and the complexed potassium ion.[9] Furthermore, it is known that a phenylsulfonyl group is one of the functional groups that induce carbanion asymmetry.[10] Consequently, the carbanion positioned α to the sulfonyl group is unable to react at the backside. On the other hand, since ion-paired potassium *t*-butoxide is forced to dissociate more or less by the added crown ether,[7] and since the thus-dissociated *t*-butoxide possesses a much greater kinetic basicity than ion-paired *t*-butoxide,[8] a bimolecular reaction with *t*-butoxide may be accelerated. Therefore, the addition of the crown ether could depress the *syn* elimination reaction and increase the *anti* elimination.

In aprotic solvents (THF and DMF), the deuterium contents of *trans*-stilbene produced indicate that the stereochemical course of the elimination reaction is more *syn*-favored than in *t*-butyl alcohol. Recently, it was reported that, in a bimolecular elimination with potassium *t*-butoxide, both the addition of the crown ether and the change in solvent from *t*-butyl alcohol to DMF operate to increase the *anti* pathway.[3] However, in the present case, the change in solvent from *t*-butyl alcohol to aprotic solvents operates to increase the *syn* pathway. This result can also be explained on the basis of the *syn* elimination mechanism described in the preceding paper.[1] It was shown there that the *syn* elimination requires the carbanion positioned α to the sulfonyl group of the substrate as an effective base. In THF and DMF, the potassium cation must be solvated nucleophilically; hence, the reactivity of the carbanion is increased. Consequently, the *syn* elimination may be highly favored.[11]

No interconversion between **2e** and **2t** was observed with *t*-butoxide in *t*-butyl alcohol.[1] However, in THF and DMF the base-induced interconversion was observed. Preliminary experiments showed that, in the reaction of **2e** with potassium *t*-butoxide in THF or DMF, the recovered ester[12] consisted of **2e** and **2t** (approximately 1 : 1), while in the reaction of **2t** under the same conditions the recovered ester[12] consisted of **2t** only. These results may reasonably be understood in terms of the existence of carbanion intermediates which are responsible for the interconversion of the ester. The kinetic isotope effect will make the rate of *syn* elimination from **2e** faster than that from **2t**. Therefore, the **2e** produced by the isomerization of **2t** is assumed to be exhausted, resulting in the absence of **2e** in the reaction mixture. If this is the case, the *syn*

selectivities for **2e** and **2t** must be larger than the values presented in Table 1.[13]

The reactions of **1** and **2** with potassium *t*-butoxide in DMSO were also examined. However, in DMSO, *trans*-stilbene produced reacted further with the solvent to give secondary products. The details will be reported elsewhere.

Experimental

Materials. Compounds **1**, **2e**, and **2t** have been described previously.[1] Crown ether **3** (2,5,8,15,18,21-hexaoxatricyclo[20.4.0.0^{9,14}]hexacosane) was prepared as has been described in the literature.[2]

Solvents and Bases. *t*-Butyl alcohol was purified as previously reported.[1] Ethanol and methanol were treated with magnesium and distilled twice under anhydrous conditions. Tetrahydrofuran was dried over sodium and distilled from lithium aluminum hydride under anhydrous conditions. *N,N*-dimethylformamide and dimethyl sulfoxide were treated with calcium hydride and distilled under reduced pressure. The alkoxide solutions were prepared from freshly-cut potassium metal and the appropriate alcohol under anhydrous conditions.

Product Analysis. The procedures employed were similar to those described in the preceding paper.[1] The reactions were performed by the sealed-ampoule technique, and the quantitative analyses of the reaction products were carried out by means of gas chromatography. The deuterium content of *trans*-stilbene was determined by mass spectrometry. The mass spectra were recorded on a Hitachi RM-50GC g.c. mass spectrometer at 70 eV.

We wish to express our appreciation to Professor Rikisaku Suemitsu for his help with the mass spectrometry.

11) One can also anticipate that potassium *t*-butoxide must dissociate more or less in DMF, and that the dissociated *t*-butoxide must operate as a strong base in the *anti* elimination, just as has been observed for usual E2 reactions. However, this is not the case. The reason for those conflicting observations remains to be determined.
12) Unpublished results. Recovered at an about 50% completion of the reaction at 25 °C. Analysis was performed by NMR.
13) Investigations of this problem are now in progress.

Optically Active Triptycenes. VII.[1] Synthesis, Optical Resolution and Absolute Configuration of 3-Chloro and 4-Chloro-7-substituted Triptycenes.

Michiaki HASHIMOTO, Yasumi SHIMIZU, Fumio OGURA, and Masazumi NAKAGAWA

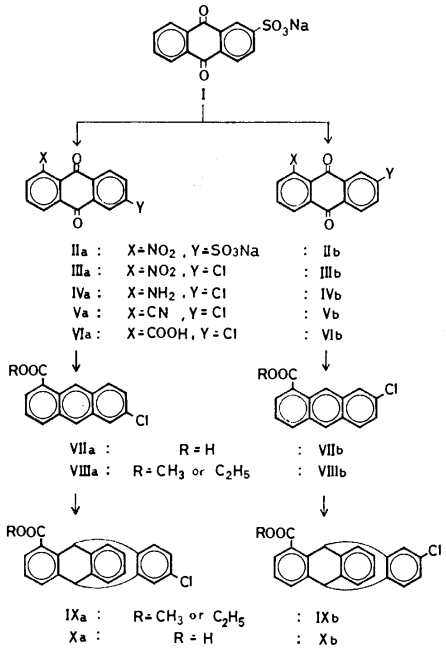
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 2, 1974)

Isomeric 3- or 4-chlorotriptycene-7-carboxylic acid was synthesized from sodium anthraquinone-β-sulfonate and resolved with quinidine methohydroxide. The absolute configurations of (−)-3-chloro- and (−)-4-chlorotriptycene-7-carboxylic acids could be determined to be 1*S*,6*S* and 1*S*,6*R*, respectively, by the chemical correlation with (+)-2,5-dimethoxy-8-chlorotriptycene whose absolute configuration was proved to be 1*R*,6*S* by X-ray and chemical means.

The synthesis, optical resolution and absolute configuration of 2,5,7-[2] and 2,5,8-trisubstituted triptycenes[3] and 2,5- and 2,7-disubstituted triptycenes[4,5] as well as the analysis of CD spectra of these and related compounds[6] have been reported. The present paper deals with the synthesis, optical resolution of 3- or 4-chloro-7-substituted triptycenes and the determination of their absolute configuration by chemical correlation which were performed with the purpose of clarifying the effect of difference in the mode of coupling on chiroptical properties.

Synthesis and Optical Resolution. The route of synthesis is outlined in Scheme 1. Chloronitroanthraquinone (IIIa or IIIb) was prepared starting from sodium anthraquinone-β-sulfonate (I) *via* sodium nitroanthraquinonesulfonate (IIa or IIb) according to a modified method of Fierz-David.[7] Aminochloroanthraquinone (IVa or IVb) obtained by reduction of the nitro compound (IIIa or IIIb) with sodium sulfide was converted into nitrile (Va or Vb) by the Sandmeyer reaction. Acid hydrolysis of the nitrile (Va or Vb) afforded carboxychloroanthraquinone (VIa or VIb), which was reduced with zinc dust and aqueous ammonia to give 6- or 7-chloroanthracene-1-carboxylic acid (VIIa or VIIb). The acid (VIIa or VIIb) was converted into methyl or ethyl ester (VIIIa or VIIIb) by the usual method.

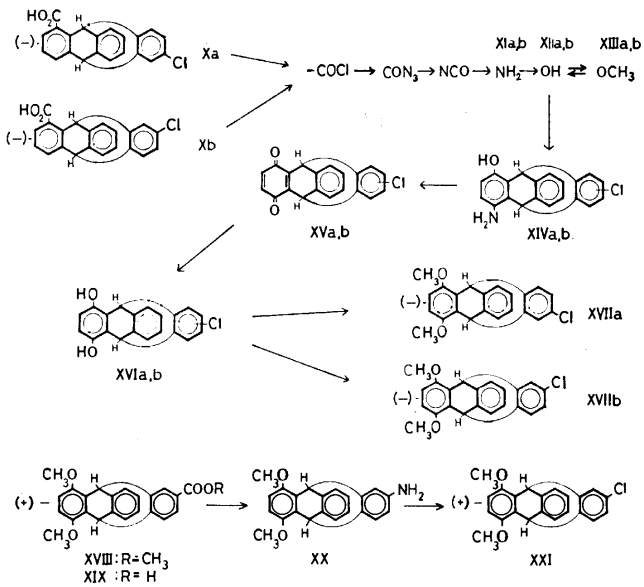


Scheme 1. Synthesis of 3,7- and 4,7-disubstituted triptycenes.

Reaction of benzyne generated by the decomposition of benzenediazonium carboxylate[8] with the ester (VIIIa or VIIIb) gave 3- or 4-chloro-7-methoxy(or ethoxy)carbonyltriptycene (IXa or IXb). Ethyl esters gave a less satisfactory result with respect to the yield and crystallinity. No significant increase in the yield of IX could be attained by varying the solvent from dichloromethane to 1,2-dimethoxyethane.[9]

The IR spectrum of IXa is almost superimposable with that of IXb, the difference in their NMR spectra being distinct in the region of aromatic protons. Racemate of 3- or 4-chlorotriptycene-7-carboxylic acid (Xa or Xb) was obtained hydrolyzing the ester (IXa or IXb) by the usual method. After several unsuccessful trials, optical resolution of Xa or Xb was accomplished with equimolar quinidine methohydroxide.[10] (−)-3-Chloro-7-carboxytriptycene (Xa) and (−)-4-chloro-7-carboxytriptycene (Xb) were isolated from the optically pure salts by decomposition with hydrochloric acid.

Absolute Configuration. Relative and absolute configurations of (−)-Xa and (−)-Xb were determined by chemical means as shown in Scheme 2. (−)-Xa



Scheme 2. Chemical correlation.

and (−)-Xb were converted into amine (XIa) and (XIb), respectively, by the Curtius reaction *via* acid chloride, acid azide, and isocyanate. In the case of XIb, a certain amount of urea derivative possibly resulting from the reaction of isocyanate with XIb was isolated. Phenols (XIIa and XIIb) were obtained by hydrolysis of diazonium salts of the amines (XIa and XIb) and purified as methyl ethers (XIIIa and XIIIb). Coupling of diazotized sulfanilic acid with the pure phenol (XIIa or XIIb) followed by reduction afforded *p*-aminophenol derivative (XIVa or XIVb) which was oxidized with ferric sulfate to yield *p*-benzoquinone derivative (XVa or XVb). Attempts to obtain the *p*-benzoquinone derivative (XVa or XVb) directly from the amine (XIa or XIb) by oxidation with sodium dichromate or chromium trioxide were unsuccessful, the only product isolated being 2-chloroanthraquinone. Oxidation of the phenol (XIIa or XIIb) with potassium nitrosodisulfonate or chromium trioxide gave the quinone (XVa or XVb) in a very poor yield, 2-chloroanthraquinone being isolated also in the case of chromium trioxide. Hydroquinone derivative (XVIa or XVIb) obtained from the quinone (XVa or XVb) by reduction with sodium hydrosulfite was converted into dimethyl ether (XVIIa or XVIIb) with dimethyl sulfate. The dimethyl ether derivatives thus prepared were found to be the same, including their chiroptical properties.

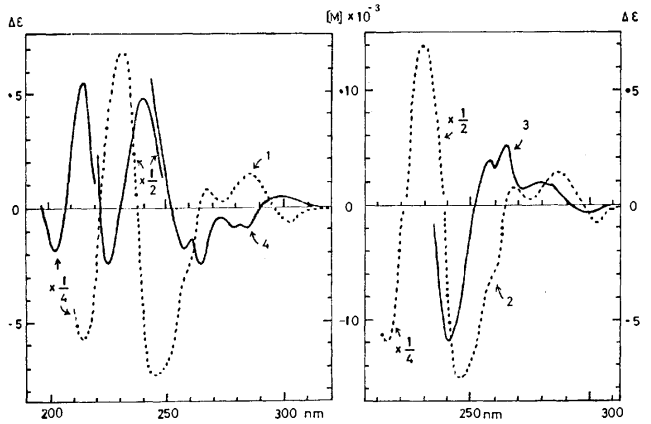


Fig. 1. CD (——) and ORD (----) spectra of (−)- and (+)-2,5-dimethoxy-8-chlorotriptycenes.
1: (−)-XVIIa, 2,3: (−)-XVIIb, 4: (+)-XXI

On the other hand, (+)-1*R*,6*S*-2,5-dimethoxy-8-methoxycarbonyltriptycene (XVIII)[3] was hydrolyzed to carboxylic acid (XIX) and then converted into amine (XX) by the Curtius reaction. (+)-2,5-Dimethoxy-8-chlorotriptycene (XXI) prepared from the amine (XX) by the Sandmeyer reaction was found to be the same as the above-mentioned chlorides (XVIIa and XVIIb) in melting point, IR, UV, and NMR spectra, but their chiroptical properties were antipodal (Fig. 1). The absolute configuration of (−)-2,5-dimethoxy-8-chlorotriptycene (XVII) was thus determined to be 1*S*,6*R*. Consequently the absolute configuration of (−)-3-chlorotriptycene-7-carboxylic acid (Xa) and (−)-4-chlorotriptycene-7-carboxylic acid (Xb) could be assigned to be 1*S*,6*S* and 1*S*,6*R*, respectively, on the combined evidence of X-ray[11] and chemical correlation.[3] Recently the X-ray crystal structure analysis was carried out on a single crystal of (+)-XXI. The absolute configuration was shown to be 1*R*,6*S* by the Bijvoet method[12] which is consistent with the results of chemical correlation.

Experimental

The melting points were measured on a Mettler FP2 apparatus and a Shimazu Kohfler micro hot stage, and are uncorrected. Purified and anhydrous solvents were used throughout the whole experiments, unless otherwise stated. The IR spectra were obtained on a Hitachi EPI-2 or a JASCO DS-301 spectrometer, electronic spectra on Hitachi EPS-3T and Zeiss PMQII4QIIId sopectrometers, NMR spectra in deuteriochloroform on a Varian A-60 spectrometer using TMS as an internal standard and given in τ-units. The optical rotations and CD spectra were obtained on Rudolf 200S-80, Yanagimoto ORD-185 spectropolarimeter, Roussel Jouan Dichrograph B, II-CD-185 and JASCO J-20 spectrometers, respectively. Shoulders and inflections are denoted by an asterisk.

6-Chloro-1-nitroanthraquinone (IIIa) and 7-Chloro-1-nitroanthraquinone (IIIb). The synthesis was performed by the reported method[7] with some modification. Sodium anthraquinone-β-sulfonate (310 g, 1 mol), dried thoroughly at 150 °C *in vacuo*, was added to 100% sulfuric acid (620 g) in small portions under stirring. To the dark brown solution was added dropwise at 90—95 °C a mixture of fuming nitric acid (d=1.52, 82 g) and 100% sulfuric acid (82 g). The reaction mixture containing yellow precipitates was heated to 100 °C for 30 min. The cooled reaction mixture was added to cold water (1.5 l). To the clear solution obtained on heating the mixture was added sodium chloride (82 g) to precipitate yellow crystals which were recrystallized from boiling water (1 l) to give sodium 1-nitroanthraquinone-6-sulfonate (IIa). 1-Nitro-7-sulfonate (IIb) in the mother liquor was not isolated as solid and subjected directly to further reaction.

1-Nitro-6-sulfonate (IIa) was dissolved in water (2.5 l) and mixed with concd. hydrochloric acid (460 g). To this solution was added at 100 °C dropwise an aqueous sodium chlorate (80 g in 800 ml) for 3 hr under stirring. After the mixture had been stirred for further 24 hr at 100 °C, light yellow precipitates were collected by filtration from the hot solution and recrystallized from benzene to give 6-chloro-1-nitroanthraquinone (IIIa 190 g, 22% based on I). 1-Nitro-7-chloro-isomer (IIIb) was prepared from 1-nitro-7-sulfonate (IIb) by essentially the same procedure and purified by recrystallization from benzene (180 g, 21% based on I).

1,6-Isomer: Mp 274—275 °C, light yellow rods (sublimed from *ca.* 220 °C), IR (KBr-disk): $\nu_{C=O}$ 1680 cm^{-1}.

Found: C, 58.34; H, 2.18%. Calcd for $C_{14}H_6O_4NCl$: C, 58.45; H, 2.11%.

1,7-Isomer: Mp 256—257 °C, yellow needles (sublimed from *ca.* 230 °C), IR (KBr-disk): $\nu_{C=O}$ 1682, 1670 cm^{-1} (doublet).

Found: C, 58.63; H, 2.22%. Calcd for $C_{14}H_6O_4NCl$: C, 58.45; H, 2.11%.

1-Amino-6-chloroanthraquinone (IVa) and 1-Amino-7-chloroanthraquinone (IVb). A stirred suspension of IIIa (50 g) in water (1.4 l) containing sodium sulfide (130 g) was refluxed for 4.5 hr. After cooling, red precipitates were collected by filtration and crystallized from benzene to yield IVa as dark red needles (34 g, 79.1%), mp 214—216 °C (sublimed from *ca.* 150 °C), IR (KBr-disk): ν_{NH} 3440, 3320, $\nu_{C=O}$ 1665, 1645 cm^{-1}.

Found: C, 65.16; H, 2.96%. Calcd for $C_{14}H_8O_2NCl$: C, 65.26; H, 3.13%.

The product obtained on treatment of IIIb by essentially the same procedure was recrystallized from benzene to afford IVb (83.9%) as bright brick red needles, mp 234—235 °C, IR (KBr-disk): ν_{NH} 3445, 3340, $\nu_{C=O}$ 1670, 1635 cm^{-1}.

Found: C, 65.40; H, 3.20%. Calcd for $C_{14}H_8O_2NCl$: C, 65.26; H, 3.13%.

6-Chloro-1-cyanoanthraquinone (Va) and 7-Chloro-1-cyanoanthraquinone (Vb). To a vigorously stirred solution of IVa (35 g, 0.13 mol) in concd. sulfuric acid (175 ml) was added powdered sodium nitrite (12.2 g, 0.18 mol) in small portions over a 40 min-period. Cracked ice (115 g) was added to the dark brown mixture maintaining the temperature at 50—60 °C. After stirring for further 1 hr, the mixture was poured onto ice (530 g) to precipitate diazonium salt. A suspension of the diazonium salt in water (900 ml) was added dropwise to an aqueous solution (350 ml) of copper sulfate (63 g) and potassium cyanide (70 g) maintained at 70 °C. After the mixture was stirred for 40 min at 100 °C, precipitate was collected by filtration and digested with 3 M nitric acid to yield brown crystals. Recrystallization of the crystals from toluene afforded pure Va as brown needles (28.0 g, 79.4%), mp 299.5—300.5 °C (decomp.) in a sealed tube, IR (KBr-disk): ν_{CN} 2220, $\nu_{C=O}$ 1680 cm^{-1}.

Found: C, 67.31; H, 2.29%. Calcd for $C_{15}H_6O_2NCl$: C, 67.31; H, 2.26%.

Application of a similar procedure to 1-amino-6-chloro-isomer (IVb) afforded Vb (crude yield 90%). Prolonged reaction time of diazotization resulted in a better yield of Vb. Recrystallization of crude product from benzene gave pure Vb as yellowish green needles, mp 299—300 °C (decomp.), IR (KBr-disk): ν_{CN} 2235, $\nu_{C=O}$ 1680 cm^{-1}.

Found: C, 67.31; H, 2.21%. Calcd for $C_{15}H_6O_2NCl$: C, 67.31; H, 2.26%.

6-Chloroanthracene-1-carboxylic Acid (VIIa) and 7-Chloroanthracene-1-carboxylic Acid (VIIb). Water (223 ml) was added dropwise under stirring to an ice-cooled solution of Va (55.7 g, 0.20 mol) in concd. sulfuric acid (668 ml). The mixture was heated to 160—170 °C for 4 hr and then poured into cold water (1 l) to give a black purple precipitate of VIa. To a stirred purple red solution of crude VIa in 15% aqueous ammonia was added zinc dust at 80—90 °C. Occasional addition of aqueous ammonia and zinc dust gave a greyish green suspension in *ca.* 7 hr. Brown filtrate, after treatment with active charcoal, was acidified with concd. hydrochloric acid to precipitate yellowish green VIIa (52.0 g, 97.1%). The precipitate could be used for esterification without further purification. Pure VIIa was obtained by recrystallization from toluene as greenish yellow needles, mp 258—266 °C (decomp.), IR (Nujol mull): $\nu_{C=O}$ 1685 cm^{-1}.

A similar reaction applied to Vb afforded VIIb (95.6%), which could be used directly for further reactions. Pure VIIb was obtained by recrystallization from benzene as yellow needles, mp 262—264 °C (decomp.), IR (Nujol mull): $\nu_{C=O}$ 1680 cm^{-1}.

6-Chloro-1-ethoxy(or methoxy)carbonylanthracene (VIIIa) and 7-Chloro-1-ethoxy(or methoxy)carbonylanthracene (VIIIb).

VIIIa (ethyl ester): To a solution of VIIa (17.8 g, 0.0690 mol) in ethanol (1500 ml) was added dropwise concd. sulfuric acid (150 nil) and the mixture was refluxed for 13 hr. After removal of a major portion of ethanol under reduced pressure, the reaction mixture was poured into water (1 l) and extracted with benzene. The extract, after being washed and dried, was concentrated under reduced pressure to yield brown crystals, which were dissolved in benzene and passed through a short column of alumina. Yellow crystals obtained by drying up benzene eluate under reduced pressure were recrystallized from ligroin to give pure VIIIa as yellow needles (14.1 g, 71.4%), mp 113—114 °C, IR (KBr-disk): $\nu_{C=O}$ 1718 cm^{-1}.

Found: C, 71.69; H, 4.58%. Calcd for $C_{17}H_{13}O_2Cl$: C, 71.71; H, 4.60%.

VIIIa (methyl ester): A mixture of VIIa (35 g), methanol (3 l) and concd. sulfuric acid (300 ml) was refluxed for 15 hr. Yellowish brown crystals deposited on cooling the mixture were collected by filtration. The filtrate neutralized by sodium hydrogen carbonate and concentrated under reduced pressure was poured into water and extracted with benzene. The extract was worked up in the usual way to give an additional amount of VIIIa (6 g). Benzene solutions of both crops of crystals were passed through short columns of alumina and the crystals obtained from the filtrates were recrystallized from benzene to afford pure material, yellow needles (total 28.1 g, 76.8%), mp 130—131 °C, IR (KBr-disk): $\nu_{C=O}$ 1710 cm^{-1}.

Found: C, 71.12; H, 4.10%. Calcd for $C_{16}H_{11}O_2Cl$: C, 70.98; H, 4.10%.

VIIIb (ethyl ester): By a similar procedure to that used for VIIIa, VIIb was converted into ethyl ester which was recrystallized from ligroin to give pure substance, yellow needles, mp 91—92 °C, IR (KBr-disk): $\nu_{C=O}$ 1718 cm^{-1}.

Found: C, 71.75; H, 4.61%. Calcd for $C_{17}H_{13}O_2Cl$: C, 71.71; H, 4.60%.

VIIIb (methyl ester): Treatment of VIIb by a similar procedure to that used for VIIIa afforded methyl ester, yellow needles, mp 128—129 °C (from methanol), IR (KBr-disk): $\nu_{C=O}$ 1710 cm^{-1}.

Found: C, 70.71; H, 4.13%. Calcd for $C_{16}H_{11}O_2Cl$: C, 70.98; H, 4.10%.

3-Chloro-7-ethoxy(or methoxy)carbonyltriptycene (IXa) and 4-Chloro-7-ethoxy(or methoxy)carbonyltriptycene (IXb). IXa (ethyl ester): To a gently refluxing mixture of VIIIa (ethyl ester, 12.3 g, 0.0432 mol), isoamyl nitrite (7.2 g, 0.0615 mol) and dichloromethane (200 ml) was added dropwise a solution of anthranilic acid (7.8 g, 0.0569 mol) in acetone (40 ml) under stirring over a period of 9.25 hr. After removal of volatile components under reduced pressure, xylene (123 ml) and maleic anhydride (6 g, 0.06 mol) were added. The mixture was refluxed for 1 hr and poured into cold water (360 ml). This was extracted with dichloromethane and the extract was worked up in the usual way to give a red brown oil. A benzene solution of the crude material was chromatographed on alumina to remove unreacted anthracene ester (VIIIa). The desired product (IXa) was obtained as colorless liquid (10.0 g, 63.5%), which was identified by NMR spectroscopy [NMR (CCl_4): 8.65 (t, CH_3), 5.65 (q, CH_2), 4.72 (s, bridgehead C^6), 2.29—3.34 (m, aromatic and bridgehead C^1)]. The reaction carried out in 1,2-dimethoxyethane reduced the yield of adduct to 52.5%. The compound showed an almost identical IR spectrum (Nujol mull) with that of IXb (ethyl ester).

IXa (methyl ester): By essentially the same procedure, VIIIa (methyl ester) could be converted into IXa (methyl ester), colorless rods, mp 153—155 °C (from methanol), IR (KBr-disk): $\nu_{C=O}$ 1718 cm^{-1}.

Found: C, 75.76; H, 4.34; Cl, 10.64%. Calcd for $C_{22}H_{15}O_2Cl$: C, 76.19; H, 4.36; Cl, 10.22%.

IXb (ethyl ester): This was prepared according to the method used for IXa (ethyl ester) in yields of 58.9% (in dichloromethane) and 38.1% (in dimethoxyethane), colorless needles, mp 178—180 °C (from methanol), NMR (CCl_4): 8.65 (t, CH_3), 5.66 (q, CH_2), 4.76 (s, bridgehead C^6), 2.29—3.34 (m, aromatic and bridgehead C^1).

Found: C, 76.48; H, 4.70%. Calcd for $C_{23}H_{17}O_2Cl$: C, 76.55; H, 4.75%.

IXb (methyl ester): The ester was prepared from VIIIb (methyl ester) by essentially the same procedure in 63% yield, colorless leaflets, mp 192.5—193.5 °C (from methanol), IR (KBr-disk): $\nu_{C=O}$ 1720 cm^{-1}.

Found: C, 75.81; H, 4.43; Cl, 10.02%. Calcd for $C_{22}H_{15}O_2Cl$: C, 76.19; H, 4.36; Cl, 10.22%.

3-Chlorotriptycene-7-carboxylic Acid (Xa). From Ethyl Ester (IXa): IXa (ethyl ester, 10.0 g, 0.0277 mol) dissolved in 99% ethanol (1400 ml) was mixed with powdered potassium hydroxide (7.8 g) and water (800 ml). The mixture was refluxed for 24 hr and then concentrated *in vacuo* to remove the solvent. A small amount of water was added to the hot residue until a faint turbidity was produced and the mixture was allowed to stand to precipitate colorless leaflets. The potassium salt collected by filtration was washed with ether and dissolved in a small amount of 99% ethanol. The ethanol solution was mixed with concd. hydrochloric acid and extracted with ether. The extract was worked up in the usual way to give Xa (5.0 g). An additional amount of Xa was obtained from the filtrate of the potassium salt (total yield 6.7 g, 72.7%). Combined crystals were recrystallized from ligroin to give pure Xa, colorless needles, mp 227—228 °C (sublimed from *ca.* 195 °C), IR (KBr-disk): $\nu_{C=O}$ 1685 cm^{-1} (the IR spectrum was found to be similar to that of Xb over the entire region), UV: $\lambda_{max}^{95\%EtOH}$ (ε) 292.5 (4190), 279.5 (4000), 270* (2240), 240* (12700), 217.5 (50400), 207.5 (61700) nm.

Xa could be obtained also by hydrolysis in acetic acid with 3 M sulfuric acid in 81% yield, but above-stated alkaline hydrolysis was superior as regards the purity of product.

Found: C, 75.92; H, 4.09%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94%.

From Methyl Fster (IXa): An alkaline hydrolysis of IXa (methyl ester) under the above-mentioned conditions afforded Xa in 96.3% yield.

4-Chlorotriptycene-7-carboxylic Acid (Xb). Hydrolysis of IXb (ethyl or methyl ester) according to the method used in the preparation of Xa gave Xb in 90 or 99% yield, respectively, mp 243—245 °C (from ligroin), IR (KBr-disk): $\nu_{C=O}$ 1685 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 293 (4170), 278.5 (4070), 270* (2320), 240* (12200), 216.5* (53500), 209 (60800), 203* (53000) nm.

Found: C, 75.81; H, 3.83%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94%.

Optical Resolution of (±)-3-Chlorotriptycene-7-carboxylic Acid (Xa). Xa (2.157 g, 0.00648 mol) dissolved in 99% ethanol (40 ml) was mixed with aqueous quinidine methohydroxide (0.592 M, 10.9 ml, 0.0065 mol). After being left to stand overnight, the solvent was removed under reduced pressure and partly crystalline residue was recrystallized from dioxane. Repeated fractional recrystallization (7 times) afforded colorless crystals of optically pure salt, 0.389 g, mp 177—179 °C, $[\alpha]_{600}^{17.5}$ +95.10°, $[\alpha]_{589}^{17.5}$ +97.96°, $[\alpha]_{500}^{17.5}$ +154.7°, $[\alpha]_{400}^{17.5}$ +326.1° (*c* 0.490, EtOH). The crystals contained two molecules of dioxane as a solvent of crystallization and were slightly hygroscopic.

Found: C, 70.66; H, 6.47; N, 3.53%. Calcd for $C_{42}H_{39}N_2O_4 \cdot 2C_4H_8O_2$: C, 70.86; H, 6.54; N, 3.31%.

An effective resolution could not be attained by the use of ethanol or ethanol–ether.

The optically pure salt was decomposed by 5% aqueous hydrochloric acid to obtain (−)-Xa (0.13 g), which was recrystallized from ligroin, mp 236—238 °C, IR (KBr-disk): $\nu_{C=O}$ 1685 cm^{-1} (almost identical over entire region with (−)-Xb, (±)-Xa, and (±)-Xb), $[\alpha]_{600}^{16}$ −15.2°, $[\alpha]_{589}^{16}$ −16.3°, $[\alpha]_{500}^{16}$ −27.7°, $[\alpha]_{400}^{16}$ −70.8°, $[\alpha]_{350}^{16}$ −168° (*c* 0.516, 99% EtOH), CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 292 (−2.1), 278* (−0.89), 260* (+1.2), 254 (+2.1), 247 (−0.816), 240 (−1.14), 232 (−0.245), 220 (+11.4), 210 (−18.9) nm.

Found: C, 75.77; H, 4.18%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94%.

Optical Resolution of 4-Chlorotriptycene-7-carboxylic Acid (Xb). A solution of Xb (2.27 g, 0.00683 mol) in 99% ethanol (80 ml) was mixed with aqueous quinidine methohydroxide (0.614 M, 11.1 ml, 0.0068 mol) and left to stand overnight. The solid obtained by evaporating the solvent under reduced pressure was recrystallized from ethanol–ether. Repeated fractional recrystallization (16 times) from ethanol–ether or ethanol afforded colorless crystals of optically pure salt containing one molecule of ethanol as a solvent of crystallization, 1.134 g, mp 175—177 °C, $[\alpha]_{600}^{16}$ +133.9°, $[\alpha]_{589}^{16}$ +137.1°, $[\alpha]_{500}^{16}$ +213.4°, $[\alpha]_{400}^{16}$ +461.7° (*c* 0.440, EtOH).

Found: C, 73.76; H, 6.47; N, 3.91%. Calcd for $C_{42}H_{39}N_2O_4Cl \cdot C_2H_6O$: C, 73.67; H, 6.32; N, 3.91%.

The salt was decomposed with 5% aqueous hydrochloric acid to obtain (−)-Xb. Recrystallization of (−)-Xb from ligroin yielded colorless crystals of mp 90 °C containing some unidentified hydrocarbon as a solvent of crystallization. Upon heating *in vacuo* they gradually lost the solvent and showed a gradual rise in the melting point. After heating to 120 °C for 6 hr under reduced pressure, crystals free from the solvent were obtained, mp 204—205 °C, IR (KBr-disk): $\nu_{C=O}$ 1685 cm^{-1}, $[\alpha]_{436}^{21}$ −4.74°, $[\alpha]_{405}^{21}$ −9.95°, $[\alpha]_{365}^{21}$ −33.1° (*c* 0.980, 99% EtOH), CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 290 (−2.7), 274 (+2.0), 264* (+0.79), 250 (+2.0), 240 (−3.5), 225 (+33) nm.

Found: C, 75.86; H, 3.91; Cl, 10.42%. Calcd for $C_{21}H_{13}O_2Cl$: C, 75.79; H, 3.94; Cl, 10.66%.

7-Amino-3-chlorotriptycene (XIa). (−)-Xa (5.0 g, 0.015 mol) dissolved in ether (250 ml) was mixed with thionyl chloride (21.4 g) and refluxed for 7 hr. The mixture was concentrated under reduced pressure to yield colorless crystals of acid chloride, 5.3 g, mp 159—161 °C, IR (Nujol mull): $\nu_{C=O}$ 1755 cm^{-1}. To an ice-cooled solution of the chloride in acetone (200 ml), sodium azide (1.06 g) in water (10 ml) was added dropwise under stirring. The mixture was stirred for further 1.5 hr at the same temperature and then a major portion of the solvent was removed under reduced pressure. The residue was mixed with cold water (300 ml) and extracted with ether. The extract was worked up as usual, giving colorless crystals of acid azide, 5.45 g, mp 105—107 °C (decomposed with frothing), IR (Nujol mull): ν_{N_3} 2150, $\nu_{C=O}$ 1685 cm^{-1}. Thoroughly dried azide spread over the bottom of 1 l Erlenmeyer flask was heated gradually to 105 °C and kept at the temperature for 1 hr to yield light yellow crystals of isocyanate, mp 124—132 °C, IR (Nujol mull): $\nu_{N=C=O}$ 2250 cm^{-1}.

The isocyanate mixed with powdered potassium hydroxide (40 g) and 99% ethanol (500 ml) was refluxed for 6 hr and then a major portion of the solvent was removed *in vacuo*. The residue was mixed with water and extracted with ether. The extract was worked up in the usual way to yield light yellow crystals which gave, after sublimation *in vacuo* followed by recrystallization from ligroin, pure XIa, 3.542 g (77.6%), colorless needles, mp 201.2—203.2 °C, IR (KBr-disk): ν_{NH} 3470, 3380, δ_{NH} 1620 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 295 (2140), 284.5 (4360), 278.8 (4120), 265.5 (4400), 255* (5910), 249* (8200), 245* (9890), 217 (50400), 207.5* (15900), 202 (11800) nm, $\lambda_{max}^{99\%EtOH\text{-}HCl}$ (ε) 283.4 (2710), 277.3 (3520), 270 (2740), 214 (64000), 203.5 (58200) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 302 (−0.65), 282 (−3.21), 278* (−2.38), 266 (+0.69), 250 (−4.0), 234 (+6.50), 226 (−7.58), 214 (−8.67), 206 (−3.03)

nm, $\lambda_{max}^{99\%EtOH\text{-}HCl}$ ($\Delta\varepsilon$) 282 (+0.78), 274* (−0.84), 270 (−1.31), 255 (+4.91), 236 (−13.7), 218 (+14.3) nm.

Found: C, 79.08; H, 4.58; N, 4.71; Cl, 11.75%. Calcd for $C_{20}H_{14}NCl$: C, 79.07; H, 4.64; N, 4.61; Cl, 11.67%.

By a similar sequence of reactions (±)-Xb afforded racemate, faintly brown crystals, 87.2%, mp 198—201 °C (from ligroin), IR (KBr-disk): ν_{NH} 3470, 3380 cm^{-1}. In the case of racemate, a small amount of urea derivative was obtained in the last stage of the reactions.

7-Amino-4-chlorotriptycene (XIb). The Curtius reaction of (−)-Xb under similar reaction conditions described above afforded optically active XIb (81.9%) which was recrystallized from ligroin to give pure XIb, mp 169—172 °C. IR (KBr-disk): ν_{NH} 3380, 3460 cm^{-1}, δ_{NH} 1620 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 295 (2070), 284 (4290), 278.7 (3960), 266 (4040), 217 (50000), 202 (47100) nm, $\lambda_{max}^{99\%EtOH\text{-}HCl}$ (ε) 283.8 (2480), 277.5 (3260), 270.5 (2510), 214 (59600), 203 (53300) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 302 (+0.58), 283 (+4.93), 268 (+0.56), 248 (−6.91), 228 (+12.2), 216 (−23.3) nm, $\lambda_{max}^{99\%EtOH\text{-}HCl}$ ($\Delta\varepsilon$) 283 (−2.36), 274 (+0.49), 269 (+2.26), 254 (+5.45), 237 (−12.7), 220 (+16.6) nm.

Found: C, 78.61; H, 4.70; N, 4.64; Cl, 11.60%. Calcd for $C_{20}H_{14}NCl$: C, 79.07; H, 4.64; N, 4.61; Cl, 11.67%.

Racemate was prepared similarly from (±)-Xb, mp 181—184 °C (from ligroin), IR (KBr-disk): ν_{NH} 3480, 3380 cm^{-1}.

Formation of a small amount of urea derivative was observed in the reaction both of (±)- and (−)-Xb. In the case of optical isomer, the urea derivative was purified by recrystallization from ligroin, mp 301—302 °C, IR (KBr-disk): ν_{NH} 3320, δ_{NH} 1550, $\nu_{C=O}$ 1650 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 284.5 (6910), 274* (12300), 261* (24700), 249* (28000), 214 (99500), 207.4 (77500), 203.5 (44400) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 290 (−0.71), 280* (+7.6), 276 (+8.5), 264 (+4.0), 256* (+2.8), 242 (−1.6), 238 (+2.4) nm

Found: C, 77.36; H, 4.05; N, 4.36; Cl, 11.04%. Calcd for $C_{41}H_{26}N_2OCl_2$: C, 77.72; H, 4.14; N, 4.42; Cl, 11.19%.

4-Chloro-7-hydroxytriptycene (XIIb). Optically active XIb (0.86 g, 2.8 mmol) dissolved in acetic acid (12 ml) was added over a period of 35 min to a stirred solution of nitrosyl sulfate at 10—15 °C prepared from sodium nitrite (0.220 g) and concd. sulfuric acid (2 ml). The mixture was stirred for further 55 min and mixed with water (3 ml) to give a reddish green solution. The cooled solution of diazonium salt was added dropwise to a refluxing 3 M sulfuric acid (60 ml) under stirring. After being refluxed for further 1 hr, the mixture was extracted with benzene. Red amorphous solid obtained by working up the extract by the usual way was difficult to purify. Pure phenol (XIIb) could be prepared *via* methyl ether (XIIIb, see below). Purified ether (XIIIb, 0.60 g) dissolved in a mixture of acetic acid (35 ml) and 47% hydrobromic acid (20 ml) was refluxed for 8 hr. The mixture was poured into water and extracted with ether. Light yellow crystals (0.551 g) obtained by working up the extract were recrystallized from ligroin to give pure optically active XIIb, colorless crystals, mp 242—246 °C, IR (KBr-disk): ν_{OH} 3520—3400 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 284 (4370), 278 (4340), 265.4 (3470), 216 (58700), 195 (56600) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 278 (+3.27), 273 (+3.22), 266 (+3.09), 252 (−6.27), 240* (−3.13), 224 (+19.0), 215 (−28.2) nm.

Found: C, 78.90; H, 4.15; Cl, 11.76%. Calcd for $C_{20}H_{13}OCl$: C, 78.82; H, 4.30; Cl, 11.63%.

3-Chloro-7-hydroxytriptycene (XIIa). By the procedure used for the preparation of XIIb, optically active XIa was converted into optically active XIIa. Though analytically pure XIIa could not be obtained by the hydrolysis of pure XIIIa, it could be used for subsequent reaction.

3-Chloro-7-methoxytriptycene (XIIIa). A mixture of crude XIIa (1.036 g), potassium carbonate (6 g), dimethyl sulfate (1.1 g) and acetone (60 ml) was refluxed for 6 hr under stirring. The residue obtained by evaporating the solvent *in vacuo* was mixed with water and extracted with ether. Crude XIIIa obtained by working up the extract was dissolved in benzene and the solution was passed through a short column of alumina (30 g). Colorless crystals (0.885 g, 85.4%) obtained from the filtrate were recrystallized from ligroin to give pure XIIIa, mp 211—214 °C, IR (KBr-disk): $\nu_{CH(OCH_3)}$ 2850 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 284.1 (3710), 277.5 (3870), 265 (3470), 261* (3000), 252* (3170), 215.8 (58500), 207 (25300), 202.5 (17800) nm, $\lambda_{max}^{isooctane}$ (ε) 284.5 (3740), 278 (3810), 265 (3460), 261.4 (3140), 254* (3100), 216.5 (63800), 199.3 (52900), 196 (47900), 194.5 (44000) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 284 (+1.8), 280* (+0.60), 270 (−1.4), 250 (−3.6), 232 (−5.2), 226 (−2.4) nm, $\lambda_{max}^{isooctane}$ ($\Delta\varepsilon$) 290 (+0.14), 284 (+1.9), 280* (+0.94), 272 (−0.85), 268* (−0.70), 252 (−3.7), 232 (−5.9), 228 (−1.9) nm.

Found: C, 79.31; H, 4.84; Cl, 10.99%. Calcd for $C_{21}H_{15}OCl$: C, 79.11; H, 4.74; Cl, 11.12%.

Racemate: Mp 196.5—198 °C (sublimed from *ca.* 150 °C), IR (KBr-disk): $\nu_{CH(OCH_3)}$ 2850 cm^{-1}.

4-Chloro-7-methoxytriptycene (XIIIb). Methylation of optically active XIIb by the above-mentioned procedure afforded XIIIb (79.7%) which was sublimed *in vacuo* and recrystallized from ligroin to give pure material, colorless crystals, mp 243—243.5 °C, IR (KBr-disk): $\nu_{CH(OCH_3)}$ 2850 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 284.3 (3980), 277.6 (3900), 265.5 (3440), 215.5 (61000), 202 (51300) nm, $\lambda_{max}^{isooctane}$ (ε) 284.5 (3940), 278 (3820), 265.5 (3410), 262* (3000), 216.6 (64700), 199 (54800), 196.5* (50500), 194.5* (45100), 192* (27700) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 290 (+0.14), 270* (+2.7), 265 (+3.7), 250* (−5.4), 240 (−13), 226 (+20) nm, $\lambda_{max}^{isooctane}$ ($\Delta\varepsilon$) 290 (+0.10), 270* (+2.5), 264 (+3.6), 250 (−5.4), 240 (−12), 226 (+23) nm.

(−)-2,5-Dimethoxy-8-chlorotriptycene (XVIIa and XVIIb).

XVIIa from XIIa: To an ice-cooled and stirred solution of sulfanilic acid (0.150 g, 0.720 mmol) in aqueous sodium carbonate (0.032 g in 12 ml of water) was added a mixture of sodium nitrite (0.050 g, 0.720 mmol), ice (1 g) and concd. hydrochloric acid (0.12 ml). After 30 min, diazonium salt deposited as colorless crystals. To this mixture was added under stirring a solution of pure XIIa (0.210 g, 0.689 mmol) in methanol (3 ml) containing sodium hydroxide (0.56 g) and water (0.4 ml). After being left to stand overnight, the scarlet mixture was slightly warmed with sodium hydrosulfite (10 g) and concd. hydrochloric acid. The reaction mixture was poured into water and extracted with ethyl acetate. The extract was worked up in the usual way to give crude aminophenol (XIVa, 0.204 g, light yellow crystals). Ferric sulfate (4 g) was added to a solution of the crude XIVa in ethanol (25 ml), concd. sulfuric acid (4 ml) and water (50 ml) and the mixture was refluxed for 2 hr. The reaction mixture was concentrated under reduced pressure and extracted with ether. Evaporation of the extract, after washing and drying, afforded brown yellow crystals (0.198 g), which were dissolved in benzene and passed through a short column of alumina (7 g) to give pure quinone (XVa) as yellow crystals (0.105 g, 45.5% based on XIIa), IR (Nujol mull): $\nu_{C=O}$ 1655 cm^{-1} (racemate 1650 cm^{-1}). XIIa was recovered in a yield of 35%. Pure XVa (0.105 g, 0.33 mmol) dissolved in ether (8 ml) was mixed with aqueous

sodium hydrosulfite (0.2 g in 0.5 ml of water) and the mixture was stirred vigorously for 20 min. The colorless reaction mixture was poured into water and extracted with ether. Hydroquinone derivative (XVIa, 0.116 g, colorless crystals) obtained by working up the extract was methylated in the usual manner with potassium carbonate (1 g) and dimethyl sulfate (0.2 g) in acetone (10 ml). Crude XVIIa (light yellow crystals) was chromatographed on alumina and then recrystallized from methanol to give pure XVIIa, mp 209.0—210.5 °C, IR (KBr-disk): $\nu_{CH(OCH_3)}$ 2840 cm^{-1}, UV $\lambda_{max}^{99\%EtOH}$ (ε) 301* (3930), 295 (4090), 284.4 (5280), 278.8 (4270), 266 (2980), 256.8 (2500), 214.2 (58000), 202.3 (48200) nm, ORD: $[M]_{302}$ −1710°, $[M]_{286}$ +3230°, $[M]_{280}$* +1750°, $[M]_{266}$ +1770°, $[M]_{260}$* −5440°, $[M]_{246}$ −14600°, $[M]_{230}$ +26400°, $[M]_{215}$ −48100° (*c* 0.00898, EtOH).

Found: C, 75.40; H, 4.96; Cl, 9.87%. Calcd for $C_{22}H_{17}O_2Cl$: C, 75.75; H, 4.91; Cl, 10.17%.

Racemate: Mp 205.5—207 °C.

XVIIb from XIIb: According to an analogous sequence of reactions used for the preparation of XVIIa, pure XIIb was converted into(−)-2,5-dimethoxy-8-chlorotripycene (XVIIb), mp 209.0—210.5 °C. IR (KBr-disk): $\nu_{CH(OCH_3)}$ 2840 cm^{-1}, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 298 (−0.22), 284 (+0.93), 280 (+1.0), 265 (+2.8), 258 (+2.0), 241 (−6.0) nm, ORD: $[M]_{302}$ −1720°, $[M]_{286}$ +3250°, $[M]_{280}$* +1580°, $[M]_{266}$ +1100°, $[M]_{260}$* −5420°, $[M]_{246}$ −15000°, $[M]_{230}$ +25600°, $[M]_{215}$ −48100° (*c* 0.00885, EtOH).

Found: C, 75.33; H, 4.83; Cl, 10.03%. Calcd for $C_{22}H_{17}O_2Cl$: C, 75.75; H, 4.91; Cl, 10.17%.

UV and IR spectra of XVIIb thus obtained were found to be completely superimposable with those of XVIIa.

Racemate: Mp 204.5—206.0 °C.

(+)-2,5-Dimethoxy-8-carboxytriptycene (XIX). To a refluxing solution of (+)-2,5-dimethoxy-8-methoxycarbonyltriptycene[3] (XVIII, 500 mg, 1.34 mmol) in acetic acid (25 ml) was added dropwise 3 M sulfuric acid (7 ml) and the mixture was refluxed for 12 hr. Colorless crystals deposited on cooling the reaction mixture were recrystallized from methanol to give pure (+)-XIX, mp 147.9—148.9 °C $[\alpha]_D$ +15° (*c* 0.2673, dioxane).

Found: C, 76.52; H, 5.04%. Calcd for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06%.

(+)-2,5-Dimethoxy-8-aminotriptycene (XX). A mixture of (+)-XIX (533 mg, 1.34 mmol), thionyl chloride (1.5 ml) and tetrahydrofuran (11 ml) was refluxed for 3 hr to afford acid chloride [IR (Nujol mull): $\nu_{C=O}$ 1765 cm^{-1}] quantitatively. Sodium azide (252 mg) dissolved in water (3 ml) was added to a stirred and ice-cooled solution of the acid chloride in tetrahydrofuran (30 ml). After the mixture had been stirred for further 3 hr at the same temperature, water was added to precipitate acid azide [IR (Nujol mull): ν_{N_3} 2150, $\nu_{C=O}$ 1690 cm^{-1}]. Thoroughly dried acid azide (552 mg) dissolved in benzene (80 ml) was refluxed for 4 hr to yield isocyanate [553 mg, IR (Nujol mull): ν_{NCO} 2280 cm^{-1}]. A mixture of the isocyanate, 99% ethanol (50 ml), water (8 ml) and potassium hydroxide (5.0 g) was refluxed to afford (+)-XX (384 mg). Vacuum sublimation of the crude product (bath temp. 210—240 °C/800 Pa) afforded pure (+)-XX, colorless crystals, mp 287—289 °C (racemate, mp 243.5—245 °C), IR (KBr-disk): ν_{NH} 3420, 3350, δ_{NH} 1630 cm^{-1}, UV: $\lambda_{max}^{99\%EtOH}$ (ε) 300* (5900), 292.5 (6730), 269* (7260), 262 (7760), 220.5* (45300), 207.5* (56300), 203 (58300), 198 (58300) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 304.5 (+1.45), 274 (−13.6), 250* (+16.2), 242.5 (+16.9), 225.8 (−21.7), 218* (−4.77), 207.5 (−17.7) nm.

Found: C, 79.88; H, 5.96; N, 4.18%. Calcd for $C_{22}H_{19}O_2N$: C, 80.22; H, 5.81; N, 4.25%.

(+)-2,5-Dimethoxy-8-chlorotriptycene (XXI). To a stirred suspension of (+)-XX (60.6 mg, 0.184 mmol) in 6 M hydrochloric acid was added sodium nitrite (13.4 mg, 0.194 mmol) in water (3 ml) over a 15 min-period at 11—15 °C. The mixture, after being stirred for further 50 min, was added dropwise to a solution of cuprous chloride (36 mg) in 6 M hydrochloric acid (6 ml). Stirring was continued for 30 min at 20 °C and then for 1 hr at 100 °C. The reaction mixture was poured into water and extracted with ether. Crude product obtained by working up the extract was chromatographed on alumina and eluted with carbon tetrachloride. The crystals thus prepared were recrystallized from ligroin to give pure (+)-XXI, mp 209.6—210.4 °C (racemate, mp 206.1—207.1 °C), UV: $\lambda_{max}^{99\%EtOH}$ (ε) 301* (4020), 294.5 (4230), 284.5 (5510), 278.9 (4400), 266 (3320), 257 (2750), 240* (8290), 214.5* (61400), 212* (60600), 202* (57900), 198.5 (59600) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 300 (+0.52), 285 (−0.98), 278.5 (−0.88), 265.5 (−2.82), 258 (−1.98), 240 (+9.49), 225.5 (−5.08), 214 (+21.8), 202.5 (−17.9) nm, $[M]_{247}^{20}$ +14000° (*c* 1.417×10^{-4} mol/l, 99%EtOH).

Found: C, 75.61; H, 4.92; Cl, 10.15%. Calcd for $C_{22}H_{17}O_2Cl$: C, 75.75; H, 4.91; Cl, 10.16%.

(Received February 16, 1974)

The irradiation of methyl acetopyruvate with cycloheptatriene by means of a high-pressure mercury lamp has yielded $(6+2)\pi$ and $(4+2)\pi$ cycloadducts, together with tropylcarbinol derivatives formed by a formal abstraction of allylic hydrogen by the excited carbonyl group, this being the major process in this reaction.

As part of our series of studies of the photo-cycloaddition reactions of α,β-unsaturated carbonyl compounds with functional substituents to olefins,[2] we have now extended the investigation to that of methyl acetopyruvate (I) with cycloheptatriene (II), a cyclic conjugated triene, in order to determine the generality of the reaction. One of our primary interests in this reactant is to ascertain whether or not we can see a $(6+2)\pi$ cycloaddition.[3] At the same time, it will be valuable from the preparative point of view if we can see the hydrogen transfer process from a very reactive allylic methylene of II by an excited carbonyl group of I, since this should produce substituted tropylidenes, whose utilization might offer a novel entry to non-benzenoid aromatic systems. In fact, the experiments which will be described below have shown the occurrences of these two features.

Results and Discussion

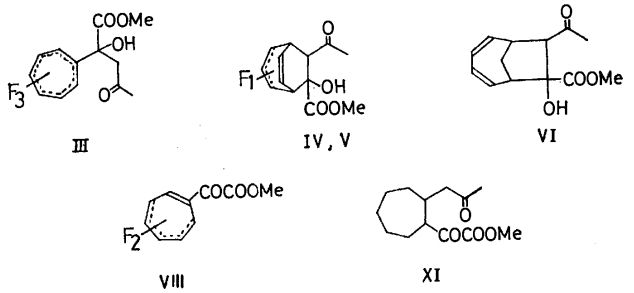
The irradiation of a mixture of I and II by a 450 W high-pressure mercury lamp with a Pyrex glass filter has slowly given a mixture of products.[4] After the completion of the reaction, as monitored by a ferric chloride test, the solvent was removed *in vacuo*; the residual oil was then chromatographed through a silica gel column to give as photoproducts III (a pale yellow liquid, 50%), IV (a faint yellow liquid, 14%), V (a faint yellow liquid, 14%), and VI (a faint yellow liquid, 5.8%). Their structure elucidation is as follows:

The Structure of III. The NMR of III indicates that it is an isomeric mixture, and repeated chromatographic fractionation of III afforded a practically pure 7-tropyl isomer, IIIa [δ: 2.12 (3H, s), 2.94 (1H, d, J=16 Hz), 3.12 (1H, d, J=16 Hz), 3.71 (3H, s), and 5.0—6.7 (6H, m)]. The mixture of III was then reduced to a single hexahydro-derivative (VII), which gave a 2,4-dinitrophenylhydrazone (DNP), (λ_{max}^{MeOH}: 359 nm (ε: 19400)), confirming that they have the same carbon skeleton. When III was heated in a sealed tube for 190 °C, a dealdolized product, VIII, was obtained after the fractionation of the pyrolysate.[5] According to the NMR spectral analysis, VIII was again shown to be an isomeric mixture of VIIIa, VIIIb, and VIIIc, the components differing in the positions of the double bonds, and through an extensive fractionation by silica gel column chromatography, an enriched sample of the VIIIa isomer was obtained. The rest of the isomers, however, could not be separated. VIIIa revealed the presence of a glyoxaloyl group in the IR ($\nu_{C=O}$: 1723, 1670 cm^{-1}) and the NMR [δ: 2.70 (2H, d, J=6.8 Hz), 3.86 (3H, s), and 5.3—7.45 (5H, complex m)] spectra. Since the presence of a tropyl chromophore is evident from the UV (λ_{max}^{MeOH}: 287 (ε: 4000) and 301 nm (3900)) spectrum as well as from the above NMR evidence, VIIIa is deduced to be methyl 1-tropylglyoxalate. VIIIb and VIIIc are considered to be 2-tropyl- and 3-tropyl-derivatives on the basis of NMR spectral evidence.[6] A mixture of VIII was easily hydrogenated to a single octahydro-derivative (IX), which was then hydrolyzed to a crystalline carboxylic acid. IX was oxidized by potassium permanganate to give pimelic acid, whose identity with an authentic specimen was proved by direct comparisons (IR and NMR spectra and glc of its methyl ester). In addition, the presence of unconjugated keto-groups ($\nu_{C=O}$: 1720 cm^{-1}) and a simple cyclic triene chromophore (λ_{max}^{MeOH}: 254 nm (ε: 3700)) clarifies that III is a methyl 2-tropyl-2-hydroxylevulinate.

The Structures of IV and V. IV and V were shown to be *cycloadducts* by the observed substitution patterns of the seven-membered rings, which exhibit four olefinic protons in the NMR. Since IV and V possess a hydroxyketo-ester function, they cannot be $(2+2)\pi$ adducts. This was confirmed as follows: The independent hydrogenation of IV and V, using platinum oxide as the catalyst, resulted in the formation of the same tetrahydro-derivative (X), which gave a crystalline DNP (λ_{max}^{MeOH}: 362 nm (ε: 19500)). On the other hand, cycloheptene and I were irradiated in a similar manner to give the photo-adduct (XI) in a good yield together with a dimer of cycloheptene (a colorless liquid).[7] The non-identity of XI, which is a normal glyoxaloyl derivative, with X has been established by IR and NMR spectral comparisons. Therefore, IV and V should possess a bicyclo [3,2,2] nonadiene frame-work, derived by the $(4+2)\pi$ cycloaddition process; otherwise, the occurrence of a positional isomerism of the double bond is impossible. Interestingly, neither the dehydration nor the dealdolization of X has been successful so far; always unreacted X has been recovered quantitatively, while XI gives a normal α,β-unsaturated keto-ester (XII, a colorless liquid), whose *mono*-DNP, (λ_{xeau}^{MeOH}: 377.5 nm (ε: 24600)) shows reasonable physical properties.

The Structure of VI. VI has also retained the

aldolic moiety, as evidenced by its NMR [δ: 2.09 (3H, s), 3.60 (3H, s), and 5.85 (4H, br.s)] and IR (ν: 3500, 1723 (strong) cm^{-1}) spectra. The presence of cyclohepta-1,3-diene chromophore is confirmed by a measurement of the UV spectrum (λ_{max}^{MeOH}: 268 nm (ε: 3370)). On catalytic hydrogenation by platinum oxide, VI afforded a single tetrahydro-derivative (XIII, colorless liquid), which was further characterized by the formation of *mono*-DNP (yellow crystals, λ_{max}^{MeOH}: 360 nm (ε: 19200). XIII was not identical with either X or XI, judging from IR and NMR spectral comparisons. The remaining carbon skeleton for VI is, therefore, bicyclo [4,2,1] nonadiene, that of a (6+2)π adduct.



In connection with the above results, a few points should be noted. First, the main product, III, was formed by an ene-reaction which was not previously observed in the photochemical reaction of I, but the phenomenon is not surprising since electron deficient oxygen of the n,π^* excited carbonyl group of I can abstract a partially-negative allylic hydrogen of II, leaving a symmetrical tropyl radical. Secondly, the mode of the concerted formation of IV and V has to be photochemically disallowed, and yet the formation of IV and V was stereospecific despite being not regiospecific, while the (4+2)π photoaddition of the cyclopentadiene and α-acetoxyacrylonitrile has been reported to be non-stereospecific.[8] Third, the acquisition of VI constitutes, to the best of our knowledge, the first example of genuine (6+2)π photocycloaddition, although a thermal (6+2)π process has been reported in the reaction of acrylonitrile and II[9] and, in a formal sense, the intramolecular[3] and intermolecular photocycloadditions[10,11] of activated olefins and benzenes to give cyclobutanes are examples of the (6+2)π process, as has been mentioned.[3] Finally, an apparent absence of the genuine (2+2)π cycloadduct in the reaction mixture is in contrast with the photocycloadditions of ordinary olefins.

This complicated behavior itself makes the mechanistic analyses of the reaction difficult. However, at least one thing is clear; since the photoreaction is strongly concentration-dependent, *i.e.*, a slight dilution of II by an inert solvent diminishes the rate considerably, there is no involvement of a charge-transfer intermediate in this reaction. Other than this, since photoproducts are extremely unstable and sensitive to the air, and since addition of arylketones to the reaction system causes a consumption of the additives,[12] an intensive investigation will be needed to obtain a deeper understanding of the reaction.

Experimental

Reaction of Cycloheptatriene (II) and Methyl Acetopyruvate (I). a) I (7.24 g) was dissolved in II (200 ml) and was then internally irradiated by a 450 W high-pressure mercury lamp through a Pyrex glass filter under a nitrogen atmosphere for 54 hr. Then the reaction mixture was heated on an oil bath under reduced pressure to remove the II. The residual oil thus obtained was repeatedly fractionated by silica gel column chromatography, using hexane–benzene–ether system as eluant, to give as products III (a pale yellow oil; 5.9 g), IV (a pale yellow oil; 1700 mg), V (a faint yellow oil; 1700 mg), and VI (a faint yellow oil; 600 mg).

b) I (4.3 g) was dissolved in II (45 ml) and anhydrous ether (180 ml) and was then similarly irradiated. After 70 hr, the presence of I in the clean mixture was still recognized, but the crude mixture (*ca.* 2.1 g) obtained by the removal of the solvent and the unreacted I showed a similar product composition.

c) I (120 mg) was dissolved in II (3 ml) and externally irradiated by means of a high-pressure mercury lamp in the presence of various amount of benzophenone (10—100 mg). Every time, the formation of benzopinacol and a tropyl carbinol derivative exceeded that of the photoadducts.

Further Fractionation of III; Isolation of Methyl 2-(7-Tropyl)-2-hydroxylevulinate (IIIa). Above isomeric mixture of III (450 mg) was further chromatographed through a silica gel column; from the least polar fraction, a practically pure isomer, IIIa (a faint yellow oil; 30 mg), was obtained.

Hexahydro-derivative of III. III (98 mg) was dissolved in methanol and hydrogenated over platinum oxide to give a hexahydro-derivative (VII) as a colorless liquid in quantitative yield.

The DNP of VII was prepared in the usual manner as yellow needles; mp 168—168.5 °C (from ethanol-ethyl acetate) (Found: C, 53.81; H, 6.10; N, 13.46%. Calcd for $C_{19}H_{26}O_7N_4$: C, 54.02; H, 6.20; N, 13.26%).

Pyrolysis of III: Formation of Methyl Tropylglyoxalates (VIII). A degassed sample of III (305.7 mg) was heated in a sealed tube for 3 hr. The pyrolysate was then separated by silica gel column chromatography to yield, together with the recovered III (76 mg), 20 mg of a pale yellow liquid (VIII).

Fractionation of Isomeric Mixture of VIII; Enrichment of VIIIa. The above sample of VIII (120 mg) was further fractionated by silica gel column chromatography. The least polar fraction, eluted by hexane–benzene (1: 10), consisted of VIIa (70% pure) as a pale yellow liquid after distillation on a cold finger (Found: C, 67.23; H, 5.75%. Calcd for $C_{10}H_{10}O_3$: C, 67.40; H, 5.66%).

Catalytic Reduction of VIII: Formation of Methyl Cycloheptylglycolate (IX). VIII (105 mg) was reduced in methanol over platinum oxide to give an octahydro-derivative, IX (bp 110—112 °C/3 mmHg) as a colorless liquid after a cold-finger distillation; the homogeneity of distillate was proven by glc (Found: C, 64.23; H, 9.59%. Calcd for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74%. ν: 3500, 1740 cm^{-1}, δ: ~1.5 (13H, br.), 3.86 (3H, s), 3.93 (1H, d, J=2 Hz)).

Alkaline Hydrolysis of IX to Cycloheptylglycolic Acid. IX (20 mg) was treated with aqueous sodium hydroxide solution to give colorless needles, mp 88—90 °C (from ethanol–ethyl acetate) (Found: C, 62.72; H, 9.39%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%).

Potassium Permanganate Oxidation of IX; Formation of Pimelic Acid. IX (98.2 mg) was mixed with water (3 ml), and into the mixture aqueous potassium permanganate (330 mg in 10 ml) was added, drop by drop, at 0 °C, and then

it was kept overnight. The mixture was subsequently acidified by hydrochloric acid and extracted with ether. An acidic material obtained by the re-extraction of the above was esterified by diazomethane to give dimethyl pimelate (40 mg (40%)) as a colorless liquid after cold-finger distillation. The sample showed essentially a single peak on a gas-liquid chromatogram and was identical with an authentic specimen (IR, NMR, and glc).

Catalytic Reduction of IV; *Formation of the Tetrahydro-derivative, X.* IV (155 mg) was dissolved in methanol and reduced with platinum oxide at room temperature. The product (X), a colorless liquid, was shown to be homogeneous; it consisted of a single peak on several gas-liquid chromatograms (ν: 3500, 1720, 1270, 1200 cm^{-1}. *m/e*: 240 (M^+), 95 (base peak)).

The DNP of X was obtained as yellow needles, mp 188—190 °C (Found: C, 54.04; H, 5.79; N, 13.37%. Calcd for $C_{19}H_{24}O_7N_4$: C, 54.28; H, 5.75; N, 13.33%).

Catalytic Reduction of V; *Formation of X.* V (255 mg) was similarly hydrogenated to give X, which was identical with those obtained from IV by a study of its IR and NMR spectra, glc, and a mixed-mp comparison with DNP.

Photochemical Reaction of I and Cycloheptene. I (115mg) was dissolved in cycloheptene (1 ml) and externally irradiated by a high-pressure mercury lamp through a Pyrex glass filter. After the evaporation of the excess olefin, the mixture was chromatographed through silica gel column to give a hydrocarbon and a 1: 1-cycloadduct (XI) (a colorless liquid (*m/e*: 240 (M^+), 95 (base peak), ν: 1730, 1270 cm^{-1})) which was not identical with either VII or X (IR, NMR, and glc).

Acid-Catalyzed Dehydration of XI; *Formation of the α,β-Unsaturated Keto-ester, XII.* XI (144 mg) was dissolved in benzene and heated with a small amount of *p*-toluenesulfonic acid to give XII (103 mg, 77.5%) as a colorless liquid (λ_{max}^{MeOH}: 245 nm (ε: 7100), ν: 1730, 1690, 1250 cm^{-1}).

The DNP of XII was obtained as orange-yellow needles; mp 180—181 °C (Found: C, 56.80; H, 5.53; N, 14.24%. Calcd for $C_{19}H_{22}O_6N_4$: C, 56.71; H, 5.51; N, 13.92%).

Catalytic Reduction of VI; *Formation of the Tetrahydro-Derivative XIII.* VI (83 mg) was dissolved in methanol and reduced over platinum oxide at room temperature. A single product (a colorless liquid), obtained after the usual work up, was characterized by the formation of crystalline DNP; yellow needles; mp 141—143 °C (Found: C, 54.33; H, 5.79; N, 13.29%. Calcd for $C_{19}H_{24}O_7N_4$: C, 54.28; H, 5.75; N, 13.33%).

H. T. and A. M. wish to thank The Ministry of Education for its financial support.

Stereochemical Studies on the Nuclear Alkylation of Phenols with 1-Phenylethyl Chloride and the Acidic Rearrangement of the 1-Phenylethyl Ethers of Phenols in the Phenolic Solvents

Kunio Okamoto, Tomomi Kinoshita, and Osamu Makino

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 22, 1974)

Phenolyses of optically active 1-phenylethyl chloride were carried out in phenol (50 °C), *p*-cresol (100 °C), *p*-chlorophenol (100 °C), and 2,6-xylenol (100 °C) in the presence of variable concentrations of the sodium salts of the respective phenols or triethylamine; the distributions (%) for the O- and C-alkylation products and the net steric courses (α%) for each product were examined. The distribution and the steric course which were graphically extrapolated to the zero base concentration indicated that, if the influence of the liberated hydrogen chloride was excluded, in the phenolyses without an added base the major products are the 1-phenylethyl ethers of the respective phenols with net *retained* configurations and the minor products are the *o*- and *p*-1-phenylethylated phenols with net *inverted* configurations. The hydrogen chloride rearrangement of the optically active 1-phenylethyl ethers of the respective phenols proceeded rapidly to give *o*-1-phenylethylated phenols with predominantly *retained* configurations (for phenol, *p*-cresol, and *p*-chlorophenol) and *p*-1-phenylethylated phenols with net *inverted* configurations (for phenol and 2,6-xylenol) in the respective phenol–benzene (1 : 1 by wt) solvents. The *p*-toluenesulfonic acid rearrangement of 1-phenylethyl phenyl ether-^{18}O proceeded to give *o*- and *p*-1-phenylethylphenols with partial loss of the oxygen-18 atom in the phenol–benzene (1 : 1 by wt) solvent, indicating the coexistence of the *intermolecular* course for the acidic rearrangement in the phenolic solvents. From these findings, it is concluded that the formation of the *ortho*-alkylates with retention of configuration, experimentally observed in the respective phenolyses without an added base, is attributed not to the direct retentive alkylation of the phenols, but to the rapid rearrangement of the 1-phenylethyl ethers with net retention of configuration, caused by the hydrogen chloride liberated in the S_N1-phenolysis of 1-phenylethyl chloride in the respective phenolic solvents.

When the S_N1 phenolysis of optically active 1-phenylethyl chloride was conducted in the presence of a base, partially (20—50%) retained 1-phenylethyl phenyl ether and partially (25—87%) inverted *o*- and *p*-1-phenylethylphenols were obtained in phenol, *p*-cresol, *p*-chlorophenol, and *p*-nitrophenol solvents.[1]

On the other hand, when the phenolysis was carried out without an added base, no phenolic ether was obtained. Instead, 1-phenylethylphenols alone were isolated; the *ortho* alkylated phenol possessed partially retained configuration, whereas the *para* isomer configuration was partially inverted.[2] These are illustrated in the following scheme.

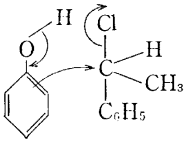
In the presence of a base:

$$(R)\text{-RCl} + \text{PhOH} \longrightarrow (R)\text{-ROPh} + (S)\text{-}o\text{-RC}_6\text{H}_4\text{OH} + (S)\text{-}p\text{-RC}_6\text{H}_4\text{OH}$$

Without an added base:

$$(R)\text{-RCl} + \text{PhOH} \longrightarrow (R)\text{-}o\text{-RC}_6\text{H}_4\text{OH} + (S)\text{-}p\text{-RC}_6\text{H}_4\text{OH}$$

Prior to these investigations,[1,2] Hart and his collaborators[3] had already reported that *ortho*-alkylations of *p*-cresol and *p*-chlorophenol with optically active 1-phenylethyl chloride proceeded with retention of configuration, but the *para*-alkylation of 2,6-xylenol involved inversion; they suggested that the *ortho*-alkylation with retention of configuration would be a direct retentive C-alkylation with a cyclic transition state as follows.



However, as we pointed out in the previous paper,[2] in view of the fact that in the phenol–acetonitrile solvent optically active 1-phenylethyl phenyl ether undergoes a rapid rearrangement to give the predominantly retained *o*-(1-phenylethyl)phenol in the presence of hydrogen chloride, it is probable that the product distribution and the steric course observed in the experiments[2,3] without an added base do not reflect the true reaction result between 1-phenylethyl chloride and phenol, but they are perturbed by the facile acidic rearrangement of 1-phenylethyl phenyl ether formed as a precursor of *o*- and *p*-alkylated phenols.

In order to confirm this anticipation, we intended to know the true product distribution and the true steric course avoided from the perturbation by the hydrogen chloride rearrangement. For this purpose we adopted an extrapolation method which we had applied to several phenolyses without an added base.[4] Namely, we carried out the phenolyses of optically active 1-phenylethyl chloride in phenol, *p*-cresol, *p*-chlorophenol, and 2,6-xylenol solvents, and examined the product distribution and the steric course for each product in the respective phenolyses with variable concentrations of sodium salts of the phenoxides or triethylamine; then extrapolated the results graphically to the zero base concentration. We considered the extrapolated values as the intrinsic results which are not affected by the liberated hydrogen chloride.

In this paper we will report that, contrary to the results of the experiments carried out without an added base,[2,3] the extrapolated results indicate that the direct *ortho*-alkylation with optically active 1-phenylethyl chloride proceeds with predominant *inversion* of configuration in phenol, *p*-cresol, and *p*-chlorophenol solvents, and that the *retained ortho*-1-phenylethylated phenols

which were obtained in the experiments without an added base are mostly produced by the retentive and rapid hydrogen chloride rearrangement of 1-phenylethyl phenyl ethers, initially-formed from the respective phenols and with net retained configurations, and consequently that a direct retentive C-alkylation[3] is not a major mechanism for the formation of the retained *ortho*-alkylates in the nuclear alkylations of phenol, *p*-cresol, and *p*-chlorophenol.

The S_N1 Phenolysis Rates and the Product Distributions in the Absence of a Base. In the presence of a base the phenolysis of 1-phenylethyl chloride obeys a good first-order kinetics, showing a good S_N1 characteristics, and gives the phenyl ethyl eher and *o*- and *p*-alkylated phenols.[1] However, as mentioned above, in the experiments without an added base the liberated hydrogen chloride seems to perturb the S_N1 phenolysis by the acidic rearrangement of the phenyl ether[2] and also by the cleavage reaction[5] of the phenyl ether with hydrogen chloride (*vide infra*).

In order to confirm such perturbation, we carried out the rate measurements without an added base. As anticipated, the first-order titrimetric rate constants of the phenolysis of 1-phenylethyl chloride tended to decrease after 19—26% completion in the mixtures of benzene and the respective phenols (1: 1 by weight). This is most probably ascribed to the occurrence of the cleavage reaction[5] of the respective phenyl ether by hydrogen chloride to give the starting 1-phenylethyl chloride. The initial first-order rate constants are summarized in Table 1.

Table 1. First-order rate constants for phenolyses of 1-phenylethyl chloride in phenol (ArOH)–benzene (1: 1 by wt) solvent in the absence of a base

Solvent ArOH–C_6H_6	Temp. °C	RCl M	k_1 s^{-1}	Conversion %
C_6H_5OH–C_6H_6	50	0.100	3.95×10^{-4}	25
p-MeC_6H_4OH–C_6H_6	50	0.103	3.85×10^{-4}	19
p-ClC_6H_4OH–C_6H_6	50	0.101	3.66×10^{-4}	20
2,6-Xylenol–C_6H_6	50	0.100	6.86×10^{-7} a)	26

a) Extrapolated value from data at 75 and 100 °C.

Hart and his collaborators[3] found that mixtures of various phenols and 1-phenylethyl chloride evolved hydrogen chloride to give 1-phenylethylated phenols, but they neither carried out the kinetic measurement, nor interpreted the reaction in terms of the typical S_N1 phenolysis.

In order to know the true product distribution which is not perturbed by the liberated hydrogen chloride, the distribution values in the phenolyses with variable concentrations of triethylamine or the sodium salt of the respective phenols were examined and extrapolated to the zero base concentration. The results obtained for the phenolyses in *p*-cresol (100 °C), *p*-chlorophenol (100 °C), 2,6-xylenol (100 °C), and phenol (50 °C) are summarized in Table 2, and illustrated in Figs. 1, 2, 3, and 4.

As it is shown in Figs. 1—4, the extrapolated values for the yield of the phenyl ether clearly indicate that, if the influence of hydrogen chloride is excluded from the reaction medium, the phenyl ether would be the major product for each phenolysis. The results, which were obtained by Hart and his collaborators[3] and confirmed in our duplicate runs, are clearly different from our extrapolated results (see Table 2).

The Steric Course of the S_N1 Phenolysis in the Absence of a Base. Hart and his collaborators[3] found that 1-phenylethyl chloride gives partially *retained ortho* 1-phenylethylated phenol in *p*-cresol and in *p*-chlorophenol. We confirmed their results under similar reaction conditions (see Table 2).

However, in the previous experiments[1b] carried out with added triethylamine in the mixtures of *p*-substituted phenols (phenol, *p*-cresol, and *p*-chlorophenol) and organic solvents (benzene and acetonitrile), we found that *ortho* 1-phenylethylated phenols exhibited partially *inverted* configurations.

In order to make the situation clearer, we examine

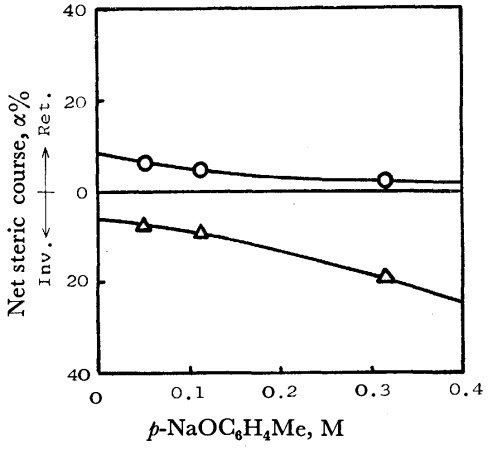

Fig. 6. The steric course for 1-phenylethyl chloride phenolysis in *p*-cresol in the presence of sodium *p*-cresoxide at 100 °C.

○: R-O-⟨⟩-Me, △: HO-⟨R⟩-Me

the effect of the base concentration on the steric course of the *ortho* 1-phenylethylated phenol formation by carrying out the phenolyses of optically active 1-phenylethyl chloride in the presence of variable concentrations of the sodium salts of phenol, *p*-cresol, and *p*-chlorophenol. The results are graphically extrapolated to the zero concentration of the respective phenoxides. These are illustrated in Table 3 and Figs. 5, 6, and 7 along

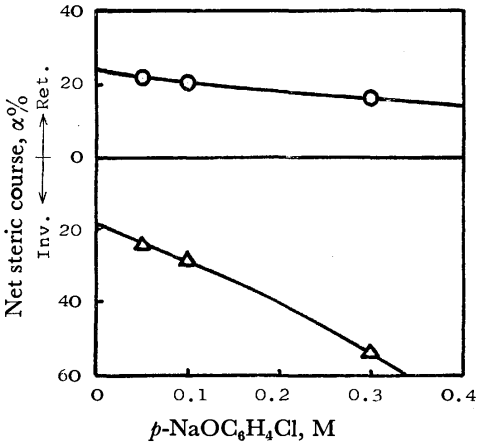

Fig. 7. The steric course for 1-phenylethyl chloride phenolysis in *p*-chlorophenol in the presence of sodium *p*-chlorophenoxide at 100 °C.

○: R-O-⟨⟩-Cl, △: HO-⟨R⟩-Cl

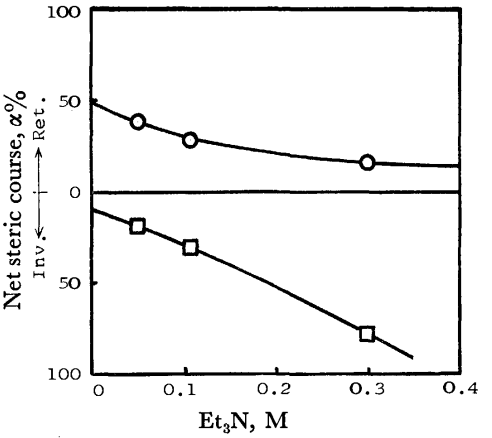

Fig. 8. The steric course for 1-phenylethyl chloride phenolysis in 2,6-xylenol in the presence of triethylamine at 100 °C.

○: R-O-⟨Me, Me⟩, □: R-⟨Me, Me⟩-OH

with the steric courses for the formation of 1-phenylethyl ether of the respective phenols. In Fig. 8 the steric course for the formation of *para* 1-phenylethylated 2,6-xylenol and 1-phenylethyl 2,6-xylyl ether in the xylenolyses with variable concentrations of triethylamine are illustrated.

It is evident that the extrapolated results show that even in the absence of the base the phenolyses give *ortho* 1-phenylethylated phenols with partially *inverted* configuration, if the perturbation of hydrogen chloride was excluded. From these results we can conclude that the intrinsic steric course for the *ortho* alkylation of phenol with 1-phenylethyl chloride is predominantly *inverted.*
